Contents

Preface

Chemistry has witnessed a phenomenal change in the last decades of the twentieth century. Research in two areas in particular have driven the emergence and significance of supramolecular chemistry. Since the Nobel prize–winning work of Cram, Lehn, and Pedersen in the late 1960's and early 1970's, work in solution host guest compounds, and latterly self-assembling and self-organizing systems, has seen a veritable explosion. The older field of solid-state inclusion chemistry has, to a very great extent, paralleled these developments with a great deal of recent effort in crystal engineering being regarded as solid-state supramolecular synthesis. Boih subfields rely crucially on an understanding of the noncovalent bond—the quintessence of supramolecular chemistry. The evolution of these areas underscores the dynamic growth of supramolecular research and the explosion of interest in the field.

Clearly one of the most important goals of the *Encyclopedia* of *Supramolecular Chemistry* then is to provide a broad-based overview of the discipline and to capture the significance of research in this area, with special emphasis on a synthesis of the concepts and language of supramolecular chemistry across a wide range of related disciplines. Furthermore, this Encyclopedia is not written by, nor written exclusively for "supramolecular chemists"; it is for students and practitioners of the chemistry (indeed science) of the noncovalent bond wherever it occurs. We have made specific efforts to direct the reader to the defining literature in the field and specifically included cross-references to help the researcher locate other entries of interest.

We hope that this two-volume work will become a useful and well-thumbed source of information and ideas, as well as a helpful teaching aid as courses in intermolecular interactions continue to grow. If browsing through this work stimulates a new idea or a new collaboration from an unusual combination of topics, or if it clarifies a point of confusion for an undergraduate or senior researcher, then we will have succeeded.

As editors, we would very much like to thank the very many contributors and the members of the Editorial Advisory Board who have donated their time and insights to this work. It is very much a community effort and we have spent more time listening and nodding, than talking. Finally, we would like to express our heartfelt thanks to the editorial and production staff at Marcel Dekker, Inc. who have organized the monumental task of gathering together all of the elements of such a diverse production. We are especially grateful to Oona Schmid not just for her extremely hard work, but also for her insight into the needs of this work and the community as a whole.

Foreword

Molecular chemistry has, over many years, developed a wide range of very powerful procedures for constructing ever more sophisticated molecules from atoms linked by covalent bonds. Beyond molecular chemistry lies supramolecular chemistry which aims at setting up highly complex chemical systems from components interacting via noncovalent intermolecular forces.

The concept and the term supramolecular chemistry were introduced in 1978, in the words: "Just as there is a field of molecular chemistry based on the covalent bond, there is a field of supramolccular chemistry, the chemistry of molecular assemblies and of the intermolecular bond," reformulated on various occasions, e.g., "Supramolecular chemistry may be defined as 'chemistry beyond the molecule,' bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces."

The breadth and especially the unifying power of the concept became progressively more and more apparent, so that recent years have seen an explosive growth, as measured by the increasing number of laboratories that join the Geld and whose work has been reported in a vast range of publications, books, journals, meetings. and research networks.

By the appropriate manipulation of noncovalent interactions, supramolecular chemistry became the chemistry of molecular information, involving the storage of information at the molecular level, in the structural features, and its retrieval, transfer, processing at the supramolccular level, through molecular recognition processcs operating via specific interactional algorithms. A further step consisted of the design of systems undergoing self-organization, i.e., systems capable of spontaneously generating well-defined supramolecular architectures by self-assembly from their components under the control of the molecular information stored in the covalent framework of the components and read out at the supramolecular level through specific interactions. Self-organization processes thus represent the operation of programmed chemical systems leading to the spccific generation of well-defined entities.

The design of such molecular information-controlled. "programmed," and functional self-organizing systems provides an original approach to nanosciencc and nanotechnology, offering a powerful alternative/complement to nanofabrication and to nanomanipulation.

Supramolecular chemistry is also intrinsically a dynamic chemistry in view of the lability of the interactions connecting the molecular components of a supramolecular entity and the resulting ability of supramolccular species to exchange their constituents. Thus, in addition to self-organization by design, which strives to achieve full control over the output supramolecular entity by explicit programming, a new development resides in the implementation of self-organization by selection, operating on dynamic constitutional diversity in response to either internal or external factors to achieve adaptation.

From molecular recognition to self-organization, to prograinmed chemical systems, supramolecular chemistry progressively leads up the ladder of complexity and opens new horizons for chemistry toward a science of informed, organized, and adaptative matter.

Supramolecular chemistry is a highly interdisciplinary field of science. A major feature is the range of perspectives offered by the cross-fertilization of supramolecular chemical research

due to its location at the intersection of chemistry, biology, and physics. Drawing on the physics of organized condensed matter and extending *to the complex entities and processes of biology,* supramolecular *chemistry expands into a supramolecular science. It has penetrated such diverse areas as for instance: polyiner chemistry and materials science, solid-state chemistry and crystal engineering, species for nonlinear optics, biological interactions and drug design, sensor and diagnostic procedures, nanoscience and nanotechnology, etc.*

Supramolecular *chemistry has thus* become *a highly diverse but coherent and lively body of concepts and objects, generating and incorporating novel areas of investigation. Such wide horizons are a challenge and a stimulus to the creative imagination of the chemist.*

As a new field of science emerges, grows, and matures, it generates novel terminology to name the concepts that define it and to describe the *objects that constitute it. The language of supramolccular chemistry, its vocabulary, and syntax have been progressively developed, leading to the introduction of new terms or to the reappropriation of old ones.*

Such conceptualizing and naming play a very important role, not only for shaping the *field but also by the ground they offer to the creative imagination. Indeed, one may let one's imagination be carried by the magic of the word and pulled by the evocative and stimulating power* of the concept.

It *is clear that the time is* ripe *for an Encyclopedia of Supramolecular Chemistry, presenting its basic concepts, its various objects, and processes as* well *as its relations to other areas of basic and applied science. It will be of great value to the many practitioners in the field as well as to those, perhaps even more numerous newcomers, who wish to get acquainted with it and may wish to join the family and become part of the adventure!*

The editors and authors deserve our warmest thanks for their timely work to the benefit of the common good.

INTRODUCTION

Alkali metals easily lose one electron at the outer s-shell to form singly charged cations. Among these, the Na^+ and K^+ ions play the most important biological roles. Because of the weak and nonspecific nature of the interaction with other ligands, the biological significance is determined primarily by the magnitude of the concentrations. Similar chemical principles are applicable in a series of alkaline earth metal cations, except these are doubly positively charged. Moreover, the sizes become smaller, because the biologically important Mg^{2+} (0.60 Å) and Ca^{2+} (1 A) ions correspond to Li^+ (0.6 A) and Na^+ (0.95 Å) ions, respectively. These concentrations of the alkali and alkaline earth metal ions reflect those of seawater, and this coincidence evidences that the first life was born in archeological seawater. Therefore, the "physiological salt solution" employs concentrations in which $Na^+ > K^+ > Mg^{2+} > Ca^{2+}$. This order, however, shows a discrepancy from the one found in the earth's crust, where Ca, Na, K, and Mg occupy the fifth to the eighth elements in this order. The reason for this difference is that the Ca^{2+} ion is selectively eliminated from solution by the tendency to form insoluble precipitates such as $CaCO_3$ or Ca_4 (PO,),. According to this tendency, $CaCO_3$ is accumulated in rocks, and Ca_4 $(PO_4)_3$ is an important component of bone and tooth in the biological systems.

Dominant alkali metal ions, Na^+ and K^+, are highly soluble in aqueous solution and are the most important components in maintaining the salt concentrations inside and outside the cell, necessary to keep homeostasis of biological cells. At the same time, their single charge is associated with relatively small solvation energies, 98.5 and 80.5 kcal mol^{-1} for Na^+ and K^+ ions, respectively, reflecting the size difference on delocalizing the positive charges. These ions are most appropriately employed as messengers of biological signal transduction by mass (i.e., charge) transport across the membrane.[1] Compared to these ions, Mg^{2+} with two positive charges is constrained in a small atomic volume and must compensate by strong ion pairing with anionic counterparts of high charge densities. Phosphate anions are the most satisfactory as a pair component, and Mg—phosphates behave like molecules in many chemical events. The high solvation energy of the Mg^{2+} ion (454 kcal mol^{-1}) makes it difficult to use as the charge messenger of signal transduction.

The Ca^{2+} ion possesses properties that are intermediate, and it is associated with various biologically important roles. It does not favor any specific coordination structure but still interacts strongly with ligands, especially with an oxygen anion, to alter the charged state and geometrical structure of the ligands, just as transition metal ions do. At the same time, the Ca^{2+} ion can be transferred into the cell across the biological membrane, in spite of its high hydration energy (379 kcal mol^{-1}), and plays a role as a second messenger in the cell. For example, acetylcholine is ejected into a synaptic crevasse triggered by the entry of a Ca^{2+} ion. However, the presence of the Ca^{2+} ion in the cell is hazardous because of its wide spectrum of actions and is eliminated from the inside cell and stored in endocellular cavities immediately after the completion of the specific role. When the Ca^{2+} concentration is monitored by, e.g., Ca^{2+}-specific sensors, a Ca^{2+} wave can actually be observed. When this control system is destroyed, cells suffer fatal damage. For example, Alzheimer's and other related diseases are believed to induce such an uncontrolled entry of Ca^{2+} ion and to cause fatal damage to nerve cells. The entry of the Ca^{2+} ion was demonstrated by single channel measurements, and its close relationship with diseases was invoked.[2]

BIOLOGICAL ENERGY CONVERSION AND ION CHANNELS

A biological energy conversion system stores energy first in the form of a proton concentration gradient across the biological membrane via coupled electron and proton transport using the action of a photosynthetic or metabolic energy-producing pathway in many plants and animals.[3] This is a universal expression of energy storage, but it relies on the presence of the membrane as the separation barrier of the H^+-concentration gradient and must be

converted to another form of stable energy in order to be transferred to the spot where energy is required This transformation is accomplished by H^+-ATPase. where the vectorial proton flux across the membrane can produce adenosine triphosphate as molecular energy or the so-called "energy coin `` This energy in the form of pyrophosphate bonds can be transported to numerous energy-demanding organs. Around one-third to one-fourth of this ATP is then consumed for the generation of Na^+/K^+ concentration gradient across the membrane of nerve cells through the action of Na^+/K^+-ATPase [4] Consumption of one molecule of ATP transports $3Na^+$ and 2K' ions outside or inside the cell. respectively. These concentration gradients are maintained across the impermeable membrane, but large ionic fluxes are generated once these ions becoine permeable through the membrane. This ion-permeating device, the ion channel, is a inolecular machine of signal transduction located in the brain and nervous systems.[1] Ion transport across the membrane, generally in a form of a large flux, induces a rapid change of membrane potentials. The opening and closing of the ion channels are controlled by

the gate systems equipped intrinsically in the channel. Ion channels can recognize cation and anion and K^+/Na^+ ions with high selectivities. Once a Na^+ channel is opened. Na^+ ions accumulated outside the membrane enter into the cell, shifting the membrane potential toward a positive value. This channel is then inactivated and followed by the opening of a K^+ channel to shift the potential toward a negative value by the outflux of K^+ ions. The temporary shift of the membrane potential is large enough to induce the opening of a second Na^+ channel. located close to the first channel, and a second cycle follows. In this way. the wave of membrane potential, termed an ''action potential.'' is transferred along the nerve axon. The ion channel is regarded, therefore; as a molecular device of signal transduction, relying on Na^+. K^+, Ca^{2+}. and C l ions as thepredominant messengers.

The chemistry of alkali and alkaline earth metal ions is understood most comprehensively through analyzing the function of ion channels, especially mechanisms of ion selectivity and gating. An ion channel with a typical conductance of 10 *pS* allows the passage of 5×10^6 ions per second through a single molecular pore. Even operating at such large ionic fluxes, ion channels generally discriminate between different ionic species. for example, cation and anion and K^+/Na^+, by passing them through the selectivity filter. Permeability ratios. P_{Na}/P_K, for several K^+ channels are less than $0.01 \sim 0.07$.[1] This remarkable selectivity of K^+ may be understood by examining how the structure of a selectivity filter manages different hydration energies and ionic radii. In this article, recent advances in this area will be described in light of mechanisms of high selectivity and gating based on x-ray crystallographies. Furthermore. approaches to the construction of artificial ion channels are focused on these specific functions.

STRUCTURE OF ION CHANNELS

X-Ray Analysis of Selectivity Filter and ion-Conducting Mechanism

The first x-ray crystal structure of an ion channel appeared in 1998 from MacKinnon's group (Fig. 1).[5] The structure of the selectivity filter forced scientists to abandon the previous hypothesis that K^+ ion should be stabilized by cation–n interactions in the aromatic cage when surrounded by four tyrosine residues. In the selectivity filter located near the extracellular surface. one Thr OH and four main-chain amide carbonyls from Val-Gly-Tyr-Gly are lined up in a 12Å length. Because the K^+ channel is composed of four identical subunits. this provides four consecutive spherical cavities for K^+ binding by wrapping each K^+ with eight neutral oxygen atoms. This mode of binding is reminiscent of valinomycin and sandwiched crown complexes. The Tyr unit does not contribute to the direct stabilization. but it is directed outwardly toward the pore and interacts with a Trp residue by a phenolic

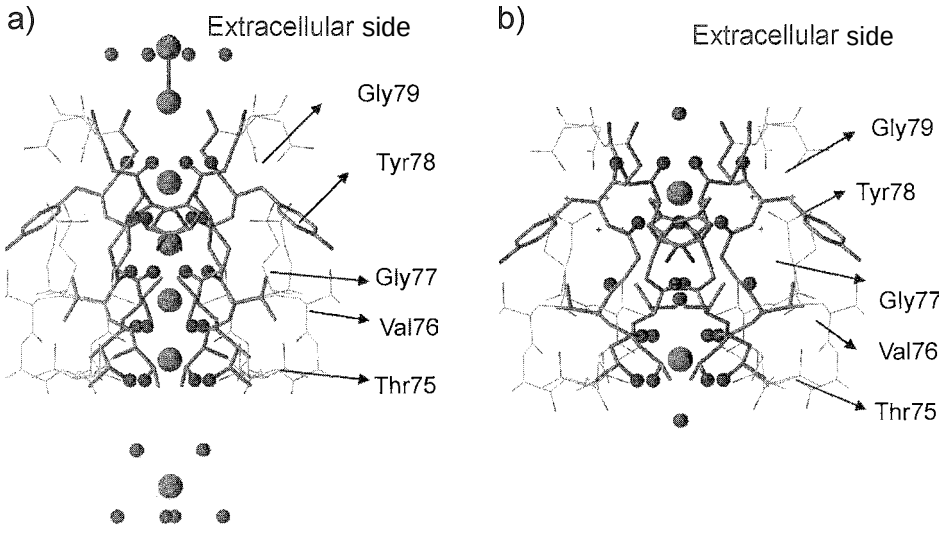

Fig. *2* Crystal structures of K^+ ion channel with different K^+ concentrations. a) K^+ channel selectivity filter with high concentration of K^+ ions (green spheres) along the ion pathway. and water molecules (pink spheres) in the vicinity. b) K^+ channel selectivity filter with low K^+ concentration of K^+ ion (green spheres). Main-chains of the selectivity filter are disordered. Fig. 2a and b were produced with PDB files (code: 1K4C and 1K4D from Ref. [8]) and ViewerLite (version 5.0 Accelrys. Inc.. U.K.).

OH···N (indolyl) hydrogen bond (Fig. 1b). This unit may keep the pore wide and contribute to the K^+/Na^+ selectivity through decreasing the stabilizing power for a smaller Na^+ ion. The selectivity filter is composed completely of neutral oxygen atoms in favor of stabilizing the K^+ rather than the Na^+ ion, which demands stronger electrostatic interactions. The selectivity filter of the Na^+ ion is believed to contain ionic pairs,[6] and its structural elucidation is highly desirable. Furthermore, the selectivity ratio P_K/P_{Na} of this K^+ channel KcsA shows only a moderate value of 11,[7] and it is interesting to imagine how highly selective K^+ channels introduce any additional recognition principle(s). Another characteristic point of this x-ray structure is that the transmeinbrane pore contains a Iarge water pool in the middle of the membrane. to which helical negative dipoles direct. Further, the inner half of the conduction pathway is lined with hydrophobic side chains and is wide enough to be filled completely with water molecules. These are thought to be features that allow a high throughput of K^+ ions (Fig. 1c).

The above selectivity filter constrained two K^+ ions about *7.5* Å apart. This configuration was thought to promote ion conduction by electrostatic repulsion. With an increased resolution, MacKinnon also determined two crystal structures at high and low K^+ concentration states.[8] At the high concentration, they found four K^+ ions in the selectivity filter instead of two, and two more hydrated K^+ ions at its extracellular entryway. Furthermore, the K^+ ion in the central cavity was fully surrounded by eight water molecules. All of these K^+ ions were embedded in a square antiprismatic geometry by water, carbonyl. and hydroxyl oxygen-donor ligand groups (Fig. 2). These ordered water molecules make dehydration and hydration interconversion processes of K^+ ion at both entryways easy. The similarity of the coordination structures, one at the central cavity, four in the selectivity filter, and two at the extracellular entryway, can promote the smooth structural interconversion and explain the rapid transport of K^+ ion through the K^+ channel.

The Cl^- channel is a physiological counterpart of cation channels, and the analysis of C l selectivity may contribute to the true understanding of the whole series of ion selectivities. In the x-ray crystal structure of the closed state of the Cl^- channel, two Cl^- ions detected inside the pore were stabilized by hydrogen bonding with main-chain amide NH and side-chain hydroxyl groups of Ser and Tyr (Fig. 3).[9,10]

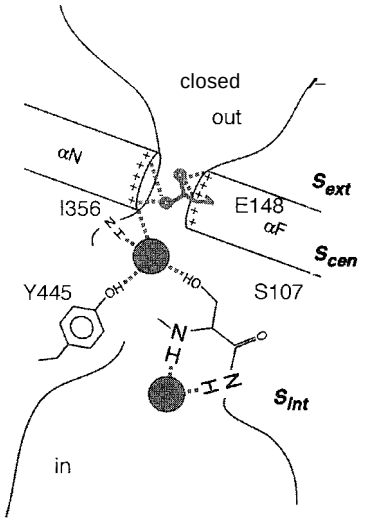

Fig. **3** Schematic illustration of the closed conformation of a ClC chloride channel. The ion-binding sites S_{int} and S_{cen} are occupied by chloride ions (red sphere) stabilized by $Cl^-\cdots H$ hydrogen bondings (dashed lines). The external ion-binding site S_{ext} constitutes the gate and is blocked by the side chain of Glul48 (red).

Gating Mechanisms of Ion Channels

Gating is one of the principal functions of ion channels. Ion permeation occurs only when the corresponding ion channels open on accepting their own stimuli. This gating information is classified into three types: voltage across the membrane (voltage-gated): binding of ligands such as neurotransmitters or second messengers (ligand-gated): and membrane deformation (inechanosensitive). In any event, in opening the gate, massive mechanical variations of channel structure must be performed when responding to the sensor unit. Recent developments in crystallographic structure determination enabled the identification of the open and closed states of several ion channels and discussion of the mechanisms based on these experimental structures.

In voltage-dependent K^+ channels, the number of gating charges amounts to 12–14 electron charges as a result of the assembly of four identical subunits having 3–3.5 charges. This large gating charge responds sharply to change of the membrane voltage. X-ray analysis elucidated the movement of this gating charge across the membrane, as shown in Fig. 4.[11,12] Here. the sensor units are composed of a highly conserved Arg-rich domain in the S4 helix. Its movement across almost the entire membrane can deform the channel geometry from trapezoidal to cylindrical forms and open the central pore (Fig. 4b). This new proposal differs from the conventional hypothesis of charge movement within the "gating pore."[13]

Voltage-dependent K^+ channels close by a process called "inactivation," rapidly after opening. In *drosophila* mutant K^+ channels, the cytoplasmic amino terminus in its own channel forms the inactivation gate. The central

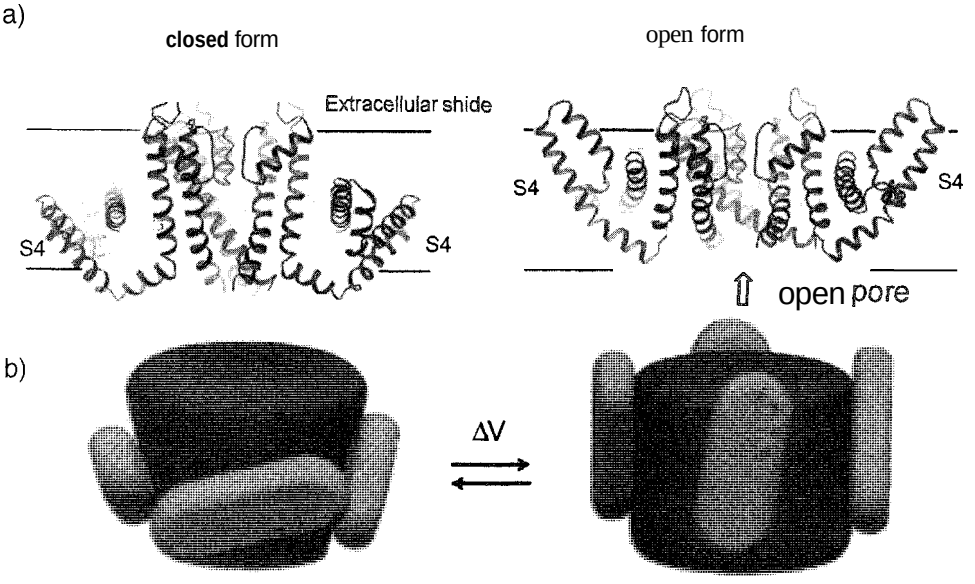

Fig. 4 Movement of voltage-sensor in voltage-gated K^+ channel. a) Positions within the membrane of the voltage-sensor paddles S4 (red) during closed and opened conformations. with coupling to pore opening. b) Gating charges (red plus signs) are carried through the membrane from inside (bottom) to outside (top) by *movements* of the voltage-sensor paddles against the lipid *membrane* and the open pore.

cavity and the inner pore of the K^+ channel provide the receptor site for the inactivation gate and inhibitors such as hydrophobic quaternary ammonium ions (Fig 5a).[14] The inactivation occurs by a sequential reaction. in which the gate peptide is bound initially to the cytoplasmic channel surface and then enters the pore (Fig. 5b).

The structural basis of ligand gating was reported for a Ca^{2+}-gated K^+ channel. Here, eight RCK (regulator of K^+

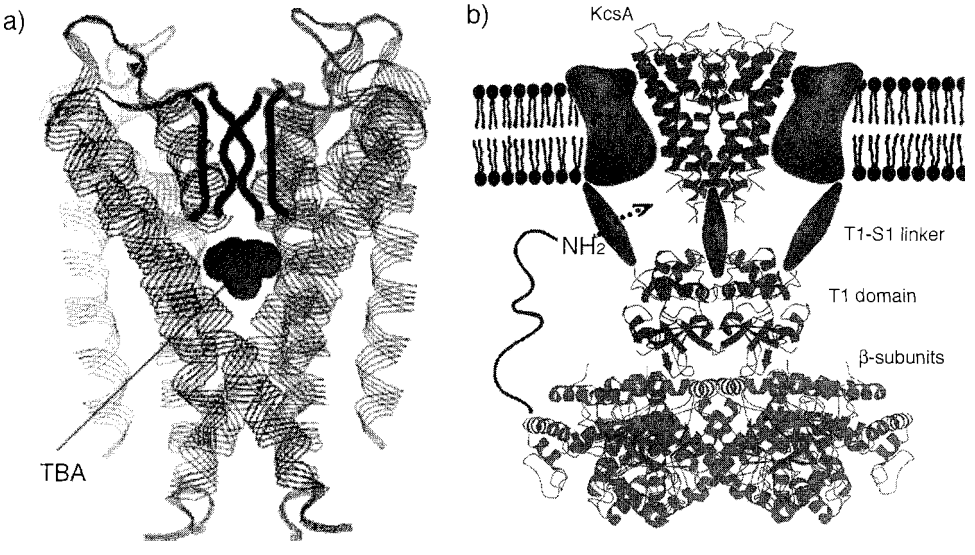

Fig. 5 Inactivation of K^+ channel. a) Crystal structure of KcsA K^+ channel with a hydrophobic cation, tetrabutylammonium TBA. b) Composite model of a voltage-dependent K^+ channel. The α-subunit is shown in blue and the β-subunit in red. The pore is represented by the KcsA K^+ channel *(5)* and the Tl-β complex (15). The structures of the linker (T1-S1) connecting the voltage sensors to the TI domain are unknown. An N-terminal inactivation gate is shown entering a lateral opening to gain access to the pore. Fig. 5a was produced with a PDB file (1J95.pdb from Ref. [14]) and Raswin Molecular Graphics (version 2.7.2. Glaxo Research and Development. U.K.).

conductance) domains assemble to form a large gating ring at the intracellular membrane surface. The cooperative binding of eight Ca^{2+} ions from the intracellular solution induces conformational change of the gating ring in such a way that it can open the inner helices of the pore to permit ion conduction. The gating behavior is shown schematically in Fig. 6, where the upper part forms an ion conduction pore in the membrane. The lower part from solution represents the RCK domain, where eight Ca^{2+} ions are bound allosterically.[16,17]

The open and closed conformations on binding ligands to the nicotinic acetylcholine receptor channel were already trapped and observed by electron microscopy. Here again. the cooperative binding of ligands induces large rotational movements of the pore-defining subunit~.~'~'

Mechanosensitive ion channels act as membrane-embedded mechanoelectrical switches that open a large pore in response to membrane deformations. It is a way of biological signal transformation of physical stresses such as touch and hearing to changes into electrochemical responses. The gating mechanism of a large-conductance mechanosensitive pentameric channel (MscL) was elucidated as shown in Fig. 7.[19,20] Transitions from the closed or intermediate state to the open states upon application of tension to the membrane are accompanied by massive rearrangements of the two transmembrane helices TM1 and TM2. The inner TM1, creating the bulk hydrophilic pore containing Thr, Lys, and Asp units, rotates along its principal axis and shifts away from the symmetrical axis to open the water-filled pore of 3040 Å, leading to conductance at nano-Siemens levels (Figs. 7c,d).

ARTIFICIAL ION CHANNELS

Construction of artificial ion channels according to simple principles[21,22] is interesting for obtaining molecular devices that mimic the biological signal transduction system. There are two ways to prepare ion-conducting artificial pores—molecular and supramolecular methodologies, along with modification of ionophoric antibiotics.

Molecular Ion Channels

A macrocyclic resorcin[4]arene with four hydrophobic substituents in the axial position provides an ion-conducting molecular pore by tail-to-tail dimerization.[23] Because the pore size and characteristics of the entryway are defined explicitly by the molecule, only one conductance level is observed. The relatively simple structure is amenable to systematic structural modifications and is, therefore, appropriate in establishing the structure–function relationships. When a methyl ether derivative of cholic acid was employed as the axial substituent,[24] the conductance was increased by 50% to 9.9 *pS*, compared with the value 6.1 *pS* observed for **1** with simple alkyl substituents.[23] The cation and anion selectivity ratio P_K/P_{Cl} was 20 for **2**. showing a significantly larger selectivity factor compared to 8 for **1**. A hydrophilic molecular plane of methoxy substituents certainly contributes to the increase of conductance and a higher cation and anion selectivity by the arrangement of a more hydrophilic environment at the central pore. Both ion channels exhibited moderate K^+ preferences compared to Na^+ by a facior of ca. 3. The aromatic moiety provides a weak electric field

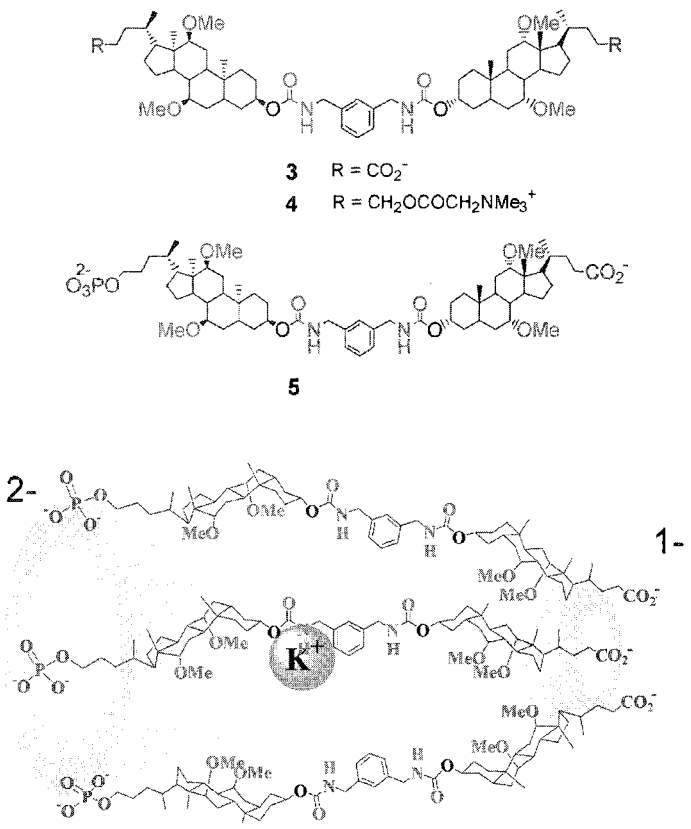

Fig. 9 Chemical structure of supramolecular ion channels with K^+ ion selectivity, 3, 4 and with voltage-dependent properties 5. Schematic illustration of supramolecular ion channels **5** with different mouth diameters in bilayer lipid membranes.

that can desolvate the K^+ ion with a lower dehydration energy to pass through the cavity but can only partly desolvate the more hydrophilic Na^+ ion (Fig. 8). The inverse selectivities. a preference for Na^+ and Cl^-, were not yet obtained. and their embodiment remains a challenging target in this field.

Supramolecular Ion Channels

r

Besides synthesizing a molecular pore of a definite diameter. supramolecular pore formation provides an attractive alternative. This methodology is also adopted in Nature for the formation of the K- and acetylcholine receptor channels as homotetrarner and heteropentamer. respectively.[1] The assembly numbe of artificial supramolecular channels is generally not controlled, and various levels of conductance are usually observed. Two cholic acid methyl ether derivatives were connected via bisurethane linkages to obtain a membrane-penetrating component in its extended conformation. The carboxylate 3 and ammonium 4 head groups provide supramolecular ion channels showing stable open durations.[25,26] Both channels are cation selective. irrespective of different charges of head groups. The cation and anion selectivity values P_K/P_{Cl} were 17 and 7.9 for **3** with negative head groups, and 4 with positive head groups, respectively. Therefore, the terminal charges reasonably perturbed the entry of the cation relative to the anion. The discrimination factor between K^+ and Na^+ ions was again moderate. P_K/P_{Na} being three for both channels. The metal ion selectivity is determined primarily at the critical domain of the pore environment and is separated substantially from the charged head groups.

Two head groups of carboxylic and phosphoric acids were introduced to displace different charges at the ends of the membrane-penetrating cholic acid dimer unit **5**.[27] The head group charges should be asymmetric under basic conditions ($-1/-2$ at pH *8.2)*. When 5 was introduced into a planar bilayer membrane under an application of the asymmetric voltage to facilitate the vectorial incorporation of the channel, the current values at a positive voltage range were larger than the corresponding values at the negative one. The current–voltage plots were fitted by curves passing through a zero point to show clear rectification properties. Without asymmetric voltage application. the current observed was symmetric. The rectification currents observed seem to be a result of the different radii of the channel mouths controlled by the displacement of different charge numbers at the molecular terminals. as shown in Fig. 9.

Ion channels can produce large ionic fluxes across the bilayer lipid membrane. Because living cells. including bacteria, rigorously maintain ionic concentrations and rely on the ion impermeability of the biological membrane. incosporation of foreign ion channels disrupts such osmotic balance. Recently, antibiotic activities of artificial ion channels were demonstrated independently by Ghadiri[28] and Gokel.[29] Supramolecular assembly of cyclic oligopeptides increased ion permeability in bacterial membranes. induced the collapse of the transinembrane ionic potentials, and finally caused rapid death of the cell. Similar activities were observed for crown-ether-based artificial ion channels against the bacterium *Escherichia coli.* These are thought to have considerable potential against the rapid emergence of drug-resistant bacterial infections.

Antibiotic-Based Ion Channels

Gramicidin antibiotics form a head-to-head dimer in a bilayer lipid membrane to afford a stable cation-selective ion channel. A half-gramicidin unit was introduced into an inner half-membrane with anchoring on gold surface and the other half counterpart was incorporated into the outer half membrane as a mobile unit.[30] The diffusion of the mobile half gramicidin unit carrying a guest molecule

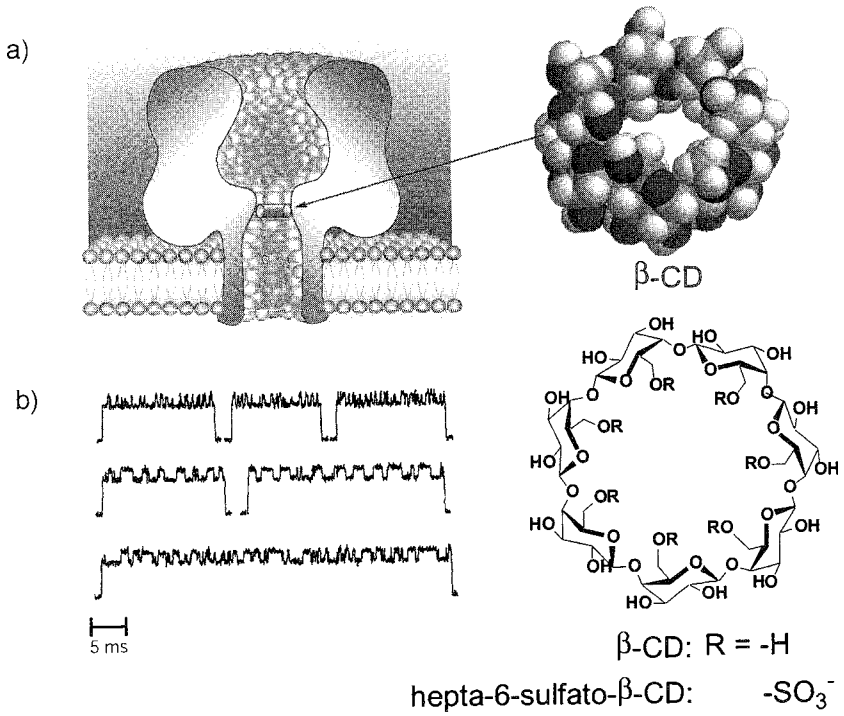

Fig. 10 Artificial ion channel with *staphylococcal α-hemolysin* (αHL) with a molecular adaptor. a) Schematic of the αHL pore showing βCD loged in the lumen of the channel with adapters. βCD and hepta-6-sulfato-β-cyclodextrin. b) Detection of organic molecules by stochastic sensing. The pore contains a noncovalent βCD adapter. which is capable of carrying out host–guest chemistry while lodged in the lumen. Upper trace, promethazine: middle trace, imipramine; loner trace, mixture of promethazine (100 μM), and imipramine (100 μM).

within the outer half of the membrane was switched off by an interaction with a receptor immobilized at the membrane surface. This prevented the grarnicidin dimer formation and decreased the ionic currents across the membrane. The addition of competitive guests recovered the conductance state. In this way, the population of molecular ion channels could be switched on and off by recognition events mimicking biological sensory functions.

α-Hemolysin (αHL) is a heptameric assembly of /?-sheet turns to make a mushroom-shaped large pore (near 30 Å diameter) surrounded by 14 *β*-sheets in a biological membrane. Through this cavity. a large ionic flux can be generated. and a-HL is a highly toxic material. This cavity interestingly can accommodate *β*-cyclodextrin (*β*-CD) to make an ion channel of a moderate pore size, therefore. affording inoderate conductivities.[31,32] Weakly anion-selective α-HL becomes more anion selective when *β*-CD is accommodated in the middle of the channel pore due to a favorable interaction of *β*-CD with anions. By contrast, hepta-6-sulfato-*β*-cyclodextrin carrying high negative charges produces reversed cation selectivities. It is noteworthy that this molecular adapter system can generate high permeability ratios (P_K/P_{Cl}) over a 200-fold range.'''']

As *β*-CD is an effective host for various substrates, the binding of guests in the cavity modifies the mode of ionic flux of the *β*-CD adapter channel. Depending on the binding characteristics of the guests. the conductance and time profiles of open–closed transitions can be modified. Because an ion channel is a molecular device used to amplify events at a single molecular level into a massive ionic flux. it affords a highly sensitive stochastic sensor for guest molecules (Fig. 10).

CONCLUSION

Alkali metal ions carry important messages and biological signals by their movements. By controlling the ionic species (Na^+, K^+, along with Ca^{2+} and Cl^- ions), magnitude of the flux (conductivity). triggering signals (voltage variation; ligand binding. and ineinbrane deformation), and dynamic behavior (duration of open–closed times), ion channels play critical roles in biological processes in the brain and nervous system. The mode of information transfer is totally different from the electronic systems we developed for computer systems. Although the achievements of dry electronic systems are magnificent.

the wet biological system is still far advanced in many respects. However, the use of wet systems in vitro is far less developed, and we need to gain an understanding of numerous principles of such biological systems. The construction of artificial ion channels may help scientists develop ways to comprehend these basic units and their systems. With further exploration to be undertaken in this area. the future picture can not easily be foreseen.

INTRODUCTION

Crystalline alkalides are salts with alkali metal anions (Na , K , Rb , or Cs) that have been known since 1974, when the first sodide was synthesized.[1] The first crystalline electride, in which trapped electrons serve as the anions, was first fully characterized in 1986.[2] The key to the formation of both classes of materials is complexation of the countercation (Li^+ through Cs^+) by organic macrocyclic or macrobicyclic molecules such as crown ethers and cryptands. Seven clcctrides and 37 alkalides have now been synthesized and their structures were determined by single crystal x-ray crystallography.[3] Their properties were studied by a number of methods, including optical, electron paramagnetic resonance (EPR), and nuclear magnetic resonance (NMR) spectroscopy, magnetic susceptibility, conductivity, and differential scanning calorimetry (DSC).

Both alkalidcs and electridcs are powerful reducing agents; so powerful, in fact, that most cannot survive, even in vacuo at temperatures above about $-30°C$. The organic complexant is irreversibly destroyed by cleavage of the O—C or N—C bonds of the complexant. This reducing ability of alkalides is, however, useful in organic synthesis when a powerful two-electron reducing agent is needed.[4] Alkalides and electridcs in solution are able to reduce nearly all metallic cations to form nanoscale metal particles.[5]

In this overview of alkalides and electrides, the methodologies and special techniques used will be briefly described, and the structural features and electronic, optical and magnetic properties will be summarized. The reference list is far from complete, but the information given can provide many additional references to the original literature in this field.

EXPERIMENTAL METHODS

The major concern in the preparation and study of alkalides and clcctrides is their extreme sensitivity to air, moisture, and especially elevated temperatures. Thus, ordinary glove box procedures do not suffice without provision to keep the samples cold (below about $-40°C$) at all times during and after synthesis. It should be noted, however, that the formation and use of alkalides such as $K^+(15\text{-crown-}5)_2\ Na^-$ in solution (in THF, for example) can bc carried out at room temperature in a glove box, Schlenk line, or by syringe techniques. Thus, organic synthetic methods that need a powerful two-electron reducing agent need not be as rigorous as those required to prepare crystalline alkalides and electrides.

Synthesis is simple and straightforward in principle. One merely needs to prepare a solution of the complexant and alkali metal in a pure aprotic solvent such as methylamine ($MeNH_2$) or dimethyl ether (Me_2O), filter the solution through a porous glass frit into a second compartment of a K-cell,[6] and add a less polar cosolvent such as diethyl ether (Et_2O) or trimethylaminc (Me_3N). Then the more polar primary solvent is removed by evaporation until the solution is saturated at about $-40°C$. Slow cooling over a I-or 2-day period (sometimes with temperature cycling back to the starting temperature to dissolve small crystals) results in crystal growth. The crystals can then be washed with the secondary solvent by pouring the liquid back through the frit and redistilling it for further washes. Finally. vacuum evaporation of all solvents leaves dry crystals for study. In some cases, solvent molecules are included in the crystal structure so that wet crystals must be harvested.

In practice, things arc not as simple as indicated above. Because the metal solutions are thermodynamically unstable, all glassware used must be rigorously cleaned, and solvents must be free of reducible impurities. Control of the stoichiometry can sometimes dctcrmine whether an clectride or an alkalide (or a mixture of the two) is formed. For example, the preparation of an electridc or a ceside can bc controlled by the relative amounts of 18-crown-6 (18C6) and ccsium metal according to

$$Cs + 2(18C6) \rightarrow Cs^+(18C6)_2e^- \quad (1)$$

or

$$2Cs + 2(18C6) \rightarrow Cs^+(18C6)_2Cs^- \quad (2)$$

By using a slight excess of 18C6, the electride is formed, while an excess of cesium gives the ceside. Because cesium mctal is insoluble in Me_2O, this solvent can bc used as a primary solvent. When preparing the clcctride, excess 18C6 is removed by washing with the secondary

DOI: 10.1081/E-ESMC 120012700

solvent. Again. complications often occur. It is easy to use cryptand[2.2.2], (C222) to prepare K^+(C222) Na by using a mixture of K and Na metals and to prepare Na^+ (C222)Na with just sodium. But, we have never been able to make crystalline Na^+(C222)e^-. Whenever sodium is present in solution, regardless of the complexant used, a sodide is formed. Another complication that can occur, especially with $MeNH_2$ and either Et_2O or Me_3N, is phase separation of the liquid solutions. One gets a concentrated $MeNH_2$-rich phase and a more dilute cosolvent-rich phase. Also, of course, the growth of high-quality crystals remains more an art than a science; we frequently obtain apparently well-formed crystals that do not diffract x-rays well enough to permit structure determination. In the descriptions of structures and properties that constitute the balance of this article, only alkalides and electrides of known structure will be considered. Many other polycrystalline alkalides and electrides were prepared and studied, but without a structure, one can never be confident that a pure compound was prepared. This is particularly true of electrides, which are frequently contaminated with alkali metal anions.

In this article. we will not describe in detail the experimental equipment used to determine the optical, electronic, and magnetic properties of these materials. Standard instruments were used for EPR, ENDOR. solid-state NMR. SQUID susceptibility, powder conductivity, optical reflectance and transmittance, and DSC. although some home-built instruments were involved. The specific equipment used is described in the references. The major consideration in designing and using equipment is the need to keep the samples cold and away from air and moisture at all times.

ALKALIDES

Origin and Synthesis

The synthesis of crystalline alkalides had its origins in the study of alkali metal solutions in amines and ethers. Although genuine alkali metal anions apparently do not form in metal–ammonia solutions, they are ubiquitous in less-polar solvents. A great deal of confusion in early work was removed when Hurley. Tuttle, and Golden[7] showed that Na' in sodium borosilicate glass was readily exchanged by other alkali cations in solution. This exchange yielded the peak of Na^-, even when no sodium was added to the solution. The optical absorption spectra of alkali metal solutions in ethylenediamine at room temperature (shown in Fig. 1) (corrected for Na contamination when necessary) were obtained by Dewald and Dye in 1964.[8] Later work[9] clearly identified the peaks of e , Cs , Rb^-, K^-, and Na^-, as labeled in the figure. Note the absence of Li . a result of the high solvation energy of Li^+.

The study of more concentrated alkali metal solutions in a variety of solvents became possible in 1970, when crown ethers were used[10] to enhance the solubility of the metal. The use of crown ethers and cryptands permitted extensive studies of the optical spectra of solvated electrons and alkali metal anions in solution. After the isolation of the first sodide salt in 1974,[1] the optical spectra of polycrystalline films of various alkalides and electrides were determined by rapid evaporation of all solvent from a liquid film on the walls of the optical cell.[11] Displayed in Fig. 1 are the optical spectra obtained in this way. Clearly. there is a 1:1 correspondence between the spectra in solution and in the solid state. Although the peak positions shift somewhat with temperature and with the complexant used, the optical peaks can be used to verify the presence of particular alkali metal anions or trapped electrons. In addition to rapid solvent evaporation. solvent-free alkalide and electride films can be made by codeposition of the complexant and alkali metal in high vacuum (10^{-8} torr).[12] This permitted the study of optical

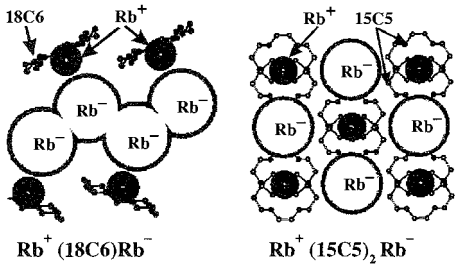

Fig. 2 Examples of M^- chain formation (left) and isolated M^- (right) in two rubidium rubidides. The Rb^+ and Rb^- ions are drawn to scale. while ball-and-stick models are used for 18C6 and 15C5.

transmission spectra, conductivity, and thermionic electron emission.[13]

Structural Features

Alkali metal anions are large and highly polarizable. With two electrons sharing the outer s-orbital, expansion occurs to yield radii of about 2.8, 3.1. 3.2, and 3.5Å for Na . K . Rb , and Cs , respectively.[14] Crystal structure determination permitted the identification of a variety of structural motifs. In addition to isolated anions. various structures include contact ion pairs between M^+ and M . dimers of the anions. $(M^-)_2$, and anionic chains. $(M^-)_n$.[14] Although one might think that coulomb repulsion would prevent dimerization of M . a theoretical study[15] showed that such dimers can be stabilized by adjacent cations. Dimers and chains presumably form by partial hybridization of the diffuse s-orbital with empty p-or *d*-orbitals.

Two extremes are shown in Fig. 2. Isolated anions, separated from the cations by the complexant. are present in $Rb^+(15C5)_2Rb^-$, while chains of Rb^- in close contact with Rb^+ form in $Rb^+(18C6)Rb^-$. The cesides, $Li^+(C211)Cs^-$ and $Cs^+(C222)Cs^-$ also form chains of anions. while anionic dimers are present in $K^+(C222)K^-$ and $Rb^+(C222)$ Wb . In most alkalides. the alkali metal anions are isolated from one another and from the cations. However. cation–anion contact pairs are present in M^+ (hexamethyl hexacyclen) Na . with M=K, Rb. Cs.[16]

Properties

Many properties of alkalide crystals. powders. and films were measured. The original alkalide, $Na^+(C222)Na^-$, has been most thoroughly studied, in part because of the high stability of pure samples. In contrast to most alkalides, single crystals and vapor-deposited films of this sodide are stable in vacuo for many hours, even at room temperature. In addition to the crystal structure, we measured the thermodynamics of formation by an EMF method, optical transmission spectra of polycrystalline films. reflectance spectra of single crystals, single-crystal fluorescence spectra, EPR of defect electrons, ^{23}Na-NMR spectra of powder and oriented single crystals. powder-and single-crystal conductivity, exciton formation and mobility, photoelectron emission spectra, and multiphoton photobleaching. Only limited sets of such measurements were made on other alkalides; Na·(C222)Na could be viewed as the best-understood model of an alkalide with isolated alkali metal anions.

Optical spectra

The optical transmission spectra of polycrystalline films are shown in Fig. 1. The spectrum clearly arises primarily from an $np \leftarrow ns$ transition. The peak positions correlate well with the corresponding dissociation transitions in the gas phase. The anisotropy in the solid leads to a small orientation dependence of the peak position in the single-crystal reflectance spectrum of $Na^+(C222)Na^-$.[12] Recent unpublished work in our laboratory showed that the effect is much larger in $Li^+(C211)Cs^-$, which forms extended chains of ceside anions.[17] This orientation dependence is a natural consequence of the removal of excited p-state degeneracy in the anisotropic solid.

Pure alkalides are diamagnetic insulators or semiconductors. It is practically impossible, however. to avoid the incorporation of defect electrons in the structure. They are easily detectable by EPR spectroscopy and contribute to defect conductivity and a "Curie tail" in the magnetic susceptibility. When defect electrons in $Na^+(C222)Na^-$ are photoexcited. they remain for many minutes in states near the vacuum level and can be photoejected with infrared (IR) photons.[18] The effect is completely absent in defect-free crystals of this sodide.

NMR spectra

Alkali metal NMR spectroscopy provides a good diagnostic tool for isolated alkali metal anions in solution and in solid alkalides. The chemical shifts are close to those calculated for the gaseous anions: much more diamagnetic (negative) than the reference state of $M^+(aq.)$. In solution, the chemical shifts of M are about -62, -100, -190. and -290 ppm for M=Na. K. Rb, and Cs. respectively, compared with calculated gas-phase values of -63, -103, -214. and -346 ppm.[19] The values in solid alkalides are somewhat dependent on the compound, but for salts with isolated anions, the values are about -61, -10.5. -190. and -220 ppm, in agreement with the solution values and. at least for Na and K, nearly the same as the gas-phase chemical shifts. The absence of significant shifts from those of gaseous M^- is a consequence of the large size of the anions and their nearly spherical shape. Shifts in the paramagnetic direction (Ramsey

shifts) are caused by mixing of the unoccupied orbitals of the alkali metals with those of surrounding molecules. The large size of the alkali metal anions tends to minimize such shifts.

When dimers or chains of alkali metal atoms are present, the anion chemical shift is considerably more paramagnetic, even to the extent of having the shift of Cs^- confused with that of Cs^+ in early work.[19] Recent studies indicate that dimer or chain formation can shift the peaks of K^-, Rb^-, and Cs^- by hundreds of ppm. The mixing of *p* or *d* orbitals to provide some bonding between adjacent anions would introduce considerable spin-orbit coupling that would result in a pronounced paramagnetic shift.

Because the alkali metal nuclei have quadrupole moments. the lines are considerably broader than those of nuclei with spin 1/2. The effect is small for ^{7}Li and ^{133}Cs and only moderate for ^{23}Na. With ^{39}K, ^{85}Rb, and ^{87}Rb, quadrupole broadening makes solid-state NMR studies difficult. but even in these cases, the static line shapes can provide considerable information about the quadrupole coupling constants. asymmetry paramete s, and chemical shifts.[20]

Stability

The tendency of alkalides to decompose above about −30°C made the study of iheir properties difficult. The decomposition mode with crown ethers and cryptands is the rupture of O—C bonds. For example. $M_a^+(C222)M_b^-$ (with M_a and M_b the same or different alkali metals) releases ethylene from the —O—CH_2—CH_2—O— moiety with formation of alkoxide units.[21] The N—C bonds in perazacryptands and cyclens is considerably more resistant to reduction. We recently prepared the sodide and potasside of fully methylated perazacryptand [2.2.2] and found them to be stable at room temperature for months.[22] The flip-side of this story is that aza coinplexants have generally much poorer complexing ability for alkali cations. When a complex forms, it frequently dissociates at elevated temperatures to yield the metal and free complexant. Thus, a synthetic challenge in this field is to find peraza complexants with just the right size and lone pair orientation to form strong complexes with alkali cations.

ELECTRIDES

Background and Definitions

In contrast to alkali metal anions. which were first positively identified as solution species in 1970. solvated and trapped electrons have been known for more than a century.[23] With the advent of pulse radiolysis, the solvated electron has become probably the most widely studied species in chemistry. Electrons trapped at defect sites in crystals (F-centers and clusters) have also been studied extensively for over a century.[24] Alkali metal incorporation in alumino-silicate zeolites to yield electrons trapped near clusters of cations has been the subject of many experimental and theoretical studies[25] since first observed in 1966.[26] Even simple alkali metals, with a "sea" of electrons filling the space between cations. have one electron per cation. What then distinguishes true electrides from all these other materials?

As the "-ide" ending suggests. the electrons in electrides take on the role of anions.[27] This implies that electrides are crystalline ionic compounds with one electron per cation. They could be viewed as salts that contain stoichiometric F-centers. with electrons as the only anions. But because one cannot suppress the quantum nature of electrons, these "anions" are special. The line between localized weakly interacting electrons and delocalized, or metallic electrons is blurred. and both extremes are encountered in electrides. Because most of the electron density in electrides is present in otherwise empty, well-defined pseudo-one-dimensional cavities and channels, they could also be viewed as forming low-dimensional correlated electron gasses.

General Structural Features

Except for zeolite-based electrides. to be considered later. the cations in all electrides synthesized to date are alkali cations, Li^+, K^+, Rb^+, or Cs^+, sequestered inside a cryptand cage or sandwiched between two crown ether molecules. Thus, the cations are well shielded from the electrons. The temperature dependence of the ^{133}Cs-NMR chemical shift (Knight shift) in two electrides shows that the unpaired electron density at the Cs^+ cation is less than 0.1% of the value for the isolated atom.[28] The structures of the complexed cations are practically identical to those of corresponding allialides and normal salts. Because the electron density of the trapped electrons is too low to detect by x-ray crystallography, the major structural difference between an electride and the corresponding alkalide is that the former has large voids at the anionic sites. To a first approximation, then. the electrons could be viewed as particles in adjacent, nearly spherical boxes. The common feature of an intense optical absorption band in the near IR at 1200–1500 nm. with a long tail into the visible, is the counterpart of the optical behavior of solvated electrons. The optical bands of solvated electrons were attributed, for many years. to electrons trapped in otherwise empty cavities.[23] The similarity to electrons in electride cavities is striking.

A complication that caused confusion in the study of electrides is structural polymorphism. Each of the electrides $Cs^+(18C6)_2e^-$, $Cs^+(15C5)_2e^-$, $Li^+(C211)e^-$, and $Rb^+(C222)e^-$ exists in at least two polymorphs.[3] Only

Fig. 3 Channel structures of four electrides. The general shapes of the cavities and channels are represented. (From Ref. [29].)

one form of each eiectride has a known structure, but the properties of the two forms are different. The factors that determine which form precipitates from solution are not known, and transitions between the types are slow. In the case of $Rb^+(C222)e^-$, mixtures of the two forms were usually produced, and it was necessary to use the magnetic properties to determine the amount of each present.[3]

Electron–Electron Interactions

The cavities and channels left by close-packing of the complexed cations tend to form uniform one-dimensional chains, like beads on a string, in five of the seven electrides of known structure.[29] The electrons are coupled antiferromagnetically, and the magnetic susceptibilities are well-fit by the Heisenberg linear-chain model, with a single negative coupling constant, J.[30] The mixed crown ether electride, $[Cs^+(15C5)(18C6)e^-]_6{\cdot}(18C6)$, has a complex structure.[''' while $K^+(C222)e^-$ has a two-dimensional channel-cavity structure with open channels in one direction and constricted channels in a second direction.[''' As with the corresponding potasside $K^+(C222)K^-$, this electride has open dumbbell-shaped cavities that contain two electrons.[32] The coupling is so strong in this case that the electride is nearly diamagnetic. The temperature dependence of the susceptibility is well-described by the alternating chain antiferromagnetic Heisenberg model.

The correlation between the magnetic coupling constant, J, and the geometry of the cavity-channel systems is remarkable. It provides strong experimental evidence for the theoretical finding that the excess electron density resides primarily in the cavities and channels.[33] The geometry of the channels in three electrides is shown in Fig. 3. Becaue the distance between cavity centers only slightly varies from one electride to another, the major effect on the interelectron coupling is the size of the connecting channel. Shown in Fig. 4 is the stron,σ correlation between the magnitude of the coupling constant and the cross-sectional area at the minimum diameter of the channel. Clearly, the overlap of the electronic wave functions is strongly influenced by the available void space between the electrons. This behavior of a well-defined; one-dimensional correlated electron gas of electrons should be a fruitful area for theoretical treatment.

Optical and Electrical Properties

The intense near-IR absorption of electride films (Fig. 1) is characteristic of localized electrons with little inter-

electron coupling. The electride $K^+(C222)e^-$ has a more open structure and far stronger coupling between electrons. This also has a profound effect on the optical spectrum and conductivity. Films of this electride. formed by high vacuum codeposition of K metal and cryptand [2.2.2] in 1:1 stoichiometry were extensively studied by optical transmission spectroscopy and four-probe conductivity.[34]

Freshly prepared films show the absorption peak of K . This tends to anneal with time to a combination of a localized electron peak at $\sim$1250 nm and an absorbance that rises steadily with increasing wavelength. The spectra are remarkably similar to those of concentrated metal–ammonia solutions as they move through the nonmetal to metal transition.[35] The rising absorbance is attributed to the plasma edge that is characteristic of metallic behavior. The electrical conductivity of powders and films of this electride is far greater than that of other electrides, as shown in Fig. 5. Whether these conductivities are intrinsic or defect-dominated is uncertain; but clearly. the open-channel nature of $K^+(C222)e^-$ has a profound effect, bringing this electride to the threshold of metallic behavior. Four-probe single crystal studies show that the conductivity is highly anisotropic.[36] It is nearly metallic along one direction in the plane of the channels and insulating perpendicular to this plane.

The Search for Stable Electrides

It is likely that the study of electrides would be more widespread if thermal stability at room temperature could be achieved. The recent success in synthesizing a sodide and potasside that are stable at room temperature[22] provided the incentive to find aza-based complexants that will permit the crystallization of stable electrides. The cation of choice would be Li^+, because there would be no competition from Li . an alkalide that has never been made. A number of candidates were tried. from methylated cyclens to fully methylated azacryptands to adamanzane-like complexants. Thus far: none produced a crystalline electride of known structure. When the cation is kinetically able to leave the complexant. dissociation without decomposition occurs. The aza complexants used to date apparently do not form strong enough complexes to yield thermodynamically stable electrides. although alkalides can be made in some cases. The search for the ideal aza complexant continues.

Inorganic Electrides

F-centers in alkali halides are stable. In 1966 Kasai and coworkers found that electrons could be trapped in a zeolite by incorporation of sodium from the vapor phase.[26] They identified the species Na_4^{3+}, an electron trapped by a cluster of four sodium cations. Since that time, a great deal of work was done on the inclusion of alkali metals in various aluminosilicates,[25] including the formation of a stoichiometric sodium sodalite that has Na_4^{3+} units inside every sodalite cage.[37] In common with electrides, these paramagnetic centers are coupled antiferromagnetically and undergo a Néel transition at 48 K. While these metal adducts to zealots could be (and have been) called ''electrides,''[25] they differ from the organic electrides by having several cations for each electron.

We recently added alkali metals from the vapor phase to two pure silica zealots to yield adducts that have a 1:1 stoichiometry of cations to electrons.[38] The properties strongly point to ionization to yield alkali cations that interact with the Si—O—Si units that line the zeolite channels. Apparently, the released electrons occupy the open spaces of the channels, which have diameters of -7 Å. The electrons are strongly coupled to form nearly diamagnetic materials. These inorganic electrides are stable to at least 100°C. Potentially, zeolite-based systems

might be made that would have an even closer relationship to organic electrides. If a pure silica zeolite could be made that contains open channels and separate cation-trapping sites, it should be possible to prepare a stoichiometric electride with trapped cations and electrons that are free to roam the channels. Such systems might have interesting properties. including, perhaps, metallic conductivity.

CONCLUSION

Although we studied alkalides and electrides for nearly 30 years. there is much that remains to be done to make them useful members of the chemistry–physics communities We hope that the existence of stable, easy-to-prepare alkalides and electrides will prompt a number of other researchers to entei this intriguing field

The Allosteric Effect

Anatoly K. Yatsimirsky
Universidad Nacional Autónoma de Mexico, Mexico City, Mexico

INTRODUCTION

The allosteric regulation of ligand binding to proteins is the principal regulatory mechanism in living systems on the molecular level.[1–3] The allosteric effect means the situation when the binding of one ligand at its binding site is influenced by the occupation of another binding site by another identical (homotropic effect) or different (heterotropic effect) ligand (effector). In biological systems. the allosteric effect is usually considered for oligomeric proteins, e.g., hemoglobin. and reflects interactions between subunits. In chemistry. it is studied with low-molecular-weight receptors possessing two or more binding sites, the interaction between which is mediated by conformational changes induced in the receptor upon occupation of one site. The positive allosteric effect, when the occupation of one site increases the affinity to the ligand on the other site, leads to positive cooperativity in ligand binding and may be used for amplification of the signal produced by the effector.[4,5] Allosteric regulation is a possible way to operate molecular switches. and it is important for the functioning of molecular machines.'''

BINDING ISOTHERMS FOR ALLOSTERIC SYSTEMS

In a general case of a receptor possessing N binding sites, the stepwise stoichiometric formation constants are defined as follows

$$K_i = [RL_i]/([RL_{i-1}][L])$$

where $1 \leq \iota \leq N$, and the overall formation constants are defined as

$$\beta_i = K_1 K_2 \; K_{i-1} K_i$$

In addition. one can define a single-site binding constant Q as

$$Q = [\text{occupied single site}]/([\text{free single site}][L])$$

The expression for the degree of complexation (or degree of saturation) Y is defined as follows:

$$Y = (\text{concentration of occupied sites})/(\text{total concentration of binding sites})$$

It has the following form:

$$Y = \frac{\sum_{i=1}^{N} i\beta_i[L]^i}{N\left(1 + \sum_{i=1}^{N} \beta_i[L]^i\right)} \quad (1)$$

Another useful function for the analysis of binding is the Bjerrum complex formation function $\bar{n}$, which gives an average number of ligand inolecules bound per receptor:

$$\bar{n} = YN$$

In the case when the receptor possesses N identical and independent sites:

$$K_i = Q(N - i + 1)/i$$

and the ratio of two successive stability constants is[6]

$$K_{i+1}/K_i = i(N - i)/((i + 1)(N - i + 1)) \quad (2)$$

Evidently each next stability constant is smaller than the preceding one due to only statistical factors. Any deviation from the statistical ratio K_{i+1}/K_i implies a nonequivalence of binding sites or some sort of interaction between sites, in particular due to the allosteric effect. In the latter case. deviations from statistical binding are commonly referred to as cooperativity, which can be positive or negative. depending on whether the ratio of successive stability constants is higher or lower than the statistically expected value.[6]

The binding isotherm for the statistical binding takes a form of Eq. 3:

$$Y = Q[L]/(1 + Q[L]) \quad (3)$$

A modified linear form[r6] of Eq. 3 is as below:

$$\bar{n}/[L] = NQ - \bar{n}Q \quad (4)$$

This is known as the Scatchard equation. Eq. 3 describes a simple hyperbolic binding isotherm, like in a case of a 1:1 complexation. The cooperative binding. however. modifies to a smaller or greater extent the shape of the isotherm, in particular. positive cooperativity leads to ''sigmoid'' binding isotherms. The oldest and still popular way to diagnose cooperativity by the analysis of the shape of the binding isotherm is to calculate the so-called Hill

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012884

coefficient h. which is the slope of the plot of $\log(Y/(1-Y))$ versus $\log[L]$:[6]

$$h = d\log(Y/(1-Y))/d\log[L] \quad (5)$$

The Hill equation was derived originally for a complexation process, which involves only one equilibrium between R and h molecules of L affording the single complex RL_h. The degree of saturation is given in this case by the following equation:

$$Y = [RL_h]/[R]_t = \beta_h[L]^h/(1+\beta_h[L]^h) \quad (6)$$

which for $h>1$ describes a sigmoid-binding isotherm. Usually a linearized form given by Eq. 7 is used for the data fitting:

$$\log(Y/(1-Y)) = h\log[L] + \log\beta_h \quad (7)$$

Evidently this equation implies an infinite cooperativity when the binding constants for all complexation processes with $i<h=N$ equal to zero. In real cases. the value of h defined as in Eq. 5 is approximately constant only in a restricted range of concentrations of L, typically around 50% of saturation. It approaches N when the positive cooperativity is high, equals unity for statistical binding. and is smaller than unity for negative cooperativity.

Typical sigmoid isotherms are shown in Fig. I for cooperative binding of dicarboxylic acids 16 and **17** to a double-decker porphyrin with pyridine substituents **15a** (see below, Fig. 5*)*. The Hill coefficient for these systems $h=4$ equals the total number of bound guests as a result of a strong positive allosteric effect.[4]

Classical models for the cooperative binding to oligomeric proteins, which are formally applicable also for synthetic receptors, include the symmetry model of

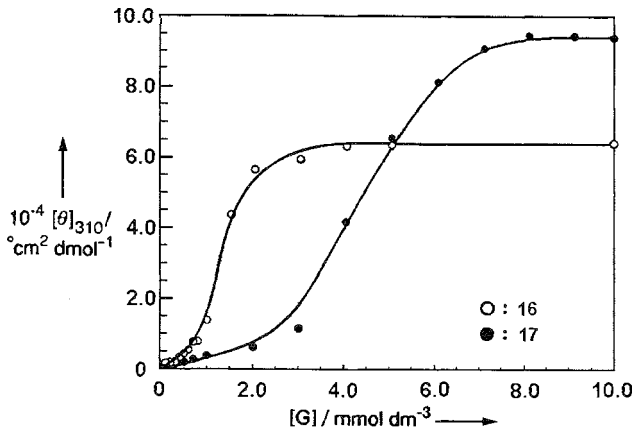

Fig. I Binding isotherms of Guests **16** and **17** to Receptor **15a** (see Fig. 5*)* followed by the complexation-induced circular dichroism.[4,25] Reprinted with permission from Ref. [4]. Copyright 2001 by American Chemical Society.

Monod–Wyman–Changeux (MWC model)[7] and the sequential or induced-fit model of Koshland–Nemethy–Filmer (MNF model).[8,9] In the MWC model. the positive cooperativity is due to a mechanism that does not involve any positive site interactions. It results from the complexation-induced shift of preequilibrium between two states of the receptor. in which all binding sites have different conformations possessing different affinities to the ligand [the tense (T) or relaxed (R) state in hemoglobin]. In the KNF model, ligand binding induces a conformational change in the receptor-binding site, which is transmitted to other binding sites. If the interaction between sites is strong, the conformational change may occur in a concerted manner involving all binding sites and, in this case, the model formally coincides with the MWC model.

A large number of allosteric systems discussed below involve a receptor R possessing two binding sites for two different ligands (heterotropic system). Analysis of such a system is straightforward: one can measure the single-site binding constant for any ligand in the absence of the other ligand and then compare it with the binding constant determined in the presence of the other ligand. Analysis of homotropic systems is more complicated. Eqs. 8–11 describe such a system:

$$R + L \rightleftharpoons RL^1 \quad (Q_1) \quad (8)$$

$$R + L \rightleftharpoons RL^2 \quad (Q_2) \quad (9)$$

$$RL^1 + L \rightleftharpoons RL_2 \quad (\alpha Q_2) \quad (10)$$

$$RL^2 + L \rightleftharpoons RL_2 \quad (\alpha Q_1) \quad (11)$$

Here. superscripts 1 and 2 refer to first and second binding sites: Q_1 and Q_2 are the respective single-site binding constants; and a is the interaction factor that shows how the binding constant for a given site changes upon occupation of the other site. Note that the interaction factor is the same for both binding sites. The stepwise stoichiometric formation constants equal:

$$K_1 = Q_1 + Q_2 \quad (12)$$

$$K_2 = \alpha Q_1 Q_2/(Q_1 + Q_2) \quad (13)$$

Obviously. in this case, the single-site binding constants and the site interaction factor cannot be calculated from the experimentally determined constants K_1 and K_2 without making additional assumptions concerning possible equivalence or mutual dependence of the binding sites. In the case of statistical binding. $Q_1=Q_2=Q$ and $a=1$: therefore $K_1=2Q$, $K_2=Q/2$, and the ratio $K_2/K_1=1/4$. If the binding sites are equivalent ($Q_1=Q_2=Q$) but not independent ($\alpha\neq1$), one observes positive ($K_2/K_1>114$) or negative ($K_2/K_1<114$) cooperativity when α is larger or smaller than unity, respectively. Alternatively. if the

binding sites are nonequivalent ($Q_1 \neq Q_2$) but independent ($\alpha = 1$), the ratio K_2/K_1 equals

$$K_2/K_1 = Q_1Q_2/(Q_1 + Q_2)^2$$
$$= (Q_2/Q_1)/(1 + Q_2/Q_1)^2 \quad (14)$$

Predicted with Eq. 14 is that K_2/K_1 has the maximum value of 1/4 at $Q_2/Q_1 = 1$, and, therefore. at all nonequal values of Q_1 and Q_2, the ratio K_2/K_1 is less than 114. In this case. a negative cooperativity without negative interaction between the binding sites is obcerved.

It should be noted that cooperativity does not necessarily result from site interaction. Often. the mutual attraction or repulsion of bound ligands leads to positive or negative cooperativity, respectively. For example. highly cooperative binding of four moleculec of n-octyl β-D-glucopyranozide to the resorcinol cyclic tetramer in $CHCl_3$, which is characterized by the Hill coefficient $h = 4$. results from intracomplex guest–guest hydrogen bonding involving the 5-CH_2OH and 2-OH groups of adjacent glucopyranozide molecules.[9]

ALLOSTERIC SYSTEMS BASED ON CROWN ETHERS AND PODANDS

The earliest examples of synthetic allosteric systems involved modification of binding properties of crown ethers by changing their conformations as a result of complexation with another metal cation at an adjacent binding site. For example, complexation of a bipyridine moiety of **1** (Fig. 2) with $W(CO)_4$ changes the selectivity of the crown ether from preferable binding of K^+ over Na^+ to preferable binding of Na^+ over K^+.[10] In a more recent study of the cooperative binding of K^+ or Ca^{2+} and monosaccharides to Receptor 2 (Fig. 2). reminiscent by its design of **1**, a negative allosteric effect was reported.[11] Cation-induced changes in the macrocycle conformation produced a disposition of boronic acids unfavorable for the saccharide complexation.

The bis-crown ether **3** (Fig. 2) showed a negative cooperativity in binding two K^+ or Na^+ cations. which resulted, however. from mutual repulsion of metal ions rather than from a negative allosteric effect.[12] Binding of two neutral Lewis acids. e.g., $Hg(CN)_2$ showed a positive cooperativity with the Hill coefficient $h = 1.5$.[12] This was interpreted as a result of positive allosteric effect due to the reduction of the conformational freedom of the second macrocycle favorable for complexation conformation upon binding of the first $Hg(CN)_2$ molecule.

A strong negative allosteric effect was found for the complexation of diquate dication by *bis*-crown receptor **4** (Fig. 2) in the presence of transition metal complexes like $Cr(CO)_4$ and $Ru(Bipy)_2^{2+}$.[13] Binding of these complexes to a bipyridine moiety of **4** induces rotation of the aromatic rings and formation of a planar structure, which does not bind diquat dication.

A large group of receptors showing a positive cooperativity in metal ion complexation is based on polyether (podand) compounds bearing terminal groups capable of chelation of transition metal ions.[14] As an example, in Fig. 2 (**5**), a complexation-induced cyclization of a podand bearing β-diketone terminal groups is shown.[15] The resulting complex is capable of complexation of alkali metal cations. Other examples of such pseudocrown ethers can be found in Ref. [14]. As pointed out in the preceding section, the interaction factor must be the same for two binding sites of a receptor. Therefore, one should expect that the complexation of a podand with an alkali metal cation in its turn must promote the interaction between the terminal groups. Such an effect was demonstrated for system **6** (Fig. 2).[16] A podand bearing two Zn(II) porphyrin complexes recognizes diamines by sandwiching them between two metal centers. The addition of sodium cations increases by a factor of 2 the affinity of the receptor to 1,2-diaminocyclohexane.

The allosteric regulation of the binding of an organic guest by complexation with alkali cations is illustrated by the molecular clip **7a**, Fig. 2.[17] It exists in three conformations *ss*. *sa*, and *aa*. interconverting slowly on the NMR time scale. The predominant conformer *sa* (as well as a minor conformer *sa)* converts upon uptake of a potassium ion in the crown ether bottom unit to *an* conformer, which then binds an aromatic guest. such as 1.3-dinitsobenzene. about four times better than without K^+ (Fig. 2. **7b**).

The allosteric effect also plays a role in the cooperative binding of anions and cations by some ditopic receptors, such as in the case of Receptor **8**, Fig. 2.[18] The positive cooperativity in the binding of Cl^- in the presence of K^+ partly results from the electrostatic attraction between oppositely charged ions. But, at the same time. binding of $H_2PO_4^-$ shows a negative cooperativity with K^+, and this specificity to the type of anion indicates a contribution of some nonelectrostatic. most probably, conformational effects.

ALLOSTERIC SYSTEMS BASED QN CYCLOPHANES

A cyclophane possesses a hydrophobic cavity suitable for complexation of nonpolar organic guests. Several heterotropic allosteric systems based on cavity formation induced by complexation with transition metal cations were reported. The idea is generally similar to metal-induced

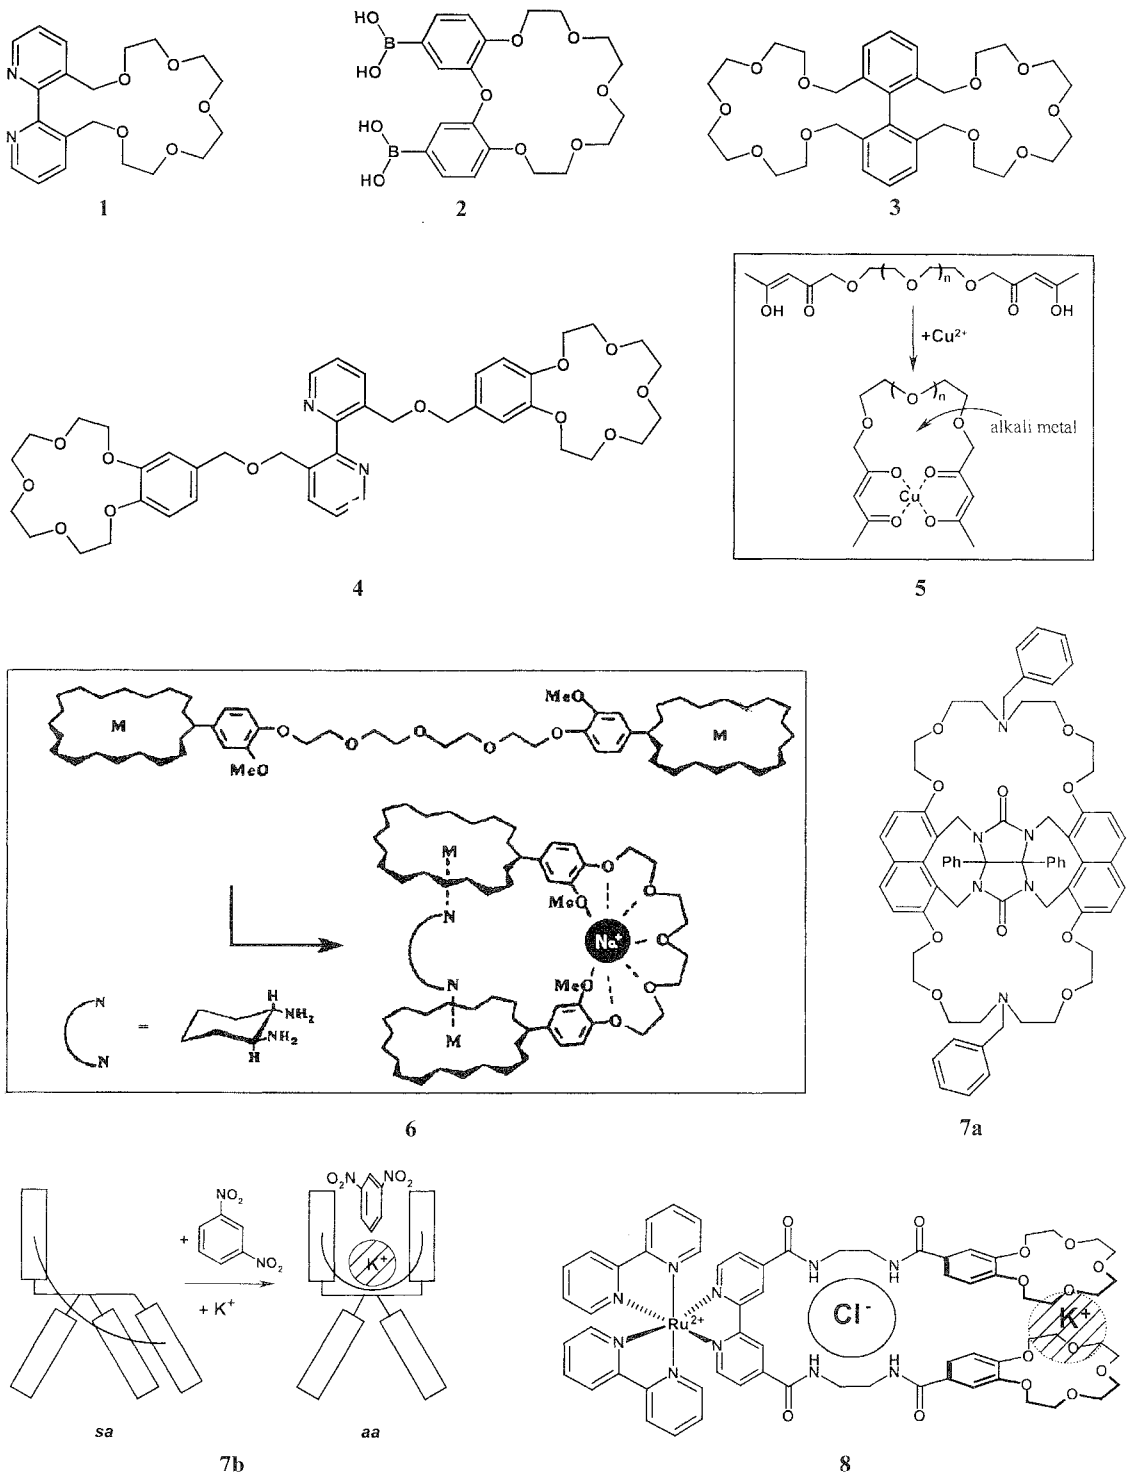

Fig. 2 Allosteric systems based on complexation with crown ethers and podands Fntry 6 From Ref [16] Reproduced by permission of The Royal Society of Chemistry (RSC) on behalf of the Centre National de la Recherche Scientifique (CNRS)

11

Fig. 3 Allosteric systems based on complexation with cyclophanes

cyclization of podands described in the preceding section [see Fig. 2 (5) as an example], but instead of leading to cooperativity between binding of two different metal ions. it leads to the cooperativity between binding of a metal ion and an organic molecule. Illustrated in Fig. 3 (9) is a coope ative complexation of Zn(II) or Cu(II) and a fluorescent indicator dansylamide to an open cyclophane precursor bearing ethylenediamine terminal groups.[19] Addition of the metal ion closes the cavity and allows the indicator to form an inclusion complex with the stability constant ca. 10 M^{-1} in water. This is ca. 100 times less than the stability constant for inclusion of the same guest in a normal azaniacyclophane of the same size. but the important thing is that in the absence of metal ions, the open host does not bind the indicator.

A similar principle was applied for the construction of metallocyclophanes 10, Fig. 3.[20] For this system. it was shown that the shape of the hydrophobic cavity depends

on the type of metal cation: when M=Zn, *the host* more strongly binds *a guest that is a naphthalene derivative than a guest that* is *a biphenyl derivative. but when* M=Cu, *the binding preference is inverted. Thus. the* distinct *coordination geometries of these metals differently affect the shape of the cavity.*

Another principle operates in System **11** *(Fig.* 3).[21] *Here. the metal binding leads to the ring contraction* and *better* accommodation *of* the *organic guest in the cavity, which is too large. The stability constant for guest inclusion increases by a factor of* 100.

ALLOSTERIC SYSTEMS BASED ON CALIXARENES

Calix[4]arenes *are* conformationally flexible *hosts particularly suitable* for *design of allosteric receptors due to a possible* communication *between binding sites situated at the upper and lower* rims.[5,22] *Positive and negative heterotropic* allosterism *was demonstrated* by *using* a calix[4]arene with *the metai-binding lower rim and the sugar-binding upper* rim *created by introducing two boronic acid* groups.[22] *Additions of hard cations* (Ca^{2+}, Mg^{2+}, *or* Na^{+}) *decreased,* but *additions of soft cations like* K^{+}, *Rb'. or* Cs^{+} *increased the sugar binding. This switch* from *a negative to a positive heterotropic allosteric effect, depending on the type of* metal *cation* within *a series of cations. which are similar by their chemical natures.* demonstrates *a possibility of a fine tuning of the binding site* conformation *of calixarene hosts.*

Receptor 12 (Fig. 4) binds urea derivatives *in* $CHCl_3$ *via hydrogen bonding to* two aryl carboxylate *groups with a positive allosteric effect based on the conformation change induced by complexation of* Na^{+} *with the* crown *ether* fragment *of the receptor.''''* In *the free receptor. carboxylic groups are at* a *short distance. favoring intramolecular hydrogen bonding. The addition of* Na^{+} *leads to a larger separation* between *the carboxylic groups. favoring the intermolecular hydrogen bonding* with *the guest.*

A similar effect of metal-induced conversion of a calixarene conformation with intramolecularly bound amide groups (closed form unable to bind guest molecules) into a conformation *with more separated unbound* amide *groups (open form) capable of complexation with* amide *guests operates in the allosteric* regulation *of the host* **13** *(Fig.* 4).[5]

Widening the opposite side of a calixarene upon complexation *of* small *cations to the oxygen* atoms *of a calixarene lower riin leads* to *the positive heterotropic allosteric effect in the inclusion of* [60]fullerene *in a cage molecule* **14** *(Fig. 4) derived* from *two* calix[3]aryl *esters by* complexation *of their pyridine groups* with Pd(II).[24]

Receptor 14 binds [60]fullerene *in* $CHCl_2CHCl_2$ *with the stability constant* $K=39\ M^{-1}$. *The addition of* Li^{+} cations *induces flattening of the cage and an increase in* K *up to 2100* M^{-1}. *Interestingly, the addition of* Na^{+} *cations produces a strong negative allosteric effect.*

DIMERIC PORPHYRINS

Face-to-face dimeric metalloporphyrins represent a new class of homotropic allosteric receptors that show strong positive cooperativity in binding different guests.[4,5,25] As *an example, in Fig. 5. the* cerium(IV) *bis*[tetrakis(4-pyridyl)-porphyrinate] *double* decker *is shown,* with **15a** *designed for* complexation *of* dicarboxylic *acids 16 and* **17**. *The addition of any of these guests to* **15a** *in* dichloromethane/ethyl *acetate (3011) leads to the appearance of circular dichroism spectra. The value of* $[\theta]_{max}$ *at* 310 *nm was found to be proportional to the amount of complexed receptor. Shown in Fig.* 1 *are the respective plots of* $[\theta]_{max}$ *versus guest concentration. which have typical sigmoid shape and give* $h=4$ *in the Hill coordinates. The binding mode of the guests* is illustrated in *Fig.* 5 *(18). It* is *proposed that successive binding of guest molecules reduces the degree of free* rotation *of porpliyrin rings in the double decker, which makes the binding of each next guest more energetically favorable. Binding of the same guests to* **15b**, *which can bind* only *one guest molecule, is too weak to be detectable in agreement with weak binding of the first guest to* **15a** *required for high cooperativity.*

Interestingly, a similarly designed double decker for the complexation *of saccharide guests.* **19** *(Fig.* 5), *shows negative cooperativity: only one guest can be bound to the receptor.* The *differencebetween these two systems is that in the case of* **15a**, *binding of the guests does not change the basic structure of the double decker. But* in *the case of 19, binding of the first guest induces deformation of the receptor structure. which makes more distant other boronic acid groups and thus precludes the binding of additional guests.*

ALLOSTERIC REGULATION OF REACTIVITY AND CATALYSIS

Enzyme regulation *is one of the most important biological applications of the allosteric effect. There is. however, little progress in reproducing regulation of reactivity and catalysis in chemical systems. Earlier works demonstrated a possibility of allosteric regulation of reactivity in several simple systems possessing a* 2,2′-bipyridyl *unit as a regulatory switch relevant to allosteric receptors of type* **1**.[26]

For example, rate of cyclization of 20 strongly increases in the presence of Ni(II) cations. Rates of nucleophilic substitution in and elimination from **21** strongly increase in the presence of Pd(II) (Fig. 6). These systems, however. did not allow a clear separation of conformational and electronic, in particular, inductive effects.

The allosteric 30-fold acceleration of the reduction of a podand bearing a quinone group by 1-propyl-1,4-dihydronicotinamide in the presence of potassium cations[27] is illustrated in Fig. 6 (22). The system is based on the same principle as 6 (Fig. 2). A different approach was proposed for the allosteric regulation of a catalyst for the phosphodiester cleavage, 23 (Fig. 6).[28] The catalyst is a trinuclear metal complex with two functional metal ions (M_F), which activate the phosphodiester substrate. and one structural ion (M_S), which has the regulatory function. With M_F=Cu(II), variation in M_S=Cu(II), Ni(II), or Pd(II) leads to significant changes in the catalytic activity attributed to subtle differences in the ionic radius and coordination geometry of the allosteric metal ion.

MISCELLANEOUS ALLOSTERIC SYSTEMS

Not unexpectedly. many attempts were made to imitate the cooperativity of oxygen binding by hemoglobin, e.g., by using his-metalioporphyrin complexes.[29] Allosteric preorganiration of oligobipyridine ligands by coordination with Cu(I) leads to self-assembly of interesting metal helicates with strand characteristics of DNA.[30] A similar effect was reported in complexation of Fe(III) with tripodal hydroxamate ligands: each next step in the consecutive

complexation of three metal ions has a larger stability constant.[31] Strong cooperativity between cation and anion binding to a cyclopeptide in $CHCl_3$ was attributed at least partially to the allosteric effect.[32]

CONCLUSION

Allosteric regulation requires a certain conformational flexibility of the receptor. The positive allosteric effect may be considered a preorganization of one binding site by a conformational change induced by the occupation of the other binding site. Many widely used types of synthetic hosts, such as crown ethers, cyclophanes, and calixarenes. have suitable conformational dynamic properties, but the recent discovery of other highly efficient allosteric systems based on. e.g., porphyrin double-decker structures points to the possibility of using receptors of different structural types. It should be noted that the actual mechanism of the allsoteric effect in many systems remains essentially hypothetical. With oligomeric proteins, binding sites are separated by large distances, excluding any mutual interaction between bound guests. In synthetic hosts. binding sites are close enough to expect some contribution of such interaction to the observed cooperativity. which is difficult to separate from the purely conformational effect. Practically. further development of allosteric systems promises considerable progress in the creation of new receptors and catalysts with tunable properties. as well as new analytical and other devices with improved sensitivity and selectivity.

Amide- and Urea-Based Anion Receptors

A

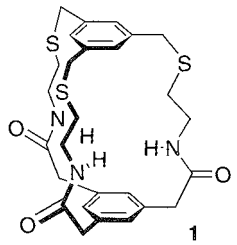
Philip A. Gale
University of Southampton, Southainpton, United Kingdom

INTRODUCTION

Among the armory of functional groups capable of binding anions,[1–4] the amides and the ureas are the most commonly employed anion binding sites in neutral organic anion receptor species (Fig. 1a. b). Oxyanion binding in proteins occurs through hydrogen bond donation from. most commonly. the peptide backbone NH groupr and from arginine.[5,6] One challenge that has been increasingly well met by the supramolecular chemistry community over the last 15 years, has been to design anion receptors with increasing selectivity for particular anionic guests. Of course. the supramolecular chemist does not (yet) have the precise control over the positioning of functional groups in three-dimensional space offered by the tertiary structure of a protein. In spite of this. great progress has been made in the design of neutral anion receptors, with systems now displaying exceptionally high association constants with anions. One of the major design criteria used in developing these systems is to prevent self-association (Fig. 1c) that competes with anion complexation and. hence. lowers association constants.

AMIDES

The first synthetic amide-based anion receptor **1** was reported in 1986 by Pascal Jr. and coworkers.[7] This neutral cyclophane-type receptor was synthesized by reaction of 1,3,5-*tris*-(bromomethyl)benzene with three equivalents of cystearnine to form a triamine which was then clipped with one equivalent of the tris-acid chloride of 1,3,5-benzenetriacetic acid. The receptor contains three amide NH groups chat may be directed into the center of the receptor to form a binding site for smaller anions. Preliminary ^{1}H- and ^{19}F-NMR studies in DMSO-d_6 suggested that there was an interaction with fluoride anions in solution.



1

In early work. *tris*-amide-based anion receptors were also prepared by the groups of Reinhoudt and Beer. Reinhoudt and coworkers prepared a series of tr-is-amides and sulfonamides (2–7) that are selective for dihydrogenphosphate.[8] The receptors were synthesized from *tris*(aminoethyl)amine (tren) by reaction with an appropriate acid chloride in the presence of triethylamine and were purified by recrystallization from methanol with isolated yields ranging from 70–90%. Association constants were determined with tetrabutylammonium dihydrogen phosphate. hydrogen sulfate. and chloride in acetonitrile by conductometry. The receptors show the selectivity trend $H_2PO_4^- > Cl^- > HSO_4^-$. with receptor **7** having the highest affinity for dihydrogen phosphate (presumably due to the increased acidity of the sulfonamide NH group and π-stacking effects of the naphthalene groups.) Beer and coworkers also synthesized tren-based anion receptors in the early 1990s.[9] These systems

9 M = Co^+

contained ferrocene **8** or cobaltocenium **9** moieties that act as electrochemical reporter groups and. in the case of **9**, add an electrostatic component to the anion complexation.[9] These systems show similar anion selectivity trends as those shown by receptors **2**–**7**. in addition to being able to sense the presence of anions via cathodic shifts in the metallocenes' redox potentials. Receptor **8**, for example. is capable of detecting dihydrogen phosphate anions in the presence of 10-fold excesses of chloride and hydrogen sulfate.

More recently, some simple and yet highly effective amide-cleft-based anion receptors were synthesized by Crabtree and coworkers.[10] Receptors **10**–**14** are based upon benzene or pyridine rings that are substituted in the 1- and 3-positions, or in the case of pyridine 2- and 6-positions. with either amide or sulfonamide groups. Proton NMR titrations in dichloromethane-d_2 were used to determine the association constants of the receptors with halide anions and acetate. All the receptors displayed solely 1:1 receptor:anion complex stoichiometry in solution. except receptor **13** that showed behavior consistent with the formation of 1:1 and 1:2 receptor:anion complexes with fluoride and acetate. Among the halides, the receptors have association constants following the trend $Cl^- > Br^- > I^-$ with fluoride and acetate binding being either stronger or weaker than chloride binding depending upon the nature of the receptor. The highest association constant observed with this set of receptors was that of the chloride complex of **11** (K_a=61,000 M^{-1}; Fig. 1d). Interestingly. the presence of the pyridine nitrogen lone pair in receptor **14** serves to decrease the affinity of larger anions for this receptor and so increases the selectivity for smaller anions. For example, fluoride and chloride bind to **14** with association constants of 24,000 and 1500 M^{-1}, respectively, compared to 31,000 and 61,000 M^{-1} for fluoride and chloride binding to receptor **11**.

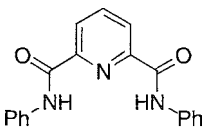
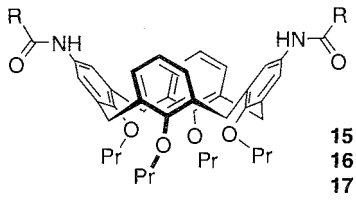
13



14

By arranging two amide groups in a parallel arrangement in space, Cameron and Loeb developed a set of receptors that are selective for Y-shaped carboxylate anions over tetrahedral or pseudotetrahedral 0x0-anions.[11] Calix[4]arenes **15**.**16**, and **17** were synthesized by reaction of the upper-rim calix[4]arene *bis*-amine with mono-, di-. or trichloroacetyl chloride. Receptor **16** proved to have the highest affinity for anionic guests. For example, receptor **15** binds benzoate in chloroform-d with a stability constant of 107 M^{-1}, whereas the receptor **16**– benzoate complex has an association constant of **5**160 M^{-1}. This increase in binding strength is attributed to the increased electron withdrawing effect of the dichloromethyl group in **16** compared to the monochloromethyl group in **15**. Compound **17** did not interact with anions. which model studies suggest is due to the steric bulk of the trichloromethyl groups that prevent the putative anionic guest approaching the upper-rim anion-binding site. These receptors proved to be selective for carboxylates over tetrahedral anions such as perrhenate. The stronger binding of Y-shaped anions is attributed to the calixarene adopting a so-called "pinched cone" conformation, with the calixarene rings attached to the two amide groups becoming parallel, so allowing the amide groups to align in a complementary manner to the carboxylate guest (Fig. 1e).

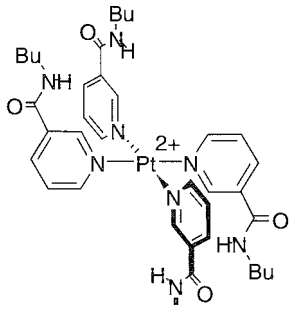
As we have seen. calix[4]arenes offer an organic scaffold upon which receptors may be constructed. Gale, Loeb, and coworkers also used a platinum tetrapyridine complex as an inorganic scaffold with which to arrange amide groups in space.[12] The square planar Pt(II)

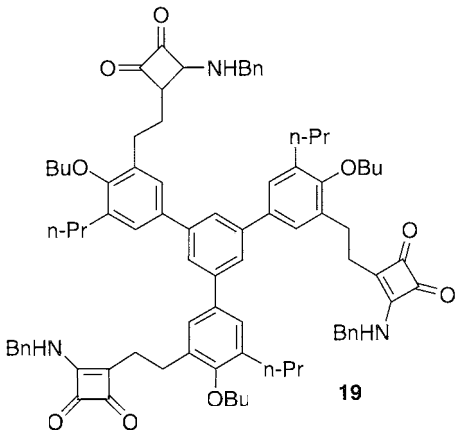


15 R = CH_2Cl
16 R = $CHCl_2$
17 R = CCl_3

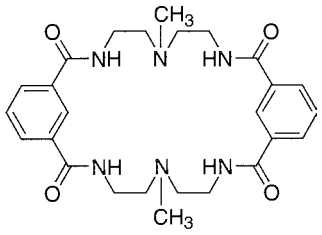
complex was prepared by reaction of one equivalent of $PtCl_2(EtCN)_2$ with four equivalents of *n*-butylnicotinamide and two equivalents of $AgPF_6$ in acetonitrile. The anion coniplexation properties of **18**$[PF_6]_2$ were studied using ^{1}H-NMR titration techniques. Unfortunately, a variety of solvent conditions were required due to solubility problems during the titrations. and therefore. association constants are not directly comparable. It was found that tetrahedral or pseudotetrahedral anions such as ReO_4^-, $CF_3SO_3^-$, and HSO_4^- form exclusively 1:1 receptor:anion complexes with receptor 18. However flat anions such as acetate and nitrate form 1:2 receptor:anion complexes (shown schematically in Fig. 1f). Of particular note is the fact that acetate anions are relatively strongly bound even in the very polar 9:1 DMSO/acetonitrile solvent mixture. The fact that K_2 (491 M^{-1}) is greater than K_1 (230 M^{-1}) infers that binding of the first anion has a positive allosteric effect.which favors binding of the second. The 1:1 receptor:anion binding observed for the weakly coordinated ReO_4^-, $CF_3SO_3^-$, and HSOJ anions is supported by the x-ray structure of **18**$[ReO_4]_2$. In particular. it can be seen that in order to try and maximize hydrogen bonding. the relatively acidic nicotinamide CHs from the ligands on the opposite side of the square plane form hydrogen bonds to the perrhenate anion (Fig. 1g). To do this. the complex must significantly distort from centrosymmetry, a fact that presumably disfavors the interaction with a second anion. resulting in the observation of 1:1 binding in solution (Fig. 1g).

In a different approach to carboxylate coniplexation, squaramide (i.e., 3,4-diamino-cyclobutene-1,2-dione) derivatives have been used by Prohens et al. as selective receptors (Fig. 1h).[13] These receptors possess a parallel ditopic hydrogen bond donor array (c.f. urea) that show good to moderate association constants with acetate anions. A variety of mono-. di-. and tritopic receptors were synthesized, including the *tris*-squaramide receptor **19** that forms strong complexes with *tris*-carboxylates such as trimesoate and *cis*-cyclohexentricarboxylate (K_a=3.9 x 10^3 M^{-1} and 7.7 x 10^3 M^{-1}, respectively, in 10% D_2O/DMSO.)





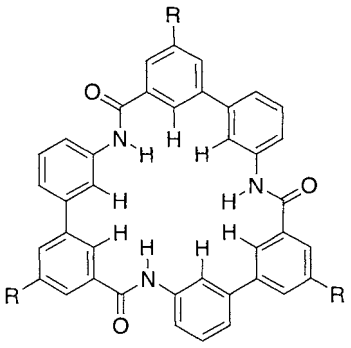
19



20

Bowman-James and coworkers showed that receptor **20**, a tetraamide-bisamine macrocycle. forms strong complexes with oxo-anions in chloroform solution.'''' Proton NMR titration experiments show that hydrogen sulfate binds with an association constant log K of 4.50, while dihydrogen phosphate has an association constant log K of 4.66. In these cases, a broadening of the NMW spectrum during the titration may be indicative of the anions protonating the amine moieties present in the macrocycle. Therefore. the simple 1:1 solution-binding model used to calculate the stability constants may no longer be valid. In contrast, aprotic anions such as nitrate. perchlorate. chloride, and iodide are bound more weakly (of these anions; chloride is most strongly bound log K_a=2.70.) Most notably, the receptor forms a sandwich complex with sulfate in the solid state. This complex was formed by slow diffusion of diethylether into a chloroform solution of 20 and tetrabutylammonium hydrogensulfate. The sulfate anion is bound by eight hydrogen bonds from the eight amide groups in the sandwich (Fig. 1i).

Receptors 21 and 22. reported by Choi and Hamilton. show a particularly high affinity for iodide and oxo-anions such as nitrate.'''' The receptor features a central hole of around 5 Å diameter lined with three amide NH groups and six aryl CH groups. The receptors are skewed in a way that allows the three NH groups to form a complementary hydrogen-bonding site suitable for pseudo-tetrahedral anions (e.g., p-tosylate.) Proton NMR spectroscopic titration studies were carried out in the

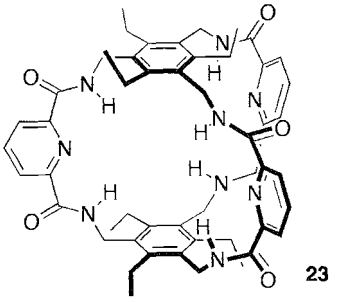


21 R = CO_2Et
22 R = NHBoc

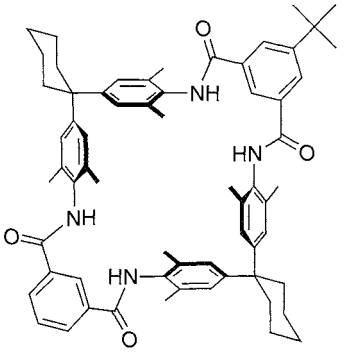
case of both receptors using either 2% DMSO-d_6/$CDCl_3$ or pure DMSO-d_6 as the solvent. The results revealed that the best-bound anion substrates, namely I^-. NO_3^-, and TsO^-, are bound with affinity constants that are on the order of $10^5\ M^{-1}$. Both receptors were found to display similar affinities for anions, indicating that the functional groups on the periphery of the macrocycles do not serve to modulate anion binding selectivity or affinity. Proton WMR titration curves involving tosylate anion and subsequent Job plot analysis revealed the exclusive formation of a 1:1 receptor:tosylate complex in the case of both receptors. However, other anions displayed more complex binding behavior. For example, the shift of the amide NM resonance of 22 observed upon the addition of iodide anions reflected the formation of a 2:1 receptor:-iodide complex during the initial phases of the titration (i.e., an iodide sandwich complex in solution), with the equilibrium at higher iodide concentrations being pushed in favor of a 1:1 receptor:iodide complex.

Anslyn and coworkers used receptor 23. a trigonal box containing six convergently arranged amide NH groups designed to hydrogen bond to the n-clouds of included guests, to examine the role of hydrogen bonding in the stabilization of enolate intermediates.[16] In particular, the role of hydrogen bonding to the enolate n-cloud versus binding to the enolate oxygen atom lone pairs was examined by comparing the pK_a shifts of a variety of ketones in the presence of 23 and also in the presence of another receptor designed to form hydrogen bonds only to the enolates' oxygen atoms. It was found that NH-π hydrogen bonding has a greater effect on carbon acidity than hydrogen bonding to oxygen lone-pair electrons.

Vogtle and coworkers employed anion complexation in new strategies for high-yielding rotaxane syntheses.[17] These workers discovered that phenolate anions. when bound to tetralactam macrocycles (Fig. 1j) such as 24. are capable of reacting with acid chlorides and therefore may be used to form ester rotaxanes. A variety of different rotaxanes were synthesized via this method, including systems with carbonate and acetyl axles.



23



24

UREA

While an amide group can donate a single hydrogen bond, urea can donate two in a parallel fashion, and so it is complementary to oxyanions such as carboxylates (Fig. 1b). One of the earliest examples of anion complexation to urea-based receptors (e.g., 25 and 26) was reported in 1992 by Wilcox and coworkers.[18] Although receptor 26 (the thiourea) proved to have a higher affinity for carboxylates than the urea-based receptor 25, the binding properties of 25 were studied in detail, as thioureas are more susceptible to electrophilic and nucleophilic attacks. NMR experiments revealed large downfield shifts of the urea NM protons upon addition of oxyanions such as carboxylates, sulfonates. and phosphates (as their tetrabutylammonium salts in chloroform-d), however, the association constants were too high to be accurately determined by ^{1}H-NMR titration methods. Therefore, ultraviolet/visible (UV/Vis) titration experiments were employed. It was found that of the oxyanions used. receptor 25 binds benzoate most strongly (K_a=2.7 x $10^4\ M^{-1}$).

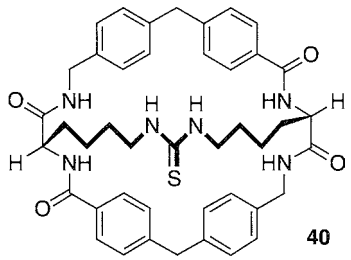
39 X = S

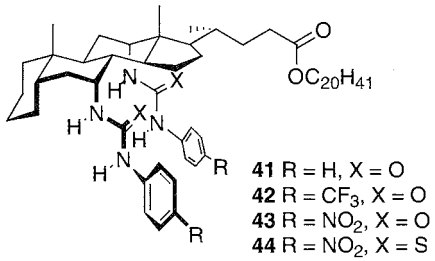
RECEPTORS THAT UTILIZE AMIDES AND UREAS

The complexation of biologically important amino acid derivatives has been the driving force behind Kilburn and coworkers' research in this area.[23] By combining thiourea and amide moieties in cryptand-like macrobicyclic structures. e.g., 40, Kilburn and coworkers synthesized receptors for amino acid derivatives that show selectivity for particular side-chain residues. Extraction methods were used to calculate association constants with a number of N-protected tetrabutylammonium amino acid salts in chloroform. Receptor 40 is selective for N^{α}-Ac-L-lysine (K_a=13 x 10^4 M^{-1}) over N-Ac-L-glycine (K_a=68,600 M^{-1}), N-Ac-L-alanine (K_a=16,900 M^{-1}), and several other protected amino-acid carboxylate salts. Kilburn showed that D-amino acid substrates bind predominantly on the outside of the macrocycle. whereas L-amino acid derivatives bind within the cavity of the receptor with the acetyl amide in a cis-configuration, the energetic penalty for forming the ***cis*** configuration being offset by the formation of hydrogen bonds between the ***cis*** amide and the rim of the macrocycle.

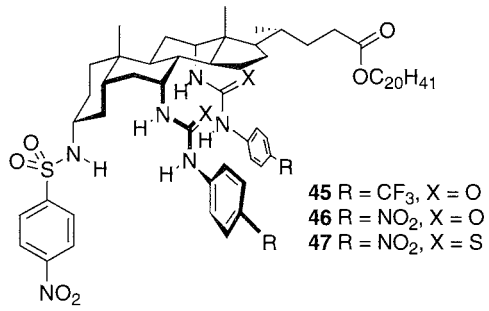


40

Over recent years, Davis and coworkers produced a variety of anion receptors based upon cholic acid. Recently, new urea derivatized receptors termed ''cholapods'' have been synthesized that form remarkably strong complexes with bromide and chloride anions in water-saturated chloroform solution.[24] Receptors 41–44 contain two urea or thiourea groups with electron withdrawing substituents linked to the chloic acid skeleton, while



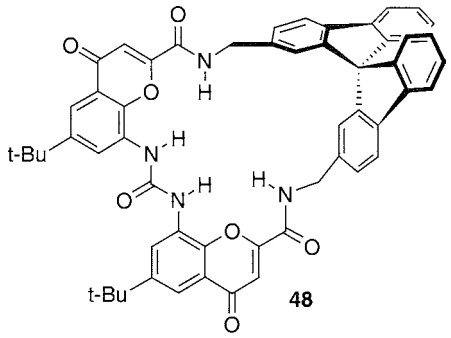
41 R = H, X = O
42 R = CF_3, X = O
43 R = NO_2, X = O
44 R = NO_2, X = S



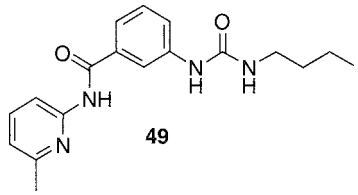
45 R = CF_3, X = O
46 R = NO_2, X = O
47 R = NO_2, X = S

45–49 contain an additional sulfonamide group. The attachment of the hydrogen bonding groups to the steroid skeleton largely prevents the formation of intramolecular hydrogen bonding. while the electron-withdrawing units serve to increase the acidity of the urea moieties and, hence, increase their affinity for anions. This is reflected in the very high association constants with chloride (K_a=1.03 x 10^{11} M^{-1} with receptor 49). These molecules may show excellent phase-transfer properties as well as display biological activity possibly as membrane transport agents for chloride.

Morán and coworkers also combined urea and amide moieties, in this case, in chiral receptors that are recognized chiral hydroxycarboxylates such as lactic or mandelic acid.[25] Receptor 48 combines a *bis*-chromenylurea with a spirobifluorenone linker in a macrocyclic structure and is capable of resolving a racemic mixture of the tetramethylainmonium salt of mandelic acid by thin-layer chromatography. Proton NMR titrations in DMSO-d_6 gave association constants for lactic acid [(*R*)-lactic acid K_a= 3.5 x 10^4 M^{-1}, (*S*)-lactic acid K_a=3.5 x 10^3 M^{-1}).

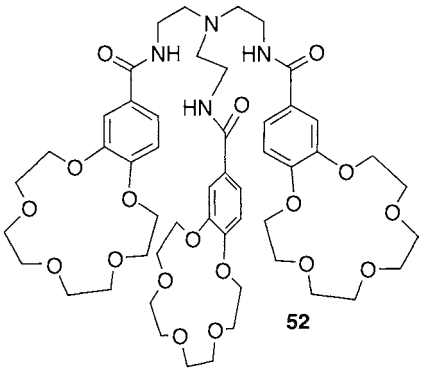


48



49

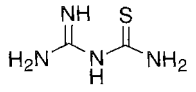
Hamilton used an anion-binding strategy with an amidourea receptor (49) to stabilize an oxyanion transition state and so catalyze the 1.4-addition reaction of a thiol to maleimide (Fig. 2d).[26] The enolate intermediate is stabilized via two hydrogen bonds to the urea group in 49, to a greater extent than the carbonyl oxygen present in the starting material. Therefore, the transition state of this reaction is stabilized relative to the starting material, and the reaction is accelerated.



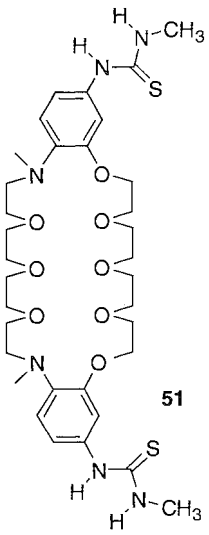
52

ION PAIR COMPLEXATION BY AMIDE- AND UREA-BASED RECEPTORS

Finally we will briefly examine receptors for ion pairs that contain amide or urea groups. An elegant self-assembly process of an amidinothiourea (50) (Fig. 2e) with $NiCl_2$ has been reported by Mingos and coworkers.[27] Complexation of $NiCl_2$ by amidinothiourea in methanol yields crystals of a cage complex (Fig. 2f). The cage $[Ni_6(atu)_8Cl]Cl_3$ consists of eight amidinothiourea units that coordinate six nickel ions through both nitrogen and sulfur donor atoms. A chloride anion is encapsulated within the cage by eight NH···Cl hydrogen bonds (as revealed by the crystal structure shown in Fig. 2g). An analogous complex can be formed between amidinothiourea and $NiBr_2$, however. when nickel salts containing noncage complementary anions such as nitrate, acetate. or perchlorate salts are used. the simple monomer $[Ni(atu)_2]^{2+}$ complexes are formed. Interestingly, if chloride anions are subsequently added to these complexes, the cage complex spontaneously assembles.



50



51

Kubo and coworkers synthesized a *bis*-thiourea functionalized dibenzo-diaza-30-crown-10 51 that wraps around potassium cations, so bringing the two thiourea groups into close proximity, forming an anion binding site.[28] NMR titration experiments with $(PhO)_2P(O)O^-$ anions (which form both 1:1 and 1:2 receptor:anion complexes with 51) in acetonitrile-d_3 solution in the absence and presence of potassium cations show an increase in K_1 from 490 to 9200 M^{-1} upon addition of three equivalents of potassium cations.

In the area of amidic receptors, the tris-crown-ether tren-based receptor **52**. synthesized by Beer and coworkers was recently shown to efficiently extract pertechnetate anions from simulated nuclear waste streams in the presence of sodium cations.[29]

Reinhoudt and coworkers produced a switchable anion receptor.[30] Receptor 53 (Fig. 2h) is a calix[4]arene substituted at the lower rim with cation-binding ester groups and at the upper rim with two distally arranged urea groups. In chloroform solution; intramolecular hydrogen bonds between the urea moieties block the potential anion-binding site. Upon addition of sodium cations, the lower rim of the calixarene contracts as the sodium ions are bound by the four ester groups. This conformational rearrangement separates the two urea groups at the upper rim, so disrupting the intramolecular hydrogen bonding and. therefore. allowing anions such as chloride to complex the receptor (Fig. 2h).

CONCLUSION

Amides and ureas have proven to be excellent anion receptor groups, widely employed by the supramolecular

chemistry community in receptors for anions and ion pairs. This is due in no small part to their ease of synthesis and stability. The roles amides play in binding to anions in protein structures is being revealed by protein crystallography, and these structures are inspiring new generations of synthetic receptors containing peptide groups capable of functioning as anion receptors in aqueous solution~.rThere is much yet to be explored in this fascinating a ea of supramolecular chemistry. For more information. the reader is directed to reviews[1-11] that provide entry to the extensive literature in this area.

Amino Acids: Applications

Arindam Banerjee
Indian Association for the Cultivation of Science, Calcutta, West Bengal, India

INTRODUCTION

J.M. Lehn first introduced the term "supramolecular chemistry" in the literature in 1969 while he was studying the inclusion complexes of Eu^{3+} with its receptor-molecule cryptands. Eehn defined supramolecular chemistry as "the chemistry of intermolecular bonds"; in a supramolecular system. the same or different chemical compounds are held together by various noncovalent interactions. Amino acids. the building blocks of proteins and peptides, are useful in constructing various supramolecular architectures and forming inclusion complexes with different receptor molecules. including cyclodextrins and calixarenes. Amino acid derivatives also form host–guest inclusion complexes with structurally different receptor molecules. such as chiral crown ethers and cyclodextrines. α-Amino-acid-derived lipids become supramolecular receptors through self-assembly. and they host styryl dyes. Many α-amino acids form complexes with various types of transition metals, including Pt^{2+} and lanthanides. Leading to the formation of different supramolecular architectures.

Peptides composed of various coded and noncoded amino acid residues self-assemble to form various types of supramolecular architectures. including supramolecular helices and sheets, nanotubes, nanorods, nanovesicles, and nanofibers. The higher-order self-assembly of supramolecular β-sheets or supramolecular helices composed of short synthetic acyclic peptides leads to the formation of amyloid-like fibrils. Synthetic cyclic peptides were used in supramolecular chemistry as molecular scaffolding for artificial receptors. so as to host various chiral and achiral ions and other small neutral substrates. Cyclic peptides also self-assemble like their acyclic counterparts to form supramolecular structures, including hollow nanotubes. Self-assembling cyclic peptides can be served as artificial ion channels. and some of them exhibit potential antimicrobial activities against drug-resistant bacteria.

SYNTHETIC CYCLIC PEPTIDES AS RECEPTORS

Artificial receptor design is an Important aspect of supramolecular chemistry. Synthetic cyclic peptides were not used extensively so far. probably due to their usual relative flexibility compared to other macrocycles that contain a rigid framework or backbone (e.g., crown ethers, calixarenes. etc.). In spite of their cyclic structure, they are hardly able to bind guests in a well-defined cavity. However, cyclic peptides with conformationally constrained subunits like aromatic or alicyclic backbones or those containing rigid subunits were used for binding substrate molecules such as amino acid derivatives,[1] aromatic compounds,[2] or dicarboxylic acids.[3] Following this approach. Ishida and his colleagues demonstrated the complexation of phosphate ions with cyclic oligopeptides (with six to 14 residues) containing 3-aminobenzoic acid (AB) and protein amino acids in an alternating sequence.[4] Kubik established that a cyclic hexapeptide composed of alternating L-glutamic and 3-aminobenzoic acids binds to quaternary ammonium ions in $CHCl_3$ through cation–π interactions.[1] The cation-binding property of this cyclic peptide was enhanced by a factor of 10^3–10^4 in presence of certain anions (e.g., tosylate or phenyl phosphonate). This is due to the allosteric effects of these anions from binding to the cyclopeptide NH groups and stabilizing the receptor structure, which is essentially appropriate for interactions with positively charged ions.[5] The introduction of L-Pro in the cyclic peptide backbone was shown to rigidify the cyclic peptide structure and to increase the cation-and anion-binding affinities. Kubik and his coworkers established that cyclo[(L-Pro-AB)$_3$] has greater cation and anion affinity than the receptor molecule cyclo[(L-Glu-AB)$_3$].[6] This is because anion complexation is reduced to a great extent. As in the latter peptide, the amide NH groups in the L-Glu residues are involved in strong intramolecular hydrogen bonds, and are. therefore. not available for binding with host anions. Consequently. the stability of the cation complex also decreases. Using different amino acid subunits in the cyclic peptide backbone can regulate the solution conformation of these cyclic hexapeptides, which. in turn, can tune receptor properties. All these above-mentioned cyclic oligopeptides exhibit ditopic receptor properties for simultaneous complexation of cations and anions. Kubik and his coworkers improved the cation-binding affinity and incurred a significant loss of anion-binding ability by using intramolecular conformational control in a cyclic hexapeptide containing alternating L-proline and

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019163

substituted 3-aminobenzoic acid residues.[7] The presence of methoxy carbonyl groups in the fourth-position of the aromatic ring of the 3-aminobenzoic acid subunits helps to form hydrogen bonds to adjacent amide NH protons. inducing the orientation of an amide group parallel to the aromatic rings. This causes the amide protons to point away from the central cavity and to be unavailable for binding with anions. The investigation of the optimum ring size required for good cation binding revealed that cyclotetrapeptides with alternating L-Pro and 3-aminobenzoic acid possess a lower affinity toward cations than the corresponding hexapeptides.[8] it was observed that the phenyl urea substituted at the benzene ring of cyclotetrapeptide can be used as the anion (iodide or acetate) receptor in DMSO-d_6 solution.[8] Artificial receptors that discriminate between two enantiomers of a given substrate are important in bioorganic and supramolecular chemistry. Recently. Kubik and his coworkers achieved the enantioselective recognition of a chiral quaternary ammonium ion (e.g., *N,N,N*-trimethyl,1-phenyl ethyl ammonium cation) using C_3 symmetric cyclic hexapeptides cornposed of L-proline and substituted 3-aminophenyl benzoic acid in 0.1% DMSO-d_6–$CDCl_3$ solution.[9]

INCLUSION COMPLEXES OF AMINO ACIDS AND THEIR DERIVATIVES WITH THEIR HOSTS

Host–guest complexation. by cyclodextrins for example. plays an important role in biomiinetic and supramolecular chemistry. Cyclodextrins (CDs) are barrel-shaped cyclic carbohydrate molecules composed of six, seven or eight glucose residues. which are termed α, β, or γ cyclodextrin. respectively. Due to the presence of an internal cavity. CDs can be used as versatile hosts. Amino acids form gas-phase inclusion complexes with CDs and they can be detected using ES-MS and a gas-phase guest exchange reaction.[10] Chiral discrimination of amino acid guests in CDs hosts was also achieved in the gas phase. The αCDs and βCDs form inclusion coinplexes with cumarin-6-sulfonyl amino acid derivatives in water. Theoretical modeling and fluorescence experimental results suggest the possibility of forming 1:2 guest–host coinplexes for βCD.[11] A recent report described the complexation of native L-α-amino acids with aliphatic or aromatic side chains by water-soluble substituted calix[4]arenes.[12] The host–guest cornplexation was studied using ^{1}H-NMR experiments. The upfield shift of some specific aromatic protons (H *meta* and H *para*) of the guest molecules compared to the free guest. due to the ring current effect of the aromatic nuclei of the host, confirms the formation of an inclusion complex. The inclusion of aliphatic or aromatic apolar amino acid residues within the calix[4]-arene cavity occurs either by CH–π interaction (for L-Val and L-Leu) or by π–π interaction (for L-Phe. L-His. L-Trp.). Another macrocyclic receptor, cyclotetrachromotropylene, forms 1:I host–guest complexes with various native Y-amino acids in water at pH 7 and 25°C. This phenomenon was studied using ^{1}H-NMR spectroscopy.[13] Sometimes host–guest complexation helps in useful chemical transformations like hydrolysis. A recent study indicated the formation of inclusion complexes of γ-CD and various amino acid methyl esters. This formation eventually leads to hydrolysis of host molecules. In the entire process. a high stereoselectivity was observed.[14]

METAL ION–AMINO ACID COMPLEXATION IN SUPRAMOLECULAR CHEMISTRY

A pentadecanuclear complex of Eu^{III} with tyrosine at high pH provides a novel supramolecular architecture, which involves 15 Eu^{III} ions and 10 tyrosine ligands plus hydroxo and aquo ligands associated with hydrolysis. In this structure. the europium(III) ions are assembled into three parallel layers. and each of the layers contains five Eu^{III} ions that occupy the vertical positions of a nearly perfect pentagon. The 10 tyrosine ligands can be grouped into two equivalent classes. each of which extends its 4-hydroxybenzyl side chains orthogonal to the crystallographically imposed C2 axis.[15] The side chains do not take part in coordination. while the amino and the carboxylate groups of each tyrosine residue participate in metal ion chelation. making each of the 10 tyrosinate groups become a tetradentate ligand. Near physiological pH (which is 6–7), multinuclear lanthanide complexes of various α-amino acids (e.g., Gly. Ala, Val. Giu) form a cubane-like cluster core that assembles to form 3D porous framework structures.[16]

SELF-ASSEMBLY OF α-AMINO-ACID-DERIVED LIPIDS

Study of the inclusion behaviors of the cavity of many commonly known macrocyclic receptors like calixarenes, cyclodextrins and cyclic oligopeptides draws considerable interest in supramolecular chemistry. However. the construction of inclusion compounds using self-assembly of α-amino-acid-derived lipids is relatively rare.[17–20] L-Glutamic-acid-derived anionic lipids act as supramolecular receptors and provide specific hydrophobic cavities for accommodating cationic dyes.[17,18] Cationic dyes are incorporated inside. due to their molecular planarity. Hachisako and his coworkers studied various types

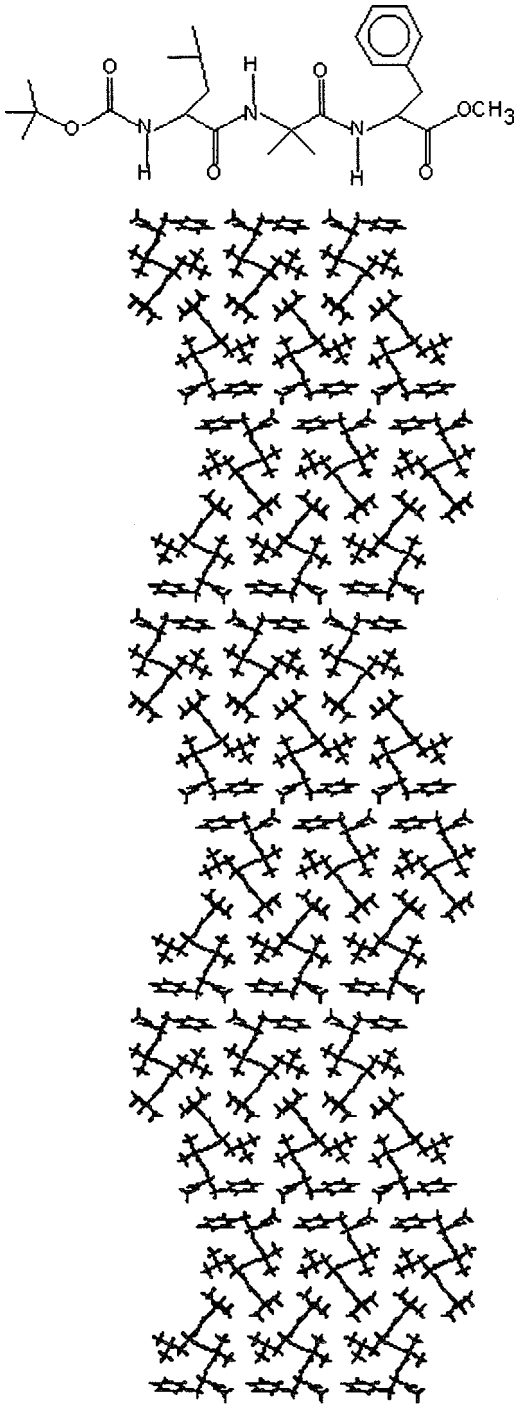

Fig. 1 Packing diagram of individual columns of the tripeptide Boc-Leu-Aib-Phe-OMe in the *c* projection, illustrating the formation of a highly ordered supramolecular helical assembly via van der Waals' interactions.

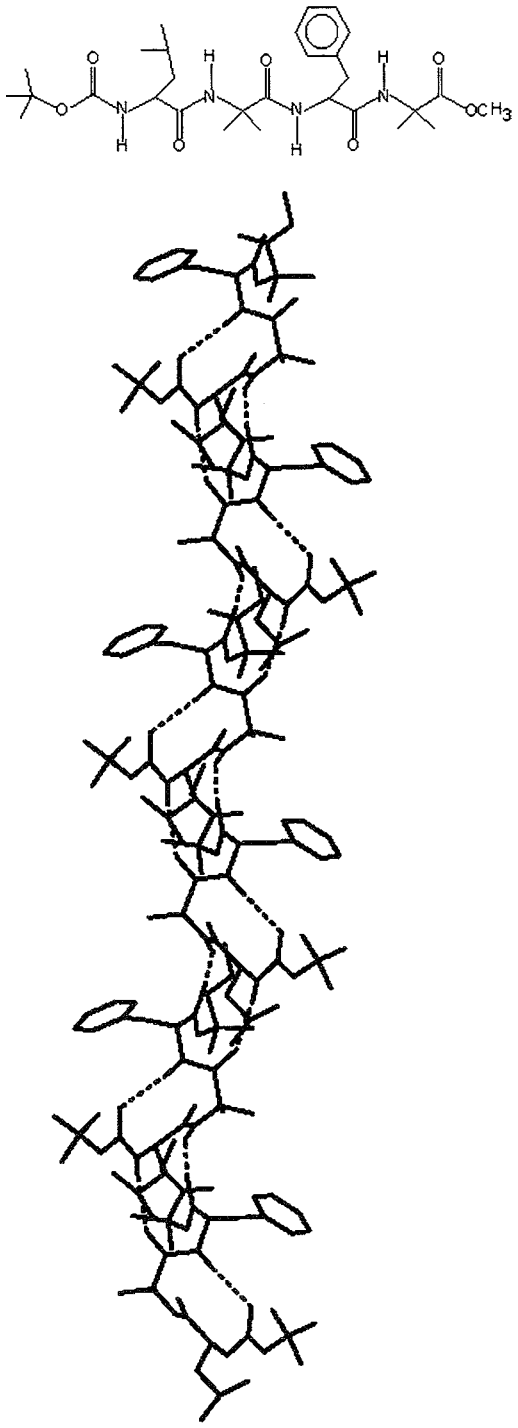

Fig. 2 The packing diagram of the tetrapeptide Boc-Leu-Aib-Phe-Aib-OMe showing a higher-ordered supramolecular helical assembly as determined by x-ray crystal structure analysis along the b axis. of α-amino-acid-derived cationic lipids containing multiple amide linkages per molecule. to probe the role of α-amino-acid residues and the chemical structural requirements needed to form specific hydrophobic cavities of supramolecular receptors in aqueous solution.[20] The role of amino acid residues on inclusion and molecular recognition were examined using structurally related cationic styryl dyes like 4[4-(dimethylamino)styryl]-*N*-methyl pyridinium iodide, 2-[4-(dimethylamino)styryl]-*N*-ethyl pyridinium iodide. and 2-[4-(dimethylamino)styryl]-*N*-methyl pyridiniuln iodide. These dyes not only act as host molecules but also serve as microenvironmental probes due to their sovatochromic nature.

SELF-ASSEMBLY OF CYCLIC AND ACYCLIC SYNTHETIC PEPTIDES

Supramolecular Peptide Helices

The design and construction of monomolecular peptide helical structures using appropriate, conformationally restricted amino acid residues were extensively studied. However. relatively less attention was paid to the construction of a supramolecular peptide helix. In biological systems. supramolecular helices with various levels of self-organization and self-assembly of the peptide backbone are common. My research group is involved in constructing various supramolecular helical structures from acyclic oligopeptides containing noncoded amino acids with appropriate conformations, which can act as subunits for self-assembly.[21–25]

The majority of the backbone torsion angles of the terminally blocked tripeptide Boc-Leu-Aib-Phe-QMe [Aib: α-aminoisobutyric acid] falls within the helical region. and it fails to form any intramolecularly hydrogen-bonded turn structures. However, this helps to form a supramolecular helical structure (Fig. 1) through noncovalent interactions in the solid state.[21] The scanning electron microscopic (SEM) picture of the tripeptide Boc-Leu-Aib-Phe-OMe shows the filamentous ribbon-like fibrillar morphology that is reminiscent of neurodegenerative disease-causing amyloid fibrils.

The terminally protected tetrapeptide Boc-Leu-Aib-Phe-Aib-OMe adopts a consecutive double-bend conformation with two successive β-turns. It self-assembles through various noncovalent interactions, including intermolecular hydrogen bonds, to form a supramolecular helical structure in crystals (Fig. 2).[22] Similarly, another double-bend-forming peptide Boc-Ala-Aib-Leu-Bib-OMe self-associates to form a supramolecular helix via intermolecular hydrogen bonding in the crystal structure.[22] However, the tetrapeptide Boc-β-Ala-Aib-Leu-Aib-OMe [β-Ala: β-alanine] adopts a new type of consecutive

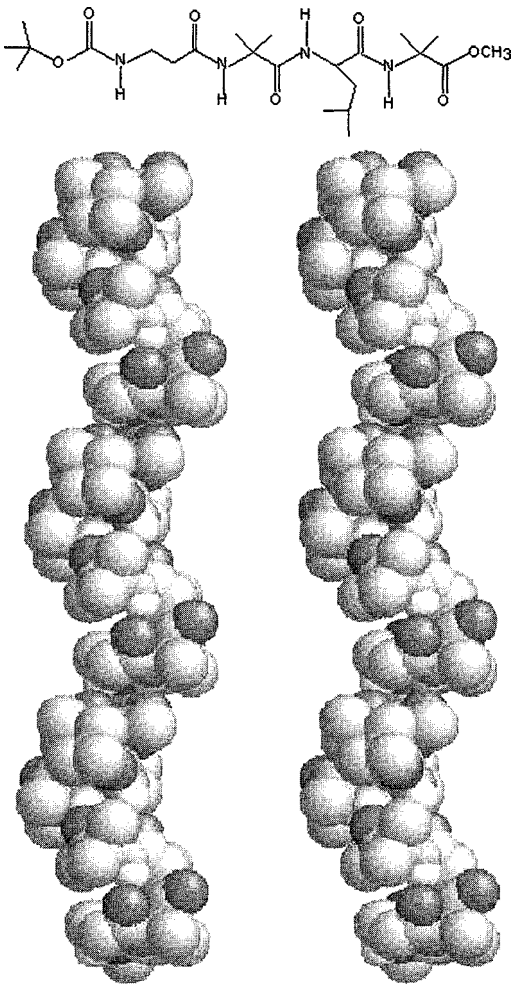

Fig. *3* A cross-eye stereo, space-filling representation of the tetrapeptide Boc-β-Ala-Aib-Leu-Aib-OMe showing a higher-ordered supramolecular helical assembly. as determined by single-crystal x-ray diffraction studies. Nitrogen atoms are blue. oxygen atoms are red. and carbon atoms are gray. Nonhydrogen-bonded hydrogen atoms and side chains of Lue are omitted for clarity. (*View* ***this*** *art in color at www.dekker.com.*)

double-turn structure, which self-associates to form a unique supramolecular helix (Fig. 3).[24] The terminally protected tetrapeptide Boc-Aib-Val-Aib-β-Ala-OMe adopts a double-turn molecular conformation that self-assembles to form an anisotropic intermolecularly hydrogen-bonded supramolecular helix with an average diameter of 1 nm in the crystal (Fig. 4). This suprainolecular helical structure further self-assembles to form polydisperse nanorods with diameters ranging from 10–40 nm.[25]

Supramolecular Acyclic Peptide β-Sheets

The design and construction of acyclic oligopeptide molecules. which form supramolecular (3-sheet structures,

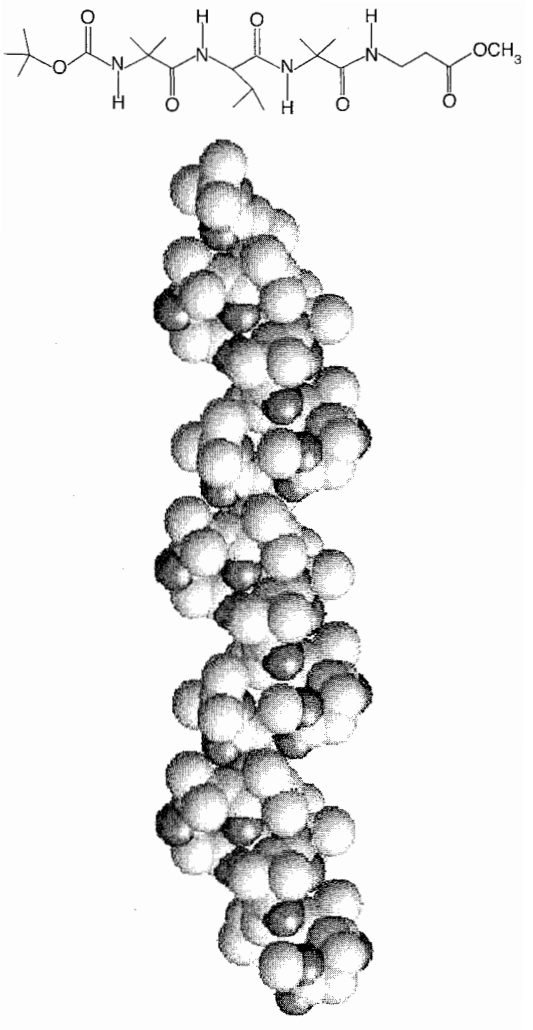

Fig. 4 Space-filling model of the supramolecular helical array of the tetrapeptide Boc-Aib-Val-Aib-β-Ala-OMe showing the staking of subunits maintaining proper registry, generating a helical structure as determined by x-ray crystallographic analysis. Nitrogen atoms are blue. oxygen atoms are red. and carbon atorns are gray. Hydrogen atoms are omitted for clarity. (*View this art in color at www.dekker.com.*)

comprise an emerging field. Formation of supramolecular β-sheet structures using various noncovalent interactions and their further self-association into highly ordered fibrillar structures are responsible for causing many fatal progressive neurodegenerative amyloid diseases, like Alzheimer's and Parkinson's. To understand the molecular bases of pathogenesis and therapeutics of these diseases. it is important to construct supramolecular peptide β-sheet assemblage. There are many reports of β-sheet stabilization involving unimolecular β-sheet formation and subsequent stabilization by only intramolecular interactions.[26,27] However, there are limited reports elucidating peptide β-sheet formation and stabilization in crystals and in solution by purely intermolecular interactions,[28–32] My research group is actively engaged in constructing amyloid-like fibril-forming supramolecular β-sheets.[28–32] The terminally blocked ti-ipeptide containing noncoded amino acids [viz., β-alanine (β-Ala) and α-aminoisobutyric acid (Aib)]. Boc-β-Ala-Aib-β-Ala-OMe, adopts a β-strand structure with an overall extended backbone conformation with a slight kink at the middle. It self-assembles to form a supramolecular parallel β-sheet structure in crystal (Fig. 5) and amyloid-like fibrils in the solid state.[28] The supramolecular β-sheet structure is formed by various noncovalent interactions, including intermolecular hydrogen bonding. This is the first crystallographic evidence of an amyloid-like fibril-forming parallel β-sheet assemblage of a synthetic tripeptide coinposed of only nonprotein amino acids. A recent report describes that components of a series of terminally protected dipeptides. composed of 3-aminophenyi acetic acid and Aib/Val/Pro, share a common structural feature—an extended backbone conformation—and they self-assemble to form an intermolecularly hydrogen-

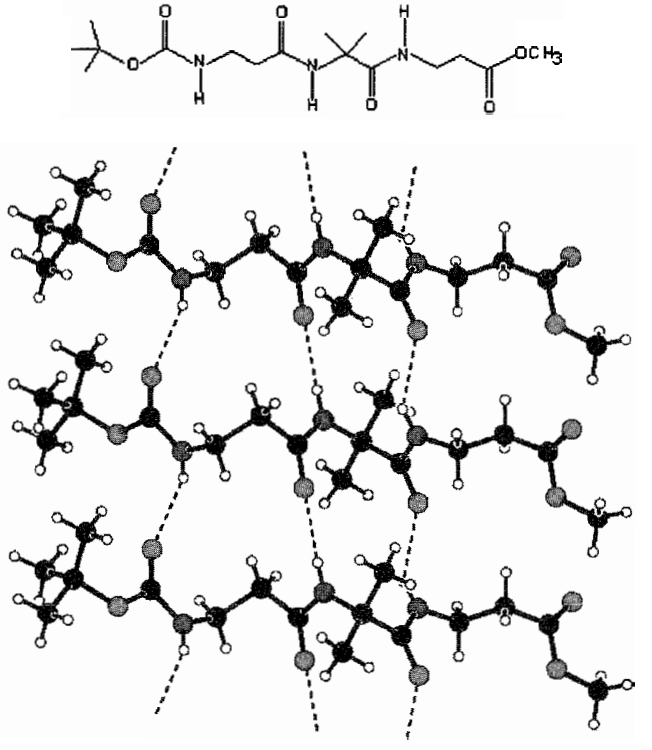

Fig. 5 Packing diagram of the terminally protected tripeptide Boc-β-Ala-Aib-β-Ala-OMe in the *b* projection, illustrating intermolecular hydrogen bonding in solid state and formation of the supramolecular β-sheet. Nitrogen atoms are blue. oxygen atorns are red. carbon atoms are black. and hydrogen atoms are white circles. Dashed lines indicate hydrogen bonds. (*View this art in* color- *at www.dekker.com.*)

bonded supramolecular β-sheet structure and show amyloid-like fibrillar morphology in the solid state.[29] Similarly. other terminally protected tripeptides Boc-Ala-Gly-β-Ala-OMe[30] and Boc-Leu-Aib-Leu-OMe[31] self-assemble through intermolecular hydrogen bonding to form supramolecular β-sheet structures in crystals. Both tripeptides form the antiparallel β-sheet structure. The tripeptide Boc-Leu-Aib-β-Ala-OMe adopts an intramolecularly hydrogen-bonded β-turn conformation in the crystals. There are two molecules in the asymeric unit to form a molecular dimer of two different conformers.[32] This peptide celf-assembles by intermolecular hydrogen bonds and other noncovalent interactions to form a supramolecular β-sheet structure in crystals (Fig. 6). This is the first example of a β-turn forming short acyclic peptide, which forms the supramolecular β-sheet structure in crystals instead of a supramolecular helix.

Self-Assembling Cyclic Peptides

Cyclic peptides with an even number of alternating D-and L-α-amino acids adopt flat ring-shaped structures in which the backbone amide groups are arranged perpendicular to the side chains and the plane of the ring conformation.

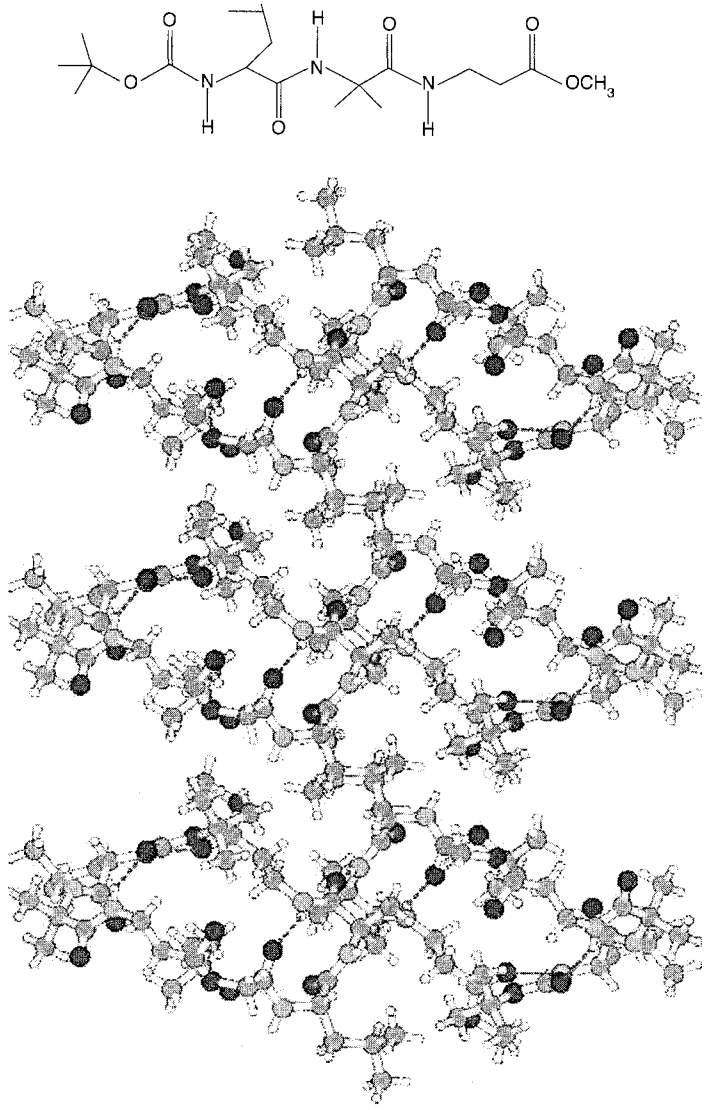

Fig. 6 The packing of the terminally protected tripeptide Boc-Leu-Aib-β-Ala-OMe, showing the formation of a continuous β-sheet column along the crystallographic *b* axis via intermolecular hydrogen bonds and van der Waals' interactions in the crystal. Dashed lines indicate hydrogen bonds. Nitrogen atoms are blue. oxygen atoms are red. carbon atoms are green, and hydrogen atoms are white. (*View this art in color. at www.dekker.com.*)

Under favorable conditions. these cyclic peptide rings self-assemble through intermolecular hydrogen bonding to form open-ended hollow β-sheet-like nanotubular structures. keeping the amino acid side chains outside the surface of the ensemble. In a pioneering work. Ghadiri and his coworkers demonstrated the formation of hollow tubular supramolecular structures with an appropriate internal diameter of 7 Å from a self-assembling cyclic octapeptide cyclo-[-(L-Glu-D-Ala-L-Glu-D-Ala-)$_2$].[33] The internal diameter of cyclic peptide nanotubes can be altered by varying the peptide ring size. The 12-residue peptide cyclo-[-(L-Glu-D-Ala-L-Glu-D-Ala-)$_3$][34] was shown to undergo proton-triggered self-assembly. which leads to the formation of a nanotubular structure of an enhanced van der Waals' diameter of 13 Å. A remarkable feature of these cyclic peptide nanotubes is that the surface properties of the tubular structures can be varied by appropriateiy selecting the amino acid side chains. Cyclic D, L-peptides with appropriate hydrophobic side chains can be partitioned in nonpolar lipid bilayers and undergo self-association to form transmembrane ion channels. In 1994, Ghadiri and his coworkers demonstrated the formation of a transmembrane ion channel based on a self-assembled. cyclic D,L-octapeptide.[35] Single-channel conductance measurements and fluorescence proton transfer assays were used to examine the channel-forming properties of cyclic D,L-peptides. These ion channels exhibit transport activity for Na^+ and K^+ greater than 10^7 ions s^{-1}. The cyclic clecapeptide cyclo[-(-L-Trp-D-Leu)$_4$-L-Gln-D-Leu] with an internal van der Waals diameter of 10 Å, was shown to transport glucose molecules across the lipid bilayer membrane.[36] A report from Seebach and his group noted that cyciic tetrapeptides containing only chiral β^3-amino acids can form hollow tubes similar to those exhibited by cyclic D,L-α-peptides.[37] Ghadiri et al. demonstrated the formation of ion channels by two self-assembling cyclic β^3-peptides.[38] Described in recent report from Ghadiri's group was that self-assembling cyclic D,L-α-peptides coinposed of six and eight residues can serve as potent antibacterial agents against drug-resistant bacteria[13''] by enhancing the membrane permeability, collapsing the transmembrane potential. and eventually causing rapid cell death. These antibacterial cyclic oligopeptides were found to be nontoxic in mice, and they hoid considerable promise in combating many drug-resistant bacterial infections in human beings.

CONCLUSION

The applications of amino acids in supramolecular chemistry are multipurpose. One purpose is to make inclusion complexes with common macrocyclic hosts. like CDs or calixarenes. Other applications include complexations of metal ions with amino acids, leading to various supramolecular architectures. In addition, various amino acids are used to synthesize cyclic and acyclic peptides that have wide applications in supramolecular chemistry. such as creating nonself-assembling cyclic oligopeptides with well-defined cavities that can be used as hosts for various cations (including the chiral one), anions, and electroneutral substrates. Finally, self-assembling cyclic and acyclic peptides not only form various supramolecular architectures, but also, cyclic oligopeptides can be used as artificial ion channels and antibacterial agents.

ACKNOWLEDGMENTS

I am thankful to Debashis Haldar, Arijit Banerjee, Apurba Kumar Das. Sudipta Rap, and Partha Pratim Bose for their help in the preparation of the entire manuscript. I am very grateful to my collaborator Prof. M.G.B. Drew, The University of Readings, Whiteknights, U.K.. for solving numerous cryrtal structures of my peptides that are cited within this article.

Anion-Directed Assembly

Ramón Vilar
Imperial College of Science, Technology, and Medicine, London, United Kingdom

INTRODUCTION

There is great current interest in developing strategies for the synthesis of complex molecular architectures with novel properties and potential in a wide range of applications. During the past few years, supramolecular chemistry provided important advances in this direction. The increased control over the assembly of molecular components led to the rational synthesis of novel species such as molecular cages, helicates, rotaxanes, and catenanes, among several others. A common strategy used to prepare such assemblies involves the use of chemical templates. As defined by Busch, "A chemical template organizes an assembly of atoms. with respect to one or more geometric loci, in order to achieve a particular linking of atoms" (p. 389).[1] When there are several potential ways of linking a group of molecular components, the template provides the instructions for the formation of a single product. In the presence of another template. a different assembly is expected. and as a consequence, a different product should be formed. In generai, after the ternplate has directed the formation of the assembly. it can be removed to yield the template-free product. However. this is not possible if the templating agent is an integral part of the final product. In this entry. a template (or directing agent) will be considered to be any species that organizes an assembly of atoms or molecules for specific linking and is either removed from the final product or kept as an integral part of it.

ANIONS AS TEMPLATES

In contrast to the well-studied templating properties of cationic and neutral species,[2,3] anions have been largely neglected as templating agents until recently. Up to 1996 there were only a handful of examples of anion-directed assemblies, the first ones being reported in the early 1990s.[4,5] The relative lack of anion-templated assemblies bas been partially attributed to intrinsic properties of anions. such as their diffuse nature (i.e., small charge-to-radius ratio); pH sensitivity, and their relative high solvation-free energies.[9] However, as demonstrated over the past few years, these limitations can be overcome by appropriately modifying the experimental conditions, and several anion-directed assemblies have now been reported. The importance of anions as templates is also seen in biological processes where, for example. anions have been identified as directing agents in protein folding.[6]

This entry provides a compilation of anion-directed assemblies and analyzes some of the factors that have made these syntheses possible. This is the first time that the subject is specifically reviewed, even though Beer and Gale incorporated a section on this topic in their three reviews on supramolecular chemistry of anions.[7–9] The current entry will be divided into two main sections: anion-directed synthesis of metalla-assemblies. and anion-directed assembly in organic synthesis. While in the first type of assemblies the anions use mainly electrostatic and Lewis-acid–base interactions to direct the syntheses. in the second case hydrogen bonds play a very important role. The size and geometry of the ternplating anions are also essential in dictating the final structure to be formed (as it is in any other templated reaction). Due to space limitations, this entry will concentrate on anion-directed assemblies that yield well-defined molecular species. The anion-directed assembly of polymeric materials, although an important area within supramolecular chemistry. is out of the scope of this review.

ANION-DIRECTED SYNTHESIS OF METALLA-ASSEMBLIES

Metalla-Macrocycles and Circular Helicates

One of the first anion-directed assemblies is the [12]mercuracarborand-4 (1) reported by Hawthorne in 1991. which can be prepared in high yields by reacting 1,2-dilithio-carborane with mercuric chloride (see Fig. 1).[4] This compound consists of four bivalent 1.2-carborane cages linked by four mercury atoms forming a macrocycle with a chloride ion located at its center. The anion displays strong Lewis-acid–base interactions with the four mercury atoms of the macrocycle. Such interactions play an important role in directing the formation of the cyclic

Encyclopedia of Supramolecular Chemistry

structures as opposed to the noncyclic ones. The same authors later showed that an analogous cyclic tetramer is obtained when mercuric iodide is used for the cyclization reaction but, *in contrast, an acyclic polymer is formed in the presence of mercuric acetate.'''''*

Elegant examples of anion-templated *synthesis are the* penta- *and hexanuclear circular helicates reported by Lehn (see Fig.* 1).[11,12] *In this work it was demonstrated that the self-assembly of* iron(II) *salts and a tris-*bipyridyl *ligand* (L) *is highly dependent on the presence of specific anions. With* $FeCl_2$, *the pentanuclear circular helicate* $[Fe_5L_5Cl]^{9+}$ *(2) is obtained. while the hexanuclear analogue* $[Fe_6L_6(SO_4)]^{10+}$ *(3)* is *formed in quantitative yields with* $FeSO_4$ *[hexanuclear systems are also formed with* $Fe(BF_4)_2$ *and* $FeSiF_6$]. *The structural characterization of* $[Fe_5L_5Cl]^{9+}$ *demonstrated it to be a circular double helix with an inner cavity radius of* 1.75 Å. *The chloride ion is contained within this cavity (which provides an excellent size match for this halide)* and *is tightly bound thanks to the* 10 *positive charges from the five* iron(II) *centers located in the periphery. By increasing the size of the* templating anion, it *is then possible to assemble structures with larger cavities such as* $[Fe_6L_6(SO_4)]^{10+}$. *In these examples, electrostatic interactions and good* ion-to-cavity *size match are the directing forces behind the* anion-templated *self-assembly process.* Using *a similar approach,* McCleverty *and Ward reported the synthesis of the cyclic supramolecular complex* $[Co_8L_{12}(ClO_4)]^{3+}$ *(where* L = *bis* {3-(2-pyridyl)pyrazol-1-yl}dihydroborate) *with a* perchlorate *anion encapsulated in the central cavity.'''' The anion is likely to play an important role in the selective formation of this structure.*

More recently, Dunbar *demonstrated that the structures resulting from the self-assembly of* metal *cations with the bis-*chelating *ligand* 3,6-*bis*(2-pyridyl)1,2,4,5-tetrazine *(bptz) are strongly dependant on the anions present in the reaction* mixture.[14,15] *In the presence of* BF_4^- *and* ClO_4^-, *the molecular squares* $[Ni_4(bptz)_4(CH_3CN)_8][X]_8$ (**4·X**) *(X =* BF_4^-, ClO_4^-*) are formed in approximately* 75% *yield (see Fig. 1). while in the presence of* SbF_6^-, *the molecular pentagon* $[Ni_5(bptz)_5(CH_3CN)_{10}][SbF_6]_{10}$ (5) *is obtained (in* 60–70% *yields). The structural characterization of the molecular square* **4·BF$_4$** *showed that it has a void space with an approximate diameter of* 4.6 Å, *which is of the ideal size match for the* BF_4^- *anion. In the case of the pentagon, the void space at its center is larger, providing a better size match for larger anions such as* SbF_6^-. *The structures observed in the solid state are retained in solution,* as *demonstrated by ESI mass spectrometry.*

Examples of metalla-macrocycles where hydrogen bonding (in addition to electrostatic and Lewis-acid–base *interactions) is used by the templating anion to direct the assembly are the* Ni/Pd *boxes reported by* Vilar *(see Fig.* 2).[16] *The* $Ni(atu)_2$ *fragment* (atu=deprotonated *arnidinothiourea) reacts with* $PdX_2(PPh_3)_2$ *to selectively form the metalla-macrocycles* $[Pd_2Ni_2(atu)_4(PPh_3)_4X]^{3+}$ (**6·X**) (X=Cl, Br, *and I) in* 55–74% *yields. In the presence of other anions such as triflate. nitrate, or acetate: the formation of the* macrocycle *is not observed, and instead* monometallic *species are obtained. Interestingly, if stoichiometric amounts of chloride, bromide, or iodide are added to these mixtures, the corresponding macrocycles are formed quantitatively.* confirming *the* templating *role of the halide anions. The structural characterization of these macrocycles demonstrates that, in the solid state, the halides located at their center form hydrogen bonds with four* NH *groups from the amidinothiourea ligands and with several* C–H groups from *the phenyl rings of the phosphines. The halides also interact with the palladium centers in a* Lewis-acid–base *fashion.* ^{31}P-NMR *studies revealed that the halides*

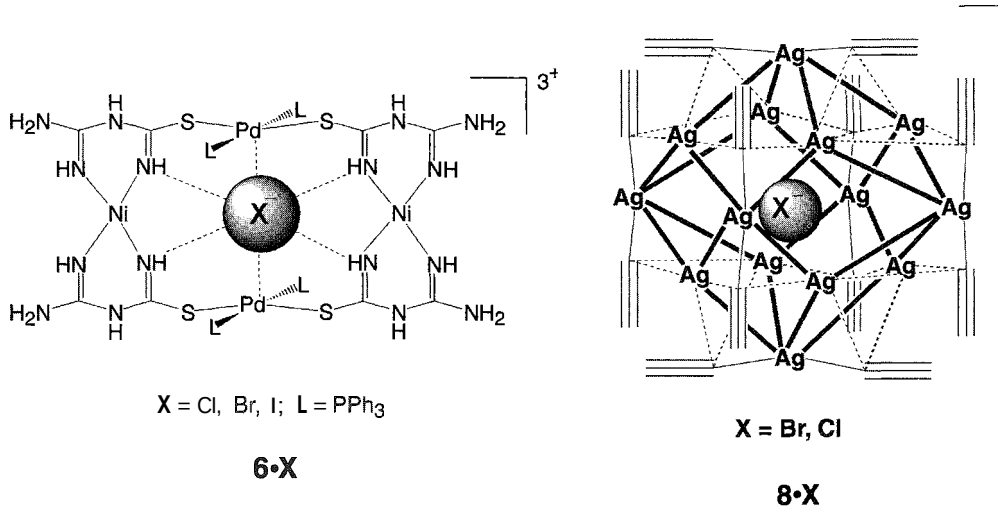

Fig. 2 Anion-templated metalla-macrocycles **6•X**[16] and silver-alkynyl cages **8•X**.[21] (*View this art in color ut www.dekker.com.*)

bound to the metalla-macrocycles can be exchanged in solution.

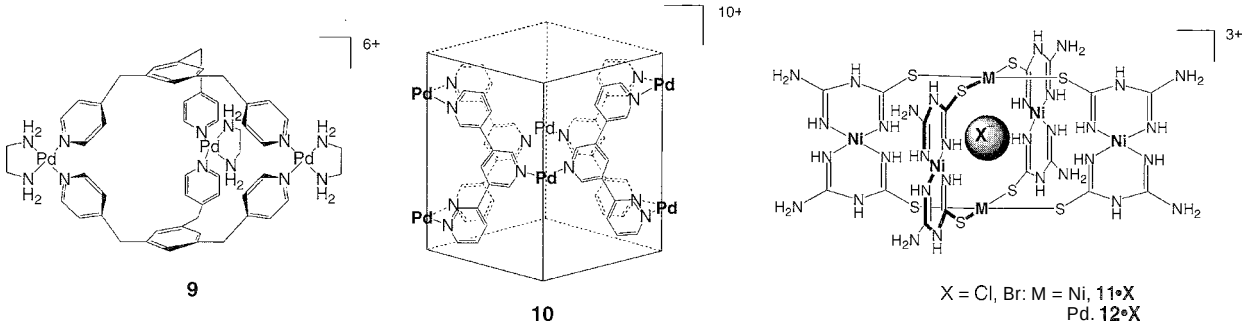
Metalla-Cages

The first examples of metalla-cages synthesized by anion-directed processes are a series of polyoxometallates reported by Müller.[5,17] In these species, anions control the aggregation of $V^{n+}O_x$ polyhedra into cage-type structures such as $[HV_{18}O_{44}(NO_3)]^{10+}$, $[HV_{22}O_{54}(SCN)]^{6+}$, and $[H_4V_{15}O_{40}(PO_4)]^{7+}$, in which the anions are situated inside the cavity of the cages. With other anions such as acetate. V–O aggregates are formed in which the anions are located on the outer surface of the shell. Similarly, Zubieta reported that the synthesis of a series of oxovanadium-organophosphates such as $[(VO)_6(t\text{-}BuPO_3)_8Cl]$ may be directed by the encapsulated chloride anion.[18]

An interesting example of anion-directed assembly is the "super-adamatoid" silver cage $[Ag_6(triphos)_4X_4]^{2+}$ (**7•X**) [X=O_3SCF_3, ClO_4, and NO_3; triphos=$(PPh_2CH_2)_3$-CMe] reported by James and Mingos.[19] The formation of these cages is anion-specific, because they are only obtained in the presence of the above-mentioned anions. When other species such as BF_4^- and SbF_6^- were used. the corresponding rigid cages were not formed but instead. more labile products in which the phosphines dissociate were obtained. These results indicate that, in order to form the silver cages, a nucleophilic anion with the appropriate geometry to bridge three silver atoms is essential. This process has been further exploited by James to prepare metallo-dendrimers by using benzylsulfate dendrons to direct the assembly of the silver cage.[20]

Another example of silver assemblies obtained by anion-directed synthesis[21] are the silver cages $[Ag_{14}(C{\equiv}C^tBu)_{12}X]^+$ (**8•X**) (X=F,Cl,Br). The reaction of *t*-butylalkyne and $AgBF_4$ in the presence of a base yields the organometallic polymer $[Ag(C{\equiv}C^tBu)]_n$, which is converted (in high yields) into the cages $[Ag_{14}(C{\equiv}C^tBu)_{12}X]^+$ (see Fig. 2) upon addition of fluoride. chloride, or bromide salts (but not when other anions such as triflate or tosylate are used). Their structural characterization demonstrated cages **8•X** to have a rhombohedra1 geometry with the corresponding halide encapsulated at their center. The cavity generated by this specific assembly is of the right geometry and dimensions to encapsulate spherical anions with a maximum radius of approximately 2.0 Å. Electrospray ionization mass spectometry (ESI-MS) and solution state infrared (IR) studies demonstrated that the cage-type structure is retained in solution. The silver atoms are held together by the bridging alkynyls and a combination of metallophilic attractions between the silver centers and Lewis-acid–base interactions between the silver atoms and the encapsulated halide.

Fujita reported a wide range of systems formed by the self-assembly of several nitrogen-donor ligands and palladium and platinum centers.[22] In the assembly of some of these systems, the ternplating properties of anions play an important role. When the square planar complex $[Pd(en)_2(NO_3)_2]$ is reacted with 1,3,5-*tris*(4-pyridylmethyl)benzene in the presence of anionic species having a hydrophobic moiety (such as 4-methoxyphenylacetate), the nearly quantitative formation of the cage structure **9** is observed (see Fig. 3).[23] In the absence of the anionic/hydrophobic species, this reaction gives rise to a considerable amount of polymeric material. Similarly, the



9 10

Fig. 3 Anion-directed cages 9. **11·X**, **12·X**,[23,25,26] and Fujita's nanochannels.[24] (*View this art in color at www.dekker.com.*)

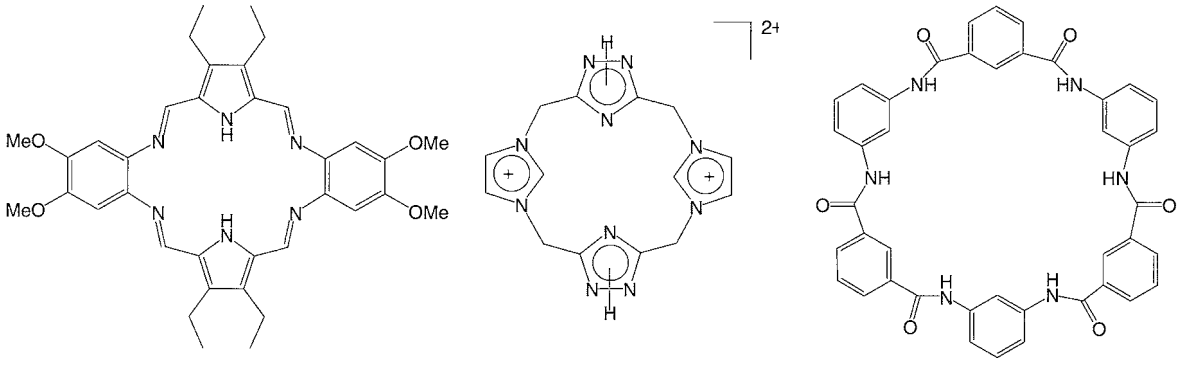
quantitative formation of coordination channels such as **10** has been reported to occur when $[Pd(en)_2(NO_3)_2]$ is reacted with oligo(3,5-oligopyridine)s in the presence of rod-like anion species such as 4.4'-biphenylenedicarboxplate (see Fig. 3).[24] In these examples. the template directs the assembly not only through electrostatic interactions but also through π-π stacking and the use of hydrophobic effects.

A combination of metal. . .anion and hydrogen-bonding interactions has been used in the anion-directed synthesis of a series of hexametal cages.[25,26] The nickel complexes $[Ni_6(atu)_8X]^{3+}$ (**11·X**) can be prepared by mixing stoichiometric amounts of NiX_2 and Hatu (X = Cl,Br; Hatu = amidinothiourea) in methanol. The structural characterization of the resulting compounds demonstrated that the six nickel atoms are assembled in an octahedral geometry around a central anion and are linked by eight deprotonated Hatu ligands. The corresponding halide anion is encapsulated at the center of the cage and forms eight M-bonds with the ligands' NH groups. There is also an important attraction between the NiS_4 units located at the poles of the cage and the central anion. The analogous hexanuclear cages $[Ni_2Pd_2(atu)_8X]^{3+}$ (**12·X**) (X = Cl,Br) can be prepared by reacting four equivalents of the preformed $Ni(atu)_2$ complex and two equivalents of $Pd(PhCN)_2X_2$. In the presence of other anions (such as I^-, ClO_4^-, OAc^-. or NO_3^-), the hexanuclear cages do not form, indicating the important geometrical constrains (both regarding their volume and spherical shape) imposed by the templating halides for the formation of these specific structures.

ANION-DIRECTED ASSEMBLY IN ORGANIC SYNTHESIS

Macrocycles

Cation-directed synthesis of organic macrocycles such as crown ethers is a well-established procedure that has been widely utilized for many years. However: the use of anionic species for this purpose has only recently begun to be exploited. One of the first examples of anion-directed organic synthesis is the oligopyrrolic macrocycle **13** reported by Sessler (see Fig. 4).[27] This macrocycle was



13 14 15

Fig. **4** Products of the anion-directed macrocyclization reactions reported by Sessler,[27] Alcalde,[28] and Kim [29]

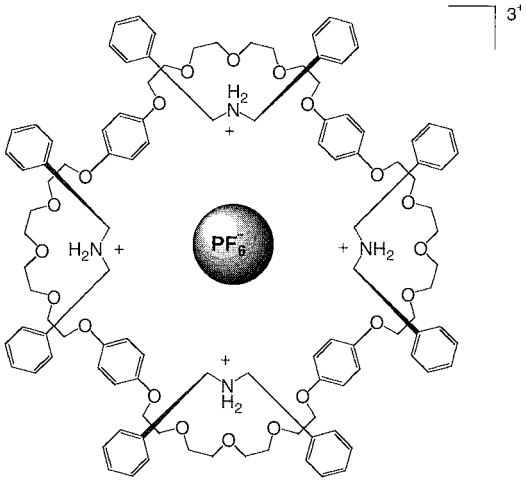
prepared quantitatively using HNO_3 (rather than HCl) as acid catalyst for the cyclization. Under these conditions. the nitrate salt of the protonated macrocycle precipitated out of the reaction mixture. These results led the authors to suggest a possible ternplating effect exerted by the anionic species. Similarly, Alcalde recently reported[28] the chloride-directed synthesis of a series of [1_4]imidazoliophanes such as **14** (see Fig. 4). The macrocyclization reaction leading to these species was studied in the presence of a wide range of anions and demonstrated to give greatly increased yields when chloride (and in some cases, bromide) was used. In the presence of larger anions (such as BF_4^-, PF_6^-, and $H_2PO_4^-$), the yields were considerably lower, suggesting a good size-match between the cavity of the macrocycles and the two halides.

Another example in which anions seem to play an important directing role is in the synthesis of oligoamide macrocycles.[29] Following observations that certain salts (such as LiCl and $CaCl_2$) have an influence on the formation of polyamides. Kim engaged in studying the influence of such salts in model macrocyclic compounds. Specifically. the high dilution reaction between isophthalic acid chloride and *m*-phenylenediamine was studied and reported to yield a complex mixture of cyclic and oligomeric species. However, when this reaction was repeated in the presence of $CaCl_2$, the main product obtained was the cyclic hexamer **15** (see Fig. 4) in preference to the other cyclic and oligomeric species. Structural characterization of **15** demonstrated it to have a $CaCl_3^-$ anion (formed in situ from $CaCl_2$ and free chloride) positioned in the inner cavity of the macrocycle. These results suggested a directing effect of the anion. because in its absence. the main product of the reactions was not the hexamer **15** but oligomers and rings of different sizes.

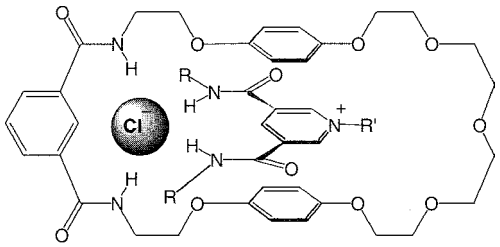
Rotaxanes and Pseudorotaxanes

The interest in rotaxanes, pseudorotaxanes, and catenanes (i.e., molecules that contain non-covalently interlocked components) stems from their potential use as building blocks in molecular devices. Their syntheses usually rely on some sort of template assistance, such as the preorganization of the assembly's components around a metal center. While cationic templates have been widely used in this context, only a few examples of anion-directed synthesis of interlocked molecules have been reported. In fact, although rotaxanes and pseudorotaxanes have been prepared in this way (as discussed in this section), to date there is no reported example of anion-directed synthesis of catenanes.

Stoddart and Williams reported the first example of anion-assisted self-assembly of a pseudorotaxane.[30] By mixing four equivalents of $[NH_2(CH_2Ph)_2][PF_6]$ with one equivalent of a large macrocycle (tetrakis-*p*-phenylene [68]crown-20), the pseudorotaxane (16) shown in Fig. 5 was obtained. This superstructure was structurally characterized, revealing the presence of the PF_6^- anion at its center, which forms multiple C–H . . . F hydrogen bonds with the hydroquinone methine and the benzylic methylene hydrogen atoms. The presence of an encapsulated PF_6^- and its multiple interactions with the receptor suggest that it plays an important directing role in the self-assembly of this superstructure. Further studies in



16



17

Fig. 5 Two examples of pseudorotaxanes reported by Stoddart and Williams[30] and by Beer.[31] (*View this art in color at www.dekker.com.*)

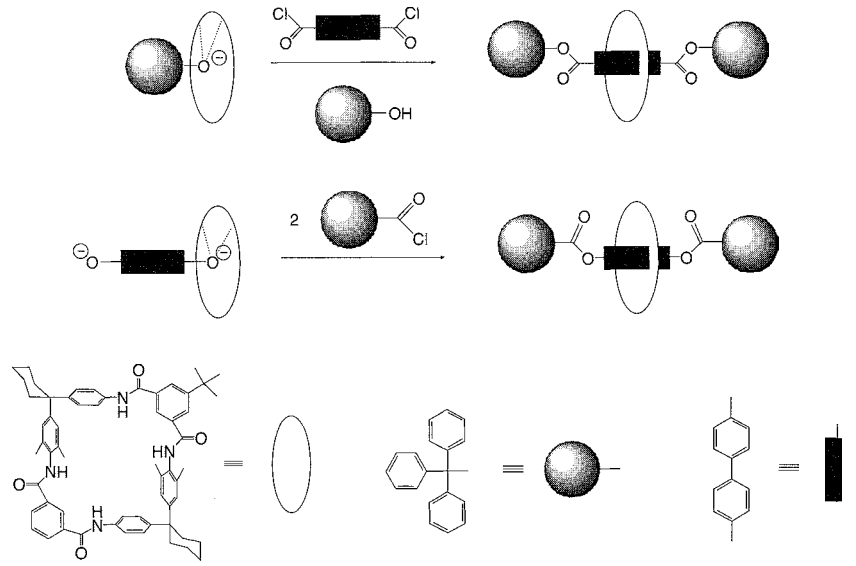


Fig. 6 Reaction scheme for the anion-directed synthesis of Vogtle's rotaxanes.[32] (*View* this art *in color at www.dekker.com.*)

the presence *of other anions would provide interesting insight into this reaction.*

Beer recently reported the anion-directed assembly of the [2]pseudorotaxane **17**.[31] *In this system (see Fig.* 5), *a chloride anion has been employed as the central core about* which *two ligands (the macrocycle and the liner species) are orthogonally disposed by means of* H-*bonding to the anion. The formation of 17 was studied in solution by* UV/Vis *spectroscopy and* ^{1}H-NMR *and confirmed in* the *solid state by an x-ray crystal structure. While chloride was demonstrated to be a good directing agent for the formation of* **17**, *other anions such as* Br^-, I^-, *and* PF_6^- *proved to be poor templates. This demonstrates the importance of the geometries and dimensions of the templating anion for the formation of a specific assembly.*

In 1999 Vögtle *reported the first example of* anion-*directed synthesis of* rotaxanes.[32] *The first step in this synthesis consisted of forming a strong host–guest complex between a* tetralactam macrocycle *and a phenolate anion (see Fig. 6). With this, the anion (also a good* nu-*cleophile)* is *properly positioned to further react with the adequate component to form a rotaxane. Using this* meth-*odology. different rotaxanes were prepared depending on whether the phenolic functionality was located at the stopper component or at the axle precursor.*

Helicates

In contrast to the well-documented assembly of helicates around metal *centers. there are only two examples of well-identified anion-assembled helicates. De Mendoza reported the first in* 1996,[33] *while Kruger and Martin only recently published the* second.[34] *The former reported that a tetraguanidinium strand self-assembled around a sulfate anion to produce a double helical structure. The formation of this* assembly *was proposed on the basis of NMR and* CD *spectroscopic studies. More recently,* Kruger *and Martin structurally* characterized *a double helicate formed by assembling a* diammonium-*bis-*pyridinium *salt around two chloride anions.* In *both of these examples, the directing forces to form the assemblies are based on H-bonding interactions between the anions and the N–H groups present in the ligands.*

CONCLUSION AND OUTLOOK

Important developments in the supramolecular chemistry of anions were seen in the last few years. As a consequence; anion-directed assemblies have started to emerge, providing synthetic chemists with a new approach for the synthesis of complex molecular architectures. The anion-directed assembly of macrocycles, *molecular cages,* nanotubes, *helicates, rotaxanes. and pseudorotaxanes is already a reality. These examples have established the foundations for a systematic and rational approach to the anion-directed synthesis of novel* supra-molecular (and *molecular) structures. Moreover, they suggest that even in well-known reactions. the participation of anions might have been ignored until now. In the years to come. we will certainly see an increasing number of assemblies prepared through anion-directed*

approaches, which will provide new methodologies for synthetic chemistry.

Annulenes

Michael J. Marsella
University of California, Riverside, California, U.S.A.

INTRODUCTION

The [nlannulenes may be defined as cyclic polyalkenes possessing a closed circuit of n π-conjugated p_z-orbitals. The first three small annulenes are shown in Fig. 1 and include [4]annulene (cyclobutadiene), [6]annulene (benzene), and [8]annulene (cyclooctatetraene). The bracketed number, n, can be classified as either a $4n+2$ (Hiickel aromatic/Möbous antiasomatic) or 4n (Huckel antiaromatic/Mobius aromatic) delocalized n-electron species. That said, it is not surprising that the concept of aromaticity[1] is closely associated with the annulenes. Indeed, the first three annulenes listed cover the concepts of Hiickel aromatic, antiaromatic, and nonaromatic properties (see Fig. 1).

Given that the annulene literature is vast and has already been covered within many excellent reviews,[2,3] this work is not intended to be comprehensive. Instead, this review will reflect a sampling of current annulene chemistry. focusing on representative aspects of [4]-, [6]-, [8]-, [12]-, [14]-, [16]-, and [18]annulenes.

DEFINITIONS AND ACRONYMS

For convenience, definitions of key terms and acronyms used in this review are provided below:

ACID (Anisotropy of the Current-Induced Density): A theoretical method for visualizing, as an isosurface, delocalization of electrons in molecules.

[*n*]Annulene: A cyclic polyalkene possessing a closed circuit of n n-conjugated p_z-orbitals.

Antiaromaticity: A property associated with [n]annulenes possessing either $4n$ electrons (Huckel) or $4n+2$ electrons (Mobius). such that the acyclic homologue is more stable than the cycle. A paratropic compound.

Aromaticity: A property associated with [nlannulenes possessing either a 4tz + 2 (Hiickel) or 4n (Mobius) number of delocalized n-electrons capable of sustaining a ring current.[1]

Hückel aromaticity: An aromatic annulene composed of a continuous circuit of p_z-orbitals oriented along the same axis (or plane) and possessing $4n+2$ electrons.

Möbius Aromaticity: An aromatic annulene composed of a continuous array of p_z-orbitals containing a $4n$ number of n-electrons, arranged such that an (ideal) 180° twist occurs within the orbital circuit.

BEE (Bond Localization Energy): The energy necessary to localize a common bond between two cyclic n-systems. See the work of Mitchell, sited herein.[4,5]

Diatropic ring current (**^{1}H-NMR**)**:** An induced ring current within the annulene n-circuit that opposes the applied magnetic field, resulting in a downfield shift of protons on the outside of an aromatic annulene.

Frost's circle: A simple, geometrical approach to approximating the HMO energy levels for planar annulenes. The lowest energy MO has an HMO energy of α+2β.

HMO theory (**Hückel** Molecular Orbital theory): A simple molecular orbital theory applied to planar π-conjugated systems. A key simplification involves treatment of the n-system independently from the σ-system. The HMO molecular orbital energies are in terms of α and β, where α is equated with the energy of an isolated p_z orbital, and β is the resonance integral, equated to the energy associated with having electrons shared by atoms. As reference, benzene is 4β more stable than an isolated p_z orbital.

Homoaromaticity: Cyclic conjugation of a n-system that bypasses one (or more) saturated atoms.

NICS (Nucleus-Independen&Chemical **Shifts**)**:** A theoretical method for determining the ring current at the center (or any position in space) of an annulene or other delocalized system.

Paratropic ring current (**^{1}H-NMR**)**:** An induced ring current within the annulene n-circuit that aligns with the applied magnetic field, resulting in an upfield shift of affected protons.

[4]ANNULENES

The instability of [4]annulene (a neutral $4n$ n-electron annulene) can be gleaned from either Frost's Circle[6] or HMO theory.[7] As shown in Fig. 2. the former predicts an open-shell triplet, implicating instability. The latter reports no gain in energy (0 β) relative to its acyclic analogue, butadiene. Experimental evidence shows that cyclobutadiene is. in fact, a closed shell species, with alternate single and double bonds. Regardless, as predicted. [4]annulene proved to be an unstable compound.

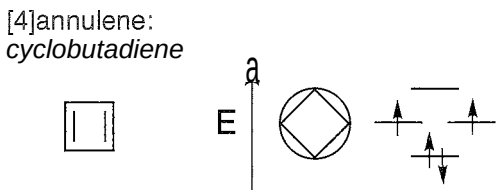

Fig. 2 Frost's circle applied to [4]annulene.

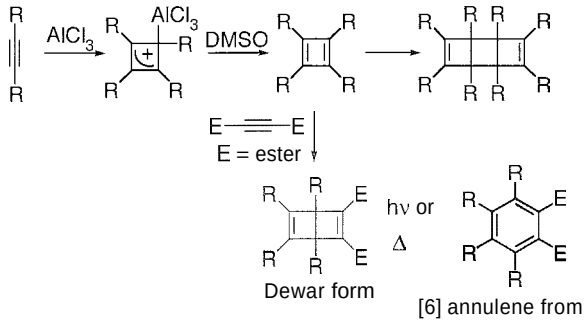
Harnessing the reactivity of [4]annulenes has allowed for their controlled use in [$4\pi_s+2\pi_s$] cycloaddition reactions, playing the role of diene, dieneophile, or both.[8–11] Transient tetraalkylcyclobutadienes can be readily prepared via DMF-promoted decomposition of the corresponding tetraalkylcyclobutadiene-aluminum trichloride complex. The complex is stable and can be readily prepared by reaction of aluminum trichloride with a dialkylacetylene. In the absence of a good dienophile. the reactive tetraalkylcyclobutadienes undergo dimerization to yield 1,2,3,4,5,6,7,8-octaalkyl-tricyclo[4.2.0.$0^{0,0}$]octa-3.7-dienes (Scheme 1). In the presence of a good dienophile, such as acetylenedicarboxylic acid or its corresponding esters, the Diels–Alder adduct can be isolated in high yield.[10,11] It is noteworthy to mention that the product of this [$4\pi+2\pi$] reaction is a substituted Dewar benzene, itself a high-energy isomer of [6]annulene. Thus, from a synthetic standpoint, a substituted [4]annulene can be converted to its isomeric [6]annulene via two pericyclic reactions: a thermal [$4\pi_s + 2\pi_s$] followed by a photochemical 4π electrocyclic ring opening (Scheme 1). Due to this fact, Dewar benzene was proposed as a supramolecular protecting group for aromatic rings, preventing aryl–aryl stacking interactions from biasing solid-state properties.[11]



Scheme 1 Synthesis of a [6]annulene via its Dewar benzene isomer. The Dewar form is prepared via a [$4\pi+2\pi$] cycloaddition with [4]annulene and a substituted acetylene.

An elegant use of [4]annulene chemistry utilizes the stable tricarbonylcyclobutadiene iron complex as a protected cyclobutadiene.[8,9] One advantage over the aluminum cyclobutadiene complex is the ability of the tricarbonylcyclobutadiene iron complex to be amenable to synthetic modifications of the four-membered ring. Typically. ceric ammonium nitrate (CAN; or other oxidants) may be used to oxidize the iron and liberate free cyclobutadiene. An example of this methodology is shown in Scheme 2, as applied to the synthesis of (+)-asteriscanolide. Further examples of reactions utilizing this chemistry are shown in Table 1.

[6]ANNULENES

Benzene embodies arornaticity and is the standard by which the property of aromaticity is measured. Given that fact. it is worthwhile to provide an overview of recent techniques that attempt to quantify the property of aromaticity.

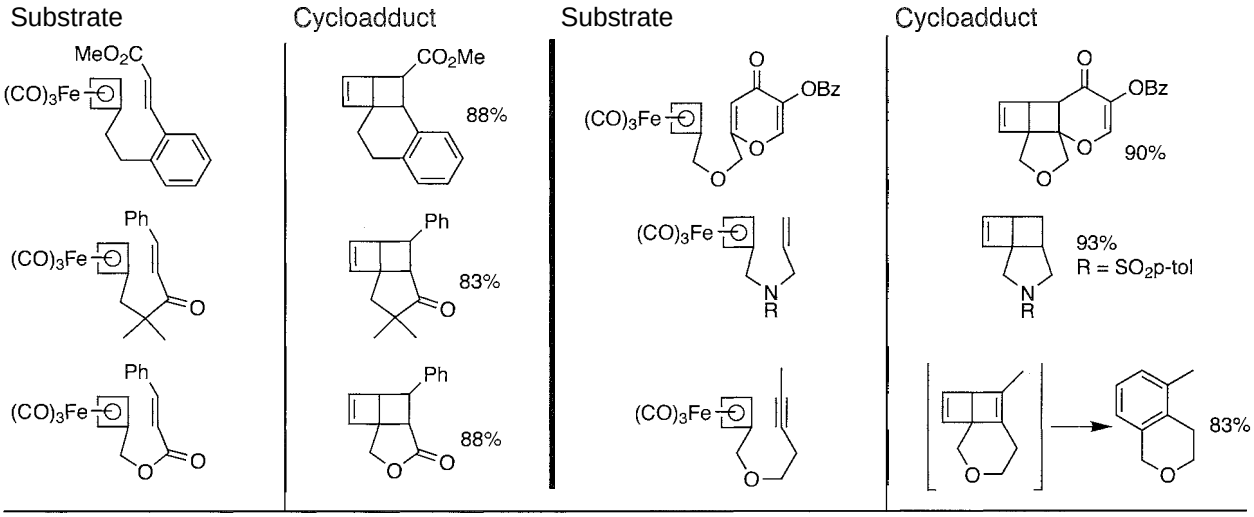
Table 1 Showing substrate and cycloadduct product from the intramolecular [4π+2π] cycloaddition involving the [4]annulene moiety



From a theoretical standpoint, simple analysis via Frost's circle yields a closed-shell system, implying stability (compare to cyclobutadiene) (Fig. 3). The HMO theory renders benzene ca. 1 β more stable than its acyclic analogue, hexatriene. Although these pen and paper methods cannot compare to modern computational methods presently available for a desktop computer. they are elegant in their simplicity and qualitative predictive power. However, given the interest in quantifying some measure of aromaticity (or antiaromaticity) among different annulenes,[a] much higher levels of theory are desired and have been developed. Recently, two new techniques were reported that integrate the power of ab initio calculations with simple protocols that are generally applicable to a wide variety of annulenes and related compounds. Both methods can take advantage of the popular Gaussian[12] suite of computational chemistry programs. Given their generality, availability. and ease of setup, they were highlighted in brief below.

NICS

Proton chemical shifts of annulenes have long been utilized as probes of ring currents.[13] For example. protons outside and inside of an aromatic annulene will shift downfield and upfield, respectively, as a function of the induced ring current. In general, those protons at (or above) the annulene center experience a greater magnitude of shift than those outside the annulene ring. One synthetic/experimental limitation of this "internal probe" technique is the ability to place an NMR active nucleus at a ring center. A theoretical technique designed to overcome this problem places a ghost atom at the ring center (or any position in space). Absolute magnetic shieldings can then be calculated using available computational chemistry programs. This facile technique, known as Nucleus-Independent Chemical Shifts (NICS), is establirhed as an effective aromaticity criterion. Some values are given in Table 2 (note that negative NICS values denote aromaticity, and positive NICS values denote antiaromaticity).

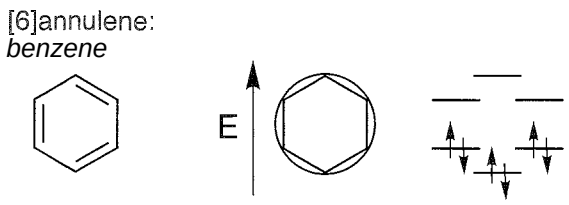


Fig. 3 Frost's circle applied to [6]annulene.

ACID

The ACID method (anisotropy of the current-induced density) provides a method to visualize, as an isosurface. delocalization of electrons in molecules.[14–16] One major advantage of this method is its invariance with respect to the relative orientation between molecule and magnetic

Table 2 Nics values for several aromatic and antiaromatic species

Annulene	Point group	NICS (6–31+G*)
Benzene	D_{6h}	−9.7
[8]Annulene dianion	D_{8h}	−13.9
[4]Annulene	D_{2h}	+27.6
Naphthalene	D_{2h}	−9.9

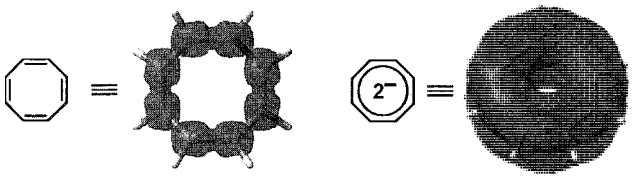

Fig. 4 ACID surface mapped onto the localized, tub conformer of [8]annulene (left), and the planar. delocalized [8]annulene dianion (right). Discontinuous surfaces imply no delocalization at those corresponding points in space (with respect to the selected isosurface value: here set at 0.05). (*View this art in color at www.dekker.com.*)

field. Furthermore. it is not a simple function of the electron density. and it utilizes the same symmetry as the wave function. In the proverbial sense that ''one picture is worth a thousand words.'' the ACID technique is best summarized by direct visualization of such an isosurface. As such, illustrated in Fig. 4 is an ACID isosurface mapped onto both the (localized) tub conformer and (delocalized) planar conformer of [8]annulene and its aromatic dianion. respectively.

In addition to the classical [6]annulene, benzene, neutral in-plane trishomoaromatic ''benzene'' frameworks (such as that depicted in Fig. 5*)* were also studied.[17] Although not yet synthesized, these compounds were collectively studied using a variety of computational techniques. Unique from benzene, the six overlapping p-orbitals lie in-plane (as opposed to orthogonal). Given that this arrangement constitutes a closed circuit of $4n+2$ π-electrons, the system. according to the definition provided herein. constitutes a (homo-) [6]annulene. Within the reported series. a maximum NICS value of -30.1 ppm was found at the ring center. Ultimately, it was determined that such in-plane annulenes may possess more than one third the aromatic stabilization energy of benzene, thus constituting the best candidates yet proposed for a neutral *tris*homoaroinatic compound.

[8]ANNULENES

[8]Annulene is a $4n$ π-electron system, and thus, the (neutral) planar form would be expected to exhibit antiaromatic behavior. Indeed, Frost's circle analysis predicts an open-shell species (as with [4]annulene; see Figs. 2 and 6). Extensive studies of cyclooctatetraene were performed,[18,19] and it was established that the neutral state avoids the problem of antiaromaticity by adopting a tub conformation. Both the anion and dianion are known to exist in a planar conformation, the latter being aromatic.[19] This fact is also predicted by simple analysis of the [8]annulene dianion by Frost's circle (see Fig. 6). It is predicted that the planar [8]annulene dianion is a closed-shell system.

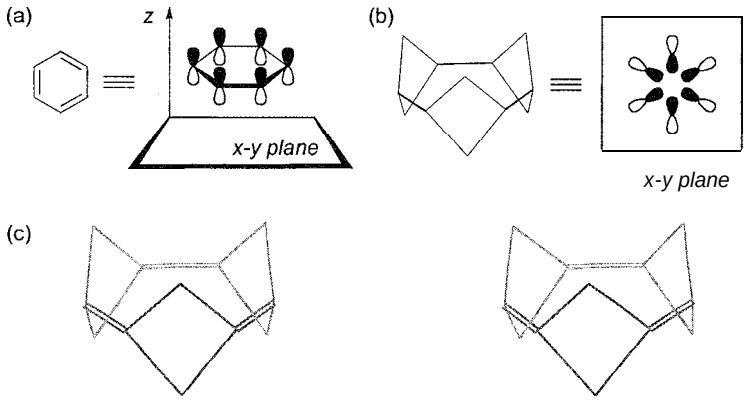

Fig. 5 (a) Benzene p-orbitals are orthogonal to the x–y plane. (h) In an in-plane benzene. six p-orbitals lie in-plane. (c) Stereoview (cross-eye) of an in-plane benzene skeleton.

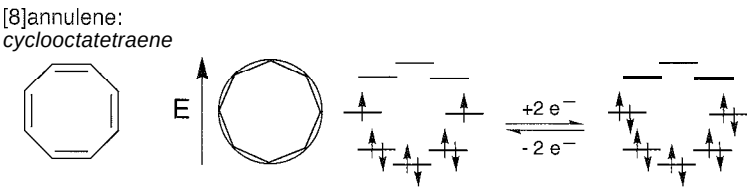

Fig. 6 Frost's circle applied to [8]annulene and its dianion.

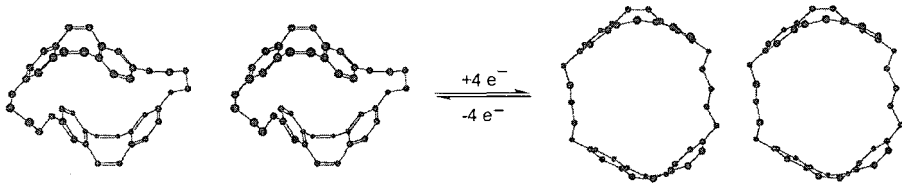

Fig. 7 Stereoviews (cross-eye) of a shape-changing cyclophane composed of two [8]annulene moieties. The stereoviews were modeled at ihe PM3 level of theory and optimized only for illustrative purposes (structures may not correspond to true global minima).

At the ab initio level of theory, a NICS calculation of the dianion yields an (aromatic) value of -13.9[13] (see Table 2). and ACID[14] clearly illustrates the corresponding shift from the localized neutral tub conformer to the delocalized planar dianion (see Fig. 4).

The redox-induced conformational change associated with [8]annulene was utilized as the key element in the design of shape-changing molecules. A shape-changing cyclophane was reported,[20] likely capable of functioning as a redox-triggered two-state host (Fig. 7). In an analogous manner. a polymer composed of tetra[2,3-thienylene] monomers (a thiophene-fused [8]annulene) was also reported,[21–23] a design intended to translate additive tub-to-planar conformational changes into an overall perturbation of polymer chain length (i.e., a polymeric electromechanical actuator or molecular muscle, see Fig. 8a,b and Table 3). In contrast to the aforementioned conformationally dynamic [8]annulenes, oxidation of the constrained tub conformer of octamethoxytetraphenylene (an *o*-dialkoxybenzene-fused [8]annulene), yields electrochromic switching via redox-triggered reversible carbon–carbon bond formation (Fig. 8c).[24]

Tetra[2,3-thienylene] was also utilized as a rigid unit, a double-helical scaffold.[25] Specifically, a racemic mixture of the corresponding octaaryl double helix. shown in Fig. 9, crystallizes to yield homochiral, supramolecular polymer chains extending in the direction of the long crystal axis. Edge-to-face stacking of neighboring (intermolecular) terminal phenyl groups dominated the homochiral supramolecular assembly (Fig. 9). Similarly, tetraphenylene was also used as a scaffold for the synthesis of octaaryl double-helical monomers (Fig. 10).[26]

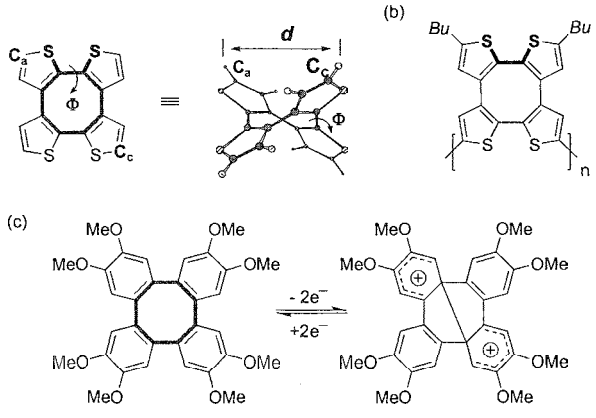

Fig. 8 (a) Depicting tetra(2,3-thienylene) and corresponding descriptors. @ and *d* (see Table 3). (b) Poly(tetra[2, 3-thienylene]). a putative molecular muscle. (c) Depicting redox-induced reversible carbon–carbon bond formation in octamethoxytetraphenylene.

MöBIUS [4*N*]ANNULENES: [12]-, [16]-, AND [20]ANNULENE

Although the concept of Mobius aromaticity was put forth in 1964,[27] no neutral [4*n*]annulene exhibiting a Mobius strip conformation (Fig. 1I) and Mobius aromatic character has yet been prepared. It was originally predicted that all [4*n*]anulenes $\geq$ [20]annulene should be capable of accommodating a Mobius strip conformation with minimal strain. Recent theoretical studies revealed that the [4*n*]annulenes, [12]-, [16]-, and [20]annulene, exhibit Mobius conformers (local minima) and corresponding aromatic character (NICS values of -14.6. -15.6, and -10.2 ppin at ring center, respectively), although the lowest-energy conformers (global minima). in all cases. are of Hückel topology.[28] Clearly, control of conformation via the targeted synthetic design of a [4*n*]annulene

Table 3 Reporting the redox-induced perturbation of S-C-C-S dihedral angle. Φ. and corresponding dimensional change, *d* (see Fig 8a)

Compound	Charge	Φ(deg)	*d* (Å)	Ad (%)
Monomer	0	49.5	6.87	—
Monomer	1+	34.8	7.27	5.69
Dimer	0	48.9	6.90	—
Dimer	1+	38.6	7.14	3.54
Dimer	2+	31.4	7.33	5.92

Charges were determined via electrochemical analysis of tetra(2. 3-thienylene) monomer and dimer. and conformer data was calculated at the B3LYP/6-31G(*d,p*) level of theory.

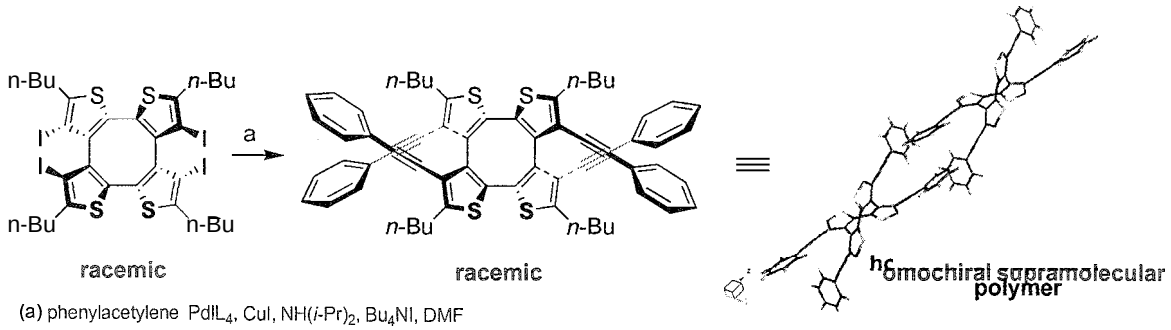

Fig. **9** Synthesis of a racemic octaaryl double helix utilizing tetra[2,3-thienylene] as a core. Supramolecular self-assembly of the racemic mixture yields homochiral supramolecular polymers (dimer repeat shown).

with true Mobius topology will be required to provide supporting experimental data to this study.

[14]ANNULENE: DIHYDROPYRENE VALENCE TAUTOMERISM AND APPLICATIONS DERIVED THEREFROM

The [14]annulene, diinethyldihydropyrene (DHP), exhibits rich cheinistry that was reviewed elsewhere in detail.[2,29] A key reaction of this annulene is the symmetry-allowed photochemical transformation between the closed [14]annulene form. and the open metacyclophanediene form (CPD; see Scheme 3a). The transition between colorless and colored forms, the perturbations in conjugation pathways, and the ^{1}H-NMR shift associated with the two methyl groups poised near the ring center (thus, reporting changes in ring currents) made DHP an excellent scaffold from which to design photochrornic switches and other n-functional molecules.

The current state-of-the-art DHP photochrornic switch is capable of accessing three unique states (CPD–CPD, CPD–DHP. and DHP–DHP; see Scheme I3b).[29,30] This multistate photochromic switch was prepared by fusion of two benzo[*e*]dimethyldihydropyrene moieties. The states can be optically read and written. although the DHP–DMP state rapidly converts back to the CPD–DHP state via a thermal (symmetry forbidden) process.

The DHP to CPD interconversion also perturbs conjugation pathways around the perimeter of the molecule. This fact was capitalized upon to yield an optoelectronic redox switch (Scheme 3c).[31] Specifically, the 16-π linear circuit extending from thiophene A through DHP to thiophene B is interrupted upon conversion to Th-CPD-Th. This process is reversible, and only the DHP form exhibits anodic activity within a window of 0.0–0.75 V. Thus, the state of the photochromic switch can be written photochemically and read electrochemically (the CPD form is redox silent, and the DHP form is redox active).

In addition to functioning as a switch. DHP also serves as a tool with which to probe aromatic character by NMR (via monitoring the "reporter" methyl groups).[4] It was shown that the BLE of any aromatic annulene benzannulated onto DHP (i.e., [*n*]annulene, shown in Fig. 3d) can be determined by the following equation:

$$\text{BLE} = [4.18 + \delta(\text{Ar})]/2.59$$

where δ(Ar) is the average chemical shift of ihe internal methyl groups.

This equation is true due to the sensitivity of the methyl groupr to the ring current of the DMP skeleton, as well as to the fact that annulated DHPs can be dissected into two π-circuits (i.e.. red and blue according to Scheme 3d). The

Scheme *3* (a) The DHP–CPD photochemical interconversion; (b) a DHP-based three-way switch: (c) a thiophene-DHP copolymer capable of attenuating effective conjugation length via the DHP–CPD photochemical interconversion; and (d) the two π-circuits in a benzannulated-DHP: blue corresponds to the DHP skeleton. and red corresponds to a benzannulated aromatic. (View *this* art *in* color *at www.dekker.com.*)

larger the resonance energy in the red fragment, the less delocalization in the blue circuit (i.e., DHP), hence, the smaller the diatropic shift of the methyl groups. Of course, one drawback of this method is that it requires covalent attachment between the DHP "probe" and the aromatic [*n*]annulene to be studied.

[16]- AND [18]ANNULENE

The [16]-annulene and [18]annulene are the smallest annulenes (antiaromatic and aromatic, respectively), possessing internal protons to be thermodynamically stable at room temperature (Fig. 12). Not surprisingly, steric interactions between internal protons affect the conformer distribution of these systems. Perdeuterated [16]- and [18]annulenes were synthesized in an effort to attenuate these internal sterics, given that C–D bonds are shorter than C–H bonds.[32] The results demonstrated increased ring currents in both of the perdeuterated annulenes, as determined by ^{1}H-NMR analysis (paratropic and diatropic, respectively). It is proposed that the shorter C–D versus C–H bond reduces internal sterics, allowing the σ-framework of the annulenes to achieve near ideal (120°) C–C=C bond angles, and thus increasing the enforcement of π-delocalization. It should be emphasized that achieving near ideal bond angles was determined to be more important than achieving complete planarity (i.e., all internal H/D atoms in the same plane).

CONCLUSION

Selected examples of recent properties and applications of [*n*]annulenes ($n = 4$, 6, 8. 12, 14. 16. and 18) were presented. Despite years of investigation. it is apparent that these cyclic systems possess many unique properties of

applications (for example. molecular devices). Furthermore, some interesting properties of as-yet unprepared

annulenes were predicted from accurate levels of ab initio theory. When coupling these facts and recognizing that the area of annulene chemistry extends far beyond this review, it is clear that interest in these systems will remain keen for many years to come.

Anticrowns

Vladimir B. Shur
Irina A. Tikhonova
Russian Academy of Sciences, Moscow, Russia

INTRODUCTION

Anticrowns are peculiar antipodes of crown ethers and their thia and aza analogues. They contain several Lewis acidic centers in the macrocyclic chain and so are able to efficiently bind various anions and neutral Lewis bases with the formation of unusual complexes, wherein the Lewis basic species is simultaneously bonded to all Lewis acidic atoms of the macrocycle. This remarkable property of anticrowns, being reminiscent of the behavior of conventional crown compounds in metal cation binding, makes them prospective aids in the areas of molecular recognition. ion transport. as well as organic synthesis and catalysis.

The first reports on the anion-binding capacity of anticrowns emerged in the late 1980s–early 1990s. Subsequently, a considerable amount of information on different aspects of the chemistry of these novel reagents was accumulated. Nowadays. data on coinplexing properties of macrocycles containing two, three. four: and five Lewis acidic centers in the chain were published. Especially impressive results were obtained for polymer-curamacrocycles. which proved to be efficient hosts for binding various anionic and neutral Lewis basic species. Polytin- and polysilicon-containing macrocycles were also studied as anticrowns.

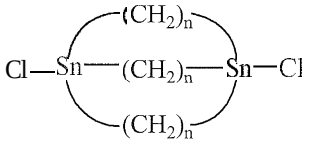
In the present article. host–guest chemistry of anticrowns as well as available data on their applications in catalysis and as ionophores will be briefly reviewed. Strictly speaking. only macrocycles with three and more Lewis acidic centers in the chain can be considered as genuine anticrowns. Nevertheless. the binding properties of some macrocycles containing only two Lewis acidic atoms in the ring will also be discussed.

HOST-GUEST CHEMISTRY OF ANTICROWNS

Polytin- and Polysilicon-Containing Macrocycles

In 1987, Newcomb et al.[1] reported the synthesis of the macrocycles $[Cl_2Sn(CH_2)_n]_2$ (n=8, 10. 12) containing two tin atoms in the macrocyclic chain. and they showed by ^{119}Sn-NMR method that these macrocycles form complexes with chloride anion in an acetonitrile solution. It was suggested that the anionic species in the resulting complexes is bonded to both tin atoms of the cycle. The most stable adduct was formed from the macrocycle with n=8.

The interaction of halide anions with a series of macrobicyclic compounds (**1**–**4**) containing two tin atoms in bridgehead positions was also studied by ^{119}Sn–NMR.[2] It turned out that bicyclic host **1** is able to bind fluoride anion. but it does not react with bulkier chloride. bromide, and iodide ions. By contrast, compounds 2–4 readily coordinate chloride ion but they are unable to bind fluoride anion. According to x-ray diffraction data, the fluoride ion in the complex with 1 is bonded to both tin centers of the Lewis acidic host. whereas the chloride ion in its adduct with 2 is coordinated only to a single tin atom.



1 (n = 6), **2** (n = 8), **3** (n = 10), **4** (n = 12)

In 1989, Jurkschat et al.[3] described the synthesis of the 12-membered rnacrocycles $[R^1R^2Sn(CH_2)_3]_3$ [$R^1=R^2=Cl$ ***(5)***; $R^1=Me$, $R^2=Cl$ (**6**)] containing three tin atoms in the macrocyclic chain. According to ^{119}Sn-NMR spectra, both rnacrocycles are able to bind successively at first one and then the second chloride ions. The complex of 5 with one chloride ion was isolated from the reaction solution. An x-ray diffraction study of this complex revealed that the anionic species is coordinated here with two Lewis acidic centers of the cycle. For the analogous 1:1 complex of macrocycle 6. the structure including the simultaneous coordination of Cl^- with all three tin atoms of the cycle was proposed.

In a subsequent study. the ability of the 15-membered polytin-containing macrocycle $[Me_2Sn(CH_2)_4]_3$ to bind chloride and bromide anions as well as to transport them through liquid membrane was demonstrated.[4] Similar capacity to transport halide anions (Cl^-, Br^-) through

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019199

liquid membranes was previously established for the macrocycle $[Me_2Si(CH_2)_3]_3$ containing three silicon atoms.[11] Recently, the synthesis of the eight-membered macrocycle [*cyclo*-$CH_2\{Sn(Cl_2)CH_2Si(Me_2)\}_2O$] with two tin and two silicon atoms in the ring was described.[6] This macrocycle reacts with chloride, fluoride. and hydroxide ions to form 1:1 complexes, wherein only tin atoms of the cycle are involved in the coordination with the anionic guest.

Perfluorinated Polymercuramacrocycles

The possibility of using polymercuramacrocycles as anion receptors was demonstrated for the first time in 1989. when it was reported that cyclic trimeric *o*-phenylenemercury (*o*-$C_6H_4Hg)_3$ (**7**)[7] containing three Hg atoms in a planar nine-membered cycle is capable of binding halide anions (Cl^-, Br^-, I^-) in halomethane solutions.[11] However, the resulting complexes could not be isolated here due to. apparently, their insufficient stability. Further progress in mercury anticrown chemistry was achieved when the perfluorinated analogue of **7**, viz. cyclic trimeric perfluoro-*o*-phenylenemercury (*o*-$C_6F_4Hg)_3$ (**8**)[9] was employed as a macrocyclic host.[10,11] The presence of fluorine atoms in the aromatic rings of 8 sharply increases the Lewis acidity of the Hg centers and. as a consequence. quite stable and isolable complexes of unusual structures are formed in the interaction of this macrocycle with anions and neutral Lewis bases. Subsequently, one other perfluorinated polymercuramacrocycle. $[(CF_3)_2CHg]_5$ (**9**),[12] with five Hg atoms in a planar 10-membered ring was also successfully used as an anticrown.

Macrocycle **8** exhibits a high affinity toward various anionic species (Cl^-, Br^-, I^-, SCN^-, BH_4^-, *closo*-$[B_{10}H_{10}]^{2-}$, *closo*-$[B_{12}H_{12}]^{2-}$, etc.), forming complexes with coinpositions and structures that are strongly dependent on the nature of the anion and the reagent ratio. In the case of bromide. iodide, and thiocyanate ions, the isolated compounds $[(o\text{-}C_6F_4Hg)_3X]^-$ (X=Br, I, SCN) contain one anionic guest per one molecule of the macrocycle.[10,11,13] The reaction of **8** with chloride ions gives the complex $\{[(o\text{-}C_6F_4Hg)_3]_3Cl_2\}^{2-}$, containing two anionic species per three macrocycle molecules.[11]

An x-ray diffraction study of the complexes of **8** with bromide and iodide anions showed[10,11] that they are polymeric in the solid state and have unprecedented structures of polydecker bent sandwiches $[(\cdots\mathbf{8}\cdot\cdot X\cdot\cdot)_n]^{n-}$ (X=Br, I), wherein every halide anion is simultaneously coordinated to six Hg atoms of two neighboring molecules of 8. A unique feature of the complexes is that the role of the coordinating centers in their molecules is played not by the metal atoms or cations. as in the case of normal sandwich complexes, but by the anions of the halogen. An analogous polydecker sandwich structure was established for a 1:1 complex of 8 with thiocyanate anion.[13] The anionic species in this complex is bonded to the Hg centers of **8** through the sulfur atom. However, the coordination of the anionic guest with Lewis acidic host is here less symmetrical: every S C N ion forms with each of the macrocycles two relatively short and one considerably longer Hg–S bonds. One may suggest that the above-mentioned complex of 8 with chloride anions. $\{[(o\text{-}C_6F_4Hg)_3]_3Cl_2\}^{2-}$, has a structure of triple-decker sandwich.[10] Quantum–chemical calculations also predict the possibility of the existence of double-decker sandwich complexes of macrocycle 8 with halide and sulfide anions.[14]

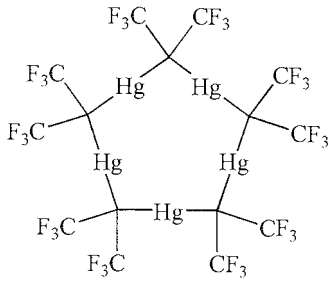
In the interaction of 8 with borohydride anions in THF. the complexes of three different compositions, viz. $\{[(o\text{-}C_6F_4Hg)_3]_2(BH_4)\}^-$, $\{[(o\text{-}C_6F_4Hg)_3](BH_4)\}^-$, and $\{[(o\text{-}C_6F_4Hg)_3](BH_4)_2\}^{2-}$ are formed depending on the reagent ratio.[11] According to IR spectra, the bonding of the BH_4^- ions to the Hg atoms is accomplished here through B–H–Hg bridges. Quantum–chemical calculations of the complexes suggest that they should have unusual double-decker sandwich, half-sandwich (pyramidal), and bipyramidal structures. respectively. The complexes are quite stable. For example, the stability constant of $\{[(o\text{-}C_6F_4Hg)_3]_2(BH_4)\}^-$ in THF at 20°C reaches a value of 10^7 l mol^{-2}.

The first structurally characterized double-decker sandwich complexes of perfluorinated polymercuramacrocycles with anions were obtained from the reactions of polyhedral *closo*-$[B_{10}H_{10}]^{2}$ and *closo*-$[B_{12}H_{12}]^{2}$ dianions with the excess of 8.[16] The anionic guest in these remarkable complexes $\{[(o\text{-}C_6F_4Hg)_3]_2(B_nH_n)\}^{2}$ (n=10, 12) is located between the planes of two macrocycles and is bonded to each through B–H–Hg bridges of two types. One type is the simultaneous coordination of the B–H group to all Hg centers of the neighboring molecule of the macrocycle. The other type is the coordination of the B–H

moiety only to a single Hg atom of the cycle. When the interaction of 8 with the above polyhedral dianions is conducted at an equimolar ratio of the reagents. the corresponding half-sandwiches $\{[(o\text{-}C_6F_4Hg)_3](B_nH_n)\}^{2-}$ are produced.[16]

For macrocycle 9. complexes with halide, acetate, trifluoroacetate, and sulfate anions were obtained. In the case of halide ions, the isolated compounds, $\{[(CF_3)_2CHg]_5X_2\}^{2-}$ (X=Cl, Br, I), contain two anionic species per one macrocycle molecule and have bipyramidal structures.[14,17,18] The halide anions in these adducts are arranged above and below the metallacycle plane, and each is symmetrically bonded to all Lewis acidic centers of the cycle, so that the coordination number of the halogen atoms here becomes equal to five. In the *bis*-acetate and *bis*-trifluoroacetate complexes of 9. the anionic guests are also disposed on different sides of the metallacycle plane and are bonded to 9 in the same manner.[19] In each of the carboxylate ligands. one of the oxygen atoms is coordinated with three metallic centers of the cycle, whereas the other is bonded to two remaining metal atoms. Different coordinated geometry is observed in the complex of 9 with sulfate anion.[19] In this 1:1 complex $\{[(CF_3)_2CHg]_5(SO_4)\}^{2-}$, the anionic guest behaves as a tetradentate ligand and forms three types of the Hg–O bonds with the macrocycle. One type is the cooperative binding of one of the oxygen atoms of the SO_4^{2-} ion by all Lewis acidic sites of the host. This oxygen atom is located nearly in the plane of a 10-membered mercuracarbon ring. Two other oxygen atoms are coordinated each to a single Hg atom of 9, while the fourth oxygen atom is bonded to two Hg centers.

Macrocycle 8 is able to bind effectively not only anions but also various neutral Lewis bases. such as nitriles,[20] carbonyl compounds,[21,22] aromatic hydrocarbons,[23] and some others.[21] As a result of the reactions. complexes containing one, two. or three Lewis basic species per one macrocycle molecule are produced. depending on the nature of a Lewis base. For example. the interaction of

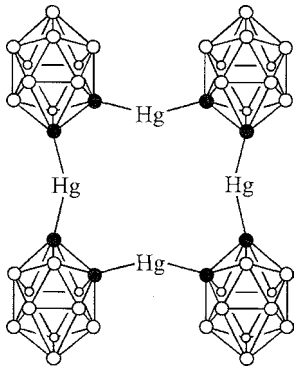


8 with acrylonitrile,[20] acetone,[22] acetaldehyde,[22] and benzophenone[22] gives 1:1 complexes having pyramidal structures in which the Lewis basic species is coordinated with all mercury centers of 8. The reactions of 8 with acetonitrile,[20] *N*,*N*-dimethylformamide,[21] and acetophenone[22] afford complexes containing two Lewis bases per molecule of 8. and these complexes have the corresponding bipyramidal structures, with the Lewis basic moieties being located on different sides of the metallacycle plane. And, at last, from the interaction of 8 with benzonitrile,[20] ethyl acetate,[21] and acetone,[22] complexes containing three molecules of a Lewis base were isolated. Interestingly, in the case of the benzonitrile complex $[(o\text{-}C_6F_4Hg)_3(PhCN)_3]$, all the nitrile ligands are disposed on one side of the metallacycle plane and, in addition, differ from each other in the geometry of coordination with the macrocycle. By contrast, in the 1:3 complexes of 8 with ethyl acetate and acetone, two of three molecules of a Lewis base are located above and below the metallacycle plane. It should be stressed that independent of their structure. all the 1:3 complexes contain at least one fragment wherein the Lewis basic guest is simultaneously bonded to all Lewis acidic sites of the macrocycle. Note also that according to IR spectra. the complexation of the above carbonyl compounds with 8 leads to a significant weakening of their C=O bonds, which is of interest for organic synthesis and catalysis.

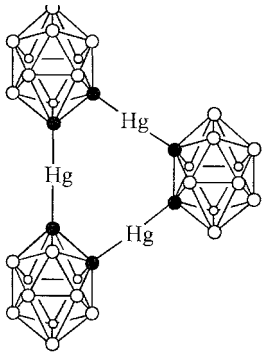
The reactions of macrocycle 8 with benzene. biphenyl, naphthalene, and triphenylene result in the formation of 1:1 complexes with polydecker sandwich structures in the solid state.[7,8] The bonding of the aromatic molecules to 8 in these unusual complexes is due to secondary π-interactions between the C=C bonds of the arenes and the Lewis acidic Hg centers. Thus, even weak Lewis bases such as aromatic hydrocarbons are able to form host–guest complexes with 8.

o-Carboranylmercury Macrocycles (Mercuracarborands)

o-Carboranylmercury macrocycles or mercuracarborands[24,25] also exhibit a high efficiency in the binding of anions and neutral Lewis bases. which is due to the electron-withdrawing character of the carborane cages increasing the Lewis acidity of the mercury centers. This class of anticrowns was developed by Hawthorne et al.[24,25] At present. data on the synthesis and complexing properties of mercuracarborands $(o\text{-}C_2B_{10}H_{10}Hg)_4$ (10). $(o\text{-}C_2B_{10}H_{10}Hg)_3$ (11). and their substituted derivatives. containing four and three Hg atoms in 12- and 9-membered cycles, respectively, are available.



10



11

In 1991, Hawthorne et al. reported that the reaction of 1.2-dilithio-o-carborane *o*-$C_2B_{10}H_{10}Li_2$ *with* $HgCl_2$ *results in the formation of a* 1:1 *complex of* mercuracarborand *10 with chloride* ion.[24,25] *The anionic guest in this* unique *complex* $[(o\text{-}C_2B_{10}H_{10}Hg)_4Cl]^-$ *(12) resides nearly in the center of the mercuracarbon ring and is symmetrically coordinated to the four* Hg *atoms of the cycle. It was proposed that the chloride ion plays a role of a template in this macrocyclization reaction. Similarly. a treatment of* *o*-$C_2B_{10}H_{10}Li_2$ *with* HgI_2 *afforded the corresponding mono- or diiodide complexes,* $[(o\text{-}C_2B_{10}H_{10}Hg)_4I]^-$ *and* $[(o\text{-}C_2B_{10}H_{10}Hg)_4I_2]^{2-}$ *(13). depending on the reaction* conditions.[24,25] *As in the above-mentioned diiodide complex* $\{[(CF_3)_2CHg]_5I_2\}^2$ *, the anionic species in* **13** *are arranged above and below the* metallacycle *plane, but their coordination with the mercury atoms is less symmetrical here. which can be explained by the electrostatic repulsion of the iodide anions. The same indirect procedure was utilized successfully for the synthesis of halide complexes with a number of substituted derivatives of* **10**.[24,25] *In particular, a 1:1 complex of the tetraphenyl derivative of* **10** *with iodide ion,* $[(3\text{-Ph-}o\text{-}C_2B_{10}H_9Hg)_4I]^-$, *having a symmetrical pyramidal structure, was synthesized in this* way.[25]

The free macrocyclic host **10** *was prepared by the reaction of its diiodide* 13 *with silver* acetate.[24,25] *In a similar fashion. a series of substituted derivatives of 10 was obtained from the corresponding dihalide complexes and silver acetate. The structure of* **10** *in a form of the* $\mathbf{10}\cdot(THF)_4\cdot(H_2O)_2$ adduct *was established by an x-ray diffraction study. A treatment of* **10** *with I regenerates the initial* 13.

Macrocycle **10** *reacts with two equivalents of* KNO_3 *in acetone in the presence of 18-crown-6 to give the bis-nitrate complex* $[(o\text{-}C_2B_{10}H_{10}Hg)_4(NO_3)_2(H_2O)]^{2-}$ *(14) containing one coordinated water* molecule.[26] *Both nitrate ions in 14 behave as monodentate ligands but differ strongly from each other in the mode of coordination with the host.* One *of the* NO_3^- *ions in* 14 *is bonded through the oxygen atom to all four Hg centers of 10, while the second nitrate is bonded to only two Hg atoms. The remaining coordination site between two other* Hg *centers is occupied by a molecule* of *water. Interestingly, when the reaction of* **10** *with potassium nitrate is conducted at a* NO_3^-:**10** *molar ratio of 3:1 the bis-nitrate complex* $[(o\text{-}C_2B_{10}H_{10}Hg)_4(NO_3)_2]^{2-}$ *(15) containing no water is formed, and this complex has a different* structure.[26] *A remarkable feature of* 15 *is that each of the nitrate ions here is coordinated to* **10** *in an unprecedented tridentate, face-on fashion, and, in addition, all four* Hg *atoms of the* macrocycle *are involved in the bonding to the anionic guests.*

The interaction of 10 and its octaethyl derivative (9,12-Et_2-*o*-$C_2B_{10}H_8Hg)_4$ *(16) with closo-*$[B_{10}H_{10}]^{2-}$ *anions in acetone solution affords 1:1* adducts even *in the presence of an excess of the anionic guest, which is indicated by NMR spectra. However. the crystal product isolated from the reaction of* **16** *with closo-*$[B_{10}H_{10}]^{2-}$ *contained two polyhedral dianions per one macrocycle molecule. This unusual supramolecular aggregate has a bipyramidal structure wherein each of the* $[B_{10}H_{10}]^{2-}$ *species is bonded to all* Hg *atoms of the cycle through B–H–Hg* bridges.[24,25] *In the case of the bulkier closo-*$[B_{12}H_{12}]^{2-}$ *ion, no complexation with 10 and* **16** *occurs. The* bi*pyramidal complexes of 16 with neutral closo-*9,12-I_2-*o*-$C_2B_{10}H_{10}$ *and closo-*9-I-12-Et-*o*-$C_2B_{10}H_{10}$ *species were also* described.[25] *In these* 1:2 *complexes, an iodine atom of each of the boron-containing guests is bound to four Hg centers of the macrocyclic host.*

Mercuracarborand **11** *is structurally similar to the above-mentioned perfluorinated* polymercuramacrocycle *8.* It *was synthesized by the interaction of* 1.2-dilithio-*o*-*carborane with* $Hg(OAc)_2$.[24,25] *The same method was applied for the synthesis of hexamethyl derivative of* **11**, (9,12-Me_2-*o*-$C_2B_{10}H_8Hg)_3$ *(17). The formation of* **11**

rather than acetate complex of 10 or free PO in the above reaction can be explained by the greater strength of a mercuracarbon ring in **11** than in 10, as well as by the inability of noncoordinating acetate ion (in contrast to halide ions) to act as a template and thereby to direct the process of the cyclization toward PO.

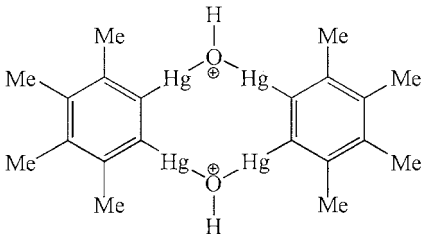
Both mercuracarborands **11** and **17** are able to bind halide anions and acetonitrile molecules. In the case of **17**, the resulting complexes with halide anions (Cl^-, Br^-, I^-) contain two molecules of the macrocycle per one anionic guest and have unique structures of double-decker sandwiches.[27] The halide ion is situated here between two parallel rnercuracarbon rings and is syinmetrically bonded to six Hg centers. Thus. the coordination number of the halogen atom in these sandwiches as in the above-discussed polydecker bent sandwich complexes of 8 with bromide and iodide anions is equal to six. Structures of the halide adducts formed by macrocycle **11** are not yet determined.

From the interaction of **11** with acetonitrile. two cocrystallized complexes, $[(o\text{-}C_2B_{10}H_{10}Hg)_3(MeCN)_3]$ and $[(o\text{-}C_2B_{10}H_{10}Hg)_3(MeCN)_5]$, containing three and five nitrile molecules. were isolated.[24,25] In each of these complexes, two acetonitrile ligands are coordinated through the nitrogen atoms with all Hg atoms of the cycle. In contrast to **11**. macrocycle 17 gives with acetonitrile the sole complex $[(o\text{-}C_2B_{10}H_8Me_2Hg)_3\ (MeCN)_3]$, wherein only one MeCN ligand is simultaneously bonded to all Hg centers of the mercuracarbon ring.

The reaction of **17** with acetone/water (50:1) mixture yields the complex containing one water and three acetone species per one inacrocyclic host.[28] The water molecule in this complex is coordinated by its oxygen atom to three mercury atoms. while the carbonyl oxygen atom of each of the acetone ligands is bound only to a single Hg center. Interestingly, all four guest species in this adduct are arranged on one side of the metallacycle plane. An even more unusual host–guest complex $\{[(o\text{-}C_2B_{10}H_8Me_2Hg)_3(H_2O)]_2(C_6H_6)\}$ was obtained from the interaction of 17 with benzene and water in dichloromethane.[29] In this complex, every H_2O molecule is η^3–coordinated at the center of 17. and the benzene ligand is disposed between two $[(o\text{-}C_2B_{10}H_8Me_2Hg)_3(H_2O)]$ fragments, forming n-hydrogen bonds with both hydrogen atoms of each water molecule. The driving force for the formation of such multiple n-hydrogen bonds with benzene seems to be an increase in the acidity of the hydrogen atoms of water due to its η^3-coordination with the Lewis acidic centers of **17**.

Other Polymercuramacrocycles

In 1987. Wuest et al. published data on the synthesis of a 2:1 complex of THF with the 22-membered macrocycle $[o\text{-}C_6H_4HgOC(O)(CF_2)_3C(O)OHg]_2$ (18) containing four mercury atoms in the ring.[29,30] In this adduct, each of the THF ligands is coordinated with two Hg centers of the corresponding o-phenylenedimercury unit. Subsequently, a complex of the octamethyl derivative of **18**. $[o\text{-}C_6Me_4HgOC(O)(CF_2)_3C(O)OHg]_2$, with four 1,2-dimethoxyethane (DME) ligands was prepared and structurally characterized.[30,31] In this complex, one oxygen atom of each molecule of DME is bound with two Hg atoms of a o-phenylenedimercury moiety, while the other oxygen atom is bonded to a single mercury center. Evidently, the sizes of both macrocycles are too large, and the distance between o-phenylenedimercury fragments is too long for cooperative binding of a Lewis base by all Lewis acidic sites of these macrocyclic compounds. Wuest et al. also described a 2:1 complex of diethylformamide with dicationic macrocycle $[(o\text{-}C_6Me_4HgO(H)Hg)_2]^{2+}$ (**19**) containing four Hg atoms in a planar 10-membered ring.[30,32] The complex has a bipyramidal structure. The amide molecules in **19** are located above and below the metallacycle plane, and each is symmetrically coordinated through the oxygen atom with all four metal centers of the host. A high Lewis acidity of this macrocycle is due to its dicationic character.



19

APPLICATIONS OF ANTICROWNS IN CATALYSIS AND AS IONOPHORES

There are at least two types of reactions wherein anticrowns could be successfully used as catalysts. The first type is reactions catalyzed or promoted by conventional monodentate Lewis acids. An application of anticrowns in such reactions could result in an additional increase in the reaction rate due to cooperative effects of several Lewis acidic centers. The ability of anticrowns to form lipophilic anionic species as a result of the complexation with anions suggests that these compounds will be capable of effectively transferring various organic and inorganic cations from an aqueous phase to an organic phase. Therefore, another field of synthetic o ganic chemistry in which anticrowns could be useful is phase-transfer catalysis of electrophilic reactions.

The first example of the successful application of anticrowns in phase-transfer catalysis was reported in 1989, when it was shown that nonfluorinated polymercuramacrocycle 3 is able to catalyze the azo-coupling reaction between benzenediazonium halides $PhN_2^+X^-$ (X=Cl, Br) and β-naphthol in the two-phase H_2O–CH_2Br_2 system.[''] Diphenylmercury proved to be totally inactive in this reaction.

Subsequently. it turned out that perfluorinated polymercuramacrocycle 8 displays high efficiency in the phase-transfer nitration of acenaphthene with 21% nitric acid in the presence of sodium nitrite as an initiator and NaCl as a promoter.[33] The process proceeds at room temperature and gives a quantitative yield of 5-nitro- and 3-nitroacenaphthenes (in a 90–93:10–7 ratio) after 40 min ($[acenaphthene]_o$=0.5 M. a 100:15 PhH–$PhNO_2$ mixture as an organic phase). In the absence of 8. the yield of the nitro compounds does not exceed 1%. even in 3 h. Noteworthy is that macrocycle 8 is stable under the nitration conditions for at least ! h and can be recovered from the reaction mixture in a 95% yield. Even greater activity in the nitration of acenaphthene with 21% HNO_3 is exhibited by macrocycle 9. in the presence of which a practically full conversion of the starting aromatic substrate into its nitro products is reached after 10 min.[34] According to the kinetic data. the introduction of 9 in the system increases the initial nitration rate by more than three orders of magnitude. Mercury dichloride and *bis*(perfluorophenyl)-mercury show no cataiytic activity.

Macrocycles 8 and **9** also catalyze the phase-transfer nitration of pyrene, acenaphthene and 1,3-dimethylnaphthalene with a mixture of sodium nitrite and 25.6% H_2SO_4 (i.e., with nitrous acid) in the presence of sodium chloride.[35] The reaction proceeds according to the following stoichiometric equation:

$$ArH + 3\ HNO_2 \rightarrow ArNO_2 + 2\ NO + 2\ H_2O$$

The highest nitration rates are observed for pyrene. which in the presence of 8 is quantitatively transformed into 1-nitropyrene within 9 min in a dinitrogen atmosphere ($[ArH]_o$=0.092 M. a $NaNO_2$:ArH molar ratio is 4:1). When the catalyst is absent. no nitration occurs for at least 4 h. The ability of 8 and **9** to transfer protons from an aqueous phase to benzene was also reported.[33,34] This result opens prospects for using macrocycles of such a type in the phase-transfer catalysis of acid-catalyzed reactions.

Mercuracarborand **17** and octamethyl derivative of 10. ($9.12\text{-}Me_2\text{-}o\text{-}C_2B_{10}H_8Hg)_4$ (20) were applied as catalysts for the Diels–Alder reactiori of a thionoester *trans*-MeCH=CHC(S)OMe with cyclopentadiene.[36] It was found that on carrying out the reaction in CH_2C1_2 at 0°C in the presence of 20 (diene:20=7.5:1, $[thioester]_o$=1 M) racemic mixtures of *endo* and *exo* adducts (in a 60 40 ratio) are formed with an 89% total ^{1}H-NMR yield (75% isolated yield) after 2 5 days When 17 is used as a catalyst almost exclusively, the *endo* isomer in a 94% 'H-NMR yield (83% recovered yield) is produced after 7.5 days under similar conditions. The replacement of *I f* or **20** by monodentate *bis*(*closo*-9,12-dimethyl-l,2-carboran-l-yl)mercury (21) leads to a further decrease in the rate of the process (65% isolated yield of the *endo* isomer after 11 days). in the absence of a catalyst or when HgI_2 or $Hg(OAc)_2$ were employed instead of **17** or 20, no reaction was observed. For an explanation of the greater activity level of macrocycle 28 as compared to **17** and **21** in this reaction. it was assumed that among the carboranylmercury compounds tested. only **20** is capable of cooperatively binding the C=S group of the thionoester by all Lewis acidic centers. Methyl crotonate does not form Diels–Alder adducts with cyclopentadiene in the presence of 17. 20. or **21**. which is due to its inability to coordinate with the mercury atoms, as indicated by ^{199}Hg-NMR spectra.

Anticrowns are also promising reagents for the development of a new type of anion-selective electrodes. The first success in this important area was achieved by Hawthorne et al.,[37] who described highly sensitive and selective chloride liquid/polymeric membrane electrodes based on mercuracarborand **11** as an ionophore and tridodecylmethylammonium chloride as a cationic additive. Optimized electrodes show a near-Nernstian behavior toward chloride anions over a wide concentration range and are characterized by a fast response time. short recovery time. long lifetime. insensitivity to pH changes over the pH range of 2.5–7.0 as well as by micromolar detection limits. Subsequently, highly selective optical sensors for chloride ions based on the same mercuracarborand **11** as an ionophore were developed.[38] In their selectivity coefficients toward chloride. both types of sensors meet the requirements for clinical applications.

CONCLUSION

Investigations of latter years led to the discovery of a novel class of highly efficient anion receptors–anticrowns that can be considered as charge-reversed analogues of crown ethers. The host–guest chemistry of anticrowns toward various anionic species was explored: the first promising results were also obtained on the use of anticrowns as catalysts and ionophores. The efficacy of the anion binding by anticrowns depends strongly on the Lewis acidity of metal centers incorporated in their macrocyclic chain. the number of these electron-deficient centers. and size of the macrocycle. The most effective anticrowns were found among perfluorinated polymercu-

ramacrocycles and mercuracarborands containing three. four. and five Lewis acidic Hg atoms in 9-. 10-, and 12-membered mercuracarbon rings. Various neutral Lewis bases such as nitriles. carbonyl compounds, aromatic hydrocarbons. and some others can also be bound by anticrowns. A unique feature of anticrowns is their capacity to bind Lewis basic species simultaneously by all Lewis acidic centers of the macrocycle. Such cooperative binding sharply increases the strength of the host–guest interaction and leads to the formation of complexes of unprecedented structures.

One of the serious problems of anticrown chemistry is a poor assortment of synthetic routes to these remarkable reagents. As a result, the range of the presently known anticrowns is narrow. being limited only by a number of polymercury-, polytin-, and polysilicon-containing macrocycles. One may expect that a successful solution of this important synthetic problem will lead to the wide application of anticrowns in various branches of chemistry.

Artificial Enzymes

Jun-ichi Kikuchi
Nara Institute of Science and Technology, Nara, Japan

Hiroki Kondo
Kyushu Institute of Technology, Fukuoka, Japan

INTRODUCTION

Study of artificial enzymes began as early as in the mid-twentieth century in pioneering work on enzyme model reactions.[1–3] On the basis of a vast amount of findings on structures and catalytic mechanisms of naturally occurring enzymes from the physical, chemical, and bioiogical viewpoints, we can now discuss the properties and reactions of enzymes in great detail at the molecular level. In general, enzymes are ingeniously designed biocatalysts. exhibiting marked rate enhancement. high substrate specificity. and distinct reaction selectivity under mild reaction conditions. Such characteristic features of enzymes are generated essentially through the formation of specific enzyme–substrate complexes as key intermediates. On these grounds. various artificial enzymes capable of performing substrate-binding behavior were developed up to the present time. In addition, while well-known hydrolases such as α-chymotrypsin, lysozyme, and ribonuclease do not require cofactors, many enzymes exhibit catalytic activity in collaboration with coenzymes and metal ions. For simulation of the latter class of enzymatic reactions, molecular design of artificial holoenzymes comprising an apoenzyme model and a cofactor is important.[5–8] Artificial enzymes can be classified mainly into the following three categories: macrocyclic compounds, molecular assemblies. and macromolecules.

MACROCYCLIC COMPOUNDS AS ARTIFICIAL ENZYMES

In general. the active site of an enzyme is regarded as a hydrophobic cavity or cleft created by folding of the polypeptide chain. Such a substrate-binding site is provided by macrocyclic compounds such as cyclodextrins[9] ((Fig. 1). crown ethers,[10–12] cyclophanes,[13–15] and calixarenes.[16–18] each having an inclusion cavity as a basic skeleton of potent artificial enzymes.

Cyclodextrins (1) are cyclic glucose oligomers of cylindrical shape having primary hydroxyl groups at the more restricted rim of the cylinder. The three most common cyclodextrins are α-, β-, y-species, which are composed of six. seven, and eight giucopyranose units. respectively. In early work in the 1950s and 1960s, it was shown that the oxyanion of cyclodextrin could react with pyrophosphates and carboxylate esters bound in the cyclodextrin cavity in aqueous media. and that acyl-group transfer from the esters could be accelerated with moderate substrate selectivity. Since then, many kinds of modified cyclodextrins were developed by introducing a catalytic group selectively into the primary or the secondary hydroxyl moieties. By employing the functional groups similar to those in the side chain of amino acids. such as imidazolyl and thiol groups. the resulting cyclodextrin derivatives were expected to serve as mimics of hydrolases. In fact. cyclodextrins bearing a metal-binding site worked as hydrolytic metalloenzyme models. Various functionalized cyciodextrins bearing a cofactor, such as vitamin B_1, B_2, B_6, B_{12}, nicotinamide. or porphyrin. were prepared as holoenzyme models. The introduction of multiple functional groups into cyclodextrins is essential to design more sophisticated artificial enzymes. For example. a β-cyclodextrin bearing two imidazolyl groups *(2)* acts as an excellent artificial ribonuclease. showing turnover behavior possibly through bifunctional catalytic assistance of the imidazolyl groups. A compound **(3)** carrying a pyridoxamine and an ethylenediamine unit attached to β-cyclodextrin on the neighboring primary methylene groups behaved as a potent artificial aminotransferase. Aromatic L-α-amino acids such as phenylalanine, tryptophan. and phenylglycine were generated with high (90–96% ee) enantiomeric excess by the catalysis of **3.** In addition, the prototropy rate observed with 3 was drastically enhanced relative to simple pyridoxamine. However. the true catalytic cycle, exhibiting amino group transfer from an α-amino acid to an α-keto acid. was not successful with this modified cyclodextrin.

While cyclodextrins are used as enzyme mimics in aqueous media, crown ethers can act as a key component of artificial enzymes in organic solutions (Fig. 2). Crown ether was discovered by Pedersen in 1967.[10] which

eventually won him, together with Cram and Lehn. the Nobel prize in 1987. This discovery triggered the research on host–guest chemistry and artificial enzymes at large, including practical applications. For example. binding of a pyridinium substrate to a crown ether bearing dihydronicotinarnide moieties (4) led to enhancement of the hydrogen-transfer rate from the dihydropyridine moiety to the pyridinium within the intermediate complex in acetonitrile. In addition, the potentiality in enantioselective reductions was examined with a series of chirally bridged macrocyclic 1,4-dihydropyridines of crown ether type. In the reduction of ethyl benzoylformate by 5 having L-valine residues in the macrocyclic skeleton. (*S*)-mandelate was obtained with an enantiomeric excess of 90% in

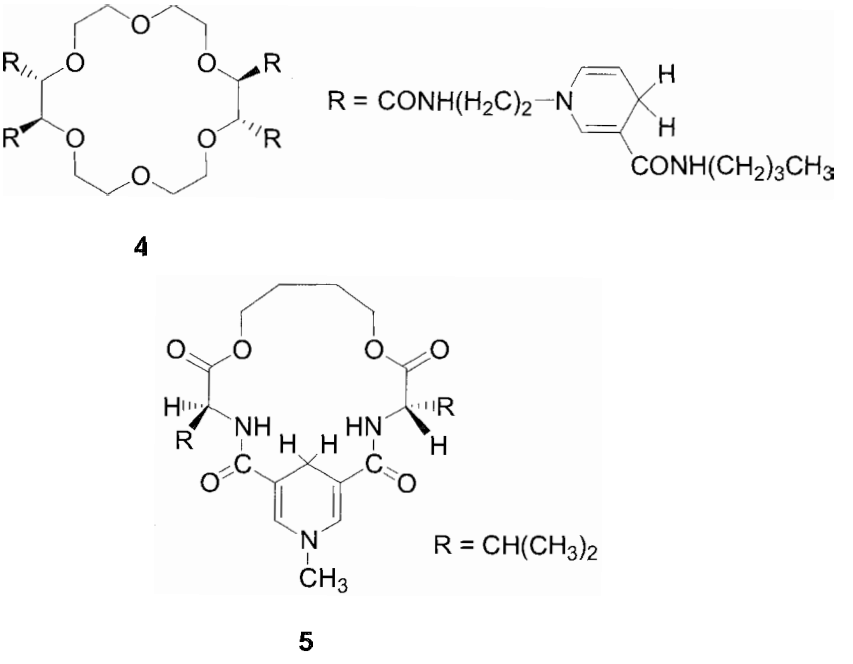

Fig. 2 Examples of crown ether derivatives (4 and 5) as artificial enzymes

acetonitrile-chloroform at room temperature in the presence of Mg(II) ions.

Cyclophanes with a sizable internal cavity also proved to be useful as supramolecular elements of artificial enzymes. While a relatively limited range of st uctural modifications is possible with cyclodextrins. a wide synthetic variation of cyclophanes can be achieved so that an appropriate recognition site with regard to size. shape, and microenvironment is provided for a target substrate molecule. In an early study in the 1970s. [20]paracyclophanes and [10.10]paracyclophanes were employed to demonstrate that cyclophanes are effective as macrocyclic enzyme models. Since then; various cyclophane derivatives were developed as artificial enzymes. While binding constants of simple cyclodextrins with typical substrates in aqueous media are ca. $10^4\ M^{-1}$ or less in general, the substrate-binding ability can be enhanced by various types of molecular design of the cyclophane skeleton, especially by creating three-dimensionally extended hydrophobic cavities. Enzyme mimetic reactions catalyzed by the artificial enzymes of cyclodextrin type would be duplicated and improvable by employing functionalized cyclophanes. For example, the octopus cyclophane (6) bearing eight hydrocarbon chains on a macrocyclic tetraazacyclophane ring provides a large and flexible hydrophobic cavity in which to incorporate as large as a hydrophobic vitamin B_{12} derivative (7) through the induced-fit mechanism (Fig. 3). The resulting host–guest complex acted as an efficient vitamin B_{12}-dependent artificial holoenzyme. showing turnover behavior for carbon-skeleton rearrangement reactions specifically catalyzed by methylmalonyl-CoA mutase and glutamate mutase. In addition, this artificial enzyme also catalyzed unique ring-expansion reactions for which naturally occurring vitamin B_{12}-dependent enzymes are not known.

Calixarenes developed by Gutsche[16] belong to a family of cyclophanes by definition. and much attention has focused on their catalytic functions as artificial enzymes based on their versatile molecular recognition

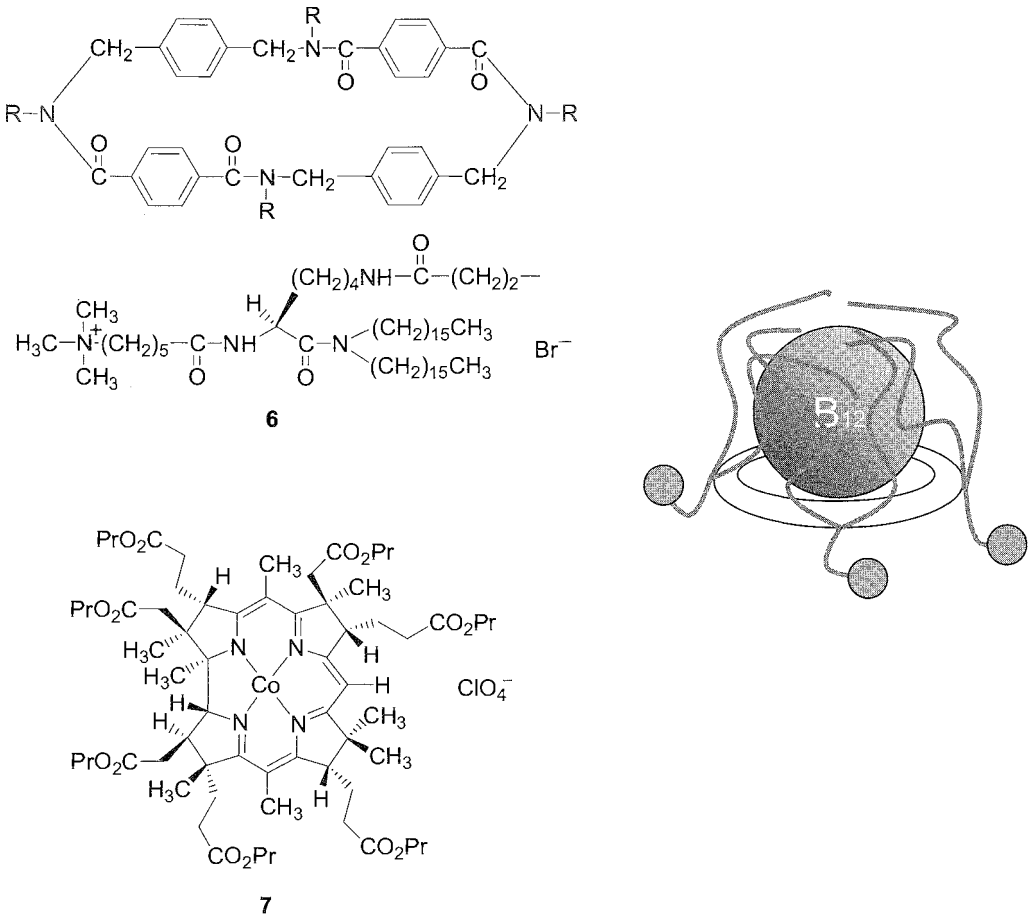

Fig. 3 An example of artificial holoenzyme formed with the octopus cyclophane (6) and the hydrophobic vitamin B_{12} derivative (7). (*View this art in color at www.dekker.com.*)

abilities. Other macrocyclic compounds such as cryptands, spherands. and cucurbiturils seem to be feasible as equally promising enzyme mimics.

MOLECULAR ASSEMBLIES AS ARTIFICIAL ENZYMES

There is another type of enzyme mimics that provide a substrate-binding site as a result of self-aggregation of functional elements through noncovalent intermolecular interactions in solution: reversed micelles in organic solutions. and micelles and lipid bilayer membranes in aqueous media.[4,18–21]

Reversed micelles formed with various surfactants in apolar solvents in the presence of small amounts of water were extensively studied on their characteristic features of cores in enzyme-mimetic reactions. In the spatially restricted microenvironment of reversed micelles, a unique catalytic behavior analogous to enzymatic reaciions was observed.

Aqueous micelles are typical and simple aggregates of surfactants, and numerous applications as enzyme models were accumulated up to 1980 (Fig. 4). In general, molecular structures characteristic of micelle-forming amphiphiles are composed of a polar head moiety, a long hydrophobic chain, and in some cases; an additional functional group for effective catalysis. Cationic amphiphiles having an imidazolyl (8)or a thiol moiety (9) in the polar head are typical examples. While micelles provide hydrophobic reaction sites effective for the acceleration of various enzyme-mimetic reactions, those aggregates are generally soft, and it is difficult to fix the disposition of substrates in space for regio- and siereospecificity of reactions to appear.

Another type of well-known molecular aggregate in an aqueous media is a bilayer membrane. In general. the bilayer membrane is superior to aqueous micelles with respect to aggregate rigidity and spacial orientation of component molecules, so that substrate specificity. catalytic activity. and reaction selectivity are more readily exhibited. In addition. phase states, gel and liquid crystalline, and phase-separation behavior among the component species can be utilized to control catalytic pathways.

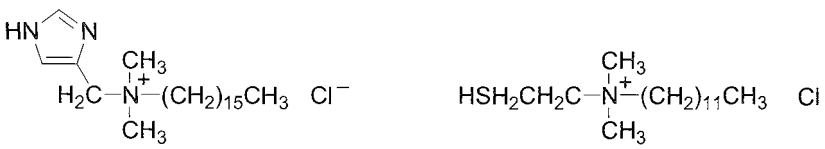
Preparation and characterization of liposomes formed with natural phospholipids were well established. However, in using liposomes for simulation of enzymatic functions, especially in acid–base catalysis. difficulties would be encountered due to their chemicai and morphological instabilities. Thus, bilayer membranes composed of synthetic amphiphiles are more favorable candidates for enzyme mimics. For example, artificial vitamin B_6-dependent enzymes were constructed from catalytic bilayer membranes in combination with a bilayer-forming peptide lipid (**10**), a hydrophobic vitamin B_6 derivative (**11**), and metal ions (Fig. *5)*. The catalyst acts as an artificial aminotransferase. showing marked substrate specificity, high enantioselectivity, and turnover behavior for the transamination of α-amino acid with α-keto acids. In addition. the reaction fields provided by the catalytic bilayer membranes are suitable to establish multienzyme systems through functional alignments of artificial enzymes and natural ones in a sequential manner.

MACROMOLECULES AS ARTIFICIAL ENZYMES

On the basis of structural resemblance to enzymes, various kinds of macromolecules were developed as artificial enzymes. These macromolecules are classified mainly into two categories: modification of biopolymers and totally synthetic functional polymers.

The design of artificial enzymes through site-directed rnutagenesis is well established.[22] By single or muitiple replacement of an amino acid residue placed in the enzyme protein, enzymatic functions such as reactivity, substrate specificity. and reaction selectivity, can be altered. Although the site-directed rnutagenesis gives rise to only a small change in the amino acid sequence of a target protein, such modification can induce a drastic change in the catalytic behavior. Incorporation of unnatural amino acids and nonamino acids into proteins is also possible.

Development of catalytic antibodies or abzymes is another fascinating approach to artificial enzymes.[5] The concept of catalytic antibodies is that if a putative transition state analogue of a reaction for which a selective and efficient catalyst is desired is used to elicit antibodies,



8 **9**

they are likely to catalyze the reaction of a parent compound. Because antibodies are specialized only for binding of ligands called antigens or haptens, semisynthetic strategies for introducing catalytic functionalities into the active site of an antibody is additionally necessary in some cases. Catalytic antibodies were elicited for reactions for which no enzyme exists. such as the Diels–Alder reaction, Claisen rearrangement. and oxy-Cope rearrangement.

Although the site-directed mutagenesis and catalytic antibody technique are useful genetic methods, chemical modification of enzymes remains a valuable tooi for protein engineering. The latter approaches are divided into direct modification of an enzyme protein and modification of a cofactor bound to the enzyme.[23–26] These chemical methods led to modification of existing enzyme activity or introduction of new enzyme functions into proteins and enzymes.

As regard to enzyme mimics formed with totally synthetic polymers, relatively simple water-soluble polymers with catalytic functionalities were employed in the early work before 1980.[4] Although simulation of enzymatic behavior was successful to a certain extent by employing such prototype models, recent interests focused on more intelligent synthetic polymers, such as imprinted polymers[5] and dendrimers.[27]

When a polymer is prepared in the presence of "print molecules" as the transition state or intermediate analogues, which are extracted after polymerization. the remaining polymer may contain catalytic cavities capable of recognizing the print molecules. By analogy to the catalytic antibodies. where a function complementary to that of the hapten can be induced in a specific place, polymers can be imprinted with print molecules containing suitable catalytic functionalities. Because dendrimers are structurally regulated polymers with an inner core like an enzyme active site, their characteristics as enzyme mimics also attract attention.

CONCLUSION

In recent years. the traditional definition of biocatalysts with enzymes that are proteins having catalytic functions in biological systems was expanded to a point where a series of ribonucleic acids, called ribozymes, also acts as a biocatalyst. Much effort was devoted to developing artificial ribozymes as well."'' In such approaches: a combination of strategies to mimic ribonucleases and to simulate complementary molecular recognition of nucleic acids is essential.

As mentioned above, studies on artificial enzymes were extensively developed to date. Although the catalytic performance of artificial enzymes rarely surpasses that of the corresponding naturally occurring enzymes from every point of view, some of them close in on catalytic performance of the natural counterparts. In addition, advantages of artificial enzymes relative to those of natural ones are flexibility in molecular design, structural stability, and possible applications to substrates and reactions for which natural enzymes are not available.

One of the targets in the study of artificial enzymes would be creation of integrated reaction systems on the nanometer scale inspired by the reaction network in cells. from the viewpoint of nanoscience and nanotechnology. For such a purpose, construction of artificial multienzyme systems. collaboration between enzymes and receptors,

and synchronization of individual supramolecules seem to be essential.[7 21,25,29]

Aurophilic Interactions

Antonio Laguna
Universidad de Zaragoza—CSIC, Zaragoza, Spain

Eduardo J. Fernández
José M. López-de-Luzuriaga
Universidad de La Rioja, UA—CSIC, Logroño, Spain

INTRODUCTION

The word "aurophilic." derived from the Latin word ''Aurum'' (gold) and the Greek word ''Philos'' (with an affinity for). was coined in the late 1980s[1–3] to describe the tendency of gold(I) compounds to form dimers. oligomers, chains. or even layers via gold(I)–gold(I) interactions. In these interactions. the distances between the adjacent gold atoms range from *2.7–3.6* A. and are shorter than the sum of their van der Waals radii (3.6 A). These interactions have a strength between 20–50 kJ/mol, close to that found in hydrogen bonds. This result is surprising. as two gold(I) centers with an external d^{10} configuration would normally be expected to repel each other. In addition. gold attractions are already present in metallic gold; where the gold–gold distances are shorter than the corresponding silver–silver distances. This phenomenon, although it can be consider a general feature when comparing the metallic radii of the second- and third-row elements. cannot be considered as the result of a lanthanoid contraction, because the rest of the "anomalies" of gold. such as its high electroaffinity and electronegativity or the presence of highly stable Au_2 molecules in the gas phase. cannot be explained in these terms. Of course. with these properties. it is considered to be the "king of the metals."

THEORETICAL CONSIDERATIONS

The latest contributions of physicists and the theoretical chemists to the explanation of this phenomenon stem from the results of ab initio and density functional theory calculations.. which refute the previous *s-d* hybridization proposed by the extended Hückel theory. They suggest that the metallophilic attraction can be considered a correlation effect strengthened by the relativistic effect. which is important in the case of gold.[4,5]

Postlanthanide elements have a large number of protons in their atomic nuclei *(79* protons for gold). Moreover, the electrons move in a field with a high nuclear charge, and therefore. their speed is similar to that of light. Electrons moving at such a speed cannot be treated in terms of classical physics. rather they have to be treated on the basis of Einstein's Theory of Relativity: $m_r=m_o(1-v^2/c^2)^{-1/2}$. According to this equation. the relativistic mass (m_r) of these electrons is larger than the conventional nonrelativistic mass (m_o), resulting in a contraction of orbital radius. This effect. known as relativistic contraction. is particularly important for the orbitals with radial functions that have local maxima in the neighborhood of the nucleus, pa ticularly in the s-orbitals. Thus, the expected marked effect on the Is electrons of postlanthanide elements also has continuity in the 2s. 3*s*, 4*s*, 5s. and *6s* orbitals. as they are orthogonal to one another. The ratio of the relativistic radius of the valence electrons to their nonrelativistic radius as a function of the atomic number strongly deviates from unity and reaches a local minimum for gold. Therefore, gold occupies a unique position among all the elements.

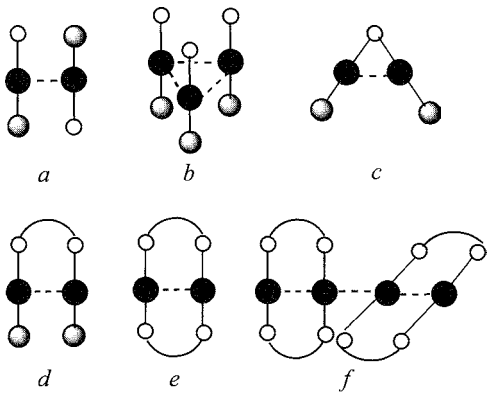
The main consequences for gold are that the energy gap between the 5*d*. 6*s*, and 6*p* orbitals diminishes. the closed-shell configuration $5d^{10}$ is no longer chemically inert. and the interaction between two gold(I) centers can be explained. Furthermore. the formation of linear two-coordinate gold(%)complexes is also favored.

Let us analyze some examples where this interaction is present. These examples establish a great affinity between gold atoms, which are as close as possible to each other and. generally, at distances even shorter than the ones found in metallic gold (2.88 A). We excluded gold clusters with formal metal–metal bonds and oxidation states between 0 and +i from the description. We will refer only to the interactions among atoms with closed-shell configurations.

GOLD(I)–GOLD(I) INTERACTIONS

The term "aurophilic interactions" was first coined in connection with the chemistry of gold(I). Gold(I)

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012925



Scheme 1 Some attractive interactions in gold(I) complexes.

complexes are of general formula X-Au-L, where the ligands X and *L* may be neutral or anionic and have a linear geometry. After the advent of crystal structure analysis in the 1960s, it became apparent that virtually all such complexes are packed or arranged in such a way that the gold(I) atoms are as close as possible to each other. This attractive interaction gathers the gold atoms in pairs, rings, chains. or even layers (Scheme 1).

As can be seen in the scheme, the presence of ligands acting as bridges between the gold centers favors the appearance of such interactions *(c.d, e, f)* and, sometimes, ligands have even been considered responsible for their presence. In the e case, inter- and intramolecular interactions are present in the same molecule. Nevertheless, the existence of these interactions is undoubtedly evident in hundreds of examples of nonbridged complexes (types *a* and b), where the distances between the adjacent gold atoms depend on the electronic nature of the ligands and their steric requirements.[6–10] A particularly sophisticated structural arrangement appears in the complex $[Au(C_5H_5NS)_2]ClO_4$, where five of the six cations in the unit cell are linked to one another by short Au···Au contacts leading to a linear chain. The sixth cation is inonomeric and does not show interaction with other cations.[10] In the *c* case. dinuclear complexes with two gold centers bonded by a monoatomic bridge ligand are limited to elements of the 16 and 17 groups. Therefore, the structure proves the existence of metal–metal interactions in the cationic complex $[Au_2(\mu\text{-}Cl)(PPh_3)_2]ClO_4$[11] or the neutral derivatives $[Au_2(\mu\text{-}X)(PPh_3)_2]$ (X=S,[12] Se[13]). In these examples, the environment surrounding gold is almost linear and, interestingly. the Au-X-Au angle is shorter than expected from the involvement of p orbitals of the heteroatom.

An aryl group can also act as a bridging ligand, bonding the two metal atoms with a carbon center. This is the case of the complex $[Au_2(\mu\text{-}C_6F_3H_2)(PPh_3)_2]ClO_4$ obtained by substituting the chloro atom of the chloro-bridged complex by its reaction with $[Ag(2,4,6\text{-}C_6F_3H_2)]$ In this case, due to the narrow Au-C-Au angle (79 3°), a three-center two-electron bond was suggested [14]

Other amazing cases of a single atom bridging more than two gold(I) metal centers are the complexes with O,[15] S [16] Se [17] N [18,19] P [20] or C,[21 22] which include striking cases of hypervalence at these atoms, a situation unknown to typical p-block chemistry or postulated as an unstable intermediate. In these examples, the aurophilic interactions seem to be the driving force that stabilizes these complexes and determines their geometry. For example. the complex $[S(AuPPh_3)_4]^{2+}$ adopts a pyramidal structure instead of the expected tetrahedral one (Fig. 1).

On the other hand, some complexes that attracted considerable attention for the study of aurophilicity are the homo- or heterobridged diauracycles. In these complexes, the two metallic centers are bonded by two bidentate ligands such as diphosphines, *bis*(ylide) or dithiocarbamates, and intra- or intermolecular interactions appear. In most of the examples described, it is possible to observe a deviation from linearity around the gold centers caused by gold–gold interactions. Besides, the nature of the bridging ligands also has an impact on their strength. Thus. while $[Au_2(\mu\text{-}S_2CNEt_2)_2]$ has gold–gold distances of 2.782 (intramolecular) and 3.004 Å (intermolecular), the heterobridged complex $[Au_2(\mu\text{-}(CH_2)_2PPh_2)(\mu\text{-}S_2CNEt_2)]$ shows distances of 2.865 (intramolecular) and 2.9839 Å (intermolecular), and the complex $[Au_2(\mu\text{-}(CH_2)_2PPh_2)_2]$ only has an intramolecular distance of 2.977 Å.[23]

A hexanuclear complex with three pairs of gold atoms displaying short contacts can be obtained by using *bis*-(diphenylphosphino)methanediide as ligand. which can act as an eight-electron donor bonded to four gold atoms. The reaction of $[Au_2(\mu\text{-}(PPh_2)_2CH)_2]$ with $[Au(PPh_3)(tht)]ClO_4$ leads to a tetranuclear derivative that can be further deprotonated by reaction with [Au(acac)(PPh3)] to give the hexanuclear complex[24] (Scheme 2).

On the other hand, and as we already mentioned. gold(I) usually has a linear two-coordinate geometry. Nevertheless, three- and four-coordination. although much less abundant, is also well established.'''' Unlike linear coordination, where the gold(I) molecules are often

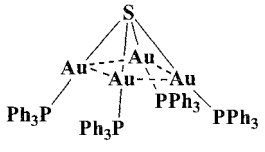


Fig. 1 Structural arrangement of the cation $[S(AuPPh_3)_4]^{2+}$.

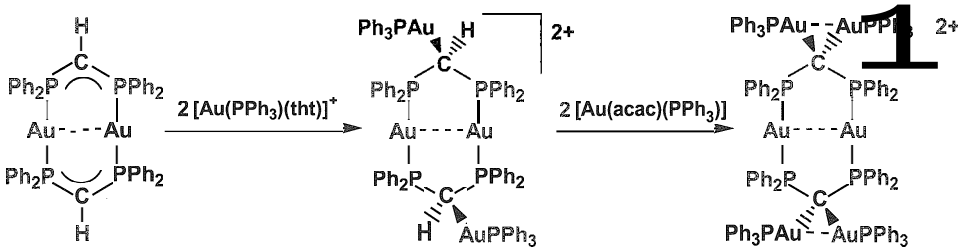

Scheme 2 Reactions from $[Au_2(\mu\text{-}(PPh_2)_2CH)_2]$

associated to form dimers, trimers. chains. or even layers through gold–gold interactions. in the rest of geometries, the presence of these interactions is almost an anecdote. Thus, there are a few cases reported. and most are examples of gold diauracycles, where solvent molecules or anions, with a coordinating capacity, interact with one or more gold centers. For instance, this is the case of the complex $[Au_2Cl_2(dppm)_2]$[26] with a gold–gold distance of 3.028 Å, visibly longer than that of the homologous $[Au_2(dppm)_2](BF_4)_2$ complex[27] with a distance of 2.931 Å, and with anions that do not interact with the gold atoms. In addition, the ligand coordination causes a small deviation from the original linearity in the L-Au-L angles.

An outstanding example of mixed coordination numbers and geometries of gold(I) is the complex $[Au_2(PPh_3)_3(SCH_2CH(OH)CH_2OH)](BF_4)$, where the coordination spheres of the two gold atoms are completely different. One of the atoms has a conventional linear two-coordination. whereas the other has a slightly distorted trigonal planar coordination with one sulfur and two phosphorus atoms. The gold centers exhibit a short gold–gold contact of 3.0162 Å, which is not forced by the presence of bidentate bridging ligands[28] ((Fig. 2).

Che's laboratory studied the strength of the three-coordinate gold–gold interaction by Raman spectroscopy in the coinplex $[Au_2(dmpm)_3](ClO_4)_2$ [*dmpm*=*bis*(dimemethylphosphine)methane], with atoms that exhibit an interaction of 3.050 Å. They obtained a wave number of 79 cm^{-1} for the gold–gold stretching mode. Significantly, the wave number increased to 165 cm^{-1}. and the gold–gold distances decreased when the sample was irradiated with 256 nm ultraviolet radiation, suggesting that the gold–gold interaction was strengthened in the excited state.[29] This result opens a new research field.

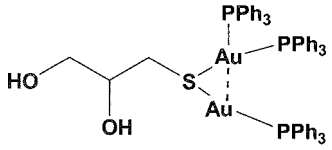

Fig. 2 Structural arrangement of the cation $[Au_2(PPh_3)_3(SCH_2CH(OH)CH_2OH)]^+$.

GOLD(I)–GOLD(III) INTERACTIONS

In addition to gold(I), gold(III) with a d^8 configuration and a square-planar geometry can be considered a closed-shell cation. Thus. interactions with other closed-shell centers such as gold(I) can be covered by the general term aurophilicity. Nevertheless, in spite of the huge number of examples of gold(I)–gold(I) contacts, interactions involving gold(III) centers are less represented, and many times. the oxidation states of the gold atoms are not completely clear. This is the case of the complexes obtained in the reaction of double-bridge ylide derivatives with gold(I) or gold(III) precursor complexes, such as $[Au_2(\mu\text{-}(CH_2)_2PPh_2)_2Au(C_6F_5)_3]$ obtained by reaction of the dimer $[Au_2(\mu\text{-}(CH_2)_2PPh_2)_2]$ with the gold(III) complex $[Au(C_6F_5)_3(OEt_2)]$. Nevertheless. the shorter distance between the two gold(I) centers of the dimer compared with the starting product, as well as the gold(I)–gold(III) distance of just 2.572 Å, are indicative of a more convincing Au(I)-Au(II)-Au(II) sequence than the expected Au(I)-Au(I)-Au(III) one.[30]

On the other hand, the reaction between the gold(II) dimer $[Au_2(\mu\text{-}(CH_2)_2PPh_2)_2(C_6F_5)(tht)]ClO_4$ and $NBu_4[Au(C_6F_5)_2]$ leads. after the displacement of the weakly coordinated *tht*. to a pentanuclear complex, where a formal gold(I) unit acts as a bridge between two adjacent gold(II) dimers. But. in this case, the theoretical calculations provide a sequence of Au(III)-Au(I)-Au(I)-Au(I)-Au(III) oxidation states based on the charges identified in the gold atoms.[31] Interactions in mixed-valence double-bridged ylide systems are often proposed due to the geometry of the ligands.[32–35]

Apart from these cases where the double-bridged ylide systems force the gold atoms to be in close proximity, there are some other examples where the gold(I)–gold(III)

interaction *seems not to be influenced by the* ligand architecture *This is. for instance, the case of the poly nuclear sulfur-centered* complex $[\{S(Au_2^{I}dppf)\}\{Au^{III}(C_6F_5)_3\}]OTf$ [*dppf*=1,1-*bis*(diphenylphosphino)ferrocene, *OTf*=trifluoromethylsulfonate],[36] *the* derivative $[Au^{I}Au^{III}Me_2(C_4F_6(PMe_3)_2)]$[37] *or the novel* $[Au^{III}(C_6F_5)_2\{PPh_2C_6H_4N(Au^{I}PPh_3)_2\}]ClO_4$,[38] which have Au(I)–Au(III) distances close to *3 3* Å

Finally, *the case of* interacting gold(III) centers with *a* d^8 configuration is *unknown* Even *with the most* appropriate structural *arrangement. i e.* a single *atom* bridging *two* gold(III) *metal centers.* this *type of* interaction *does* not *appeal Examples of this are.* among others. $[S(AuPPh_3)_2(Au(C_6F_5)_3)_2]$[39] *or* $[Se(AuPPh_3)_2(Au(C_6F_5)_3)_2]$ [40] *In all these cases. the* Au(III)–Au(III) *distances are* longer *than the sum of* their van *der* Waals radii

FUTURE PERSPECTIVES

The great development *of structural* analyses *in the last few years allowed us to realize that the interactions among metal centers at distances shorter than the sum of their* van *der* Waals *radii are not exclusive to* homometallic *gold systems. In fact, they also appear in molecules containing gold* and *other closed-shell metal centers. Therefore, words such as* aurophilicity *or* aurophilic *interactions are being replaced with* more *general* terms such *as* metallophilicity *or metallophilic interactions. Apart from the unquestionable interest of these* molecules from *a theoretical point of view, recent studies on their synthesis are being performed due to their fascinating and* unique physicochemical *properties, properties such as luminescence or conductivity. for instance. which might be exploited by industry in the near* future.[41]

There are many examples *of* heterometallic molecules *with gold-closed-shell interactions, including ions such as* Rh(I), Ir(I), Pd(II), *or* Pt(II) *with a* d^8-square planar *configuration, or* Cu(I), Ag(I), *or* Hg(II) *and* Tl(I) *and* Pb(II) with d^{10} *and* s^2 *configurations,* respectively.[4,5] *A recent ab* initio *study on bridged* dinuclear *Au–Ag and* Au–Cu *molecules concludes that the presence of* just *one gold atom is enough to induce metallophilic attractions in their group congeners and that this effect can be modulated depending on the gold* ligand[42] *involved.* In this *case,* the *relativistic effects of gold force a* numismophilicity. *On the other hand. theoretical studies on an* Au–Pd *interaction show* that *the dispersion* is *the key* contribution *to ihe* Pd(II)–Au(I) *attraction, whereas the* charge-transfer *type* contributions *are about half as important.* considering *that the* two *contributions Pd* → *Au and* Au → Pd *are energetically comparable.'''*

In short, it is *clear that gold makes an essential contribution to metallophilic interactions.* Thus, *the design of synthetic strategies to prepare systems* with *these bonds of unique versatility and flexibility must* include *gold as an essential building block.*

Biological Ligands

Andrew Hinton
Paul Taylor
Malcolm D. Walkinshaw
University of Edinburgh, Edinburgh, United Kingdom

INTRODUCTION

The binding of a small-molecule ligand to a protein enzyme or receptor is governed by a host of weak nonbonding electrostatic effects like hydrogen bonds and van der Waals interactions. Entropic changes caused by displacement of water and by changes in ligand flexibility are also important in determining binding strength. An understanding of these processes is crucial for the design of novel enzyme inhibitors and other protein ligands. This is an area of great importance in the pharmaceutical industry, where more protein targets are becoming available. We now have high-resolution structures of over 1700 protein–ligand complexes as determined by protein x-ray crystallography.[1] This information coupled with the measured binding data of many protein–ligand systems is now providing insight into what factors are important for ligand binding. We provide a broad overview of the field, with examples of structures from a variety of ligand classes (Table 1). Current computational approaches for discovering new ligands and estimating the strength of ligand binding are also described.

ENERGETICS OF PROTEIN–LIGAND INTERACTIONS

The simple picture of protein–ligand binding is given by a bimolecular equilibrium (Eq. 1) in which a ligand in solution binds to the receptor protein to form a complex. In the context of this article, we define a ligand to be a mainly organic molecule with a molecular weight of up to 1500 Dalton, which may be reasonably expected to form a complex with a protein. We restrict our discussion to noncovalent complexes, though as in the case of enzymatic reactions or the binding of suicide inhibitors, covalent bonds can frequently be formed. The binding constant (or equilibrium constant) relates the concentrations of free and bound components.

$$\mathbf{P \cdot L} \rightleftarrows \mathbf{P} + \mathbf{L} \qquad (1)$$

where $K_d = [P][L]/[P{\cdot}L]$ or (the reverse reaction) $K_b = [P{\cdot}L]/[P][L]$, K_d = dissociation constant. K_b = binding constant, $[P{\cdot}L]$ = concentration of protein–ligand complex, $[P]$ = concentration of unbound protein, and $[L]$ = concentration of unbound ligand.

Drug–protein interactions tend to have dissociation constants (K_d) in the nanomolar to picomolar range. In the field of drug discovery, so-called lead ligands with potentials for being developed into drug candidates bind to their target proteins with K_d values in the micromolar range. The dissociation constants[i''] can be converted (Eq. 2) to binding energies from the following:

$$\begin{aligned} \Delta G^\circ &= -RT \ln Kd \\ &= -5.6 \log_{10} K \end{aligned}$$

x (at room temperature 20°C or 293°K) (2)

where K_d = dissociation constant (Mol), ΔG° = Gibbs free energy change of the reaction (kJ mol^{-1}), R = 8.31 (J/° mol), and T = temperature (°K).

Thus, a change in the binding constant by an order of magnitude only corresponds to a difference in binding energy of about 5.6 kJ/mol. A K_d of 10^{-9} M gives a calculated dissociation energy of +50.4 kJ/mol (which equals a free energy of binding of −50.4 kJ/mol), while a ligand that binds with a micromolar K_d has a dissociation energy of +33.6 kJ/mol (see also Table 5).

This overall binding energy can be regarded as consisting of a number of components including hydrogen bonding, van der Waals interactions, and other thermodynamic terms. Approximate energies for these components (Table 2) were calculated by correlating structural data with measured thermodynamic binding data.[3,4] A number of empirical energy terms were published, and one such example is shown in Eq. 3.[3,4]

$$\begin{aligned} \Delta G_{binding} &= \Delta G_0 + \Delta G_{polar} + \Delta G_{apolar} + \Delta G_{solv} \\ &\quad + \Delta G_{flexi} \end{aligned} \qquad (3)$$

As shown in Table 2. ΔG_0, ΔG_{hb}, ΔG_{ion}, ΔG_{rot}, ΔG_{aro}, and ΔG_{esrep} are enthalpic terms that describe contributions made by H-bond, ionic, rotational, aromatic, and nonspecific interaction energies. The ΔG_{lipo} includes lipophilic

Table *2* The relationship and approximate value of individual energy terms to the change in Gibbs free energy of binding (ΔG)

Energy component	Value (kJ/mol)	Interaction type	Example
ΔG_0	−2 8	ΔG_0	Nonspecific
ΔG_{hb}	−3 2	ΔG_{polar}	=O − − −H− − −O
ΔG_{ionic}	−5 7	ΔG_{polar}	NH_4^+ − − −COO^-
ΔG_{lipo}	−0 09	ΔG_{solv}	C_n− − −H_2O
ΔG_{rot}	+1 0	ΔG_{flexi}	C− − −CH_3 Rotation about single bond
ΔG_{aro}	−26	ΔG_{apolar}	C− − −C
$\Delta G_{lipo\ water}$	−1.3	ΔG_{solv}	C_n− − −H_2O
ΔG_{esrep}	+0 5	ΔG_{polar}	NH_4^+− − −COO

interaction energy as a function of all pair-wise atom−atom interaction energies. The $\Delta G_{lipo\ water}$ describes energy change through desolvation effects. These energy terms contribute to a simple representation of the components that make up $\Delta G_{binding}$, including polar (ΔG_{polar}), apolar (ΔG_{apolar}), solvation (ΔG_{solv}), and flexibility (ΔG_{flexi}) interactions as given in Eq. 3. Approximate energies for these terms were calculated by correlating structmal data with measured thermodynamic binding data.[3,4]

MEASUREMENT OF LIGAND BINDING STRENGTH

A number of spectroscopic and thermodynamic measurements can be used to measure the strength of protein–ligand interactions. including fluorescence spectroscopy, surface plasmon resonance, calorimetry, and enzyme inhibition. The change in property (for example, fluorescence signal,[5] heat of reaction,[6] crystallographic occupancy,[7] and NMR chemical shift[8,9]) is measured as a function of increasing concentration of added ligand until a maximum signal is obtained. For a simple protein–ligand binding experiment (with no substrate or other inhibitory ligand present); the K_d value can be simply determined by titrating a ligand solution into a protein solution of known concentration. The K_d is the slope of

Table *3* Techniques for measuring binding constants

Technique	Description	Example	Ref.
NMR (^{15}N-HSQC)	Observation of change in two-dimensional ^{1}H- or ^{15}N-heteronuclear single quantum correlation (HSQC) backbone chemical shift spectra upon ligand binding; described as $\Delta\delta(^1H,^{15}N) = [L]/([L] + K_d)$	FKBP	[9]
Fluorescence spectrophotometry	Measurement of fluorescence signal quenching of an active-site tryptophan as a function of ligand binding: described as $\Delta F = \Delta F_{max} - K_d(\Delta F/[L])$	FKBP	[5]
X-ray cry-stallography	Crystallographic refinement of ligand occupancy from a range of ligand soaking concentrations	Cyclophilin	[7]
Isothermal calorimetry (ITC)	Isothermal titration calorimetry (ITC) measures the enthalpy change caused by a binding event; the gradient of the generated ITC curve can be used to determine the binding constant K_b	OppA	[10]
Surface plasmon resonance (SPR)	SPR-biosensors measure the change in refractive index units (RU) of a solvent near the surface that occurs during complex formation with an immobilized protein target	HIV1-protease	[6]
Enzyme inhibition	The measurement of the rate (v) of products/reactants formation can be measured by spectrophotometry; the dissociation constant K_d corresponds to the concentration of inhibitor at which the observed constant (k_{obs}) is half its maximum value	Bovine cyclophilin	[9]

the straight-line plot of *[PL]* against $[PL]/[L]$ used to fit Eq. 4.

$$[PL] = P_o - K_d([PL]/[L]) \quad (4)$$

where $[PL]$ = concentration of the ligated protein, $[L]$ = concentration of the ligand. and $[P_o]$ = total protein concentration.

The IC_{50} value is the ligand concentration that produces *50%* reduction (or increase) in the measured effect (i.e., the coilcentration of unbound protein *[Pj* equals the concentration of ligand-bound protein *[PL])*For a simple binary protein–iigand mixture. the dissociation constant K_d is identical to the IC_{50} value.

In Table 3. a description of different techniques employed in the measurement of binding constants is presented, where $\Delta\delta(^1H,^{15}N)$ is the average weighted change in ^{15}N- or ^1H-amide chemical shift in two-dimensional ^1H- or ^{15}N-heteronuclear single quantum correlation (HSQC) spectra, where $[L]$ and K_d are ligand concentration and dissociation constants, respectively. The ΔF and ΔF_{max} is the change in fluorescence measured at 340 nm.

The relationship between IC_{50} and K_d (Eq. *5)* for competitive enzyme inhibition or competitive receptor ligand studies is complicated by the additional presence of substrate (S). Note that in such experiments, K_d the dissociation constant and K_i the inhibition constant can be used synonymously:

$$K_i = IC_{50}{*}K_m/([S] + K_m) \quad (5)$$

where K_i = equilibrium dissociation constant of the inhibitor ligand. IC_{50} = inhibitor concentration that produces 50% change in the measured effect. [S] = substrate concentration used in the assay. and K_m = substrate concentration (in the absence of inhibitor) at which the velocity of the reaction is half-maximal.

The K_i is an equilibrium dissociation constant corresponding to the concentration of the inhibitor ligand [I] that would bind to half of the binding sites at equilibrium (in the absence of other substrates). If [S] is small (usually in the nanomolar range) and the IC_{50} is in the micromolar range. then measured IC_{50} still closely approximates the K_i.

FINDING MEW LIGANDS

Over the last 10 years, the pharmaceutical industry invested in automating high-throughput screening (HTS) methods that enable libraries of ligands consisting of over 250.000 compounds to be screened in biological assays. A typical threshold for a hit is binding to or inhibiting a ligand with a K_i of less than about 10^{-6} M. It was estimated that it takes over 2 million trials to discover one lead compound (roughly defined as a ligand that proceeds to preclinical trials). A complementary approach to high-throughput screening is a structure-based computer-aided approach. A prerequisite is the availability of an accurate three-dimensional structure of the protein target. The protein data bank PDB[1] now contains nearly 20,000 entries mainly determined by protein x-ray crystallography. Of these, over 650 are different domain folds,[111] and 1700 are protein–ligand complexes.[1]

The structure of a protein's ligand-binding pocket provides a template into which novel (mainly inhibitory) ligands can be designed and visualized with the aid of computer graphics. The traditional method is to make use of a known inhibitor complex and make small changes to the ligand to modify the binding properties. This is exemplified in the development of influenza neuraminidase antivirals.[12] Prior to the elucidation of the crystal structure of influenza neuraminidase, N-acetylneuraminic (Neu5Ac) inhibitors had K_i values of above 1 μM. Knowledge of the enzyme structure allowed the addition of the bulky basic substituents at the 4-position to produce the 4-guanidino-Neu5Ac2en. Known as Zanamivir, this compound has a K_i of 0.1 nM. An ester prodrug of a cyclohexene–carboxylic derivative of Zanamivir called GS4071 was resolved to 1.8 Å (2QWK) complexed with wild-type neuraminidase. GS4071 has subnanomolar potency against Types A and 5 influenza neuraminidase.[12] An overlay of the crystal forms of wild-type neuraminidase complexed with GS4071 and a carboxyamide analogue (G2800) can be seen in Fig. 1.

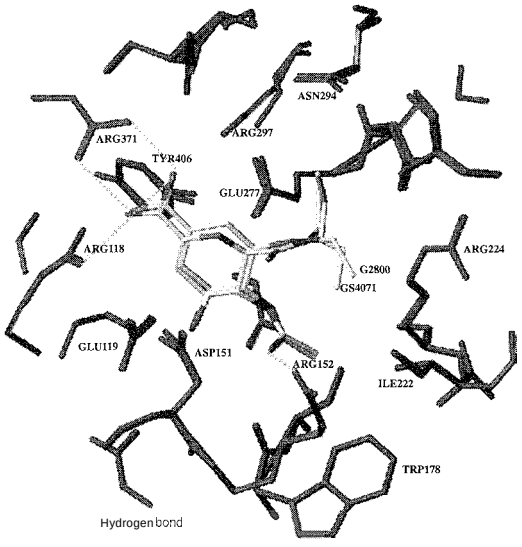

Fig. 1 A superimposition of two neurainidase–inhibitor complexes. (*View this art in color at www.dekker.com.*)

Shown in Fig. 1 is a superimposition of the inhibitor 634071 and a carboxyamide analogue crystallized with wild-type influenza neuraminidase. *The clinical inhibitor 634071* (2QWK) *and the carboxyamide analogue* G2800 (2QWG) *can be seen to be making a range of electrostatic and hydrophobic* interactions *with the residues of the sialic acid-binding pocket of wild-type influenza* neuraminidase (blue).[12]

COMPUTATIONAL TECHNIQUES IN LIGAND DISCOVERY

De novo Design, Database Mining, and Filtering

A more radical approach is to attempt *the design of completely novel entities in the binding pocket with the required* complementarity *of shape and charge properties. Computer programs such as* LUDI[13] *and* SMoG[14] use *libraries of small* chemical *building blocks to generate such theoretical inhibitors.*

Another related computational approach to ligand discovery is the method of database mining. Here. the HTS *approach* is *essentially carried out* in-silico. *Libraries of* small *molecules are converted to three-dimensional structures using molecular mechanics methods incorporated into programs such as* CONCORD[15] *and* CORINA.[16] *These three-dimensional libraries of small* molecules *can. in theory. contain almost infinite numbers of potential ligands.* In *practice, it is convenient to consider compounds that are already (commercially) available. The Available Chemicals Database* (ACD),[17] *for example. contains some* 260,000 *compounds and is frequently used as the basis for database mining trials.*

Further prescreening steps in the search for potential drug ligands can be made *by excluding molecules with properties that make them unlikely to be biologically accessible. These properties are summarized in Lipinski's* Rules,[18] *which are based on the fact that 2245 known small molecular drugs* (as *cataloged in the* USAN[19]) *show poor absorption or permeation when the following occur:*

1. *There are more than five H-bond* donors *(expressed as the sum of* OHs *and* NHs).
2. *The molecular weight is over 500.*
3. *The* LogP *is over 5.*
4. *There are more than 10* H-bond *acceptors (expressed as the sum of* Ns *and* Os).

LogP *is a partition coefficient defined as the ratio of concentrations of a compound in aqueous phase to the concentration in an* immiscible *solvent* (e.g., *octanol). According to Ghose et* al.,[20] 80% *of all drugs fall in the range of* 160–480 Da, *with an average of 357 Da, and have calculated log* P *values in the range of* −0.4–5.6, *with an average value of 2.3. Theoretically. there are at least* 10^{12} compounds *that would fit these* Lipinski *criteria. (The estimate is based* on *molecules derived from* consideration *of a tetrahedral lattice of 20 points. each of which can be occupied by four possible* substituents.) *Current FITS approaches. even using libraries of 1* million *compounds, are therefore sampling* less *than one* millionth *of potential ligands.*

Automated Docking

A number of computer programs are now available to carry out the automated docking of molecules selected from databases into the pi-otein-binding pocket.

Shown in *Fig. 2* is *a schematic representation of the stages of automated docking of ligands into a* protein-*binding pocket. The stapes include* the *generation of a description of a binding pocket using spheres or grid points (1). matching the ligand to the points or spheres (2). Finally, the fitted ligand is given an energy score (3).*

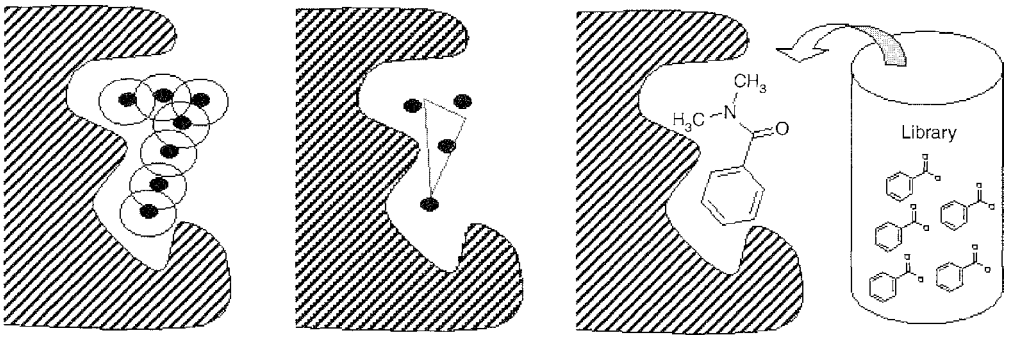

Fig. 2 Stages of automated docking

Table 4 Scoring functions employed in docking algorithms

Docking algorithm	Scoring functions	Attributes	Ref.
GLIDE	$\Delta G_{binding} = \Delta G_0 + \Delta G_{hbond} \sum_{il} g_1(\Delta r) g_2(\Delta\alpha) + \Delta G_{metal} \sum_{aM} f(r_{aM}) + \Delta G_{lipo} \sum_{IL} f(r_{IL}) + \Delta G_{rot} H_{rot}$ ΔG_0 is a nonspecific energy term. $\Delta G_{hbond} \sum_{il} g_1(\Delta r) g_2(\Delta\alpha)$ is an H-bond term between ligand and receptor atoms with an ideal bond length and angle deviation penalty. $\Delta G_{metal} \sum_{aM} f(r_{aM})$ is a term accounting for metal atoms. $\Delta G_{lipo} \sum_{IL} f(r_{IL})$ accounts for lipophilic atoms. $\Delta G_{rot} H_{rot}$ is a flexibility penalty for frozen bonds.	• Screens at 6 min per ligand • Includes entropic flexibility penalty • Lipophilic terms account for long-range terms • Incorporates metal ligand binding	[24]
GOLD	Score $= \sum(-E_{pair} - (E_{ij} + (E_{ijkl} + Eij)))$ $=$ −H-bond energy − (Internal energy + Complex energy) E_{pair} is a weighted H-bond interaction energy term between donor–acceptor aiom pairs, accounting for water displacement. E,, is a ligand steric energy using 6–12 Leonard–Jones factors accounting for dispersion of atom pairs caused by ionization and polarization. E_{ijkl} is a ligand torsion angle value calculated with a Tripos forcefield for four connected atoms. Eij is an energy distance constraint with a 4–8 Leonard–Jones potential, accounting for close contacts with a covalent bond energy term.	• Screens 12 min per ligand • The genetic algorithm (GA) explores full ligand and partial receptor flexibility • AG difficult to calculate, as only enthalpic consideration is considered • Surface-accessible area. term is not included	[25]
FlexX	$\Delta G = \Delta G_0 - \Delta G_{rot} \times N_{rot} - \Delta G_{hb} \sum_{\text{natural hbonds}} f(\Delta R, Ax) + \Delta G_{io} \sum_{\text{ionic int}} f(\Delta R, Ax) + \Delta G_{aro} \sum_{\text{aro int.}} f(\Delta R, An) + \Delta G_{lipo} \sum_{\text{lipo cont.}} f^*(\Delta R)$ ΔG_0, ΔG_{hb}, ΔG_{io}, ΔG_{rot}, ΔG_{aro} are entropic terms that describe contributions made by nonspecific, H-bond. ionic. rotational, and aromatic interaction energies offset by an idealized penalty function $f(\Delta R,\Delta\alpha)$. ΔG_{lipo} includees lipophilic interaction energy as a function of all pair-wise atom–atom interaction energies.	• Screens at 3 min per ligand • Large number of ligand conformations are generated • Lipophilic interactions are accounted for • Limited to ligands with less than 17–20 rotatable bonds	[23]
DOCKv4 GB/SA	$G_{binding} = \sigma_1 \Delta(SA_{hp}) + \beta .VDW - \sigma_2 \Delta(SA) + G_{pol}$ $\Delta(SA_{hp})$ and $\Delta(SA)$ are a measure of change in hydrophobic and total accessible surface areas. σ_1, σ_2 are solvation parameters for nonpolar atoms and a linear coefficient for the scaling of van der Waals interactions β.VDW. G_{pol} includes ligand-receptor electrostatic energy and partial desolvation energy terms for receptor and ligand atoms.	• Screens at 7 min per ligand • The desolvation states of ligand and receptor are included in term accounts for hydrophobic interactions • Effects of translational. rotational. and conformational entropy loss upon binding not included in function	[22]

Table 5 Structural and thermodynamic data for a selection of different classes of protein–ligand complexes

Protein–ligand		Number of H-bonds contacts	Number of non-H-bond contacts	Solvent accessible surface area (Å^2) of the ligand				K_i M^{-1}	$\Delta G°$ kJ mol^{-1}
				Uncomplexed Å^2	Complexed Å^2	Buried Å^2	%Buried		Calculated ($\Delta G° = -RT \ln K_i$)
OppA (1B1H.pdb)	K–Hph–K	12	103	201.151	5.687	195.464	97.17	9.3×10^{-8}	+40.1
Cyclophilin-A (1CWA.pdb)	CsA	5	15	342.429	193.203	149.226	43.57	5–200 10	45.6 to + 51.5
FKBP (1FKF.pdb)	FK506	3	110	261.332	126.936	134.396	51.42	4.0×10^{-10}	+52.6
FABP (2IFB.pdb)	Palmitate	1	109	154.195	9.744	144.451	93.68	$7 \times 10^{-}$	+46.4
ConA (1I3H.pdb)	Dimannose	8	58	121.752	51.562	70.19	57.64	4.2×10^{-3}	+13.5
HIV-1-protease (1HVR.pdb)	Cyclic urea inhibitor complex XK2 263	6	153	230.994	17.829	213.165	92.28	3.1 10^{-10}	+54.2
Estrogen receptor (1ERR.pdb)aps	Raloxifene	3	137	196.285	16.911	179.374	91.38	IC_{50} = 0.2 nm	+55.3

The process allows for whole libraries of ligands to be screened against a single binding pocket.

The steps in the process are as follows:

1. Generate a description of the binding pocket. This is usually in the form of a set of grid points or spheres.
2. Match the ligand to the grid points by fitting atoms of the ligand onto grid points that have appropriate electrostatic propesties.
3. Calculate an energy score showing how well the ligand fits into the binding pocket.
4. Rank and order the hits.

The well-established DOCK algorithm[21] generates a sphere-filled inverse representation of the binding pocket, subsequently matching thousands of ligand orientations to the spheres. DOCK version 5[22] includes a desolvation term in its scoring system to account for the shedding of water upon ligand binding. The incremental construction algorithm FlexX[23] considers ligands as totally flexible: fragment placing allows subsequent reconstruction of the ligand within the receptor. The scoring function (Table 4) is relatively computationally efficient and includes entropic terms covering lipophilic, aromatic, and ionic interactions. The GOLD (genetic optimization for the ligand docking) program[25] developed at the Cambridge Crystallographic Data Centre (CCDC) employs a genetic algorithm to fully explore ligand flexibility within a partially flexible receptor. The scoring system uses observations of nonbonded contacts from crystal structures to rank ligand orientations.

A BROAD SURVEY OF LIGAND CLASSES

For structural and thermodynamic data for a selection of differentclasses of protein–ligand complexes, see Table 5.

Peptides: OppA Complexed with 8-Peptides

The structures of eight OppA–peptide complexes were determined by protein x-ray crystallography[10] (Fig. 3a). OppA is a peptide transport receptor in gram-negative bacteria that binds a wide range of peptides between two to five amino acids in length. In a study by Davies et al.,[10] eight complexes of tripeptides K–X–K (X = abnormal side chain) were prepared. and the enthalpy, entropy, and binding affinity were measured when bound to OppA. The resultant K_d values ranged from 15 nm–29 ym. The complexes revealed a rigid binding pocket with well-ordered water molecules. The OppA system shows preferential binding for hydrophobic groups over positively charged groups. Small differences in ligand side chains cause a disproportionately large effect on ligand binding, resulting in an inability to rank or predict binding affinities within classes of ligands. Predictions of binding affinities are complicated due to favorable enthalpy changes being offset by a compensating cost in entropy change, making it difficultto correlate structure with binding affinity. The observed water displacement upon ligand binding associated with the Opp–A system and the resultant enthalpy–entropy compensation makes predicting binding affinities using scoring functions that do not account for unreliable solvent interactions.

Peptides: Cyclophilin A Complexed with Cyclosporin A

Cyclosporin A (CsA) is a cyclic undecapeptide that has seven of the 11 amides in the N-methylated form and is used as an immunosuppressent to prevent the rejection of organs after transplant sugery. CsA's immunosuppressive qualities arise from the formation of a tightly bound complex of CsA with Cyclophilin A (CypA); a ubiquitous 165 amino long cytosolic protein. The CsA/CypA composite surface binds and inhibits the serine/threonine phosphatase calcineurin. preventing further signal transduction. The CsA/CypA complex was solved to 1.8 Å resolution. Analysis of 11 CypA/CsA derivative crystal complexes by Kallen et al.[27] provides a useful database of protein–ligand interactions. revealing the effect of small chemical differences on hydrogen bond, van der Waals. and water interactions. Only six of the CsA residues form van der Waals or hydrogen-bonded contacts with the binding pocket of cyclophilin. There is an excellent complementarity of fit between the MeVal side chain and the hydrophobic active site pocket of cyclophilin, which is designed to accommodate proline. There are five direct hydrogen bonds between CsA and CypA and a solvent-excluded area of 150 $Å^2$. Despite only half the residues being involved in the interaction with the protein, there is a strong interaction with a K_d of 15 nM. The conformation of the ligand undergoes a dramatic conformational change from its uncomplexed state in organic solvents.

Macrolides: FKBP Complexed with FK506 and Rapamycin

FKBP is the soluble receptor for the immunosuppressant drug FK506 (see Fig. 3b). The native crystal structure of FKBP as well as with FK506 and rapamycin-bound forms were determined to a resolution of better than 2.0 Å.[5] A range of bound ligands describes the enthalpic and entropic contributions caused by differing electrostatic, chiral, and solvation properties of the ligand. X-ray

structures of a series of ligand molecules related to dimethylsulfoxide were complexed with FKBP. The structures allow for the correlation of physiochemical properties with experimentally observed binding affinities.[''] Analysis of rnacrolide and small-ligand FKBP complexes reveals an active site cavity able to flex in relation to the size of the bound ligand. Coinparison of FKBP complexed with DMSO and methyl sulfinylmethylsulfoxide (DSS) shows similar protein and solvent structures. The observed threefold increase in K_d in the FKBP/DSS complex compared to DMSO can be contributed to increase in enthalpic (van der Waals) interactions energy due to the presence of the methyl sulfide group. The correlation of three-dimensional structure with

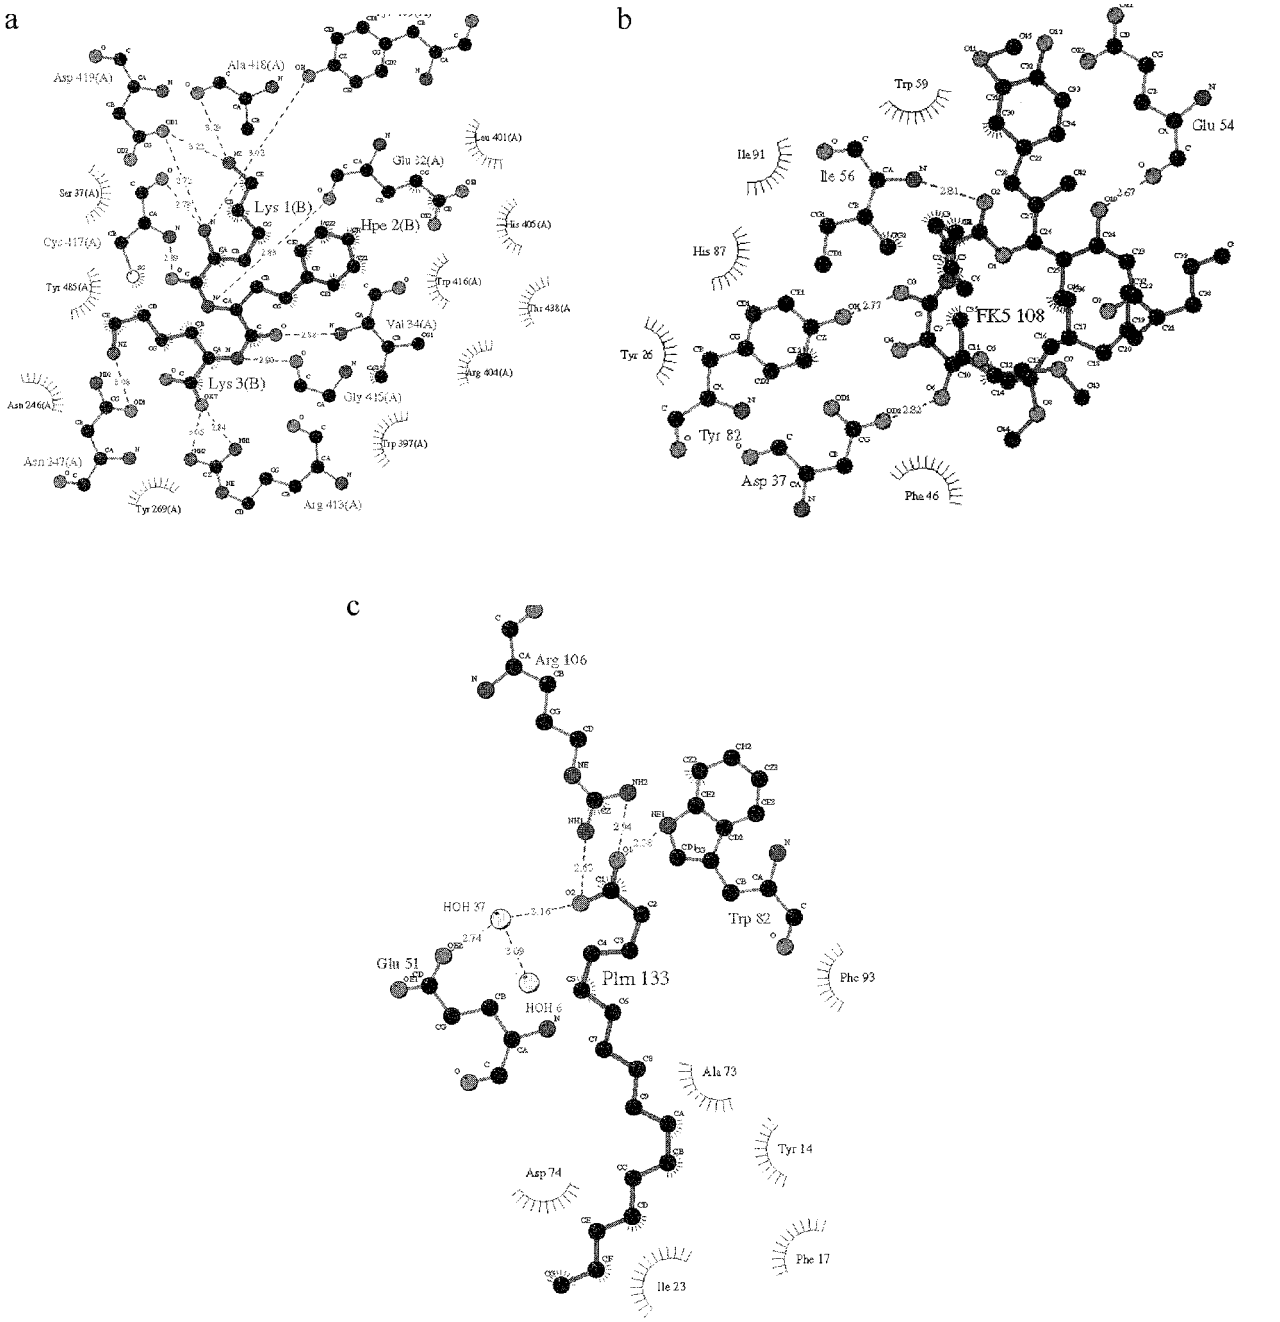

Fig. 3 (a) OppA K–HpH–K complex (1B1H.pdb); (b) FKBP–FK506 complex (1FKF.pdb); (c) FABP–palmitate complex (2IFB.pdb); id) ConA–dimannose complex (1I3H.pdb); (e) HIV-I protease–cyclic urea inhibitor (1HVR.pdb). Fig. 3 (*Continued*).

ligand-binding data suggests that for each Å^2 contact between ligand and protein contributes between -0.1 kJ/mol[4] up to an estimated -0.5 kJ/mol binding energy.[5] FK506 binds to human FKBP with a K_d of 0.4 nM. With an estimated 134 Å^2 buried contact area. each Å^2 contact contributes -0.4 kJ/mol binding energy.

r

Lipids and Fatty Acids: FABP–Palmitate Complex

Fatty acid binding protein (FABP) is involved in fatty acid transport (Fig. 3c). High-resolution crystal- and NMR-derived structures of apo and holo forms of rat intestinal FABP complexed with palmitate allowed Bakowies et al.[28] to derive a 5 nsec molecular dynamics (MD) simulation.'''' The FABP family shares a common β-barrel motif with a large internal binding cavity, which when uncomplexed, contains 20 to 25 well-ordered wate molecules. Thermodynamic studies conclude that binding is enthalpically driven but cannot distinguish between entropic compensations between the ligand and water effects. Side-chain PI-bond interactions are consistent between MD simulations and crystal structures. however, crystal and NMR representations show poor agreement in the apo-FABP form. The holo-FABP complex MD simulation shows that palmitate ligand moves 3–4 Å back toward the cavity entrance. Crystal structures overestimated the electrostatic contribution, while the MD simulation shows that palmitate is able to sustain substantial flexibility and motion while bound in the protein cavity. The apo-FABP shows a high-density droplet of water in the cavity center. The holo-FABP complex reveals that water molecules are displaced from the cavity by palmitate, with one water molecule being replaced by three methylene fragments. The observed high mobility of water molecules within the interior and exterior of FABP when palmitate binds is due to a combination of water droplet dispersion and a more favorable exchange pathway via the portal region of FABP. Displacement of several β-strands around the exit channel observed in the NMR and MD representations but absent from ihe crystal form of apo-FABP show the importance of solvation on the overall protein structure.

Saccharides: Concanavalin-A Complexed with Dimannose

The interaction of plant lectin concanvalin-A (Con A) with different saccharides was studied in great depth and provides a unique insight into protein–oligosaccharide interactions. Sanders et al.[29] crystallized the structure of Jack Bean Con A in complex with dimannose (Man-(XI-2)Man) to a resolution of 1.2 Å.[29] Comparison with the complexed and uncomplexed forms shows that the water displacement that occurs upon ligand binding forms a network of well-defined H-bonds that helps to stabilize the Con A–dimannose complex. The H-bonding network provides an explanation for the observed preferences in

binding α1-2 linked disaccharides. The formation of eight direct hydrogen bonds (and seven indirect interactions. with well-observed waters) between dimannose and Con A combined with a buried contact area of 70.2 Å^2 gives a K_d of 4.2 mM. The high resolution of the structure revealed the protonation of an Asp208 OD1. a feature that was unaccounted for in previous modeling studies (Fig. 3d).

Steroids: Estrogen Receptor Complexed with 17β-Estradiol and Raloxifene

Estrogens play an important role in tissue growth, development, and homeostasis. These steroids mediate their effects ihrough direct interactions with a ligand-inducible nuclear transcription factor termed the estrogen receptor (ER), resulting in the activation or repression of target genes. How estrogens mediated their biological effects at the molecular level has been a source of continuous debate. The cocrystallization of the endogenous estrogen agonist 17β-estradiol (3.1 A) and the clinically used selective antagonist Raloxifene (2.6 A) with the α-estrogen receptor, respectively. by Brzozowski et al. provided insight into the molecular basis of agonism and antagonism of the ER.[30] Comparison between these structures reveals that the large side chain of Raloxifene protrudes from the cavity and causes a 10 A rigid body displacement of one of the receptor helices (Helix 12). The formation of three hydrogen-bond interactions and a 179 Å^2 buried contact area between Raloxifene and the ER results in Raloxifene having an IC_{50} of 0.2 nM. It is proposed char the failure of Helix 12 to fully cap the entrance of the binding cavity prevents the forination of a competent transcriptional activation function (AF-2) site that is able to effectively recruit coactivators. It is thought that this observed helical rearrangement of Helix 12 leads Raloxifene to behave as an antagonist in certain tissues.

Related in Table 5 are protein–ligand complexes described with the number of intermolecular contacts made and solvent-accessible surface area to thermodynamic binding data. The number of H-bonds, inhibition concentration (K_i), and change in Gibbs free energy (AG), respectively. were taken from original sources. The number of non-H-bonded contacts was generated using the Ligand–Protein Contact software.[31] The solvent-accessible surface was generated using the Connolly[32] accessible surface of the ligand in isolation and when bound in the protein (without water). The buried surface is taken as the difference between these values. A probe radius of 1.5 A was used with the implementation of the Connolly algorithm within the modeling program WIT-NOTP.[33]

Synthetic Drugs: HIV-1 Protease Inhibitors

In the fight against HIV. the National Cancer Institute developed a database of HIV protease–ligand complexes. The HIV-PR database[34] holds the coordinates for 142 different crystal structures of HIV protease–ligand complexes (Table 6). In conjunction with the Autodock3 docking package, a modified combined energy weighted grid system was used to predict the correct ligand-binding conformation for 21 of these complexes. The results showed ihat the energy grid could allow structural flexibility of the binding site and distinguish between ligands that required water for binding. The cyclic urea inhibitor that was tested, which does not require the presence of water for binding to HIV protease. was accommodated within the energy grid system. returning a predicted conformation close to that of the crystal structure.[35]

HIV Protease Database	Structure database of HIV proteases complexed with their inhibitors	**http:l/srdata.nist.gov/hivdb/**

Described in Table 6 is a list of online databases that hold thermodynamic data on protein–ligand complexes.

CONCLUSION

The event of ligand binding is thermodynamically complex and is composed from a range of enthalpic and entropic factors. Recent technological developments allowed for improved experimental measurement of ligand binding. Linking binding data to the type of intermolecular forces observed within protein–ligand complexes (Table 5 and Fig. 3) provides a route to improving energy terms used in structure-based drug design. Listed in Table 6 are online databases that give thermodynamic and enzymatic information about relected protein–ligand complexes. However, current techniques can still only sample a small percentage of the total available ligands. Increasingly. computational techniques such as de novo design. database mining. and automated docking are being employed to predict new sources of protein–ligand interactions

The future prospects for this in-silco technology depends on incorporating improved parameters for describing the dynamic effects of water and protein flexibility in the system. The ability to achieve these coinputational advances will be helped by the increasing number of high-resolution crystal structures of protein–ligand complexes becoming available in publicly accessible databases. Such structures provide an opportunity for the detailed analysis of the poorly defined factors that influence the strength of protein–ligand interactions.

ACKNOWLEDGMENTS

We are grateful to Prof. J.W. Keillor at the Universite de Montreal. Department of Chimie, for his many useful discussions.

The authors would like to thank the BBSRC for their financial support.

Biological Models and Their Characteristics

INTRODUCTION

The ability to mimic and take advantage of the complexity of living matter as a way to store and transfer information, accelerate chemical reactions, selectively recognize chemical species, self-replicate, and so on is at the basis of supramolecular chemistry in the biological field. The concepts that spurred the growth of supramolecular chemistry came from the biological world, as scientists started to comprehend the extreme difficulty (if not the impossibility) of obtaining complex systems with specific function just by connecting building blocks via covalent synthesis. It is apparent that in the biological world, the most challenging and intriguing systems express their functions as collections of simpler elements held together not by covalent bonds but by reversible, singularly weak, interactions. Supramolecular chemistry was the response of scientists to this clear evidence: complex structures able to perform spectacular achievements can be obtained minirnizing chemical synthesis and relying on weak interactions, i.e., the way molecules reciprocally communicate without the formation of covalent bonds."] In order to do this; they had to master the way these weak interactions (like hydrogen bonds. hydrophobic forces, for instance) operate.

In order to address the characteristics of biological models, we have to first define the basic principles of biological systems that a supramolecular model may mimic. Among the most important are selective molecular recognition of a molecular entity: selective and highly accelerated modification of a substrate (typical role of enzymes): compartmentalization and selective translocation of chemical species across boundaries (typical role of biomembranes): harvesting and transformation of energy; and self-replication.

SELECTIVE MOLECULAR RECOGNITION

Molecular recognition relies on weak to moderate forces,[2] and the process depends critically on the structure of the molecular partners involved as well as on the nature of the surrounding solvent. Typical interactions involved in molecular recognition are ion–ion, ion–dipole, dipole–dipole, cation–π, π–π stacking, dispersion (London), and solvent effects. The classical recognition process requires two entities: the molecular receptor (host) and the recognized molecule (guest). However; self-recognition should not be overlooked, as it is one of the most important processes in the biological world. Self-recognition, for instance. is what dictates the folding of a protein into its secondary and tertiary structures. Those synthetic oligomers showing the property to fold into a specific conformation following the information encoded in their synthesis were dubbed Foldamers.[3] Interesting examples are those constituted by β-peptides[4,5] (unnatural oligomers composed of β-amino acids) that fold into a 3_{14} helix already at the level of a dodecamer. Even more striking are short oligomers (six to eight units) composed of Cα-tetrasubstituted unnatural amino acids[6] that fold into 3_{10} helices. Probably the system most studied as a model for molecular recognition is that constituted by cyclodextrins (CDs), cyclic oligomers (six to eight units) composed of glucose units with a doughnut shape and an hydrophobic interior.[7] This property led to the use of functional cyclodextrins as enzyme models (see below). However, as an example to illustrate molecular recognition, we will show a cage receptor for glucose able to extract the sugar from an aqueous solution into an organic one.[8,9] This is a challenging endeavor. because water is obviously an excellent solvent for a saccharide. The molecule (Fig. 1) comprises a rigid cavity (a tricycle), with amide groups pointing inward into the cavity and suitable for hydrogen bonding the sugar molecule. The design resembles key structural motifs present in carbohydrate-binding proteins that, as stated by the authors. "commonly place aromatic surfaces against patches of carbohydrate CH groups while accepting the hydroxyl groups into networks of hydrogen bonds." This receptor has an affinity for D-glucose, which is five times larger than that for D-galactose and >10 times that for D-mannose.

DOI: 10.1081/E-ESMC 120012671

CATALYSIS

An essential prerequisite for enzymatic catalysis is the binding of the substrate to the protein before its transformation into products. The two processes (binding and modification) may occur on different sites of the protein. The binding site should not change during the catalytic process. while. in the reactive site, bonds are broken and new ones are formed, charge is developed or disappears.[10] Accordingly. the mimicry of a recognition site, compared with a catalytic site that is dynamic in nature: is much easier in a supramolecular system. Supramolecular (enzyme-like) catalysts typically provide the recognition site for a substrate, while they are much less effective as far as the catalytic site is concerned. Apart from the dynamic aspect mentioned above. a catalytic site requires the refinement of the pKa of acids or bases eventually involved in the process and accurate control of the solvation of all species. Nevertheless. effective supramolecular catalysts were reported, because just the proximity of reactant and catalyst achieved upon binding is enough to guarantee (sometimes) impressive rate accelerations. A typical example is that provided by cyclodextrins.[11] The hydrophobic cavity of these natural molecules was used to recognize substrates, while the hydroxyl rim was used as a source of a nucleophile for a transacylation process. By optimizing the substrate, Breslow and collaborators[12] were able to achieve 6-million-fold rate accelerations compared with the uncatalyzed hydrolysis reaction. The critical aspect stressed by these systems is that a substrate, rather rigid and complementary to the cavity, may be designed with the ester group sitting precisely over the CD secondary side

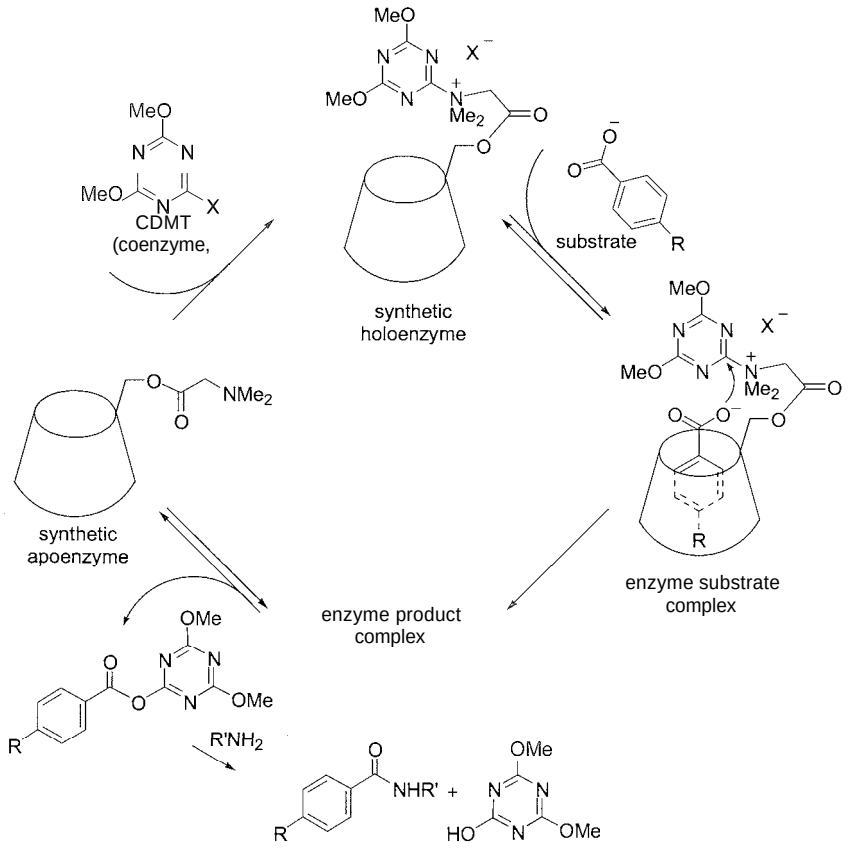

Fig. 2 Catalytic cycle for a CD-based artificial acyltransferase

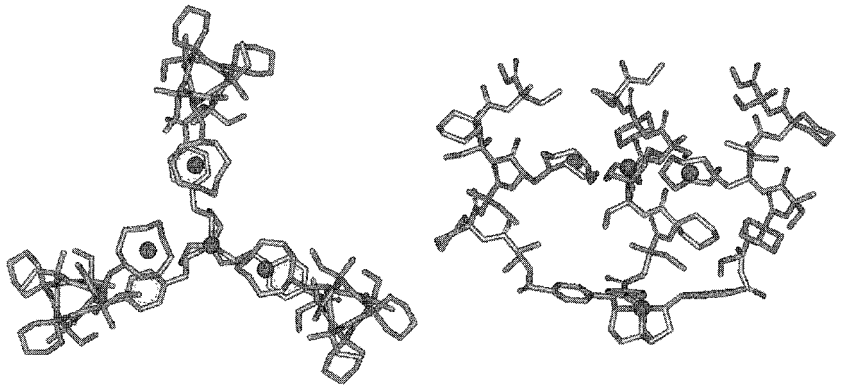

Fig. *3* Tripodal polypeptide used as a biomimetic supramolecular catalyst for the cleavage of phosphate esters. The tren platform is an allosteric control site. (*View this art* in *color at www.dekker.com.*)

hydroxyl group. Thus, the proximity is the source of the rate acceleration. More sophisticated systems require the modification of the cyclodextrin so that a catalytic site can be designed by placing suitable functional groups. An example[13] illustrating this point was recently reported by Kunishima et al. They simply esterified one of the primary hydroxyls of β-CD with *N,N*-dimethylglycine (see Fig. 2), transforming it into a catalyst (holoenzyme) for the amidation of carboxylic acids in aqueous solution. The process requires 2-chloro-4,6-dimethoxy-1,3,5-triazine (CDMT) as a coenzyme consumed during the reaction. The results indicate that, in the catalyst. the substrate-binding site (the CD cavity) and the catalytic site (the dimethylamino group at the rim) must be linked to each other in order to achieve substrate-specific amidation. Other molecuiar receptors can be used as supramolecular. biomimetic catalysts. For instance, Diederich[14] functionalized a cationic cyclophane with flavin and thiazolium groups and obtained a pyruvate oxidase mimic. Pyruvate oxidase is an enzyme that employs two cofactors: flavin and thiamine-diphosphate to catalyze the transformation of pyruvate to acetyl phosphate. The coexistence of the two cofactors on the same inolecular receptor makes this molecule one of the most active artificial enzymes known to date. In an attempt to mimic the catalytic site of a nuclease we synthesized[15] the molecule shown in Fig. 3 by attaching three copies of an helical heptapeptide to a derivative of tren (tris-aminoethylamine). The sequence of each single peptide is designed in such a way that by folding into an helical conformation, two ammonium groups are placed on one side of the helix. and a triazacyclononane ligand of synthetic amino acid ATANP is placed on the other. The tripodal derivative can bind up to four metal ions: one on the tren platform and three on the triazacyclononane moieties. The tren site is used to control the conformation of the molecule (like an allosteric site in proteins). while the remaining triazacyclononane coinplexes define a catalytic site for the metal-catalyzed hydrolysis of a phosphate. The metal complex is active in the cleavage of a phosphate model of RNA, with clear evidence of cooperativity between the metal centers. Surprisingly. however, it is active as the free amine in the cleavage of linear RNA. It appears that the allosteric site is responsible for this behavior of striking selectivity in the interaction with the substrate. By using natural sequences the group of Baltzer[16–19] recently described a series of fully synthetic polypeptides that are good catalysts of the cleavage of esters. The molecules contain 42 amino acids and were designed to fold into a helix-loop-helix conformation. The monomers dimerize into a four-helix bundle that provides a shallow reactive site for the substrate (Fig. 4). Here, the emphasis is on the careful control of the properties of the catalytic units placed on

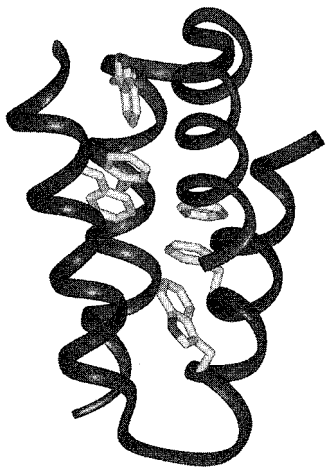

Fig. 4 Four-helix bundle formed by two helix-loop-helix peptides. The self-assembly of the two monomers provides a shallow reactive site for the substrate. (*View this art in color at www.dekker.com.*)

the reactive site. Thus. by introducing flanking amino acids with charged side chains. the authors were able to finely tune the pKa of the imidazole of the histidines so as to maximize their cooperative role at the optimum pH for the occuri-ence of the catalytic process. As stated above, this is a major challenge for everybody trying to prepare an artificial (supramolecular) catalyst. To conclude this section. we will mention two extremes in the design of supramoiecular enzyme models. The first takes advantage of putting together. in a polymer, several functional groups and hydrophobic units. These successful molecules were called synzimes.[20–22] The second is that represented by catalytic antibodies,[23] where the catalyst is a protein generated by the immune system against a model of the transition state of the reaction under investigation. The first is rude and devoid of any specific geometrical design of the catalytic site, while the second is highly sophisticated, although the recognition of the model of a transition state does not necessarily imply acceleration of the related reaction. Nevertheless, both provided promising results.

COMPARTMENTALIZATION AND TRANSLOCATION

Biological membranes play a fundamental role in compartmentalizing and insulating the living cell from the external medium. However. an organized trafficking of molecules and ions across the membrane is needed to sustain life. In nature. this traffic is regulated by a variety of systems able to form ion channels or to act as molecular carriers and to selectively affect the membrane permeability.[24] In particular, ion channels are formed following two general approaches: the first rely on molecules that, due to their peculiar structures. form a discrete pore in the membrane as exemplified by the β-helix of the gramicidin A dimer. The second is based on the hydrophobically driven self-assembling of amphipatic units in the membrane that form a cluster where the hydrophilic face of each unit points inward, defining a channel with a polar inner surface (barrel-stave model).[''' Examples of this include the ion channel proteins of the nervous system in which the channel is formed by four or five homologous α-helices containing several serine residues lining the pore.[26] Several other shorter peptides like peptaibols[27] or nonpeptidic systems like amphotericin B[28] are thought to affect rnembrane permeability with this mechanism. Supramolecular chemists undertook the ambitious challenge of preparing systems able to rival the natural ones. Example of models inspired to both types of ion channels described above are present in the literature. Recently. the group of Ghadiri[29–32] reported channel obtained from self-assembled cyclic peptides. The key feature of these cyclopeptides is the presence of alternating L, D amino acids; so that hydrogen bonding assembles them in a stack of rings. This strategy resembles that adopted by gramicidin A. When the assembling of the tubes (diameter > 7 Å, depending on the size of the cycle) occurs in a membrane, this leads to the alteration of its permeability (Fig. 5, left). The group of Voyer[33] synthesized a 21 amino acid peptide composed of 15 L-leucines and six 21-crown-7-L-phenylalanines: the sequence is such to allow the partial alignment of the macrocycles, one over the other, when the peptide adopts an α-helical conformation (Fig. 5, right). forming a pore in the membrane. A similar design was used by Matile in realizing a rigid oligo(*p*-phenylene) rod functionalized with several monoaza-18-crown-6 subunits.[34] Models based on the self-assembling of amphipatic subunits were also developed. They are based on peptides,[26] polyhydroxylated p-biphenyl oligomers,[35] cholic acid.'''' or polyhydroxylated steroid[37] derivatives. Often. the design of these systems is inspired by the naturally occurring ionophores. amphotericin B (AmB) and squalamine,[38] which are thought to form pores in lipid bilayers. The analysis of these two ionophores made by Regen is interesting in understanding how a biological model may be constructed.[39] AmB and squalamine have different structures but share some common elements: a long and rigid hydrophobic unit; a hydrophilic chain that is linked to the hydrophobic unit and can extend across its ''face''; and a polar head group. On these bases, the author designed the sterol derivative shown in Fig. 6. which mixes elements taken from squalamine. like the sterol-based hydrophobic unit and the polar head group, with the polyoxygenated chain, taken from AmB. This derivative is able to affect the membrane permeability of model liposomes with an activity and a mechanism of action comparable with that of AmB.[40] In particular, it is suggested that the ionophore assumes a folded conformation, like the one shown in Fig. 6, and is inserted in the rnembrane with the sulfate and the protonated amino group anchored to the surface of the liposome. Eventually, clusters are formed where the oxygenated chain points inward. toward a water-Filled pore. Furthermore. because the system is too short, the alignment of two of these clusters is needed to span the membrane across and alter its permeability.

HARVESTING AND TRANSFORMING ENERGY

Photoinduced electron and energy transfer are fundamental processes in nature[41] In photosynthetic organisms, photoinduced electron transfer that induces conversion of light into chemical energy begins when photonic excitation reaches the so-called reaction center (RC) Usually.

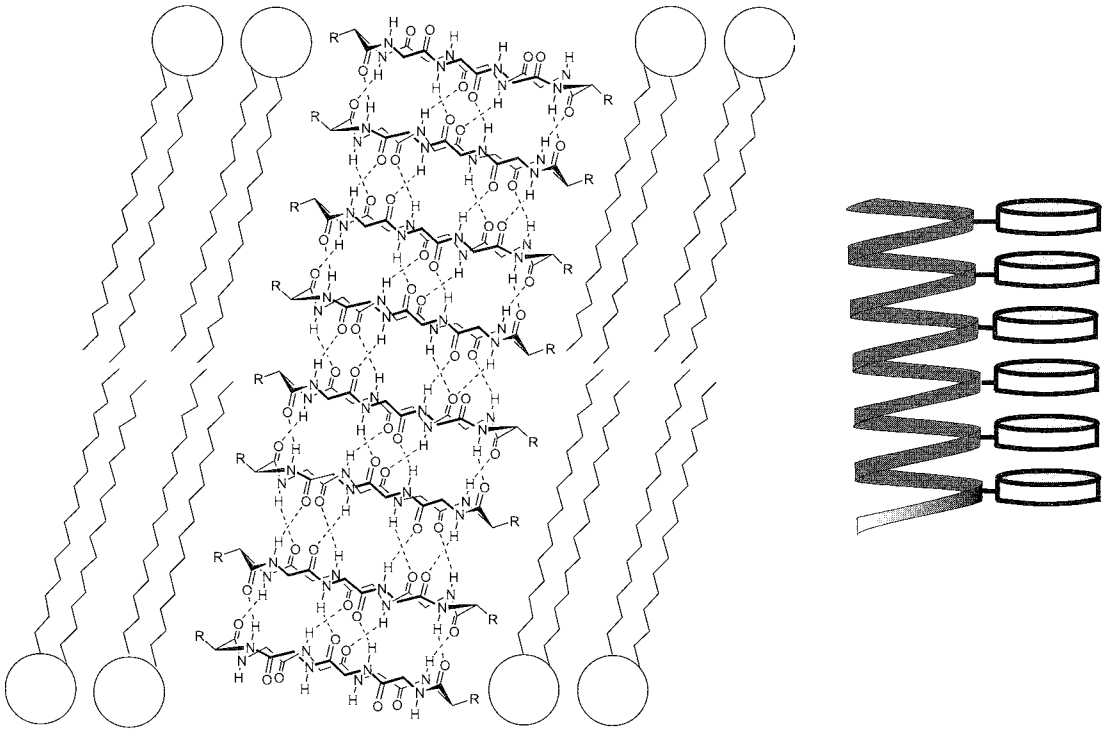

Fig. 5 Examples of systems able to form channels in membranes. Left: the Ghadiri's self-assembled nanotube formed by cyclopeptides. Right: The Voyer's 21 amino acid peptide containing six 21-crown-7 L-phenylalanines. In a membrane. the peptide adopts an α-helical conformation that allows the partial alignment of the macrocycles, one over the other.

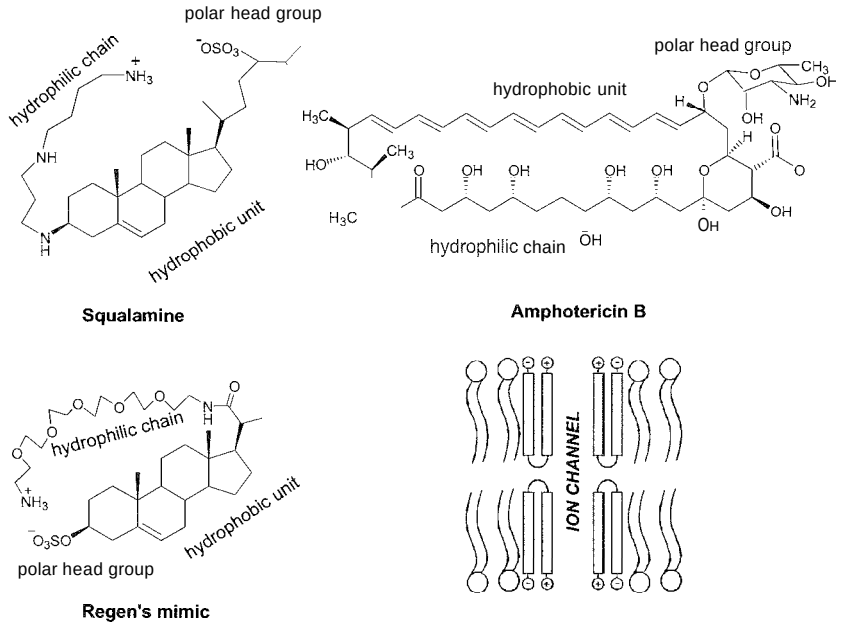

Fig. 6 Regen's mimic of amphotevicin B and squalamine. In the bottom left corner. the cartoon illustrates the proposed mode of action of this ionophore.

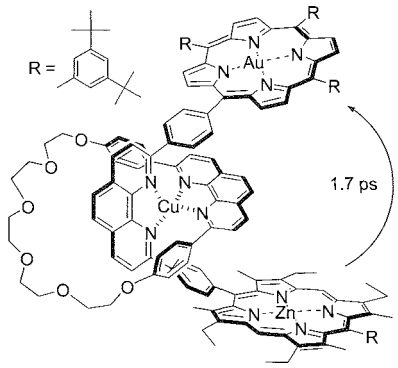

Fig. 7 A rotaxane that mimics the special pair/bacteriopheophytin (BPh) arrangement and electron-transfer properties of the bacterial photosynthetic reaction center.

light is trapped and transferred through a pool of well-organized chromophores included in the light-harvesting antenna protein. For example, in the bacteria *Rhodopseudomonas acidofila*, the light-harvesting system is formed by two rings of noncovalently linked bacteriochlorophyll chrornophores (BCh), one consisting of nine pigments and the other of 18 chromophores. This highly organized structure enhances the spectral width of the light trapped and the efficiency of energy transfer toward the RC. where electron transfer to a quinone group generates a long-lived charge separation state.[42]

Energy-transfer and electron-transfer processes inspired many research groups. and a variety of systems employing different chromophores were exploited.[43] Popular are tetrapyrrolic systems, the naturally occurring chromophores in the photosynthetic reaction center. In particular. supramolecular chemists are trying to reproduce the naturally occurring electron- and energy-transfer processes occurring through noncovalently linked proteins, using self-assembled systems. Sophisticated and efficient models of the photosynthetic RC and antenna systems were obtained.[44] For instance, Sauvage designed the rotaxane shown in Fig. 7 that mimics the special pair (SP, a closely associated dimer of BCh)/bacteriopheophytin (BPh) arrangement and electron-transfer properties of the bacterial photosynthetic RC.[45] In the natural system, the electron transfer from the excited state of SF to BPh occurs at a rate of 3 ps^{-1}. In the synthetic model, the electron donor is a zinc porphyrin in its excited state, and the electron acceptor is an Au(III) porphyrin. Light irradiation of the zinc porphyrin chromophore is followed by electron transfer to the gold porphyrin acceptor. which occurs at a rate similar to the natural system (1.7 ps^{-1}). The rotaxane structure is important, and in the absence of the Cu(I) ion that positions the second phenanthroline ligand in between the two porphyrin rings, the electron transfer process is substantially slower (36 ps^{-1}).

Self-assembling of multiporphyrin arrays was also exploited to model the properties of the antenna system. For instance, using a cooperative self-assembly process based on hydrogen bonding and metal–ligand interaction, Hunter was able to assemble five porphyrin rings in a well-defined structure in which a central free-base porphyrin is encapsulated in a spherical array of four zinc porphyrins.[46] Light excitation of these peripheral chromophores results in an efficient energy transfer to the central one, mimicking the funneling effect of the antenna system. A step forward is constituted by a self-assembled array of 16 zinc-porphyrins delivering energy to a central free-base porphyrin.[47]

SELF-REPLICATION

One of the peculiar characteristics of the living world is the ability to self-replicate. Undoubtedly, reproducing such a characteristic in the abiotic world is a demanding challenge. Supramolecular chemists have done it. Historically. the first example is that provided by von Kiedrowski,[48] who reported evidence of self-replication in a nonenzymatic nucleotide-based system. More exciting examples were subsequently reported.[49–51] These systems rely on the fact that the product of a reaction recognizes the reactants and catalyzes their transformations into the product. A typical problem of these systems is product inhibition. circumvented by von Kiedrowski by using solid-phase cycling. Examples of self-replicating peptides[52] were also reported by Ghadiri[53,54] and Chmielewski.[55–57] These systems take advantage of Kent's chemical ligation strategy for the formation of a peptide bond.[58] Recent advances comprise the mimicry of many fundamental properties of living systems, like sensitivity to the environment,[59] sensitivity to chirality,[60] and ability to correct errors.[61] A recent example from the work of Chmielewski[62] provides an illustration of the principle. Two halves of the peptide **I**. namely, **Ia** and **Ib** (Fig. 8), are subject to ligation under Kent's conditions in the presence and absence of **I**. Peptide **I** provides a remarkable rate acceleration to the process due

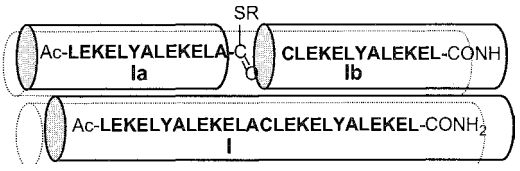

Fig. 8 A self-replicating system. Peptide **I** binds the two halves of **I** (actually a coiled-coil trimer. I_3), acting as a template, and placing **Ia** and **Ib** in the correct position for the occurrence of the ligation reaction.

to the binding of the two halves to I (actually a coiled-coil trimer. I_3) that acts as a template. thus placing Ia and Ib in the correct positions for the occurrence of the ligation reaction. The relative stability of the coiled-coil complexes appears to be the basis of the enhanced catalytic efficiency and low product inhibition of this system. A step forward into complexity in self-replication is provided by many of the systems described by Luisi and his group.[63–65] The basic idea behind this chemistry is that the lipid aggregates that are the constituents of a liposome (or vesicle) provide the elements for the minimal reaction vessel, a protocell. where reactions pertinent to living systems may occurr.[66] They were able to show that under appropriate conditions; these lipids can be continuously generated from a precursor. thus providing new constituents for new vesicle formation. If the vesicles catalyze the process of the generation of the constituent lipids from the precursor. the system becomes self-replicating. This proved to be the case. and self-replicating vesicles were reported. Now the system can be even more complex, in that self-replication may be controlled via a competing reaction that consumes the lipids. Depending on the conditions. the relative rates of lipid formation (v_f) and consumption (v,) may be such as to produce the growth of the vesicles ($v_f > v_c$), their death ($v_f < v_c$), or homeostasis ($v_c = v_f$). A chemical model for such a system was reported.[67] The basic component of this chemical model is a vesicular solution composed of an oleic acid/oleate lipid mixture charged with dihydroquinidine and OsO_4. These vesicles are continuously fed with oleic anhydride that is hydrolyzed in the oleic acid/oleate bilayer thus providing the source of new lipids (and, hence, new vesicles) and an oxidizing agent [$K_3Fe(CN)_6$]. This latter oxidizes the *cis* double bond of the lipid in a process that is OsO_4 catalyzed. If the hydrolysis reaction induces the growth of the vesicles, the oxidation one brings about their destruction, because the dihydroxystearic acid derivatives produced do not form vesicles. The careful control of the conditions leads to $v_f = v_c$ and to homeostasis of the system. As pointed out by the authors, the model is primitive, but it sets the basis for the obtainment of more complex and biologically relevant systems and, perhaps, to a metabolic model of a cell.

CONCLUSION

The mimicry of biological systems and, even more interesting, the synthesis of molecules working on the basis of the same principles that govern the natural ones but with unprecedented properties. are the challenges that supramolecular chemistry faces in this new century. The overview provided above gives readers an idea of some of the avenues chemists working in this field are undertaking. More exciting results are expected in the future.

Biomaterials

Judith R. Meakin
University of Aberdeen, Foresterhill, Aberdeen, United Kingdom

INTRODUCTION

A biomaterial is any natural or synthetic material that is employed as. or part of. a medical device. Typical materials include metals, ceramics, glasses. polymers, and tissue-engineered materials. The requirements of a biomaterial are that it should have the correct properties to allow it to achieve its intended function and be biocompatible. Over recent decades. there have been many developments in biomaterials research. Some of these developments have involved a movement from the use of inert materials to more sophisticated ones, which actively invoke a beneficial response from the body.

WHAT ARE BIOMATERIALS AND WHY DO WE NEED THEM?

Biomaterials are natural or synthetic materials that can be used as. or part of, a medical device to augment, repair, or replace a natural tissue within the body. They include tissue from the recipient's body (autograft), from another human being (allograft). from an animal of another species (xenograft). or a synthetic substitute. In this article. emphasis will be given to synthetic materials (metals, glasses. ceramics, polymers. and tissue-engineered materials) and some of the recent developments in this field.

The types of medical devices that require biornaterials arc wide ranging across most medical disciplines.[1] Artificial heart valves. contact lenses, drug delivery implants. urinary catheters. and replacement hip joints are just a few examples that demonstrate where biomaterials can be employed in the body.

Medical devices, and hence biomaterials, are becoining increasingly important in developed countries due to changes in society. With increasing life expectancy and better health care. people expect to remain active into their seventies and eighties. An increase in leisure time has led to an increase in injuries frotn sports. e.g., skiing. Furthermore. diseases such as heart disease and diabetes. which have become more prevalent in recent decades. require biornaterials to provide long-term solutions rather than the palliative treatments currently available.[2]

In the U.K.. there is a demand for medical devices that are quick and easy to implant, that minimize postsurgical complications, and that last the intended duration.[1] The importance given to this demand is demonstrated by the "Building up Biomaterials" program. which was recently launched by the Department of Trade and Industry. This program aims to promote the growth and competitiveness of the Bioinaterials industry in the U.K. by bringing together clinicians. researchers, and the medical device industry.

GENERAL REQUIREMENTS OF A BIOMATERIAL

The two principal requirements of any biomaterial used in a medical device are that it should have the correct physical properties in order for it to perform its intended function, and it should be biocompatible. Other requirements are that it can be easily manufactured and can be suitably sterilized. There are various sterilization methods; the use depends mainly on the material being sterilized. Gamma-ray or high-temperature sterilization methods, for example, are unsuitable for polyurethanes. as they produce toxic and carcinogenic compounds.[3]

The physical properties of a biomaterial include mechanical properties. such as stiffness. strength. and durability, together with other properties. such as oxygen permeability. The properties need to be suitable for the intended lifetime of the implant, which can range from the few weeks required for resorbable sutures to the lifetime of the patient receiving a hip replacement.

Biocompatibility essentially means that the material produces no adverse response from the body; this may be toxic, allergenic, carcinogenic, or mechanical. However. the body can tolerate even nonbiocompatible materials if the quantity of the material is small enough. Adverse responses can arise in response to chemical or particulate products that are released from a biomaterial. Metals, for example. are particularly susceptible to corrosion by body fluids. and the products of corrosion, such as metallic ions. salts. and oxides, can induce an immune response.[4] Particles. resulting from mechanical wear of an implant. may also invoke an immune response, even if this would

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012816

not be induced by the bulk material.[5] Not only can loss of material from an implant lead to an adverse reaction, but it can also compromise the integrity. and hence function, of the device.

As well as physiological effects, implants can have adverse mechanical effects. Ideally. the mechanical properties of an implant should be compatible with those of the surrounding tissues. Large differences in stiffness though, can result in high interfacial shear stresses. The resulting micromovement may then lead to loosening and eventual failure of the implant. A difference in stiffness also changes the distribution of mechanical stress on the surrounding tissues. This can cause the tissue to degenerate or reinodel. In hip replacements. for example, the high stiffness of the implants compared to the bone of the femur can reduce the stress in the bone.[6] This "stress shielding" results in the bone being resorbed by the body. It is also hypothesized that modified stress distributions may result in continuing pain for the patient.[7]

TYPICAL BIOMATERIALS

Metals

The metals commonly used in medical devices are stainless steel (Types 316 and 316 L), cobalt-chromium-based alloys, titanium. and titanium-based alloys. Metals are used extensively in orthopedic surgery for load-bearing devices. such as artificial joints and fixation devices (wires. pins. screws; fracture plates. etc.). Other metals include tantalum, gold, and mercury alloys: the latter two are used predominantly in dentistry.

One of the main problems of metallic orthopedic implants is that they are much stiffer than the natural tissues they replace (see Table 1). As described above, a difference in stiffness between adjacent materials can lead to a number of problems. including loosening as a result of micromovement and bone resorption due to stress shielding. Adequate fixation of an orthopedic implant to the surrounding bone is therefore of paramount importance. It can be achieved using a number of methods. such as interference fitting. screws, poly(methyl methacrylate) bone cement. and coatings to achieve a chemical bond or porous ingrowth.[5]

Table I Typical material properties of metals and bone

Material	Elastic modulus (GPa)
Stainless steel	200
Co-Cr-Mb alloy	230
Titanium	110
Cortical bone	12–17
Cancellous bone	0 1

Cortical bone it a dense structure located at the surfaces of bones: cancellous bone is an open pore structure located internally. (From Ref. [5].)

Titanium may appear to be the ideal metal. as its stiffness is the closest to bone (Table 1). It has the lowest density (nearly half that of the other two metals). and it has the highest resistance to corrosion due to the formation of a nonreactive layer of titanium oxide on the surface of the metal. However. its shear strength is low, making it unsuitable for use in screws and bone plates. It also has a high coefficient of friction when in contact with itself or another metal. making it unsuitable as a load-bearing surface.

Stainless steel. which is typically used for bone plates, screws, and nails. is particularly susceptible to corrosion, although its chromium and molybdenum content (about 17% and 3%. respectively) helps to make it more resistant. Cobalt-chromium-molybdenum alloys exhibit excellent durability and strength. making them apposite for artificial joints, although their coefficients of friction make them unsuitable for load-bearing surfaces.

One interesting alloy of titanium and nickel, called Nitinol, exhibits shape-memory properties. Below a particular temperature (the transformation temperature), the crystal structure of the alloy is such that it can be plastically deformed (martensitic). As the alloy is heated, the crystal structure alters to one that is more ordered and rigid (austenitic). and the deformed metal reverts to its original shape.[8] This effect has been exploited in a number of devices. including a stent (a device used to hold open passageways such as arteries). The stent is placed inside a small-diameter catheter for insertion into the body, where it expands on being warmed to body temperature.[8]

Tantalum, which is used for a number of applications,[9] was recently made into a porous material that could be used for bone reconstruction. The porous structure is made by depositing the metal onto a vitreous carbon scaffold using chemical vapor deposition/infiltration techniques. Its low structural density means that its stiffness (2.5–4 GPa) is closer to that of natural bone than the solid metal. and the porosity means that bone can fully integrate into the structure. forming an excellent bond.[9]

Ceramics and Glasses

Ceramics, such as the coinmonly used Alumina ($A1_2O_3$) and Zirconia (ZrO_2), tend to have a very high elastic modulus (around 400 GPa), have a low coefficient of friction. and are resistant to wear. These properties make them useful as the load-bearing surfaces in orthopedic implants,

such as hip prostheses.[6] Another of their properties. which leads to them being popular for dental applications. is their inertness, which makes them very biocompatible. However, more interesting ceramics exist that, rather than being inert. provoke a beneficial response from the body.

Calcium phosphate is a mineral found in several different forms. including hydroxyapatite. β-whitlockite, and tricalcium phosphate. The crystal structure of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], is similar to that of the calcium and phosphate apatites that are present in the mineral phase of bone. It was found that if a metallic implant is coated with a calcium-phosphate-based material, the formation of bone around the implant is accelerated, and surface contact in the early stages of healing is improved.[10,11] This is because, in addition to providing a porous surface with which the bone can integrate. the coatings are able to form a direct chemical bond with the bone.

Bioactive glasses are another type of material that actively promote a useful response from the tissue into which they are implanted. Bioactive glasses are a family of glass materials made from Na_2O–CaO–P_2O_5–SiO_2. Certain formulations of these glasses are able to form very strong bonds with bone. When the glass is exposed to fluids in the body. a 12-stage reaction occurs[1*] that involves formation of a hydroxyl carbonate apatite (HCA) layer on the outer surface of the glass. It is this outer layer that is thought to be crucial for bonding to bone to occur.

A smaller subset of the bioactive glasses can also form bonds with collagen.[12] In vitro tests showed that the collagen fibrils integrate into the outer HCA layer. This is similar to the way that collagen fibrils in natural tissues such as cartilage. ligament. etc.. bond to the underlying bone. Hence. bioactive glasses have the potential to provide a solution to the problem of how to attach replacement soft tissues such as ligaments or the menisci of the knee.

The main drawback of bioactive glasses is their brittle properties and insufficient strength, making them unsuitable for load-bearing applications. However, combining them with polymers was shown to improve the mechanical properties while retaining the bioactivity.[13]

Polymers

Many different polymers are used in a variety of medical devices.[1] These range from ultrahigh-density polyethylene, which is used as the load-bearing surface of artificial joints,[6] to much softer elastomers. such as silicones. which are employed. among other uses, as finger joint replacements and maxillofacial prostheses.

One particular class of polymers that absorb and retain significant amounts of water are called hydrogels. The water in a hydrogel is retained in the gel by hydrogen bonding to hydroxyl groups along the polymer backbone. Over the years, there has been considerable controversy on the exact state of the water.[14] However, some of the most recent research, using thermal analysis suggests that the water is present as three different phases in dynamic equilibrium.[15]

Bydrogels have many actual or potential uses—most notably as contact lenses, wound dressings. coatings, and drug delivery systems.[16] The hydrophilic nature of hydrogels, plus their high water content. makes them extremely biocornpatible. As a coating on a device such as a catheter, particularly in combination with antimicrobial agents. they can help prevent the buildup of bacteria that may otherwise lead to blockage and infection.

As a contact lens. their soft rubbery properties make them comfortable to wear. However. one of their limitations is the high water content and thin cross section required to achieve sufficient oxygen transport to the cornea. This is extremely important. as the cornea does not have its own vascular supply and relies on obtaining oxygen in this way.

The more recently developed silicone hydrogels have the potential to solve this problem because although they have relatively low water contents (about 30%). in comparison to the conventionally used hydrogels, their oxygen permeability is far higher.[1] This characteristic, combined with their good biocompatibility, has allowed them to be manufactured into lenses that can be worn continuously for up to a month.

Another exciting development for hydrogels is self-assembly.[18] Self-assembly means that the constituent molecules of a material organize themselves, under thermodynamic equilibrium, into a well-defined and stable configuration, held together by noncovalent bonds. The structural form of the molecules determines the way they fit together. and this can be influenced by environmental factors including temperature and pH value.[18]

Biodegradable polymers. as their name suggests. slowly degrade once they are implanted into the body. Several biodegradable polymers have been approved for implantation [poly(glycolide), poly(lactide), poly(ε-caprolactone), poly(dioxanone), and their copolymers] and have been manufactured into a number of medical devices, such as sutures, screws, and tissue repair barbs.[1] One advantage of using a biodegradable material is that additional surgery to remove a temporary device is unnecessary. Also, in applications such as fixation of a broken bone, the gradual degradation of the device means that load is transferred to the bone as it heals; this can help the bone regain its complete strength.

Degradation occurs due to hydrolysis of the polymer backbone or by enzymatic attack. which breaks the polymer into increasingly smaller units. The resulting

compounds may then dissolve into the surrounding body fluids or may be metabolized and excreted by the body [e.g., lactic acid removed as a product of poly(lactide)].

Tissue-Engineered Materials

Tissue engineering is perhaps most memorable to many people as an image of an ear growing on the back of a mouse.[20] Currently, the only commercially available product is skin grown from human fibroblasts on a biodegradable mesh. However, research continues toward achieving the ultimate aim of growing a fully functioning tissue or organ using cells from the patient's own body (e.g., Ref. [21]).

One of the potential benefits of tissue engineering is that it could eliminate the need for donor tissue and organs, which are in short supply. Additionally, there is less likely to be the problems of rejection or disease transfer that occur when using allografts or xenografts.

Essentially; the technique involves seeding cells onto a scaffold and providing them with the appropriate nutrients, growth factors. and environmental conditions.[22] When they sufficiently proliferated, the structure can be implanted into the patient, where it becomes integrated into its surroundings with the formation of blood vessels, etc. The scaffold not only determines the shape of the tissue but can also provide mechanical support as it develops. Once the tissue forms. the scaffold becomes redundant. Hence, materials for scaffolds are ideally made from synthetic biodegradable polymers, as described in the previous section. or from natural polymers such as collagen.

Fabrication of a three-dimensional scaffold can be achieved using a number of methods. One technique that was recently explored is fused deposition modeling (FDM). This is a rapid prototyping method, where the material [poly(ε-caprolactone)] is heated to just above its melting temperature and extruded as a thin thread that is laid down in layers.[23] Effectively. any three-dimensional structure can be made providing there is a computer file describing its geometry; this has useful applications for defining scaffolds from medical images.

The future success of tissue engineering is heavily dependent on understanding what external factors influence cell behavior (e.g., cell attachment, proliferation, migration, and expression of extracellular matrix). The laying down of extracellular matrix components such as collagen, for example, is important for growing tissues like ligaments, which require the collagen to be aligned in a specific direction.[24] So far, various external stimuli have been shown to influence cell behavior. These include surface topography in the form of grooves or surface texture and mechanical deformation.[22]

CONCLUSION

Since the first metal implants used in the early part of the twentieth century, biomaterials for use in medical devices have developed significantly. In the last few decades, materials technology has become more sophisticated, and there has been a move from the use of passive, inert materials toward ones that interact with the body to elicit a beneficial response or more closely mimic the natural tissues. However, there is still a need for further developments, and a recent report highlighted the desperate need for new biomaterials in all clinical disciplines.[2]

In the shorter term. improvements in existing materials are required. For example, 10% of hip replacement operations are revision surgeries. These are more technically difficult than the primary surgeries, are considerably more expensive, and tend to be less successful.[2] Hence, improvements can still be made in the materials used for hip prostheses and the methods used to fix them in place.

Over the longer term, a demand exists for materials that can provide permanent solutions. Tissue engineering may provide solutions to some of these needs in the future. However, despite recent success in this area, the development of functional tissue may still be a long way off. For example, it was estimated that it may take another 10–15 years to develop tissue-engineered kidneys.[2] Furthermore, for load-bearing tissues such as ligaments. the mere development of a material with suitable mechanical properties is only one concern. A major problem that requires resolution. is how to attach the ligament to the bones. However: as previously described, bioactive glasses may provide a solution.

In this article. the various biomaterials described have, in general, been considered separately. However, the use of biodegradable polymers in tissue engineering[23] and the fabrication of hydrogels by self-assembly[25] suggest that future developments in biomaterials research may benefit from an increasingly integrated approach.

Biosensors

Jun-ichi Anzai
Tohoku University, Sendai, Japan

INTRODUCTION

Enzyme–substrate, antibody–antigen, and other protein–ligand interactions are representative constituents of biological supramolecular systems. The structure and function of some of these biological supramolecular systems were mimicked by chemists in order to construct synthetic counterparts such as host-guest compounds, self-assembled monolayers and ordered multilayers, and related molecular assemblies. On the other hand, little was reported on the development of artificial supramolecular systems that use proteins as building blocks. Described in this article is the fabrication of biosensors using protein-based supramolecules based on avidin–biotin and lectin–sugar interactions.

BIOSENSORS

Biosensors comprise a class of analytical devices that are fabricated by combining transducers. such as electrodes and optodes, with biological materials. including enzyme. antibody, and other proteins, for medical. environmental. or industrial applications. The biological materials are usually immobilized on the surface of the sensing part of the transducers in order to fabricate biosensors. Therefore, the technique of protein immobilization is crucial for developing high-performance biosensors. Numerous procedures for protein immobilization. including physical adsorption. entrapment into a polymer matrix, covalent bonding to a reactive surface, self-assembling on the surface, and others were reported. Physical adsorption is a convenient and simple way to immobilize proteins on the surface of the transducer, because proteins tend to be adsorbed more or less to any type of solid surfaces. Thus. the surface of the transducer can be modified irreversibly by immersing the transducer in an aqueous solution of dissolved proteins, which are then adsorbed into the transducer. However. this protocol suffers from the drawback that proteins often lose their biological activity due to denaturing on the surface (i.e., surface-induced conformational changes). resulting in a short life of the sensor. This drawback can be overcome by entrapping proteins into a polymer matrix on the surface of transducer. because the proteins are entrapped in organic materials without direct contact with the surface of transducer. On the other hand: covalent bonding and self-assembly of proteins on the surface are sophisticated techniques that enable one to design structures and functions of sensors, although training to learn certain skills is often required. Recently, attention was devoted to the molecular-level modification of the surface of an electrode with proteins, in which the electrode surface is covered with a nanometer-sized thin film. One of the advantages of the molecular-level modification is that rapid-response sensors can be fabricated by removing the conventional type of thick membrane from the surface of the electrode. Another merit is that this method makes it possible to arbitrarily tune the performance of the sensors on the basis of the molecular-level design of the protein film.

AVIDIN–BIOTIN SYSTEMS

Avidin is a tetramer protein (molecular mass: 67.000) found in egg white, and each subunit of avidin contains a binding site to biotin and forms a highly stable complex noncovalently (the binding constant; $10^{15}\ M^{-1}$) (Fig. 1).[1] Therefore, a single avidin molecule can accommodate up to four biotin molecules simultaneously. This strong and specific binding led to its widespread use in diagnostic and biochemical assays in which the formation of practically irreversible complexes is required. This is because avidin binds not only biotin but also its derivatives, with a carboxyl side chain that is modified covalently with protein and other macromolecules. Many kinds of activated biotins for labeling and biotin- or avidin-labeled reagents were developed for this purpose and are now commer-. cially available.

A crystallographic study of avidin shows that the interactions include a hydrogen-bond network between the biotin ureide group and amino acid residues in the binding site, an interaction between the biotin sulfur atom and hydroxyl group of threonine in avidin, and a hydrogen bond between carboxylate in the biotin side chain and protein backbone.[2,3] Among these. the first interaction plays a dominant role in biotin binding. In the binding pocket, several polar residues are available, including asparagine, tyrosine, serine. and threonine, which participate in the network of hydrogen bonds with biotin

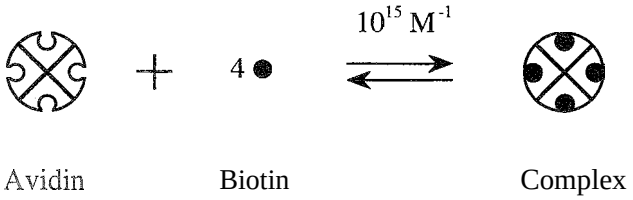

Fig. 1 Avidin–biotin complexation

ureide groups. In addition, the contributions of hydrophobic and van der Waals' interactions between biotin and aromatic residues in the binding pocket were also suggested. Avidin is a tetrameric protein with 222 molecular symmetry. and each subunit is organized in an eight-stranded antiparallel orthogonal β-barrel.[4] An avidin molecule (tetramer) is in a cubic-like shape (ca. 5.5 x 6 *x* 4 nm). The binding sites to biotin are arranged in two pairs on opposed faces of the molecule. The two binding sites on the same faces (6 x 5.5 nm) are separated 2–2.5 nm from each other.[5] The shape and size of avidin makes its use promising as a building block for constructing supramolecular protein architectures.

BIOSENSORS MODIFIED WITH AVIDIN–BIOTIN ARCHITECTURES

Electrochemical biosensors are usually fabricated by immobilizing enzymes or other functional proteins on the surface of electrodes. Illustrated in Fig. 2 is a typical structure and reactions involved in a glucose sensor fabricated by immobilizing glucose oxidase (GOx) on the surface of a inetal electrode. The chemical events on the electrode surface induced by GOx can be transferred into the output signals (i.e., electric current). Thus, the immobilization technique of enzyme is crucial to the development of high-performance biosensors. Therefore. many techniques were developed for immobilizing proteins. Early studies of enzyme biosensors often employed thick polymer membranes (thickness: 0.01–1 mm) in which enzymes are physically or chemically anchored. They sometimes suffer from such drawbacks as insufficient reusability and slow response due to the suppressed diffusion of analytes in the thick polymer membrane. To overcome these probiems. attention was recently devoted to the molecular-level modification of electrode surfaces (thickness: 10–100 nm) with enzymes or other proteins. An avidin–biotin system was employed for this purpose. For another example. in 1989, Walt and coworkers iinmobilized biotin-modified enzymes (urease. esterase. and penicillinase) on the surface of biotin-modified optical fibers using avidin as a binder.[6] They demonstrated the general use of this procedure in immobilizing any kind of enzyme. Gunaratna and Wilson also used an enzyme column in which enzymes were immobilized through avidin–biotin complexation.[7]

It may be possible to build up a two- or three-dimensional architecture composed of proteins. using avidin and biotin-labeled enzymes as building blocks. An enzyme multilayer (illustrated in Fig. 3) would be constructed using enzymes tagged with more than two biotin residues. because avidin contains four biotin-binding sites per molecule. The biotin-binding sites are fortunately located in two pairs on the opposing faces of an avidin molecule. In order to check the possibility of multilayer formation, we immobilized fluorescein-5-isothiocyanate (FITC)-conjugated avidin and biotin-labeled GOx alternately on a quartz slide and monitored the absorption spectra of the modified slide.[8] A silylated quartz slide was immersed in FITC-avidin and biotin-labeled GOx solutions alternately and repeatedly. which provided both sides of the slide with the protein multilayer. FITC-avidin is immobilized in each layer as a roughly monomolecular layer.

An electrochemical technique. cyclic voltammetry (CV), was employed for further characterization of the GOx multilayer film.[9] In the GOx-catalyzed oxidation reaction of glucose, a cofactor flavine adenine dinucleotide (FAD), which is contained at the active center of GOx, oxidizes glucose to gluconolactone. The resultant $FADH_2$ is converted back to the active FAD form by O_2. In the conventional type of enzyme sensor. the H_2O_2 generated from O_2 is oxidized at the electrode surface. It was reported that a GOx-catalyzed reaction can be mediated by synthetic redox compounds such as hydroquinone and ferrocene.[10–13] These redox compounds mediate electron relay from $FADH_2$ in GOx to electrode (i.e., electron mediator). In this situation, the magnitude of oxidation current in CV of the electron mediator would be a function of the loading of the enzyme on the electrode surface. Therefore. the CV measurements in the solution of a constant amount of dissolved mediator and glucose

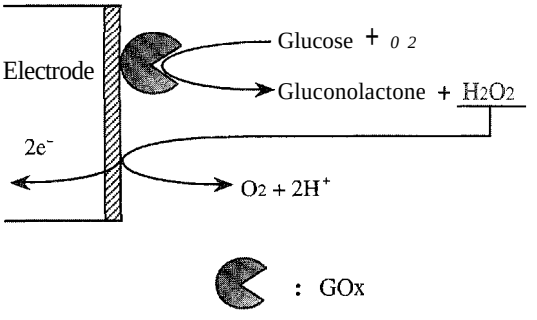

Fig. 2 Chemical reactions of a glucose sensor

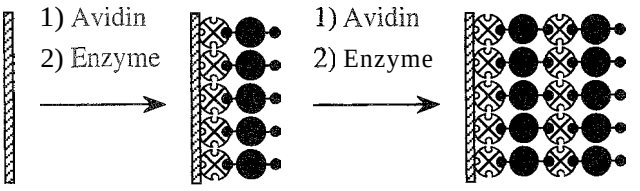

Fig. 3 Enzyme multilayer films composed of avidin and biotin-labeled enzymes

reveal the loading of GOx immobilized on the electrode. Thus, the oxidation current in CV was measured in the presence of ferrocenemethanol as mediator. The oxidation current depended linearly on the number of GOx layers. confirming that the present procedure can afford an enzyme multilayer composed of layers containing a constant amount of GOx.

A merit of enzyme multilayer films is that two or more different kinds of enzymes can be assembled simultaneously in the film, resulting in multienzyme biosensors. As an example, we prepared interference-free glucose sensors by assembling ascorbate oxidase (AOx) together with GOx on the Pt electrode.[14] Glucose sensors often suffer from interference arising from the direct oxidation of oxidizable substances such as ascorbic acid (vitamin C) and uric acid in biological fluids.[15] For the elimination of ascorbate interference, the enzyme multilayers composed of 10 GOx layers and an additional 10 AOx layers were assembled by depositing avidin and biotin-labeled GOx and AOx in a stepwise formation. In this glucose sensor, ascorbic acid is oxidized to an electrochemically inactive clehydroascorbic acid in the outer AOx layer, and the interference can be eliminated. Another example of the bienzyme multilayer-modified sensor includes acetylcholine sensors prepared using choline oxidase (ChOx) and choline esterase (ChE).[16]

It should be noted here that the avidin–biotin system can be applicable to the construction of many different types of protein architectures containing enzymes[17–19] and antibodies.[20,21] The biggest advantage of an avidin–biotin system is that the proteins can be strongly immobilized through biological affinity without cross-linking or chemical bonding. resulting in acceptable long-term stability.

LECTIN–SUGAR SYSTEMS

Eectins are made up of a group of sugar-binding proteins widely found in plants and animals. Concanavalin A (Con A) is isolated from jack bean (*Canavalia ensiformis*) and is studied extensively among lectins. Con A (molecular mass: 104.000) is known to contain four identical binding sites to α-D-mannose and α-D-glucose (binding constant: 10^5–10^6 M^{-1}).[22,23] Therefore, if an enzyme molecule is labeled with several residues of mannose or glucose units. one can expect that an alternate deposition of Con A and the sugar-labeled enzyme gives rnultilayer structures. as in the case of an avidin–biotin system. Glycoproteins can be used directly as materials for this purpose. because they inherently contain sugar chains on the surface. In case proteins do not contain a sugar chain. the surface of the protein may be labeled with sugar by using phenyliso-thiocyanate derivatives of sugar (Fig. 4). which react to an amino group in the protein. We used Con A and GOx and horseradish peroxidase (HRP), which contain sugar chains on the surface, for constructing supramolecular protein architectures, and they are employed as a sensitive layer of enzyme biosensors.

BIOSENSORS MODIFIED WITH CON A–SUGAR ARCHITECTURES

Con A–GOx inultilayer films were constructed using a native GOx, which inherently contains mannose residues on the surface of the polypeptide chains.[23,24] A layer-by-layer deposition of Con A and native GOx afforded a inultilayer thin film composed of Con A and GOx layers. The multilayer film was coated on the surface of a Pt electrode to prepare glucose biosensors. The output current of the Con A/GOx inultilayer film-modified electrode increased with an increasing number of layers; confirming that GOx is catalytically active in the film. Also, a constant amount of GOx was immobilized upon each deposition. The Con A–GOx multilayer-modified glucose sensors showed rapid responses to glucose. the response times being 10–15 sec for the sensors modified with 10 Con A–Gox layers. The rapid responses of the sensors can be ascribed to the thin nature of the rnultilayer films (the thickness of the unit layer: 10–15 nmj. The sensors exhibited a linear calibration over the concentration range of 1×10^{-5} to 2×10^{-2} M glucose, which covers the normal and diabetic blood levels of glucose.

We also used HRP. because this enzyme is reported to contain ca. 18% sugar chains on the surface.[25,26] A layer-by-layer deposition of Con A and HRP afforded a rnultilayer film as expected. and HRP exhibited catalytic

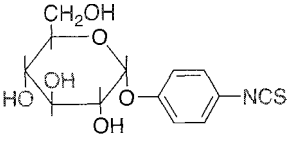

Fig. 4 Phenylisothiocyanate derivative of sugar

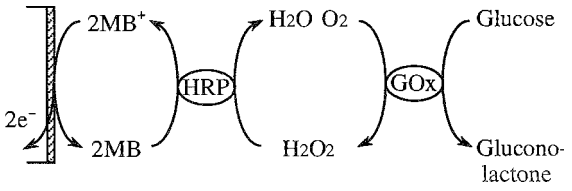

Fig. 5 Successive reactions of GOx and HRP.

activity to H_2O_2 *in the presence of methylene blue* (MB) *as the electron mediator. The* HRP–GOx *bienzyme* multilayer *films were prepared on the surface of a* Pt *electrode so as to develop glucose sensors. which detect glucose through successive reactions depicted in* Fig. 5. *In these bienzyme sensors. the response* current *depended on the geometry of the enzymes in the film. In practice, we prepared* four *different types of* multilayer *films:* $(HRP)_5$ + $(GOx)_5$, $(GOx)_5$ + $(HRP)_5$, $(HRP + GOx)_5$, *and* (GOx + HRP)$_5$. *These* films *contained an identical* number *of enzyme layers. but the sequence* of *enzyme layers differed. Among* the *films, the highest response was observed for the* $(HRP)_5$ + $(GOx)_5$ *film. which* is *composed of inner* $(HRP)_5$ *and outer* $(GOx)_5$ *layers. Thus. the present technique is useful for designing the* molecular geometry *of the* film.

We emphasize here that the Con A system can be used for immobilizing glycoproteins directly, without chemical modifications. which often induce deactivation of the biological activity of the protein.

CONCLUSION

Supramolecular protein assemblies prepared by a layer-*by-layer deposition technique are useful in the development of high-performance biosensors. Avidin–biotin and* lectin–sugar *systems are employed for this purpose. Many* kinds *of enzymes can be used as building blocks for the protein* assemblies *by modifying them with biotin and sugar residues.* Glycoenzymes *can be used to prepare* Con *A and enzyme* multilayer *assemblies without pretreatment. The advantages of this technique include rapid response of the biosensors due to the thinness of the* multilayer *film and versatile design of the geometries of bienzyme films.*

Bond-Stretch Isomerism

Gerard Parkin
Columbia University, New York, New York, U.S.A.

INTRODUCTION

Bond-stretch isomerism may be defined as the phenomenon whereby molecules of the same spin state, on the same potential energy surface, differ only in the length of one or several bonds.[1–4] In contrast to exhibiting a single-minimum on the potential energy surface for the stretching of a bond. the existence of bond-stretch isomers requires the presence of a double-minimum, with a significant barrier between the two minima (Fig. 1). The theoretical concept of bond-stretch isomerism, with the existence of a double-minimum on a potential energy surface. was first discussed by Hoffmann in a 1972 study on a series of hypothetical organic molecules, of the types illustrated in Fig. 2.[5–7] Interestingly. experimental evidence in support of bond-stretch isomerism was actually reported shortly prior to Hoffmann's proposal. Specifically. Chatt reported in 1970 that the molybdenum oxo complex *mer*-$MoOCl_2(PMe_2Ph)_3$ could be isolated in blue and green isomeric forms.[6] Originally, these complexes were considered to be geometric isomers, namely *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ and *trans-mer*-$MoOCl_2(PMe_2Ph)_3$, differing only in whether the two chloride ligands were cis or *trans*. X-ray diffraction studies on the blue isomer established a *cis* configuration. from which it was assumed that the green isomer possessed a *trans* configuration (Fig. 3).[6,8] However, X-ray diffraction studies on the green analogue *mer*-$MoOCl_2(PEt_2Ph)_3$ revealed that the chloride ligands were also cis and not *trans*.[8] Thus, the structures of blue *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ and green *cis-mer*-$MoOCl_2(PEt_2Ph)_3$ were similar. with the exception that the Mo=O bond length in green *cis-mer*-$MoOCl_2(PEt_2Ph)_3$ [1.803(11) Å] was significantly longer than that observed in blue *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ [1.676(7) Å]. As a result, Chatt suggested that the principal difference in the blue and green isomers of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ centered on their Mo=O bond lengths, and he termed these complexes "distortional isomers" (Fig. 3).[7a] In accord with his proposal. the actual green isomer of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ was structurally characterized and also found to possess a long Mo=O bond length of 1.80(2) Å.[10] Consistent with the different Mo=O bond lengths, the blue and green isomers exhibited slightly different $\nu_{Mo=O}$ stretching frequencies (blue. 954 cm^{-1}; green 943 cm^{-1}), and different stabilities, with solutions of the green isomer irreversibly converting to the blue isomer upon gentle heating.

Following Chatt's report, experimental evidence for bond-stretch (or distortional) isomerism was reported for a variety of systems, as illustrated in Fig. 4.[3] The blue and green tungsten oxo derivatives $[(Me_3tacn)W(O)Cl_2]^+$ represented particularly important examples. since these were reported to be the first set of bond-stretch isomers that were stable in solution for several days and also did not interconvert at temperatures up to ca. 180°C. The blue and green isomers also exhibited different $\nu_{W=O}$ stretching frequencies of 980 cm^{-1} and 960 cm^{-1}, respectively, with the higher energy vibration corresponding to the shorter W=O bond. With a series of transition metal complexes that exhibit bond-stretch isomerism now in existence. Jean, Lledos. Burdett, and Hoffmann extended the earlier calculations on hypothetical species to rationalize the presence of double-minima in the potential energy surfaces of the complexes actually reported to exhibit the phenomenon.[11]

A REINVESTIGATION OF BOND-STRETCH ISOMERISM IN *cis-mer*-$MoOCl_2(PMe_2Ph)_3$

In 1991, a series of detailed crystallographic studies resulted in the discovery that the original example of bond-stretch isomerism in transition metal complexes was an artifact due to crystallographic disorder."'".'" Specifically, the green "isomer" of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ was identified as a mixture of *blue cis-mer*-$MoOCl_2(PMe_2Ph)_3$ and yellow *mer*-$MoCl_3(PMe_2Ph)_3$. Evidence for the presence of *mer*-$MoCl_3(PMe_2Ph)_3$ was provided by ^{1}H-NMR spectroscopy. Thus, although the ^{1}H-NMR spectrum of *mer*-$MoCl_3(PMe_2Ph)_3$ is characterized by broad paramagnetically shifted signals, careful examination provided evidence that the green ''isomer'' of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ was contaminated by *mer*-$MoCl_3(PMe_2Ph)_3$. It is important to emphasize that the green "isomer" of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ was not a heterogenous mixture of crystals of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ and *mer*-$MoCl_3(PMe_2Ph)_3$ but was actually a homogenous mixture such that each single crystal was a solid solution of the two compounds. The formation of

Fig. **I** Potential energy surfaces for (a) a normal X–Y bond and (b) a pair of X–Y bond-stretch isomers

such a solid solution is made possible by the fact that ***cis***-*mer*-$MoOCl_2(PMe_2Ph)_3$ and *mer*-$MoCl_3(PMe_2Ph)_3$ are isostructural and only differ by the exchange of oxygen for chlorine.

The impact of small amounts of the impurity *mer*-$MoCl_3(PMe_2Ph)_3$ on the structure determination is profound and strongly influences the *apparent* Mo=O bond length. The apparent lengthening is a result of the fact that the location of an ''atom'' at the disordered site is a weighted average of oxygen and chlorine positions (Fig. 5). Since the Mo–Cl bond is longer than the Mo=O bond. the presence of a chloride contaminant has the effect of apparently lengthening the Mo=O bond. Examination of Fig. 5 indicates that only very small amounts of the *mer*-$MoCl_3(PMe_2Ph)_3$ impurity are required to have a significant effect on the apparent Mo=O

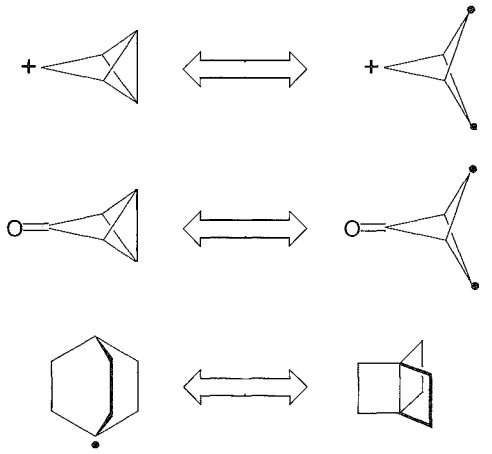

Fig. *2* Some hypothetical isomers that were studied theo retically.

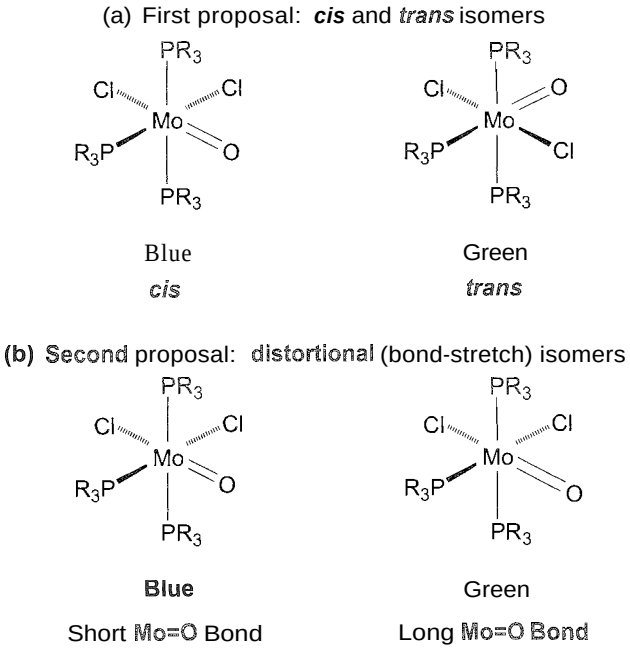

Fig. *3* Original. incorrect proposals for the structures of blue and green isomers of $MoOCl_2(PMe_2Ph)_3$. (a) ***cis*** and *trans* isomers: (b) distortional (bond-stretch) isomers with short and long Mo=O bonds.

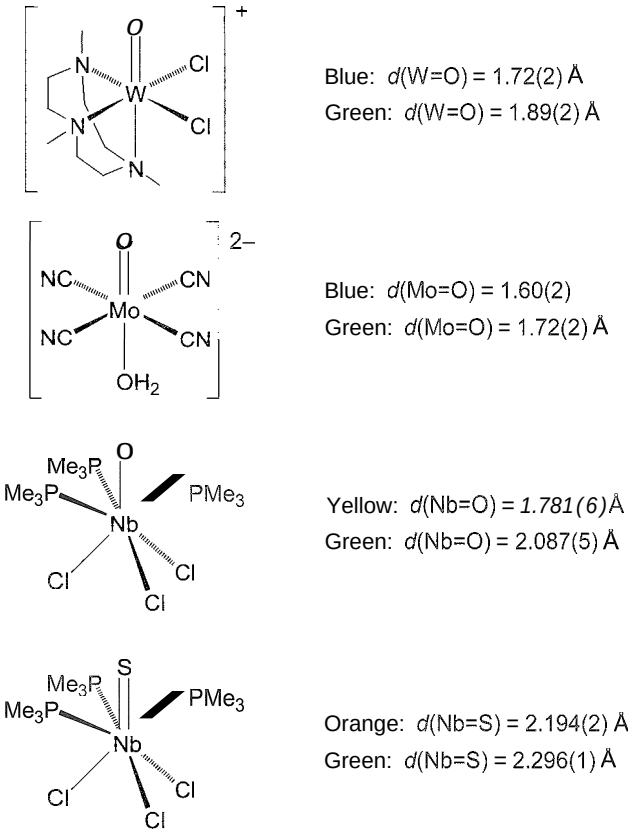

Fig. **4** Other examples of originally proposed bond-stretch isomers.

bond length. The reasons for this are twofold: (i) the Mo–Cl bond (ca. 2.45 Å) is considerably longer than the Mo=O bond (ca. 1.68 Å), and (ii) the scattering power (which is a function of the number of electrons) of chlorine is much greater than that of oxygen. Despite the contamination by chlorine being sufficient to apparently lengthen the Mo=O bond, the thermal parameter was not abnormal, and so the x-ray structure provided no evidence for contamination.

The reevaluation of the structures of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ demonstrated that there was no structural evidence for bond-stretch isomerism for the complexes that were originaily proposed to exhibit the phenomenon. Furthermore. the origin of the two different $\nu_{Mo=O}$ stretching frequencies for *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ in the solid state was attributed to the existence of two different modifications, with only one value being observed in solution.[9,10] This reevaluation of bond-stretch isomerism in *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ also cast doubt on the other proposed examples of bond-stretch isomerism. Indeed. subsequent studies on $[(Me_3tacn)W(O)Cl_2]^+$ demonstrated that the system was considerably more complex than that for *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ and was composed of three components with different oxidation states: $[(Me_3tacn)W(O)Cl_2]^+$, $[(Me_3tacn)W(O)_2Cl]^+$, and $[(Me_3tacn)W(O)Cl(solv)]^+$.[15] Likewise, $NbCl_4(PMe_3)_3$ has been recognized as an impurity for influencing the apparent Nb=O and Nb=S bond lengths in $Nb(O)Cl_3(PMe_3)_3$ and $Nb(O)Cl_3(PMe_3)_3$, respectively.[16]

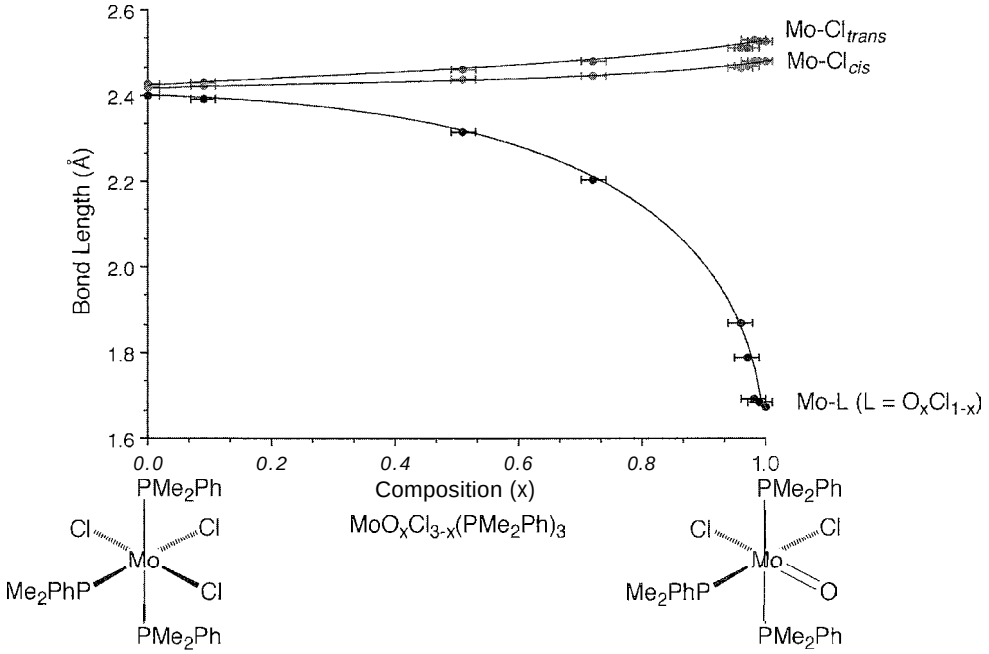

Fig. 5 Variation of apparent Mo=O bond length as a function of composition.

SPIN-STATE ISOMERISM AND RELATED PHENOMENA

Blue and green *cis-mer*-$Mo(O)Cl_2(PMe_2Ph)_3$ were originally classified as bond-stretch (distortional) isomers because there was no simple explanation for the existence of a pair of complexes in which the only significant difference resided in the length of one of the bonds. In this regard, it is important to note that there are several other examples of isomerism in which a bond between a pair of atoms differs in length. but the situation is fundamentally different than that proposed for *cis-mer*-$Mo(O)Cl_2(PMe_2Ph)_3$, because the change in bond length is accompanied by other significant geometric and/or spin-state changes.[17] For example. there are many transition–metal complexes that exhibit different spin states (high-spin/low-spin equilibria) for which significant structural changes are also observed.[18,19] Likewise, $[Cp^*RuCl_2]_2$ exists as singlet and triplet isomers that differ substantially in their Ru–Ru separations (2.93 A versus 3.75 Å), Ru–Cl–Ru bond angles (76.5° versus 100.2°), and Ru–Cl bond lengths (Fig. 6).[20] In addition. $[(MesP^*)_2CHCSiMe_3]$ exists in monocyclic and bicyclic structures (Fig. 6) with planar and puckered geometries. respectively, with the latter having a shorter C–C bond length (1.52 A versus 2.47 Å).[21] The trinuclear dipyridylamide cobalt complex $Co_3(dpa)_4Cl_2$ [dpaH = di(2-pyridyl)amine] exhibits a particularly interesting structural variability (Fig. 6).[22] Specifically. depending on the crystalline form. the Co_3 chain may be symmetrical (*s*-), with Co—Co distances of ca. 2.3 Å, or unsymmetrical (u-) with Co—Co distances of ca. 2.29 Å and 2.47 Å; however, only the symmetrical species exists in solution. It should also be noted that while the *s*-$Co_3(dpa)_4Cl_2$ and *u*-$Co_3(dpa)_4Cl_2$ species are isomeric, the compositions of the crystals are different by virtue of the solvents of crystallization, and thus the crystalline materials are not isomeric. Related chromium complexes $Cr_3(dpa)_4X_2$ are also known. and depending upon the nature of the axial ligands and the solvent of crystallization. the Cr_3 chain is likewise either symmetrical or unsymmetrical.[23] The complexes $(Cp^*RuCl_2)_2$, $[(MesP^*)_2CHCSiMe_3]$, and $Co_3(dpa)_4Cl_2$ represent extremely interesting examples of isomerism but are distinct from the bond-stretch isomerism proposed for *cis-mer*-$Mo(O)Cl_2(PMe_2Ph)_3$ by virtue of the fact that the lengthening of one bond is compensated for by other significant geometrical changes.

OTHER EXAMPLES OF CRYSTALLOGRAPHIC DISORDER RESULTING IN ANOMALOUS BOND LENGTHS AND THE INCORRECT FORMULATION OF COMPOUNDS

The interpretation of x-ray diffraction data in providing experimental evidence for bond-stretch isomerism in *cis-mer*-$Mo(O)Cl_2(PMe_2Ph)_3$ provides an extreme illustration

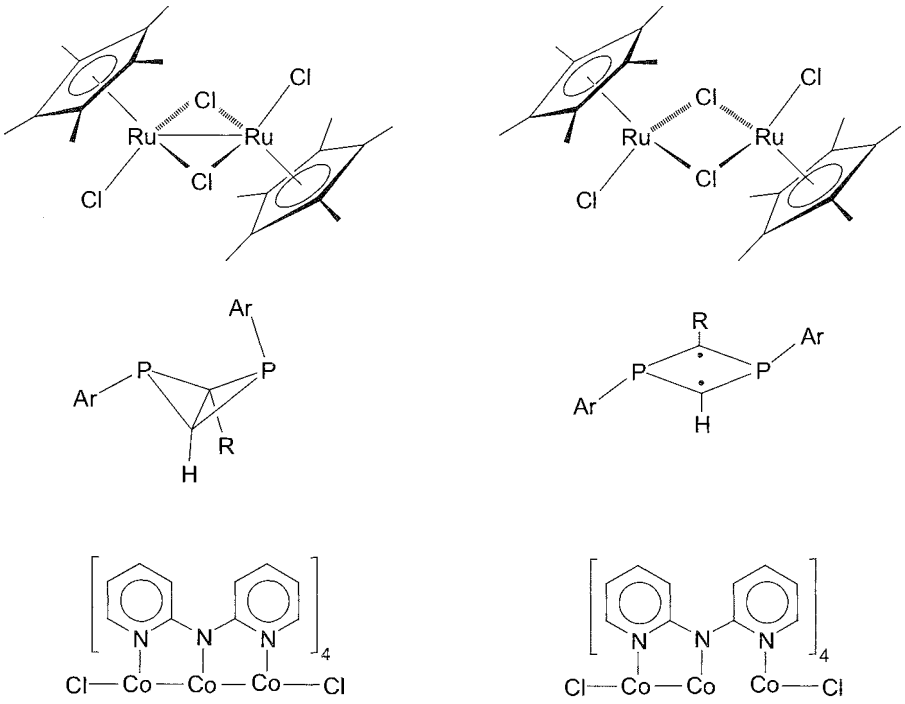

Fig. 6 Structurally characterized examples of isomers with different X–X bond lengths and other structural modifications

of how crystallographic disorder may be deceptive. In this regard. although crystallographic disorder is well known. the presence of a disorder is normally only discerned at the stage of refinement when an anomaly is detected. It is likely that there are many other circumstances where disorder has gone undetected but has, nevertheless, had an impact on the derived structure. Indeed. this notion was reinforced by a series of studies on *tris*(pyrazolyl)hydroborato zinc complexes $[Tp^{Bu^t}]ZnX$ to quantify the sensitivity of the apparent bond length to the composition of a disordered site.[24] Significantly, it was noted that for the series $[Tp^{Bu^t}]ZnCl_{1-n}I_n$, reasonable thermal parameters could still be obtained at irnpurity levels that were sufficient to result in a significant apparent change in the true bond length. Furthermore. the disordered site of the crystal of composition $[Tp^{Bu^t}]ZnCl_{0.5}I_{0.5}$ could be refined very well as bromine. with none of the unusual lengthening of the thermal ellipsoid along the bond vector that would have been anticipated given the true locations of Cl and I. Representative examples of how initially unrecognized disorder resulted in incorrect bond-length determinations include the following:

1. The complex *mer*-$WCl_3(PMe_2Ph)_3$ was reported to possess three different W–Cl bond lengths [2.295(2) Å, 2.437(1) Å, and 2.441(1) Å], with one exceptionally short W–Cl bond.[25] Further studies demonstrated that the origin of the short W–Cl bond was due to disorder with the isostructural oxo complex *cis-mer*-$WOCl_2(PMe_2Ph)_3$.[26]
2. The molecular structure of $Cp_2Hf(CH_3)_2$ was originally reported to exhibit two significantly distinct Hf–CH_3 bond lengths [2.318(8) A and 2.382(7) Å].[27] The origin of this inequivalence was subsequently reinterpreted as arising from cocrystallization with the chloride derivative $Cp_2Hf(CH_3)Cl$.[28]

Crystallographic disorder is not restricted to pairs of structurally similar groups, and controlled disorder between structurally inequivalent groups was investigated by determining the effect that partial occupancy of a halide ligand (X = Cl. Br. I) may exert upon the apparent structure of the cyanide derivative $[Tp^{Bu^t}]ZnCN$.[29] For chloride- and bromide-doped crystals of composition $[Tp^{Bu^t}]Zn(CN)_{0.8}Cl_{0.2}$ and $[Tp^{Bu^t}]Zn(CN)_{0.95}Br_{0.05}$, the disorder between the halide and the carbon of the cyanide ligand was not resolved. Although $[Tp^{Bu^t}]Zn(CN)_{0.8}Cl_{0.2}$ did not refine well in the absence of a disorder model. the bromide-doped crystal of composition $[Tp^{Bu^t}]Zn(CN)_{0.95}Br_{0.05}$ refined well; however, the bond lengths associated with the CN ligand were observed to be incorrect. with a iong Zn–C bond length and a short C≡N bond length. More extreme examples of disorder may also occur. For example, the complex $[Tp^{Ant}]Tl$ cocrystallizes with $[Tp^{Ant}]CoNCS$, so that in effect, a site that is disordered between a vacancy and a chain of *three* atoms results.[30] A representative example of how initially unrecognized disorder between pairs of structurally dissimilar groups resulted in incorrect bond length determinations is provided by the observation that the dinitrogen complex *trans*-$Cr(dmpe)_2(N_2)_2$ was reported to have an unusually short N–N bond length of 0.985(4) Å;[31] however, subsequent studies suggested that the origin of the exceptionally short N–N bond length in this molecule is compositionai disorder with the chloride impurity. *trans*-$Cr(dmpe)_2Cl_2$.[32]

It is important to note that crystallographic disorder is not restricted to the positions of ligands. and the metal centers may also be disordered. As an illustration, the entire $Zr(\eta^2\text{-}Te_2)(CO)$ moiety of the tetragonal modification of $Cp^*_2Zr(\eta^2\text{-}Te_2)(CO)$ is disordered.[33] The nature of the disorder is such that the $Cp^*_2Zr(\eta^2\text{-}Te_2)(CO)$ molecules pack so that the carbonyl ligands are statistically distributed about the crystallographic twofold axis, which bisects the two Zr–Te bond vectors. In the absence of modeling disorder of the zirconium atom, the derived Zr–CO bond was observed to be anomalously long. However. after deliberately displacing the Zr from the twofold axis and refining with half-occupancy, a more reasonable value for Zr–C bond length is obtained.

In addition to affecting observed bond lengths, crystallographic disorder may also result in the incorrect formulation of a compound. Furthermore. the incorrect determination of bond lengths, or misformulation of a compound. do not require a crystal to be impure. because disorder between inequivalent groups can also be achieved as a result of packing identical molecules in different orientations in the crystal. As an illustration. a molecule originally believed to be a dicarbonyl derivative of a ruthenium porphyrin complex, $Ru(TPP)(CO)_2$ (TPP = *meso*-tetraphenylporphyrin dianion) was reported to possess *bent* carbonyl ligands. with a Ru–C–O bond angle of 153.3(9)°.[34] The structure was reinvestigated and determined to be. in fact. a monocarbonyl–ethanol complex Ru(TPP)(CO)(EtOH).[35] However. the CO and EtOH ligands were statistically disordered so that a superposition was observed, resulting in the appearance of an apparently bent carbonyl ligand.

A related example of undetected disorder between the methyl (CH_3) and ethylidyne (CCH_3) ligands of $W(PMe_3)_4(CH_3)(CCH_3)$ resulted in the terminal carbon atom of the disordered ethylidyne ligand not being located. so that the molecule was originally formulated as the dimethyl derivative $W(PMe_3)_4(CH_3)_2$.[36] However. x-ray diffraction studies on a better-quality crystal successfully revealed the presence of the disordered methyl group of the ethylidyne ligand. thereby reformulating $W(PMe_3)_4(CH_3)_2$ as $W(PMe_3)_4(CH_3)(CCH_3)$.[37]

Other examples of disorder resulting in misformulation, include: (1) the structure of the unusual technetium

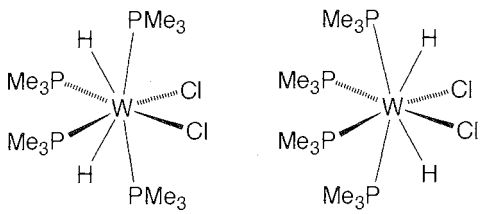
oxo polymer $[Cp^*Tc(\mu\text{-}O)_3Tc]_n$ has been reinterpreted as that of the monomeric rhenium complex, $Cp^*Re(O)_3$, with the original misassignment having been due to a combination of disorder and twinning;[38] and (2) dinitrogen molecules of crystallization have been reinterpreted as disordered dichloromethane solvent.[39]

ANOMALOUS BOND LENGTHS AND INCORRECT FORMULATION OF COMPOUNDS IN THE ABSENCE OF CRYSTALLOGRAPHIC DISORDER

Structural errors in interpretation of x-ray diffraction data are by no means limited to problems resulting from disorder. Thus. it is well known that errors in atom assignment. apace group assignment, and the refinement into a false minimum may each have a dramatic impact upon the accuracy of a structure determination.'" In terms of atom assignment; atoms of similar atomic number have similar x-ray scattering powers, and so it is often difficult to distinguish definitively between such pairs by using x-ray diffraction techniques. As such, the incorrect formulation of a compound can occur even when the crystal is pure and there is no crystallographic disorder. For example, the structures of the bridging chloride complexes $Nb_2(\mu\text{-}Cl)_2Cl_4(SMe_2)_4$, $Ta_2(\mu\text{-}Cl)_2Cl_4(SMe_2)_4$, and $Nb_2(\mu\text{-}Cl)_2Cl_4(EtSCH_2CH_2SEt)_2$ were reformulated as having two μ-S groups. rather than two μ-Cl groups;[40] the structures of the cobalt complex $Co(\eta^2\text{-}S_2CSEt)_3$ were reformulated as that of the chromium derivative $Cr(\eta^2\text{-}S_2CSEt)_3$;[41] the structure of the nickel(III) 1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetate was shown to be that of the cobalt(III) derivative;[42] the structure of the unusual compound $[ClF_6]^+[CuF_4]^-$ was proposed to be that of $[SiF_6]^-[Cu(OH_2)_4]^+$;[43] the structures of both the copper and silver complexes $[1,3,5\text{-}C_6Ph_3H_2]Cu$ and $[1,3,5\text{-}C_6Ph_3H_2]Ag$ were reforinulated as that of the bromine compound $[1,3,5\text{-}C_6Ph_3H_2]Br$[44] and the structure of $Mo(PMe_3)_2Cl_2$ was reformulated as $Zn(PMe_3)_2Cl_2$.[45] The latter is a particularly striking example. because the scattering powers of Zn ($Z = 30$) and Mo ($Z = 42$) are very different.[46]

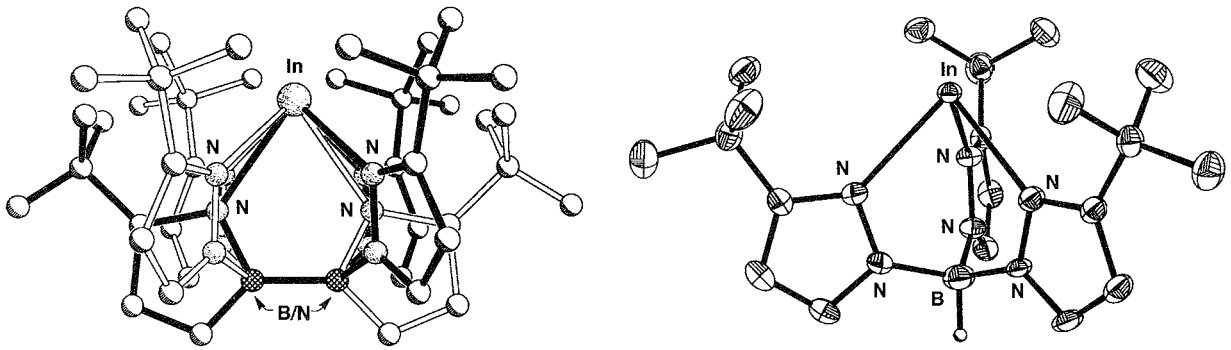
Knowledge of the correct space group is essential for obtaining the correct structure of a molecule. Frequently, however. the space group is incorrectly assigned,[47] with the result that derived bond lengths are in error. In many such examples. the noncentrosymmetric space group is erroneously selected in preference to the true centrosymmetric space group. Noncentrosymmetric space groups present an additional problem in that it is important to establish that the correct absolute structure was determined. For a molecule that crystallizes in a polar space group. two minima exist in a least-squares refinement procedure, corresponding to chemically identical structures related by a reflection perpendicular to the polar axis. The structures corresponding to the two polar configurations typically differ slightly in bond lengths as a consequence of the ''polar dispersion error.''''' so that it is essential to establish that the correct polarity was determined by refining both configurations. As an illustration, the alternating C–C bond lengths in *s-cis*-1,3-butadiene transition metal complexes, and specifically $(\eta^4\text{-}C_4H_6)_2Mn(CO)$, is an artifact due to the incorrect absolute structure being refined.'''' The redetermined nonalternation of bond lengths is more in line with calculations. which predict that donation from the butadiene HOMO and back-donation into the butadiene LUMO should lengthen the terminal C–C bond.

A more extreme problem associated with polar space group results when the derived structure is a hybrid of the two possible polar configurations. Such a situation becomes feasible when the x-ray scattering is dominated by a heavy atom. As an illustration, the structures of $W(PMe_3)_4H_2Cl_2$[50] corresponding to false minima in the refinements are compared to its true structure in Fig. 7. A similar effect was observed for $[\eta^4\text{-}Me_8taa]Pb$.[51] Since the incorrect structures are related to the true structure by a reflection perpendicular to the polar axis of only a *selection* of the atoms. the effect is described as a ''partial polar ambiguity'' to distinguish it from the well-known ''polar dispersion error,'' an effect concerned with two structures related by a reflection perpendicular to the polar axis of *all* atoms. The severity of the pseudosymmetry problem is such that truly noncentrosymmetric structures were incorrectly refined as disordered centrosymmetric structures. For example. the *tris*(pyrazolyl)hydroborato indium complex $[Tp^{Bu^t}]In$ was originally reported to possess an unusual twofold disorder in such a manner that a nitrogen atom of one molecule was coincident with the boron atom of its disordered configuration, as illustrated in Fig. 8. Thus, the disordered configurations are related by a twofold rotation about the In···**B** axis, coupled with a canting of the molecules. Further studies. however. demonstrated that refinement of the correct model in the noncentrosymmetric space



True Minimum False Minimum

Fig. 7 *True and false minima* for $W(PMe_3)_4H_2Cl_2$.



disordered structure in centrosymrnetric space group

ordered structure in non-centrosymrnetric space group

Fig. *8* Incorrect. disordered structure of [Tp^{Bu^t}]In refined in the centrosymmetric space group (left). The true structure refined in the noncentrosymmetric space group (right).

group resulted in a well-behaved. ordered structure.[7,9] Thus. [Tp^{Bu^t}]In provides an interesting counter example, where the structure is much better described as ordered in the noncentrosymmetric space group, rather than disordered in the centrosymmetric alternative.

CONCLUSION

Reinvestigation of *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ demonstrated that the original proposai for bond-stretch isomerism is erroneous due to a crystallographic artifact resulting from disorder. The fact that the original x-ray diffraction study was not questioned at the time it was reported, and was considered sufficiently reliable to prove the existence of such isomers, is a consequence of two facts: first. the widespread notion that x-ray diffraction is the ultimate arbiter of a chemical structure; and second, the disorder was not detected, even though it had a significant effect on the apparent bond length. The apparent experimental verification of bond-stretch isomerism represents the tip of the iceberg and indicates that other unrecognized problems exist. as illustrated by the examples described above. These problems range from incorrect atom assignments to incorrect molecular geometries.

A variety of molecules, such as [$Cp^*RuCl_2]_2$, [$(MesP^*)_2CHCSiMe_3$], and $Co_3(dpa)_4Cl_2$, exhibit isomerism in which there is a variation in bond lengths. However, to date there has been no convincing evidence presented to support the existence of isomers analogous to the bond-stretch isomerism proposed for cis-met-$Mo(O)Cl_2(PMe_2Ph)_3$, in which the difference is principally associated with the mere lengthening of a bond between a single pair of atoms.

Brillouin Scattering

Claude Ecolivet
Université de Rennes, Rennes, France

INTRODUCTION

Brillouin scattering is a technique in which, through an inelastic scattering process of photons by acoustic waves (also called acoustic phonons),[1,2] the investigation of the elastic properties of materials can take place. Although transparent materials make experiments easier and more fruitful, some measurements can be successfully performed on opaque semiconductors and even metals.[3,4] One of the interests of this noncontact technique is that it does not require large samples. Some experimental setups even use microscopes to collect the scattered light, allowing measurements on microscopic or heterogeneous samples.[5] This is an advantage on ultrasonics or inelastic neutron scattering that can also measure sound velocities but usually necessitate larger samples. The essential microscopic physical information provided by Brillouin scattering is the magnitude of the interatomic or intermolecular elastic interactions revealing what actually occurs inside the material. In supramolecuiar crystals consisting in host and guest molecules, it can then be possible to identify and evaluate the interactions between the different constituents.

Moreover, the technical progress in Brillouin scattering spectroscopy, mainly due to the use of tandems of Fabry Perot interferometers,[6] allows us to investigate. in the same experiment, the acoustic phonons and the low-lying Raman lines and the Rayleigh wings often generated by instabilities and relaxations.[7] Often, these modes are coupled to ihe acoustic waves. and their scattering geometries and polarizations facilitate their assignment and give a deeper insight to their dynamics. Brillouin spectra. like the Raman spectra, appear as doublets. where their intensity. frequency. and line width are the main characteristics that can be used to produce quantitative data about elastic, photoelastic,[8] and anharmonic properties of the materials.

In this article. we briefly recall the principles of the technique and the state of the art of the technique as it is currently used in laboratories. Then we present some results obtained on supramolecular compounds: charge–transfer crystals and inclusion compounds (clathrates and channel-like composites). These results were chosen to give a broad scope of what the interest of Brillouin scattering is for supramolecular scientists. More details on the technique or its application to other materials can be found in other review papers.[9,10]

PRINCIPLE

It is well known since the beginning of the last century that acoustic waves (longitudinal and transverse) are generated by thermal agitation even at very low temperatures. The Debye T^3 law of specific heat is but one of the numerous consequences. These waves of frequency v and wave vector $q = 2\pi/\lambda$ have a linear dispersion:

$$2\pi v = Vq$$

where V is the phase velocity (longitudinal or transverse). They carry a (pseudo) momentum $\hbar\mathbf{q}$ that can combine with the one of an incident photon $\hbar\mathbf{k_i}$ to satisfy a conservation law defining the wave vector of scattered photons $\mathbf{k_s}$:

$$\hbar\mathbf{k_s} = \hbar(\mathbf{k_i} \pm \mathbf{q})$$

This process can also be considered a Bragg diffraction of incident photons by an index grating resulting from the refractive index modulation by the density variations of the longitudinal acoustic mode or the shearing strains for the transverse modes. Because the energy of the incident photon ($\approx$2 eV) is much larger than that of the acoustic phonon ($\approx$0.1 meV), the magnitude of $\mathbf{k_s}$ is similar to the one of $\mathbf{k_i}$, yielding:

$$\|\mathbf{k_s} - \mathbf{k_i}\| \approx 2\|\mathbf{k_i}\| \sin(\theta/2)$$

like in a Bragg reflection, where θ is the scattering angle; which will define the magnitude of the phonon wavevector. Because the scattering grating moves at the sound of velocity in opposite directions $\pm\mathbf{q}$, the scattered intensity is Doppler shifted and appears as a double? centered on the incident photon frequency:

$$v_s = v_i \pm v_{phonon} = v_i \pm 2(nV/\lambda)\sin(\theta/2)$$

This relation is obtained through the linear dispersion relation of acoustic phonons and photons in the simple case

DOI: 10.1081/E-ESMC 120012848

of an optically isotropic material of index n. The last term of the righi-hand side (rhs) of the above equation is called the Brillouin shift. which is equal to the frequency of the detected phonon. In the case of an optically anisotropic material. the scattered and incident wave vectors can be very different, and the $2n\sin(\theta/2)$ term in the above formula is replaced by: $(n_i^2+n_s^2-2n_in_s\cos\theta)^{1/2}$, where n_i and n_s are the refractive indices for the incident and scattered beams.

Thus, the choice of an incident radiation λ_i defines $\mathbf{k}_i$, whereas the choice of a scattering angle (usually 90° or 180") unambiguously determines $\mathbf{k}_s$ and, henceforth. the Brillouin shifi related to each of the three acoustic modes with their own velocities. Typically. for an incident visible radiation. and a material characterized by an index of refraction about 1.5 and sound velocities of a few km/s, the Brillouin shift lies in the range of 10–30 GHz (0.33–1 cm^{-1}) in backscattering geometry. Obviously, the study of Brillouin lines requires a more consequent resoiution than the one of a conventional Raman spectrometer.

In the absence of any perturbation by other modes. the Brillouin lines can be described by a damped oscillator profile derived from the imaginary part $\chi''(\omega)$ of the oscillator susceptibility:

$$I(\omega) = I_0[n(\omega,T) + 1/2 \pm 1/2]\chi''(\omega)$$
$$\approx I_0kT\gamma/\{[\omega^2 - (\omega_i \mp Vq)^2]^2 + \gamma^2\omega^2\}$$

where $n(\omega,T)$ is the Bose factor defining the phonon population at a given temperature T; γ is the half-width at half height; and ω_i is the pulsation of the incident light. The upper sign is related to what is called the Stokes process. where an acoustic phonon is created by a photon inside the sample. and the associated frequency is then:

$$\nu_s(\text{Stokes}) = \nu_i - \nu_{\text{phonon}}$$

whereas the lower sign is related to the opposite case, called Antistokes, where an acoustic photon is destroyed in the scattering process corresponding to a line located at a frequency higher than the incident one:

$$\nu_s(\text{antiStokes}) = \nu_i + \nu_{\text{phonon}}$$

The probability of this process being strictly proportional to the phonon population by the Bose factor decreases at low temperatures. Except at very low temperatures. there is no detectable intensity difference between the Stokes and anti-Stokes contributions at variance to Raman scattering.

The intensity I_0 depends on geometric factors characteristic of the setup and also on the photoelastic constants. which relate the refractive index variations to the elastic strains and soine internal rotations. Brillouin scattering. by comparison with a substance where the photoelastic constants are well known (usually benzene. quartz,...). is a method for determining these coefficients.[8] In some scattering geometries, the calculated intensity of some well-polarized modes can be zero. but at variance to Raman scattering where optic modes are not always active. acoustic modes can always be seen. at least theoretically. in some other scattering geometry. usually labeled in the Porto notation $\mathbf{k}_i(\mathbf{E}_i, \mathbf{E}_s)\mathbf{k}_s$, where $\mathbf{E}$ is the radiation electric field (Fig. 1).

The line width γ is related to the damping of elastic waves. which results from anharmonic interactions of the acoustic phonons with other phonons, relaxation

Notice through the logarithmic intensity scale the practical absence of the longitudinal component in that spectrum. (From Ref. [30].)

processes, or structural disorder. Due to the high frequency of the investigated phonons, inherent to the technique. the influence of linear defects like dislocations is usually negligible. In solids. typical line widths are within tens to hundreds of MHz, and because it is the same order of magnitude as the experimental broadening due to the apparatus function and the finite aperture contribution, a deconvolution is needed in order to obtain a better estimation of the true line width.

The phonon frequency $\nu_{phonon}=Vq/2\pi$ is determined by the Christoffel equation,[11] which relates the phase velocity of acoustic waves to the elastic constants of the material. The number of elastic constants of a material depends on its symmetry. varying from one for liquids to three for cubic crystals and up to 21 in triclinic crystals. By measuring a number of independent sound velocities at least equal to the number of elastic constants in nonequivalent directions, it is theoretically possible to determine all the elastic constants of the material. Often, structural phase transitions generate acoustic anomalies. which can then be studied by Brillouin scattering by following the evolution versus temperature or pressure of the Brillouin shift and the line width of selected phonons.[9] High-frequency noncritical relaxations, in the ps range. also create some anomalies that are more gradual.

EXPERIMENTAL

Due to the small value of the Brillouin shifts and their line widths. experimental techniques involve interferometric devices. However. resolution is not all. perhaps the more important quality is the contrast, i.e., the ability to distinguish a small Brillouin line in the wing of a huge elastic Rayleigh line. In the case of a low contrast like in nonscanning interferometers,[12] studies are limited to high optical quality materials in right-angle scattering geometry. where the stray light is minimum. Obviously, usual samples are most of the time not of high optical quality, and they do not always present right-angle faces oriented along the more interesting directions. Nowadays. the best trade-off for Brillouin spectrometers is the tandem of plane Fabry-Perot (FP) interferoineters (Sandercock mounting) that may offer a resolution about 0.1 GHz and a contrast larger than 10^{11} with an acceptable transmission.[6] An FP interferometer consists in two partially reflecting parallel mirrors between which light undergoes multiple reflections. ensuring a higher contrast than with a two-wave interferometer like a Michelson device. A drawback of FP interferometers is the periodicity of their transmission characterized by the free spectral range $\Delta=c/2ne$ obtained by scanning the distance e (or the refractive index n) between the mirrors by more than a half-wavelength. An interesting feature of the tandem is the "vernier" ratio between the periodicities of the FPs defined by the ratio between their distances e_1 and e_2 chosen to be close to an incommensurate value. In such a case. the free spectral range of the tandem may be 20 times the one of an individual FP. The apparatus function of an FP interferometer characterized by its maximum transmission T_M is an Airy function:

$$T_i(\nu) = T_M/[1 + (2F_E/\pi)^2 \cos^2(\pi\nu/\Delta_i)]$$

where F_E is the effective finesse defined as the ratio of the free spectral range Δ over the width at half height of the

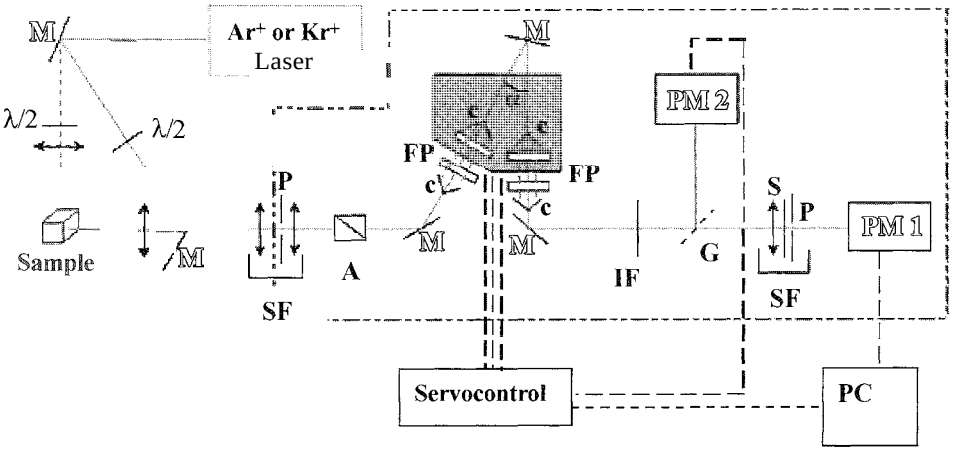

Fig. 2 Typical Brillouin scattering setup using a tandem of triple-passed Fabry-Perot interferometers. M: mirrors, SF: spatial filters. FP: Fabry Perot interferometers. c: corner cubes. [13].) (*View this art in color at www.dekker.com.*)

maximum of the Airy function. The apparatus function of the tandem being the product of the individual Airy functions, the interest of the loss of periodicity in the total apparatus function is that it allows for easier measurement of the Brillouin shifts, and more specifically. it allows in the same experiment the observation of sharp Brillouin lines and broad quasielastic components with a good rejection of the contribution of higher-order interferences.

The high contrast of the spectrometer is achieved either by triple passing each FP or the whole tandem setup. It results theoretically in an elevation of the apparatus function of each interferometer to the cube, which strongly enhances the contrast defined as the ratio of the maximum transmission over its minimum value. In order to achieve this high contrast, the tandem sits in a highly collimated beam between spatial filters, which also allows the stray light at the entrance to be diminished and the bandwidth at the exit pinhole in front of a photoinultiplier or an avalanche diode to be selected (Fig. 2).

Spectra are acquired by a linear scan of the piezoelectrically driven tandem, and data acquisition lasts between a few seconds and several hours, according to experimental conditions and sample characteristics. The long-term stability usually required to collect spectra is realized via a maximum transmission servo-controi keeping the best alignment of the tandem checlted by an auxiliary photodetector (PM2).

RESULTS

Results obtained by Brillouin scattering range from the determination of the elastic and photoelastic constants of materials to the analysis of material transformations: phase transitions. polymerization. glass transitions, photoinduced transformations. etc. (It is out of the scope of this presentation to present all.) We will limit our discussion to some examples selected in the field of supramolecular products defined as complexes consisting of two or more chemical entities associated through van der Waals interactions, hydrogen bonds, or charge-transfer mechanisms.[14]

Weak Charge-Transfer (CT) Complex Crystals

Tetracyanobenzene (TCWB) is an electron acceptor that forms charge-transfer complexes with aromatic donor molecules: anthracene (A), naphthalene (N), phenantrene (Ph), etc. These weak CT complexes crystallize in alternated stacks, leading to insulating properties with CT bands of rather high energy, yielding to colored but transparent crystals. Like many organic crystals, they crystallize in a monoclinic group and are known to present

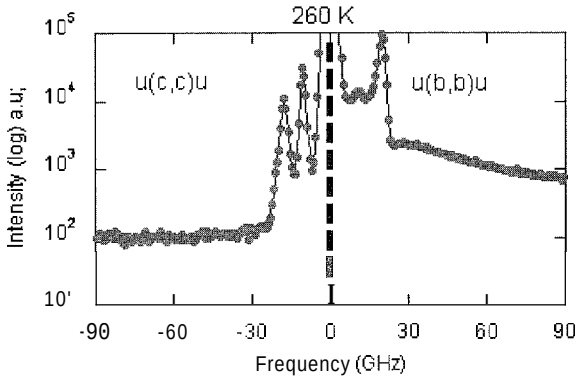

Fig. 3 Brillouin spectra of naphthalene-tetracyanobenzene taken in a backscattering geometry showing (on the right) the interference scattering between acoustic modes and a quasi-elastic component generated by an overdamped reorientational optic mode. (*View this* art *in* color at *www.dekker.com.*)

an orientational disorder, because the cyanide arms of the acceptor define a volume larger than that of donors.[15]

In N-TCNB, the disorder is well characterized by molecular jumps of the donor molecule between orientations separated by 36°.[16] At room temperature, the relaxation time of these jumps in the few ps range lead to a coupling with acoustic phonons. Then the quasielastic component generated by this relaxational behavior with a width in the 10 GHz range is distorted by coupling with the acoustic modes, which also undergo a severe asymmetry of their profile with a dip on the high-frequency wing (Fig. 3). These profiles can be described by a coupled susceptibilities equation[17] relating the oscillator susceptibility of the acoustic phonon with a relaxational susceptibility (Debye type). Another common result from coupling the acoustic modes to other modes is the increase of their line-width. Shown in Fig. 3. on a semi-log scale, are two spectra demonstrating this coupling. On the left side. one observes a usual uncoupled Brillouin spectrum with two peaks: a QL mode around 20 GHz and a QT mode around 10 GHz. In this experiment, the incident and scattered electric fields are perpendicular to the molecular plane (c,c) and, consequently, are not influenced by the electric polarization generated by the rotation of an asymmetric molecule. On the contrary, the right side was recorded along the same direction but with incident and scattered electric fields in the molecular plane (b,b). One also sees two Brillouin lines at about the same frequencies as with fie other polarization (except for the birefringence shift). but they are accompanied by a quasielastic component of about 22 GHz half-height half-line-width interfering severely with the QL mode. A signature of this interference scattering is the difference of intensity between the low- and high-frequency wings of a Brillouin line. The dots on the spectra are the

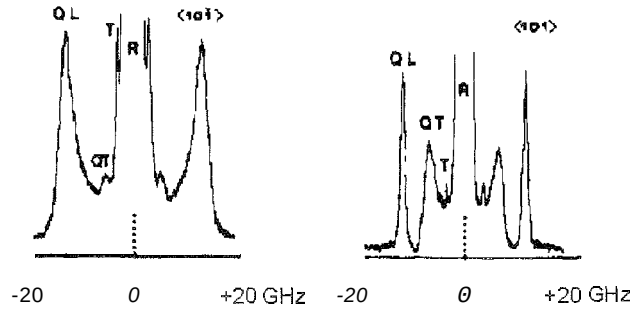

Fig. 4 Brillouin spectra recorded at atmospheric pressure at T_c 5 K in right-angle geometry along the direction $(10\bar{1})$, nearly parallel to the anthracene long axis (left), and the (101) direction almost perpendicular to this long axis (right). The R. *T*, *QT*, and *QL* indicate. respectively. the Rayleigh elastic line. the transverse mode polarized along the b monoclinic axis. and the quasitransverse and quasilongitudinal modes polarized in the (a,c) plane. The free spectral range is 39.15 GHz. (From Ref. [18].)

experimental data. whereas the continuous line is the fit by the coupled susceptibilities.

By cooling the sample. one observes a narrowing of the quasielastic component and the apparition in the Raman spectrum of a low-frequency mode (40 cm^{-1}) at about 200 K. This mode shifts toward higher frequencies due to the decrease of its damping and presents only a small frequency anomaly at the phase transition (T_C=73 K).

The disorder is so fast in A-TCNB at atinospheric pressure, that no physical method is able to distinguish well-defined orientations of the donor, which librates in an anharmonic double well. but above the internal energy barrier. It then results in a displacive structural transition characterized by an optical soft mode coupled to acoustic phonons and leading to large elastic anomalies of the relaxational type.[18] However, under pressure. this disorder slows. probably under the effect of an increase of the internal barrier, and the structural transition becomes an order–disorder one with an overdamped optic mode that no longer softens."'' This structural phase transition was extensively studied by different techniques, including Brillouin scattering. In particular. it was shown that all elastic anomalies occurring in that compound derive from the coupling between the (A) librations and the longitudinal acoustic mode propagating along the molecular long axis. The relaxation time of the order parameter presents a critical slowing $\tau(T)=\tau_0/(T_C-T)$, with T_C=212 K and τ_0=50 ps. Shown in Fig. 4. at T_c-5 K. is the effect of the coupling with the soft optic mode on the Brillouin spectra related to acoustic phonons propagating nearly along the (A) Long molecular axis $(10\bar{1})$, where the quasilongitudinal acoustic mode (QL) is strongly coupled to the soft mode and is, consequently. broadened. In a perpendicular direction (101), this occurs for the quasitransverse mode (QT). also polarized along the (A) long axis. The true transverse mode polarized along the monoclinic axis is always narrow. because it is not good symmetry to be coupled to the soft mode. Further studies of the fluctuation dynamics also revealed the contribution of disorder to this typical displacive transition.

Clathrates

Clathrates are typical supramolecular objects with molecules playing the role of host. whereas others are guests. A large variety of structures were imagined and realized (for a recent review see Ref. [20]), but they can be sorted by the dimensionality of the guest asse bly. At the lowest level. we get cages inside with zero, one, or two rnolecules included. With a dimension one, we have tubular or cylindrical pores inside which guests molecules will have a longitudinal interaction. At two dimensions, we will have intercalated molecules between host planes.

A general problem of clathrates is the interaction of guests and host molecules and eventually between guests. In the simplest approach, these interactions are neglected, and it is expected that the elastic properties of the clathrate are only sensitive to the degree of filling of the cages and to the mass of the guest molecules.[21] Brillouin scattering is a well-suited technique for such investigations, which should look into the sound velocities of the empty clathrand and differently filled clathrates. First Brillouin scattering experiments on such materials were performed in the early 1990s on methane and xenon clathrate hydrates.[22] In these compounds. water rnolecules build a cubic lattice through hydrogen bonds and define two types of cages inside the lattice—large and small ones—inside which atoms or small molecules are present. Further studies on a larger variety of guests show a decrease in proportion to the square root of the guest mass but not as large as expected in the absence of guest–host interactions. which are found to be repulsive.[23]

For these clathrate hydrates. a problem is the comparison to the empty clathrand properties. because the stability of the empty clathrate is often a problem. Dianin's compound and its clathrates are an opposite case. because the stability of the pure compound is good. Consequently, they were more extensively investigated. The structure of this compound is based on a hexamer linked by a network of hydrogen bonds involving the phenolic hydroxyl groups of 4-(*p*-hydroxyphenyl)-2,2,4-tritrimethylchroman, which is represented in Fig. 5b. A projection of the cell perpendicular to the threefold axis of the space group (R3i) is represented in Fig. 5a,[24] showing the six arms of the hexamer. which are

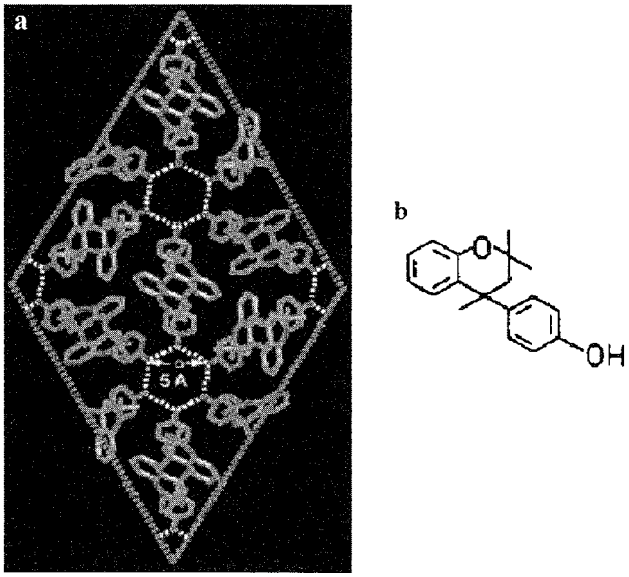

Fig. 5 (a) Projection of the structure of the Dianin clathrand in the basal plane.[24] Carbon atoms are represented in green; oxygen in red: and H bonding by yellow dashed lines. (b) Its building molecule. (From Ref. [24].) (*View this art in color at www.dekker.com.*)

alternately up and down. building around each H-bonded ring an hourglass-like architecture. In the next above layer, three downward arms with the three upwards arms of the represented layer build a cage that is locked by van der Waals interactions. It was shown that the dimensions of the unit cell increase when the cages are occupied, but the more affected distance is the c axis, which is mainly dependent from the van der Waals interactions between hexamers.

Recently, by comparing sound velocities and elastic constants between Dianin clathrand and the ethanol and heptanol clathrates. quantitative data related to the interactions were reported.[25] The main difference between both clathrates lies in the number of molecules per cage: two for ethanol with a noticeable disorder. but only one for heptanol which adopts a folded "gauche" conformation for a better fit inside the cage. Brillouin scattering results show that for the clathrand and the ethanol clathrate, similar sound velocities are observed for the longitudinal modes in the basal plane, whereas the longitudinal mode along the threefold axis presents a 15% decrease of its velocity for the ethanol clathrate. This fact could be explained by the 0.5% elongation strain along the c axis produced by the two guest molecules. If one compares the heptanol clathrate to the clathrand, more isotropic longitudinal sound velocity decreases are observed in the basal plane (12%) and along the c axis (18%). This seems in agreement with the more isotropic elongations of the a and c parameters of these compounds, 0.67% and 0.7310, respectively. These strain values lead to the concept of internal pressure that guest molecules would apply to the host ones. It reaches 1 kbar for the heptanol clathrate and two to three times less for the ethanol one. This pressure is produced by an energetically less-favorable state of the guest molecules. estimated at 18 kJ/mol for heptanol. Such studies exemplify the interest of what can be learned from Brillouin scattering experiments coupled with other data sources.

Urea Inclusion Compounds

Channel-like compounds can also be considered clathrates, because guest molecules are confined inside these channels. Here also, the nature and magnitude of the interactions between the different kinds of molecules are major problems. In addition to the cage situation, the channel geometry may allow longitudinal end-to-end interactions between the guests. Depending on the thickness of the channel walls. a weaker lateral guest–guest interaction is also possible. Elastic properties are again a good probe for all of these interactions. Such compounds are commonly obtained with molecules such as urea or thiourea. but in the case of thiourea, the channel diameter is strongly modulated and firmly localizes guest molecules in pockets along the channels, in a similar fashion as in cages rejoining the previous cage-like compounds. Consequently. we will be more interested in smoother channels like those of urea. Depending on the nature of interactions developed between the host and the guest molecules, it will be possible to obtain a regular crystal by periodic packing of the guests along the channels or to obtain an aperiodic structure.[26] The first case is, for example, obtained when firm hydrogen bonds are developed with the host, like in 2–10 undecanedione.[27] whereas the second case is typical of alkane molecules that only interact by van der Waals forces. All of these structures are derived from infinite honeycomb-like channels made up of three urea helices interwoven by hydrogen bonds. inside which guest molecules are densely packed to ensure the stability of the composite. The symmetry is often hexagonal. but distortions resulting from the shape of the guest molecules usually lead to orthorhombic symmetries at low temperatures. When such a ferroelastic transition occurs, Brillouin scattering gives valuable data on the order and the regime of transition by recording sound velocity anomalies.[13,28]

In aperiodic composites, another degree of freedom occurs due to the infinite degeneracy of the ground state. i.e., all relative positions of the host and guest molecules exist in the structure due to its incommensurability, so that the whole composite has the same energy for any relative

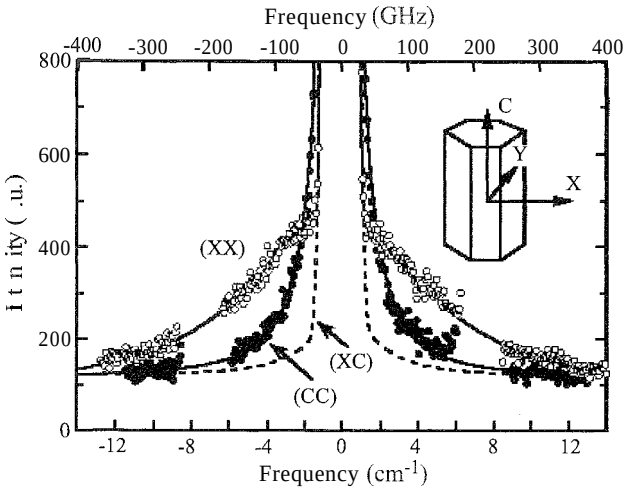

Fig. 6 Quasielastic components observed in nonadecanelurea at room temperature in tandem with Fabry-Perot interferometers. The central intensity is due to the longitudinal Brillouin doublets. The (XX) component is assigned to the reorientation of alkane molecules, whereas the (ZZ) component is compatible with an overdamped "sliding" motion. (From Ref. [30].)

position of a given host–guest pair. Such a degeneracy leads to a possible sliding motion of the whole urea sublattice with respect to the guest sublattice without any energy cost. This feature is also the one of acoustic phonons. which have zero energy *for infinite wavelengths. The main difference is located in the energy dissipation of these vibration modes: sound waves are* hydrodynamic *modes. and their damping goes* to *zero like* q^2, *because the atomic relative* motion *also goes* to *zero for infinite wavelengths. On the contrary.* the *relative sliding motion is. by essence.* optic-like *with large relative motions of the hosts and guests so* that *rhis* motion *will dissipate energy or* can *also be* quenched *by* Nabarro *barriers that in crystals.* impede *the* dislocation *motion. giving birth to a gap in its dispersion branch at low wave-vectors. The search of an experimental observation of sliding modes is* still *active and relies on inelastic techniques like neutron and light scattering. Many experiments were performed* in alkane/urea *compounds* without *any direct observation of an inelastic* peak *unambiguously assignable to rhis sliding mode. The apparition of an extraneous fourth Brillouin peak in the spectrum of* heptadecane/urea[29] *was not confirmed by* the following experiments,[30] *which evidenced the existence of quasielastic components (Fig. 4): one related to the reorientational–librational motion of alkane molecules around their long axis and another one polarized along the channel. which could be compatible with an* overdamped *sliding mode. Elastic properties* of *several urea inclusion* compounds *were investigated, and they showed the weak influence* of *the nature of the guest molecules on the sound velocities inside the* composites. *This is striking, because, along the channel axis. one can expect that the addition of the* sublattice *stiffness and the one of the guest sublattice should vary with the length and the end-to-end interactions between these molecules. Recently, by applying a hydrostatic pressure to the guest* molecules *by He atoms directly inside the channels. it was possible to determine the force constant between alkane* ($C_{19}D_{40}$) molecules.[31] *Its weak value* 1 N/m *compared to the average* 10–15 N/m *for H-bonded molecules allows us to understand the very small influence of the alkane length on* the *composite sound velocity. Another characteristic of the* dynamics *of such* a *system is the broadening of the longitudinal Brillouin line along the channels, as shown in Fig. 1a, which was taken on nonadecanelurea. High-pressure experiments showed that about* 25% of *this anomalous broadening (1.7* GHz) *is due to the* conformational *defects of alkane chain* ends.[13] *but the* major *part is still nonidentified and could be due to a coupling between the overdamped sliding* motion *and the longitudinal phonon. It should be noticed that the transverse acoustic mode seen in Fig. 1b has a very small* damping *that is barely measurable on this spectrum. Recent experiments on periodic and aperiodic ketones included in urea also showed relaxations coupled differentlyto the acoustic phonons than those in* alkane/urea *inclusion compounds. and this will be reported elsewhere.*

CONCLUSION

All of these results and many *others not reported here due to a lack of space prove* the *interest of Brillouin scattering as a technique of investigation of the elastic and* dynamical *properties of materials.* in *particular. for* supramolecular *compounds. The conclusions derived give better insight to the materials when they are carefully crossed with structural or other* dynamical *results provided for by complementary techniques.* In *photoexcitable materials. Brillouin scattering offers the unique opportunity of measuring the elastic properties of the excited volume. because at the* same *time, the light* beams *modify the sample and* measure *its properties. Despite the high technical* level *reached now. there is* still room *for further* experimental *improvements allowing faster and more precise measurements to be made.*

Calixarenes and Their Analogues: Cation Complexation

Anthony W. Coleman
Adina N. Lazar
Eric Da Silva
Institut de Biologie et Chimie des Protéines, Lyon, France

INTRODUCTION

The calixarenes. calixresorcinarenes. and analogues are macrocyclic molecules containing phenolic rings bridged by methylene functions and are among the most ubiquitous of organic molecular host molecules in supramolecular chemistry.[1] The basic molecular scaffolds are, in general. simple to prepare in high yields from inexpensive starting compounds. In the case of the calixarenes; the size of the macrocycle synthesized is dependent on the nature of the cation used in the base-catalyzed cyclization, demonstrating that from the start, these molecules are excellent choices for cation complexation.

They possess sterically divergent reactive centers, either phenolic or aromatic in chemical nature. that may be modified fully or selectively to introduce functionalities capable of complexing a wide variety of cations. The chemical and physical robustness of the macrocycles allows their use for the complexation of a wide range of metal cations, including radioactive isotopes.

The introduction of ligand groups, such as ethers or crown ethers. amides. esters, or caroboxylic acids, or sulfonates and phosphonates allows for the fine tuning of capacity for coinplexation with regard to mono-, di-. tri-. and tetravalent metal cations: cationic metal complexes; and organic cations. including mono-, di-. and trivalent ammonium systems, amino acids. peptides. and even certain proteins.

Further fine-tuning of the physicochemical and chemical properties of the derivatives allows for their use for extraction of cations, sensing at surfaces and interfaces, conducting of polymers. and specific-site targeting in biological macromolecules.

CATION COMPLEXATION: GENERALITIES

The structures of the calixarenes and analogues are given in Figs. 1A.B. While calix[4]arene possesses four conformers—cone, partial cone. 1,2-alternate cone, and 1,3-alternate cone—that are sufficiently stable to be separated or to be blocked in place under certain conditions, the higher analogues have a much higher degree of conformational mobility. These conformational properties were used to prepare preformed receptors for cation binding or to allow the ligands to wrap around the cation to form the binding site.

The basic molecular skeletons do not possess useful ligand sites for the binding of cations and a large body of research was devoted to the selective introduction of ligand groups for cations Fig. 1c. In general. these groups are of two types: soft or hard electron donor groups for coordination (sulfur. nitrogen, and oxygen donor atoms). or negatively charged groups for electrostatic (ion-pairing) interactions with cations (phosphonates, phosphates. sulfonaies, and carboxylates).

INORGANIC CATION COMPLEXATION

Direct Complexation

Direct complexation of cations to unmodified calixarenes or their analogues occurs generally by formation of ion pairs arising from deprotonation of one or more phenolic groups under basic conditions. A comprehensive study of alkali metal–calixarene ion-pair complexes in soluton and the solid state was undertaken by Gutsche.[1] Extraction of alkali metals from basic aqueous solutions shows strong selectivity for Cs^+ by calix[4]arene and calix[6]arene and selectivity for both Rb^+ and Cs^+ for calix[8]arene.[2]

Interfacial complexation of various alkali cations by the amphiphilic acyl-calix[4]arenes is achieved without deprotonation and shows strong selective binding for Rb''. The binding of cations by these molecules is also strongly dependent on the counteranion.[3]

Ester, Amide, and Ketone Derivatives

The main classes of calixarene derivatives for the complexation and extraction of alkali and alkali earth cations are based on the total subsitution at the lower rim by alkoxyester. alkoxyamide. or alkoxyketone functions. Fig. 2. In this way. suitable donor ligand functions for cation complexation are introduced. Such derivatives were used for the complexation and solvent-to-solvent

extraction of a wide range of metal ions. including alkali metals Li^+, Na^+, K^+, Rb^+, Cs^+, Ag^+; alkali earth metals Mn^{2+}, Mg^{2+}, Ca^{2+}, Cu^{2+}, Sr^{2+}, Ba^{2+} and lanthanides La^{3+}.

The size of the calixarene macrocycle can govern the selectivity with regard to the different cations. For example. the ester derivative of calix[4]arene presents a high selectivity for the smaller cations Na^+ and Li^+.[4] However, the analogous ester derivative of calix[5]arene and calix[6]arene interact strongly with $Cs^+ = Rb^+ > K^+$. No selectivity with regard to cations is observed for the calix[7]arene and calix[8]arene ester derivatives.

The conformation of the calixarene derivative also plays a role, and thus. the 1,3-alternate conformation of calix[4]arene can interact with other metals such as silver.[9]

The selectivity of the complexation and extraction is also determined by the chemical nature of the ligand group, where inversion of the selectivity between Na^+ and Cs^+ is achieved by changing the ligand function from ester to ketone or amide for the calix[4]arene derivatives. Amide substituents play a role in the extraction of alkali metals or alkali earth metals.[6] The calixarene amide derivatives interact with $Na^+ > K^+ = Li^+ >> Rb^+ = Cs^+$. With regard to the divalent cations, Ca^{2+} and Sr^{2+}, high selectivity in complexation is seen for derivatives carrying amide functions, and similar selectivity is seen for the mixed diacid, diamide derivative.[7,8]

Ether and Crown Ether Derivatives

Given the structural analogy with the crown ethers, the calixarenes were alkylated to produce ether ligands at the phenolic face. These molecules complex various cations including alkali metals ions. Coinplexation may take place

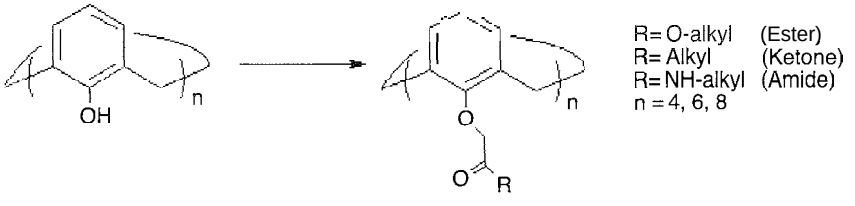

Fig. 2 Molecular structure of calixarene derivatives substituted at the lower rim

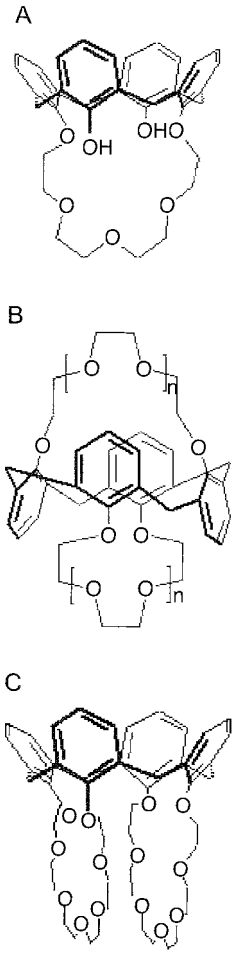

Fig. **3** Molecular structure of 1.2-his-calix crown ether (A): 1–3 alternate calix crown ether (B); and 1.3-his-calix crown ether (C).

at the phenolic groups for Na^+ and by cation–aromatic interaction in the case of Ag^+ and K^+.[9,10]

The construction of calix-crown molecules is achieved by grafting ethylene glycol chains in a loop at two of the phenolic functions (Fig. 3A).

The 1.3-bis crown-ether calix[4]arene (Fig. 3B) was shown to be highly effective in the extraction of the radioactive isotope cation Cs^+.[11] As compared to other possible extractants, the stability of the calix[*n*]arene skeleton is an important factor in their potential use. The 1.2-*bis*-crown ether calix[4]arene (Fig. 3C) interacts more strongly with the Rb^+ cation than with the K^+ and Na^+ cations. In this case. the binding of the Cs^+ is relatively weak.[12]

Amino Derivatives

In order to complex transition metal cations. including chromium (VI), molybdenum (VI), rhenium (VII) and selenium (VI), suitable hard ligands based on nitrogen donor groups were introduced onto the basic calix[*n*]arene skeleton, for example, alkyl amino chains.[''] Recently, Regnouf de Vains synthesized calixarene derivatives having heterocyclic pendant ligands. including bipyridyl, and observed strong bonding of transition metal cations, including Co^{2+}. Cu^+, and Cu^{2+}.[14,15]

Sulfonate Derivatives

The sulfonate derivatives (Fig. 4A), in which introduction of suitable ligand functions takes place at the *para*-position of the aromatic ring, are the most widely studied of the water-soluble calixarenes. Their solid-state binding to a wide range of metallic cations and complexes was reviewed by Raston and Atwood.[16] The ability of these molecules to intercalate cations in expandable layers between bilayers of *para*-sulfonato-calix[4]arene led Atwood and Coleman in 1988 to name these systems ''Organic Clays.'' (Fig. 4C).[17] Since then. Atwood extended the structural types observed to include liposomal analogues. tubes. and various Archimedian and Platonic solids.''[8]

Phosphonate Derivatives

The calix[4]arene molecule was modified at both the upper (para) and lower (phenolic) rims by the introduction of phosphate and phosphonate groups, mainly by the group of Kalchenko (Fig. 4B).[19] Such derivatives complex and allow the extraction of lanthanide and actinide tri- and tetravalent cations. Detoxification of radioactive waters may be possible in this way, as the chemical and physical robustness of the calix[*n*]arenes makes them particularly suitable for this task.

Double complexation of the Zn^{2+} and Histidine amin oacid cations to 1.3-diphosphate cation occurs selectively with regard to the cation and the amino acid. as demonstrated by electrospray mass spectrometry.[20]

Miscellaneous

Cations bind to nanoscopic colloidal assemblies, supramolecular solid lipid nanoparticles of amphiphilic calix[4]arene derivatives, leading, in certain cases. to the clustering of such assemblies in the presence of divalent cations Mg^{2+} and Ca^{2+}. Such clustering was imaged by atomic force microscopy.[21] Such effects have particular relevance to the use of such transport systems in physiological media.

Others

The interaction of thiacalixarene ester derivatives (Fig. 1A) alkali metal cations. is strongly conformation of calixarene

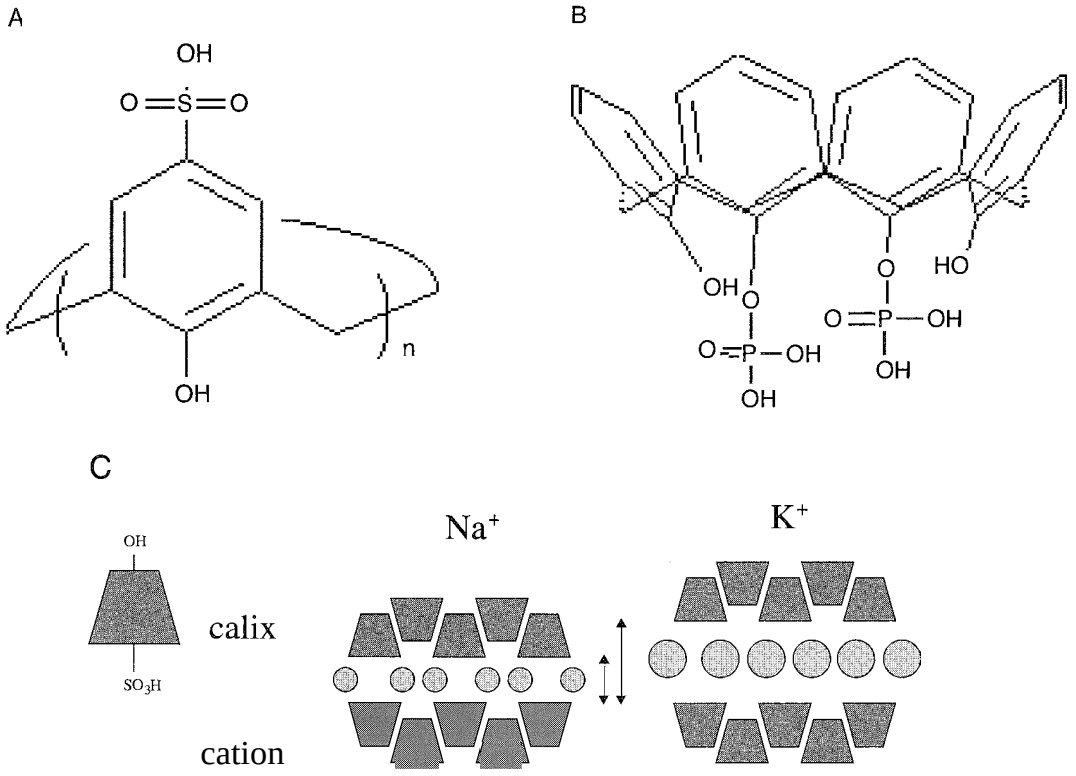

Fig. 4 Molecular structure of water-soluble calixarene: (A) *p*-sulfonato-calix[*n*]arene, where $n = 4$, 6, 8; (B) crystal packing of *p*-sulfonato-calix[4]arene in the presence of salts b calix[4]arene diphosphonic acid: and (C) schematic of the bilayer packing of para-sulfonato-calix[4]arene showing how, as with clays, an increase in the cation size leads to an increase in the height of the hydrophilic interbilayer space. (*View this art in color at www.dekker.com.*)

The cone conformation presents a high selectivity for the sodium cation, while the partial cone and 1,3-alternate conformations show selectivity for potassium and cesium cations.[22]

In the presence of cations, such as bipyridinium, included as guests. *c*-methylcalix[4]resorcinarene is induced to adopt a boat conformation.[23]

ORGANIC CATION COMPLEXATION

In 2002. Abraham published an extensive review of organic cation complexation by calixarenes.[24]

Direct Complexation

The receptor cavity of calix[*n*]arenes favors the formation of complexes with amines by proton transfer. NMR spectrometry and calorimetry techniques allowed for the evaluation of the role of the cavity and the phenolic oxygens in the case of calix[4]arene complexes with aliphatic amines. Hydrophobicity and bas strength are important, and thus, the order of binding is *tert*-butylamine>iso-propylamine (>*n*-hexylamine>piperazine>-diethylamine>piperidine)>triethylamine.[25]

For *p-tert*-butylcalix[6]arene, the tetramethylammonium cation is one of the cations included in the cavity. the other one forms an exterior ion pair.[26]

The use of electrospray mass spectrometry allowed for observation of complexes of calix[4]arenes with alkylammonium ions. either directly from solution[27] or by gas-phase ion–molecule reactions.[28]

Ether and Grown Ether Derivatives

The crown ether derivatives of calixarenes, having a more rigid structure. prove to be more selective in their complexation of organic ammonium cations and are only large enough to accommodate the mono-methylammonium ion and not the larger di-, tri-. and tetramethylammonium ions.[29]

A significant improvement in the ammonium-ion-binding properties can be achieved by covalent bridging of two cone conformation crown-ether derivatives. By adjusting the ethylene bridge length and rigidity. the

association constants can be increased by several orders of magnitude.[30]

Esters, Amides, and Carboxylic Acid Derivatives

Selective recognition of butylamines by *p-tert*-butylcalix[6]arene ester derivatives shows the influence of steric effects on the binding strength, with *n*-butyl>iso-butyl-*sec*-butyl>*tert*-butyl.[31]

NMR studies proved that the calix[4]arene tetracarboxylaie is able to form complexes with tetramethylammonium and trimethylanilinium cations, but with a lower stability than in the case where the calixarene is sulfonated at the upper rim.[32]

Sulfonate Derivatives

The presence of a hydophobic cavity and multiple anionic ligand groups in the *para*-sulfonato-calix[*n*]arenes coupled with their high aqueous solubility, made these molecules the derivatives of choice for the study of binding of organic cations, usually containing ammonium functions.

The stoichiometries of binding organic ammonium cations, such as trimethylanilinium and adamantrimethylammonium, to the para-sulfonato-calix[*n*]arenes is controlled by the macrocycle size formed. Thus, for the calix[4]arene and calix[6]arene derivatives, complexes of stoichiometry I:1 are observed, while for the larger calix[8]arene derivatives a 1:2 stoichiometry occurs.[33]

As with the inorganic cations, solid-state organic clay bilayer structures are favored by *p*-sulfonatocalix[4]arene and were observed with organic cations such as, $[H_4TMTAA^{2+}]_2$ [*trans*-{$Na^+\subset$(18-crown-6)$(H_2O)_2$ and $[H_4TMTAA^{2+}]_2$ $[(C_7N_2OH_7^+)_2$.[34]

Phosphonate Derivatives

1,3-Diphosphatecalix[4]arene is present in the solid state as a self-included dimer with two sets of anionic ligands capable of complexing a wide range of organic ammonium cations, with the propane diammonium cation a complex structure containing a selective water channel (Fig. 5a).[35]

The calix[4]arene α-aminophosphonates are highly selective receptors for amino acids. They exhibit excellent selectivity as carriers of the zwitterionic form of aromatic amino acids through supported liquid membranes.

BIOMOLECULAR COMPLEXATION

The study of the interaction between calix[*n*]arene derivatives and biomolecular cationic functions is mainly limited to two groups of anionic water-soluble calix[*n*]arene derivatives. the *para*-sulfonato- and 1,3-diphosphate systems. These anionic molecules complex strongly to the cationic lateral chains of the amino acids, lysine (Lys, K). arginine (Arg, R). and histidine (His. M). Association constants. as determined by NMR and microcalorimetry, for these three amino acids vary as follows: His <Lys <Arg for the three *para*-sulfonato-calix[*n*]arenes, where *n*=4, 6. or 8; the stoichiometries of the observed complexes are 1:1 with *para*-sulfonato-calix[4]arene, and are

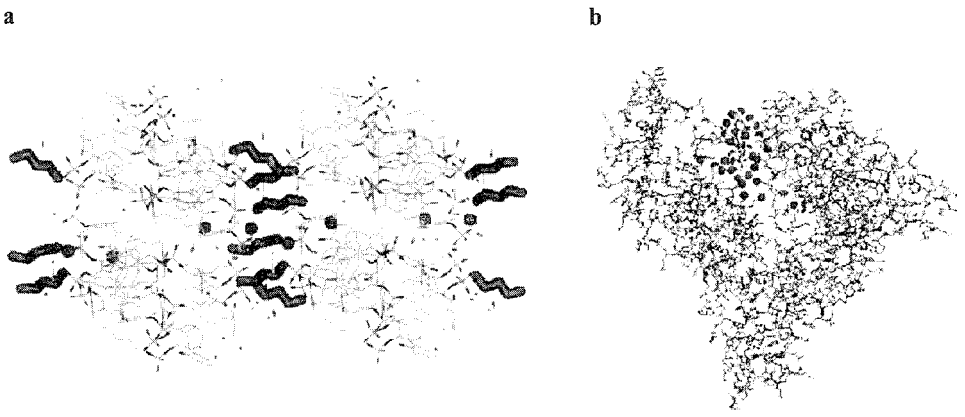

Fig. 5 View of the large self-asembled structure generated by the complexation of the propane diammoniuin cation by calix[4]arene diposphonic acid showing a selective water channel in the crystal packing. The propane diammonium groups act as linkers along the channel (a). Molecular model of bovine serum albumin showing one of the binding sites for *para*-sulphonato-calixarenes. 1:2 *for para*-sulfonato-calix[6]arene *and para*-sulfonato-calix[8]arene. *Di-and* tri-peptides *based on* Lys *and Arg binding increase with the number of basic amino acids*

Recognition *of this binding to* cationic *amino acids present* at *the surface of* many *proteins and often clustered either by the amino acid sequence or by the tertiary protein structure explains the biological activity of the para*-sulfonato-calix[*n*]arenes, *for example. their enzyme inhibition properties with regard to* lysyl oxidase.[38]

The binding of the para-sulfonato-calix[*n*]arenes *to bovine serum albumin* (BSA), *as demonstrated by* electrospray mass *spectrometry,* involves *complexation to* lysine *and arginine* present *in anion-binding pockets* on *the protein surface (Fig.* 5b).[39]

APPLICATIONS

The capacity of *the calixarenes to exhibit cation selection or to recognize the chirality of* amines *and amino acids, as well as their ability to form complexes with quaternary ammonium. led to a number of potential and actual applications.*

The use of the *ethoxycarbonylmethyl derivative of p-tert*-butylcalix[6]arene *as a selective carrier for the separation of amino acids through a chloroform liquid* membrane *was demonstrated by Chang et* al.[40] Ion*ophoric calixarene esters and ethers were applied to* ion *transport through phospholipid bilayer membranes.*

The most *widely studied and developed application of* the *calixarenes* is in *sensing devices for cation* recogniton. *Devices based on* Langmuir Blodgett *films. thermally deposited thin films. or where the calixarene derivatives are immobilized into polymer films have been used in such applications. Sensing may occur through* potentio*metric. fluorometric, or* photometric measurements.[41]

Their application in the biomedical field is clearly demonstrated by the preponderance of patents as compared to publications in the field. Calixarenes functionalized at the wide rim with sulfonic *acid and* sulfonamide *groups showed anticoagulant and antithrombotic properties. approaching the activity of heparin and* coumarin, *currently used as* anticoagulants *in antithrombotic therapy.* Calixarene *derivatives are also active as antiviral, antimicrobial. and antifunga! agents.*

CONCLUSION

Since the recognition *of the cyclic nature of the calixarenes by* Zinke in *1942. their use in* supramolecular *chemistry and for the* complexation *of cations has seen* almost *exponential growth. Given the diversity of the nature of the* chemical modification *is* seemingly *only limited by* the *imagination of the chemist. we can expect this growth to continue. The design and construction of calixarenes carrying highly specific ligand functions are leading to their application* in *the areas of environmental control for detoxification of poisonous metal ions. The field of biological application of calixarenes by their cornplexation to* cationic *groups present in* biomacromolecules *is* just *starting. but it can be expected that this field* will *prove to be of great impact in the* future.

Calixarenes and Their Analogues: Molecular Complexation

C

Ivan Stibor
Pavel Lhoták
Institute of Chemical Technology, Prague, Czech Republic

INTRODUCTION

The ability of calixarenes to act as baskets is said to be one of their most intriguing properties, accounting for much of the interest they received.''' Generally speaking, molecules having convergent concave surfaces are frequently potent receptors; and their cavity can form a binding site where recognition events take place. It is well known that calix[4]arenes and calix[5]arenes, particularly when in their cone conformations, possess an intramolecular cavity that can host neutral molecules or their neutral parts of complementary size. Other conformations of calix[n]arenes (n=4,5) as well as larger calix[n]arenes are also known to form numerous molecular complexes, but factors controlling their complexation selectivity are not well understood, mainly due to their greater conformational flexibilities.[2–4]

This entry deals with various facets of molecular complexation by calixarenes. Most studies published on this subject are connected with cone conformation of calixarene skeleton.

The subject is traditionally divided into two parts, considering solid-state systems, first and then proceeding to solution-state systems, having in mind aqueous and nonaqueous solvents. Finally; gas-phase recognition will be mentioned briefly.

SOLID-STATE COMPLEXES

Many calixarenes form complexes in the solid state, this property having been observed even before the structure of compounds was established. Among the simple calix[n]arenes, for example, *p-tert*-butylcalix[4]arene forms complexes with chloroform, benzene. toluene. xylene, nitrobenzene, nitromethane, acetonitrile, and many others, while *p-tert*-butylcalix[5]arene complexes were studied with lower alcohols, ethyl acetate, toluene. and tetraline. More flexible *p-tert*-butylcalix[6]arene was found to form complexes with acetonitrile and *p-tert*-butylcalix[8]arene with chloroform. The tenacity with which the guest molecule is held by the calixarene hosts varies widely with the size of macrocycle. Whereas tetramers to hexamers usually hold their guests tightly. retaining a residual amount of the crystallization solvent even after prolonged heating at high temperature under vacuum (which makes traditional elemental analysis completely useless at times), *p-tert*-butylcalix[8]arene crystallizes from chloroform in beautiful glistening needles that change to white powder within a few minutes at atmospheric pressure.

The structures of complexes of calixarenes are most effectively revealed by x-ray crystallography. The first solid-state complex published was that of *p-tert*-butylcalix[4]arene with toluene[5] (Fig. 1).

It was quickly found that there are many difficulties connected with the structural studies of even the simplest calixarene complexes.[6] In general: the compounds are disordered, often with involvement of guest and host sublattices. and there is evidence for dynamic coupling between them. That is why the use of a synoptic approach has been advanced, where the use of complementary techniques resulted in improved structural models. Without doubt, the combination of crystallography and solid-state nuclear magnetic resonance (NMR) spectroscopy has proven to be remarkably effective in solving a number of complex problems. We can illustrate the complexity of these studies by looking at an almost 10-year-long structural study of the first crystalline calixarene complex mentioned above. The parent *p-tert*-butylcalix[4]arene has a flexible upper rim defined by *tert*-butyl groups. In contrast, the lower rim is fixed by in-plane hydrogen bonding. It was found that at room temperature, the toluene guest rapidly reorients between equivalent guest sites, but that below 248 K, the transition to a lower symmetry host lattice takes place. There are two crystallographically distinct molecules. each with a toluene guest that is disordered over two equivalent sites. More detailed study using ^{2}H, ^{13}C, variable temperature NMR, calorimetry. and 150 K crystallography show that toluene is static at 129 K. and that it undergoes rapid 180° flip about the molecular C_2 symmetry axis at 180 K and above (E_a=34±3 kJ mol^{-1}). These results are consistent with the final structural analysis in which each of two crystallographically different complexes has only a twofold axis of symmetry. Apparently, the structure of solid-state

DOI: 10.1081/E-ESMC *120012851*

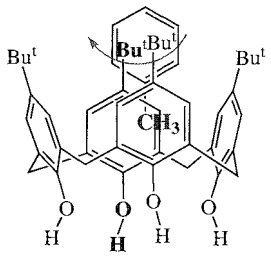

Fig. **I** The structure of *p-tert*-butylcalix[4]arene with toluene. (*View this art in* color *at www.dekker.com.*)

calixarene molecular coinplexes is far from being trivial because of the dynamic structural complexity. Similarly, the dynamic structures of other calixarene complexes were recently examined,[6] namely. complexes of *p-tert*-butylcalix[4]arene with benzene, pyridine, 4-nitrobenzene, cyclohexane, hexane. dodecane, heptane-1-ol, octane-1-ol, and. 1,4-dichlorobenzene. The following extremely important conclusions can be drawn from this pioneering work:

> "Most. if not all, molecules of appropriate size form reasonably stable inclusion compounds with *p-tert*-butylcalix[4]arene, and this observation suggest that considerable caution should be exercised in interpreting compound stability in terms of specific interactions. By examining series of structurally-related guest compounds it can be seen that the deep cavity is chlorophobic, but the space filling seems to be more important than the avoidance of unfavorable interactions in determining whether compound formation will take place. A similar conclusion can be drawn from the fact that a long molecule will curl up in order to fill space effectively in an inclusion compound rather than exist in a favored all-trans conformation without inclusion compound formation."[6]

In an alternative approach. all data available in the Cambridge Structural Database (CDS) for inclusion complexes formed by calix[4]arenes, calix[4]resorcinols, and thiacalix[4]arenes in the cone conformation with neutral organic molecules having acidic CH groups were retrieved. The data for 39 guests and two types of organic molecules with CH acidic groups. namely, CH_3X and CH_2XY (X,*Y*=EWG groups) were critically evaluated.[7] First; suitable geometrical descriptors were introduced for precise definition of host geometry as well as position and orientation of the guest inside the cavity. Nitromethane and acetonitrile were chosen as typical guests of CH_3X type. No obvious correlation between simple geometrical characteristics of the host or guest and the strength of inclusion was found. Nonetheless, what is important is the specific position of the guest methyl group inside the cavity, a position that must facilitate the strongest possible intermolecular interaction with all aromatic wails of the host. Accordingly. dichloromethane, chloroacetonitrile. and malononitrile were chosen as typical guests of the CH_2XY type. The data obtained showed that the intermolecular interactions between the aromatic cavity of the calix[4]arene hosts and the molecule having acidic CH groups are different for CH_3X and CH_2XY guests. There is no evidence for hydrogen-bond-like characteristics of CH_3X interactions. These results are in agreement with more sophisticated studies (e.g., inelastic neutron scattering) that show that the guest methyl group behaves as an almost free quantum rotor. Conversely, rotation of CH_2XY guests is somewhat inhibited by complex formation. This entropic cost is partially compensated for by a higher value of the enthalpic contribution to the bonding, as reflected by the cotrelation of CH-aromatic distance and acidity of the guest.

There have been several attempts to apply quantum chemistry to the evaluation of structure and properties of solid-state complexes of calix[4]arene receptors. Usually, only inolecular mechanics and dynamics can be used to do this job, and information obtained has usually been regarded as supporting evidence of the structure of the complex formed. Recently. an advanced approach was applied to structure elucidation of solid-state inclusion complexes formed by *p-tert*-butylcalix[4]arene with different solvents. The method reported[8] is based on the following procedure. Various possible geometries of host–guest complexes are modeled using fast force-field optimization. Based on minima structures obtained by this approach, quantum chemical (GIAO)-DFT NMR calculations were performed. Then comparison of theoretical and experimental chemical shifts for free ligand and complex with solvent furnish the spatial arrangements of host and guest. Thus, it is possible for calix[4]arene complexes. using a combination of force-field geometry optimization and CIAO-GFT NMR shift calculations. to screen various starting geometries against experimental data, yielding good structural models for these complexes in the solid state.

COMPLEX FORMATION IN LIQUID PHASE

Apolar Media

Calixarenes in general are known to form weak complexes with neutral organic guests in apolar media. This behavior is different from that of cavitands based on calix[4]resorcinols. Molecules of solvent compete with the guest with respect to interaction with the host molecule. That is why the crucial problem to be solved is the proper choice of solvent that is able to dissolve both components and that is not able to interact with the host molecule. For

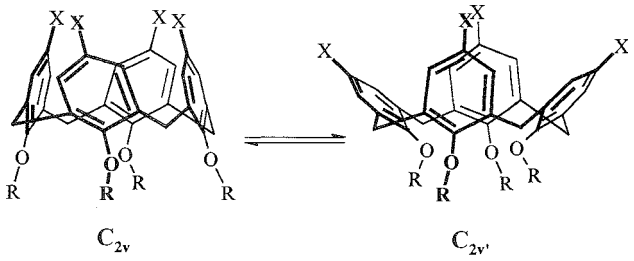

Fig. 2 Dynamic stereochemistry of tetraalkoxycalix[4]arenes in the cone conformation.

calix[4]arenes in the cone conformation, tetrachloromethane is a good example. as it is too big to fit within the cavity and at the same time it has acceptable properties as a solvent. This is perfectly true for calixarenes with rigid cavities, as for example. parent *p-tert*-butylcalix[4]arene. with a circular array of four hydrogen bonds. It is. however. not true for tetraalkylated *p-tert*-butylcalix[4]arenes. where large alkyl substituents are believed to lock the cone conformation. The reason is that most of these compounds retain a limited degree of conformational flexibility, as their cone conformation in which apparent C_{4v} symmetry is in fact the result of fast interchange between two C_{2v} flattened cone structures. These are sometimes referred to as pinched cone conformations. This behavior was directly established by variable temperature NMR measurement of tetrakis-*n*-octyloxy-*p-tert*-butylcalix[4]arene (Fig. 2).[9]

The role of the lower-rim substitution pattern of *p-tert*-butylcalix[4]arene was studied for a series of complexes formed by 12 *p-tert*-butylcalix[4]arene hosts with 13 guests (eight nitriles and five nitroalkanes).[10] It was proven that the complexation ability of these hosts follows the order: monosubstituted > disubstituted > unsubstituted > tetrasubstituted. The suggested explanation of this order is based on the shape of the host cavity and the time-averaged proportion of the host molecule adopting transition shapes during flipping through the annulus. The structure of complex acetonitrile **C 1** was proven by ^{1}H-NMR spectroscopy, in which NOEs were found between metaprotons of ail the phenolic units of hosts. with the methyl protons of acetonitrile as guests (Fig. 3).

Doing the same study with propionitrile, it was found that methyl and methylene groups are found inside the cavity of the host. with the methylene group positioned somewhat deeper.

These findings are in perfect agreement with other approaches to binding enhancement by "covalent shaping" of the *p-tert*-butylcalix[4]arene cavity. The first involves selective 1,2 (proximal) lower-rim functionalization of parent *p-tert*-butylcalix[4]arene, yielding the series of *p-tert*-butylcalix[4]arene *bis*crowns 2–6 (Fig. 4), where the conformational flexibility can be tuned by varying the length of the bridging unit.[11]

In fact, *p-tert*-butylcalix[4]arene *bis*crown-5 6 is flexible and adopts a flattened-cone conformation in solid state, while *p-tert*-butylcalix[4]arene *bis*crown-3 derivatives 2–4 possess a rigid cone structure. The recognition properties of **3** in solution were evaluated in organic solvents ($CDCl_3$ and CCl_4) using nitromethane as guest.[12] By adding variable amounts of guest to a solution of **3,** a significant upfield shift of the CH protons of the guest and fast exchange conditions were observed. These shifts clearly show an interaction of the acidic protons of the guest with the n-electrons of the calixarene cavity, while excluding a possible interaction of these protons with the crown-ether region. which should result in a downfield shift. The analysis of the data showed the formation of 1:1 complexes and provided quantitative information on host–guest interactions (Table 1).

To gain further insight into the role of rigidity on the molecular recognition properties of hosts. comparison was made with the more mobile hosts 6 and **7**. Interestingly, in **6** and **7**. with nitromethane and malononitrile, nu variation of the chemical shift of the guest was observed, while with 5, coinplexation occured but only in CCl_4 and with a lower association constant than with the more rigid 3. These results deinonstrate the importance of rigidity in determining the complexation properties of the n-donor cavity of calix[4]arenes. The group present at the upper rim strongly affects the stability of complexes formed as witnessed by data for compounds **2–4**. In fact. increasing the extension of the cavity increases the complexation efficiency toward nitromethane (Table 1). In contrast, malonodinitrile is bound with comparable efficiency by all three hosts. probably for steric reasons. Another interesting observation. which confirms the importance of rigidity and, consequently. the preorganization of the calix[4]arene in the cone conformation, was observed by comparison between hosts 8 and 9. Here. the well-known

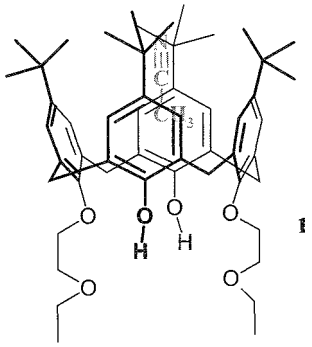

Fig. *3* Complex **1**⊂ acetonitrile in CCl_4 proven by ^{1}H-NMR (*View this art in* color *at www.dekker.com.*)

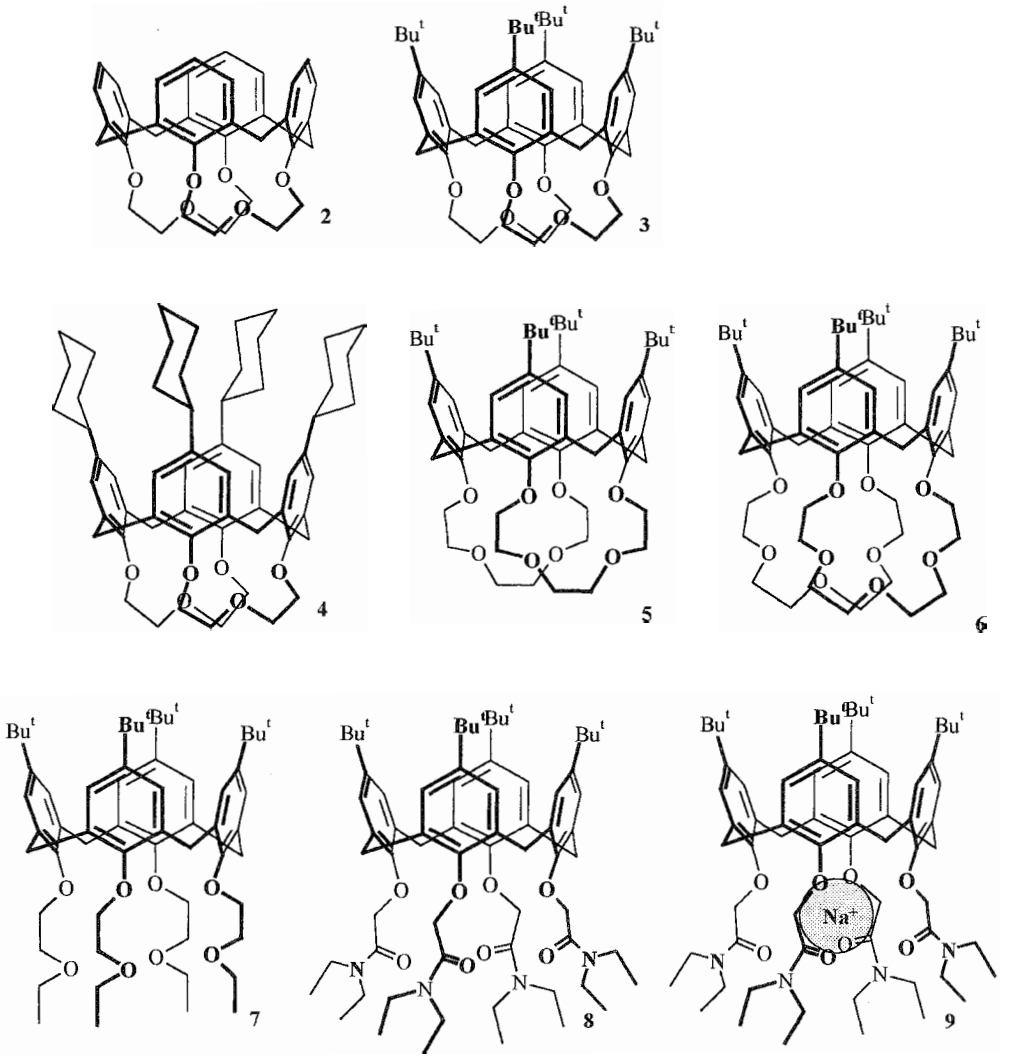

Fig. 4 *p-tert*-Butylcalix[4]arenes with different flexibilities of cone conformation

free ligand and its codium picrate complex were compared in the complexation of nitromethane in $CDCl_3$. While the conformationally mobile 8 does not show significant complexation, its rigid sodium complex 9. through a positive allosteric effect, binds nitromethane (Table 1). Similar results were obtained with a corresponding tetraester–acetonitrile system.[10] There is also a recent report involving the correlation between the guest acidity and the association constants in the recognition of neutral CH_3X and CH_2XZ species by rigidified calix[4]arene.[13] Comparison of K_{ass} of acetonitrile (pK_a – DMSO = 31.3) and nitromethane (pK_a – DMSO = 17.2), measured in CCl_4, shows that these two guests are bound with similar efficiency. This indicates. in agreement with the results obtained in solid state,[7] that the complexation of the CH_3X guests is not determined by their acidity. Conversely. as verified in the solid state, the similar. data on guests CH_2XZ strongly suggest their dependence on the acidity of the CH_2 group. This finding is also in agreement with the solid-state study.[7] The energetics of the inclusion of guests by rigidified cone conformer of calix[4]-arenes in CCl_4 was also recently reported.[14]

Table 1 Association constants (K_{ass}, M^{-1}) of 1:1 complexes of nitromethane and malononitrile with rigidified calix[4]arenes 2–9 at 300 K

	CH_3NO_2		$CH_2(CN)_2$

4	36±8	123±25	23±5
5	[a]	50±10	[a]
9	34±7	[a]	[a]

[a] Not determined.

The influence of upper-rim substitution was also studied in the series of calix[4]arenes with identical substitution patterns on the lower rim but differing in their upper-rim substitution pattern. Namely, hydrogen, *tert*-butyl, and adamantyl were used as upper-rim substituents.[15] The association constants obtained for *p*-adamantylcalix[4]arene complexes are close in their values to those of the corresponding *p-tert*-butylcalix[4]arene complexes. The ^{1}H-NMR spectra of these compounds undergo similar changes caused by complexation as the spectra of their *p-tert*-butyl analogues. Thus. complexation-induced shifts of OH and aryl protons of the ligands of both types have similar values, and a significant upfield shift of the protons of the substrate (up to 6 ppm) is observed. It seems apparent that both hosts behave in a similar way, at least in tetrachloromethane solution. In contrast. upper-rim unsubstituted calix[4]arene derivatives form weak complexes with all guests studied. This result can be explained by the fact that the calixerene apolar cavities are not shielded by any substituent and are easily accessible for solvent molecules of any shapes and sizes. The results from all the above studies can be rationalized in the following way. First. the ability of calix[4]arene hosts to form complexes with neutral molecules is controlled by the solvation of its cavity. Second. C–H···π interactions play an important role in the complexation process—the strength of complexes formed by the guests with similar geometries and nature strongly depends on their C–H acidity. Third, the association constants of observed complexes do not exceed 300 M^{-1} in CCl_4 and 30 M^{-1} in $CDCl_3$.[15]

In order to improve the recognition efficiency of neutral organic species. suitable binding sites were attached at one or two rims of calix[4]arene or calix[5]arene platform. usually with the ability to act as hydrogen bond donor or acceptor groups. Using this approach, selective binding of several primary amines by a carefully designed dicarboxy- calix[5]arene receptor was studied. As usual with calix[5]arenes, the synthesis of the receptor is complicated and results from a low-yielding synthetic sequence.[16] Also, a molecule of water was found to be complexed selectively by adamantylated calix[4]arene diamide.[17] Clear evidence that the hydrogen-bonding groups linked at the upper rim and the cavity are able to cooperate in binding was obtained when rigidified calix[4]arene **10** bearing a methylenephenylureido additional binding site at the upper rim was exploited to recognize low-molecular-weight amides.[18] The structure of host and the cooperative binding is shown in (Fig. 5).

The complexation properties of host **10** were evaluated in $CDCl_3$, and it was found that it is able to efficiently recognize amides with NH_2 or NHR groups, whereas the substantial decrease of this ability was observed with the guests bearing *N,N*-dialkylamino groups.

Aqueous Media

One of the main reasons for studying the interactions of calixarenes in water is to exploit hydrophobic effects in order to enhance complexation of apolar guests in their cavities. In order to study this phenomenon, the water-soluble calixarenes are needed in analogy of cyclodextrins and water-soluble cyclophanes. To engender water solubility generally, calixarenes need to be functionalized with groups containing positive or negative charges or with neutral but highly hydrophilic moieties. A predominant part of the work concerning the complexation of neutral molecules by water-soluble calixarenes was carried out in the 1980s and was critically reviewed.[19] Classical work was devoted to the inclusion of small neutral organic guests (alcohols. ketones, and nitriles) by water-soluble calix[4]arene hosts (solubility was introduced by sulfonyl groups at the upper rim or carboxy groups at the lower rim, sometimes in combination, and with an ethoxyethoxy group at the lower rim). The guests are included in the host hydrophobic cavity by their apolar aliphatic residues.

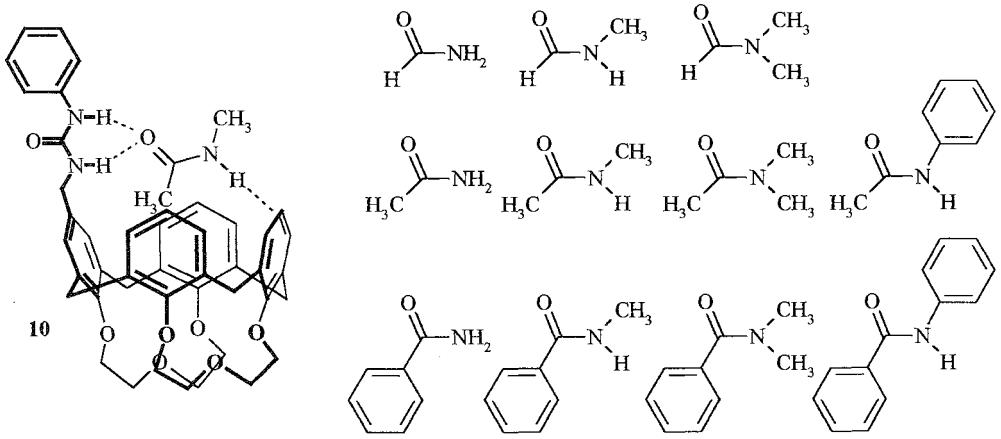

Fig. 5 Structure of complex formed by **10** and several amides

The binding constants at neutral pH confirm the importance of charge assistance in the apolar binding of guests inside calixarene cavities, and they highlight the role played by the conformational properties of host in the recognition process."'' Recently, the rennaissance of interest in all aspects of molecular recognition in water were easily observed in chemical literature. A number of papers appeared on the application of water-soluble calix[*n*]arenes as catalysts or cocatalysts. Thus, Wacker oxidation of alkenes,[20] aldol-type condensation and Michael addition,[21] and Suzuki coupling,[22] were recently reported to be catalyzed by water-soluble calix[*n*]-arenes. These results are apparently connected with ''green chemistry'' procedures with the potential for industrial application, a fact that should boost the research in this area profoundly. The second subject of recent interest is centered around medicinal chemistry application in a broad sense. Water-soluble *p*-sulfonatocalixarenes were recently reported to bind dipeptides and tripeptides containing lysine and arginine. This process, taken as a model for interaction of glycosylaminoglycans with polypeptides, was thoroughly studied by NMR and microcalorimetry.[23] There are, however, many examples of water-soluble neutral calixarenes, and most of them belong to the neoglycoconjugates family.[24] Such compounds can be used as models of important biological processes like interactions taking place on the surface of the cell. Among them, embryogenesis, cancer metastasis, inflammation. and bacterial and viral infections are examples of biological events that involve the selective recognition of carbohydrates by proteins. However, isolated carbohydrate–protein interactions are typically weak. Nature compensates for the weakness of these isolated interactions by tending to cluster together multiple copies of carbohydrate receptors in order to allow for stronger cooperative binding to take place—the so-called multivalent effect. The role of calixarenes as cyclic oligomers of phenolic nuclei is immediately apparent. No wonder that many water-soluble carbohydrate-appended calixarenes were reported and their properties studied. A recent report on this subject illustrates the state-of-art in this direction.[25]

Gas-Phase and Gas–Solid Interface

The study of host–guest interactions recently expanded from solution chemistry to the gas phase. where solvent effects are not present. allowing better understanding of the intrinsic phenomena responsible for molecular recognition. Many calixarenes were used as hosts in this respect[26,27] using CI MS. The less-demanding approach (at least as far as the instrument costs are concerned) involves the application of GC headspace analysis applied for gas-phase complexation of parent calixarene[28,29] and thiacalixarene.[29]

CONCLUSION

No conclusion can adequately summarize the developments in the topic of this article. Host–guest chemistry is still in its infancy as a typical multidisciplinary subject. The progress in all basic disciplines will immediately provoke progress in the level of our knowledge on molecular complex formation by calixarenes. The synthesis of many new ligands and their thorough study will definitely be required to better understand the multifaceted problem of molecular recognition and complex formation.

NOTE ADDED IN PROOF

Parent *p-tert*-butylcalix[4]arene has been found to undergo unprecedented single-crystal-to-single crystal phase transition upon guest uptake and release. Despite the lack of porosity of the material, guest transport through the solid occurs readily until a thermodynamically stable structure is achieved. In order to actively facilitate this dynamic process, the host molecule undergo significant positional and/or orientational rearrangement. This transformation is triggered by weak van der Waals interaction between host (*p-tert*-butylcalix[4]arene) and guest (vinyl bromide) molecules.

Calixarenes: Synthesis and Historical Perspectives

C. David Gutsche
Texas Christian University, Fort Worth, Texas, U.S.A.

INTRODUCTION

The modern era of calixarene chemistry had its inception in the early 1970s in the laboratories of Washington University in Saint Louis." Motivated by an interest in designing enzyme mimics but faced with a paucity of easily synthesized basket-like molecules. Gutsche and his research group became intrigued with the compounds involved in an industrial process at the Petrolite Corporation in nearby Webster Groves. In response to a problem of sludge formation in one of the crude oil-demulsifying surfactants marketed by this company. the Petrolite chemists isolated a high melting material that seemed to be similar to compounds described by the Austrian chemist Alois Zinke in the 1940s. Zinke treated various phenols with formaldehyde along with a strong base in boiling linseed oil and obtained materials assumed to be pure entities to which he assigned cyclic tetrameric structures.[b] This conclusion appeared to be substantiated by a rational. stepwise synthesis of a cyclic tetramer by the English chemists Hayes and Hunter[7,8] in the 1950s, although a direct coinparison with the Zinke compound was not made. The first hint of a problem with the Zinke inaterials emerged at about the same time from the work of another English chemist, Sir John Cornforth. who isolated pairs of compounds fi-om *p-tert*-butylphenol and *p*-(1,1,3,3-tetramethylbutyl)-phenol and who noted the extraordinarily capricious nature of the reaction.''' The work of the Gutsche group in the 1970s confirmed the fact of mixtures'''' and showed that by careful control of the reaction conditions, pure samples of the cyclic tetramer, cyclic hexamer, and cyclic octamer can be easily and reproducibly obtained from *p-tert*-butylphenol.[11] The structures of these,[12 14] and now many other calixarenes that have been made, have been firmly established by x-ray crystailographic analyses. Work in many laboratories shows that a number of other phenols also yield cyclic oligomers. although none allow as precise product control as does *p-tert*-butylphenol. Perceiving a visual resemblance between the CPK space-filling model of the cyclic tetramer and a type of Greek vase known as a Calix Crater. the name ''calixarene'' was chosen to define this particular class of [1_n]metacyclophanes, using a bracketed number [*n*] to designate the size of the calixarene, i.e.. calix[4]arene for the cyclic tetramer, calix[6]arene for the cyclic hexamer, etc. The special ease of synthesis of the major calixarenes 1, 3, and 5 (R = *tert*-Bu) followed by the relative ease of synthesis of the minor calixarenes 2 and 4 (R = *tert*-Bu) played a key role in the rapid expansion of the field. bringing dozens of laboratories and hundreds of chemists into the fold of calixarene chemistry. As the early experiments of Hayes and Hunter demonstrated. however. the one-step synthesis is not the only route to calixarenes, and stepwise syntheses, now called fragment condensations, have aiso played a significant role.

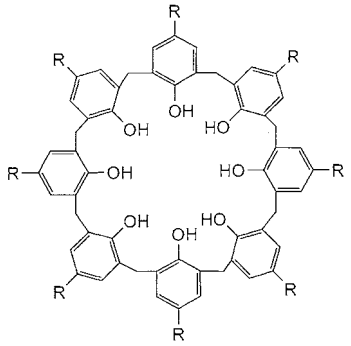
SINGLE-STEP CONDENSATION OF PHENOLS AND FORMALDEHYDE

The original Zinke *synthesis employed* NaOH *as the base to induce the condensation of* *p*-alkylphenols *and formaldehyde, and base induction* remains *the method of choice noi only for the three major calixarenes* 2, *4, and* 6 (R = *tert*-Bu) but *also for the* two *minor calixarenes 3 and* 5 (R = *tert*-Bu). *With* NaOH *(in* small *amounts) as the base and* refluxing *diphenyl ether as the solvent, a* 50% *yield of pure* *p-tert*-butylcalix[4]arene *2 is produced.*[16] *With* KOH *(in larger amounts) as the base and* refluxing xylene *as the solvent. ca.* 85% yields *of p-tert*-butylcalix[6]arene *4 are* produced.[16] *With* NaOH *(in small amounts) as the base and* refluxing *xylene as the solvent, ca.* 65% yields *of p-tert*-butylcalix[8]arene 6 *are* produced.[17] *The* *p-tert*-butylcalix[5]arene **3**[18,19] *and* *p-tert*-butylcalix[7]arene **5**[20] *require more effort to synthesize, entailing separation* from *the various other calixarenes* in *the product* mixture, *but are isolable in pure form in yieids of ca.* 15–20%. *Phenols that do* not *yield calixarenes* when *treated with formaldehyde and base include* *p*-nitro, *p-cyano,* *p*-phenoxyphenyl, *p*-carboxy, *p*-acetyl, *p*-hydroxymethyl, *and* *p*-hydroxy (hydroquinone) *Success* is generally limited *to phenols carrying* nondeactivating *p*-substituents *For example, p-*cresol gives *4* (R = *Me) in* 74% yield[21] *or* 5 *(R = Me) in* 22% yield[22] *p*-phenylphenol gives *a* mixture *of 4* (R = *Ph),* 5 (R = Ph), *and* **6** *(R =* Ph),[23] *p*-benzyloxy-*phenol* gives *6* (R = Bn) in 48% yield,[24] *but* p-methoxyphenol *yields a* complex mixture *ol* oligomeric *compounds Phenol, carrying long-cham* *p*-alkyl substit-*uents often* give poor *results.* but *those* carrying alkyl groups highly *branched near the point of attachment at the* *p*-position sometimes react *more* like *p-tert*-butylphe-nol *For example.* *p*-(1,1,3,3-tetramethylbutyl)phenol *gives 2 and 6* (R = 1,1,3,3-tetramethylbutyl) in *modest* yields,[25,26] *and* *p*-adamantylphenol gives *6* (R = ada-mantyl) in 72% *yield* [27]



6

For many years, it was thought that no calixarenes larger than $n = 8$ *are formed in the one-step process. However, it* is *now known that calixarenes* with *sires well beyond this can be formed, extending to at least* 20 *aryl* residues.[28] *Although several of the "large" calixarenes* ($n > 8$) *can be obtained via base-induced condensation. an acid-catalyzed reaction provides a better source: treatment of* *p-tert*-butylphenol *with s-trioxane and* *p*-toluenesulfonic *acid in* $CHCl_3$ *solution produces an almost quantitative yield of a calixarene mixture that is richer in the large calixarenes than the product from base* induction.[28]

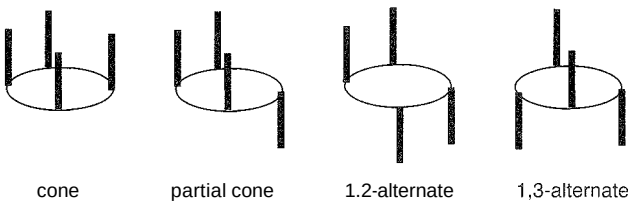


Fig. 1 Conformations *of* calix[4]arenes

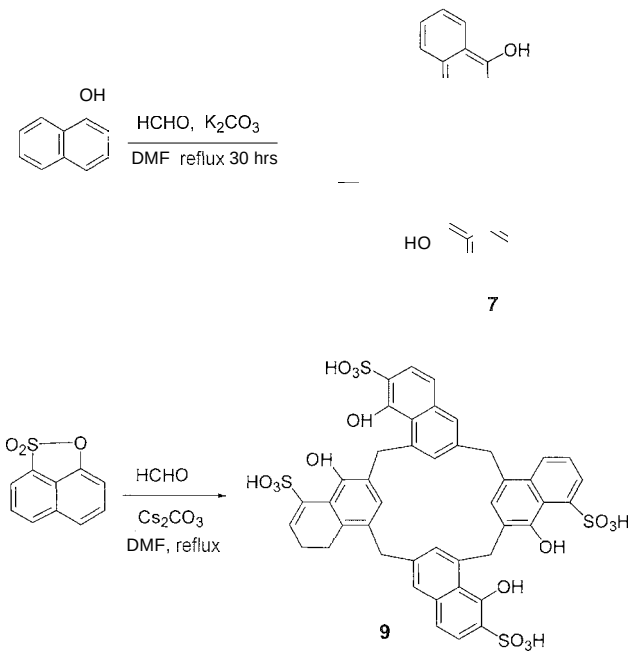
One of the interesting characteristics of calixarenes is their ability to assume a variety of conformations in which the aryl groups are oriented *syn* or *anti* with respect to one another. Calix[4]arenes, for example. can assume a cone, partial cone, 1.2-alternate, or 1,3-alternate conformation, and the energy barrier to interconversion among the conformers can be determined by dynamic ^{1}H-NMR spectral measurements (Fig. 1). A study of the entire family of *p-tert*-butylcalix[n]arenes shows that conformational stabilities (i.e., higher barriers to interconversion) reach maxima when n = 4,8,12,16, and 20, probably the result of the interplay of intramolecular hydrogen bonding and molecular packing.[28]

SINGLE-STEP CONDENSATION OF NAPHTHOLS AND BISPHENOLS WITH FORMALDEHYDE

r-Naphthol reacts with formaldehyde in a comparable fashion to p-alkylphenols to furnish calix[4]naphthol **7** along with two positional isomers in which, in contrast to the phenol-derived calixarenes. all of the OH groups are *exo* rather than *endo* to the annulus.[29–32] Analogously. 1,8-naphthalene-sultone 8 yields the sulfonated calix[4]naphthalene 9. Bisphenols of the general structure **10** (m = 0, 2, and 3) produce calixarenes **11** (a = 2 and 3) upon reaction with paraformaldehyde in the presence of bases including NaOH. KOH. and CsOH.[33–38]

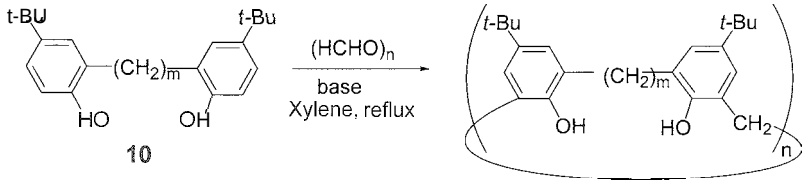


MECHANISM OF BASE-INDUCED CALIXARENE FORMATION

Although the mechanism of the base-induced formation of calixarenes has been studied in some detail, the reaction pathways remain uncertain. The most intuitively reasonable proposal is that the immediate precursor of any particular calixarene, regardless of size, is the linear oligomer carrying the requisite number of aryl residues. Another proposal, however, postulates that calix[8]arenes, for example, arise from intermolecularly hydrogen-bonded dimers (hemicalixarenes) formed from a pair of crescent-shaped, intramolecularly hydrogen-bonded linear tetramers.[3] Calix[4]arenes, formed under considerably more strenuous conditions. have been postulated to be the result not of direct cyclization of the linear tetramer but of reversion of the calix[8]arene.[39] The cyclic octamer is viewed as the product of kinetic control, and the cyclic tetramer is viewed as the product of thermodynamic control. The particular efficacy of KOH and RbOH for the formation of calix[6]arenes suggests that the hexamer is the product of template control.

SINGLE-STEP CONDENSATION OF RESORCINOLS AND ALDEHYDES

Concurrent with Zinke's work with phenols and base in the 1940s was Niederl's[40,41] reinterpretation of the structures of the products formed by the acid-catalyzed reaction of resorcinol and aldehydes, which he postulated to be cyclic tetramers 12. The cyclic tetrameric structure was conclusively established in 1968 by Erdtman[42] through x-ray crystallographic analysis, and the synthesis of the Niederl tetramers was greatly improved through the work of Högberg[43,44] in the 1980s. A wide variety of aldehydes were condensed with resorcinol and substituted resorcinols, including aliphatic aldehydes (saturated, unsaturated, functionalized). aromatic aldehydes [with R. OH. NO_2, halogen; CN, NH_2, RCO, and $B(OR)_2$ substituents]. heterocyclic aldehydes, and ferrocenylaldehyde. Failing to yield cyclic tetramers are HCHO (which forms a polymeric glue), highly hindered aldehydes such as 2,4,6-trimethylbenzaldehyde, and aldehydes containing functionality proximate to the CHO, such as $ClCH_2CHO$. Employing the Wiederl coinpounds as starting materials. Cram elaborated them into enforced baskets called cavitands, and these, in turn, into hollow spheres called



10 11

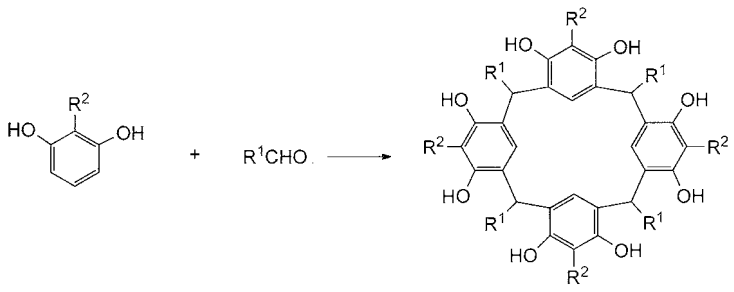
carcerands, capable of incarcerating molecules with no way of escape.[45]

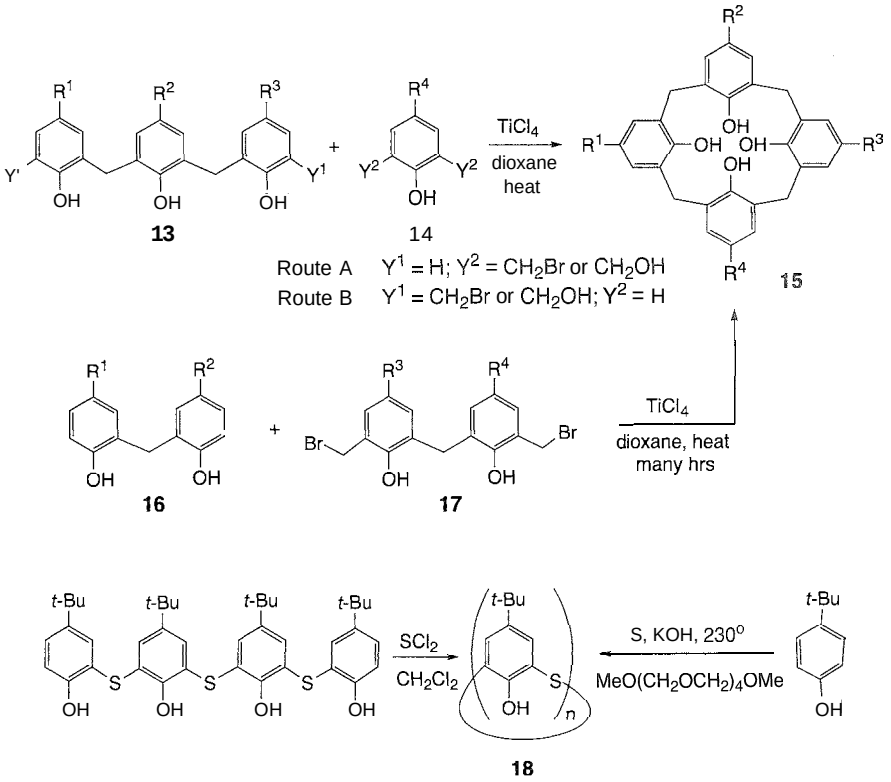
NOMENCLATURE

The name "calixarene" (the prefix ***calix*** because of the vase-like shape of the cyclic tetramer; the suffix *arene* because of the aryl groups in the cyclic array) most accurately describes the shape of the cone conformers, of the cyclic tetramers and cyclic pentamers. However, the descriptor is less apt for the other three conformers. of these two calixarenes as well as for the larger members of the series that can assume a wide variety of conformations. Nevertheless, calixarene provides a convenient name for the entire extended family of cyclooligomers in which aryl (or heterocyclic) moieties are connected at the 1 and 3 positions by bridging moieties. Thus, the phenol-derived. naphthol-derived, and resorcinol-derived cyclooiigomers belong to the calixarene family and are appropriately named calix[*n*]phenarenes, calix[*n*]-naphtharenes, and calix[*n*]resorcarenes, respectively. The first of this group. however, are more generally designated simply as calix[*n*]arenes, the second as calix[*n*]naphthalenes, and the last as resorc[*n*]arenes which. lamentably lacking the prefix calix. belies their membership in the family. Substituents attached to calixarenes are specified as being on the upper (or wide) rim or on the lower (or narrow) rim. The OH groups of p-*tert*-butylcalix[4]arene, for example, are on the lower rim, and the tert-butyl groups are on the upper rim. When applying systematic nomenclature to a calixarene compound; the calixarene descriptor is taken to designate only the basic carbon framework, and all substituents (OH, tert-butyl, etc.) are specified by name and position. Thus, *p-tert*-butylcalix[4]arene becomes 5.11,17,23-tetra-*tert*-butylcalix[4]-25,26,27,28-tetrol; the calix[4]resorcarene derived from acetaldehyde becomes 2,8,14,20-tetramethylcalix[4]arene-4,6,10,12, 16.18,22,24-octol.

STEPWISE SYNTHESIS OF CALIXARENES

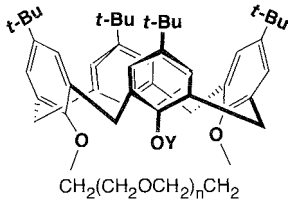
The multistep synthesis of calixarenes. introduced by Hayes and Hunter[7,8] and perfected by Kämmerer,[46] has been largely supplanted by the more convergent approaches for which the terms "fragment condensation" and "directed synthesis" have been applied by Böhmer.[47] In a ''3 + 1'' fragment condensation[48–50] for synthesizing **15** a linear trimer **13** is condensed with a monomer 14, one or the other of these units carrying a pair of appropriately placed hydroxymethyl or halomethyl groups. In similar fashion. a ''2 + 2'' fragment condensation[51] involves the reaction of the two linear dimers **16** and **17**. Other variations on the fragment condensation include ''2 + 1 + 1'' and ''1 + 1 + 1 + 1'' processes for the synthesis of calix[4]arenes (15), "3 + 2'' and "4 + 1'' processes for calix[5]arenes, "3 + 3'' processes for calix[6]arenes, etc. The major advantage of the fragment condensation over the one-step process resides in the control that it affords over the identity of the *p*-substituents. The major disadvantage is that it is generally more time consuming and provides lower yields, often in the 15–30% range, sometimes lower than 15% and rarely higher than 40%.



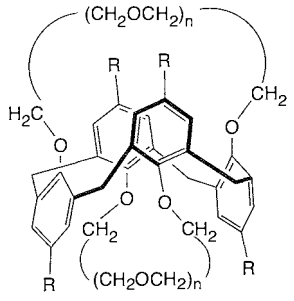


THIACALIXARENES

When p-tert-butylphenol. elemental sulfur, and NaOH are heated at 230°C in tetraethylene glycol dimethyl ether, the thiacalixarene 18 is produced in better than 50% yield [52 53] The same material was rynthesized in stepwise fashion but in far lower overall yield [54]



19



20

FUNCTIONALIZATION OF CALIXARENES

The *p-tert*-butylphenol, in addition to making the major and minor calixarenes readiiy available. provides these compounds in an easily functionalized form. The OH groups on the lower rim can be directly converted to a wide variety of esters and ethers. The tert-butyl groups on the upper rim can be readily removed by treatment with $AlCl_3$ and then replaced by a wide variety of functional groups. In this fashion. hundreds of calixarenes have been prepared carrying all manners of groups on the two riins. Saryl groups themselves have been achieved, as exemplified by the calixspirodienones.[55] Among the many interesting examples of functionalized calixarenes are the calix crowns, in which crown-ether moieties are introduced onto pairs of OH groups, as illustrated by 19 and 20.

CALIXARENE-RELATED COMPOUNDS

The calixarene family has become increasingly extended with the passage of time. and a variety of compounds now claim membership. Among the present family members.

inter alia. are homocalixarenes **21**,[56] homooxacalixarenes **22**.[57] homoazacalixarenes **23**,[58] calixfurans **24**,[59] calixpyrroles **25**,[60] calixthiophenes **26**,[61] and silacalixarenes 27 [62]

APPLICATIONS OF CALIXARENES

Among the early commercial applications of calixarenes are their use by the Petrolite Corp as demulsifiers and the Loctite Corp as adhesive moderators. Among the more recent commercial applications is the sequestration of cesium ions from nuclear wastes, using calix crowns such as 19. Much of the intense research activity in calixarene chemistry during the last decade focused on the ability of appropriately functionalized calixarenes to form complexes. In addition to complexation with cesium cation, the complexation of many other cations of the elements in the periodic table has been studied; with the promise of useful applications.[63] Complexation of anions as well as molecules has also been demonstrated. the latter providing the basis for investigations of enzyme mimics. Particularly interesting applications are illustrated by the wide variety of sensors that take advantage of the complexation properties of calixarenes.[2] Calix[4]arenes fixed in a cone conformation by large OR groups on the lower rim provide rigid platforms from which metal-based catalysts can be elaborated.[64] Two hundred or more patents have been issued in which calixarenes play the central role and deal. inter alia. with adhesion promoters. electrophotographic photoreceptors, photographic toners. hair dyes. diesel fuel additives. curing agents. antistatic agents. antioxidants. stabilizers. temperature-sensing devices. pressure-sensitive recording materials. flame-proofing compounds. safety glass composition, optical recording materials. and antibacterial agents.

CONCLUSION

Calixarenes. now easily synthesized on any scale in a variety of ring sizes by the one-step process and also accessible by the more flexible fragment condensation process. have taken their place alongside the cyclodextrins and crown ethers as the dominant ring structures in host–guest chemistry. Research in the field of calixarene chemistry continues at a rapid pace throughout the world, and new. interesting: and useful applications of these molecules are certain to be revealed in the years ahead.

The Cambridge Structural Database

Frank H. Allen
Karen J. Lipscomb
Cambridge Crystallographic Data Centre (CCDC), Cambridge, United Kingdom

INTRODUCTION

The Cambridge Structural Database (CSD) is the world's repository of crystal structure data for organic and metal–organic compounds. In addition to the primary results of each diffraction experiment. the CSD also contains bibliographic and chemical text, two-dimensional (2D) chemical structural diagrams, and any crystal properties that are available in the formal publication. The CSD will exceed 300,000 structural entries during 2003. The CSD System comprises the database together with software for the search and retrieval of information, structure visualization and data analysis. and is distributed to scientists in 56 countries worldwide. The CCDC is also developing structural knowledge bases derived from the CSD: IsoStar is a knowledge base of intermolecular interactions, and Mogul is a knowledge base of intramolecular geometry (bond lengths, valence angles, and torsion angles). The CSD is widely used as a basis for fundamental research, and nearly 1000 papers in the open literature are collated in a subsidiary database that is freely available via the CCDC web site.

BACKGROUND

The value of crystal structure data to the understanding of supramolecular processes is inestimable, because a crystal structure is the archetypal supermolecule. X-ray and neutron diffraction are the only experimental techniques that routinely generate precise and detailed information about nonbonded interactions at atomic resolution. This information forms the basis for the recognition, description and understanding of the key interactions through which molecules associate in the condensed phase, an understanding that is vital in supramolecular synthesis: crystal engineering, and the study and prediction of protein–protein and protein–ligand interactions.

In October 2001. the CCDC archived its 250,000th small-molecule crystal structure to the Cambridge Structural Database (CSD),[1,2] and this total will exceed 300,000 structures during 2003. The ongoing creation and maintenance of the CSD has been the CCDC's core activity since its inception in 1965. The CSD System, the database together with associated access software,[1,3] is now widely used in industry and in academic institutions in 56 countries.

The CCDC began life in the Department of Chemistry, University of Cambridge, U.K., with the aim of compiling a database of small-molecule crystal structures, i.e., organics and metallo-organics, determined using x-ray and neutron diffraction. A specific aim was to store the key numerical results of each analysis (cell parameters, atomic coordinates, etc.), which are embellished with chemical and bibliographic information, together with any physical and biological property data that can be gleaned from published crystal structure reports. In the late 1960s, just a few hundred structures were published each year, but fueled by scientific and technological advances, annual totals increased to more than 20,000 structures since 2001.

Early software development centered on systems for validating and storing crystal structure data. but systems for search, retrieval, analysis, and visualization began to be developed in the late 1970s and were significantly upgraded over recent years.[3] During the 1990s, the CCDC began to develop structural knowledge bases derived from the CSD and other data. The first of these. IsoStar—a knowledge base of information about intermolecular interactions,[4]—has been available since 1997, and Mogul, a knowledge base of intramolecular geometry, will be available during 2004. Since the late 1970s, the CSD has been increasingly used as a basis for fundamental research in structural chemistry,[5,6] crystal chemistry,[5] and the life sciences,[7] and nearly 1000 papers use CSD data as the basis for detailed research investigations. References to these applications are gathered in a database, DBUse,[5] which is available via the CCDC web site at http://www.ccdc.cain.ac.uk/dbuse.

INFORMATION CONTENT OF THE CSD

Each crystal structure forms an entry in the CSD and is identified by a CSD reference code (refcode). e.g., BAGFIT02. Six letters identify the chemical compound.

DOI: 10.1081/E-ESMC 120012882

and two suppleinentary digits identify additional determinations of the same structure. e.g., an improved refinement. studies by different scientists, studies under different experimental conditions, etc. The information content of each entry is summarized in Table 1.

The most important information item added by CCDC staff is the 2D chemical structure representation, which forms the basis for 2D and three-dimensional (3D) substructure searching[3] at the molecular and supramolecular levels. To increase the speed of these searches, each connection table is analyzed in order to assign cyclic/acyclic flags to bonds and to generate a bitmap or "screen" record. This contains codified yes/no information indicating the presence or absence of specific substructural features in each chemical diagram. e.g., atoms with specific connectivity patterns, coinmon functional groups, rings of specific sizes and constitutions, etc. The screens then act as search heuristics: screens generated from a search substructure must all be present in a candidate CSD entry before that entry is further analyzed using cpu-intensive atom-by-atom and bond-by-bond substructure matching. Bit screens are also generated from other CSD information fields, including text fields, for similar reasons.

Table I Information content of the Cambridge Structural Database.

Bibliographic and chemical text
Compound name(s): systematic and trivial
Amino-acid sequence for peptides
Chemical formula
Author name
Journal name and literature citation
Text indicating special experimental conditions or results (e.g., neutron study, powder study, polymorph, nonambient temperature or pressure, absolute configuration determined. etc.)
Chemical class (e.g., alkaloid. steroid. etc.)
Text comment concerning disorder and errors located during validation
Crystal data
Cell dimensions and standard uncertainties
Space group and symmetry operators
Reduced-cell parameters
Z' (number of chemical entities per asymmetric unit)
Calculated density
Chemical connection table
Formal two-dimensional chemical structure diagram in terms of atom and bond properties. Bond types used in the CSD are single, double, triple, quadruple (metal–metal), aromatic. delocalized double, and π-bonds
Bit-encoded screen records (see text)
Crystal structure data
Atomic coordinates and standard uncertainties

DATA ACQUISITION

Until the mid-1990s much of the information entering the CSD was laboriously retyped from coordinate listings in published papers or associated deposition documents. All that has now changed since the universal acceptance of the Crystallographic Information File (CIF) format,[8] adopted as an international standard for the electronic interchange of crystal structure data by the International Union of Crystallography in 1991. Most major journals now require electronic data deposition using the CIF, and 90% of new structures now enter the CSD processing system via this route. The CCDC currently acts as the official depository for over 70 journals, receiving data at the same time as the associated manuscript is submitted for publication. Full details of CSD data deposition facilities can be found at http://www.ccdc.cam.ac.uk/conts/depositing.html. The vast majority (>99%) of CSD entries arise from published work abstracted from the 1011 cited journals. However, the CCDC also encourages Personal Communications of data that would otherwise be lost to the scientific community. Only 262 such entries were archived in the period up to 1995. but since the general acceptance of the CIF. a further 1286 structures were deposited via this route.

DATA PROCESSING AND VALIDATION

The addition of chemical information forms a vital part of CSD data-processing activities. This involves the encoding of chemical connectivity data via the generation of a formal 2D chemical diagram and the checking or adding of chemical compound names and any common synonyms. Scientific Editors also add bibliographic data. together with any other CSD information that may be in the printed paper but not recorded in the CIF.

Complete information, crystallographic and chemical. is then validated using the CCDC program PreQuest. The principal checks carried out are self-consistency of crystal data (i.e., cell parameters, Z-value and density) and chemical constitution; a cross-check that the atomic connectivity derived from the coordinate data and standard covalent radii matches that in the encoded 2D chemical diagram; self-consistency of the geometry calculated from the atomic coordinates with the published geometry; and a check that there are no unreasonably short intermolecular contacts or any large unexplained voids in the extended crystal structure, perhaps indicative

Table 2 CSD entry statistics (June 1, 2003)

	Structures	%
Total number of structures	291,965	100.0
Number of different compounds	264,576	—
Number of literature sources	1011	—
Organic structures	128,367	44.0
Transition metal present	141,449	48.4
Li–Fr or Be–Ra present	16,080	5.5
Main group metal present	19,058	6.5
3D coordinates present	261,622	89.6
Error-free coordinates	255,795	97.8[a]
Neutron studies	1155	0.4
Low/high temperature studies	75,124	25.7
Absolute configuration determined	5376	1.8
Disorder present in structure	55,415	19.0
Polymorphic structures	9384	3.2
R-factor <0.100	264,903	90.7
R-factor <0.070	225,763	77.3
R-factor <0.050	144,027	49.3
R-factor <0.030	24,422	8.4
Average *N*(atoms)/structure in 2002[b]	75	—
Data added in 2002 (Mb)[c]	95	—

[a]Taken as a percentage of structures for which coordinates are present in the CSD.
[b]Data for 1970. 1980. 1990. 2000 were 27. 44. 53. 73 atoms. respectively.
[c]Data for 1970, 1980. 1990. 2000 were 2. 14. 29, 84 Mb, respectively.

of an incorrect space group or missing solvent molecule(s). Any unresolved errors are referred back to the original author(s) for clarification. Editors also resolve issues connected with crystallographic disorder and add text remarks concerning special aspects of the crystallographic experiment or its results.

STATISTICS

Some summary statistics for the CSD as of October 30, 2001 are given in Table 2, and more detailed information is presented elsewhere.[2] Shown in Fig. 1 is the cumulative rate of growth of the CSD for the period 1970–2000. These data can be analyzed to reveal two related facts: the time taken for the CSD to double its number of entries increased from 3.6 years in the 1980s to 8.0 years in 2001; and continuation of current trends indicates that the CSD will archive its 500,000th structure during the year 2010. However, these projections cannot take account of increased publication rates due to improved technology or any changes that may occur in methodologies for placing crystal structure data into the public domain.

CSD SYSTEM SOFTWARE

The distributed CSD System comprises the database, together with software for search. retrieval. visualization, and analysis of CSD content.

Searching The CSD: The ConQuest Program

ConQuest provides search, retrieval. and display facilities for the CSD.[3] Individual queries can be set up to interrogate the bibliographic, chemical text, and crystal data fields listed in Table 2, and, in particular, the program provides extensive graphical facilities for the definition of 2D and 3D substructure searches. The 2D searches interrogate the chemical connection tables alone, while

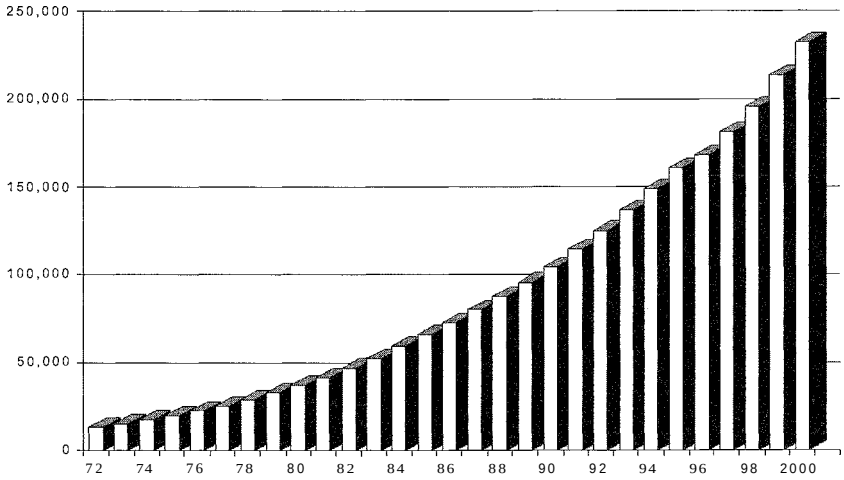

Fig. 1 Growth of the CSD over the period 1970–2000.

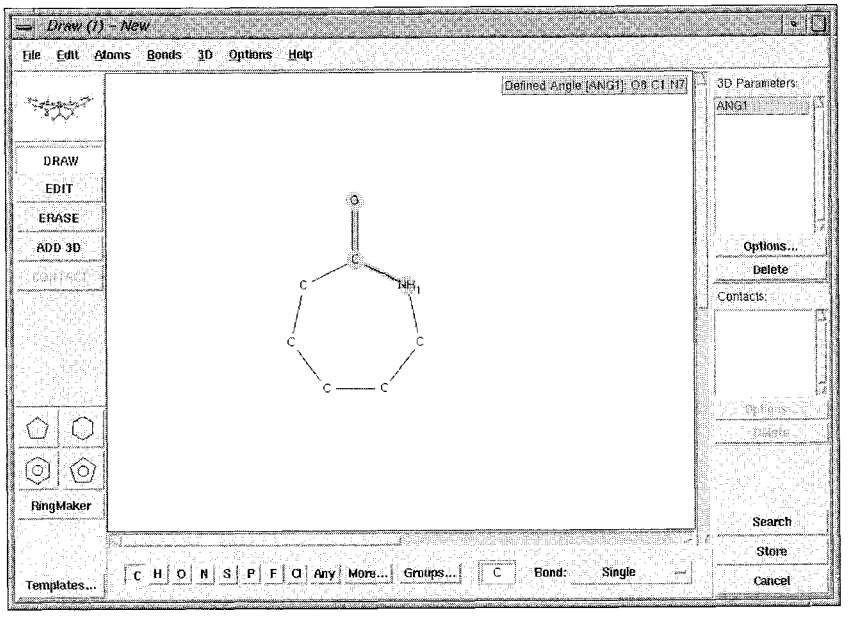

Fig. *2* Substructure search defined in the drawing window of ConQuest; output of a specific valence angle for each hit fragement is requested. (*View* this *art in* color at *www.dekker.com.*)

the atomic coordinates and connection tables. used together, form the basis for the following:

The retrieval of calculated 3D geometrical parameters for a substructure, as shown in Fig. 2, which can be used in further analyses. e.g., using the Vista program described below.

- 3D substructure searching, either in molecules (e.g., to locate substructures with specific conformations, 3D pharinacophoric patterns. etc.), or in extended crystal structures (e.g., to locate hydrogen bonds or other nonbonded interactions), using specific chemical and geometrical constraints in both cases.

ConQuest has facilities for combining individual queries, including 2D and 3D substructure queries. using Boolean logic. The program also displays the information content of CSD entries. selected from the main database (browse function) or from a subset of entries resulting from a search. Display panes show bibliographic and chemical text. crystal data, 2D chemical diagrams, and 3D structures. ConQuest can call up Mercury

Table *3* Principal facilities of the Mercury visualizer

- Browse the entire CSD. load hit lists from ConQuest searches. or read in crystal structure data in other common formats (*mol2*, *pdb*, *cif*, *mol*), supporting drag-and-drop on suitable platforms.
- Rotate. translate. and scale the 3D crystal-structure display and view cell axes, reciprocal cell axes. and normals to planes.
- Range of visualization options. e.g., different display styles. coloring, and labeling options. ability to hide and then redisplay atoms, molecules. etc
- Measure distances. angles. and torsion angles.
- Create and display centroids. least-squares mean planes. and Miller planes
- Display unit cell axes and the contents of any number of unit cells in any direction (including fractions of unit cells).
- Locate. display. and build networks of hydrogen bonds or other nonbouded contacts.
- Display a slice through the crystal in any direction.
- Undo and redo actions.
- Save the display as a file of molecules or as a graphics image, and copy images onto a PC clipboard.
- Save and read displays using its own binary format, retaining all program settings (except view direction and scale).

(see below, and Table 3) to provide more extensive 3D structure visualization facilities. Finally, ConQuest can output information for search hits in a variety of formats (e.g., cif, mol2, etc.), and transfer data to other programs.

Visualizing Crystal Structures: The Mercury Program

Mercury provides general and advanced Sunctionality for viewing crystal structures in 3D, as summarized in Table 3.[3,9] A unique feature of Mercury applied to CSD entries is its ability to import chemical bond types from the 2D connection tables and display them on the 3D image, as shown in Fig. 3. However, the most important functionality in Mercury, and one that is vital in supramolecular studies, is the ability to locate, build, and display networks of intermolecular and intramolecular hydrogen bonds, short nonbonded contacts, and user-specified contact types. Mercury will use distance criteria relative to van der Waals radii sums, or direct (Å) values. An example H-bonded network, constructed and viewed in Mercury, is shown in Fig. 4a. The facilities for displaying a slice through a crystal in any direction are illustrated in Fig. 4b, and such displays can be valuable in rationalizing crystal morphology and predicting how to control it.

Display and Analysis of Geometrical Parameters: The Vista Program

Vista displays molecular geometry and other parameters relating to a molecular or supramolecular substructure in a

spreadsheet format.[12] Such data are retrieved from the CSD by ConQuest according to user-supplied specifications. Vista performs a variety of analytical and display functions, including generation of the following

- Simple descriptive statistics for parameter distributions.
- Histograms and scattergrams referred to Cartesian or polar axes.
- Statistical analyses, including linear regression and principal component analysis.
- Hyperlinks from geometrical data back to the original CSD entry.
- Preparation of plots for reports and publications.

Exploring Intermolecular interactions: The IsoStar Knowledge Base

IsoStar gathers a vast amount of information on intermolecular interactions in a readily accessible form.[4] For a given contact between a central group (A) and a contact group (B), the CSD search results for an interaction A...B are transformed into an easily visualized form by overlaying the A moieties. This results in a 3D scatterplot showing the experimental distribution of the B-moieties around the (static) central group A (see Fig. 5a), which can also be presented in contoured form (Fig. 5b). IsoStar contains data retrieved from the CSD and from protein–ligand complexes stored in the Protein Data Bank (PDB),[13] and also contains nearly 1000 potential energy minima calculated using distributed multipole analysis and intermolecular perturbation theory calculations.[4]

Version 1.5 of IsoStar, released in October 2002, covers 300 central groups, 45 contact groups, and contains over 25.000 scatterplots. The user may interact with the basic scatterplots to generate contoured surfaces, to change the A...B distance limit for data presentation, to control the display style, etc. Importantly, the scatterplot data are hyperlinked to the master CSD and PDB files, so that the structural environments of specific interactions can be examined in detail. IsoStar, therefore, contains a vast amount of information of use in supramolecular chemistry, crystal engineering, and organic crystal chemistry,[5,6] and also provides ready access to information that is invaluable in rational drug design.[7]

RESEARCH APPLICATIONS OF THE CSD: THE DBUSE DATABASE

Research applications of the accumulated data in the CSD began to be published in the mid-1970s, as software for searching, manipulating, and analyzing the data began to be widely distributed. Indeed, software developments and research methodologies were always closely intertwined. Since the mid-1970s, nearly 1000 publications made use of CSD data as the essential basis for research projects that address topics such as the following:

- Mean molecular dimensions.[14,15]
- Structure correlation and reaction pathways.[16]
- Conformational analysis.[17,18]
- Hydrogen-bond geometry and directionality.[19,20]
- Weak hydrogen bonds.[21]
- Nonbonded interactions not mediated by H.[22,23]
- Crystal engineering.[24]
- Crystal structure prediction.[5]

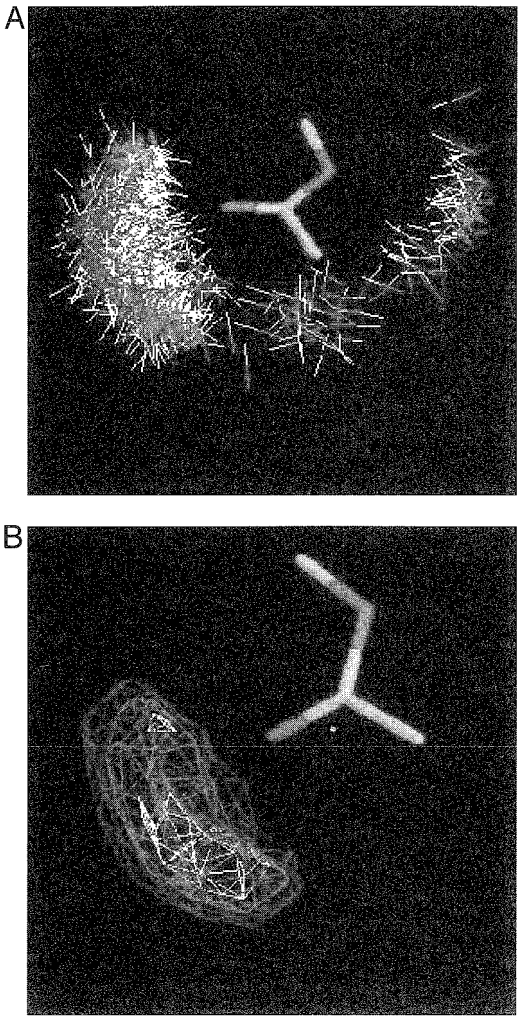

Fig. 5 IsoStar plots of N—H and O—H contact groups around a carboxylic ester central group (a) basic IsoStar plot and (b) contoured plot. (*View this art* in color *at www.dekker.com.*)

Protein–ligand interactions and protein–ligand docking.[25,26]
Applications in metallo-organic chemistry.[6]

All of these topics. and more, are covered in three recent reviews[5–7] published in a special issue of *Acta Crystallographica* devoted to the status and research applications of all of the crystallographic databases.

While these articles[5–7] and the other papers and monographs noted above cite many relevant CSD studies, the CCDC compiled a more complete and classified collection of references to CSD research applications in its DBUse database. This database not only provides full bibliographic data but also contains short synopses of each published project, prepared by CCDC staff. The DBUse is freely available and searchable via the CCDC web site at http://www.ccdc.cam.ac.uk/dbuse.

CONCLUSION

The CSD system. comprising the complete database. together with ConQuest, Mercury. Vista. IsoStar, and PreQuest (software for database creation) is available on CD for Unix, Linux, and Windows platforms. and full subscription details can be found at http://www.ccdc.cam.ac.uk/ or by e-mailing admin@ccdc.cam.ac.uk. The web site also contains full details of other CSD-related products. Data for individual crystal structures are freely available on request for bona fide research use, by citing CCDC Deposition Numbers (printed in many journals) and bibliographic information. Full details of this service are given at http:/lwww.ccdc.carn.ac.uW.

Carbohydrates, Recognition of

Arne Lützen
University of Oldenburg, Oldenburg, Germany

INTRODUCTION

Carbohydrates are now recognized to be among the most important compounds involved in intercellular recognition events. Viral or bacterial infections. certain immune responses. fertilization, or the regulation of enzyme and other protein functions and even protein folding, are all processes that are—at least to some extent—ruled by carbohydrate recognition through specific proteins. This binding is achieved by complex arrays of weak noncovalent interactions involving hydrogen bonding, hydrophobic interactions. as well as metal ion coordination.

Given the importance of the above-mentioned processes, it is not surprising that a lot of effort was made in supramolecular chemistry over the last 15 years to develop artificial receptors for these classes of compounds. which is. however. a challenging problem. because saccharides provide a complex three-dimensional array of functional groups that makes the design of a suitable receptor a difficult task. Up to now. mainly two binding motifs were employed to approach this problem: boronic acids that bind to the saccharides through the formation of covalent boronic ester linkages, which provides strong binding even in highly polar solvents: and the more supramolecular and biomimetic approach to use a mixture of hydrogen bonds and hydrophobic effects. which is. however, still in its infancy with regard to effective binding in polar solvents. especially water.

CARBOHYDRATE RECOGNITION IN BIOLOGICAL SYSTEMS

Saccharides have an enormous information-storing potential that is substantially higher than that of peptides and nucleotides of comparable molecular weights.'" Thus. it is not surprising that carbohydrates. beside their structural, property-modulatory. and energy-storing functions. can act as recognition markers in numerous physiological and pathological processes.[2–4] Many of these processes occur on cell surfaces, where oligosaccharides are found in the glycocalix as components of giycoproreins and glycolipids. The encoded information is deciphered by carbohydrate-binding proteins that can be subdivided into antibodies, enzymes involved in sugar utilization and glycoconjugate turnover, and other carbohydrate-binding proteins—also called lectins. which are neither enzymes nor immunoglobulins.[5] Especially. carbohydrate–lectin interactions play a crucial role in many intra- and intercellular recognition and communication processes, including protein folding, clearance of glycoproteins from the circulatory system. control of intracellular traffic of glycoproteins, cell adhesion, bacterial and viral infections, tumor metastasis, certain immune reactions, like. e.g., the recruitment of leukocytes to inflammatory sites. and fertilization, just to name a few.

But how do these proteins actually recognize carbohydrate structures on a molecular level?

The structural basis for selective recognition was mainly investigated by x-ray crystallography and. more recently, by advanced NMR spectroscopic techniques.[2,5–12] According to the broad variety of events involving carbohydrate recognition processes, a multitude of diverse protein frameworks evolved. providing binding sites for carbohydrates either deeply buried in the protein structure as found in most enzymes and bacterial periplasmic carbohydrate-binding proteins or in rather shallow indentations in the protein surface, as is typically the case for lectins (Fig. 1).

However, despite this enormous diversity, they share some common key features.

Hydrogen Bonding

Carbohydrates display a high density of hydroxyl groups, and therefore. it is not surprising that hydrogen bonding plays an important role in their recognition. Although the energetic contributions of hydrogen bonds to protein–carbohydrate binding are still uncertain, it is clear that the directionality of hydrogen bonds is critical to the specificity of the recognition process.

As shown in Fig. 2, the protein usually exploits cooperative hydrogen bonding in which a sugar hydroxyl group acts simultaneously as a hydrogen bond donor and acceptor in order to distinguish between different carbohydrate epitopes. Generally. one acidic amino acid side chain is used as a hydrogen-bond acceptor for one or two sugar OH groups. The primary hydrogen bond donors

are main-chain amide groups and side-chain amide groups. Charged side-chain donors also occur with some frequency. However, protein hpdroxyls are much less common. Thus. the most common hydrogen-bonding scheme is as follows:

protein $(NH)_n \rightarrow$ sugar OH $\rightarrow$ protein C=O

Water-mediated hydrogen bonds

In addition to direct interactions between the protein and the sugar hydroxyl groups, water was also observed to mediate (indirect) hydrogen bonds between amino acid residues and the saccharide OH groups. In these cases. the water molecules act as fixed structural elements, equivalent to hydrogen-bonding groups of the protein, and can. therefore, be considered as part of the binding site architecture.

The particular sugar functionalities that form hydrogen bonds with the protein are those required for specific recognition and discrimination. whereas those positions not used as recognition elements tend to stay solvent exposed and form no direct contact with the protein (Fig. 2). However. in these cases, higher selectivity is often achieved by extending binding sites through additional contacts between oligosaccharide structures and the protein surface (''subsite multivalency''[11]).

In this context, it is also interesting to note that charged groups on sugars like carboxylate moieties usually interact with main-chain amides. polar side chains (especially serine), or ordered water molecules by means of charged hydrogen bonds rather than through salt-bridge formation with fully charged side chains. In many cases, it is even energetically favorable to maintain these highly polar groups exposed to solvent.

Nonpolar interactions

Although carbohydrates have many polar functional groups. most biologicaliy relevant saccharides still present nonpolar patches on their surfaces that can interact with complementary hydrophobic amino acid residues. This is particularly true for β-D-galactose, which is almost always observed to pack against aromatic amino acid side chains. Also. the binding of other sugars. like mannose, was observed to involve hydrophobic interactions of nonpolar areas of the saccharide unit. with aromatic and aliphatic amino acid side chains (Fig. 2). Hydrophobic interactions are believed to provide a significant contribution to the overall binding energy, because apolar patches on the sugar as well as the compleinentary side chains of the protein are removed from bulk solvent. thereby expelling unfavorably bound water molecules.

Divalent Cations

Direct interactions with the sugar

C-Type lectins are unique among the structurally characterized lectins, because most of them require a calcium(II) ion to form direct coordinative bonds with the sugar ligand. Shown in Fig. 2 is such a case, where the full noncovalent binding potential of two vicinal OH groups is used: One lone pair of electrons from each OW group forms a coordinative bond with Ca^{2+}, and the other lone pair accepts a hydrogen bond from a side-chain amino group, and the proton is donated to an acidic oxygen in a hydrogen bond.

Indirect roles

However. calcium as well as other ions like manganese(II) ions are required for the activity of many families of carbohydrate-binding proteins, even when they do not directly interact with the ligands. In these cases. the most common function of these ions is structural. in that the metal ion coordination shell orients important protein functional groups for optimal ligand binding.

Multivalency

Despite the manifold interactions between proteins and carbohydrates described above that result in a lot of cases in specific binding of single monosaccharide epitopes, the binding affinity of Iectins is still surprisingly low—usually in the order of millimolar dissociation constants. However. multivalency, i.e., the simultaneous association of several ligands of one biological unit (macromolecule, cell surface, etc.) with several receptors of another biological unit, is applied by nature to accomplish high-affinity interactions.[12,17,18] Thus, high-affinity carbohydrate–protein interactions in the nanomolar range can be achieved through oligomerization of several lectin polypeptides. each containing similar or identical simple binding sites (''subunit multivalency''[11]) or through clustering of several lectins on cell surfaces and interaction of these architectures with multiple carbohydrate epitopes presented in an appropriate manner on lipid or protein carriers.[19]

The strategy of employing structurally defined multivalen: interactions is also efficient to get maximum recognition of certain carbohydrate-coated surfaces, like cell surfaces. while minimizing competitive binding to smaller or soluble saccharides at the same time. Structural studies revealed that many Iectins that bind surfaces achieve the required planar array of sugar-binding sites by arrangement of polypeptide subunits in oligomers that

have cyclic symmetry, with all binding sites located on one end of the oligomer.

CARBOHYDRATE RECOGNITION BY ARTIFICIAL RECEPTORS

Given the importance of the various processes involving carbohydrate recognition events in nature. it is not surprising that a lot of efforts were made in supramolecu-Iar chemistry to develop efficient artificial receptors for these substrates over the last 15 years.[20–23] However, the recognition of carbohydrates is one of the biggest challenges for structurally as well as for preparatively orientated chemists. because they dispiay a complex three-dimensional array of functional groups. This presents an interesting problem for the design of suitable receptors. and supramolecular "bottom up" approaches could help to further elucidate natural processes. although one has to admit that effective. truly biomimetic carbohydrate recognition is still far away at the moment. Nonetheless. nonbiomimetic systems also promise some interesting (future) applications in medicinal chemistry in that they could possibly be employed in the prevention of bacterial and viral infections: in the monitoring of the health condition of cells, and in the identification of malignant cells. for instance. cancer cells: as transport vehicles for saccharides or 'elated pharmaceuticals; or as sensors for saccharides in biological fluids.

Like lectins that undergo few if any changes in their global conformations upon binding to sugars, most of the receptors reported so far have rigid structures that provide more or less well-preorganized binding sites for the substrates. According to the high density of hydroxy groups displayed by carbohydrates, it is not surprising that most receptors are designed to target these functions to obtain binding. So far, there are mainly two classes of receptors:

First. there are a number of effective receptors that use boronic acid functions to form five- or six-membered cyclic boronate esters with two appropriately orientated hydroxy groups (at least in organic and basic aqueous media). This approach was used intensively with regard to sensing applications. However, this approach is neither biomimetic nor strictly supramolecular. because. although

only moderately strong and reversible, covalent bonds are formed during binding.[21–28]

Second, noncovalent intermolecular binding can be achieved by means of hydrogen bonding through (an)ionic or neutral hydrogen bond donor and acceptor groups. as in their natural examples." However. other than their natural models. most of the receptors reported so far are designed to be effective in organic solutions in order to profit not only from the directionality of hydrogen bonds but also to get a maximum energetic contribution to overall binding.

Molecular Receptors Based on Boronic Acids

Boronic acids are extensively used in carbohydrate chemistry. for example, in chromatographic separations, for a long time. However, Wulff and coworkers were the first to employ boronic esters in imprinted polymer carbohydrate receptors.[35] About a decade later. the first aryl-boronic-acid-based receptors and sensors other than the long-known phenyl boronic acid mere reported and the area has seen tremendous development since.[20–27] The most noticeable advantages of this binding motif are that strong binding can even be obtained in water. and that boronic acids can easiiy be incorporated in molecular architectures useful for different sensing techniques. Shown in Fig. 3 are some examples for boronic-acid-based saccharide sensors.

Sensing methods reported include circular dichroism (**1**),[21–23] fluorescence (**2–3**),[21–23] mainly based on photoinduced electron transfer but also on intramolecular energy transfer. electrochemistry (**4**),[24] and visible color changes (**5–7**).[21–23,26] However, boronic-acid-based receptors were also used for the transport of monosaccharides.[27,28]

In addition, boronic-acid–carbohydrate interactions can be used to transfer stereochemical information. e.g., to a newly formed stereogenic center (usually the metal ion) in

[a]Selected recent examples not covered by Ref. [20]: Refs, [29–34]

metal coordination compounds (8) built from ligands that carry one boronic acid group each. These can only bind to a saccharide in a cooperative fashion when the complex has the proper configuration (Fig. 4).[36,37]

Furthermore, boronic-acid-substituted metal coordination compounds were used as heterotropic allosteric receptors (9), where the coordination to a metal ion changes the conformation of a covalently assembled ditopic ligand in a way that the boronic acids can cooperatively bind to a single saccharide substrate.[38] This strategy was further extended when cerium *bis*(porphyrin) double-decker systems (10) were demonstrated to show positive homotropic allosteric effects in the binding of two saccharide guest molecules.[39]

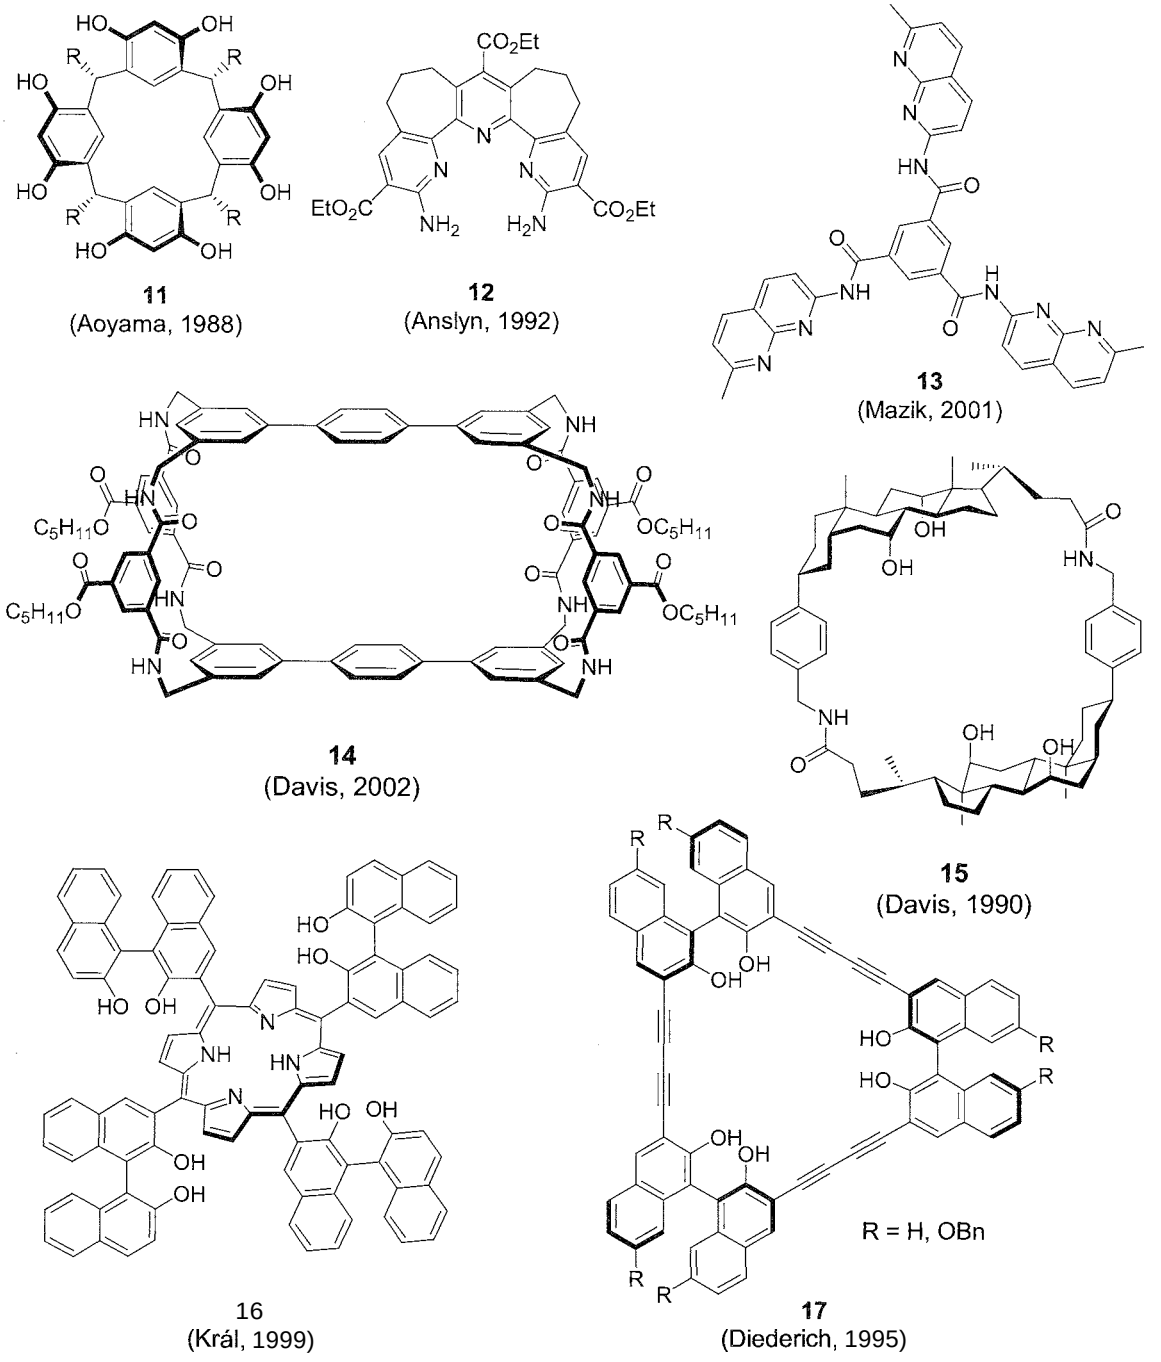

Fig. 5 Achiral and chiral artificial receptors for the recognition of carbohydrates via neutral hydrogen bonds. (From Refs. [20,29–34].)

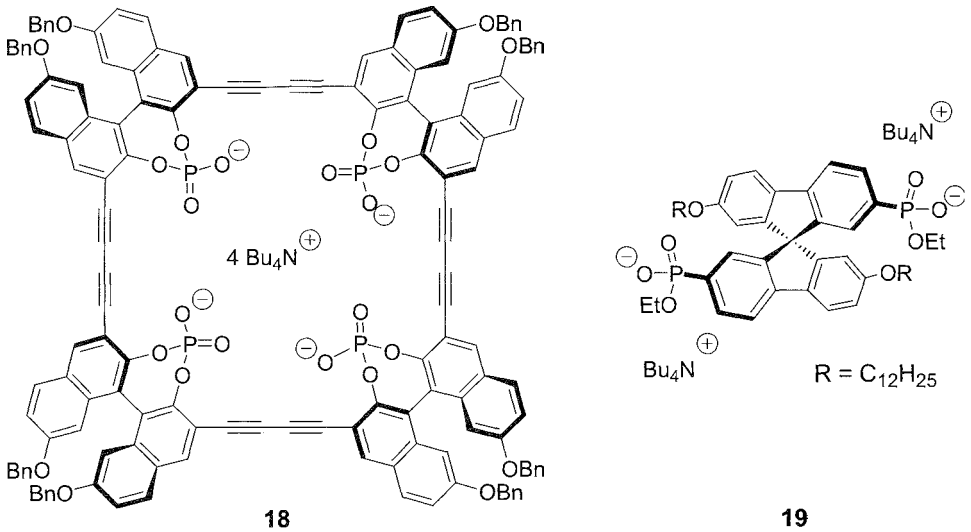

18
(Diederich, 1995)

19
(Hamilton, 1997)

Fig. 6 Chiral artificial receptors for the recognition of carbohydrates via charged hydrogen bonds. (From Ref. [20].)

Molecular Receptors with Hydrogen-Banding Functionalities

Like their natural examples, almost all artificial receptors of this type offer an array of functional groups (pyridines. amide NH and CO groups. amino, or phenolic hydroxyl groups) in order to exploit cooperative hydrogen bonding. in which the sugar hydroxyl groups can act simultaneously as a hydrogen-bond donor and acceptor (**11–17**,[20,29-34] Fig. 5). Only in the cases where phosphonates or phosphate groups (**18** and **19**,[20] Fig. 6) are used to bind carbohydrates via strong ionic hydrogen bonds. can the sugar OHs act as hydrogen-bond donors.

In addition. most of the receptors bear hydrophobic patches in their binding sites in order to bind complementary areas of carbohydrates. Although the energetic contributions of this interaction to overall binding are obviously neglectable in organic solutions. these contacts might play a more prominent role in terms of specificity and in recognition events in more polar solvents. like DMSO, acetonitrile/methanol, or even mixtures containing water, as observed for instance for **14**,[34] **16**[30–31] **18**,[20] and **19**.[20]

The results obtained with these receptors show that diastereoselective binding of single sugar epitopes is. to some degree, possible even with nonchirai structures although the order of preferred binding often reflects the monosaccharides' tendency to self-aggregate in the order α-galactosides≤α-glucosides<β-glucosides<α-mannosides. Improved diastereoselectivity and. of course. enantioselectivity can be observed with chiral receptors; where **19** was found to show the highest enantioselectivity of approximately 5:1 for the binding of *n*-octyl β-glucopyranosides.

Association constants for the binding of mono- or disaccharides are usually in the range of $1 \times 10^2\ M^{-1}$ (12 and **17**) to $3 \times 10^4\ M^{-1}$ (13 and 15) in organic solvents, like chloroform or dichloromethane. but can also reach up to $1 \times 10^4\ M^{-1}$ (14, 16. 18, and 19) when measured in more competitive solvents. like acetonitrile. acetonitrile/methanol, DMSO. or dichloromethane/water.

CONCLUSION

Nature developed a diversity of independent protein architectures for the recognition of carbohydrates. However. these structures share some common key features. as the molecular basis of carbohydrate binding involves a complex array of noncovalent interactions. like hydrogen bonds; hydrophobic interactions. and in some cases, an essential contribution of divalent cations to protein structure fixing and direct coordination to the substrate. In the end. it is a question of the number of attractive contacts and the degree of shielding from aqueous solution that cause the differences in binding affinity to a single saccharide epitope.

However. on a higher level of molecular organization. the affinity and specificity of carbohydrate-mediated cell–cell recognition events depend not only on the inherent specificity of one binding site for a specific saccharide epitope but also on factors that are not operative in monovalent interactions. These multivalent factors include. for example. the location of a protein.

the oligomerization state of the protein, its display of saccharide binding sites. and the display of saccharide recognition epitopes. Given this range of variables, the factors that contribute to favorable multivalent protein–carbohydrate interactions are difficult to dissect. Much work remains to be done to fully elucidate these important and fascinating processes.

For biomimetic and for other reasons. a lot of efforts in supramolecular chemistry are directed to the development of artificial receptors for carbohydrates over the last 15 years. Like their natural examples — the lectins — most receptors have rigid structures and try to address the saccharide's hydroxyl functions through the formation of covalently linked aryl boronic acid esters or hydrogen bonding to obtain binding. Although the first approach is not biomirnetic or truly supramolecular, it provides strong binding in polar solvents and even in water. Because these functionalities can easily be incorporated in aggregates with signaling abilities, boronic-acid-based receptors are currently mainly used as chemosensors for carbohydrates.

Although a number of examples of receptors capable of binding saccharides through hydrogen bonding were reported, nearly all were designed to bind carbohydrates in nonpolar solvents. Thus, much work needs to be done to develop artificial receptors that combine sufficient orientation through an array of hydrogen-bond contacts with favorable hydrophobic effects, in order to provide sufficient binding energy and reach the ultimate goal — the effective and biomirnetic recognition of carbohydrates in water.

Carbonic Anhydrase Models

Hiroshima University, Hiroshima, Japan

INTRODUCTION

The zinc(II) ion is a biologically essential element. Recognition of its importance is ever increasing. as more enzymes are discovered containing zinc(II) at the active centers. Model studies of zinc enzymes (e.g., carbonic anhydrase and alkaline phosphatase) by us and a number of other groups are establishing a deeper and wider scope of knowledge about the zinc(II) ion in relation to its biological functions. In this article, we present the latest results obtained with recently designed carbonic anhydrase models. Although these models are simple zinc(II) complexes. they have helped to disclose the hitherto unsettled intrinsic properties of zinc(II)-dependent enzyme functions. The discussion emphasizes how H_2O is activated by zinc(II) for nucleophilic attack toward electrophilic substrates (i.e., CO_2) and also how the HCO_3^- ion is dehydrated by zinc(II) ion in carbonic anhydrase.

CARBONIC ANHYDRASE MODELS WITH MACROCYCLIC TRIAMINES

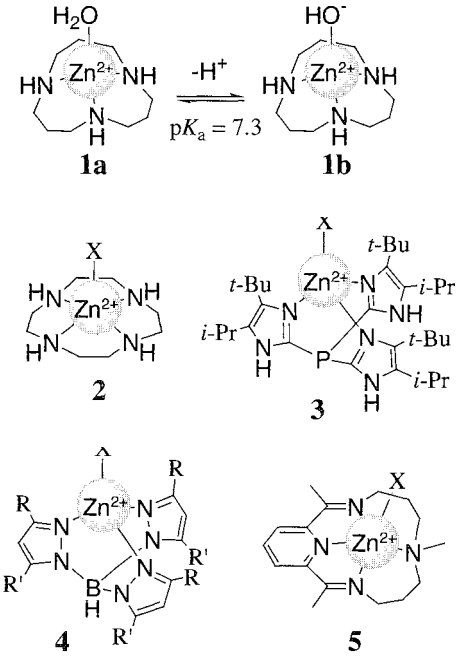
There are several kinds of mononuclear zinc(II) complexes· **1**,[1–6] **2**,[1–4,7–10] **3**,[11] **4**,[12–15] and **5**.[16] designed to mimic the zinc(II)-coordination structure or the function of zinc(II) ions at the active center of carbonic anhydrase (CA), the enzyme that catalyzes CO_2 hydration ($CO_2+H_2O \rightarrow HCO_3^-+H^+$) and its reverse reaction HCO_3^- dehydration ($HCO_3^- \rightarrow CO_2+OH^-$).[17]

However. the 12-membered macrocyclic triamine ([12]aneN$_3$) zinc(II) coinplex **1** has. for the first time, provided a chemical mechanism that shows the role of zinc(II) ion in the reversible CO_2 hydration and HCO_3^- dehydration catalyzed by CA.[6] The fast kinetics of the CO_2 hydration catalyzed by **1** was followed by H^+ production at 25°C. which was detected by using a pH-indicator in buffer solution (pH 6–10). The kinetics demonstrated the catalytic nature of the zinc(II) complex **1** at various pHs. A plot of the initial rates against total zinc(II) complex concentrations (=$[\mathbf{1}]_{total}$) indicated that the CO_2 hydration rate varied linearly with $[\mathbf{1}]_{total}$ and $[CO_2]$ to give an observed second-order rate constant $(k_{cat}^h)_{obs}$. Shown in Fig. 1a is a plot of $(k_{cat}^h)_{obs}$ data as a function of pH. The sigmoidal curve is characteristic of a kinetic process controlled by an acid–base equilibrium and exhibits an inflection point (pK_{kin}) at about pH 7.4. which is almost the same as the potentiometrically determined pK_a value of 7.3 for zinc(II)-bound water of **1a**.[3] Thus. **1b** must be the genuine active species in the catalytic hydration of CO_2. The sigmoidal pH dependence for the CO_2 hydration with CA (although its pK_a is 6.9)[17] can thus be accounted for by a hydroxo complex zinc(II)–O H at the active center of CA reacting with CO_2. A proposed CO_2 hydration mechanism by CA is shown in Fig. 2. The rate law for the suggested CO_2 hydration mechanism by **1** is more precisely given by $(k_{cat}^h)_{obs} = k_{cat}^h \cdot K_a/([H^+]+K_a)$, and from this were calculated the kinetically obtained pK_a value of 7.4 and the k_{cat}^h value of 6×10^2 M^{-1} sec^{-1} at 25°C. The much faster reaction of CA [e.g., k_{cat}=ca. 10^8 M^{-1} sec^{-1} for human CA II at 25°C].[18] in comparison to **I** may partially be explained by an effective preassociation of CO_2 within the hydrophobic pocket in CA.[19,20] If this preassociation of CO_2 is characterized by a large binding constant of 10^5 M^{-1}. it can account for the large difference observed in the catalytic activity during the hydration of CO_2.

The kinetic study of the reverse HCO_3^- dehydration catalyzed by a model complex was successfully conducted for the first time with the zinc(II) complex **1** at 25°C.[6] The rate was followed by measuring the evolution of O H for the reaction ($HCO_3^- \rightarrow CO_2+OH^-$) in a similar fashion to the CO_2 hydration in buffer solution (pH 6–9). The rates increased with iowering pH (see Fig. lb). The kinetic data showed that the kinetically reactive species was **1a**, and the second-order rate was followed with [Pa] and $[HCO_3^-]$, each first-order dependent. The dehydration constant k_{cat}^d with **1a** was found to be 5 M^{-1} sec^{-1}, and the kinetically obtained pK_a value of 1a was 7.3 at 25°C. Important conclusions for HCO_3^- dehydration with the catalyst **1** are that the reactive species is the zinc(II)–OH_2 form: substitution of the zinc(II)-bound H_2O with HCO_3^- is rate determining; and decarboxylation of the zinc(II)-bound HCO_3^- is much faster (see a similar proposed mechanism for CA-catalyzed reaction in Fig. 2).

Although the magnitude for the k_{cat}^h and k_{cat}^d significantly differs, the two curves (Fig. 1a and b) have an inflection point at the same pH (ca. 7.4) and are symmetrical (a·ith scales adjusted). Thus, the model complex **I** is the first example to mimic the pH-dependent

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120017675



behavior of reversible CO_2 hydration catalyzed by CA. This fact implies that in CA, too, the CO_2 hydration1 HCO_3^- dehydration is determined by the zinc(II)–OH^-/ zinc(II)–OH_2 equilibrium at the active center. A similar CA model study with macrocyclic tetraamine zinc(II) complex 2 gave an analogous reaction mechanism.[10]

The zinc(II) complex **1b** is significantly more reactive (k_{cat}^h=6 x 10^2 M^{-1} sec^{-1}) than Woolley's model complex (X=OH) (k_{cat}^h=2 x 10^2 M^{-1} sec^{-1}).[16] In another model involving *tris*(imidazole) zinc(II) complexes (analogues of **3**), higher rate constants of HCO_3^- dehydration (k_{cat}^d=900–2800 M^{-1} sec^{-1}) were reported in 80% EtOH/H_2O at pH ca. 6.5. However, the system failed to mimic the characteristic pH profile for the hydration

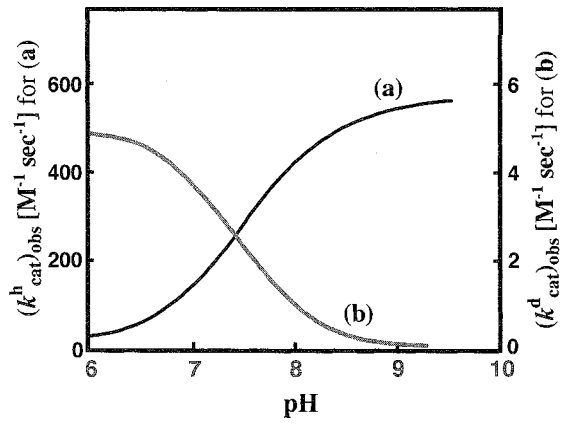


Fig. 1 The rate-pH profile for (a) CO_2 hydration and (b) HCO_3^- dehydration catalyzed by 1.

reaction and dehydration reaction of CA. The model complex 1 demonstrated the unique properties of a labile water molecule that is susceptible to substitution reactions with substrate HCO_3^-, anion inhibitors. and a nonlabile OH– ligand that acts as a nucieophile to attack CO_2. By changing the pH (around physiological pH). zinc(II) can choose either reactant. The zinc(II)-bound HCO_3^- has the choice to be substituted by O H for the reverse aqueous reaction at alkaline pH, or to lose CO_2 for the decasboxylation at acidic pH. In this context. it is of great significance that the bicarbonate anion (HCO_3^-) has the highest 1:1 affinity constant (K=[ZnL–$^-OCO_2H$]/ [ZnL][HCO_3^-]=$10^{4.0}$ M^{-1}) to 1a, only next to hydroxide anion (K=$10^{6.4}$ M^{-1}): e.g., K=$10^{1.3}$ M^{-1} for Cl^-, $10^{2.6}$ M^{-1} for CH_3COO^-.[5] Taken together. it is concluded that zinc(II) with a pK_a value of ca. 7 for the zinc(II)-bound H_2O is probably the most appropriate metal ion to perform the functions of CA at physiological pH. Also. the very high affinity of zinc(II) to HCO_3^- that binds as a monodentate ligand is a critical property of zinc(II) ion. If the metal were more acidic or had higher coordination numbers [e.g., cobalt(III) ion], HCO_3^- may be deprotonated to CO_3^{2-} and act as a bidentate ligand that would no longer be susceptible to decarboxylation.

OTHER CARBONIC ANHYDRASE MODELS

A *tris*(imidazolyl)phosphine zinc(II) complex 3. where X is a monodentate ligand (=OH . I^-, and NO_3^-), was synthesized and examined by x-ray crystal analysis.[11] The zinc@)-bound OH^- complex is claimed to be the first structurally characterized monomeric zinc(II) hydroxide complex sequestered by three imidazole groups and. therefore, may become an excellent structural model for the active site of carbonic anhydrase.

A *tris*(pyrazolyl)borate zinc(II) complex 4 (*R*=*p*-isopropylphenyl. *R'*=Me. *X*=OH^-) was prepared by mixing zinc(II) ion. ligand. and KOH in MeOH/ CH_2Cl_2.[15] Due to insolubility or instability of the zinc(II) complex in aqueous solution. the pK_a value for the zinc(II)-bound H_2O was not reported. The zinc(II)–OH in 4 showed sufficient nucleophilicity toward hydrolyzable substrates. carboxylesters, activated amides (β-lactam or CF_3CONH_2), and phosphonates in organic solvent. where the reactions are not catalytic but are stoichiometric. The seemingly high nucleophilicity of the *tris*(pyrazolyl)borate zinc(II) complex was attributed to steric hindrance and hydrophobic environment around the zinc(II)-bound OH . It is of interest to see whether 4 acts as a catalyst in H_2O-containing solvents. The earlier zinc(II)–OH^- species 1b and 2 (*X*=OH^-) catalytically hydrolyze esters,[3] β-lactams,[8] and *bis*(4-nitrophenyl) phosphodiester in aqueous solution.[4]

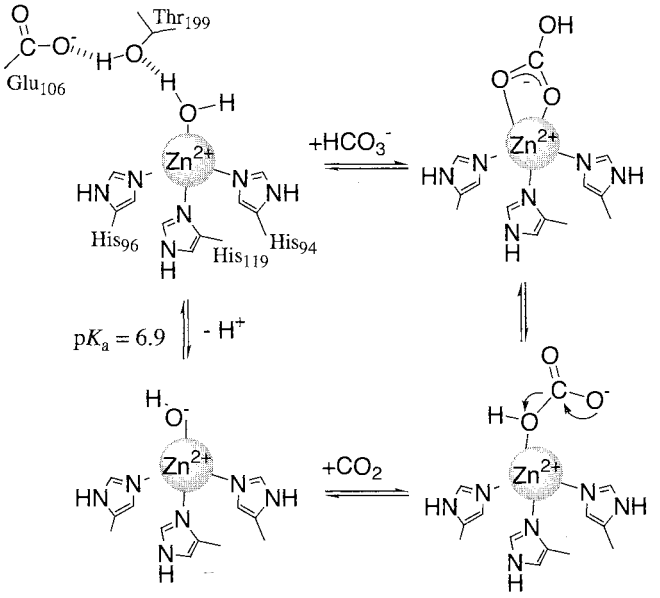

Fig. 2 A proposed mechanism of CO_2 hydration at the HCA II active center

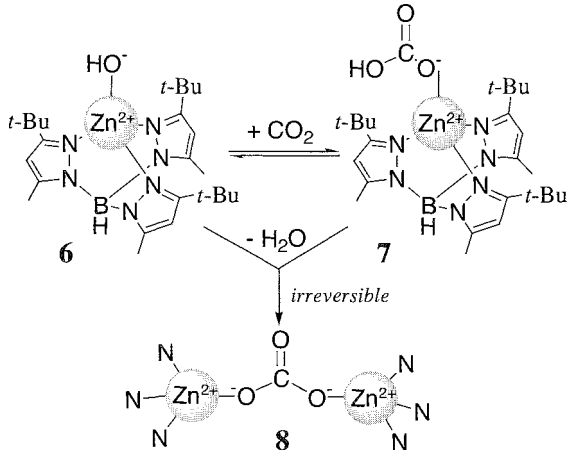
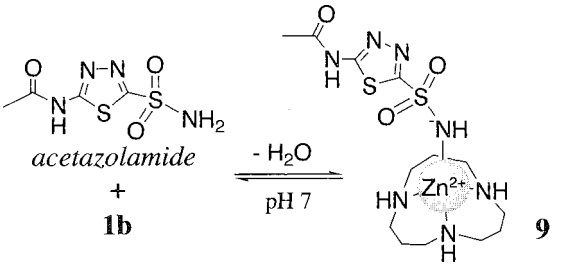
As a structural model of the zinc(II)–OH^- species of carbonic anhydrase. the first mononuclear OH -bound zinc(II) complex 6 was prepared by mixing zinc(II) ion. the ligand. and KOH. and was characterized by x-ray crystal analysis.[12] The zinc(II)–OH^- complex **1b** is a cyclic trimer linked by three hydrogen bonds between each zinc(II)-bound hydroxide group, as shown by x-ray crystal study.[3] However, in aqueous solution. this trimer dissociates into monomeric zinc(II)–OH^- species **1b**. The zinc(II) complex **6** in $CHCl_3$ reacted immediately with CO_2, possibly to form a HCO_3^- complex 7 that ultimately and irreversibly gave a bridging carbonato complex 8. However. quantitative determination of the pK_a value for the zinc(II)-bound H_2O or of the nucleophilicity of 6 was not reported. The HCO_3^- complex **7** was characterized by IR spectroscopy [1675 and 1302 cm^{-1} for zinc(II)-bound bicarbonate].[11] The formation of the bicarbonate complex **7** is reversible, and removal of the CO_2 atmosphere results in regeneration of *6*. In view of the labile equilibrium between 6 and **7**. attempts to crystallize **7** were made under CO_2. However. a syminetrically bridging carbonato complex 8 was isolated instead. The hydroxide complex 6 effectively promoted the exchange of oxygen atoms (^{17}O) between CO_2 and H_2O, which somewhat served as a good functional model for CA. The authors suggested that the facile equilibrium between zinc (11)–OH– and zinc(II)–$^-OCO_2H$ may be a critical function for CA activity. An increased tendency toward bidentate coordination (due to stronger acidity) across the metal series (Zn^{2+}<Co^{2+}<Ni^{2+} and Cu^{2+}) was observed that resulted from stronger binding of the bicarbonate ligand. The authors concluded that in this context, too. zinc(II) ion is probably the best-suited metal for CA.



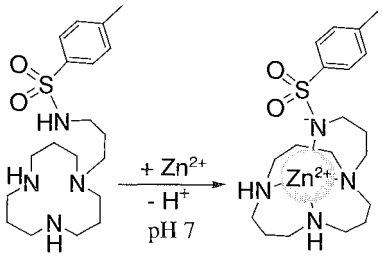
BASICITY OF ZINC(II)–BOUND HYDROXIDE IN CARBONIC ANHYDRASE

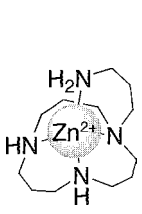
Aromatic sulfonamides are strong inhibitors of carbonic anhydrase. among which acetazolamide [K_D=6.0 nM for



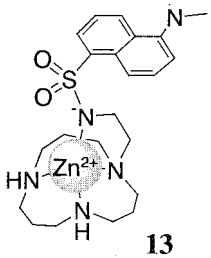
human carbonic anhydrase II (HCA *II)] at pH 7.4 is therapeutically prescribed as a diuretic* drug.[17] *A question as to how acetazolamide is bound to the active center appears to have been settled by x-ray crystal studies.''' although the precise inner-sphere binding* mode *of the sulfonamide to* zinc(II) *ion is not completely solved. The focal point is whether or not the sulfonamides are deprotonated. The resolution of* the *x-ray study was insufficient to afford a clear-cut answer. Chemically, it is puzzling that undeprotonated sulfonarnides* (pK_a=7–10) *can be good* donors, *forming strong coordination bonds with the* zinc(II) *ion.* One *of the pieces of indirect evidence for the deprotonation is that the lower the* pK_a *values of the* sulfonamides (e.g., pK_a *value of 7.4 for acetazolarnide). the* higher *the* 1:1 *affinity constants. On the basis of strong fluorescent complex formation of* CA *with dansylamide* (pK_a=9.9 *for the sulfonamide.* K_D = 0.25 μM *with HCA* II *at pH* 7.4[122]), *it was concluded that the deprotonated form of dansylamide binds to* zinc(II) *ion* at *the CA-active center. In any case, an interaction of the aromatic group of* dansylamide *with the protein must* make *a large contribution to the observed stability* of *the complex.* A *question concerning the intrinsic* zinc(II) *properties was whether it is acidic enough to displace the proton of sulfonamides, or* whether *the* zinc(II)-bound *O H (generated at physiological pH) is basic enough to neutralize the weak acid* sulfonamide *group. However, this fundamental* study *remained unaddressed. To date, only* model *studies give insight* into *the interaction of aromatic* sulfonamides *with* zinc(II) *ion.*

Treatment of a typical CA inhibitor. acetazolamidc with la. yields the product as a precipitate, which was identified as a 1:1 *complex 9. wherein the sulfonamide is deprotonated to coordinate with* zinc(II) *ions.''' It is of interest to point out that with other transition metal ions* (e.g., Ni^{2+}), *acetazolamide binds to the thiazole* N *but not to the deprotonated sulfonamide nitrogen. This different behavior of* zinc(II) *best illustrates its outstanding (hard) acid nature that favors the anionic* N^- *donor over the neutral (soft)* N *donor. The* pK_a value *of 7.4 for deprotonation of acetazolarnide is close to that for the* zinc(II)-bound H_2O *in 1. which would be extremely favorable for* simultaneous *coordination and* deprotonation *to yield the* 1:1 *complex* 9. *Aromatic sulfonamides*





12



13

with higher pK_a *values are* more *difficultto deprotonate at neutral pH, and hence. the apparent* 1:1 *affinity with* zinc(II) *is weaker. More convincing evidence of the basicity of* zinc(II)-bound *O H was obtained at the interaction of* tosylamidopropyl-[12]aneN$_3$**10** *(HL) with* zinc(II) *ion.''' A* stable *amide-deprotonated complex* **11** (ZnL) *was formed at physiological pH, despite the* pK_a *of the* tosylamide *being 11.2. The structure of* **11** *was determined by an x-ray crystal analysis. The comparison of the complex stability for* **11** *(log* K=log([ZnL]/[Zn][L])=*14.7) with those of* ***la*** *(log* K=8.4) *and 12 (log* K=*11.7) indicates that* zinc(II) *ion in the* triamine *complex prefers the fourth ligand in the order of anionic nitrogen>neutral nitrogen>water. The complex 9 does not catalyze ester hydrolysis. Thus,* 9 *may represent chemically the* sulfonamide *inhibition of CA.* On the *basis of this model study, we consider that the* zinc(II) *coordinated by three* histidyl *imidazoles at the active center of* CA *(see Fig. 2)* is *sufficiently acidic to deprotonate the aromatic sulfonamides. Other neutral organic compounds, such as phenols and carboxylic acids. are also inhibitors of* CA.[17] *Similar acid–base properties should operate in their interactions.*

Recently. dansylamidoethyl-[12]aneN$_3$ *(the ligand of 13) as a model for the CA–dansylamide* complex *has been* synthesized.[23] *The* 1:1 zinc(II) *coinplex 13 was shown* again *to contain* zinc(II)-bound *sulfonamide*N^- *anion as a monodentate ligand by x-ray crystal analysis. The dan-*sylamidoethyl-[12]aneN$_3$ *is a novel type of* zinc(II)-fluo*rophore, which forms stable complexes with* zinc(II) *and* copper(II) *ions under physiological conditions. The* 1:1 zinc(II) complex *13 shows a* fluorescent *maximum at 538 (quantum* yield=0.19, 320-nm *excitation) in aqueous solution, while the free ligand shows a weaker fluorescence (quantum* yield=0.05). *The* copper(II) *complex. on the contrary.* completely *quenches the fluorescence. The* zinc(II)-dependent *fluorescence is quantitatively responsive at* μM *concentrations of* zinc(II) *ion and is not affected by the presence of* mM concentration *of biologically important metal ions. such as* Na^+, K^+, Mg^{2+}, *and* Ca^{2+}. *Because* Cu^{2+} *is strongly bound to amino acids, peptides, or proteins in ordinary biological* systems, *dan-*sylamidoethyl-[12]aneN$_3$ may *be useful for the* dynamic *analysis of the biologically important* zinc(II) *ion.*

From the kinetic study of **1b**-catalyzed *hydrolysis of 4-nitrophenyl acetate inhibited by various aromatic sulfonamides, the apparent* 1:1 *affinity constants* were *determined at pH* 8.4.[5] *A* comparison *of* intramolecular [$K_{intra}=10^{6.3}=K$(for **11**)/K(for *1a*)] *and intermolecular* ($K=10^{2.4}$ M^{-1} *for* **1a** *with p*-toluenesulfonamide) *contribution of p-toluenesulfonamide anion coordination to the* zinc(II)-[12]aneN$_3$ complex *gives an effective* molarity *of* $K_{intra}/K=10^{3.9}$ M *by the intramolecular location. These* 1:1 *anion complexation constants for the* zinc(II) *macrocyclic triamine complexes with various aromatic sulfonamides exhibit a trend paralleling that reported for* CA,[24] suggesting *a similar inhibition mechanism* [i.e., *the deprotonated sulfonamide anions can coordinate to the* zinc(II) *in a CA-active center].The effectivemolarity of the pendant sulfonamide in the model complex may be viewed as the noncoordinating contributions to bring the inhibitors to* the zinc(II) *center of CA.*

When going back to the question of the basicity of zinc(II)-bound OH^-, *we can conclude that despite* **1b** ($pK_a=7.3$ *for its conjugate acid* 1a) *being a weaker base than* aromatic sulfonamides *of higher* pK_a (e.g., $pK_a=10.5$ *for p*-toluenesulfonamide), zinc(II)–OH^- *can still* deprotonate *the aromatic sulfonamides. because the resulting sulfonamide anions* ($ArSO_2NH^-$) *have extremely strong interactions with* zinc(II), *compensating for the unfavorable* interaction *between the weak base and the weak acid. It may be inferred that while* NaOH *releases* OH^- *anion without any favorable contribution from* Na^+, ZnL–OH^- *releases OH-, with* ZnL^{2+} *waiting to accept the conjugate base.*

CONCLUSION

All of these recent CA *models qualitatively or quantitatively illustrate the importance of nucleophilicity of* zinc(II)-bound OH^- *species in aqueous or nonaqueous solutions. This aspect is important in almost all of the zinc enzymes and will be presented again* for *models of other hydrolytic enzymes. However, in* CA *and many other zinc enzymes. the basicity of the* zinc(II)-bound *hydroxide is similarly important. Although I offers an excellent* CA *model, its catalytic activity is moderate in* comparison *to* CA. *Model* 1 simply *shows the essence of the intrinsic properties of* zinc(II) *at the active center of CA. Other important features such as the hydrophobic pocket for* CO_2, *proton relay (network), and other structures in* CA[25,26] *are missing. More sophisticated next-generation models should be equipped with these functions.*

Carboxypeptidase A

Shinji Sueda
Hiroki Kondo
Kyushu Institute of Technology, Fukuoka, Japan

INTRODUCTION

Hydrolysis of proteins is found in all scenes of life, from fertilization. growth, and aging. to disease. Thus, it is not surprising to see a *large* number *of proteases that mediate these* proteolyses *to occur within or outside the cell. But when viewed from a* mechanistic *standpoint, they are classified into one of only several groups. They are serine proteases, cysteine proteases. acid* proteases, *and* metalloproteases. *Carboxypeptidase A (CPA. peptidyi-L-amino acid* hydrolase, EC *3.4.17.1) belongs to the last group and requires zinc ion for activity.* Another *way of dividing proteases is by using endopeptidase and exopeptidase. which cleave inner and terminal* peptide *bonds, respectively. As its* name *indicates. CPA cleaves* peptide *bonds* from *the carboxyl terminus sequentially. Herein.* the *structure and catalytic mechanism of* CPA *are described. but because a number of* excellent *reviews are already* available,[1–3] *emphasis is placed* mainly on *recent topics concerning this thoroughly studied enzyme.*

HISTORY AND OVERVIEW

The occurrence of CPA was first noted by Walschmidt-*Eeitz and Purr in* 1929.[4] *The physiological* function *of CPA is* to *digest foodstuffsin the intestine. Proteinaceous foodstuffspartially digested by pepsin in the stomach are further processed into smaller* peptide fragments *or even into amino acids for reabsorption in the large intestine. CPA* is *synthesized in the pancreas and secreted to the intestine as inactive* zymogen (preproenzyme) *together with other proteases (see below). During this process,* multiple proteolytic *events occur on* CPA; *the signal* peptide is *cleaved from the* amino *terminus to form a proenzyme, and then an activation* peptide is *lost to* form *a fully active mature* enzyme *(see below).*

It is interesting to note that there is another carboxy-*peptidase. carboxypeptidase* B (CPB), *in the* same *tissue that has an* amino *acid sequence homologous to that of* CPA *but differs in substrate specificity. Whereas CPA prefers aromatic (phenylalanine. tyrosine, and tryptophan) or hydrophobic amino acid residues* (valine, leucine. *and isoleucine) at the C terminus; CPB prefers basic arginine and lysine residues there. This situation is reminiscent of the fact that the* same *tissue secrets other proteases, such as chymotrypsin and trypsin, both serine endopeptidases. which differ* in *their substrate specificity: the former prefers aromatic or hydrophobic amino acid residues. whereas the latter prefers basic residues.*

CPA seems to *occur only in mammals. but it should be noted that there is a related* Zn *endopeptidase,* thermolysin *(EC* 3.4.24.4), *in* thermophilic *bacterium Bacillus thermoproteolyticus. Although its amino acid sequence and three-dimensional structure are unrelated to CPA. the active site structure is similar. and the mechanism of action also seems to be* similar.[5] *This is an example of convergent evolution; just like the case of serine proteases mammalian chymotrypsin and microbial subtilisin.*

ASSAY

CPA is available commercially *in pure form.* Benzyloxycarbonylglycylphenylalanine (Z-Gly-Phe) *is one of the* commonly *used* substrates.[1] *The progress of reaction is conveniently tnonitored spectrophotometrically at* 220–*225 nm.* In *addition to* peptides, *esters such as* O-(*N*-benzoylglycyl)-L-β-phenyllactate (Bz-Gly-(O)Phe) *and* -L-mandelate *are hydrolyzed easily by* CPA. *Typical* Km *values for these artificial substrates are* 0.5–5 mM *with a turnover* number *of* 20 s^{-1} *for* amides *and* 100 s^{-1} *for esters under standard assay* conditions.[1]

Bz-Gly-(O)Phe

PRIMARY STRUCTURE

The primary structure of CPA was determined first in 1969 for bovine enzyme.[1] Because of heterogeneity in the *N*-terminal sequence. three forms of CPA are generated: Form a is the largest with 307 residues, and Forms b and g lack 2 and 7 of the N-terminal residues, respectively. of Form a. In addition. allelic polymorphism was observed at three sites: Ile/Val, Ala/Glu, and Val/Leu at residues 179. 228. and 305. respectively.

It later turned out that there are isozymes of CPA, CPA1,[7] and CPA2[8] in some organisms. According to the cDNA sequence for rat CPA! gene,[7] the prepro-enzyme is coinposed of 419 amino acids (Fig. 1). The N-terminal 16 residues are cleaved upon secretion. and the following 94 residues are cleaved for activation of the enzyme, making the 111th residue (Ala) constitute the *N*-terminus of mature CPA. The gene for CPA1 is composed of 10 exons of 80–200 base pairs each, while that for CPB of 11 exons.[9] The N-terminus is encoded on Exon 2 in both cases. All of these carboxypeptidases seem to have evolved from a common ancestral protein, and their estimated evolutional relationship is illustrated in Fig. 2.[8]

Fig. 1 Amino acid sequence of the prepro form of rat CPA1 deducecl from its cDNA sequence. taken from Ref. [6] with GenBank accession number 500713. The peptide bonds cleaved during secretion and activation are indicated by arrows, and some of the key residues that appear in the text are boxed.

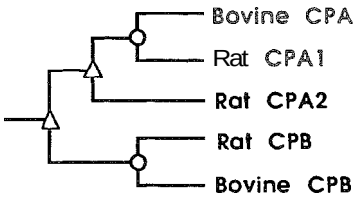

Fig. 2 Phylogenetic tree for carboxypeptidases CPA1. CPA2. and CPB from rat and cow, taken from Ref. [7]. The three enzymes seem to have evolved from a common ancestor. and the individual proteins were generated by gene duplication (triangles) and upon speciation (circles).

THREE-DIMENSIONAL STRUCTURE

The three-dimensional structures of bovine CPA alone and complexed with a poor substrate were solved by x-ray diffraction to high sesolution in 1970.[10] CPA is a globular protein of roughly ellipsoidal shape, with a dimension of 50 Å x 42 Å x 38 Å (Fig. 3a). The structure is composed of eight-stranded twisted β-sheets and nine x-helices which seemingly constitute two "bowls" facing each other. Between their boundary is the active site cleft, where His-49, Glu-72, and His-196 bind to Zn to form a nearly tetrahedral metal complex with the fourth ligand being water (Fig. 3b). Arg-145 forms a salt bridge with the C-terminal carboxylate of substrate, and Tyr-198, Ile-247. Tyr-265, and Phe-279 constitute a hydrophobic pocket to accommodate the side chain of the residue at P1′ (designating the residue nearest to the scissile peptide bond in the leaving group) of substrate. Some other residues that seem to play an important role in catalysis are Glu-270. Arg-127. and Tyr-248. The former is supposed to participate directly in catalysis, either as a base to abstract a proton from the zinc-bound water or as a nucleophile to undergo attack on the substrate carbonyl, as described below. The latter two residues seem to assist in the formation and collapse of a tetrahedral intermediate that forms during hydrolysis of amides and esters by donating a proton.

CHEMICAL MODIFICATION AND SITE-DIRECTED MUTAGENESIS

CPA is inactivated by alkylation of Glu-270 with *N*-bromoacetyl-*N*-methyl-L-phenylalanine,[11] suggesting that it plays an essential role during catalysis (see above). In addition to Glu-270. Tyr-248 is located in proximity to the reaction center, undergoes a large conformational change upon substrate binding. and is regarded to be one of the key residues for catalysis. For one thing, chemical modification of this and probably other tyrosine residues by acetylation or nitration affected the catalytic activity of CPA drastically.[12] Peculiarly. however. these types of modification enhanced the esterase activity up to sixfold, whereas the peptidase activity decreased to Lower than 10%. suggesting that the catalytic mechanism may be different between peptides and esters. Alternatively. however. it is also possible that the rate-determining step may be different between the two types of substrates. though the mechanism is basically the same. It is easily

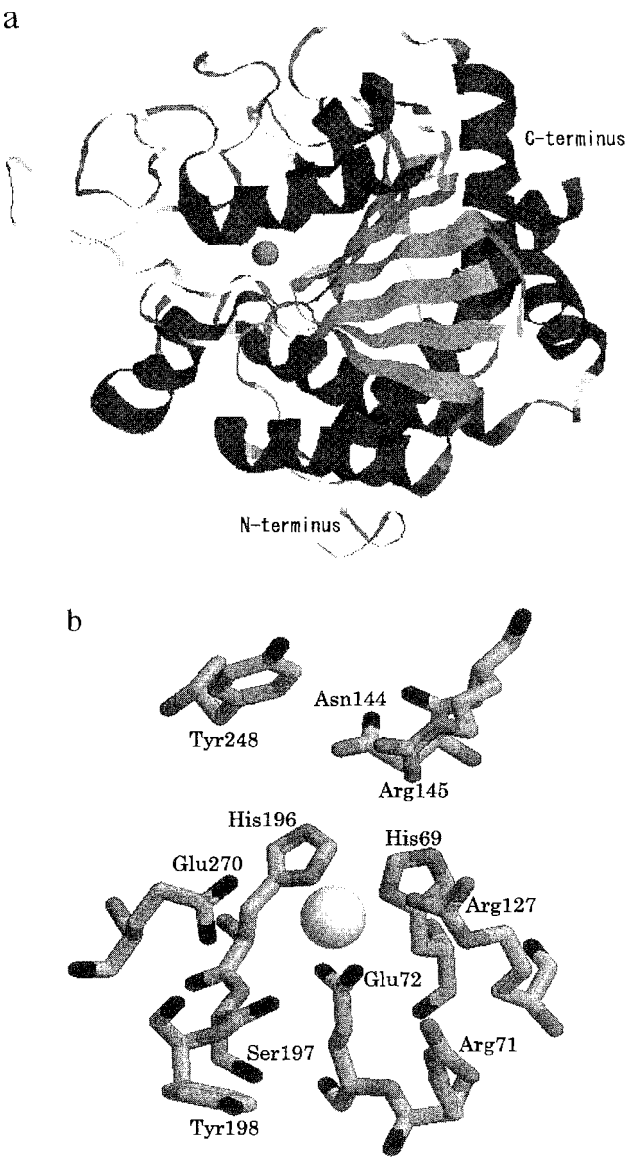

Fig. 3 (a) Three-dimensional structure of bovine CPA. taken from Ref. [10], with Protein Data Bank accession number 5CPA. For clarity. only the peptide backbone is depicted. (b) Nearly in the center of the ellipsoidal protein is the active site cleft where zinc (central sphere) is coordinated by His-69, Glu-72. His-196, and water (not shown).

imagined that in amides with a poor leaving group, the formation of a tetrahedral intermediate can be rate determining, whereas in esters having a good leaving group. the collapse of the intermediate could be the rate-limiting step. At any rate. the role assigned to Tyr-248 was a proton donor; it may donate a proton during the formation and collapse of a tetrahedral intermediate. If this is the case. replacement of Tyr-248 with any other amino acid will abolish all or most of its catalytic activity. Contrary to this expectation, an engineered enzyme with this Tyr replaced by Phe lost little activity, though the Km for substrates increased severalfold.[13] These data may be best interpreted to suggest that Tyr-248 does not serve as a key proton donor but instead is involved somehow in substrate binding. Instead of Tyr-248, which had long been regarded to be a plausible candidate, this electrophilic function seems to be played by Arg-127, as described below.

CATALYTIC MECHANISM

Upon binding to the enzyme, the carbonyl oxygen of a substrate seems to interact with the guanidium group of Arg-127. thereby enhancing polarization of the carbonyl to facilitate nucleophilic attack on the carbonyl carbon by Zn-bound water or Glu-270. The negative charge developing on the carbonyl oxygen and subsequent departure of the amino anion should be stabilized by proton donation from some group of the enzyme. Arg-127, rather than Tyr-248. seems to do this job.

There is dispute over the role of the active site Glu-270: one theory advocates a general base mechanism, while the other advocates a nucleophilic mechanism. If a nucleophilic attack on the substrate carbonyl by Glu-270 occurs, an acyl anhydride intermediate covalently bound to the enzyme is generated. If the general base is the real mechanism. no such intermediate intervenes. The putative acyl intermediate may be detected by some means, such as spectroscopic ones under cryo conditions or those trapped by suitable chemical agents such as hydroxylamine. There are claims for successful detection of a covalent intermediate.[14] but this assertion does not seem to be widely approved. In fact, the alternative general base mechanism appears to be more consistent with various data. Hence, the hydrolytic mechanism of CPA depicted in Fig. 4 is based on this notion.

SPECIFIC INHIBITORS

There are a number of natural and synthetic inhibitors known for CPA. Thus, a potent proteinaceous inhibitor was isolated from potato tuber that can inhibit not only CPA but also CPB with a Ki of 5 and 50 nM, respectively, but is inactive toward other common proteases, such as chymotrypsin and trypsin.[15] The mode of its inhibition was found to be a classical competitive one with respect to substrate, i.e., it binds to the same active site of the enzyme as do substrates; as later proven by x-ray crystallography.[16] The inhibitor is a mixture of two sequences of 38 or 39 amino acid residues with a single difference of whether a glutamine residue is present or not in Position 2 from the amino terminus. These proteins possess three disulfide bonds within the molecule. which may be responsible for the high thermostability for their size. This inhibitor binds to CPA at its C-terminus, but it is interesting to note that the C-terminal peptide bond between valine and glycine was already cleaved in the complex. In other words, the enzyme-inhibitor complex represents a complex of CPA and products. It is not known why further proteolysis of the truncated inhibitor does not proceed.

There are other CPA inhibitors reported from a parasitic roundworm *Ascaris lumbricoides*.[17] They have a molecular weight of 7.5 kDa. with about 65 residues that seem to be charge isomers. The apparent Ki values for

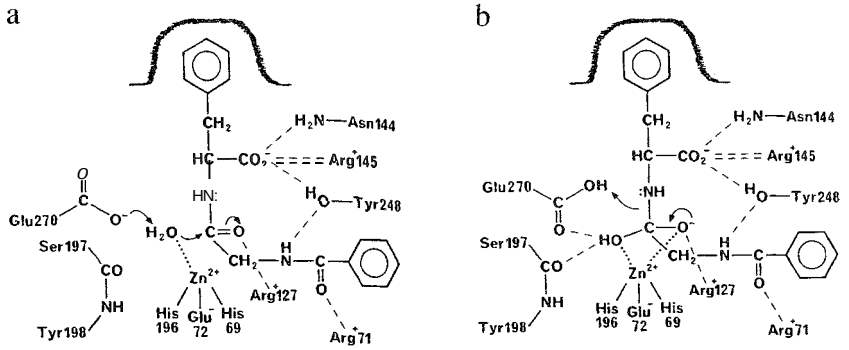

Fig. 4 The catalytic mechanism of CPA in the hydrolysis of peptides. taken from Ref. [3]. (a) Upon anchorage of a substrate to the active site, the carboxylate of Glu-270 triggers the reaction by abstracting a proton from zinc-bound water. which in turn. undergoes nucleophilic attack on the scissile carbonyl. (b) A tetrahedral intermediate is generated: its formation and collapse may be assisted by proton donation from Arg-127 or other residues.

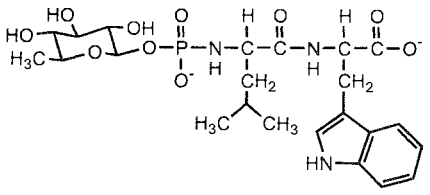
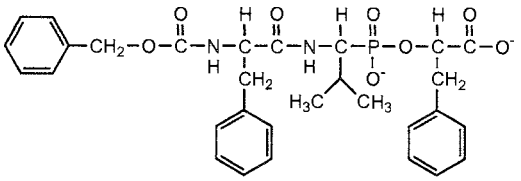
bovine CPA lie in the nM range, but the stoichioinetry of binding is anomalous in that two moles of inhibitor bind per enzyme. The exact mode of binding to enzyme remains to be clarified. There is another CPA inhibitor known from the medicinal leech *Hirudo medicinalis*.[18] This inhibitor is composed of 66 amino acids. contains four disulfide bonds within the protein. and binds not only to CPA but also to CPB with a subnanomolar Ki (0.2–0.4 nM). Although amino acid sequence homology is rarely found between the inhibitors from potatoes and medicinal leech except for their C-termini, the mode of binding is siinilar in that their C-terminal carboxylate coordinates to the active-site zinc.[19]

Phosphoramidon [*N*-((*a*-L-rhamnopyranosyloxy)hydroxy-phosphinyl)-L-leucyl-L-tryptophan], a metabolite produced by *Streptomyces tanashiensis*. is a potent inhibitor of zinc metalloproteases, especially of thermolysin.[20] Synthetic phosphonate and phosphonamidate analogues of substrates are also potent inhibitors of CPA. The inhibitors containing (O)Phe at the PI' position of tri- or tetrapeptides are the most potent inhibitors; for example, the Ki of Z-Phe-Val^{P}-(O)Phe for CPA is as low as 11 fM.[21] a potency not far from that (1 fM) for the well-known. tightest binding of biotin with avidin. The phosphonate replacing the scissile peptide bond of substrates confers much higher affinity for CPA because of the resemblance of its structure to that of a putative tetrahedral intermediate of amide or ester hydrolysis (transition-state analogy). In fact, both of the phosphonate oxygen atoms are bound to zinc in the crystal of a complex of CPA and inhibitor.[22]

Much less potent as they are. aldehyde. ketone, and haloketone analogues of substrates are also reversible inhibitors of CPA. For example, (RS)-2-benzyl-4-oxobutanoic acid is a competitive inhibitor of CPA with a Ki of 480 nM.[23] These classes of compounds are more or less hydrated in water to form a gem-diol(ate), with a structure that mimics that of a putative intermediate of hydrolysis of substrates (see above). In other words. these compounds seem to serve as a transition-state analogue. just like the phosphonates described above. and hence. they bind more tightly than substrates. It may be noted that the structure of these transition-state analogues more closely resembles that of a putative intermediate of hydrolysis generated by



Phosphoramidon



Z-Phe-Val^{P}-(O)Phe

the general base pathway than that generated by a nucleophilic attack by Glu-270.

TISSUE DISTRIBUTION AND ENZYMES RELATED TO CPA

CPA is basically localized in the digestive tract. but a transcript of its gene or the messenger RNA is detected in nonpancreatic tissues. such as in brain tissues, though CPA activity is not observable there.''] A plausible explanation for this observation is the occurrence of an inhibitor. In fact: such an inhibitor was reported. with a molecular weight of 26 kDa and a Ki for CPA of 3 nM.[25] The physiological significance of CPA activity and its inhibitor(s) in nonpancrealic tissues remain to be clarified.

CPA does not seem to have been a target of medication. but there are a number of related zinc metalloproteases in the human body, such as angiotensin-converting enzyme (ACE. EC 3.4.15.1), collagenase (EC 3.4.24.7), and enkephalinase (EC 3.4.24.11). Because these enzymes play a role in various physiological processes. they are good targets for the rational design of therapeutic agents.[26] In this respect. because CPA may be regarded as the prototype of all the zinc metalloproteases, its structure. free and complexed with substrate or inhibitor, and the mechanism of its action should give clues to the development of lead compounds capable of specifically regulating one of the zinc metalloproteases.

CONCLUSION

CPA is often used for sequencing protein samples. Whereas there is an effective way to sequence from the amino terminus, such as with Edman degradation with phenyl isothiocyanate, there are few such methods for sequencing from the carboxyl terminus (hyclrazinolysis is one such chemical method). Hence, digestion with CPA is a choice whe e one needs to know the amino acid sequence from the C-terminus. The time course of amino acid release is monitored on the amino acid analyzer. This way to use CPA seems to be made even more effective by immobilizing it on a solid support. Bovine enzyine was

immobilized covalently to polyacrylamide beads to 125 U/g solid.[27] The immobilized CPA exhibited characteristics nearly equivalent to chose of intact enzyme.

Carcerands and Hemicarcerands

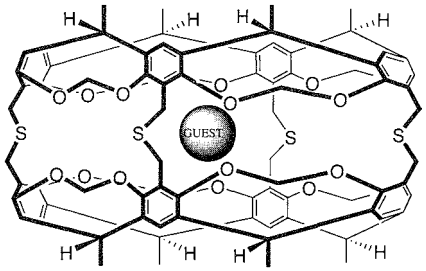
Bruce C. Gibb
University of New Orleans, New Orleans, Louisiana, U.S.A

INTRODUCTION

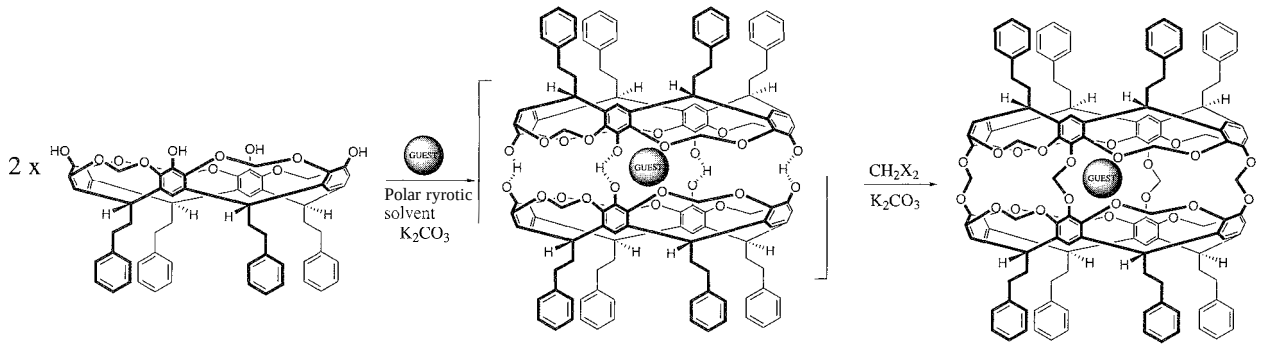
In the words of Cram,[1] ''Carcerands are closed-surface, globe-shaped molecules with enforced hollow interiors large enough to incarcerate simple organic compounds, inorganic ions. or both.'' Although this term can be applied to a number of different chemical systems including cryptophanes[2,3] and even C_{60},[4] the term has become synonymous with shell-like molecules based on cavitands. More often than not, the hollow interior of a carcerand is occupied by a guest molecule. In these cases, the term. ''carceplex'' is used to describe the carcerand–guest complex.

By definition,'' it is not possible for the guest molecule or ion in a carceplex to escape without rupturing covalent bonds in the shell of the host or the guest. For those cavitand-based hosts that possess holes large enough for guest entry or egression to occur, the term ''hemicarcerands'' has been coined. The term for the corresponding host–guest complex is a ''hemicarceplex.'' In the archetypical hemicarceplex (vide infra), guest exchange is usually slow at room temperature.

Since their conception.'' carcerands and hemicarcerands have been used for a number of applications including trapping reactive intermediates and studying templation processes.[6] Examples of these applications,



1



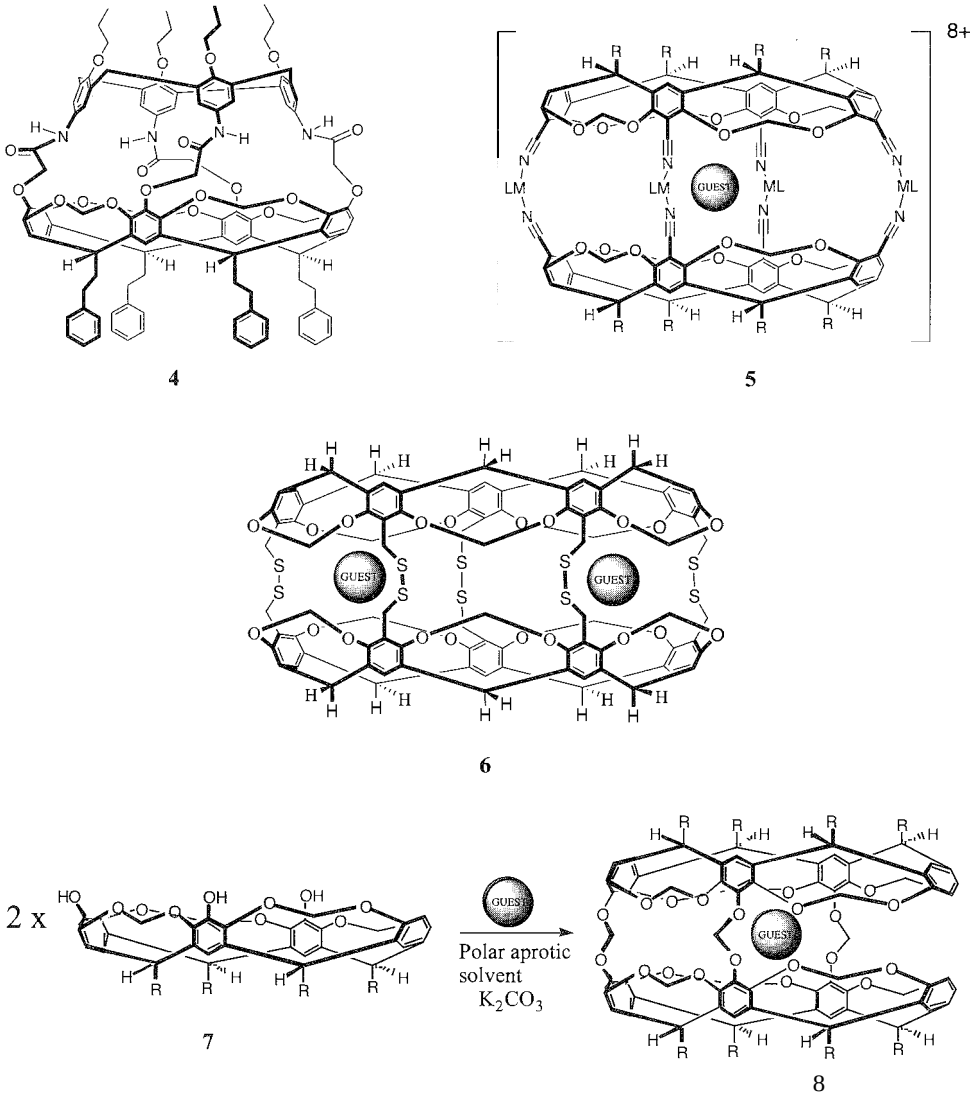
2 3

Scheme 1 The formation of carceplex 2.

as well as examples that demonstrate the structural variations to these types of molecules. are given belou.

CARCERANDS AND CARCEPLEXES

The first carcepiexes that were formed. 1, possessed very poor solubility.''' As a result. it was only possible to partially characterize mixtures of carcerands containing, among other species. dimethyl formamide and cesium chloride. The next generation of carcerands possessed larger. phenethyl ''feet'' and a different mode of linking together the two cavitand hemispheres.[8] Thus. two molecules of tetrol 2 were Iinked by acetal groups to form the more soluble 3 (Scheme 1). In the first examples of these types of carceplex reactions. the entrapped guests were the solvents of each reaction: dimethyl sulfoxide (DMSO). dimethyl acetamide (DMA), or dimethyl formamide (DMF). Yields of the isolated complexes were reinarkable: 61% for the DMSO complex. 54% for the DMA species. and 49% for the carcerand containing DMF. Addressing the question as to why these processes are so efficient has led to a greater understanding of templation by neutral molecules.[9,10] Thus, Sherman et al. identified the importance of the charged hydrogen bond ternary complex shown in Scheme 1. and determined that the differing topology of guests leads to a one-million-fold template effect.'''[11-14] The best template for the shell closure is pyrazine. which gave a yield of 87% of the corresponding carceplex when the poorly templating solvent, *N*-methyl-2-pyrrolidinone (NMP) was used. This



Scheme 4 Synthesis of the first hemicarceplex 8.

yield corresponds to a greater than 98% efficiency for each of the eight bonds formed.

A number of important variations to carceplexes such as **3** have been reported. For example, the Reinhoudt group synthesized carceplex **4**, which is one half cavitand and one half calixarene.[15] The lower symmetry of this derivative provided the opportunity to study how the guest can adopt different orientations within the confines of the shell. Another fascinating class of carceplex includes those that utilize metal links to join the two cavitand hemispheres. For example, Dalcanale's group in Parma synthesized carceplex **5** (M = Pd or Pt, R = $C_{11}H_{23}$), where the guest within the shell is one of the eight, triflate counterions.[16] The good thermal stability of the complex confirms its status as a carceplex, however, the shell-forming process was confirmed to be fully reversible by the addition of competing ligands such as triethylamine. Finally, a recent report from Sherman's group detailed the synthesis of complex **6** (Guest = DMF or DMA), the first carceplex derived from a [5]cavitand.[17] Details of how templation affects the synthesis of carceplex **6** were not given; however, the ideal guest is likely to be somewhat larger than the guests in complex **3**.

HEMICARCERANDS AND HEMICARCEPLEXES

There are two general types of hemicarcerand (and likewise two types of hemicarceplex).[6] Either one or two of the linking groups that join the hemispheres of molecules such as **3** can be removed to form lower symmetry analogues, or the linking groups can be elongated to engender D_{4h} hosts with much larger portals in their sides. It was the former that were synthesized first. As Sherman pointed out,[6] the isolation of significant quantities of triol **7** as a by-product in the synthesis of tetrol **2** inevitably led to the synthesis of the prototypical hemicarceplex **8** (Scheme 2). As expected, the formation of **8** is templated by the same types molecules as those most efficient in promoting the formation of **3**.[6]

The shell of **8** can be considered to be a molecular-sized reaction chamber capable of isolating reactive species from the external environment.[18] The first example arising from this line of reasoning was the photolysis of encapsulated α-pyrone and the resulting generation of cyclobutadiene.[19] Protected by the hemicarcerand shell, the normally highly reactive diene is stable at room temperature and was shown to exist in a singlet ground state.

As a rule, the longer the linking group inserted between the cavitand hemispheres, the weaker the templation and the lower the overall yield of the reaction. Be that as it may, the second approach to hemicarcerand formation, whereby four large linking units are inserted between the cavitand hemispheres, has led to a broad range of different hosts and host–guest complexes. A series of illustrative examples follow. Methylene-linked hemicarceplexes with up to six methylene units have been synthesized. The tetramethylene-linked derivative **9**[20] (Fig. 1) is perhaps the most studied of these, with a number of guest molecules as large as 1,2,3-trisubstituted benzene derivatives successfully encapsulated.[21–23] One of the more interesting guests reported inside **9** is *o*-benzyne.[21] Following on from using the shell of **8** as an inert reaction vessel, benzyne·**9** was synthesized by the photolysis of benzocyclobutenedione·**9**. As always, no reaction vessel is impervious to attack. Thus, over time, the highly reactive guest reacted with the relatively inert walls of **9** in an unusual intermolecular Diels–Alder reaction.[24]

By linking together cavitands with moieties that possess elements of chirality, a number of chiral hemicarceplexes including **10**[25] and **11**[26] were synthesized. These chiral hosts demonstrated chiral recognition in the presence of racemate guests. Linking groups can also be used to bestow sought after solubility properties to these hosts. The water-soluble hemicarceplex **12**, which was capable of binding a number of organic molecules, is one such example.[27]

All these hemicarcerands demonstrate hosting properties, the thermodynamic and kinetic aspects of which are intrinsically tied to the sizes and shapes of the cavity, portal, and guest. There is, however, a limitation to the

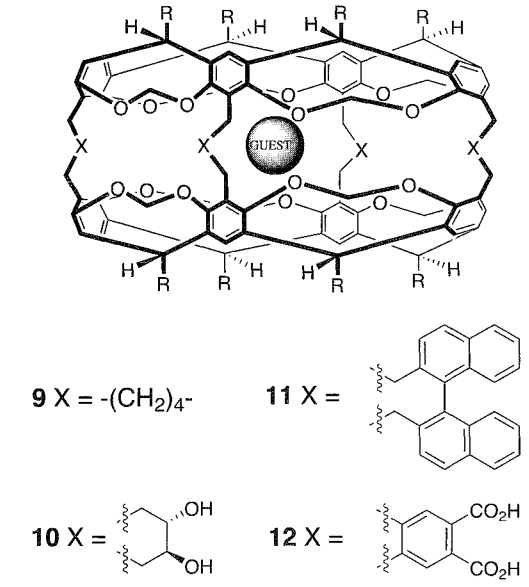


Fig. 1 Examples of hemicarceplexes based on tetrol **2**.

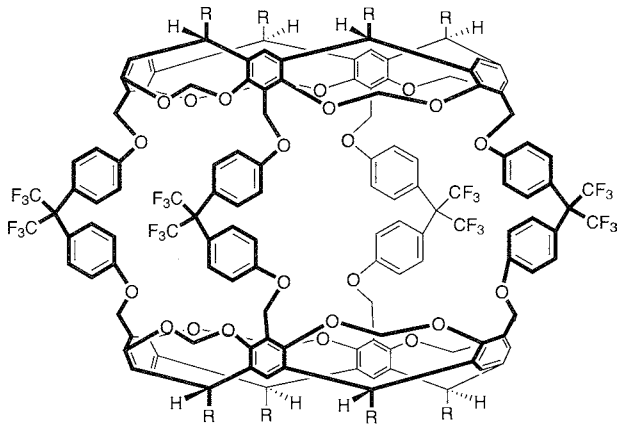

13

Scheme **3**

size of the host. Thus, as the linker groups and hence the portals increase in size, the cavity tends to become less defined. and guest complexation becomes more transient. Correspondingly, no complexation properties of large hemicarcerand **13**[28] have been reported.

CONCLUSION

d

We have defined the terms carcerand, carceplex, hemicarcerand. and hemicarceplex The formation of carcerands an carceplexes has led to some important information regarding templation by neutral molecules Similarly, the properties of hemicarcerands and hemicarceplexes has led to some interesting host–guest properties, including the storage of highly reactive species such as cyclobutadiene or benzyne

Catalytic Antibodies

Kim D. Janda

Da-Wei Chen
Achillian Pharmaceuticals Inc., New Haven, Connecticut, U.S.A.

INTRODUCTION

Catalytic antibody research was derived from the demand for new biocatalysts and the existing knowledge of enzyme catalysis mechanisms. By challenging the immune system with haptens mimicking the structure of the transition state of a given reaction; antibodies can be elicited to bind congruent substrates, to stabilize the transition state of the reaction, and ultimately. to catalyze the targeted reaction."' Following this concept, antibodies succeeded in the catalysis of more than 50 chemical transformations.[2–4] Summarized in this article are important technologies used in generating catalytic antibodies and interesting applications derived from these biocatalyses.

BACKGROUND

An antibody, also termed an immunoglobulin, is a component of the immune system produced by B cells. Typically, an antibody (G-type) molecule is around 150 kDa in mass and has a Y-shaped configuration consisting of two longer identical polypeptide chains (heavy chains) and two shorter identical polypeptide chains (light chains). They are intimately held together by disulfide bonds. Each of these chains folds into domains of approximately 110 amino acids. At the *N*-terminal end of each chain are three regions of greatest sequence variability (nine to 12 amino acids long for each), referred to as complementarity-determining regions (CDRs). These hypervariable regions in total form the antigen-binding site. This combining region can be deep cleft for a small molecule or extended surface for a binding protein. Up to 20 kcal mol^{-1} of binding energy is estimated to be deliverable by an antibody. Within the human body, approximately 10^{10} different antibodies reside. Each has a unique specificity that can be made to recognize nonself substances. This diversity and specificity of an antibody results from the integration of a series of complicated but elegant DNA processes in a B cell known as gene rearrangements, which entail imprecise joining. and somatic hypermutations. during its maturation and differentiation. Because of the limitless number of antibodies that are available and the potential to tap into their binding energies makes antibodies attractive vehicles for catalysis.

Standard protocols with the key component known as hybridoma technology were established to produce monoclonal antibodies with predetermined specificity for small organic molecules.[5] The technique is based on three steps: 1) preparation and immunization of mice with a hapten-carrier protein conjugate; 2) immortalization of the antibody-producing B cells and the production of antibodies; and 3) selection and screening for catalysis.

Because antigen–antibody interactions occur in a defined region, the antigen-binding fragment of an antibody termed Fab usually provides the same binding affinity as a whole antibody molecule. Proteolytic cleavage of an antibody by papain leads to a Fab fragment, which also can be constructed by recombinant engineering. A single-chain variable fragment (ScFv) is a highly simplified version of an antibody containing the two essential V_H and V_L domains that form the binding site and a peptide linker (10–14 amino acids long) that prevents two domains from dissociating. Combinatorial libraries of ScFv can be created and are usually displayed on the surface of filamentous phage for high throughput selection.

ANTIBODIES AND CATALYSIS

Similar in many ways to the binding of enzymes to their substrates. antibodies bind to their antigens. with noncovalent interactions exhibiting high specificities and high affinities (association constants range from 10^4–10^{14} M^{-1}). Several mechanisms employed by enzymes to accelerate reactions can be adopted as rules to follow for creating catalysis in antibodies. These include transition-state stabilization, proximity effects. general acid–base, and cofactor catalysis. Hapten design is typically based on the mechanism for the reaction of interest and usually combines several external mechanistic factors in order to obtain highly efficient catalytic antibodies.

Transition-State Stabilization

The transition-state analogue (TSA) strategy is one of the major methods used to elicit catalytic antibodies. A tremendous number of studies were directed at producing antibodies with hydrolytic activity toward activated esters. carbonates, and amides because of the potential biological importance of these reactions. The mechanistic features of these reactions are well known to involve the attack of a water or hydroxide ion at a carbonyl center. forming an oxyanion. which is a transient tetrahedral intermediate. This is followed by decomposition of the tetrahedral intermediate to the corresponding acid and alcohol or amine. More than 80 cataiytic antibodies were generated against a variety of transition-state analogues, including phosphonates. phosphates, phosphonamidates. sulfones, sulfonamides, boronic acids. and hemiketals. Among this group. the tetrahedral phosphorus compounds have been the most successful in the generation of catalytic antibodies. This success was rationalized by the ability of these structures to resemble the oxyanion intermediate of a hydrolytic reaction in terms of configuration, negative charge distribution. and bond lengths. Catalytic antibodies elicited with phosphorus-based haptens usually have a key basic residue in their combining site that forms an oxyanion hole. This residue stabilizes the transient intermediate electrostatically and provides hydrogen bonds necessary for the catalytic process.

Antibody 48G7,[6] generated against a *p*-nitrophenyl phosphonate hapten, catalyzes the hydrolysis of an activated ester (Fig. 1A). From the crystal structure of the 48G7 Fab–hapten complex,[7] it is hypothesized that the source of catalysis is the stabilization of an oxyanion transition state formed in the reaction. Binding energy for catalysis is mainly derived from ArgL96, which forms an electrostatic interaction with the anionic phosphonate moiety embedded in the hapten, as well as the TyrH33 and HisH35 residues that form hydrogen bonds with the phosphonyl oxygen atoms in the hapten.

Analysis of the binding and catalysis data of 48G7 and its precursor germline antibody (which differs by nine amino acid residues) reveals that the dissociation constant K_d of the hapten–antibody complex decreased by $>10^4$ during affinity maturation, while the k_{cat}/K_m (catalytic efficiency) increased by 100-fold.[8] This study indicates that improvements in transition-state binding are positively correlated with improvements in catalysis, although only a small fraction of the additionally gained binding energy is converted to transition-state stabilization. Interestingly, none of the nine residues in which somatic mutations were fixed directly contact the hapten. This further indicates that the catalytic motifs were determined by a TSA at an early stage of antibody evolution. Affinity maturation in the case of 48G7 merely plays a conformational role. wherein there is reorganization of active-site residues to an optimal geometry for hapten binding rather than provision of new functional residues in the active site for catalysis.

Sequence comparison between 4867 and other hydrolytic antibodies generated with similar phosphonate TSAs reveals a high degree of conservation in the binding-site residues.'" Similar observations are obtained for three catalytic antibodies D2.3. D2.4, and D2.5. also elicited against a phosphonate TSA and identified by screening for catalytic activity through the entire hybridoma repertoire.[10] X-ray structural data indicate that the three antibodies use identical binding-site residues to stabilize the oxyanion intermediate, thus they all achieve catalysis in essentially the same mode. This strongly supports the notion that the immune system tends to quickly reduce the broad diversity initially existent in the antibody repertoire to a small number of "best solutions." However, structural convergence is not always the only solution adopted by the immune system to create catalytic antibodies using the TSA method.

Antibodies 6D9 and 7C8,[11] generated against a phosphonate transition-state analogue. hydrolyze a prodrug of chloramphenicol monoester to yield the parent drug chloramphenicol (Fig. 1B). Amino acid sequence analysis demonstrates that these antibodies share only 55% and 44% homology in V_L and V_H, respectively. Evidence from catalytic and binding assays. substrate specificity investigations, pH profiles, and chemical modifications indicates that different motifs and mechanisms are employed to achieve catalysis by these two antibodies. Judging by comparisons of differential binding energies K_S/K_{TSA} (dissociation constants for substrate *S* and TSA with antibody) and rate enhancements k_{cat}/k_{nucat}, the antibody 6D9 catalyzes hydrolysis solely by transition-state stabilization ($K_S/K_{TSA}=900$; $k_{cat}/k_{nucat}=895$). but 7C8 does not ($K_S/K_{TSA}=12$: $k_{cat}/k_{nucat}=707$).

Different binding modes are clearly shown in the structure complexes of the TSA (a compound without glutaroyl linker in the hapten) with 6D9 Fab and 7C8 Fab.[12] TSA binds to 6D9 in a folded form. with its two aromatic rings stacked and the trifluoroacetyl group buried deeply in the combining site. In contrast, the TSA is extended in a shallow groove in 7C8. The key side-chain residue is HisL27d, in 5D9 forming a hydrogen bond to the phosphoryl oxygen. In 7C8, TyrH95 is the critical residue that also determines a completely distinct catalytic mechanism from the former antibody. This diversity of catalytic antibodies generated against a single TSA hapten demonstrates that several catalytic solutions are available throughout the complete immune repertoire for a same reaction. Each provides a distinct starting point for reaching higher optimized efficiency.

More interestingly; functional residue arrays that provide a well-fashioned binding mode with a transition-state

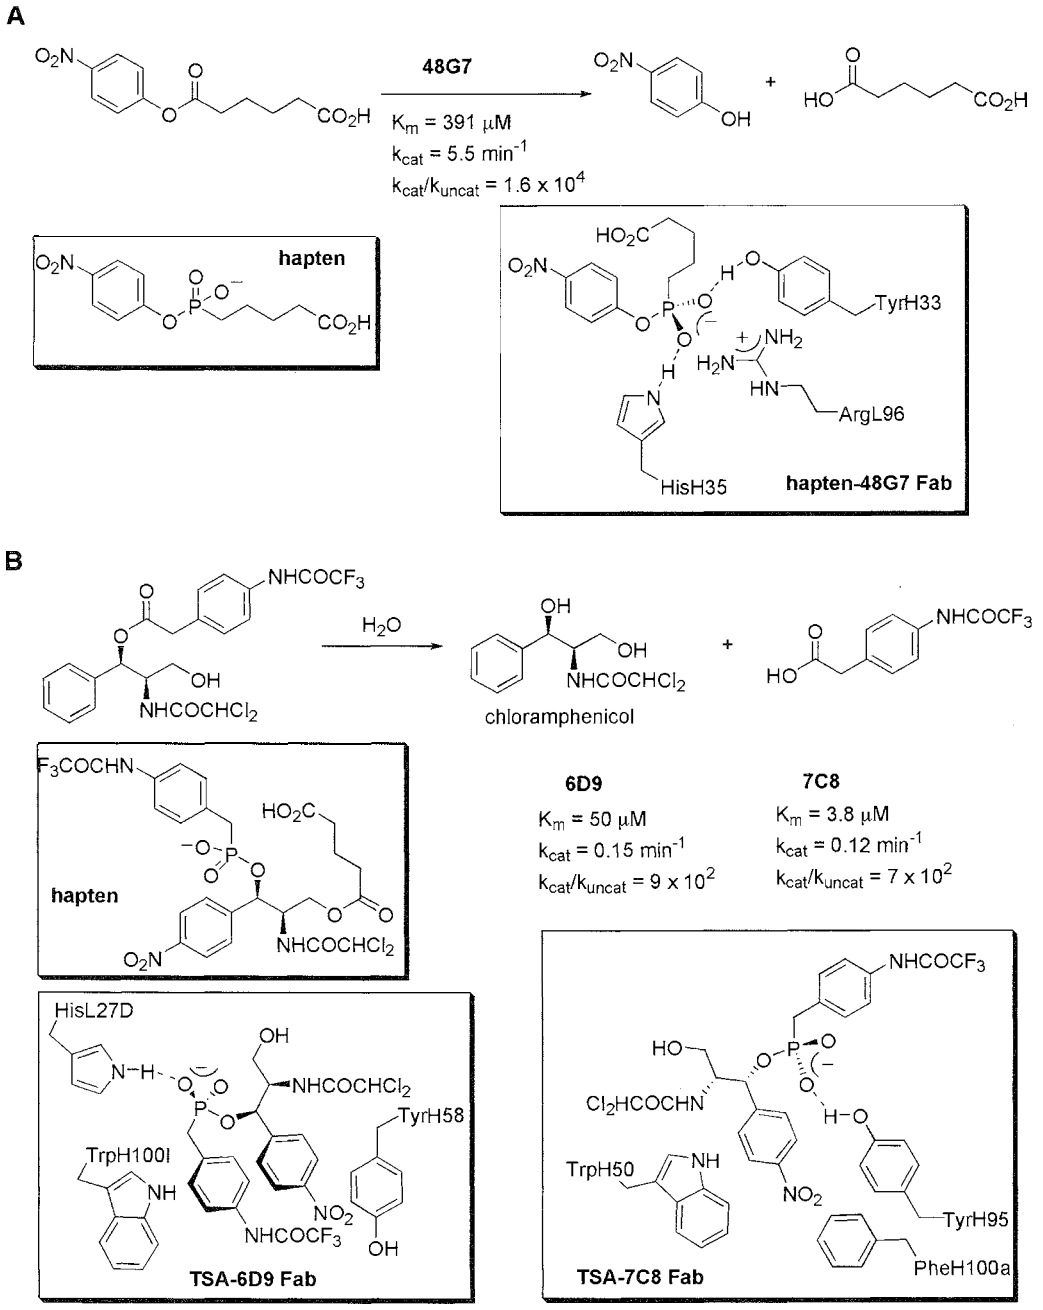

Fig. 1 (A) Antibody 48G7, elicited against a phosphonate hapten, catalyzes the hydrolysis of an activated ester. The hapten-48G7 Fab coinplex shows the key residues that comprise the oxyanion hole. (B) Two antibodies. 6D9 and 7C8, elicited against a phosphonate hapten, catalyze the release of chloramphenicol from its prodrug ester. The Fabs of 6D9 and 7C8, cocrystallized with a TSA (with the glutaroyl linker removed from the hapten), reveal completely different binding modes for the TSA.

analogue in the combining site can transform the antibody into a new catalytic factor in the reaction process. Antibody 43C9.[13] which was generated against a phosphonamidate, significantly accelerates the hydrolysis of an activated amide by a factor of 10^5 (Fig. 2A). Although there is a good match between the differential binding energy and rate enhancement (K_m/K_d=2.3 x 10^5; k_{cat}/k_{uncat}=2.5 x 10^5), solid evidence reveals that 43C9 employs covalent catalysis forming an acyl-antibody intermediate as its chemical mechanism to hydrolyze the p-nitroanilide substrate.[14]

Crystal structural data combined with a computational model of 43C9 scFv explained how active residues arrayed to bind a hapten turned to play an unexpected role of

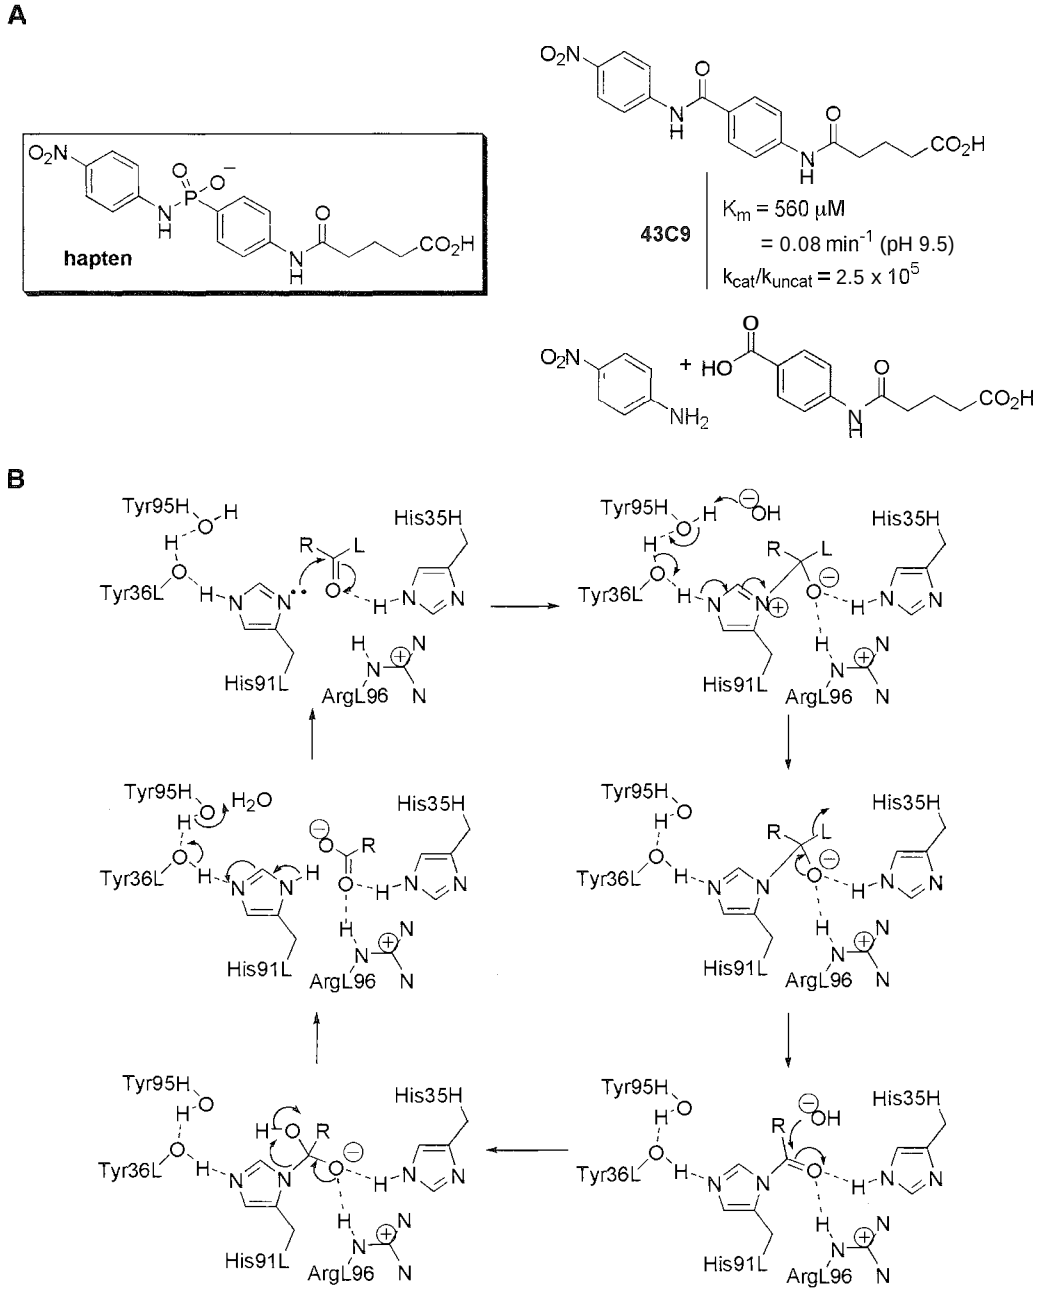

Fig. 2 (A) Antibody 43C9. elicited against a phosphonamidate hapten, catalyzes the hydrolysis of an activated amide. (B) Evidence reveals that antibody 43C9 employs a covalent catalytic mechanism. HisL91 is the nucleophile that attacks the substrate's amide carbonyl. Residue HisH35 assists in transition-state stabilization. while TryL36 and TryH95 are probably involved in proton transfer.

nucleophilic catalysis in the reaction.[15] In the combining site. HisL91 is arranged in a perfect orientation (N to carbonyl $C-4$ Å) for nucleophilic attack on the substrate. while TyrL36 and TyrL95 are involved in proton transfer. Residues ArgL96 and HisH35 assist in transition-state stabilization of the reaction by forming hydrogen bonds (Fig. 2B). This covalent mechanism demonstrates that the immune system has the ability to evolve unprogammed catalysis in antibodies with a simple TSA hapten to achieve higher catalytic efficiency.

Proximity Effects and Entropy Trap

In many cases. enzymes catalyze bi- or unimolecular reactions by providing organized active sites that collect substrates in sufficient proximity to react with one

another. or by freezing the substrates into reactive conformations. These processes lead to a decrease in the enthalpy of activation or an increase in the entropy of activation, or both, compared to the uncatalyzed reaction. Hence. they reduce the Gibbs' activation energy of reaction and accelerate the process.[16] An antibody combining site can be sculpted for shape complementarity to the reaction's transition state. Thus, changes in activation enthalpy and entropy from uncatalyzed to catalyzed reactions could be compensated with binding energy provided by the preorganized combining site.

Antibody 11F1-2E11[17] catalyzes a [3,3] sigmatropic rearrangement of chorismate to prephenate with a rate acceleration of 10^4 over the uncatalyzed reaction (Fig. 3A). This is only two orders of magnitude lower than the enzyme isolated from B. *subtilis*. In this scenario, the hapten is a shape mimic of a cyclic transition state having a pseudodiaxial conformation. It was programmed to induce a complementary combining site in the antibody that restricts the rotational degrees of freedom of chorismate and constrains it into a chair-like conformation; thereby inducing the reaction to occur. Kinetic analysis showed that the antibody-catalyzed reaction has 18.3 kcal mol^{-1} and -1.2 e.u. of activation enthalpy and entropy.[18] Compared to the 20.5 kcal mol^{-1} and -12.9 e.u. of activation enthalpy and entropy for uncatalyzed reaction. it is clear that antibody 11F1-2E11 successfully acts as an entropy trap to -accelerate the reaction.

Antibody 1E9,[19] the first catalytic antibody for the Diels–Alder reaction. catalyzes the cycloaddition between terachlorothiophene dioxide and *N*-ethylmaleimide. This reaction occurs via a bridged sulfone intermediate forming tetrachlorophthalimide through sulfone elimination and spontaneously oxidative aromatization (Fig. 3B). This catalyst displays an effective molarity ($EM = k_{cat}/k_{uncat}$) of 1000 M, which is extremely efficient for a bimolecular reaction catalyzed by an antibody. The hapten used to elicit this antibody is a derivative of endo hexachloronorbornene. which is a shape mimic of the transition state. Because it has less structural similarity to the aromatic product, product inhibition in the 1E9-catalyzed reaction is avoided.

Interestingly, experimentally determined entropy and enthalpy of activation for the catalyzed reaction indicate that 1E9 does not function as a classical entropy trap. as the activation entropy is even more negative than that of the uncatalyzed reaction in solution (-22.1 e.u. and -21.5 e.u for catalyzed and uncatalyzed reactions, respectively).[20] Instead. the enthalpy-controlled process by which the substrates are arranged to a reactive conformation in the combining site dominates the reaction. Thus, the rate enhancement of 1E9 is derived entirely from a reduction of the activation enthalpy of the reaction (11.3 kcal mol^{-1} and 15.5 kcal mol^{-1} for the catalyzed and uncatalyzed reactions. respectively). In fact, as crystallographic structural data and quantitative calculations indicated. the binding site of 1E9 provides over 120 van der Waal interactions to facilitate the correct organization of the substrate and an increased electrostatic complementarity compared to water to yield the catalysis observed.[21]

A particularly efficient mechanism for manipulating the entropic issue to attain rate acceleration is through covalent catalysis. Antibody 21H3 is a remarkably efficient catalyst for the transesterification reaction between sec-phenethyl alcohol and an enolic ester in water to form the corresponding chiral ester (Fig. 3C).[22]

The antibody is found to be highly efficient, with an effective molarity of approximately 10^6–10^8 M, corresponding to a gain of about 35 e.u. in entropy of activation. Steady-state kinetics show classic ping-pong behavior in double-reciprocal plots: indicating that the reaction proceeds through two half-reactions in which the initial step consists of formation of a covalent antibody complex. The maximum entropy loss is achieved with a tight fixation of one of the reacting partners to the antibody combining site. Moreover. the second step of the reaction shows an induced fit mechanism that involves transferring the acyl group from the covalent intermediate to the alcohol acceptor to form the product ester. The observed covalent intermediate and the induced fit mechanism of catalysis are the most notable features of this catalytic antibody, as it possesses catalytic machinery previously thought to be the purview of only highly evolved enzymes.

General Acid/Base Catalysis

For the reactions where the appropriate transition state analogues are not accessible or that require the involvement of a specific catalytic group in the reaction process, the strategic use of haptenic charges could generate antibody active residues acting as general acid/base catalysis. This strategy, also known as "bait and switch,"[23] relies on the fact that point charges in hapten can induce complementary but opposite point charges in the combining site of an antibody.

Antibody 43D4-3D3,[24] which catalyzes the β-elimination of a β-fluoro ketone with a rate acceleration of approximately 10^5 over that of the corresponding background reaction, is generated against an ammonium hapten (Fig. 4A). The positively charged alkyl ammonium ion is expected to induce a complementary negatively charged carboxylate residue in the antibody combining site. positioned to function as a general base in the reaction. Because hapten structure has less resemblance to the transition state of reaction, achieved catalysis is largely due to the presence of a catalytic base. Chemical modification and affinity-labeling experiments confirm

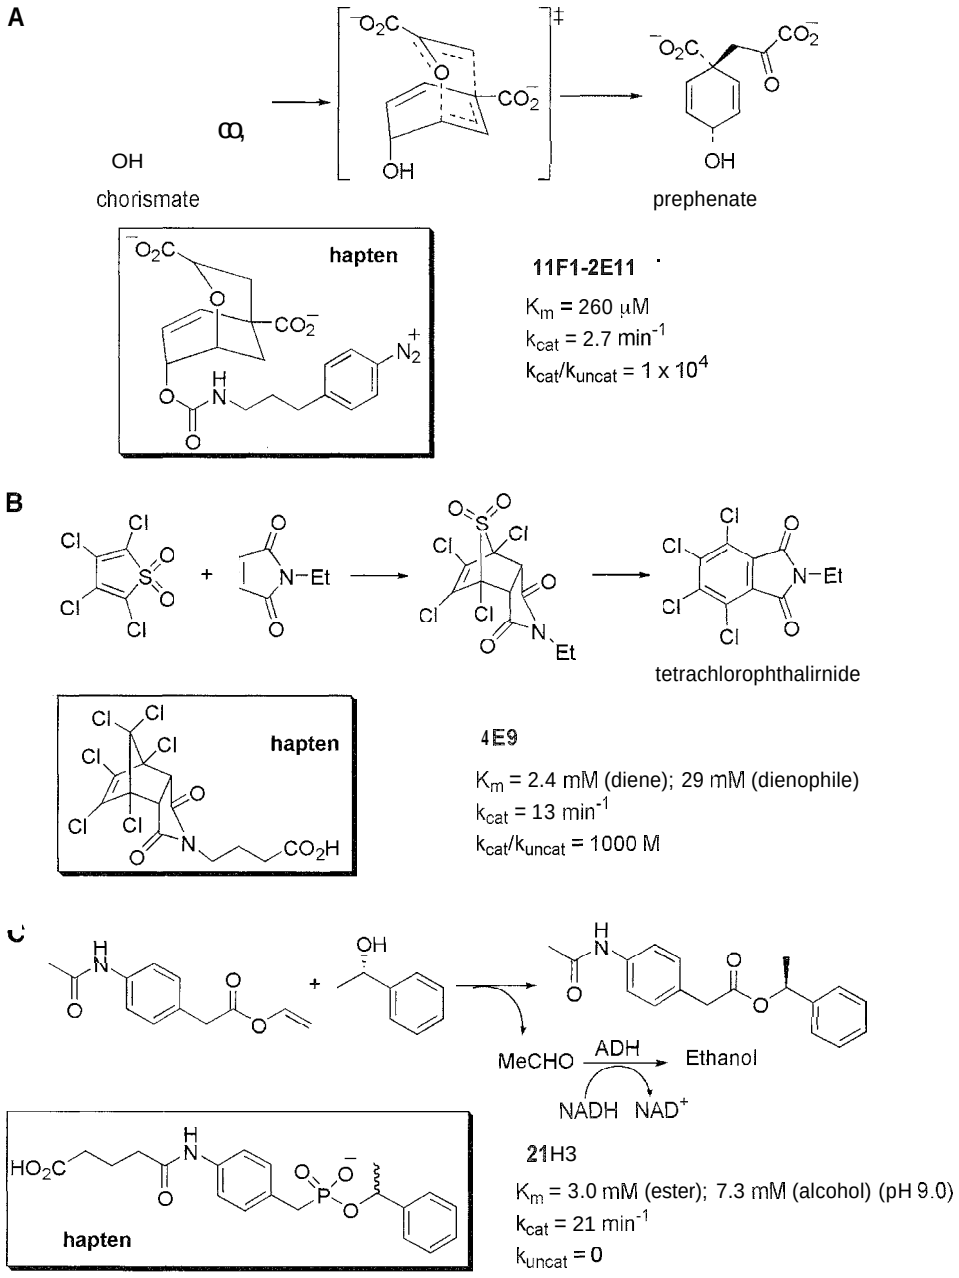

Fig. 3 (A) [3,3] Sigrnatropic rearrangement of chorismate to prephenate catalyzed by antibody 11F1-2E11. The hapten is a shape mimic of the cyclic transition state. (B) Antibody 1E9 catalyzes a Diels–Alder reaction of tetrachlorothiophene dioxide and *N*-ethylmaleimide. The hapten is comprised of the endo hexachloronorbornene unit. that the carboxylate side chain of GluH46 on 43D4-3D3 is responsible for removal of the proton in the elimination reaction.

General acid/base catalysis was also exploited to generate highly efficient catalytic antibodies for hydrolytic reactions.[25] A hapten with an *N*-methyl-pyridinium group was designed with a positive charge in order to elicit a negatively charged carboxylate, with an appropriate distance in space, acting as a general base or nucleophile for the acyl moiety to be hydrolyzed (Fig. 4B). Antibody 30C6, generated against this hapten, is found to accelerate the hydrolysis over a million-fold with its ester substrate. A pH rate profile of it reveals a basic form of a dissociable group with pKa of 6.25 evolved in the catalytic process. As a clear comparison for the success of the bait and switch strategy, no antibodies against a

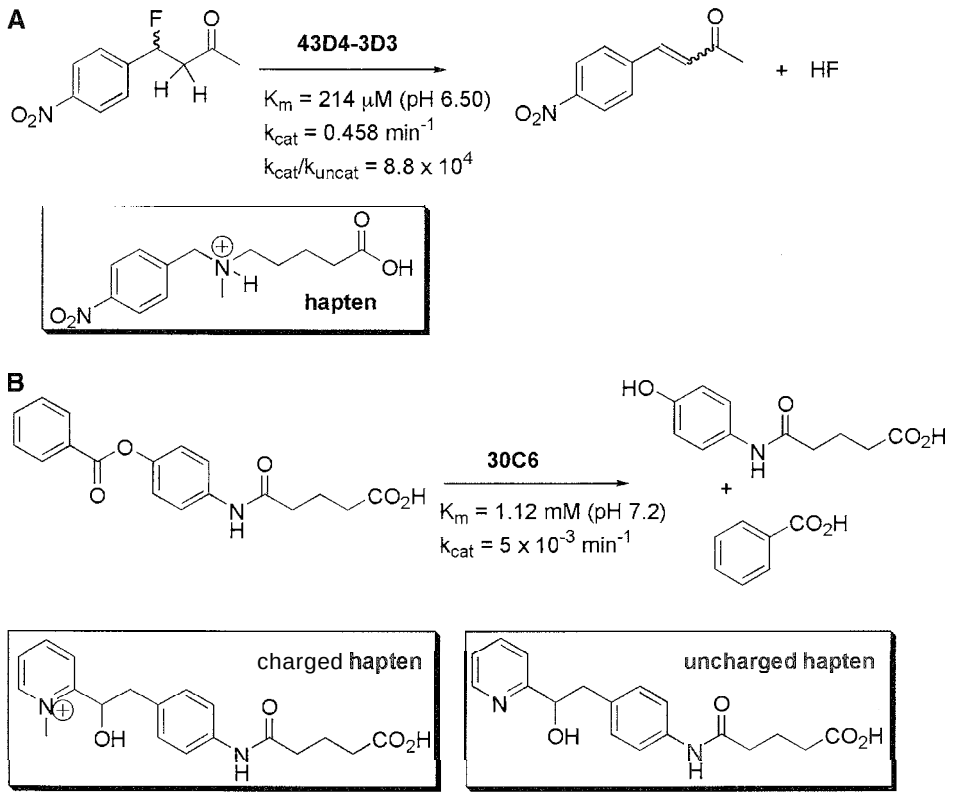

Fig. **4** (A) Antibody 43D4-3D3, elicited against an ammonium hapten, catalyzes an elimination reaction. (B) The hydrolytic reaction of an ester catalyzed by antibody 30C6. The pyridinium compound is the hapten used to elicit catalytic antibody 30C6. The uncharged hapten did not elicit catalysis for this reaction.

hapten that differs from the charged hapten by simply lacking a positive charge at physicological conditions are found to be catalytic.

It has further been demonstrated that by appropriate presentation of point charges on haptens, general acid/base catalysis could be achieved in a variety of catalytic antibody reactions, including condensation, isomerization, elimination, and hydrolytic reactions.

Cofactor Catalysis

Enzymes use nonpeptidyl catalytic auxiliaries termed cofactors to gain additional chemical functionality. These include metal ions, hemes, thiamine, flavins, and pyridoxal. To expand the scope of antibody catalysis, the introduction of cofactors into an antibody-combining site could be a powerful tool to improve catalysis. The diversity of the immune response should allow one to use not only the natural cofactors but also a host of unnatural cofactors unavailable to enzymes.

Antibody 28F11 achieves sequence-specific cleavage of the Gly-Phe bond at neutral pH with metal complex cofactor (Fig. 5A).[126] The hapten is designed to ensure correct approximation of the functional portions of the cofactor and substrate. Thus, a stable cobalt(III)-trien is linked to a peptide substrate for immunization, so that the antibody binding site could accommodate the substrate and trien simultaneously. The trien can form complexes with Co(III) as well as many other metal ions in the antibody binding site. Particularly effective metal ions include Zn(II), Fe(III), Ga(III), Cu(III), and Ni(II). The trien-Zn(II) as a cofactor is determined to have a k_{cat} of 6×10^{-4} s^{-1} and 400 turnovers per antibody binding site.

This principle of using a ligand analog or metal–ligand complex as a hapten to produce antibodies with cofactor catalysis was also applied to a number of redox-active cofactors.[27,28] Basically. antibodies generated by this method do not bind metal ions directly but bind them through ligand binding induce a metal ion into its combining site.

Antibody 3862 is a metalloantibody that incorporates mercury(II) as a Lewis acid cofactor.[29] It is generated against a coordinatively unsaturated mercury complex with the phosphorodithioate shown in Fig. 5B. In this case, the antibody-combining site is developed to coordinate directly to the metal and stabilize the

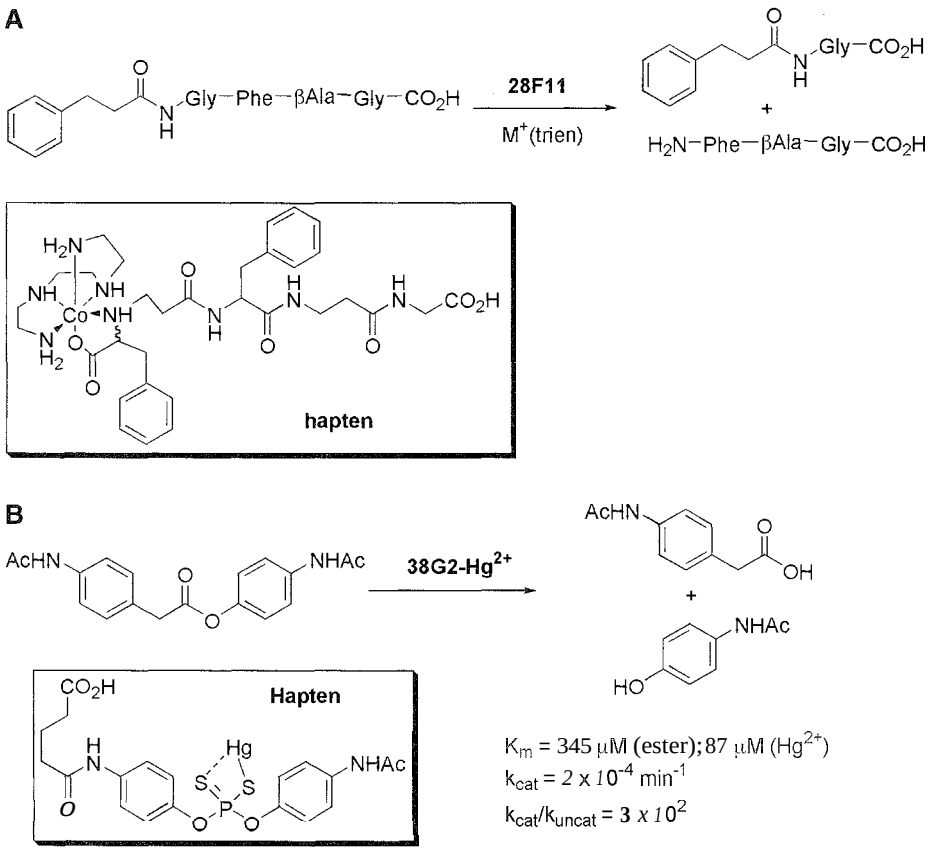

Fig. 5 (A) Antibody 28F11 catalyzes Gly-Phe bond cleavage. The hapten is a stable cobalt(III)-trien complex. (B) Antibody 38G2 specifically uses Hg(II) as a cofactor to catalyze the hydrolysis of an ester. The hapten in this case is a phosphorodithioate-Hg(II) complex.

transition state of the hydrolysis reaction simultaneously. Antibody 3802 is highly specific for Hg(II) *catalysis of the ester hydrolysis with a race enhancement of over 300-fold with multiple turnovers. Significantly, this approach opens new avenues for the exploitation of* metal cofactors *thought previously beyond the* realm *of even enzymes.*

IMPROVEMENTS IN THE GENERATION OF CATALYTIC ANTIBODIES

Toward the end of finding antibodies with new catalytic properties or greater efficiency,methodological and technical improvements have been continuously explored through the aspects of novel hapten design/immunization, enlargement *of pooi size of hapten-specific antibodies, and new screening and selection methods.*

One *of the* methods *has been termed "reactive* immunization."[30] *This strategy requires a reactive compound for immunization so that a chemical reaction takes place in the combining site of antibody during the process of induction. This chemical reaction is "ingrained" in the hybridoma and used later as part of the catalytic mechanism. Phosphonate diesters and* β-diketones *are two types of compounds explored as* haptens *to generate hydrolytic antibodies[31] and aldolase antibodies.[32]Reactive residues such as cysteine, serine, and lysine are elicited to form a covalent bond with the* haptens *in combining site.*

Combining transition state theory and reactive immunization *design into a single* hapten *can result in an increase in the output of catalysts* from *the immune* system *as well as their efficiency.[33]The synergistic application of these two approaches has been* employed *in the design of aidolase antibody 8463 (Fig.* 6A). In *the structure of* hapten *for this antibody. a* 1,3-diketone *moiety is* strategically *placed to induce lysine in the binding site,* mimicking *the mechanism of a Type I aldolas. In addition, a sulfone* is embedded *in the molecule, acting as transition state analogue of* C–C *bond formation between the enaminone intermediate and the acceptor aldehyde. Antibody 8463 catalyzes a retro-aldo reaction*

with rate enhancement of 10^8, and its catalytic proficiency is found to be 1000-fold higher than that of any other catalytic antibody.

A successful immune response to a given hapten will generate a large diversity of antibody-producing B cells. However. current procedures generally termed ''hybrid.ma technology'' are limited to the production of only a few hundred hybridoma clones. This inevitably results in a significant loss of initial diversity. Alternatively, antibodies can be produced using combinatorial cDNA libraries from immunized mouse spleen cells to generate antibody (or functional antibody fragments like Fab and scFv) libraries for screening and selection.[34] This technique provides libraries on the order of 10^8–10^9.

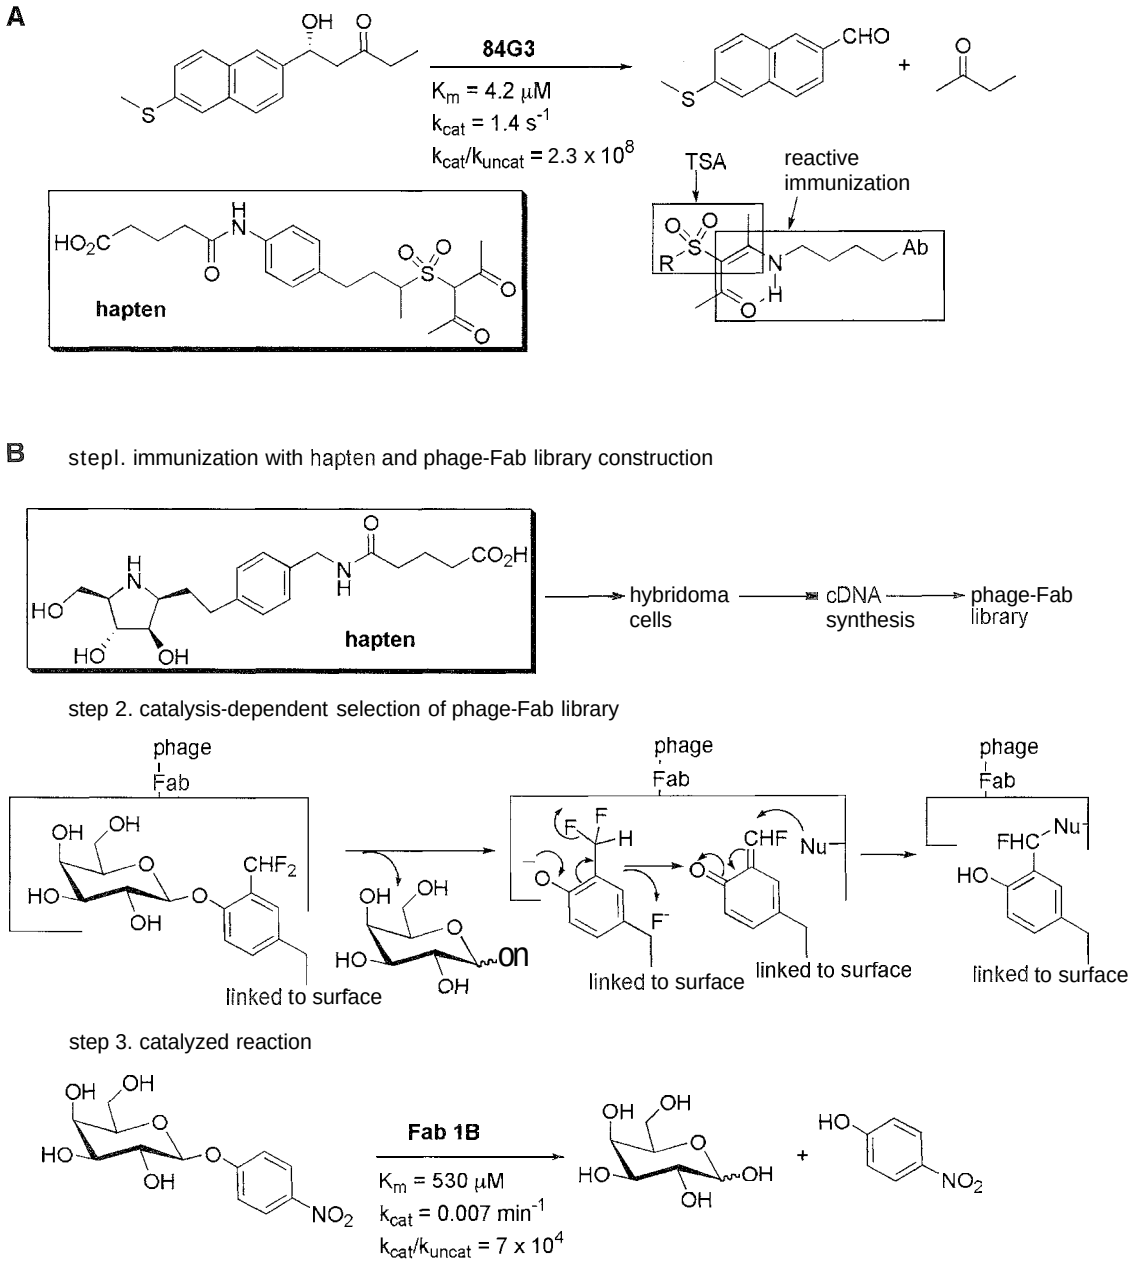

Fig. 6 (A) A retro-aldol reaction catalyzed by the antibody 8403. The hapten's structure combines reactive immunization and transition state analogue theory. (B) A phage-Fab library combined with direct selection of catalytic activity was used to discover the antibody catalyst Fab 1B for glycocidic bond cleavage.

Phage display technology facilitates the creation of such large libraries so tha-t the odds of finding a desired catalytic antibody are greatly increased.

Whether one uses hybridomas or phage libraries, screening and selection methods are crucial.[35] In essence, the screen or selection determines what products will be obtained from a library. and a poorly organized screen or selection can severely hamper catalytic searches. CatELISA,[36] which was developed from the conventional enzyme-linked immunosorbent assay (ELISA) for antibody affinity, uses substrate instead of hapten in the screening process. This then provides a more direct link to effectively screen for catalysis.

Fab 1B,[37] a catalyst for glycocidic bond cleavage, is selected from a phage-Fab library using a mechanism-based "trap" to uncover catalysts (Fig. 6B). Compared to the best antibody obtained from a simple hybridoma screen for binding, catalytic activity of Fab 1B is 700 times greater. This provides an excellent example, showing that if one can couple a clever design and selection strategy with a large diverse library, improved catalysts can be identified.

APPLICATIONS OF CATALYTIC ANTIBODIES

In Organic Synthesis

As antibody catalysis has progressed; one catalytic antibody, 38C2,[33] became commercially available, with much attention being drawn to its practical application in organic synthesis. In fact, there are many publications reviewing applications of antibody catalysis in asymmetric reactions,[38,39] pericyclic reactions,[40] cationic reactions:[41] and general organic synthesis.[42,43]

One of the most exciting developments in the catalytic antibody field is the demonstration of a disfavored

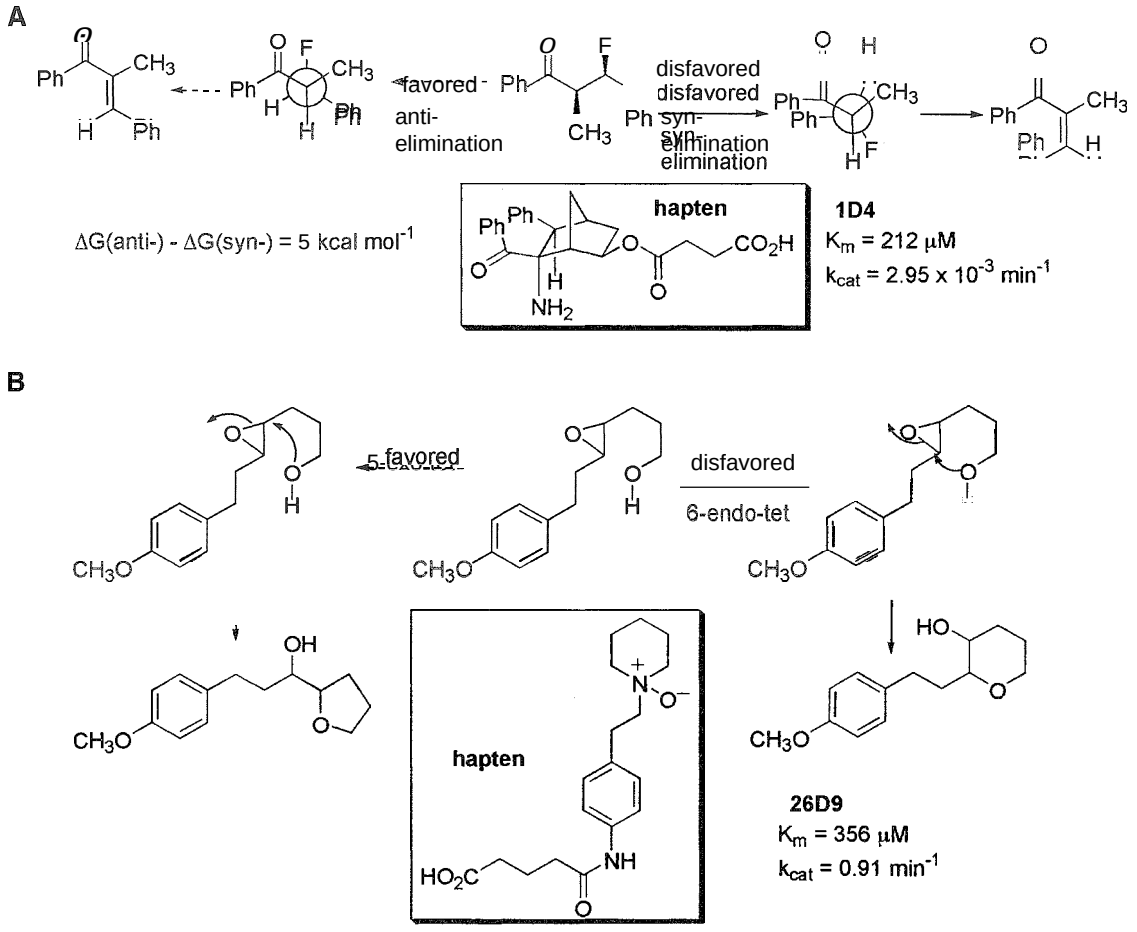

Fig. 7 (A) Antibody 1D4 catalyzes a disfavored *syn*-elimination reaction. (B) Antibody 26D9 catalyzes a difavored 6-endo-tet reaction.

chemical reaction providing products and stereochemical results that cannot be obtained under uncatalyzed conditions. Syn elimination[44,45] and an anti-Baldwin rules' cyclization[46,47] are examples of processes having unfavorable energy barriers that were surinounted through the use of antibody catalysis (Fig. 7A, B). Antibodies elicited against the appropriate hapten can provide sufficient binding energy to allow the disfavored process to become the only viable direction of a reaction in the antibody-combining site.

Other Developments

As a logical outgrowth of their utility in organic synthesis. catalytic antibodies are finding new applications in a wide variety of areas. Therapeutic use of catalytic antibodies is one of these emerging applications.[48] Acting as a local activation reagent, a catalytic antibody was found that demonstrates promising treatment for cancer.[49] Antibody catalysis to cure drug addiction[50] received broad interest from scientific and public communities. In addition, the generation of catalytic antibodies for polymer degradation[51] is another new avenue with industrial and environmental potential.

CONCLUSION

Catalytic antibodies have proven to be an outstanding platform on which to provide biocatalysts for many types of chemical transformations on a practical time scale. Antibodies can be programmed to achieve catalysis using the same mechanistic features employed by enzymes. Significantly, the short evolution time of a catalytic antibody is a highly desirable feature that allows for the discovery of catalysts in a matter of months versus enzyme evolution that takes years. As concepts and methods are no longer restricted to the TSA approach only, we are now seeing upper rate limits for catalytic antibodies on the order of 10^8, with some antibodies displaying catalytic efficiencies superior to the comparable natural enzymes. For many antibodies, however. improvement of catalytic efficiency is still necessary for their widespread utility. The increasing understanding in the structure–function relationship between haptens, combining sites, and catalysis should be helpful for designing and preparing better catalytic antibodies.[52] Clearly. biotechnological methods such as in vitro evolution could provide a powerful solution for the production of future generations of catalytic antibodies with greater efficiency.[53] The chemical versatility of catalytic antibodies in rerouting chemical transformations and the catalysis of nonenzymatic reactions. as well as the broad substrate tolerance, were demonstrated in organic synthesis. However. the most exciting feature for this new type of biocatalyst likely lies in the catalysis of reactions for which there are no natural enzyme counterparts.

Catenanes and Other Interlocked Molecules

Alexander Rang
Christoph A. Schalley
Kekulé-Institut für Organische Chemie und Biochemie der Universitdt, Bonn, Germany

INTRODUCTION

Since the concepts of "asymmetry" were developed by Jacobus Henricus van't Hoff, a scholar of Friedrich August Kekulé, and Joseph Achille Le Bel, in 1874. dealing with asymmetric carbon atoms. chemistry has developed rapidly: meso-compounds were found, and chiral allenes and biaryl systems with high rotational barriers were discovered. synthesized, and separated into their enantiorners. The same is true for molecules with planar and helical chirality. A newer form of chirality is topological chirality. which is, nevertheless. as fascinating as the long-known types. Catenanes (from the latin word "catena" for "chain") are two entangled macrocycles mechanically linked with each other. They cannot be separated without breaking a covalent bond, although they are not bound to each other by such a bond. These and other interlocked molecules are perfect examples with which to outline this topic in greater detail. These complex molecules cannot be obtained in adequate yields without templated synthesis. Therefore. we would like to address this topic in this article. New supramolecular complexes were found by the participating research groups as precursors for interlocked species and will be discussed. Also, catenanes feature some challenging properties as polymers. switches, or potentially as molecular machines. in that they are able to circumrotate. But how exactly do they rotate? The article will terminate with a brief discussion of their dynamic properties, which are due to the high flexibility of the mechanical bond.

MOLECULAR TOPOLOGY OF CATENANES AND KNOTS

Catenanes are not only mechanically bound molecules with enormous aesthetic appeal but also feature interesting topologies. The topology of a molecule is described by reducing the structure to its simplest form. the molecular graph, which neglects substituents and just follows the backbone of the molecule. Consequently, a inacrocycle is reduced to a simple circle that can be represented in a flat graph (Scheme 1). In topology. which as a certain type of geometry is a mathematical discipline. all transformations of an object are allowed that can be done and reversed by a continuous transition. Consequently, if two macrocycles are intertwined and connected by a mechanical bond, the result equals the molecular graph of a catenane. The graph is nonplanar. because both circles cross each other two times.[1] In other words. a simple catenane is characterized by the fact that any projection of the molecular graph on a plane will have two crossing points."' It is important to realize that the two rings cannot be separated without opening one of them. This would be a noncontinuous transition and is. therefore, forbidden in topology. The number of crossing points of a trefoil knot's graph is three, and once again, the graph is nonplanar (Scheme 1). Naturally. an infinite number of knots with more than three crossings exists and is waiting to be synthesized as chemical molecules.

TOPOLOGICAL CHIRALITY OF CATENANES AND KNOTS

Molecules possessing a nonplanar graph can. but do not necessarily. exhibit topological chirality. While molecular trefoil knots are inherently chiral. i.e., they do not require a particular arrangement of atoms to be chiral;[3,4] catenanes are achiral. because they require a particular arrangement of atoms or otherwise can easily be mirrored. As discussed by Schill,[5] an achiral catenane can be dissyinmetrized by suitable substitution. In fact, this approach is equivalent to one making use of macrocycles that bear a defined directionality due to a nonsyminetrical sequence of atoms. In 1995. Vogtle and his group reported the first synthesis of a chiral amide-based catenane containing one sulfonamide group in each of the two macrocycles[6,7] (Scheme 2). Due to the directionality defined from *S* to *N* in these sulfonamides, this catenane is topologically chiral. The enantioseparation of the catenane via HPEC on a chiral column was successful. and the CD spectra shown in Scheme 2 could be obtained.

It should be noted that in contrast to the mentioned trefoil knot. the square knot (Scheme 1) is achiral. Like the classical mesoform of tartaric acid. the square knot bears a mirror plane and. consequently, shows that symmetry considerations are important. For more complex

knots. it may even be impossible to determine with complete certainty whether or not a knot is topologically chiral. To find such invariants remains an unsolved problem to this day.[4]

TEMPLATED CATENANE SYNTHESIS

Three different synthetic strategies toward catenanes can be distinguished:

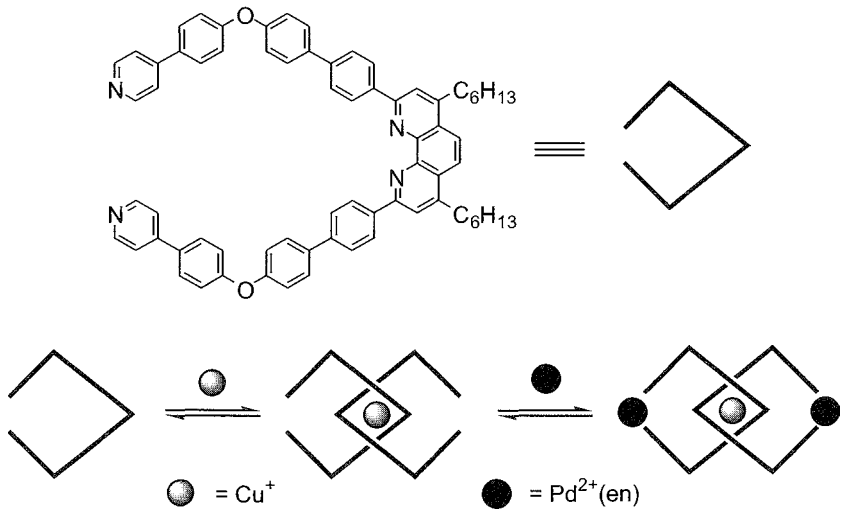
1. A preformed macrocycle binds the open precursor of a second one inside its cavity to form what could be called a pseudorotaxane. The threading step is then followed by connecting the two ends of the pseudorotaxane with each other in a inacrocyclization reaction.
2. Two open precursors are brought together into a suitably preorganized supramolecular complex and are then cyclized in a one-pot-two-step sequence.
3. The third possibility requires a reversible bond formation. Then, preexisting rings could be opened, threaded into each other, and cyclized again when intertwined.

All of these strategies require ihe operation of suitable template effects for an efficient threading.

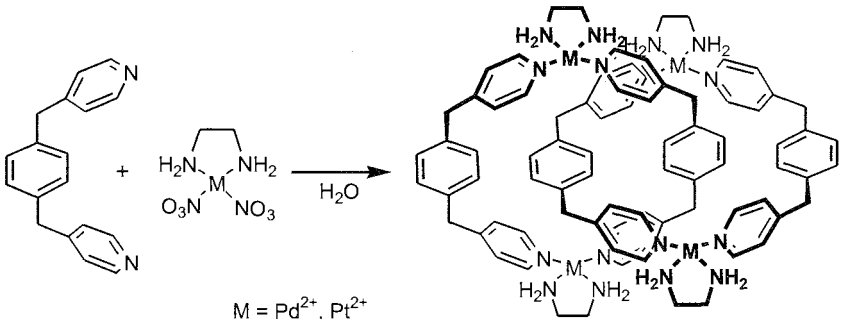
The first templated synthesis of a catenane was published 20 years ago.[8,9] Since then, synthetic strategies based on various template effects were proposed by several groups. Therefore. modern template strategies[10] give satisfying yields and make these molecules accessible from a preparative viewpoint. How important template strategies are becomes clear when considering the synthetic efforts needed for the first statistical catenane syntheses in the early 1960s.[11] Since the modern template effects used for catenane synthesis resemble those employed for the preparation of rotaxanes, the reader is referred to the article on "'Rotaxanes and Pseudorotaxanes" of this Encyclopedia, where they are discussed in greater detail. Here. we would like to focus on several other aspects in order to avoid unnecessary repetition.

SELF-ASSEMBLY AS A SYNTHETIC STRATEGY

In the following examples, self-assembly may be regarded as another form of templated synthesis. but because of the topicality of this synthetic strategy and the achieved results, this approach should be discussed in greater detail. Metal-directed self-assembly is particularly attractive, as the metal-to-ligand bonds are reversibly formed, and the catenanes can often be obtained almost quantitatively as the thermodynamically most stable products. In 2001. Fujita, Sauvage. and their groups presented a [2]catenane consisting of 41-membered interlocking rings, which is formed quantitatively: following strategy based on two different metal coordination steps.[12] Two building blocks of the [2]catenane, i.e., the unclosed rings, are held together by attractive interactions between a copper(I) ion and two [1,10]-phenanthroline moieties to form a precursor of the desired [2]catenane. Furthermore. the organic building blocks of the [2]catenane are equipped with two pyridine ends. which can be "closed" with palladium(II) ethylene diamine [enPd(II)] corners (Scheme 3).



Scheme 3 *Self-assembly* of *a* [2]catenane using *a metal–ion template effect*.



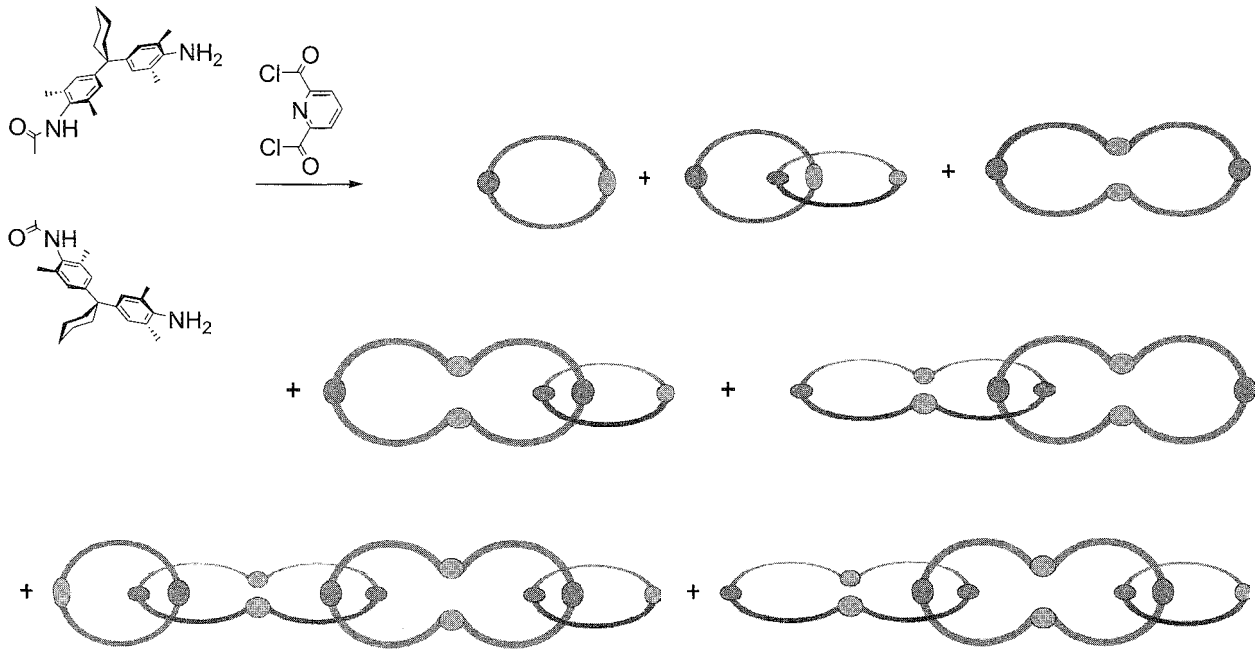
Scheme 4 Self-assembly of a [2]catenane using a solvophobic template effect.

A different type of catenane is formed through the action of hydrophobic forces through self-assembly of building blocks bearing inetal ions (M=Pd, Pt) and ditopic pyridine ligands (Scheme 4).[113] When the two components are mixed in water, the catenane forms spontaneously, minimizing the hydrophobic surfaces by including unpolar ligands of one macrocycle in the cavity of the other and vice versa. An interesting feature of these compounds is the reversibility of catenane formation. if the metai is Pd(II). Even at room temperature, the Pd complexes equilibrate, while the analogous Pt(II) complexes require higher temperatures or high salt concentrations in order to make the coordinative bonds sufficiently labile for an exchange of the ligands.

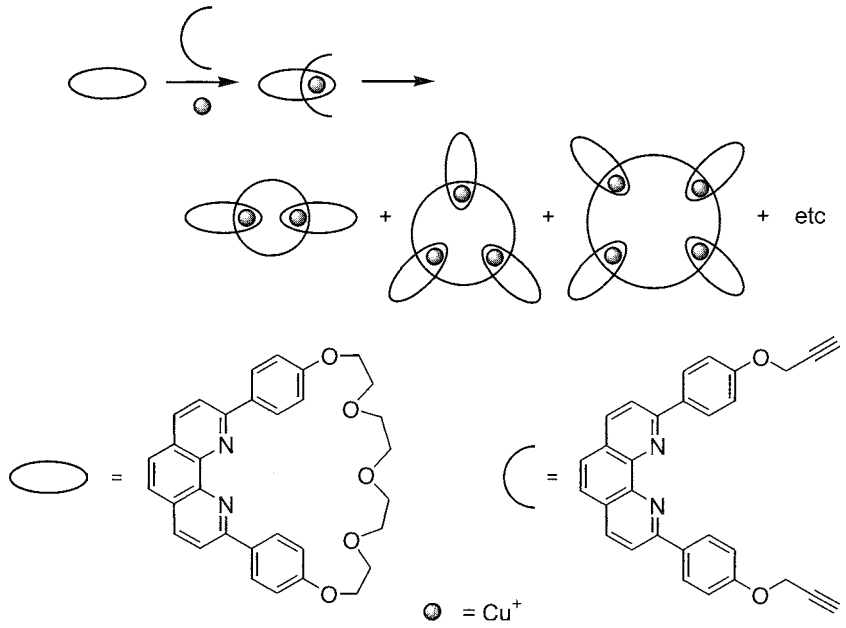
MORE COMPLEX CATENANES

A catenane may bear more than two intertwined macrocycles. In this section, we wish to introduce several more complex topologies. The increasing complexity not only caused synthetic problems but also prompted Vogtle et al. to introduce a systematic nomenclature for mechanically linked molecules.''''

The synthesis of larger [n]catenanes with $n>3$ is a fascinating challenge for preparative organic chemistry. A prerequisite for the formation of oligocatenanes is to find appropriate ditopic host macrocycles that can bind two guests from the other catenane wheels in a subsequent macrocyclization step. So far, catenanev with up to seven



Scheme 5 Vogtle's [n]catenanes



Scheme 6 Multiring Interlocked [*n*]catenanes synthesized by Glaser's oxidative coupling

intertwined rings have been published. Stoddart et al. developed an approach to larger self-assembling catenanes in 1995.[15] The methodology relies on the stereoelectronic complementarity between n-electron-deficient bipyridinium-based components and n-electron-rich hydroquinone- or 1.5-dioxynaphthalene-based components. The driving forces responsible for the self-assembly are π–π stacking and C—H···O hydrogen-bonding interactions. By employing this approach. they were able to self-assemble a large number of [2]catenanes, [3]catenanes, [4]catenanes, and two [5]catenanes (including the so-called olympiadane). A related approach by Stoddart and Balzani led to the construction of catenanes, comprised of up to seven interlocked rings.[16] Two *tris*-1,5-naphtho-57-crown-15 macrocycles template the formation of cyclo*bis*(paraquat-4,4′-biphenylene) to yield a [3]catenane, acting as a template for the construction of one and then another cyclo*bis*(paraquat-*p*-phenylene) to give a [4]- and a [5]catenane. When high pressure was used in these templated syntheses, the corresponding [6]- and [7]catenanes were obtained.

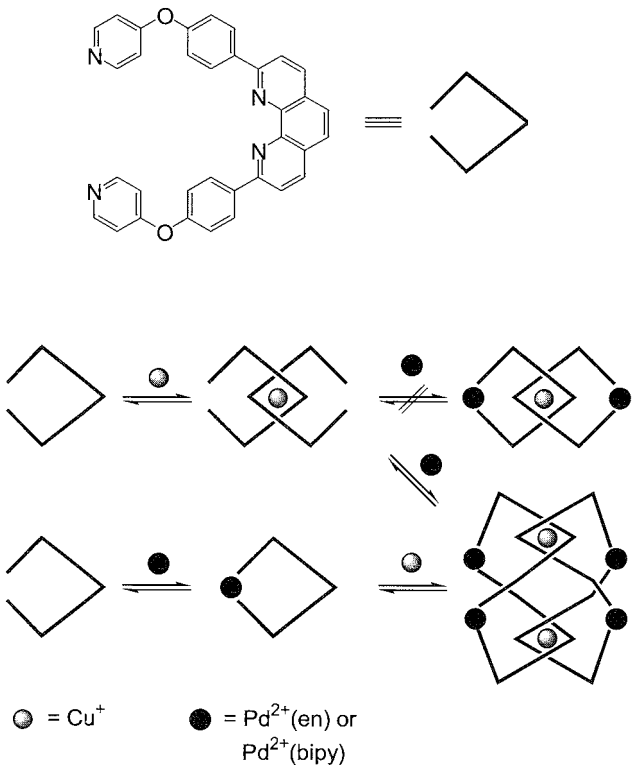
In 2000. Vogtle et al. found another route toward [*n*]catenanes[17] —new tetralactarn and octalactam macrocycles were used to obtain [*n*]catenanes (Scheme 5) with up to five rings. The largest of these is the first amide-type olympiadane, which, however, could not be isolated. The octalactam macrocycle served as a ditopic host permitting the threading of two other macrocycles.

Topological isomers of linear [*n*]catenanes are the so-called multiring interlocked systems that bear a number of smaller rings all threaded on the saine larger macrocycle.[18] The ends of the axles of n pseudo-rotaxanes are covalently connected by Glaser's coupling of triple bonds to form a large macrocycle that carries all the smaller rings (Scheme 6). Higher catenanes with up to seven rings are found that display similar ^{1}H-NMR properties and have identical elemental analyses. They can, however, easily be distinguished from one another by electrospray ionization mass spectrometry (ESI-MS).

While simple [2]catenanes that have two crossings in their molecular graphs were among the first interlocked species synthesized, the development of a doubly interlocking [2]catenane with four crossings in the molecular graph has taken a few decades and was not realized before the 1990s. Two similar self-assembly routes toward the same chiral catenane were developed by the groups of Fujita and Sauvage[19] (Scheme 7), which differ by the sequence of metal addition. Both lead to the desired four-crossing-[2]catenane in quantitative yields.

REGIO- AND STEREOSELECTIVITY IN CATENANE SYNTHESIS

Wegio- and stereoselectivity in chemical reactions are long known to chemists, whereas their supramolecular analogues are just starting to be discovered and are yet to be understood. In the beginning of the current millennium, Vögtle and his group described a regioselective templated synthesis of a topological chiral sulfonamide [2]catenane.[20] The large cyclohexylidene residues hinder circumrotation of both wheels by steric bulk. Due to these



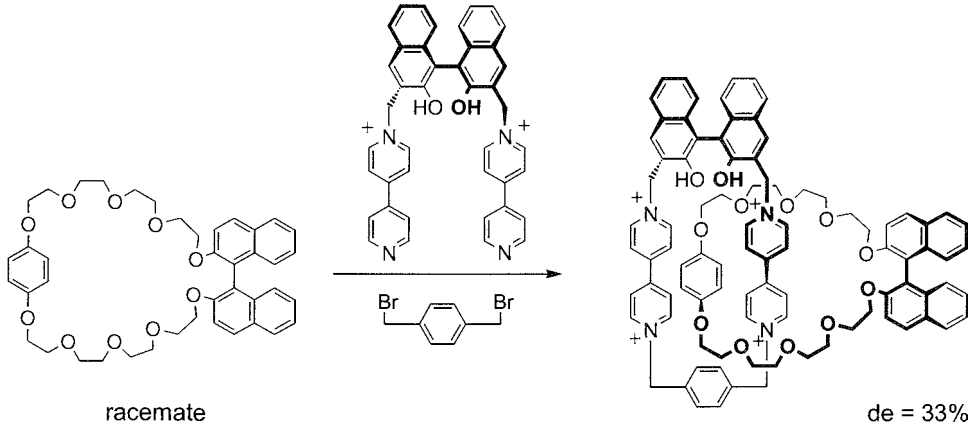
Scheme 7 Four-crossing-[2]catenane

effects, the structure of the catenane reveals an interesting control of selectivity during formation of the intertwined ring system. Only two out of four possible isomers are formed. This allows more distinct conclusions regarding the reaction mechanism leading to amide-based catenanes. The already-formed macrocycle is able to interact with the yet to be closed diamine through hydrogen bonds, forming a precursor of the desired catenane, once again a pseudorotaxane. Differences in hydrogen bonding between the intermediates finally gives rise to the products. and those that would lead to the products not observed are likely the reason for this "supramolecular regioselectivity effect." The x-ray single crystal structure analysis, at the same time, is the first crystal structure of an amide-based topologically chiral catenane.

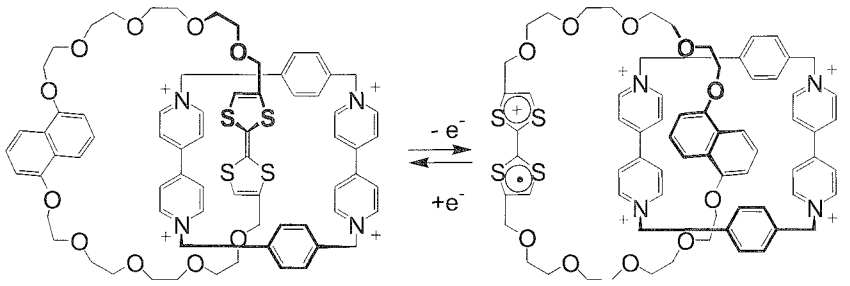
One year before, Stoddart et al. described the diastereoselective self-assembly of [2]catenanes[21] (Scheme 8). Catenanes incorporating complementary π-electron-rich and π-electron-deficient macrocyclic components with binaphthol building blocks self-assemble from appropriate precursors. If one of the components is present as a racemate and the other as an enantiopure compound, the formation of two diastereoisomers is possible. The diastereoselective self-assembly into [2]catenanes occurs through the formation of intermediate diastereoisomeric complexes. In a subsequent step, the open ring is again cyclized and the catenane formed with a diastereomeric excess of 33%.

DYNAMIC PROCESSES IN **CATENANES: HOW DO** CATENANES CIRCUMROTATE?

Most catenanes can undergo rotation of one ring through the cavity of the other. Benzylic amide catenanes show unambiguous evidence for the spinning of the interlocked macrocycles about one another in solution.[22] Leigh, Zerbetto, and colleagues showed for benzylic amide [2]catenanes how this circumrotation happens.[23,24] They investigated the structure and dynamics of these catenanes using molecular mechanics calculations and employed unimolecular reaction rate theory. Lowest-energy pathways for the circumrotation of the macrocycles were identified. The process is a sequence of several large-amplitude motions. involving several rearrangements to minimize steric and electrostatic interactions via the interplay of weak interactions. The rate constants and barriers



Scheme 8 *Diastereoselective formation of a* [2]catenane.



Scheme 9 A molecular switch, based on redox reactions at tetrathiafulvalen subunits

are in agreement with temperature-dependent NMR experiments. The rate-determining steps do not necessarily correspond to the passage of the bulkiest groups. Rather. the transition structures suggest that circumrotation of one macrocyclic ring induces — or synergistically eases — rotation of the other in a coupled motion.

A detailed experimental investigation of circumrotation in catenanes is limited by the complexity of the network of hydrogen bonds and other weak interactions as well as the steric constraints that exist in most catenanes, leading to a large number of degrees of freedom. Complete circumrotation must involve some breaking of attractive inter-ring interactions. If hydrogen bonds are involved, variation of the solvent can control the rate constants of the circumrotational motions of catenanes. Therefore, the circumrotation in benzylic amide catenanes can, to a fair approximation, be described in a classical manner.

PROPERTIES AND POSSIBLE APPLICATIONS

Catenanes are experiencing a spectacular revival in relation to topology as well as to their possible applications as polymers, switches, machines, and motors at the molecular level. Several poly([2]catenane)s together with poly(*bis*[2]catenane)s poly([2]catenand)s, and poly([2]catenate)s were described over the last decade by different groups;[25] the synthesis of cyclic oligo[2]catenands is also possible.[26] The characterization of these compounds includes NMR spectroscopy and mass spectrometry as well as gel permeation chromatography for the determination of the molecular weight distribution and viscometry. These molecules are rare examples of mechanically interlocked polymers, a class of intriguing supramolecular polymers with potentially unusual properties.

Another topic of current chemistry should be addressed here briefly, again with reference to the article on "Rotaxanes and Pseudorotaxanes," where further aspects of molecular machinery are discussed in greater detail. A solid state, electronically addressable, bistable [2]catenane-based molecular switching device was fabricated from a single monolayer of the [2]catenane.[27] The catenane can be switched at +2 V and switched back at −2 V, thus allowing us to write information into it that is stored in the catenane structure through circumrotations. It is possible to read out that information between 0.1 and 0.3 V, and the switch survives at least a few hundred cycles of switching back and forth over a period of 2 months without substantial changes in its properties. Upon further engineering and optimization, this system may be useful as a memory device at the molecular level (Scheme 9).

CONCLUSION

Catenanes and other interlocked molecules remain fascinating, even if their first successful synthesis was accomplished 45 years ago. Since the early days of the first catenane synthesis, more and more functionality has been introduced into molecules, either in relation to electron and energy transfer processes or with regard to controlled molecular motions. While Vögtle et al. claim that "with the natural ATP synthase as a prototype in mind, it is comforting to know that the generation of such a motor is at least in principle possible, and we trust that the goal to build an artificial analogue will be reached within a decade or so",[28] Sauvage argues that "it would of course be unwise to predict that nanoscopic motors and related machines will have any practical application in the future as molecular storage devices or as nanoscale components in electronics".[2] The future will show who will be right in this controversy. But the search for further, more complex, interlocked molecules should not be terminated, because in Sauvage's words, "the search for such molecules or molecular assemblies is important in itself."

Cation–π Interactions

Dennis A. Dougherty
California Institute of Technology, Pasadena, California, U.S.A.

INTRODUCTION

The cation–n interaction is a noncovalent binding force of broad importance in biological systems and in supramolecular chemistry." It is defined as the attraction between a cation and the face of a simple π system. such as in benzene or ethylene (Fig. 1). The physical origin of the cation–n interaction is primarily electrostatic. involving an attraction of the cation to a locus of negative electrostatic potential associated with the face of the n system. It is a common and pervasive contributor to protein secondary structure and to a wide range of small molecule–macromolecule binding interactions in biology. The cation–π interaction was also used as a key design component in a number of synthetic supramolecular systems.

Intensive studies in recent years led to the conclusion that the cation–n interaction should be considered along with the hydrophobic effect, hydrogen bonding. and ion pairing (salt bridges) as a major structural force in biology. It was also extensively characterized using gas-phase ion methodologies and was used to design artificial receptors and supramolecular systems. Although usually associated with aromatic systems, it should be emphasized from the start that the effect has nothing to do with aromaticity. Ethylenes and acetylenes can also participate in cation–n interactions.

THE ESSENTIAL INTERACTION

Many studies of simple cations binding to prototype π systems were carried out in the gas phase, and these provided crucial insights into the fundamental nature of the interaction. Some of these studies are summarized in Table 1. High-level theory accurately reproduces the experimental data. For simple cations, such as alkali metals. lower-level ab initio quantum mechanical methods provide acceptable descriptions of cation–π interactions, allowing more extensive studies of trends (Table 1).

As early as 1981. Kebarle showed that K^+ binds well to benzene.[8] Importantly, these studies also established that the binding of K^+ to benzene was enthalpically stronger than the binding of K^+ to water. a remarkable result that presaged the importance of cation–π interactions in biological recognition. These early studies were confirmed and extensively expanded by Lisy using more advanced techniques.[13] Studies of the full series of alkali ions reveal a classical electrostatic trend (Table 1). Smaller ions bind more tightly, with correlation between ionic radius and binding energy. Because all the ions have the same total charge, the smaller ions must have a more intensely focused charge, enhancing an electrostatic interaction. Comparable trends are seen for binding to ethylene and acetylene.

In this light, Meot-Ner's early results on the binding of NH_4^+ and $N(CH_3)_4^+$ to benzene[9,10] are easily understood (Table 1). It is generally accepted that NH_4^+ and K^+ have comparable ionic radii, and their cation–n binding energies are similar. The reason $N(CH_3)_4^+$ has a much smaller binding energy is simply explained by noting the much larger effective ionic radius of this quaternary ammonium ion. There is no need to invoke special effects like "hydrogen bonds to benzene" or "C—H hydrogen bonds" to explain the data for ammonium ions. These "organic" ions follow the same patterns as the alkali metal ions.

Substituent effects on the π system follow an intriguing and telling pattern (Table 1).[12] Not surprisingly. fluorine is deactivating. consistent with the expected electron-withdrawing effect. However, OH (and OCH_3) substituents have no significant effect on the cation–n interaction, although they are often considered to be "electron donating." This theoretical prediction was confirmed experimentally. An amino substituent is strongly activating, and in fact. only nitrogen-based substituents enhance the cation–π interaction. This novel sequence (NH_2 > OR ~ H > F) is nicely rationalized by electrostatic arguments. Qualitative inspection of electrostatic potential surfaces (Fig. 2) and quantitative analysis of the electrostatic component of binding lead to the conclusion that the variation in cation–n binding ability is due to a substituent's modulation of the electrostatic component. That is not to say that other factors—induced dipoles, polarizability, dispersion forces, and so on—make no

"Several comprehensive reviews of the cation–π interaction were published,[1–4] and the reader should consult these for further details and original references. Especially significant and more recent articles are explicitly cited here.

Encyclopedia of Supramolecular Chemistry

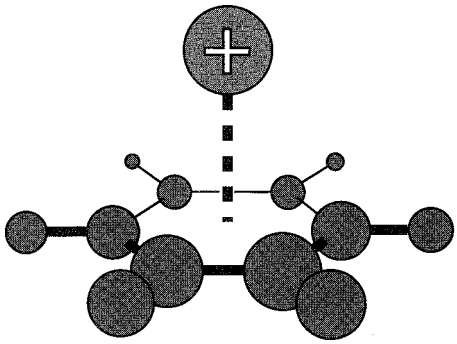

Fig. 1 The cation–n interaction. Shown is the interaction of a generic cation with the face of a benzene ring. (*View this art* in color *at www.dekker.com.*)

contribution to the cation–rt interaction. However, none of these other forces provide the defining characteristic of the interaction. For example. cyclohexane is more polarizable than benzene, but it is a decidedly weaker cation binder.

What is the origin of this electrostatic effect? Simply, all the major observations concerning the cation–n interaction can be understood by recognizing that sp^2 carbon is more electronegative than hydrogen. This introduces $C^{\delta-}$—$H^{\delta+}$ bond dipoles into the system. In the geometries of prototype structures such as benzene and ethylene, these bond dipoles combine to create a focused buildup of negative charge over the center of the π system. Cations bind to this region. Of course, the edges of these structures, the location of the hydrogens. are positively charged. The net effect is the now-familiar electrostatic map for benzene (Fig. 2). with a focus of negative (red) electrostatic potential over each face of the ring and a belt of positive (blue) electrostatic potential around the edge.

In benzene and ethylene: the sum of the individual bond dipoles produces an overall molecular quadrupole moment, and this is an alternative way to describe the electrostatics of these molecules. More extensive discussions of the quadrupole moments of benzene and ethylene were presented elsewhere.[1,3,14,15] We simply note here that it is well established that just as the dipole moment of a molecule like water can bind ions strongly, so can the quadrupole moment of a molecule like benzene or ethylene.

While the gas-phase studies provide insights into the fundamental nature of the cation–n interaction, a key question is the viability of the interaction in solution. A recent computational study[16] indicated that, unlike an ion pair (salt bridge) interaction, the cation–n interaction is not dramatically attenuated when it moves from the gas phase to an aqueous medium. In fact. in water, a simple cation–rt interaction is predicted to be stronger than a comparable salt bridge. The many examples of biological recognition cited below support the view that the cation–π interaction is viable in aqueous media.

LIGAND RECOGNITION USING CATION–π INTERACTIONS

Beginning in the 1980s, a number of studies of cyclophanes, calixarenes, and related structures established that the cation–rt interaction can be a potent force for molecular recognition in aqueous media.[3] Quaternary ammonium ions, including acetylcholine [ACh; $CH_3C(O)OCH_2CH_2N(CH_3)_3^+$], and alklylated pyridine/quinoline derivatives, such as *N*-methylquinolinium, proved to be especially effective substrates. These studies clearly established that a hydrophobic binding site could pull a cation out of the highly favorable environment associated with aqueous solvation and into the binding site, as long as the binding site is comprised of aromatic groups.

An important result to emerge from such studies was a better appreciation of where the positive charge is actually

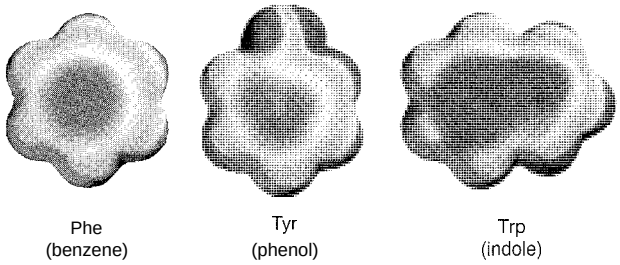

Fig. 2 Electrostatic potential maps for benzene, phenol, and indole, models for the side cnains of phenylalanine. tyrosine. and tryptophan. (*View this art in color at www.dekker.com.*)

located in cations such as ACh and other "onium" compounds. Although we draw a positive charge (+) associated with the nitrogen, high-level theory consistently reveals that the CH_3 and CH_2 groups attached to the nitrogen carry the charge. Most models of tetramethylammonium $[(CH_3)_4N^+]$ place a charge of $\sim+0.25$ on each methyl and roughly a charge of zero on the nitrogen. Thus, when an alkylated ammonium or similar-type structure makes contact with the face of a π system, it is delivering a region of positive charge to the buildup of negative potential on the π system.

Systems that combine a crown ether-like structure with an appropriately positioned π system have proven to form effective binding sites for alkali metal cations.[17] Cation–π interactions were also used to incorporate n facial selectivity into catalysts for asymmetric synthesis.[18]

Cation–n interactions were also established as important contributors to a large number of binding events between small organic molecules and protein-binding sites.[1–4] In proteins. the side chains of phenylalanine (Phe). tyrosine (Tyr), and tryptophan (Trp) can contribute to ligand recognition through a cation–n interaction. Given the substituent effects mentioned above (Table 1). it can be anticipated that Trp should provide the best cation–π binding site. and this result is supported by electrostatic potential maps (Fig. 2) and by several experimental studies (see below). To first order. Phe and Tyr are predicted to be similar, and electrostatic maps (Fig. 1) support this view. Note, however, that hydrogen bonding to the OH of Tyr can make it a more effective cation–n binding site."'' and certainly. this is expected to be operative in some protein structures. Interestingly. theory predicts that for Trp. the optimal cation–n binding site is over the 6-ring of the indole, not the 5-ring. This prediction is supported by statistical studies of preferred binding modes to Trp in proteins.

It has been known for some time that Phe, Tpr, and Trp are overrepresented at protein-binding sites, and part of the reason for this is, no doubt. the potential to use cation–π interactions in binding. Antibody binding sites. including those in catalytic antibodies, are well documented in using cation–n interactions in binding cationic ligands or transition states. Other "generic" binding sites have binding regions that are rich in aromatics, including the multidrug resistance protein (*P*-glycoprotein), which pumps a wide range of compounds out of cells.

A considerable array of small molecules of biological importance make use of cation–n interactions when binding to their protein targets. A well-documented example is the neurotransmitter acetylcholine (ACh). At two different binding sites — acetylcholine esterase (AChE), the enzyme that terminates synaptic transmission by hydrolyzing ACh; and the nicotinic acetylcholine receptor (nAChR), a prototype membrane-spanning neuroreceptor involved in synaptic transmission — the quaternary ammonium ion of ACh makes close contact with a Trp side chain. Note that this was anticipated by earlier cyclophane studies.

Most neurotransmitters have a cationic group, and cation–π interactions are likely involved generally in their binding sites. A similar cation–n interaction to that seen in the nAChR is involved in binding serotonin (5-HT) to the $5\text{-}HT_3$ receptor,[20] and it may be present in the $GABA_A$ receptor. Glutamate. the most common excitatory neurotransmitter of the CNS. is recognized in part by a cation–n interaction in both the metabotropic glutamate receptor (mGluR), a G-protein-coupled receptor, and in the ionotropic glutamate receptors, such as the NMDA receptor.

Another prominent ligand-binding site that exploits cation–π interactions is the SH2 domain, a ubiquitous regulatory unit that binds phosphotyrosine. The cationic side chain of an arginine from the protein makes contact with the π face of the phosphotyrosine.

A well-documented example is the binding of the N7-methylated guanosine (m^7G) present at the 5' end of eukaryotic mRNA. This "5′ cap" is essential for proper processing of mRNA. Crystal structures of VP39, a viral mRNA methyltransferase, and eIF4E, a eukaryotic translation initiation factor with no structural homology to VP39, show the cationic m^7G sandwiched between two aromatic amino acid side chains. exactly as was anticipated by cyclophane studies of N-methylquinolinium. It was also proposed that the "inverse" of such an interaction — a cationic amino acid (Arg) stacking on a DNA base — is important in DNA repair enzymes and perhaps in other proteins that recognize DNA.

Cation–π interactions are also prominent at the active sites of enzymes involving cationic substrates. Key examples include the blood coagulation serine proteases Factor Xa and thrombin. and a number of enzymes that use S-adenosylmethionine. a sulfonium ion that serves as nature's ubiquitous methyl transfer agent. A spectacular series of examples is the array of enzymes that catalyze the cationic cyclizations of polyenes in a key step of terpene and steroid biosynthesis. It is now clear that

precisely positioned aromatic side chains guide the migrating positive charge and influence the structure and stereochemistry of the final product.

An interesting question is the energetic contribution to an overall binding event that can be made by a cation–n interaction. As with all noncovalent binding interactions. determining the magnitude of a cation–π interaction is challenging and expected to be significantly context-dependent. Still, several studies using unnatural amino acid mutagenesis led to estimates of 2–4 kcal/mol for binding of a cation to an aromatic side chain.[20,21] That Trp is the optimal side chain for ligand binding and is supported by mutagenesis studies on the VP39 protein mentioned above. When the Phe and Tyr that bind m^{7}6 are replaced by Trp, either individually or simultaneously, the single and double mutants bind more tightly by 10-fold and 50-fold, respectively.[''] These data show the enhanced binding ability of Trp relative to Phe/Tyr, and they are also in line with the overall magnitude expected for a cation–n interaction.

CATION–π INTERACTIONS IN STRUCTURAL BIOLOGY

Another prominent role for cation–n interactions is in stabilizing the secondary structures of proteins. The cationic amino acids Arg and Lys can interact with Phe, Tyr, and Trp in favorable ways. His, if protonated, can serve as the cation of a cation–n interaction. and several studies showed that the pK_a of a His side chain can be inodulated by a cation–π interaction. Neutral His is not a favorable n system for a cation–π interaction. A pioneering analysis by Burley and Petsko considered the ''amino-aromatic interaction,'' in which NH groups from Arg. Lys, Asn, or Gln contact Phe, Tyr. or Trp.[23] It is now appreciated that Arg and Lys are involved in cation–n interactions. while interactions involving Asn or Gln must be "polar-n" interactions. which are inherently much weaker than cation–n interactions. While this coupling of two different interactions clouded the statistics,[24] the importance of pointing out the potential for such interactions was substantial.

Several more modern analyses established how prominent cation–n interactions are in structural biology. Considering only (Arg/Lys)···(Phe/Tyr/Trp) interactions, Gallivan and Dougherty showed that, throughout the protein data bank. there is one cation–n interaction for every 77 amino acids.[''] Thus. a typical protein will have several cation–π interactions. As expected. Trp is overrepresented in the data set. In fact. a remarkable 25% of all trypiophans are involved in cation–n interactions. A recent study suggests that proteins from thermophilic organisms are enriched in cation–π interactions.[''] further supporting the notion that cation–π interactions are a significant stabilizing force.

Note that when considering such interactions. it is again important to appreciate where the positive charge is on an amino acid side chain. For Lys, the ε CH_2 group, i.e., the CH_2 next to the NH_3^+, carries a substantial positive charge. Just like positioning a CH_3 group of ACh over an aromatic ring is a cation–n interaction, so too is placing the ε CH_2 of Lys over an aromatic. A large fraction of cation–n interactions involving Lys are of this type. which frees the NH_3^+ for other types of interactions, such as hydrogen bonds and salt bridges.

All possible combinations of amino acids and interacting geometries were documented to occur in protein structures. The key feature; of course, is that the cation must be oriented toward the face of the Phe/Tyr/Trp side chain, not the edge. An especially iinpressive cation–n interaction was first noted by Wilson in the erythropoietin receptor extracellular domain.[27] An interdigitated stack of side chains follows the sequence Lys-Tyr-Arg-Phe-Arg-Trp-Lys, a remarkable string of cation–π interactions. Similar motifs are seen in growth hormone receptors and related structures.

CONCLUSION

It is now clear that the cation–π interaction is a significant noncovalent binding force in the gas phase, in solution. and in biological systems. It should be considered on par with the hydrophobic effect. hydrogen bonding. and ion pairs (salt bridges), when considering molecular recognition and supramolecular chemistry in aqueous media.

Cavitands

Bruce C. Gibb
University of New Orleans, New Orleans, Louisiana, U.S.A

C

INTRODUCTION

As originally defined by Cram. cavitands are "synthetic organic compounds *with enforced cavities large* enough *to complex* complementary *organic compounds or* ions.''[1,2] *The two key words in this definition are "enforced" and "cavity." The former implies highly preorganized, rigid molecules.* i.e., *those types of molecules constructed in such a way that few (if* any) *conformational or rotational options are available to them. Cavitands are then generally* macrocyclic *compounds. comprised of multiple aromatic rings covalently linked in a highly constrictive manner. Implicit in the word "cavity"* is *a range of topologies ranging* from *a concave, or bowl-shaped feature, to a fully* encapsulating *molecular surface. When Cram originally* invoked *the* term, *he did not differentiate between these two different degrees of* curvature.[1] *However with the development* of *bowl-shaped molecules, along with Cram's introduction of the* term *"carcerand" to define hosts that can* fully *encapsulate guest molecules. the term cavitand has become synonymous with open.* concave-*shaped hosts. The two most* prominent *examples of* bowl-*shaped hosts are those based on* resorcin[4]arenes[3–5] *and* cyclotriveratrylenes[6,7] *(Fig. 1). It is the former. having shown a broader repertoire of chemical and structural variabilities.* that *have come to epitomize the definition of* .'cavitand.''

STRUCTURES OF CAVITANDS

Resorcinarene cavitands can be broken down into roughly three types. examples of which are shown in Fig. 2. "Normal" cavitands are simple *derivatives of resorcin* [4]arenes. *The second type, formed by adding a second layer of aromatic rings to the resorcinarene* framework, is termed *"deep-cavity* cavitands.'' *Recently. a third group of molecules emerged. We will use the term* ''wide-*bodied" cavitands to relate to these molecules derived from resorcinarenes* comprised *of more than four* resor-cinol *rings. The structure of all these cavitands lends* them *to a* number *of uses and potential applications that require their hosting properties or the spatial arrangement of their functionality. As such, it* is *their structural features rhat define* them. Correspondingly, we *focus here on structure and avoid expressly highlighting the uses and applications of cavitands to specific problems. Readers interested in these examples should consult some of the more recent* reviews.[2,5,8.9]

Apart from the overall concave topology, there are three structurally important *features of cavitands to which we frequently refer. The "feet" of a cavitand are the R-groups situated at the base of the molecule (Fig.* 1). *These often significantly influence the solubility of a cavitand. Frequent reference is also* made *to the "rim" of a cavitand. This corresponds to the upper-most portions of the cavity of the host, where functional groups can he readily attached. Finally. the "bridging groups" of a* cavitand *are the moieties rhat bridge between the pairs of phenol OH groups of the original resorcinarene. These groups control the splay of the aromatic rings,* i.e., *the steepness of the walls of the cavity.* and *the width of the rim of the cavity. They can also serve as introduction points for the extra row of* aromatic *rings in deep-cavity cavitands. We will highlight some examples* from *each of the three categories to emphasize the wide variety of structures that have been synthesized.*

CAVITANDS

The earliest cavitands[2,5,9] *(Fig. 3) were designed and synthesized in the Cram* group.[1,2] *The first reported was a series of methyl-footed,* methylene-bridged *cavitands* **1** (X=H, *Br,* CO_2CH_3). Variations *to this first series concentrated on changes to the rim of the cavitand and the bridging groups. In terms of the functionalization of the rim, we will note here in passing that it is relatively straightforward to introduce* functionality *into* the *rim of a cavitand. The primary reason for this is that even if the desired functionality is not compatible* with *the resorcin-arene-forming process, the highly activated aromatic rings of resorcinarenes or cavitands inake electrophilic substitution at the 2-position readily accomplishable. A more difficult task is to selectively functionalize some of the positions on the rim. However. the* Sherburn *group* is making *advances into this* area.[10]

In terms of different bridging groups. the first variations to methylene *bridging* were *ethylene. propylene. or* dialkylsilyl *bridges. These resulted in cavitands with*

DOI: 10.1081/E-ESMC 120012742

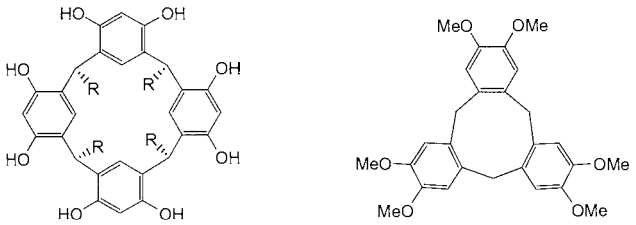

Fig. 1 A resorcin[4]arenes and cyclotriveratrylene. (From Refs. [3–7])

slightly deeper- or wider-rimmed cavities.[11,12] Compounds 2 and 3 are examples. By controlling the bridging conditions, it is aiso possible to introduce less than the maximal four bridges (see references in Ref. [5]). Methylene bridging is typical. Usually, the first three bridges are ı-elatively easy to insert. whereas the fourth bridge is more difficult. Hence, isolation of a ti-is-bridged derivative is easier than the corresponding *mono-* and A/B or A/C his-bridged derivatives. Finally. it should be noted that bridging groups are not limited to the Group 14 elements. For example, phosphorous-bridged cavitands have also been synthesized.[13,14]

Investigations into varying the feet of cavitands were conducted subsequent to the studies into rim functionalization or bridging reactions: presumably because the feet do not directly affect the size and shape of the most

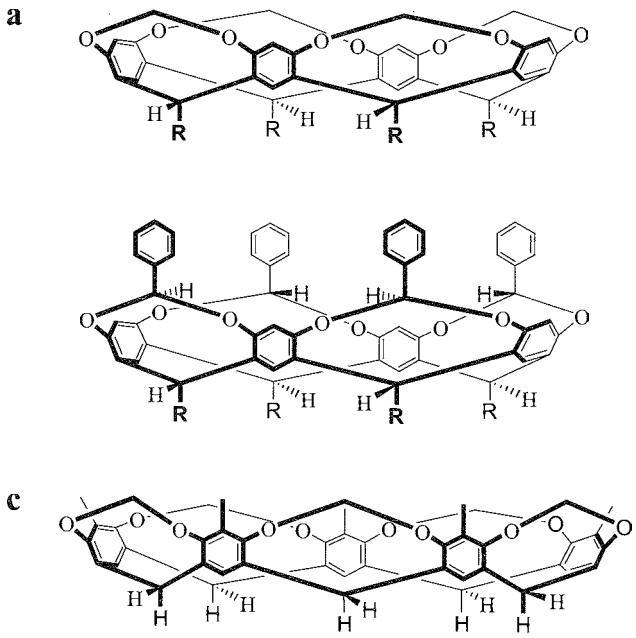

Fig. 2 Typical frameworks of (a) normal cavitands. (b) deep-cavity cavitands. and (c) wide-bodied cavitands.

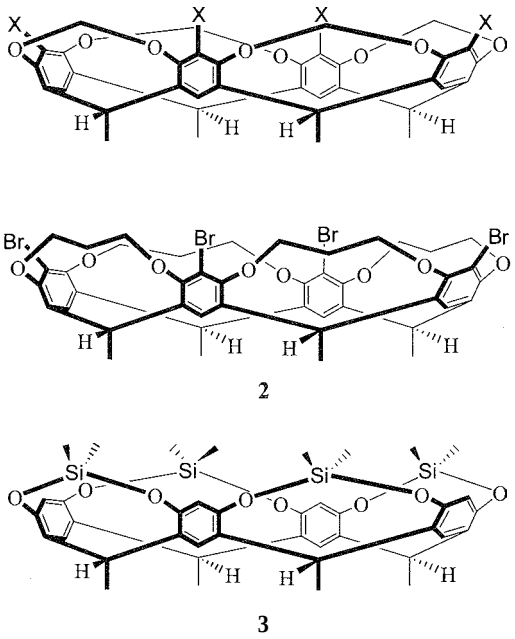

Fig. *3* Three example5 of normal cavitands.

interesting part of the molecules (the cavity), and because the corresponding resorcinarenes had to be synthesized.[4] Once investigated. however. it became apparent that the feet have considerable influence on properties such as solubility. For example. it is possible to bestow water solubility on the cavitand framework by suitable functionalization of the feet.'''' Partially as a result of their importance to solubility, there are now literally dozens of

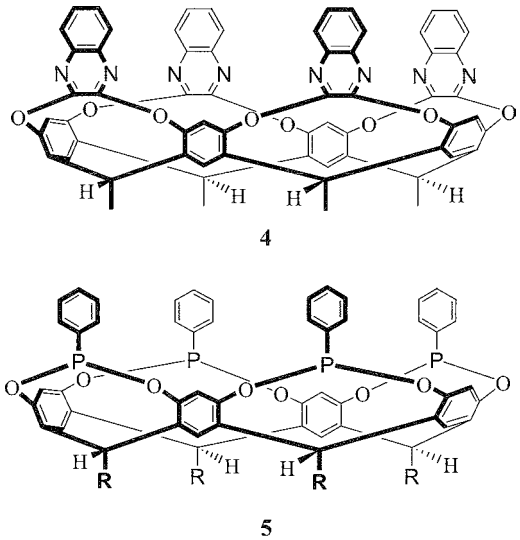

Fig. 4 Representative example5 of deep-cavity cavitands

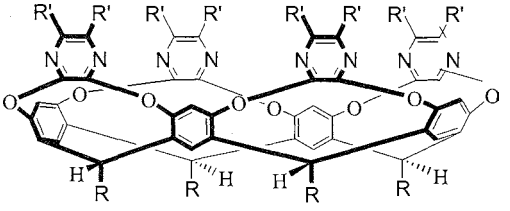
different feet to chose from when considering a cavitand target.[5]

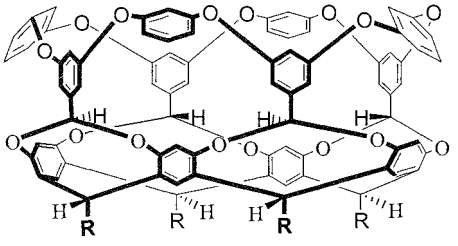
DEEP-CAVITY CAVITANDS

The first deep-cavity cavitand[8] to be synthesized was the 2.3-quinoxaline derivative 4 (Fig. 4).[1] This second row of aromatic rings in this cavitand. and related cavitands formed by the condensation of resorcinarenes with 2,3-dichloropyrazines. is conformationally flexible. Thus. they exist in a range of conformers between the vase-like C_{4v} form (shown) and a flat C_{2v} form.[16] These families of compounds were termed velcrands, because in the flat. "kite-like" form, they have a propensity to dimerize.[2] When not binding themselves, these types of cal-itands also bind mono-[17] or di-substituted[18] benzene derivatives.

An alternative to deepening the cavity in the manner of cavitand 4 comes in the form of the stereoselective bridging of resorcinarenes. The first successes in this regard were carried out with a number of phosphorus derivatives, e.g., **5**.[13,14,19] Stereoselective bridging with carbon (benzal bridging), for example. see Fig. 2b. followed shortly thereafter.[20,21] In these derivatives, there is a degree of flexibility to the structure, but instead of a conformational flipping being available to the second row of aroinatic rings. each ring is free to rotate.



6



7

Fig. **5** Rigidified deep-cavity cavitands.

It is also possible to increase the depth of the cavity of a cavitand by adding a second row of aromatic rings to the 2-position of each resorcinol moiety.[22] However, in the resulting biaryl derivative, the second row rings must adopt an orientation perpendicular to the cavity wall defined by the first row. Consequently. the cavities of such derivatives, although deeper, are narrower.

With the idea of improved or more selective guest binding, recent efforts were made to instill in deep-cavity cavitands some of the structural integrity seen in normal cavitands. Two general approaches have been demonstrated (Fig. 5). In the first. hydrogen-bonding groups were introduced into the rims of deep-cavity cavitands to engender a more defined but still highly dynamic cavity.[8,23–25] Cavitand 6 is one such example. Alternatively, just like the first row of aromatic rings. the second row can be covalently bridged to prevent their moveinent. Molecular basket **7** is one such example.[26,27] In both of these examples, the cavity of the cavitand is large enough to bind disubstituted adamantanes.

WIDE-BODBED CAVITANDS

Following on from the work of Monishi and cowork-e r ~ , ' ~ the Maier and Sherman groups recently reported the synthesis of the first cavitands coinprised of more than four resorcinol rings.'"' These [*n*]cavitands, where $n = 5$, 6. or 7. were isolated in low yield by direct bridging of the crude kinetic products of the reaction beiween 2-methylresorcinol and formaldehyde. The NMR evidence and x-ray crystallography detnonstrated that the [5]cavitand (see Fig. 2c) adopts the familiar bowl-shaped structure seen in [4]cavitands. However, by similar means. it was shown that the structures of the [6]- and [7]cavitands are more complex. For example. because of steric crowding, the former adopts a conformation that results in a rectangular C_{2v} cavity.

CONCLUSION

We have outlined the range of cavitands derived from resorcinol. There are currently three general families of these cavitands. Two are prominent in the general trend toward synthesizing large cavities for the selective binding of sizable guest molecules. Hence. deep-cavity and wide-bodied cavitands show promise in a number of developing areas of supramolecular chemistry.

Channel Inclusion Compounds

Maria Gdaniec
Adam Mickiewicz University, Poznań, Poland

INTRODUCTION

The occurrence of channels is a relatively common structural feature of inclusion compounds encountered across a range of different host structures. Among well-known solid organic inclusion compounds belonging to the channel-type family are those formed by urea, thiourea, perhydrotriphenylene (PHTP), tri-o-thymotide (TOT). 2,2,6,6-tetramethyl-4-oxopiperidine N-oxide (TANO). bile acids. alicyclic diols. cyclodextrins. and others. The wide-ranging interest in these compounds has a theoretical and a practical background. Confining the functionalized guest molecules in one-dimensional. parallel channels is one of the routes toward the design of new materials with attractive structural, electronic, optical, and magnetic properties.

Different terms like "channel," "tunnel." "canal," and ''tube'' were used to describe host cavities extended in one dimension without introducing any restrictions on the cross-sectional contours of these cavities. Channels can be of cylindrical shape with only small fluctuations in channel diameter on moving along the channel (e.g., urea inclusion compounds). Thread-like guest molecules pack closely in these channels. end to end: and form stable inclusion compounds when some critical value of the molecular length is exceeded. Significant bulges and constrictions at different positions along the channel (e.g., thiourea inclusion compounds) are sometimes observed. These constricted regions give channels partially cage-like properties. and the guest molecules occupy preferred sites along the channel. In general. the distinction between channels and cages is poorly defined.

Crystalline inclusion coinpounds are usually composed of two chemically discernible species. the host and the guest. The guest molecules act as templating agents on which the porous host substructure is constructed. In a prevailing number of cases. the guest inolecules are needed to maintain the stability of the host structure. which collapses on removal of the guest component. Many efforts are currently being made to design organic and coordination channel-type host networks, analogues of channel-type inorganic zeolites. which would reinain stable when the guest component is removed (see *Organic Zeolites*).

EXAMPLES OF CHANNEL-TYPE HOST STRUCTURES

The host architecture has some gross structural characteristics, which are repeated in a series of its inclusion compounds. Among the most extensively studied channel-type inclusion coinpounds are the conventional urea inclusion compounds (see *Urea)*, in which the urea molecules form an extensive hydrogen-bonded honeycomb network containing parallel helical tunnels (Fig. 1a) with diameter between 5.5–5.8 A and the tunnel centers separated by ca. 8.2 Å.[1,2] The walls of the tunnels are covered with the smooth faces of the urea molecules joined together via hydrogen bonds into two helical ribbons running in opposite directions. A variety of guest molecules, among which are not only *n*-alkanes. *n*-alkenes. and their derivatives but also linear polymers. pack in the tunnel. The minimum chain length required for inclusion of a given class of guest molecules depends strongly on the size, polarity, and position of the substituent. Guest molecules interact only weakly with the channel walls and undergo substantial translational and vibrational motions about the tunnel axis. Urea inclusion compounds are frequently nonstoichiometric.

Honeycomb-type network-containing tunnels (Fig. 1b) are also typical of the conventional thiourea inclusion compounds[1,2] (see *Thiourea and Selenourea*). However, in contrast with the urea inclusion compounds the tunnels are not helical, and there are large fluctuations in tunnel diameters (5.8–7.1 A). The distance between centers of adjacent channels is ca. 1 Å longer than in the urea inclusion compounds. Guest molecules enclosed in the thiourea channels are larger and differently shaped than those accommodated in the urea channels, e.g., linear 12-paraffins do not form inclusion compounds with thiourea. while branched hydrocarbons are easily included. Thiourea uses all of its hydrogen-bonding potential for construction of the host network. Guest molecules, which occupy specific sites along the channel. interact only weakly with the host and are generally disordered. Thiourea inclusion compounds are typically stoichiometric.

The inclusion compounds formed by triangularly shaped hydrocarbon host molecule perhydrotriphenylene

Encyclopedia of Supramolecular Chemistry

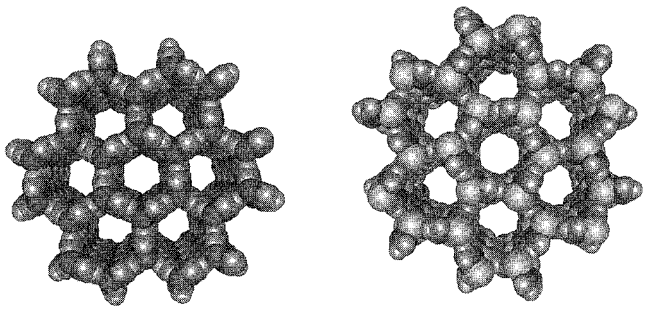

Fig. 1 Perspectir e view along the channel axis of the honeycomb host network in (a) an urea inclusion compound and (b) a thiourea inclusion compound (*View this* art *in color at www dekker corn*)

(PHTP) also exhibit the honeycomb arrangement of narrow tunnels (Fig. 2). The hose lattice is built from the stacks of PMTP molecules; which are placed in corners of the honeycomb motif.[3] The channels are formed between six closely packed host stacks and have their walls covered with equatorial hydrogen atoms of PHTP. Their diameters are ca. 5 Å, and channel centers are 15 Å apart. The PHTP forms channel inclusion compounds of similar construction in the racemic and in the optically active forms. In the racemic PHTP, host molecules are statistically disordered: however, there is strong evidence that individual stacks of PHTP are homochiral.[4] The spectrum of guest molecules accommodated in the flexible PHTP channels is much wider than that for urea inclusion compounds. Moreover, a special class of guest molecules consists of macromolecular substances. which easily cocrystallize with PHTP.[3]

The free radical nitroxide 2,2,6,6-tetramethyl-4-oxopiperidine *N*-oxide (TANO) forms stable channel inclusion compounds with linear or slightly branched molecules.[5] The arrangement of the host inolecules is close to a 3_1 helix, and two such helices define a channel lined with methyl groups of TANO. Again, nearly cylindrical parallel channels, which are 18 Å apart and have effective diameter ca. 5 Å, show a honeycomb arrangement. The TANO and guest molecules are dynamically disordered in the crystal. The most studied of the compounds of TANO are its inclusion compounds with n-alkanes.

Tri-o-thymotide (TOT) is able to include an enormous variety of guest molecules. and depending on the guest component, it forms cage-type or channel-type structure~.'-With unbranched long-chain guests (longer than ca. 9.5 Å), a TOT host network comprises linear, parallel tunnels of effective diameter 5.5–6 Å, with their centers separated by ca. 14.2 Å. During crystallization. TOT spontaneously resolves into (−)-*M* and (+)-*P* conformers, forming chiral crystals with space group symmetries $P6_1$, $P6_2$, or $P3_1$, with the screw axis directed along the tunnel.

Porous host substructures with parallel channels are typical of many inclusion compounds formed by bile acids and their derivatives[7] (see *Deoxycholic, Cholic,* and *Apocholic Acids). In* this class of compounds. host molecules are always optically active. and the resulting host networks are chiral. The best known among them are inclusion compounds of deoxycholic acid (DCA) (also known as choleic acidsj. With most guests. DCA molecules assemble via hydrogen bonds into a corrugated

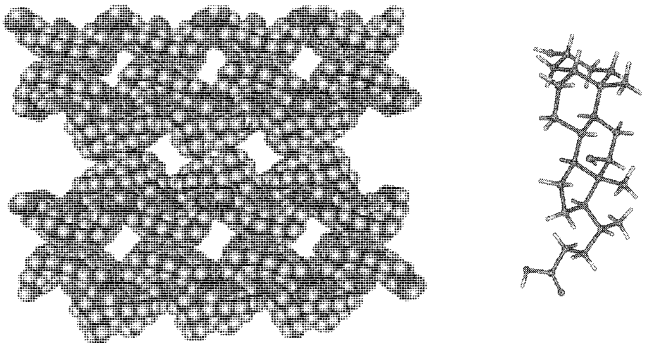

Fig. 3 A DCA molecule and CPK model of the DCA host substructure Channels are formed between corrugated host bilayers constructed from hydrogen-bonded DCA molecules *(View this art in color at www dekker com)*

bilayer structure with a hydrophilic interior and hydrophobic outer surface. Parallel hydrophobic channels running in one direction are formed between adjacent host bilayers (Fig. 3). The shape of the channel can be adjusted to the template guest molecule, mainly via translations in the directions parallel to the layer. In the presence of thread-like molecules, the channels have nearly uniform rectangular cross-sections. For more spherical guests. they exhibit considerable constrictions and bulges. as in thiourea inclusion compounds.

Channel structures can also be produced when monomolecular species with intramolecular tubular cavities arrange into an one-dimensional stack. For example, cyclodextrins (see *Cyclodextrins*), with their truncated funnel shapes, can form channels that have an effective diameter dependent on the number of monosaccharide units of the cyclodextrin.[8] This type of packing enables cyclodextrin accommodation not only of small molecules but also of longer guests,[8] which can be extended over several host cavities (e.g., the α-cyclodextrin–methyl orange complex). Cyclodextrin molecules can be threaded onto a polymeric chain (e.g., the α-cyclodextrin–polyethylene glycol complex) producing a molecular "necklace" that. after the cross-linking of adjacent cyclodextrin units. transforrns into a molecular nanotube able to reversibly bind small molecules.[9]

DESIGN OF CHANNEL INCLUSION COMPOUNDS

Discovery of the inclusion properties of many channel-type compounds was mainly made by chance. The creation of crystal lattices with tailor-made properties or even the fine tuning of properties of known crystal architectures represent significant challenges for materials chemists. Worth mentioning here is a large family of alicyclic diols, called helical tubulands.[10] These compounds have structures closely related to urea and thiourea inclusion compounds. The diol molecules form a three-dimensional hydrogen-bonded network with helical parallel channels (Fig. 4). The common hydrogen-bonding motif of the host lattices is a spiral chain of hydrogen-bonded O—H groups arranged about a 3_1 axis. In contrast with the urea and thiourea hosts. which cannot be modified without destroying their host networks, helical tubulands can be designed and engineered by preparing modified alicyclic diol molecules with structures conforming to certain rules. These modifications do not alter the hydrogen-bond motif, host packing, or crystal symmetry, but by changing dimensions of the channel, they significantly influence inclusion properties of the alicyclic diol host.

STRUCTURAL ASPECTS OF CHANNEL INCLUSION COMPOUNDS

An important property of the channel inclusion compound, which has significant implications with regard to its structural and dynamic properties. is the degree of structural registry between the host and guest substructures (see *Commensurate and Incommensurate Structures*). When the guest molecules are arranged inside a one-dimensional extended cavity in a periodic manner, the relationship between the periodicities of the host and guest components along the channel axis can be of two types.[2] A channel inclusion compound is considered to be commensurate if the ratio of the guest repeat distance c_g and the host repeat distance c_h along the channel axis is rational, i.e.. the relationship $pc_h = qc_g$ holds true when p and q are sufficiently small integers. An incommensurate relationship between the host and guest substructures occurs if the ratio c_g/c_h is not a reasonably small integer. Incommensurate phases are mainly observed ainong channel inclusion cornpounds of urea,

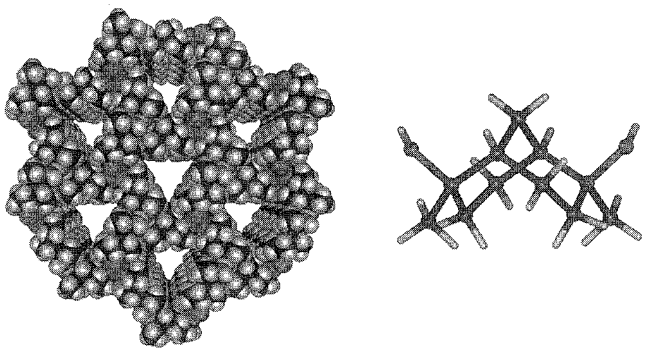

Fig. 4 Representative alicyclic diol molecule and CPK model of its helical channel-type host structure. (*View* this *art in color at www.dekker.com.*)

PHTP. TOT. TANO, and DCA. In many cases, it is difficult to distinguish commensurate from incommensurate inclusion compounds. In an incommensurate relationship between the host and guest structures, the guest molecules are found in a wide range of environments with respect to the host. The fluctuation in interaction energy associated with translating the guest substructure relative to the host substructure along channel direction should be relatively small for true incommensurate behavior. This property is related to the appearance of an additional acoustic mode in the incommensurate crystal. so-called ''sliding mode.'' Observation of the sliding mode can prove the incommensurate nature of the system.'']

Some information about periodic properties of channel inclusion compound can be obtained from x-ray diffraction oscillation photographs. For incommensurate crystals rotating about the channel axis. this photograph will contain layer lines of reflections arising mainly from the guest substructure and layer lines arising mainly from the host substructure and the ''0'' line. which can be attributed to guest and host substructures.[2] The positions of the guest layer lines depend on the periodicity of the guest molecules along the channel. while their patterns, which usually contain discrete Wragg scattering or diffuse scattering. depend on degree of disorder within the guest substructure. The discrete Bragg scattering in the guest diffraction pattern is observed when some interchannel ordering of the guest molecules takes place in the inclusion crystal.

The structure periodicity of composite incommensurate inclusion compounds generally requires four basis reciprocal lattice vectors for lattice description and a four-dimensional superspace group to characterize its symmetry.[2] The use of the superspace approach in structure determination of channel inclusion compounds is scarce but was applied recently in the study of urea inclusion compounds.[11] For a commensurate inclusion compound, its periodicity can be described by a three-dimensional lattice and symmetry represented by a three-dimensional space group. In the diffraction pattern; there is no need to assign separate contributions from the host and guest subsystems.

In addition to periodic properties. incommensurate channel inclusion compounds provide an opportunity to study local structural properties like. for example, the pairwise interaction of functional groups of guest molecule~.'Narrow channels allow the functional groups of the guests to interact only with one nearest guest molecule on each end. Incorporation into inclusion compounds of an asymmetsic guest molecule with two different functional groups as the end groups permits us to study the recognition properties of functional groups by solid-state NMR techniques.

APPLICATIONS OF CHANNEL INCLUSION COMPOUNDS

Channel inclusion compounds are of great importance from theoretical and practical points of view. Many of their properties are related to the alignment of closely packed guest molecules in parallel channels.''' However. the most widespread practical application of channel inclusion compounds is their use for separation of mixtures of different molecules based on discrimination of molecular size and shape. For example, urea is employed by industrial and research chemists to separate linear from branched molecules. The narrow urea channel selectively includes straighi-chain alkanes over their small, branched analogues.[2] It is important that the requirement of size and shape compatibility of the host and guest offers a means of separating compounds that differ only slightly in chemical functionality and that cannot be separated by other methods. Chiral channel-type host networks were successfully used in enantioselective separations. Not only are inherently chiral hosts like, e.g., DCA or cholic acid,

able to discriminate between the enatiomers of the guest,[13] but also achiral urea and configurationally labile TOT, which crystallize in chiral space groups and exist in the forms of enantiomorphous crystals, exhibit some degree of chiral recognition.[2,6]

Many interesting chemical reactions can be carried out in channels, however. the most specific for channel inclusion compounds are polymerization reactions (see *Inclusion Polymerization*). Soon after the channel-type structure was proposed for urea and thiourea inclusion compounds. Classen carried out for the first time the polymerization reaction of 2.3-dimethylbutadiene in channels of thiourea.'''' Further extensive studies of Brown and White on urea and thiourea and some 30 monomers showed that inclusion polymerization can be initiated by high-energy radiation leading to highly stereoregular polymers. Later. PHTP was shown to be an excellent host for inclusion polymerization, and a series of highly stereoregular polymers was synthesized from 1,3-butadiene and its derivatives. The most spectacular was the synthesis of an optically active polymer from achiral monomers, *trans*-1.3-pentadiene. using optically active PHTP as a host.[15]

Polymer inclusion compounds. which can be prepared not only by inclusion polymerization but also by direct cocrystallization of polymers with small molecule hosts, are interesting composite materials awaiting practical applications, e.g., incorporation of conjugated polymers into channels should lead to new composite materials with potential use as molecular wires.[12] New polymer–polymer molecular composites with interesting properties can be produced by embedding polymer inclusion compound into a carrier polymer.[16]

In recent years, considerable effort has been devoted to the design of organic solid materials exhibiting nonlinear optical effects (NLO), such as second harmonic generation (SHG; doubling frequency of light) or electrooptical (EO; modulation of the refractive indices of materials by application of an electrostatic field). In order for a crystalline solid to exhibit SHG or EO, the crystal structure must be noncentrosymmetric. In the case of organic or metalloorganic substances, the constituent molecules should have high molecular hyperpolarizabilities. Typically, such molecules have rod-like shapes with an electron-withdrawing group and an electron-donating group attached to the ends of a π-conjugated core. However, to minimize electrostatic repulsions. such molecules tend to pack antiparallel in their crystals, giving rise to centrosymmetric structures. One of the ways to produce noncentrosymmetric NLO materials is to confine these molecules to channels formed in a substructure of the organic host. With hosts such as TOT. PHTP. DCA, and thiourea. a variety of channel inclusion compounds with organic and metalloorganic guest molecules exhibiting high molecular hyperpolarizabilities were prepared. Many exhibited pronounced SHC and EO effects.[17,18] Interestingly. macroscopically. polar inclusion compounds are surprisingly often formed when dipolar guest molecules are incorporated into the host substructures that are typically centrosymmetric (e.g., thiourea or raceinic PHTP). The fact that dipolar guest molecules in neighboring channels of PHTP point in the same direction was explained in terms of a Markov model of a crystal growth.[4,19]

CONCLUSION

As shown above, channel inclusion compounds exhibit a wide range of interesting properties and fundamental physicochemical phenomena. An enormous amount of progress was made in recent years in understanding the physical and chemical properties of these compounds.'' [2] and there is no doubt that new applications of channel-type composite materials are to be expected in the future.

Chemical Topology

David B. Amabilino
Institut de Ciència de Materials de Barcelona (CSIC), Cerdanyola del Vallès, Spain

INTRODUCTION

The importance of topology of molecules on their supramolecular chemistries and, consequently, on the properties of their aggregates, is absolute. Chemical topology. in general; is the connectivity and linkage of atoms and molecules in space."' This connectivity and linkage play vital roles in determining the chemical and physical characteristics of the molecules (such as the boiling points of differently branched alkanes) and assemblies of them (such as the inclusion properties of crystals).

In terms of connectivity, chemists normally consider principally the covalent bonds between atoms, where the latter are regarded as points. In terms of linkage. we infer crossing points between chains of molecules, as in catenanes—from the Latin *catena* meaning chain, comprised of two or more interlocked macrocycles (with catenands and catenates being ligands and complexes, respectively)—and knots—self-crossing macrocycles. (Refs. [2,3] see also articles on ''Catenanes and Interlinked Structures.'') Supramolecular chemistry played a pivotal role in the preparation of different topological stereoisomers such as catenanes, that have topological diasatereomers that are the component macrocycles. and knots.[4] Just as the topology of molecules can be described. so can the topology of assemblies of them, in which the noncovalent bonds are regarded as a connection. in addition to the covalent bonds. Perhaps the most striking example of this idea is in the study of nets in the solid state.[5,6] All of these aspects are discussed in this short overview, which should act as a springboard to further reading; of the wide implications of chemical topology.

MOLECULAR GRAPHS AND TOPOLOGICAL ISOMERS AND DIASTEREOMERS

It is perhaps easiest to envision the concepts of topological isomerism and diastereoisomerism for the case of molecules, although all the concepts can be extended in dimensionality to interpenetrating supramolecular networks. For understanding the chemical topology of any system. it is important to define the molecular and supramolecular graphs. Any graph is a collection of points and lines. which in the chemical world are generally defined as atoms or ions and bonds; respectively. Changes in connectivities of atoms give rise to constitutional isomers. with different molecular graphs that are planar, that is to say they can be represented in a plane with no crossing points.[1,2] This case pertains to the isomers of linear or branched alkanes or the isomers pyrazine and pyrimidine (Fig. 1). The latter example is particularly relevant because it demonstrates the importance of constitution in determining topology. The coordination compounds of these two heterocycles show different conneciivities in the solid state. It should also be pointed out that enantiomers that are chiral by virtue of stereogenic centers or planar chirality are identical from the topologicai point of view. Topology only distinguishes geometrical properties that remain unchanged upon continuous deformation. Increasing the connectivity leads to the Platonic and Archimedean polyhedra, each with distinct planar molecular graphs.

Topological isomers cannot be converted into one another by continual deformation of the bonds between the atoms that comprise them. They have nonplanar graphs in three-dimensional space—a [2]catenane cannot be represented without having at least two crossing points or nodes (to avoid confusion with point nodes, here we will call these crossing points topological nodes) and is, therefore. a topological isomer of its component rings. Rotaxanes are not topological isomers of their component macrocycle and dumbbell. because by (hypothetically) expanding the ring until it can slip over the stoppers. they may be interconverted.

Increasing the number of crossing points in the molecular graph increases the topological complexity of the compound. A macrocycle presenting three crossing points is better known as the trefoil knot. A simple [2]catenane is not chiral: however. a trefoil knot is topologically chiral because the two enantiomers cannot be interconverted without breaking the link. They are topological diastereomers of the macrocycle that has no crossing points. Note that the synthetic template for the formation of a trefoil knot is a double helix. which is not topologically chiral. although in principle. its helical chirality. if presented in the synthesis, could be converted into topological chirality. When a [2]catenane presents four crossing points. the doubly interlocked [2]catenane,

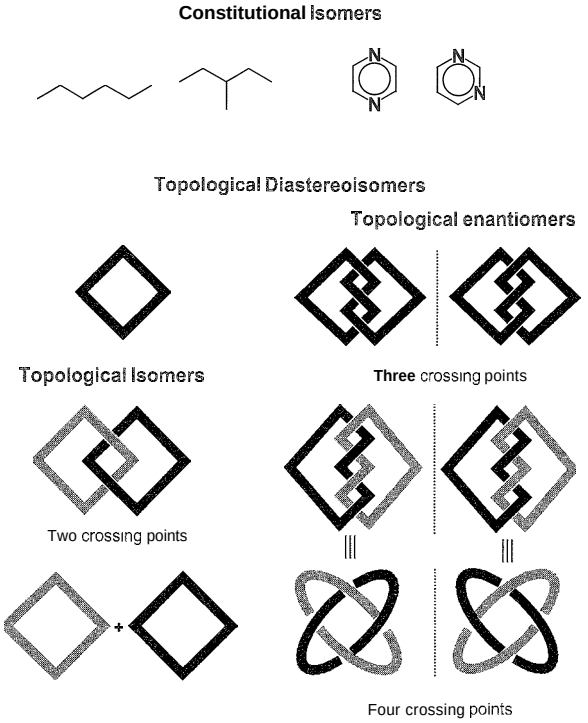

Fig. 1 Constitutional isomers, topological isomers. topological diastereomers, and topological enantiomers. (*View* this *art* in color *at www.dekker.com.*)

two enantiomers exist that are diastereomeric with the singly linked molecule and topologically isomeric with the component macrocycles.

SUPRAMOLECULAR POLYGONS AND POLYHEDRA

Dramatic advances, in resent years, were made in preparing supramolecular polyhedra (the tetrahedron. cube, dodecahedron, etc) from molecular and supramolecular polygons (triangles, squares. pentagons, and so on), especially because of potential interest in them as supramolecular hosts This statement holds true for the more developed coordination compounds[7] as well as for hydrogen-bonded ''containers ''[8] For example, a capsule with the topology of a tetrahedron can be constructed fiom four triaminoguanidine-based ligands and 12 cadmium ions. in which the planar triangular blocks are hinged through Cd–O interactions between chelated metal ions and oxygen atoms from the adjoining faces [9] Also, a truncated trigonal bipyramid can be prepared from a palladium(II) diamine complex and the hexadentate ligand 1,3,5-*tris*(3,5pyrimidinyl)benzene [10] Here, 24 components self-assemble to give the unique polyhedron structure in solution

The formation of polyhedra can also be achieved using hydrogen bonds as the directing force [8] An example is the formation of a chiral spherical supramolecular capsule with the topology of a snub cube (Fig 2A) by six calix[4]resorcinarene moleculer (Fig 2B) in combination with eight water molecules [11] A partial view of the hydrogen-bonding network around the sphere is shown in Fig. 2C. The vertices of the square faces of the snub cube correlate with the corners of the calixarenes. while the centroids of the eight triangles thai link the three squares are represented by the eight water molecules.

SUPRAMOLECULAR CHEMISTRY AIDING THE FORMATION OF TOPOLOGICALLY COMPLEX MOLECULES

It is clear from the drawings in Fig. I that pure chance is an inefficient way to make topologically complex molecules. While covalent-bonding strategies are valid, supramolecular chemistry has all but come into its own in the

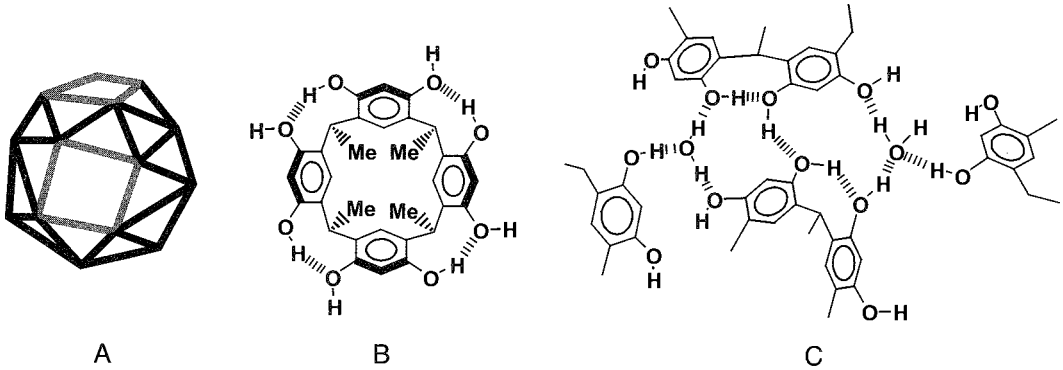

Fig. 2 (A) A representation of the snub cube. (B) The calix[4]resorcinarene that forms the polyhedron. six in combination with eight water molecules. (C) A partial view of the hydrogen-bonding network around the sphere. (From Ref. [1I].) (*View* this *art in* color *at www.dekker.com.*)

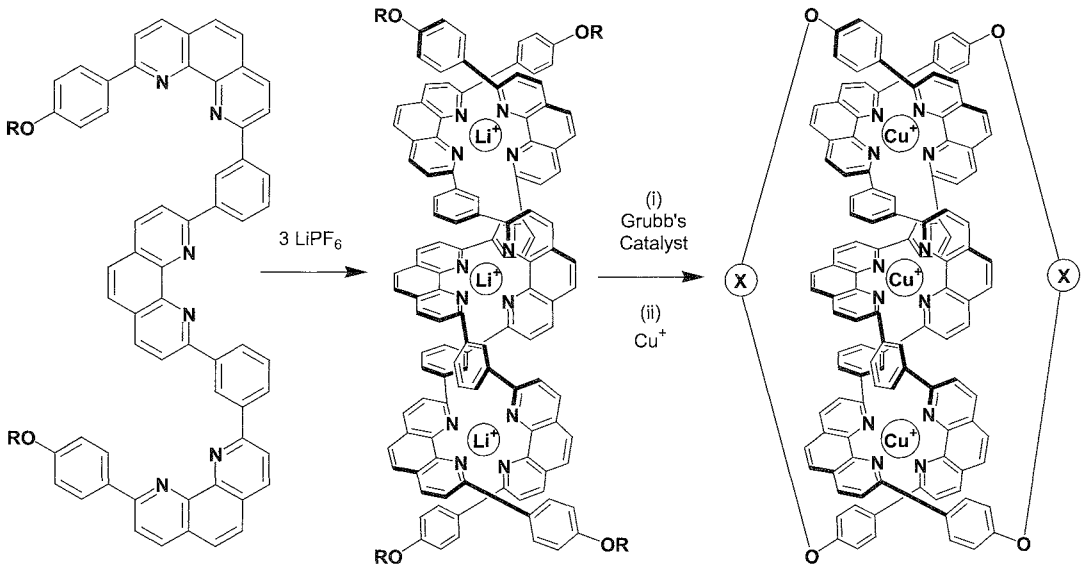
preparation of molecular catenanes and knots. Metal ion. π–π stacking (aided by edge-to-face and [C–H···O] hydrogen bonding), ammonium to crown hydrogen bonding, and amide hydrogen-bond-assisted templating afford isolable. stable molecules with an element of entanglement.[3] Because these methods were amply reviewed elsewhere, emblematic examples follow. All show that orthogonally oriented fragments are a prerequisite for interlocking.

The use of reversible metal ion coordination to pyridinic ligands can be used to form [2]catenanes in a quantitative way.[12] Thus: the mixing of 1,4-*bis*[4-pyridyl)methyl]benzene (Fig. 3, *R*=H) with ethylenediamine palladium(II) nitrate in aqueous sodium nitrate leads to practically total conversion to the [2]catenane. It is believed, on the basis of the x-ray crystal structure of the platinum analogue and the fact that the ligand with R = F is not so efficient in catenane formation, that edge-to-face aromatic interactions play a key role in the formation of this catenane. The *para*-xylyl unit acting as a spacer unit is particularly efficient for the formation of nets of difunctional ligands with metal ions (vide infra).



R = $CH_2(CH_2OCH_2)_3CH{=}CH_2$ X = $CH_2(CH_2OCH_2)_3CH{=}CH(CH_2OCH_2)CH_2$

Fig. 4 Lithium-ion-templated formation of a doubly interlocked [2]catenane. (From Ref. [13].)

The preparation of the challenging doubly interlocked [2]catenane, with four crossing points, was achieved on several occasions. One example involves the intertwining of molecular strands incorporating three 1,10-phenanthroline units linked by *meta*-phenylene spacers around three lithium ions (Fig. 4).[13] The mild ring-closing metathesis of the resulting trinuclear double helicate followed by exchange of the lithium ion for copper(I) afforded the catenate (in a remarkable 30% yield) that was liberated of its metal ions using KCN to give the doubly interlocked catenand. This metal-free compound shows the kind of slow dynamics in NMR spectroscopy characteristic of the hindered intramolecular motions in the self-entangled compounds.

The double-helical topography is not the only one to be able to produce the doubly interlocked topology of a [2]catenane. For example, a precatenate based on coordination of phenanthroline units to copper(I) ions can be linked through the coordination of pendant pyridine groups to palladium(II), as described previously.[14] The interaction of the gold(I) ion with alkynes [both end-on with the anions and side-on (η^1 and η^2 modes)] led to the formation of simple [2]catenanes as well as to the creation of a doubly interlocked [2]catenane.[15] In the latter example, the compound is formed under thermodynamic control, because the gold(I)-acetylide link is relatively labile, which leads to formation of the compounds in high yields when the ligand design is good."''

Higher catenanes showing topological stereoisomerism were prepared. For example, a [5]catenane that is the topological equivalent of the Olympic rings is formed along with a branched isomer through a two-step procedure based on self-assembly of π-electron-rich and deficient components.[16] Although noncovalent interactions were used to great effect for the preparation of these and other topologically nontrivial compounds, the control in their syntheses makes the formation of molecules with more crossing points challenging. The use of DNA as a construction unit, on the other hand, makes possible the synthesis of extremely complex molecules,[17] as will be discussed in a subsequent section.

TOPOLOGY OF NETS IN CRYSTALS AND POLYMERS

Two levels of topology can be defined in nets in crystals: first, the connectivity in sheets or frameworks: and second, the way in which the nets interpenetrate, or not. In coordination chemistry, the degree of connectivity is determined largely by the nature of the metal ion and the number of coordinating groups in the ligands, which are usually rigid or at least semirigid.[6,18] The topology of noncovalent interactions in compounds containing organic coinponents can also be rationalized using graph set analysis.[19] A good example with which to show the different levels of topology is that of the organic compound 1,3,5-benzenetricarboxylic (trimesic) acid.[20] The dimerizations of carboxylic acid groups are defined by various topologies, in this case, the $R_2^2(8)$ (a ring, *R*, with eight members maintained by two hydrogen bond donors, the subscript 2, and two hydrogen bond acceptors, the superscript 2) holds any pair of molecules together (Fig. 5). The planar topography and trigonal symmetry of these molecuies makes them ideal for the formation of an infinite two-dimensional hexagonal net. This net is designated (6,3), because the complete circuit involves six sides, and each point (which is at the center of each benzene ring in the structure) is connected to three others.[6] Because the presence of void space in crystals is usually disfavored, the compound relieves this effect through interpenetration. Each net is interpenetrated by three others, as indicated schematically in Fig. 5. For many, interpenetration is not desired, for example, if the aim is to prepare an "organic zeolite." The interpenetration can be avoided through complexation with guest molecules in the net.[20] Changing the functionality, topology, and topography of the molecule to adamantine-1,3,5,7-tetracarboxylic acid leads to three-dimensional fivefold interpenetration.[21] The size of the connectors in the hexagonal nets of 1.3.5-benzenetricarboxylic acid can be increased in a supramolecular way by crystallization with 4.4'-bipyridine, giving rise to a triply interpenetrated undulating hexagonal sheet.[22]

In these organic structures, the connecting points are the centers of the molecuies, while in coordination compounds, the metal ions are usually considered as the points; and the organic ligands form the sides of the nets.[5,6,18] The connectivity of the nets (which is determined by the point metals), usually between two and six for the early transition metals, can be pushed as far as seven and eight in the case of lanthanide ions complexed to 4,4-bipyridine-*N,N'*-dioxide.[23] The interpenetration of nets is observed frequently, although the rules determining whether or not it will take place are not established in a general sense. These nets were reviewed extensively,[6] and it is beyond the scope of this short overview to give more detail. It is interesting to note that the *para*-xylyl unit is often present in interpenetrating networks of various topologies,[6] presumably because of its penchant for edge-to-face hydrogen bonds.[24] A recent article by Carlucci et al. illustrated that the interpenetration is often anion dependent, and as many as 10 diamondoid nets car! be interwoven by the use of 1,12-dodecanedinitrile and silver(I) salts.[25] This example has additional interest in the sense that the ligand is flexible and can "breathe in'' to its fully extended

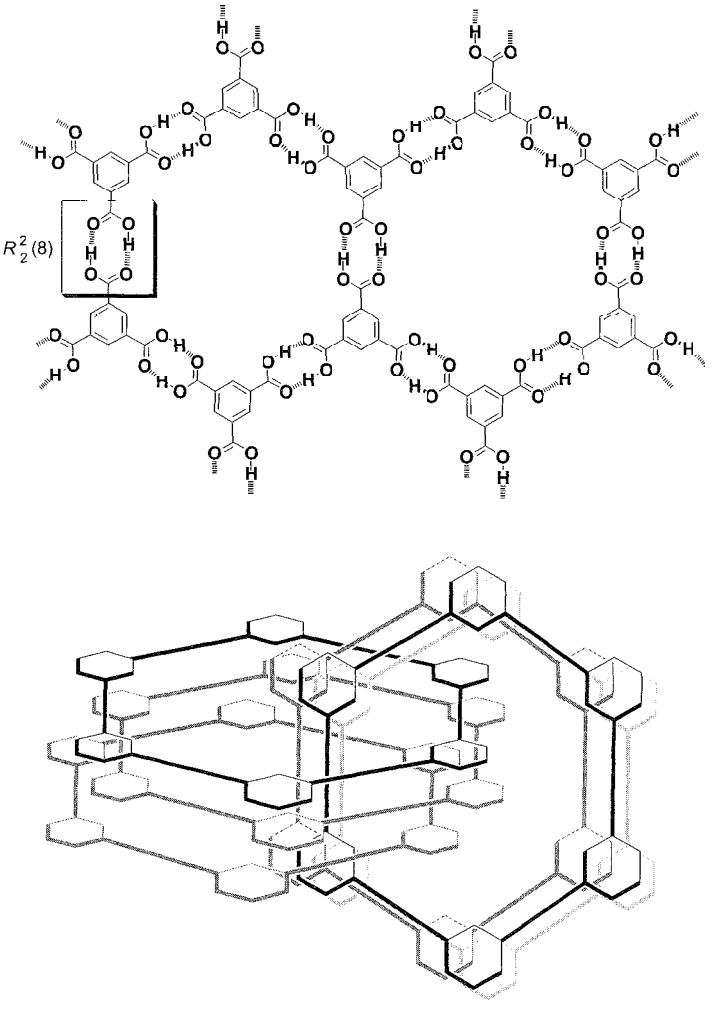


Fig. 5 The (6,3) net formed by 1,3,5-benzenetricarboxylic acid and its triple interpenetration. (From Refs. [6,20].) (*View this art in color at www.dekker.com.*)

all-trans form to give the 10-fold net when nitrate acts as counterion to the silver(I). In the hexafluorophosphate salt, the ligand adopts gauche conformations at the termini of the spacing chain in half of the molecules, resulting in an eightfold network with an unusual [4 + 4] interpenetration, while in the perchlorate salt, all molecules present gauche conformations at their termini; and a fourfold net results.

Interpenetration is not limited to ordered crystalline materials. The polymeric interpenetrating networks are frequently believed to contain mechanically trapped polymer chains.[4,26] Interpenetration has effects on the properties of the polymers when compared to their noninterpenetrating counterparts and is important in their applications. It is extremely difficult to define the exact topology of many of these systems. due to their polymeric nature, and the interested reader is recommended to read around the subject to explore the importance of chemical topology in these interesting materials.[26,27]

EFFECTS OF MOLECULAR TOPOLOGY ON SUPRAMOLECULAR CHEMISTRY

The topology of molecules can drastically influence their supramolecular chemistries and properties in general. For example. dendrimers or hyperbranched polymers show dramatically different properties when compared with their linear counterparts. To take a recent example. hyperbranched polyglycerols with a core-shell amphiphile structure encapsulate guests and thereby act as phase-transfer agents. while their strictly linear counterparts do not.[28]

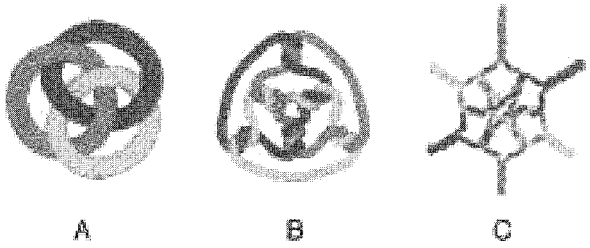

Fig. 6 (A) The classic Borromean rings. (B) The Borromean rings as in A, but with each single topological node (crossing point) replaced with three. (C) The DNA molecule that was synthesized. (From Ref. [17].) (Many thanks to Ned Seeman for providing the images.) (*View this art in color at www.dekker.com.*)

The effect of interlocking on the properties of molecules is dramatic. For example, the basicity of the 2,9-diphenyl-1.10-phenanthroline unit is enhanced by several orders of magnitude when it is present in a [2]catenand.[29] The proton catenate displays a similar molecular structure to that of the corresponding copper(I) catenate. whereas that of the catenand is completely different. The special topology of the catenands and knots makes them unique ligands, with strong complexes being formed with a variety of metal ions.[30]

TOPOLOGICALLY INTRICATE DNA-BASED MOLECULES

The topological complexity of the synthetic compounds described above pales in insignificance when compared with that observed in naturally occurring DNA[31] and with that created using the nucleic acids as building blocks for the construction of molecular objects, including polyhedra and all kinds of knots.[17]

in naturally occurring DNA, catenanes and knots are observed that are crucial for the replication cycle of the genetic data with the help of the various families of topoisomerase proteins.[31] However, to quote Ned Seeman. "there is far more to DNA than a repository for genetic information!"[17] The use of "sticky-ended" DNA duplex strands. in combination with control of branch junctions. design of B-DNA and Z-DNA segments. and restriction and ligation sequences led to the creation of molecules beyond the dreams of non-DNA chemists. The synthetic DNA chemistry even provided the challenging Borrornean rings—three macrocycles linked together. but no two of which are entwined, and the breaking of any one of the macrocycles results in the disconnection of the other two (Fig. 6). The Borromean rings remain a daunting confrontation for those involved in the synthesis of topologically complex molecules through supramolecular assistance.

CONCLUSION

Topology in all of its forms has important consequences in molecular and supramolecular chemistry, and in the properties of the materials that result. Great control was demonstrated over the creation of polyhedra using coordination chemistry based on appropriate design of the topology and topography of ligands and the coordination numbers of the metal ions employed, strategies that also apply to the formation of coordination nets. Purely organic systems of analogous nature. in which the branch points are located at the center of the component molecules, are in their early days, although significant progress has been made. The preparation of topologically complex molecules and assemblies through the employ of noncovalent bonds has made remarkable progress, but it is fair to say that the doubly interlocked [2]catenane and the [5]catenanes are at the limit of present capabilities. it is likely that new supramolecular motifs with orthogonal topography will be needed to progress in this area. These motifs would also be applicable to the preparation of interpenetrating nets. Precise control over polymeric structures and detailed proof of their topologies are still challenging. and a lot can be learned from the topological heights that were reached in DNA structures.

Chiral Guest Recognition

Anthony P. Davis
University of Bristol, Bristol, United Kingdom

INTRODUCTION

Enantioselective recognition is a long-standing preoccupation of supramolecular chemistry. On the one hand. the phenomenon is of great theoretical interest, being critical to the functioning of biology. On the other, it has practical importance deriving from the need for enantiomerically pure compounds in the chemical industry. To quote from a recent monograph. "The separation of enantiomers may well represent the economically most important application of supramolecular chemistry."[1] It is a substantial topic, and coverage herein must be selective. This entry will focus on recognition in solution and selectivity in the sense of differential binding free energies. Solid-state host–guest chemistry and spectroscopic differentiation (as for chiral NMR shift reagents) will not receive general consideration. Chromatographic chiral stationary phases (CSPs) will be mentioned only briefly; for more detailed discussions, see reviews by Pirkle and Pochapsky[2] and Okamoto and Yashima.[3] After a short section on general principles, the account will be organized according to substrate type. following the sequence amines/ammonium ions. carboxylic acids/carboxylates, underivatized amino acids, peptides and peptide models, carbohydrates, and nonpolar guest molecules.

GENERAL PRINCIPLES

General discussions of enantioselective recognition are given in a number of reviews.[2,4,5] A prevalent concept is the "three-point rule."[6] formulated by Pirkle. as "Chiral recognition requires a minimum of three simultaneous interactions between the CSP(/receptor) and at least one of the enantiomers, with one of these interactions being stereochemically dependent."[2] Schematically; receptor 1 is a match for 2 but not for ***3***. However, while undoubtedly true, this principle encourages a design concept that may not be optimal. When 1 and **3** interact. they should be capable of two interactions as in 4, and it is the third interaction C···C′ that determines the degree of enantioselectivity. This third interaction will be the weakest of three noncovalent bonds and, in most cases, is not likely to represent a large energy difference. In practice, the most successful enantioselective receptors seem to present a complex array of functional groups and steric barriers. such that one enantiomer can make good binding contacts but the other has minimal opportunities for interaction. Beyond this, it may be difficult to generalize, but there is a case for saying that rigidity and bulky substituents are often helpful for achieving good selectivity,[4] and it is true that strong interactions are necessary (the larger of the binding energies sets an upper limit for the useful difference in binding energies).

ENANTIOSELECTIVE RECOGNITION OF AMINES AND AMMONIUM IONS

Primary ammonium ions can bind to crown ethers, especially 18-crown-A derivatives. via formation of three H-bonds as shown in ***5***. In seminal work by Cram and coworkers, this interaction was exploited in a series of chiral receptors based on the twisted 1,1′-binaphthyl and 1,1′-ditetralyl units. A key example is receptor 6, containing two binaphthyl units. of which one carries methyl substituents. This cornpound was capable of extracting protonated methyl D- and L-phenylglycinates (**7**.H^+ and **8**.H^+, respectively) from racemic aqueous solutions into chloroform in the ratio 31:1,[7] setting a standard that has proved difficult to match with newer systems. The system was used to demonstrate a "resolving machine" based on the transport of the cations through a chloroform barrier.[8] The machine consisted effectively of two U-tubes filled with chloroform and placed in contact with a central reservoir of aqueous racemate. One chloroform soiution contained 6 and selectively removed **7** from the central reservoir into a receiving phase. while the second contained ent-6 and transported 8. The two receiving phases accumulated phenylglycinates in up to 90% e.e.

8 (L)

A variety of other chiral crown ethers were studied. although selectivities usually peaked at 10:1 or less.[4] Pyridine-based systems. typified by **9**,[9] were subject to especially detailed investigations. The incorporation of phenolic units allows the crowns to bind amines, as opposed to ammonium ions, and may also be used to introduce a spectroscopic response to binding.[10,11] For example. the calixarene-crown **10** acts as a colorimetric chiral sensor for amino alcohols, changing from red to blue on exposure to *R*-phenylglycinol **11** in ethanol (K_a=66 M^{-1}) but unresponsive to the enantiomeric substrate.[11]

An alternative strategy for binding amines is to use a Lewis acidic metal atom. Zn-porphyrin complexes prove especially useful in this context. For example, the doubly bridged α,α,β,β-system **12** bound the methyl esters of α-amino acids with moderate but fairly general enantioselectivities (7.5:1 for valinate, 4:1 for alaninate) in dichloromethane.[12] The "Troger's-base-linked" *bis*-porphyrin **13** was designed to make two Zn–*N* interactions and was shown to bind histidine methyl ester **14** with an enantioselectivity of 13:1 in $CDCl_3$.[13] Recently, the relatively accessible α,β,α,β-complex **15** was found to give 22:1 selectivity in binding the enantiomers of methyl phenylglycinate (**7**+**8**) in dichloromethane.[14]

ENANTIOSELECTIVE RECOGNITION OF CARBOXYLIC ACIDS AND CARBOXYLATES

Carboxylic acids/carboxylates are popular substrates in supramolecular chemistry. offering various opportunities for hydrogen bonding and electrostatic and donor–acceptor interactions.[15] Especially prevalent are duplex H-bonded motifs. as shown in **16**–**18**. A number of groups incorporated these motifs in enantioselective receptors. A simple but effective example is **19**, due to Morán.[16] This receptor was targeted at *O*-carbamoyl lactic and mandelic acids **20** and is thought to bind them via an array of H-bonds, as shown. The chiral centers in host and guest are held close in space. allowing the receptor to differentiate between guest enantiomers. The best results were obtained with lactic derivatives **20** (R = Me), for which the *R* receptor (shown) preferentially bound the *S* substrate with exceptional enantioselectivity of 90:1 in $CDCl_3$.

Motif **16** was also employed in receptors **21** and **23**. designed respectively to bind dicarboxylic acids and C-terminus dipeptides. Receptor **21** is part of a series in which different linkers were used to connect the binaphthol oxygens and thus control the dihedral angle between the naphthyl groups.[17] The $MeN(CH_2CH_2)_2$ unit in **21** gave optimum results, including an affinity ratio of 16:1 in $CDCl_3$ for L-aspartic derivative **22** versus the D-enantiomer. Tweezer **23** was aimed especially at the D-Ala-D-Ala unit in **24**, the target in nature of the Valinomycin family of antibiotics. In $CDCl_3$, **24** was bound 23 times more strongly than its enantiomer.[18] The guanidinium-based motif **17** was exploited in the steroid-based receptors **25**.

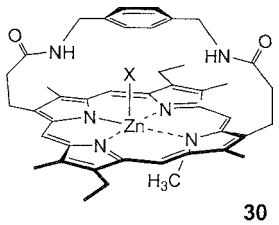
enantioselective recognition. The amino acids themselves are of particular interest, considering their direct participation in biocheinistry. A natural approach to the enantioselective recognition of amino acids is the incorporation of well-established ammonium- and carboxylate-binding motifs in a chiral framework. The bicyclic guanidinium receptor 31 conforms to this strategy. It also features a naphthoyl unit that should bind to the side chains of aromatic amino acids. providing an especially clear example of three-point contact. Indeed, 31 binds L-tryptophan 32 and L-phenylalanine with good enantioselectivity, extracting them from racemic aqueous solutions into chloroform in ca. 80% e.e.[23,24]

Metal ions can bind amino and carboxylate groups (vide supra), so are well-adapted to amino acid recognition. The cobalt(II) coinplex 33 (racemic) reacts with DL-alanine to give diastereomeric products **34** and 35 in ~2:1 ratio. A controlling influence is the tendency of the carboxylates to locate *trans* to each other. Interestingly, ***35*** is converted almost exclusively to 34 upon treatment with



30

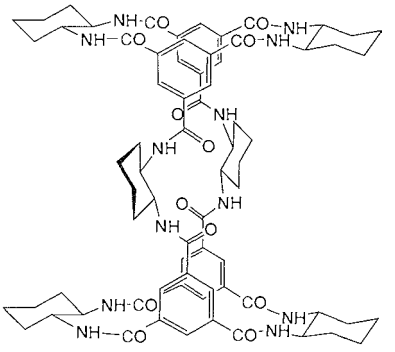
aqueous base. implying *a substantial energy difference between the two* complexes.[25]

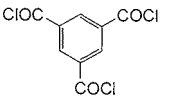
Amino acids may be bound in *water by* molecules *with hydrophobic cavities. Cyclodextrin derivatives were studied extensively. Enantioselectivities are usually modest, with some exceptions. For example, a* diphenoxyphosphoryl-substituted β-cyclodextrin *bound serine with* 3.6:1 enantioselectivity[26] *and an* α-cyclodextrin *with a* pyridinium substituent *showed* 10:1 enantioselectivity *toward the same* substrate.[27] *Synthetic cyclophanes were also used. The* bipyridinium-based *macrocycle 36 bound DOPA 37 with 13:1 R:S selectivity in acidic aqueous* solution.[28]

PEPTIDES AND PEPTIDE MODELS

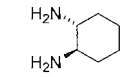
Peptides *and* peptide *models* (i.e., amides *derived from* α-*amino acids) are also important targets for* enantioselective *receptors:* many *of the* most extreme *selectivities were obtained* with *these substrates. An example is Rebek's tetra-amide 38. derived from two* molecules *of*



45



46



47

"Kemp's *triacid." One enantiomer of the* diketopiperazine *(cyclodipeptide) substrate 39 can bind through four hydrogen bonds. as shown. The other enantiomer cannot form a similar complex without a steric clash between the* isobutyl *groups and the naphthyl system. Accordingly, the receptor gives* ~*100:1* enantioselectivity *with this substrate in* $CDCl_3$.[29]

Still *and coworkers also described some remarkably selective* peptide *receptors. Tricyclic systems 40–42 represent an interesting sequence. These* molecules *adopt bowl-shaped* conformations *in which the central aromatic ring serves as the "base." and the outer rings of* amide *groups define the* "rim." *The first example 40 was found to bind a range of N-Boc* α-amino *acid* amides *with excellent enantioselectivities, peaking at* 130:1 *for valine derivative 43* in $CDCl_3$.[30] *Receptor 41 was then used to demonstrate, with unusual clarity. the importance of a well-defined preorganized architecture. This slightly* more *flexible molecule* was still *a good receptor but showed just 9:1* enantioselectivity *for 43.*[31] *The colored system 42 was used to explore the application of combinatorial chemistry to molecular recognition. When exposed to a library of bead-bound peptidic substrates, it bound preferentially to certain members.* turning *the*

64

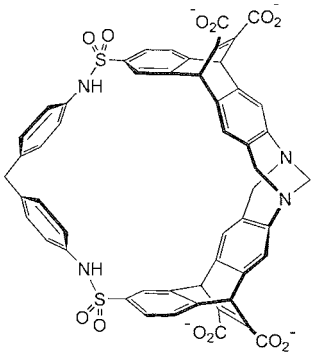
corresponding beads a deep red. High affinities were indicated for peptides with terminal cyclopropanoyl groups, and when amide 44 was tested in solution, it was bound exceptionally strongly. Strong binding will often imply an exact fit and, therefore, high selectivity. in this case. 44 was bound with ~300:1 enantioselectivity, probably the highest recorded value for a synthetic receptor.[31,32]

Still and coworkers reported a second tricyclic system 45. This host was accessible in a single step from 46 and 47 (13% yield) and also showed exceptional enantiodiscrimination. For example, L-phenylglycine derivative 48 and its enantionier were bound in the ratio ~160:1, with $CDCl_3$ as solvent.[33]

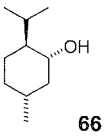
Finally, Pirkle's pioneering work on enantioselective separations was especially successful with *N*-3,5-dinitrobenzoyl peptide models. For example, a CSP of form 49 was able to separate the enantiomers of 50 with $\alpha=18$,[34] while the later-generation phase **52** gave $\alpha=30$ for **51**.[35] These simple but effective systems are amenable to detailed structural analysis and, thus, can be especially informative. For example, NMR[35] and x-ray crystallography[36] were used to show that the more stable 51.52 complex possesses a compact structure held together by a π–π interaction and two intermolecular NH···O=C hydrogen bonds.

CARBOHYDRATES

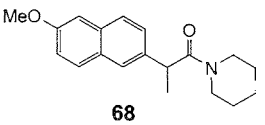
Carbohydrates are challenging targets for molecular recognition. being complex yet only subtly different from



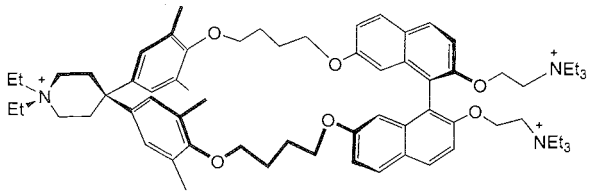
65



66



68



67

each other.[37] *Enantioselectivity is usually achieved through host structures that can* surround *the carbohydrate nucleus. accessing all the recognition features of the substrate.* Examples *are* **40**. ***53.*** *and* **54**, *which were tested against organic-soluble octyl glucosides* ***55–58*** *in* $CDCl_3$. *The steroid-based system 53 showed moderate* selectivities in α- *and* β-series, *preferring* **58** (α-L) *over* **57** (α-D) *by a factor of 2. and* 55 (β-D) *over 56* (β-L) *by a factor of* 3.[38] *Chiral "bow!" 40 gave values of 2 and 4 in the* α- *and* β-series, *respectively, favoring the* D-*substrate in each case."'"* Receptor **54** *(the S,S,R-*member *of* a *family of* stereoisomers) *showed better selectivity in the* α-series, *binding* **58** *and* **57** *in the ratio* 4:1.[40] *Unfortunately. a figure could not be obtained for the* β *anomers, because* **56** *bound* with *slow kinetics.*

Bis-phosphonate 59 *is exceptional in that it cannot* encapsulate *the substrate, providing instead a chiral cleft to act as binding site. The receptor was not resolved, but* NMR *studies with* **55** *and* **57** *in* CD_3CN *could be analyzed to give binding constants for both diastereo*meric *complexes. The selectivity was only* 1.4:1 *for the* α-series. *but the ratio for* β-anomer *55 was 5:1.*[41] *This* figure, though *moderate, is still the record for enantioselective carbohydrate recognition through non-covalent interactions."*

"An alternative approach to carbohydrate recognition involves covalent B-O bond formation. For a review of this area see Ref. [42].

ENANTIOSELECTIVE RECOGNITION OF LESS-FUNCTIONALIZED SUBSTRATES

Selective molecular recognition usually relies on strong and specific attractions involving *polar functional groups.* Enantioselective *recognition is favored by several such interactions. Substrates with* just *one functional group. or none at all, are therefore especially challenging targets. An extreme* example is *the chiral* haloform CHFClBr *(60). Merely binding this* molecule *is nontrivial. especially* in organic *solvents. The solution was found in* "cryptophane" *61, a host molecule with an enclosed chiral cavity that is closely matched in size to* **60**. *The cavity appears to be too small for* $CDCl_3$, *so this solvent does not* compete *with the substrate. At low temperature (215 K), receptor* **61** formed *a* 2:1 *ratio of diastereoineric complexes with excess of* racemic **60**.[43] *A related chiral* hemicarcerand, *constructed from two calixarenes linked face to face via a binaphthyl unit. was employed for soinewhat larger substrates. In this case. the substrates were used neat or dissolved in* noncompeting *diphenyl ether. The* hemicarcerand *showed an enantioselectivity of* 2.7:1 *with* $BrCH_2CH_2CHBrMe$ *as guest, and it appeared to be* completely *selective for one* enantiomer *of p-*tolyl *methyl* sulfoxide.[44] An *interesting recent development is the formation of capsular hosts by self-assembly. The sulfa*mido-glycoluril *unit* **62** forms *an enclosed, symmetrical* tetrameric *structure capable of accepting sizeable guests. Desymmetrization as in 63 distorts this structure so that it can show* enantioselectivity. *With ketone 64 as guest. the results are remarkable: the self-assembled capsule* shows *4:1 selectivity in favor of the S-*substrate.[45]

With water as solvent. hydrophobic interactions can be used to drive complex *formation. Cyclodextrins were widely used to study hydrophobic binding. and* they *often show enantioselectivity.* However, *strong enantiodiscrim*ination *is* rare, *especially* for less-functionalized *substrates."'" synthetic water-soluble receptors gave* similar *results. For example,* cyclophane *65 bound the enantiomers of menthol* **66** *in the ratio* 5:4,[47] *while macrocycle* **67** *bound Naproxen derivatives 68 in* D_2O/MeOH (60:40) *with 1.9:1* enantioselectivity.[48]

CONCLUSION

*Chiral guest recognition is a success story in supramo*lecular *chemistry. with* many *examples of good selectivity and some that are impressive. However. there is plenty of room for improvement. By their nature, the most effective receptors are complementary to specific substrates and, therefore.tend to be limited in scope. Also, some substrate classes have proved far* more *resistant than others. The goal of binding a wide range of substrates with. say.* >95% e.e., is *still unrealized. Success* will *probably require an*

equally wide range of receptors, and one may foresee an increased role for combinatorial chemistry in future work.[49] It is unlikely that interest will lapse—chirality continues to fascinate chemists. and the supramolecular community is unlikely to drop this challenge for many years to come.

ACKNOWLEDGMENT

The author thanks his coworkers for their efforts toward chiral. and achiral, molecular recognition over the past two decades. Funding for our programs has been provided by the EPSRC, the European Commission, the University of Bristol, and Enterprise Ireland.

Chiral Induction

David B. Amabilino
Jaume Veciana
Institut de Ciència de Materials de Barcelona (CSIC), Cerdanyola del Vallès, Spain

INTRODUCTION

Chiral induction is the generation of a chiral molecular structure or superstructure in an otherwise achiral or racemic system by use of some stimulus (Fig. 1).[1] It is important, because it guarantees creation of chiral organizations of a determined handedness. which is not available through spontaneous resolution.[2] The chirality of the organization is determined from the molecular level in the conformations that the molecules adopt: the way the molecules come together through covalent or noncovalent means, and the way in which these aggregates self-assemble.

The most obvious stimulus to chiral induction is the use of stereogenic centers, but external perturbation, such as physical fields; can also be used to induce chirality.[3] The term is applied to traditional asymmetric synthesis through covalent bonds as well as to supramolecular synthesis. which is our interest here. Mention the word "chirality" to any chemist. and thoughts will be conjured of the right-handed B-DNA double helix. the right-handed α-helices formed by peptides of the natural L-amino acids, of thalidomide, and other emblematic and dramatic examples of the importance of stereochemistry. It is clear that the chirality of the components of biological systems play a key role in their function. in which induction of chirality through noncovalent bonds is inherent. But beyond natural systems and related phenomena, there is a wealth of unnatural chemical systems that display remarkable and important properties.

The scope of the area is so wide that all we can attempt to do here is discuss key examples and encourage the interested reader to investigate the other interesting results cited therein. We concentrate strictly on supramolecular effects in chiral induction. There is a separate article in this Encyclopedia that deals with the related field of chiral guest recognition.

OBSERVING CHIRAL INDUCTION

Induction of chiral structure is precisely observed in the crystal structures of compounds. In this sense. x-ray crystallography is a precise and informative tool in the study of chiral induction. Ideas can be given of how chirality is transmitted through the systems via the conformations and intermolecular interactions from the packing of molecules in the crystal. The obvious limitation is that high-quality single crystals are essential. Electron microscopy is useful when it comes to the induction of chirality in fibrous self-assembled systems. especially transmission electron microscopy (TEM), where direct observation of the twisted threads can be realized, as we will discuss. The use of scanning tunneling microscopy (STM) and atomic force microscopy (AFM) are also emerging rapidly as alternatives in this regard,[4] as well as in the study of chiral induction in monolayers.[5]

However. perhaps the most widely used techniques for observing chiral induction are the optical ones. polarimetry and, especially. circular dichroism (CD) spectroscopy, both in solution and in the solid state.[6] While induction of chirality implies the formation of a chiral structure, care must be exercised when drawing parallels between optical activity (as witnessed by these methods) and "real" structural chirality. For example, binding of a rigid achiral molecule to another chiral molecule may give rise to a Cotton effect in the absorption of the chromphores of the former. Optical activity was induced, but was chirality induced? The electronic structure is clearly chiral, there is a Cotton effect, but the conformation of the molecule is not. If the achiral molecule is flexible, and a Cotton effect is observed upon complexation with a chiral molecule, we cannot be sure that this is the result of a chiral conformation or merely the influence of the chiral complexing molecule on the electronic transitions. The problem becomes more complex in the case of complexation of a chiral agent to a racemic molecule, as highlighted by Krois and Lehner for the case of bilirubins.[7] These problems do not apply when the chirality is amplified to larger assemblies, where the increase in the magnitude of the Cotton effects cannot possibly be caused by proximity effects.

CHIRALITY IN CRYSTALS

The induction of chirality in crystals is usually achieved through the incorporation of stereogenic centers in one

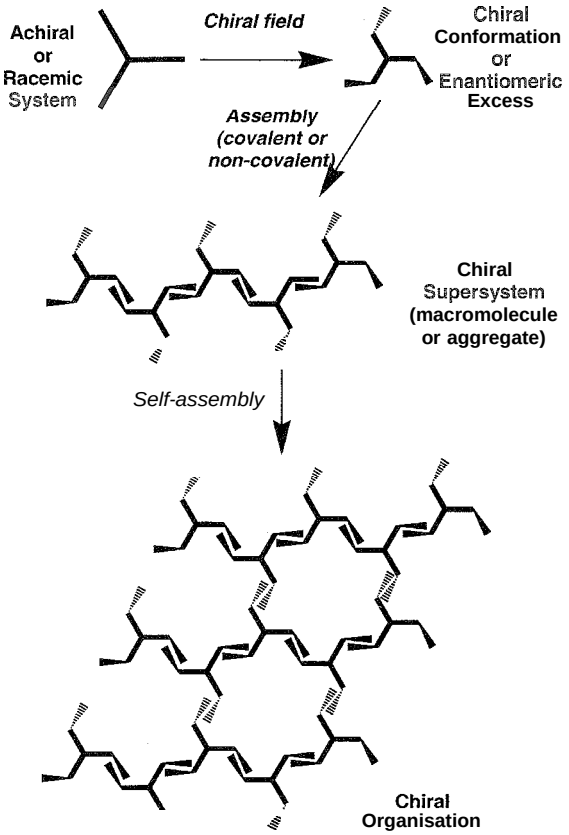

Fig. 1 A representation of the hierarchy of chiral induction, leading in this case to a principally two-dimensional chiral assembly.

molecule. which is complementary with an achiral or racemic compound. The resolution of racemates is a model example. but chiral compounds can also be used to confer chiral structures on otherwise achiral systems. The inclusion compounds formed by the chiral cholic acid host and achiral N-aryl-N-nitrosamine guests result in the adoption of a chiral conformation of the latter.[9] Here, the conformation observed by x-ray crystallography was correlated with the Cotton effects observed in the solid-state CD spectra. This type of trapping of chiral conformations in the solid state can be used to perform covalent-bond-forming photochemistry.[9] Thus, the inclusion compound formed between the chiral host 1 and the achiral anilide 2 contains the latter in a chiral conformation (Fig. 2). Irradiation of the crystals with UV light results in photocyclization of the anilide to form compound 3 in 98% ee and in a yield of 46%, and the reaction could be followed by x-ray crystallography. Even more efficient reactions. in which chiral host crystals act to induce chiral conformations in reagents prone to photocyclization, were observed.[9]

The use of anions or organic ligands as inducers of chirality to metal ion centers is well documented. if not entirely predictable because of high coordination numbers and a throng of possible metals.[10] As an example of induction by organic ligands, we take our own work on the formation of metal complexes by α-nitronyl nitroxide radicals, such as 3MLNN, in which a basic phenyl α-nitronyl nitroxide is substituted with a methyl lactate moiety.[11] When (*R*)-3MLNN is crystallized with manganese(II) hexafluoroacetylacetonate, a coordination polymer is formed through coordination of the radical's oxygen atoms to the metal ion (Fig. 3), and in which the chirality in the ligand induces a chiral A configuration in the manganese coordination sphere. Interestingly. the chiral conformation adopted by the ligand—regarding the helicity between the phenyl ring and the imidazolyl ring and that of the imidazolyl ring—is of the same type as that seen in the isolated ligand's crystal structure. In addition to being chiral, this metal-radical-based material is interesting, because it is a magnet at low temperatures.

CHEMICALLY INDUCED CHIRALITY IN SUPRAMOLECULAR SYSTEMS IN EQUILIBRIUM

The induction of chiral structure in supramolecular systems at equilibrium was widely studied, partially because of surging interest in the hierarchical nature of the self-assembly of chiral aggregates. It is also of utmost relevance in the study of chiral information in unnatural systems displaying new properties.

The transmission of chirality in membranes and other types of aggregates formed by surfactants was widely studied. The superstructures of bilayers formed by gemini dicationic surfactants based on quaternary ammonium centers can be modulated through the employ of enantiomeric tartrate salts.[12] The twisted ribbons (Fig. 4) are formed when an enantiomeric excess of one of the tartrates is present, with the period (helical pitch) shorten-

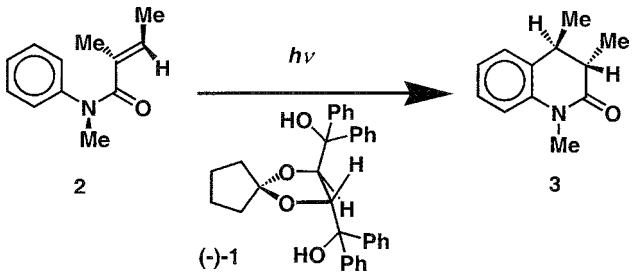

Fig. 2 Chiral induction in the photochemical reaction of *2* included in **1.** (From Ref. [9].)

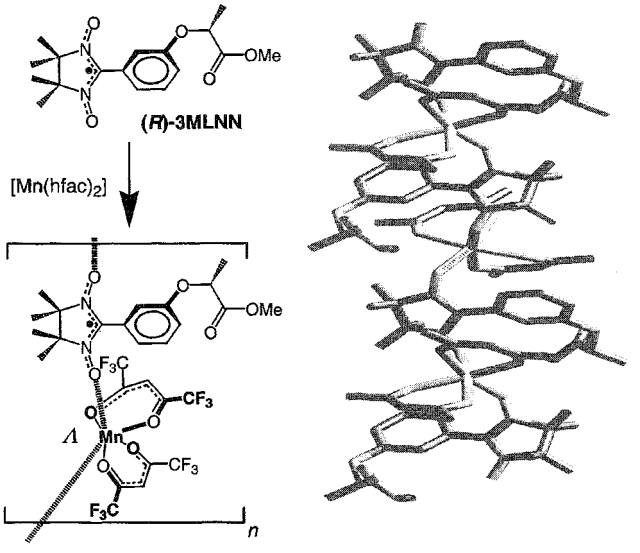

Fig. 3 Formation of the coordination polymer (*R*)-**3MLNN**·$Mn(hfac)_2$ and a view of the crystal structure of the molecular material showing part of the 2_1 chain. (From Ref. [11].)

ing as the enantiomeric excess of the anion increases. When there is no enantiomeric excess of tartarate or in the presence of achiral anions, flat ribbons are observed. The gemini nature of the surfactant is crucial in observing the effects. This effect is probably due the possible chiral conformers that the surfactant head group can adopt.[13]

Perhaps one of the most important applications of chiral induction is in the area of liquid crystals. Upon addition of a wide range of appropriate chiral compounds, the achiral nematic, smectic C, and discotic phases are converted into the chiral cholesteric (or twisted nematic). the ferroelectric smectic C*, and the chiral discotic phases. As a first example, we take the induction of chirality in the columns of aromatic chromophores present in some liquid-crystalline polymers.[14] The polymers. achiral polyesters incorporating triphenylene moieties, display discotic mesophases, which upon doping with chiral electron acceptors based on tetranitro-9-fluorene, form chiral discotic phases in which the chirality is determined by the dopant. These conclusions were reached on the basis of CD spectra in which strong Cotton effects were observed. Interestingly, the chiral dopants were unable to dramatically influence the chiral winding of triphenylene polymers that already incorporated stereogenic centers.

The induction in smectic C phases of chirai order in the form of smectic C* phases is interesting and important in view of the applications of this phase in displays.[15] The calamitic (rod-like) molecules in this phase are organized in layers, with the long axes of the molecules forming an angle with the normal to the layer plane. Upon addition of a suitable chiral dopant, this angle is forced into a helical arrangement about the normal to the layer plane, with a pitch of a few microns. The induction mechanism is believed to operate by incorporation of the dopant into the layers of achiral molecules, which interact in a host–guest type of way such that an orientational bias is inferred on the host. These chiral superstructures may be induced by molecules with stereogenic centers in the alkyl chains attached to rigid cores, with relatively high flexibility of the stereogenic center in general, which induce chirality in host phases with a wide variety of structural features.[16] Meanwhile. when rigid atropoisomeric cores are used in the dopant molecules. specific interactions take place between host and guest, and a more pronounced dependence on the structure of the two is observed.[17] Dopant molecules of Type 4 in Fig. 5 interact with host smectic C liquid crystals with a phenyl pyrimidine core (**PhP1**) in such a way that a preferred axially chiral conformation of the host is induced by the dopant guest, and this conformation is propagated through the layers.

Just as chiral induction can be realized in discotic liquid crystals, so it can in assemblies of disc-like molecules or disc-like aggregates. As far as molecules are concerned, C_3-symmetrical *tris*-amides (Fig. 6), which exhibit discotic liquid-crystalline phases, also form chiral columnar stacks through π–π interactions when dissolved in apolar solvents,[17] which are depicted schematically in

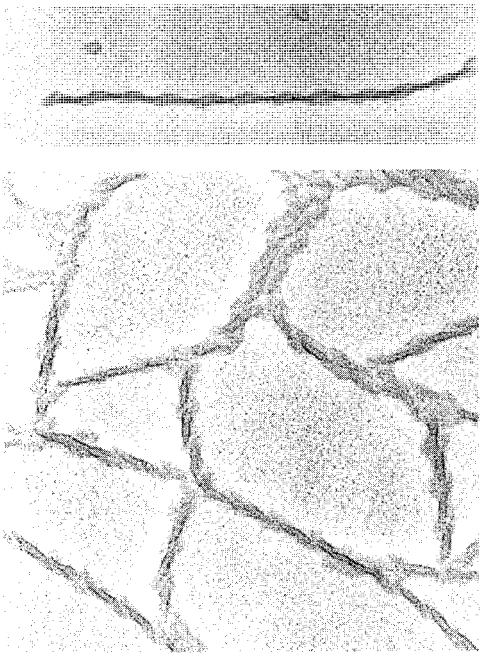

Fig. 4 The twisted ribbons formed by the addition of tartrate ions to aggregates formed by gemini ammonium surfactants. (From Ref. [12].) The authors thank Dr. Reiko Oda for supplying these TEM images.

Fig. 4. An achiral compound of this type exhibits no optical activity in dodecane, but when the compound is dissolved in the chiral (*R*)-(−)-2,6-dimethyloctane, significant Cotton effects (only slightly less intense than those observed in a chiral derivative) are detected. A chiral disc-like *tris*-amide compound can also be used as a dopant at concentrations as low as 2.5% to induce supramolecular chirality in the stacks of achiral compound. The presence of the additional hydrogen bonds in the form of the self-complementary urea unit is detrimental to chiral induction in this case.

Disc-like aggregates are also capable of forming chiral aggregates, in which chiral induction can be realized. The rosette-type aggregates formed by melamine derivatives and cyanurates or barbiturates form the basis of chiral aggregates formed from a calix[4]arene dimelamine **Mel1** and a complementary cyanurate or barbiturate.[18] Because there is a twist between the layered rosettes in the 3:6 aggregate, a helical twist exists between upper and lower decks, as seen in Fig. 7 by the orientation of the calixes. In the absence of any chiral influence. the *M* and *P* enantiomers are formed in equal amounts (Fig. 7), but when a stereogenic center is included in the barbiturate component (for example, **Bar1**), the point chirality is transmitted to the twist between the two decks of the assembly. Furthermore. the chiral component can be replaced through equilibration with an achiral cyanurate derivative (**CY1**), and the assembly retains the induced chirality. This kind of memory effect can also be achieved using an achiral calix[4]arene dimelamine with pendant pyridine moieties combined with achiral cyanurate to form the double-decker rosette and inducing a chiral secondary structure by adding tartaric acid derivatives that hydrogen bond to the pyridine moieties.[17] Efficient chiral induction requires the presence of two sterogenic centers in the his-acid. Subsequent precipitation of the acids through slat formation leaves the enantiomerically enriched supramolecules.

The chiral induction seen in the double-decker supramolecule we just discussed can also be seen in stacked systems that form nanotubes. A self-complementary heterobicyclic base CC—which incorporates the hydrogen bond donor–donor–acceptor sequence of guanine and the acceptor–acceptor donor sequence of cytoseine—suitably substituted with crown ether rings, undergoes formation of a cyclic hexamer which in methanol subsequently piles up on itself to give a nanotube-type structure, as observed by TEM. dynamic light scattering, and small-angle x-ray scattering.[17] When chiral amino acids are added to this preassernbled nonchiral system in concentrated methanol solution, the ammonium moieties bind the crown ether ring and induce a CD spectrum indicative of a helical superstructure. At lower concentrations, where the aggregation number is lower, the addition of amino acids leads

to a slow hierarchichal assembly of the rosette nanotubes with chirality that is determined by the nature of the amino acid used as the inducer. The optical activity of the helical nanotubes formed from the stacked rosettes depends critically on the nature of the amino acid inducer. L-Met being the best. Furthermore, the assembly process seems to be all or nothing. the maximum optical activity is obtained in a small range of concentrations and the aggregate can be disassembled upon heating and reassembled on cooling.

Treatment of a number of covalent polymers substituted with molecular recognition capability with suitable guests leads to chiral induction. The same crown ether–amino acid complementary pair described for the rosettes above was employed in the form of crown-ether pendant cis-transoidai poly(phenylacetylene).[20] When the achiral polymer is treated with amino acids (in the form of their hydroperchlorate salts in acetonitdle) a large induced CD signal is observed in the backbone of the polymer. The polymer is sensitive to small enantiomeric excesses in the amino acid, as little as 0.005% enantiomeric excess of alanine can be detected. In a similar vein, *cis*-transoidal poly(carboxyphenylacetylene) shows induced circular dichroism when treated with nonracemic chiral amines.[21] In addition, the system displays chiral memory, in that treatment of the complex with achiral amino alcohols results in retention of the chiral polymer backbone.

Supramolecular polymers are also partial to induction of chiral structures.[22] Biureidotriazines form polymeric chains maintained by the extremely strong complex formed by the self-complementary unit through four hydrogen bonds. When chiral "arms" are attached well away from the ureidotriazine units, chiral induction is seen in the polymers of the difunctional monomers, thanks to stacking of the neighboring hydrogen-bonded pairs.[23] Also, startlingly. when a chiral monofunctional ureidotriazine was used to cap a polymer formed in dodecane from an achiral biureidotriazine, significant chiral induction was observed from the end of the polymer chain through the secondary structure. Heterocomplementary monomers, just one of which contained a stereogenic centers, were also used for the formation of chiral suprarnolecular polymers.[24] In this case, the transfer of chirality was observed in the helical fibers witnessed in electron microscope images.

SUPRAMOLECULAR ASSISTANCE IN REACTIONS DISPLAYING CHIRAL INDUCTION

The diastereoselectivity of covalent bond-forming reactions can also be influenced by supramolecular effects. The polymerization of isocyanides shows this effect. When isocyanopeptides are polymerized under certain conditions. a dramatic dependence of reactivity on the stereochemical nature of the amino acid residues present in the monomer.[25] The origin of this difference appears to lie in the orientation of the hydrogen bonds acting between the monomers, which line the isocyanides up into chains in the solid state as well are present in the polymer chains.

Supramolecular effects were also observed during the formation of poly(isocyanide)s derived from chiral promesogenic phenyl benzoate-containing monomers.[26] These effects were seen through the degree of chiral induction from the stereogenic centers in the side chains to the polymer backbone during the kinetically controlled polymerization in different solvents and at different concentrations. Importantly, the sense of chiral induction seen during the polymerizations in certain cases was identical with the helicity induced in nematic and smectic C phases by the monomers.

PHYSICAL FIELD-INDUCED CHIRALITY IN SUPRAMOLECULAR SYSTEMS IN EQUILIBRIUM

Simple stirring is known to induce chirality through different mechanisms. Stirring during crystallization, for example, can lead to enantiomerically enriched samples. The origin of this chiral induction lies in the breaking of the first formed crystals into many pieces, which in turn, act as nucleation sites. Stirring solutions of protonated porphysins — which form aggregates as concentration is increased or as the ionic strength is changed — results in the formation of vortices that are able to influence the chirality of the growing supramolecular system,[27] as observed in the CD spectra of the aggregates. It was suggested that this kind of vortex effect, observed under rotary evaporation and stirring, may be general for supramolecular systems that are formed under kinetic control.[28]

Irradiation of switchable systems by circularly polarized light is another way of inducing chirality in racemic compounds. Racemic sterically hindered alkenes can be switched in solution using circularly polarized light to give enantiomeric excesses of only about 0.1%.[29] In order to amplify this small effect, the racemate was used as a dopant in a nematic liquid-crystal phase. and the resulting achiral mesophase was irradiated with circularly polarized light. A cholesteric phase resulted because of the small enantiomeric excess of the sterically hindered alkene. This system is a three-way switch. Irradiation with left or right circularly polarized light generates differently handed cholesteric phases. while irradiation with linearly polarized light affords the nematic phase.

Irradiation of racemizing species in solution with unpolarized light in a strong magnetic field can also give rise to small enantiomeric excesses. thanks to magneto-chiral anisotropy.[30] The effect was observed for the potassium salt of chromium *tris*(oxalate)—an ideal system for magnetochiral anisotropy in that it has high natural CD and magnetic CD asymmetry factors—in water. In a field of 10 Tesla, an enantiomeric excess of about 1×10^{-4} was observed. which equilibrated back to zero with time. But it was proved beyond doubt that photochemistry with unpolarized light in a magnetic field are enantioselective, and it was suggested that it be considered when addressing the origins of the homochirality of biological systems.

CONCLUSION

The ability of chemists to induce chirality through noncovalent bonds in systems in which it is absent was achieved in certain systems with efficiency on a number of occasions. some of which were highlighted in this review. The phenomenon is dramatic and potentially useful. However, the exact pathways of chiral transfer from the molecular through supramolecuiar to the macroscopic level are poorly understood in general. The use of physical fields in the induction of chirality has a long history but is still poorly understood. It is surely the conformations of molecules and their relative dispositions in aggregates that are key in the propagation of chirality. and the battery of analytical and theoretical techniques available today are sure to help in determining these factors and will aid in the rationalization and prediction of chiral induction.

ACKNOWLEDGMENTS

We warmly thank Dr. Reiko Oda (Institut Européen de Chimie et Biologie, Pessac, France) for supplying the TEM images in Fig. 3. and Dr. "Bert" Meijer (Eindhoven University of Technology, Holland) for supplying the graphics for Fig. 6. Classical Descriptions of Inclusion Compounds

Yuri Alexseevich Dyadin (Deceased)
Irina Sergeevna Terekhova
The Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russia

INTRODUCTION

Clathrates. or inclusion compounds, are the typical representatives of supennolecular species. We may define them as the compounds formed by inclusion of one kind of molecules, called guest molecules. into the cavities of a crystalline framework composed of the molecules of another kind (or into a cavity of one large molecule), called host molecules, without forming any specific chemical bond between guest and host. Unlike the case of traditional chemical compounds, favorable spatial complementarity of the guest and host subsystems. not chemical reactivity. plays the important role in formation of these compounds from the components. This principle of formation allows molecules that are coordination saturated and do not interact chemically with each other to be brought together, so that they form supermolecules or supermolecular crystalline phases that are thermodynamically more stable than a mixture of initial components.

BRIEF HISTORY

J. Priestley (1778) seems to be the first to have observed the formation of a compound that today we call clathrate. He described "anomalous" ice formed at positive temperature. which sank in the aqueous solution of sulfur dioxide (also discovered by him). Since then, for nearly 170 years, outstanding chemists of the world H. Davy, M. Faraday, F. Wohler, and B. Rooseboom[1] often encountered these compounds. In some cases, they approached the understanding of their nature, however, for a long time these coinpounds were mainly considered as laboratory curiosity. The crucial role of van der Waals forces in the formation of these compounds was highlighted for the first time by Russian chemist B. A. Nikitin in 1936–1938 during the investigation of molecular compounds of noble gases.[2] However, the nature of the compounds under question was discovered in the most complete manner by H. M. Powell in 1947–1948 in x-ray crystallographic studies on the compound of β-hydroquinone with SO_2 (and also with other volatile components: HCl. HBr. Ar, Xe), which showed that the guest molecules were enclosed into the cavities of the framework formed by hydroquinone molecules and were not bound to the framework by any other forces than weak van der Waals interactions.[1] Independently, but somewhat later (in 1949); the same conclusion was made by M. von Stackelberg on the basis of x-ray analysis of the hydrate of sulfur dioxide,"' and by W. Schlenk who investigated channel adducts of urea and thiourea.[4] In 1956 to 1959, van der Waals and Platteeuw[5] constructed a statistical–thermodynamical ideal model of clathrate formation. Later, the compounds were discovered in which weak chemical interactions occur between guest and host molecules; these compounds are coordinatoclathrates, an example being trimethylamine hydrate $(CH_3)_3N{\cdot}10{,}25H_2O$, in which the amine molecule occupies the cavity of the water framework and is bonded to it through a hydrogen bond."' In the 1960s, C. J. Pedersen[7] and J. -M. Lehn[8] introduced new species into the class of inclusion compounds: complexes of the alkali metal salts with crown ethers and cryptands (clathratocornplexes): in this case. the interaction between guest and host subsystems is rather strong, but spatial complementarity has a pronounced effect on the properties of the resulting compounds.

MAJOR IDEAS, TERMS, CLASSIFICATIONS

The term "clathrate" (originating from Latin word ''clathratus,'' which means closed, surrounded from all sides (in turn, originating from the Greek words κλειθρον, κλεις=lock, key) was introduced by H. M. Powell in 1948, as we mentioned above, for the inclusion compounds of β-hydroquinone that have a crystalline framework with cavities shaped as isometric cages in which the guest molecules are located. In 1949, W. Schlenk introduced the term "inclusion compounds" (Einschluβ-verbindungen) for channel compounds of urea and thiourea. At first, the term clathrate was used to denote only cage inclusion compounds. At present: along with the term inclusion compounds, it is used independently of the shape of cavity; this points to the fact that there are no specific chemical interactions between the guest and host.

Clathrates may be classified according to the shape of the cavity into the following types: cryptatoclathrates— the compounds of this type have cage structures (κρυπτον is secrecy in Creek); tubulatoclathrates — one-dimensional channel inclusion compounds (tubus is the Latin tube):

DOI: 10.1081/E-ESMC 120006062

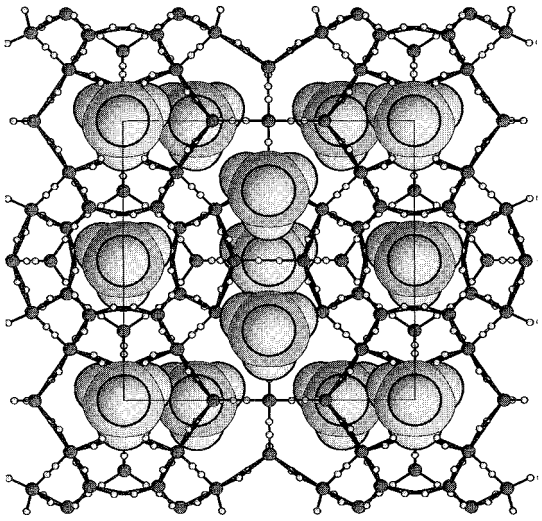

Fig. 1 The cubic structure I (CS-I) hydrate with methane molecules accommodated in the dodecahedra] (D) and in the tetradecahedral (T) cavities. (*View this art in color at www.dekker.com.*)

iiltercalatoclathrates — layered inclusion compounds. Another classification is based on the type of bonding of the host molecules in the framework. The host framework in lattice clathrates is composed of molecules bonded with each other with relatively weak specific bonds (most often hydrogen bonds). The guest molecule located within a cavity of such a frainework is surrounded by several host molecules (for example, by six molecules in hydroquinone clathrates or 20–38 molecules in aqueous clathrates). When dissolved or melted. the clathrate compound of this type decomposes. Thermal stability of a clathrate may be higher than that of a host component by several tens of degrees but not more: for lattice clathrates, the upper limit of stability is about 200–250°C. The host framework in macromolecular clathrates is completely constructed using covalent bonds: it is impossible to distinguish an individual host molecule. and the framework is a macromolecule as a whole. Clathrasils[9] may serve as an example of this type of clathrates. SiO_2 being the formula unit in the framework. The structure of melanophlogite is identical to that of methane or xenon hydrate (Fig. 1). with silicon atoms occupying the positions of oxygen atoms of water molecules, and Si–0–Si bonds presenting instead of H-bonds. Guest molecules in clathrasils can be the same as those in the hydrates. because the cavities are close in size; however, it is clear that tremendous differences are observed in thermal properties. The host molecules in monomolecular clathrates are large: each has one (or more) cavities in which guest molecules can be located. A feature of monomolecular clathrates is that they can also exist in the liquid phase. The typical examples of monomolecular clathrates are inclusion compounds of cyclodextrins.[10] Some examples of inclusion compounds classified in accordance with the type of cavities are given below.

Cage-Type Inclusion Compounds

The major structural motif determining the structure of host framework in β-hydroquinone clathrates is a hexagonal ring $(OH)_6$ composed of hydrogen-bonded terminal OH groups of six hydroquinone molecules (Fig. 2). Because a hydroquinone molecule has two hydroxyl groups occupying *p*-positions, a three-dimensional hydrogen-bonded single β-hydroquinone structure (δ-framework) can be constructed; however. it is absolutely

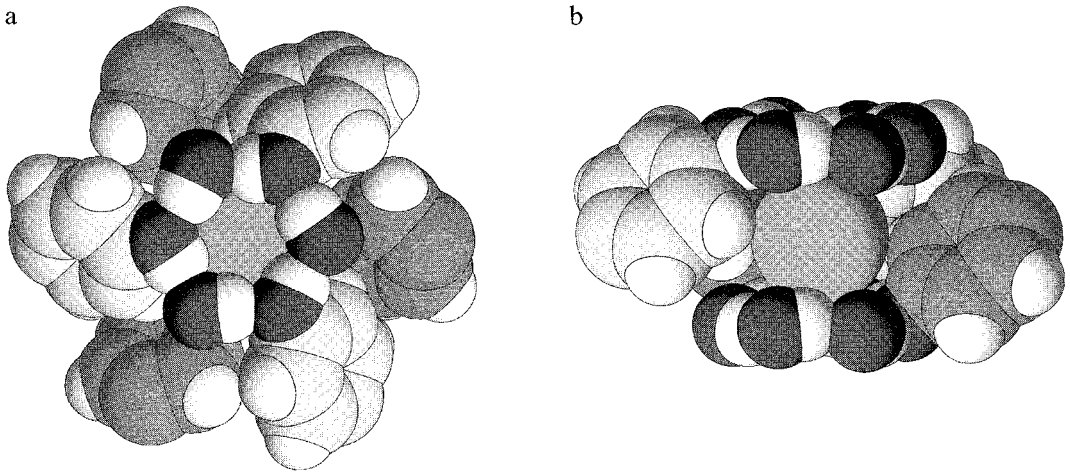

Fig. 2 The cavity in the β-hydroquinone structure with included Xe molecule. (a) the top view. (b) the side view. (*View this art in color at www.dekker.com.*)

unstable in the absence of a guest. The host framework in β-hydroquinone clathrates consists of these two mutually interpenetrating translation-equivalent unconnected networks. Cavities in this structure can accommodate small guest species HCl, HBr, CH_4, and CH_3OH, inert gases, each sandwiched between two $(OH)_6$ rings positioned at distance 5.5–5.6 A. The structural stoichiometry (ratio of the number of cavities to the number of host molecules) is 1:3, however, the real degree of cage occupancy can change depending on clathrate formation conditions.[11] The molecules of phenol and Dianin's compound (which can be considered as a phenol derivative with a large substituent) do not have a second functional OH group and, hence, cannot create the three-dimensional network, so the structural fragment described; composed of 12 host molecules (Fig. 2) is a supermolecule with a cavity inside of it. These supermolecules are packed in a structure tightly (in this case, cavities are only inside a supermolecuie, as in the structure of Dianin's compound), or there is a free space of a molecular size between them, in which the guest molecules can also be accommodated (phenol clathrates). Small cavities in the phenol clathrate framework of a size of 4–4.5 Å may enclose the same guests as the cavities in the β-hydroquinone framework: HCl, HBr, inert gases. SO_2. Each large cavity can enclose several molecules: 4HCl. 4HBr, $3SO_2$; thus, the stoichiometry of clathrates with small guests like HCl is 5:12, and for SO_2 and similar molecules it is 4:12.[12] In the cavities of Dianin's cornpound clathrate framework, the distance between hexagonal $(OH)_6$ rings is ~11 A, and different numbers of guest molecules (CCI_4, CH_3OH, CH_3NO_2, C_6H_5Br), depending on their size, can be located within the cavity. At present, several 10s of analogues of Dianin's compound capable of clathrate forination were synthesized.[12] Replacement of the structure-defining motif in the host frameworks of phenol clathrates and similar compounds, i.e., a six-membered $(OH)_6$ ring, by a benzene molecule with voluminous substituents led to the synthesis of a new type of host, the "hexahost.'' Hexahosts based on polynuclear aromatic hydrocarbons (naphthalene, anthracene, coronene) were also synthesized.[13]

Water can build a number of frameworks close in energy content. Because of this, clathrate hydrates of different structures can be formed, depending on the sizes and shapes of the guest molecules and on the conditions of clathrate formation. More than a dozen water clathrate frameworks are known.[6] The most common structures found in the gas hydrates are Cubic Structure I (CS-I), Cubic Structure II (CS-II), Hexagonal Structure III (HS-III), and Tetragonal Structure I (TS-I). The first two occur most frequently. Such guest molecules as argon, krypton, xenon; methane, acetylene, and hydrogen sulfide, chlorine stabilize CS-I (Fig. 1). The unit cell contains 46 water molecules and eight cavities. The eight cavities contain two so-called ''small'' dodecahedral *D*-cavities and six ''large'' tetradecahedral *T*-cavities, thus giving the stoichiometry 8:46=1:5.75; however, because a small fraction of cavities remains empty, the hydrate number often increases to six or more. If a guest molecule is larger [for example: $CHCl_3$, CCl_4, tetrahydrofuran (THF), etc.], CS-II hydrates are formed, their stoichiometry being 1:17. In this case, guest molecules occupy only large cavities (hexadecahedral H-cavities that are somewhat larger than T-cavities in CS-I). Small D-cavities, the number of which in the structure is two times more than the number of large ones (unit cell formula is $8H{\cdot}16D{\cdot}136H_2O$), remain unoccupied. More complicated molecules can aiso stabilize the water clathrate frameworks. For example, tetrabutylammonium and tetra-i-amylammonium salts with water form clathrate polyhydrates under definite conditions. Water molecules with simple anions (like halide, hydroxy, nitrate, formiate, etc.) build a crystalline water–anion framework, forming hydrogen bonds between them (hydrophilic inclusion), while each substituent of the cation occupies one of the large cavities arranged in the structure tetrahedrally. The vertex shared by all four cavities is occupied by the central atom of a cation (nitrogen in the case under consideration) that displaces a water molecule and does not form any H-bonds with adjacent molecules (hydrophobic inclusion). Hydrophobic–hydrophilic inclusion of an anion is also possible. For example, a carboxylate anion displacing two water molecules with its oxygen atoms builds one of the framework edges, while the hydrocarbon part of the anion (starting frorn acetate) occupies vacant dodecahedral (small) cavities, the number of which in these structures is not less than the number of anions.

Because in the structures of different hydrates the ratio of the small cavities to the large ones varies within the broad range $(2 > Rt > 0)$ (if the small D-cavities are vacant), the packing coefficients (k) vary considerably $(0.47 < k < 0.60)$. Therefore, the behavior of hydrates under pressure varies, too: from destabilization (dt/dp = −2.5 K/kbar for $THF{\cdot}17H_2O$; k = 0.485) in the case of CS-II, to a considerable stabilizaion in the case of CS-I hydrates (dt/dp=7.0 Wkbar for $C_2H_4O{\cdot}6.7H_2O$; k = 0.537), and of hydrates with completely occupied cavities (dt/dp=10 K/kbar for $THF{\cdot}0.5(C_3H_7)_4NF{\cdot}16H_2O$; k = 0.591).[14,15] In the latter example, the large *H*-cavities are occupied by the TMF guest molecules, and the small dodecahedra1 ones are occupied by tetrapropylammonium-cation guests. The CS-II hydrates can also be stabilized with the help of small molecules of inert gases (for example, Xe) or CH_4. In the case of THF hydrate, the double hydrates of the composition $THF{\cdot}2Xe{\cdot}17H_2O$ (k = 0.619), $THF{\cdot}2CH_4{\cdot}17H_2O$ (k = 0.568) are formed that are stabilized by pressure (Fig. 3). In the classic CS-II hydrates with 1:17 stoichiometry, *R*t is the largest (for the hydrates that can exist with absolutely vacant small

cavities). their packing coefficients are the smallest (k = 0.47–0.52, after the ice *Ih*. k = 0.43). and, therefore, they are destabilized by pressure. With a pressure increase, they become thermodynamically unstable, and a? relatively low pressure (P < 3 kbar), they are replaced by hydrates with a stoichiometry about 1:7 (CS-I hydrates), which are stabilized by pressure (Fig. 3).

Clathrates sf Metal Complexes

In Hofmann's compounds. the clathrate nature discovered by H. M. Powell in 1952,[1] the host coordination molecule. composing the framework: has a chemical formula $[Ni(CN)_4Ni(NH_3)_2]$. These units are bound with covalent bonds via bridging CN ligands, forming layers of the host framework positioned one above another at a distance of 8.28 Å and touching each other with ammine ligands, protruding above and below the layer at the octahedral Ni atom (Fig. 4). Cavities between layers are efficiently filled with guest molecules. for example, benzene, forming the compound $[Ni(CN)_4Ni(NH_3)_2]\cdot 2C_6H_6$. Replacement of one of the two nickel atoms in the structure, i.e., octahedral nickel, by the metal ions with the same coordination geometry (divalent Mn. Fe, Cu. Cd) does not result in any substantial change in clathrate formation ability. Replacement of the square planar $Ni(CN)_4$ by tetrahedral $Cd(CN)_4$ or $Hg(CN)_4$ groups leads to a substantial change in the structure and the cavity shape, but the ability to form clathrates is not lost.[16] Similar clathrates form so-called Schaeffer complexes. The host complex has a formula $[M(MePy)_4(A)_2]$, (here, *MePy*=4-methylpyridine, *M*=divalent octahedrally coordinated metal atom, *A*=monovalent acido ligands like halides, nitrate, and, most frequently, NCS).[17] Unlike the Hoffmann clathrates, the host molecules in the Schaeffer clathrates are not bound by covalent bonds; they are packed in a crystal together with guest molecules by van der Waals forces. Some host complexes are stable in their own crystalline phase. for example, $[NiPy_4(NCS)_2]$; clathrate formation causes their additional stabilization. Others can exist in a crystal only when cocrystallized with guest molecules, which stabilizes the structure. For example. the complexes $[Zn(MePy)_4(NCS)_2]$ and $[Cu(MePy)_4(NCS)_2]$ are completely unstable, although clathrates $[Zn(MePy)_4\text{-}(NCS)_2]\cdot G$, $[Zn(MePy)_4(NCS)_2]\cdot 2/3G$, or $[Cu(MePy)_4\text{-}(NCS)_2]\cdot 2G$ are stable—they were isolated, and their structures were determined. However. when a guest molecule is removed, two methyl pyridine ligands split off immediately, and the complex $[M(MePy)_2\text{-}(NCS)_2]$ is formed. These examples demonstrate contact stabilization of molecules, in this case. of the host molecules.[18] Contact stabilization is responsible for the stability of polyiodide guest molecules in the channels of starch amylose or polyvinyl alcohol. The polymeric guest molecule composed of iodine atoms is unstable without noncovalent support of the host.

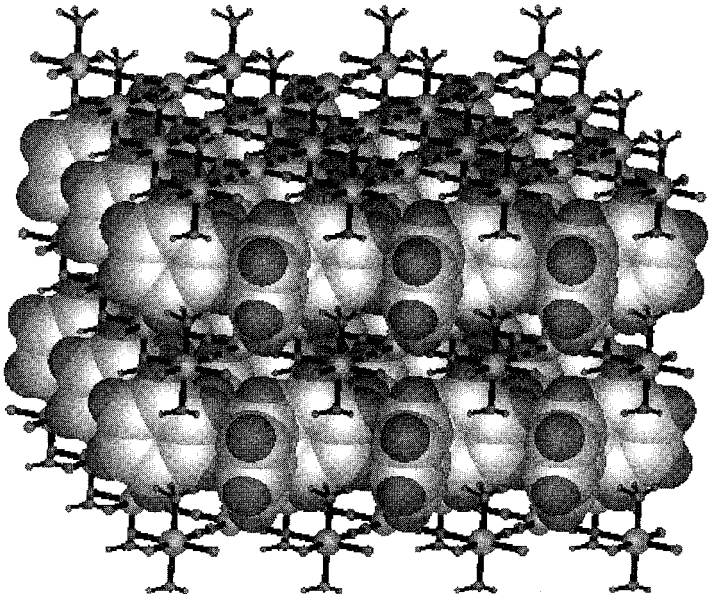

Fig. 4 The structure of Hofmann compound $[Ni(CN)_4Ni(NH_3)_2]\cdot 2C_6H_6$.

Channel-Type Inclusion Compounds

In urea clathrates,[1-4] the hydrogen-bonded host framework (β-urea) consists of an array of parallel hexagonal channels, the diameter of which (5.5 Å) is practically the same along their length (Fig. 5). There are six urea molecules in the unit cell of β-urea, and the corresponding channel length is 11.00 Å. So. the composition of a clathrate (the ratio of a number of urea molecules to a number of guest molecules) is $m=6\cdot l:11.00$, where l is the length of the guest molecule in Å. The most suitable guests are *n*-alkanes and others with minimal branching (alcohols. amines). With an increase of the length of a guest molecule, the thermal stability of urea clathrates increases; for example, the compound of urea with *n*-hexane decomposes at 38°C, with *n*-hexadecane at 106°C and with polyethylene at 148°C (which is 15° above the melting point of pure urea). In the absence of a guest. the clathrate β-framework is absolutely unstable. Channel compounds of thiourea are similar to those of urea. but the channels have broadened (≈7 Å) and narrowed (≈6.2 Å) regions. Clathrates are formed with CCl_4, cyclo-C_6H_{12} and isoparaffins. Perhydrotriphenylene forms a hexagonal β-framework with channels about 5.5 Å in diameter when cocrystaliized with nonbranched guest molecules (*n*-paraffins). Because the host molecules, constituting the channel walls, are bound by van der Waals forces, the structure is flexible; clathrates can be formed with larger guest molecules (cyclohexane, bromoform, butadiene).[20] Triorthothymotide (TOT) is a universal host molecule able to form inclusion compounds of channel and cage types. As in the case of perhydrotriphenylene, host–host interactions in the host framework are only of the van der Waals-type, resulting in flexibility of the structure. Surprising is the ability of TOT to form inclusion compounds with guest molecules of various sizes, from alcohols to polynuclear aromatics and organometallic complexes of Cr, Mn, W.[21] Cholic acids belong to channel inclusion compounds in which desoxycholic acid is the host, while the guests are such molecules as stearic, palmitic, and oleic acids.[22]

Layered-Type Inclusion Compounds

A characteristic feature of layered compounds is that the interaction within a layer is much stronger than the interaction between the layers. In the majority of layered compounds (graphite: sulfides of transition metals, clays, phosphates and phosphonates of Croup IV metals). molecules of a layer are bonded by covalent bonds, thus forming a giant macromolecule, while the interaction between the layers is mainly via van der Waals forces. As a consequence. layered solids usually exhibit a high degree of anisotropy in physical properties. There are several classifications of layered solids.[23] Based on layer charge, they can be divided into two groups: layers characterized by the presence of charge and uncharged layers. The first group includes some cationic and anionic clays: montmorillonite. muscovite, hydrotalcite-type anionic clays, and Group IV metal phosphates α-$M(HPO_4)_2\cdot H_2O$ (M=Ti, Zr, Ge, Pb, Sn). The compounds

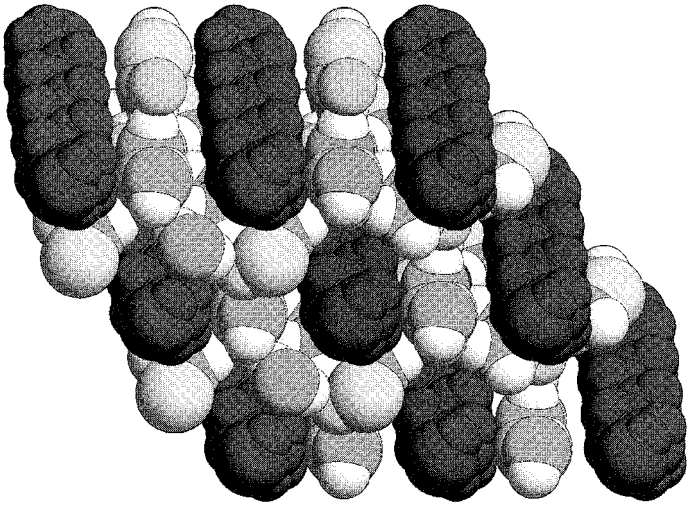

Fig. 5 The molecules of n-alkane in the urea channels. (*View this art in color at www.dekker.com.*)

of the second group. in turn. can be subdivided into insulators and electronic conducting layers.

The typical examples of insulators are nickel cyanide, nickel hydroxide. and alkyl- and arylphosphonates of Group IV metals. Among this group. α-Zr diphosphonates of general formulae $Zr(O_3P-R-PO_3)$ (pillared compounds) are of interest due to their application potential as ion and molecular sieves. In these compounds, adjacent inorganic layers consisting of tetravalent Zr atoms bound to oxygen atoms belonging to $R(PO_3)_2$ groups are covalently joined by divalent organic groups R (aryl, alkyl). Changing the length of organic pillar R and the distance between adjacent voluminous pillars, materials of desired interlayer distance and porosity can be obtained.[7,8]

The electronic conducting layers include graphite and transition metal dichalcogenides exhibiting intercalation and redox properties. Graphite layers can act as acceptors of electrons in the interaction with strong reducing agents (alkali metals) and as donors of electrons in the interaction with oxidizers (halogens. metal halides PtF_6, IrF_6, OsF_6, AsF_6). Intercalation of metal atoms (M) makes carbon layers (A) move apart and shift, so that they stand exactly one above another (an *AMAMA*. . .stacking sequence, unlike pristine graphite, in which layers are shifted with respect to each other and form an *ABABABA*. . .stacking sequence). If the interlayer space is completely occupied by metal atoms. Stage 1 intercalation compounds are formed. The stoichiometry for this arrangement of atoms is MC_8 for heavy alkali metals (starting from potassium) (Fig. 6). If metal layers are separated from each other by two, three, or more graphite layers. Stage 2, Stage 3, and so on compounds are formed. Stage 1 compounds with alkali earth metals (Ca, Sr. Ba) and lanthanides (Sm, Eu, Yb) were synthesized and under definite conditions, compounds with iron were obtained. Graphite acts as a donor of electrons when it interacts with halogens. and intercalation compounds with Br_2, ICl, IBr molecules are easily formed, while the compound with Cl_2 is extremely unstable. At low temperatures (15–100°C), graphite interacts with fluorine with the help of catalysts (HF, AgF). This fluorination results in the formation of graphite

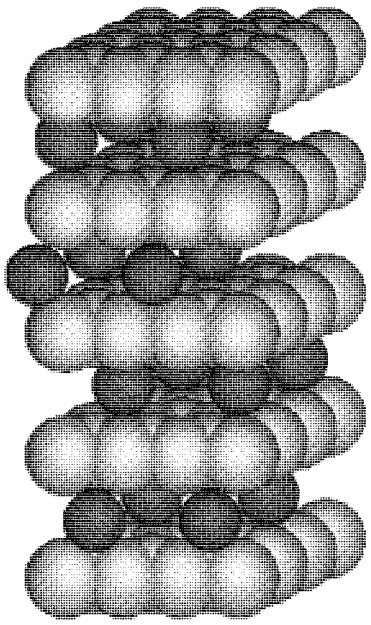

Fig. 6 The Stage 1 graphite intercalation compound of potassium KC_8. (*View this art in color at www.dekker.com.*)

fluorides with different compositions. Among them, C_6F[25] is the intercalation compound of fluoride ions into graphite. In layered compounds of Ti, Zr. Hf, Nb and Ta dichalcogenides, the slabs comprising the structure are not monolayers. as in the case of graphite or boron nitride, but are coinposed of two anionic monolayers framing a cationic layer. Dichalcogenides of transition metals form inclusion compounds with alkali metals. some alkali earths, as well as with Eu and Yb. Similar to the case of graphite, compounds of different staging can be formed with alkali metals.[26]

STOICHIOMETRY

The stoichiometry of clathrates may be easily determined from structural data—it is numerically equal to the ratio of the number of cavities to the number of host molecules in the unit cell. The real stoichioinetry can differ from the structural if the cavities are only partially filled with guest molecules. It is reasonable to consider three cases:

1. The composition of the clathrate compound is constant. as is possible in the case of host frameworks that are extremely unstable in the absence of a guest. As examples, the compound of urea with n-decane $C_{10}H_{22}\cdot(8.06 \pm 0.06)(NH_2)_2CO$, or the hydrate $(i\text{-}C_5H_{11})_4NF\cdot(26.8 \pm 0.03)H_2O$ may be cited. In both cases, the clathrate composition corresponds to the structural within the experimental error and remains constant in the whole stability region.
2. The host framework is thermodynamically stable in the absence of the guest molecules. In this case. solid clathrate solutions are formed on the basis of the α-modification of the host. which means that no new phase is formed. The inclusion of the guests results in additional stabilization of the α-structure. For example. α-hydroquinone with included krypton melts at a temperature 1°C higher than that of the pure α-phase.
3. The host component has a metastable modification with cavities of molecular size, which becomes stable above a certain value of the degree of filling the cavities. In this case. the clathrate is a new phase of variable composition due to changing the degree of cavity filling upon changing equilibriuin conditions. Examples include the classic hydroyuinone clathrates based on the β-hydroquinone framework, with such guests as Ar. Kr, Xe, H_2S, SO_2, HCl, HBr, etc.[11]

CONCLUSION

Similarity in the chemical behavior of atoms. molecules, or their fragments (functional groups) is determined predominantly by the similarity of their electronic structures. It suffices to look at the elements in the groups of the Periodic Table or to compare chemical reactions, for examples, those of amines, ketones, or alcohols. The decisive role in supramolecular chemistry is played by the sizes and shapes of molecules rather than their chemical natures. For example, from the viewpoint of clathrate chemistry, xenon. hydrogen sulfide. chlorine, methane, sulfur dioxide, and phosphine are all analogous. In spite of different chemical natures, these molecules have a common feature, which is the correspondence in size and shape to the geometry of the cavities in the CS-I hydrate framework. And. all of these form hydrates of this structure. These guest molecules can also stabilize the β-hydroquinone framework (besides chlorine, which oxidizes hydroquinone). On the other hand, the behavior of chemical analogs, for example, normal and branched secondary alkylamines, differs significantly on reaction with urea: the first ones form tubulatoclathrates, while the latter do not. This difference provides the possibility of efficient separation of isomers. As the cavity shape becomes more complicated. the selectivity of clathrate formation reactions increases substantially. In 1894, the Canadian scientist Emil Fisher introduced the lock and key principle (see "The Lock and Key Principle") to explain highly specific enzyme reactions. In other words, if the substrate is complementary to enzyme (or guest–host in our terms). like a key to a lock, the reaction proceeds. However, as a rule, a host (and a guest if its molecule is complicated) does not exist beforehand in the clathrate form. The necessary modification of the host framework and proper conformation of the guest is induced during their interaction. Cascade inclusion processes are possible. For example, hernoglobin is composed of a protein part (globin). including a nonprotein heme molecule (iron porphyrin complex) without any valent bonding. This heme molecule attains a conformation with a basket-shaped cavity which. in turn, includes an oxygen or carbon dioxide molecule. known to exchange for each other easily.

As a discipline, clathrate cheinistry is the most advanced part of supramolecular chemistry. because its subjects. despite relative complexity, are amenable to strict quantitative experiment and interpretation. which allows for the forming of concepts that would simplify the understanding of more complicated supermolecular species (as in the example mentioned above).

Classification and Nomenclature of Supramolecular Compounds

Edwin Weber
Technische Universität Bergakademie Freiberg, Freiberg, *Germany*

INTRODUCTION

Although suprainolecular compounds are general and were recognized more than 100 years ago, beginning with Emil Fisher's "lock-and-key principle" of enzyme-substrate recognition."' the real rise of this field started in the late 1960s or early 1970s. after the discovery of the crown compounds and cryptands by the pioneers of the field, C. J. Pedersen and J.-M. Lehn, and also including the pioneering work on host–guest chemistry by D. J. Cram. In 1987. these leading proponents of what is now called supramolecular chemistry[1,2] were awarded the Nobel prize in chemistry.[3–11] With this. the era of supramolecular coinpounds rapidly expanded into different disciplines and fields, from supramolecular organic to the rising new field of nanotechnology, including special subjects such as molecular recognition. self-assembly. and crystal engineering.'".'" All that produced new classes of compounds, with new names, scientific terms, acronyms, and notations being illustrated and specified briefly in the following. However. as the so-called host–guest chemistry[14] sponsored to the great majority and most remarkable structural variations in the field, having as a consequence a variety of detailed nomenclature, the host–guest (or receptor–substrate) compounds take precedence over other supramolecular compounds. which are discussed more briefly or referred to under specific keywords (see cross-references at the end of the article).

DEFINITION AND BASIC CLASSIFICATION

Supramolecular chemistry may be defined as ''chemistry beyond the molecule." bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular noncovalent forces, such as metal ion coordination, electrostatic forces. hydrogen bonding. van der Waals interactions, and others.[6–15] These supramolecular entities derived from supramolecular association are generally called supermolecules or supramolecular compounds. Thus. one may say that ''supramolecules are to molecules and the intermolecular bond what molecules are to atoms and the covalent bond." This kind of definition is highlighted in Fig. 1a.

Supramolecular Compounds Designed for Host–Guest/Receptor–Substrate interactions

Within the above context. host–guest chemistry and host–guest compounds[1,"] might be seen as particular cases of suprainolecular chemistry and supramolecules, respectively (Fig. 1a). In a more specific determination. hosts are defined as (organic) molecules containin,g convergent binding sites. and guests are defined as molecules or ions containing convergent binding sites.'"[11] The terms receptor and substrate, originating from biological systems and inodels, are now largely synonymous with host and guest. respectively. in artificial supramolecular systems. However, while the hosts are usually convergent in the construction of the binding sites, receptors can be convergent or divergent, i.e., forming endo- or exoreceptor-type supramolecular associations (Fig. 1b). In particular, when the host or the receptor provides a hollow space. or any not precisely defined cavity. an inclusion compound results."' Moreover, it has become useful to divide inclusion compounds into two major classes (Fig. Ic). Those where the host substance is a single molecule possessing intramolecular cavities, and the guest molecule or molecules reside completely within the host. are designated ''cavitates'' (used here in a broad sense). In this case. the supermolecule is limited to the particular host–guest entity, accounting also for the descriptions of intramolecular. endomolecular. or monomolecular inclusion compound. Concerning the second class of inclusion compounds. there is more than one host molecule with which to construct the cavity for accommodation of the guest. In the terminology of supramolecular compounds, this species is called an extramolecular. exomolecular, or multimolecular inclusion compound. The vast majority of inclusion compounds where predominantly formed in the solid state belong to this latter category. These inclusion compounds of relevance only in the solid state are

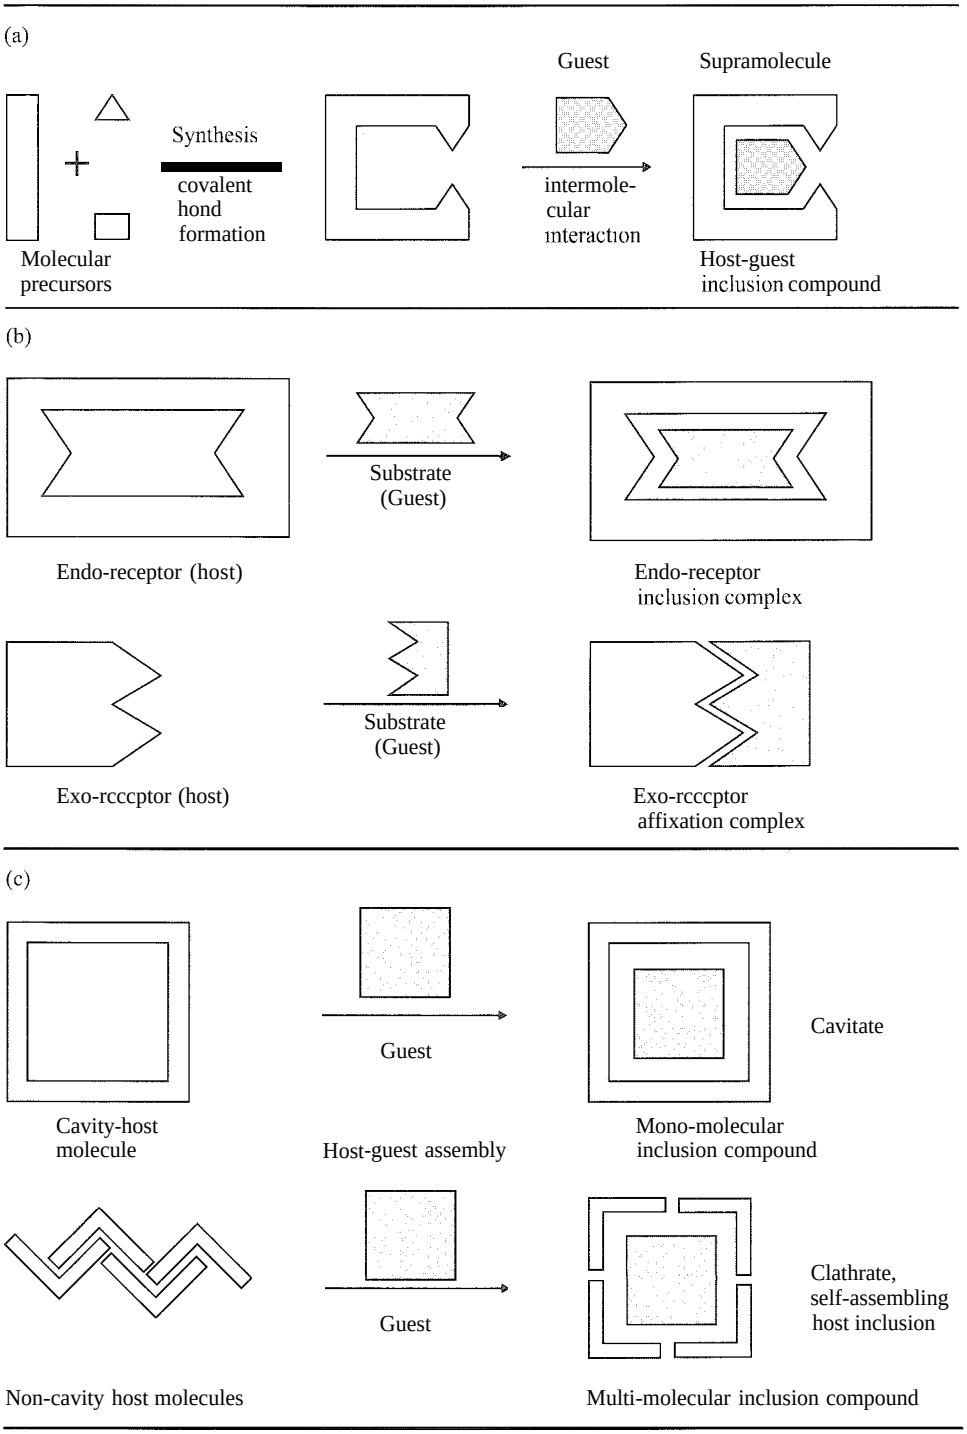

Fig. 1 Definitions and overall scheme of supramolecular events: (a) chemical host synthesis and formation of a supramolecule (host–guest inclusion compound); (b) endo- and exosupramolecular receptor–substrate (host–guest) chemistry; and (c) formation of mono- and multimolecular inclusion compounds.

Fig. 2 General classification/nomenclature and descriptive terminology of host–guest supramolecular inclusion compounds

commonly termed ''clathrates'' or "lattice-type inclusion compounds.''[17]

A further fundamental subdivision of supramolecular host–guest compounds may be made on the basis of the forces between host and guest (Fig. 2a). If the host–guest aggregate holds together by primarily electrostatic forces. including ion–dipole, dipole–dipole. hydrogen bonding, etc., the term "complex" is used. On the other hand, if species are held together by less specific and often weaker, nondirectional interactions, such as hydrophobic, van der Waals, or crystal close-packing effects, then the terms ''cavitate'' and ''clathrate'' are more appropriate.[17] Thus;

another potential way of distinguishing between complexes. cavitates. and clathrates is to make use of the fact that complexes mostly retain their identity in solution, which is largely observed also for cavitates. whereas clathrates decompose on dissolution. However, it should be noted here that there is a significant trend in the current literature to use the word "complex" to cover all of these phenomena. Nevertheless. because a great number of intermediate types of host–guest compounds exist; these borderline cases are sometimes treated as hybrids between the most applicable terms, such as "clathratocomplex" or "coordinatoclathrate." In the first case, the host–guest interaction is largely of the complex type. but there is also a distinct crystal close-packing participation. while it is the reverse in the latter case. The hybride terms ''cavitatocomplex'' and "cavitatoclathrate" are also topologically descriptive designations describing that the guest resides partly in a host cavity of a complex- or clathrate-type inclusion compound.[18]

Other subsidiary descriptive terms used to illustrate the spatial relationships between host and guest refer to the designations "layer-type" (two-dimensionally open), "channel-type" (one-dimensionally open). and ''cage-type" (totally enclosed) inclusion compound, also termed "intercalates." "tubulates.'' and "cryptates," respectively, which makes further coinbinations of descriptive hybrid terms possible, e.g., tubulatoclathrate indicating a channel-type clathrate: and so on.[15] Even more precise descriptions are possible when using terms such as ''capsular..' ''nesting,'' "perching," "sandwich." or ''wrapping" to visualize spatial relationships between host and guest (Fig. 2b–g). In addition. with respect to the number and nature of the bound guests (substrates), the resulting supermolecule (host–guest compound/receptor–substrate complex) may be mono- or polynuclear and homo- or heteronuclear, if the guests (substrates) are identical or different. The respective hosts (receptors) are monotopic or polytopic. i.e., containing one or more discrete binding subunits. Moreover, the mode of guest (substrate) binding may be monohapto or polyhapto, depending whether fixation occurs via a single or via multiple association(s)[15] (Fig. 2h–k). Another specific phenomenon involving an onion-skin- or cascade-type structure of the supermolecule is defined as a "second-sphere''[19,20] or "doll in the doll" complex (Fig. 21).

Finally. it is advantageous to distinguish in the naming between the free host (receptor) capable of forming the host–guest aggregate and the complete host–guest compound. This is achieved by using the suffix-"and.' to mean free host or uncomplexed ligand, and the ending "-ate" for the host–guest compound.[17] Thus. the cavitate-forming host cornpound is termed a cavitand. tubulands correspond to tubulates. and so on (Table 1). However, it was pointed out that this naming is misleading.

Table 1 Specification/nomenclature of hosts (ligands) and suplamolecular compounds they form (decriptive terms or names of supramolecular compounds, if existing. are given in parentheses)

a) Hosts/ligands typical of supramolecular complex formation:
Catenand (catenate)
Corand (coraplex)
Coronand (coronate)
Crown ether
Cryptand (cryptate)
Cryptaspherand (cryptaspheraplex)
Cyclam
Glyme
Helicand (helicate)
Hemispherand (hemispheraplex)
Hexacylen
Lariat ether (lariate)
Metallacoronand (metallacoronate)
Metallacryptand (metallacryptate)
Molecular cleft host
Octopus host
Pincer host
Podand (podate, podaplex)
Sargophagine
Sepulchrand (sepulchrate)
Siderophore, siderand (sideraplex)
Soccer ball cryptand
Spherand (spheraplex)

b) Hosts typical of cavitate inclusion formation
Calixarene
Capsule host
Carcerand (carceplex)
Cavitand (cavitate. caviplex)
Cyclodextrin
Cyclointercaland (cyclointercalate)
Cyclophane
Cryptophane
Hemicarcerand (hemicarceplex)
Kohnkene
Metal array host
Molecular box
Molecular square
Resorcarene
Speleand (speleate)
Softball host
Tennis ball host
Torand (toraplex)
Tubuland (tubulate)

c) Hosts typical of clathrate (crystal inclusion) formation
Clathrand (clathrate. clathraplex)
Coordinatoclathrand (coordinatoclathrate)
Hexahost
Piedfort host
Roof host
Scissors host
Spider host
Wheel-and-axle host

Specific cases: Cyclotriphosphazene. cyclotriveratrylene, Dianin's compound, hydroquinone, perhydrotriphenylene. tetraphenylene. trimesic acid. tri-o-thymotide.

because the suffix ''-ate'' is usefully used for anions, whereas a great many of the host–guest compounds referred to are cations or uncharged species. This is why it was proposed to replace it with the suffix ''-plex,'' to give caviplex, clathraplex, and so on[1**] (Table 1). Unfortunately. this suggestion for improvement has not yet been generally accepted.

Supramolecular Compounds Involving Objects Other Than Host–Guest/Receptor–Substrate Association

Because by definition supramolecular coinpounds include any chemical species resulting from association of molecules, the number and variety of compounds or materials that fall under the category are immense,[2] and the host–guest compounds. although important, make up only a relatively small segment of the whole range. Nevertheless. this majority of supramolecular compounds is far from producing descriptive terms and names compared to the host–guest compounds. Generally. they are classified into different bur broad fields, where engineered supramolecular structures and pattern motifs, mostly of nanoscale or communicating functional systems, are the center of interest. They include the so-called interlocked and interwoven systems, the crystal engineering supramolecular materials and liquid crystals. the surfactant-type aggregates and mono-/multilayers, the catalytic systems and biological mimics. the self-replicating systems, and the supramolecular devices. to mention only relevant fields of classification.[12,13,23] The structures belonging to these supramolecular compounds or materials are usually complex. yet in many cases they contain a host–guest component as part of the framework.

STRUCTURAL VARIATIONS AND TRIVIAL NAMES

Apart from the basic classification scheme given above. extremely varied structural types of supermolecules were developed. supplying a more detailed specification of supramolecular compounds by using trivial names. In the cases of the host–guest compounds. they normally refer to a particular feature of the host molecule.

Crown-Type and Cryptand Hosts

Typical examples of this category of compounds[24,25] are illustrated in Fig. 3. The essential property common to this family of host molecules is a flexible framework of multidentate donor atoms, such as oxygen. nitrogen. or sulfur. to mention but the most important. Depending on the topology with which these donor atoms are arranged. one basically distinguishes between the acyclic podands (from Greek. meaning ''foot''j. the macrocyclic ''coronands'' (from Latin. meaning "wreath or ring"). and the macropolycyclic cryptands (from Greek, meaning ''hidden'').[26] Another term occasionally used for the multidentate monocyclic coronands is ''corand,''[21,22] while the term ''crown ether" is reserved for cyclic oligoethers containing oxygen donor atoms only (Fig. 3a). Historically, these appealing structures of crown ethers are the basic units of the nowadays varieties of supramolecular hosts. That is why the term "crown compound" is also loosely used for any macrocyclic ligand having a crown-like shape. and even the acyclic podands are sometimes called ''open-chain crown compounds" in this connection. Moreover. structure types of higher category involving each compound family and hybrids between the three basic compound families are known. Thus. extending the podand concept to three dimensions gives a tripodal molecule specified as "tripodand" (see Fig. 3d). Important examples of this compound type are the naturally occurring siderophores and synthetic siderands (from Greek, meaning "iron bearer'').[12] Multiarmed representatives of the podands are the "octopus molecules",[27,28] and in the final analysis, also the ''dendrimers''[2] when containing donor sites. A molecular combination of two separate coronand rings leads to a dicoronand. and so on. The podandocoronands, e.g., are hybride compounds featuring a coronand ring with a podand side arm. Because of their graphic resemblance to a lasso they are usually called "lariat compounds'' (lariat ethers, from the Spanish ''la reata." meaning "the rope'').[29] The analogs with two side arms are named "bibracchial ethers" (BIBLEs).[29]

Other descriptive names for particular cornpounds are common in the literature. The term ''glyme'' (mono-. di-. triglyme. etc.), is actually short for ethyleneglycol dimethylethers, which are perhaps the simplest representatives of podands[27,28] (see Fig. 3b). Furthermore. azacoronands (azaanalogues of crown ethers, cf. Fig. 3g) often have unusual names. such as ''cyclam'' or ''hexacyclen'' for the respective 14- or 18-membered tetra- or haxaaza-coronands.[30] Similarly; there are trivial names such as sarcophagine (from the Greek meaning ''luxory coffin made from stone") and sepulchrates (from the Latin meaning "grave") named by analogy with the bicyclic cryptands with nitrogen (cf. Fig. 3h) and carbon bridgehead atoms, respectively. but having all-aza donor sites.[2] Another special case of an amphiphilic cryptand combining the macrocycle cyclotriveratrylene and a coronand fragment as hydrophobic and polar binding sites, respectively. is called speleand (from the Greek meaning ''cave'').[15]

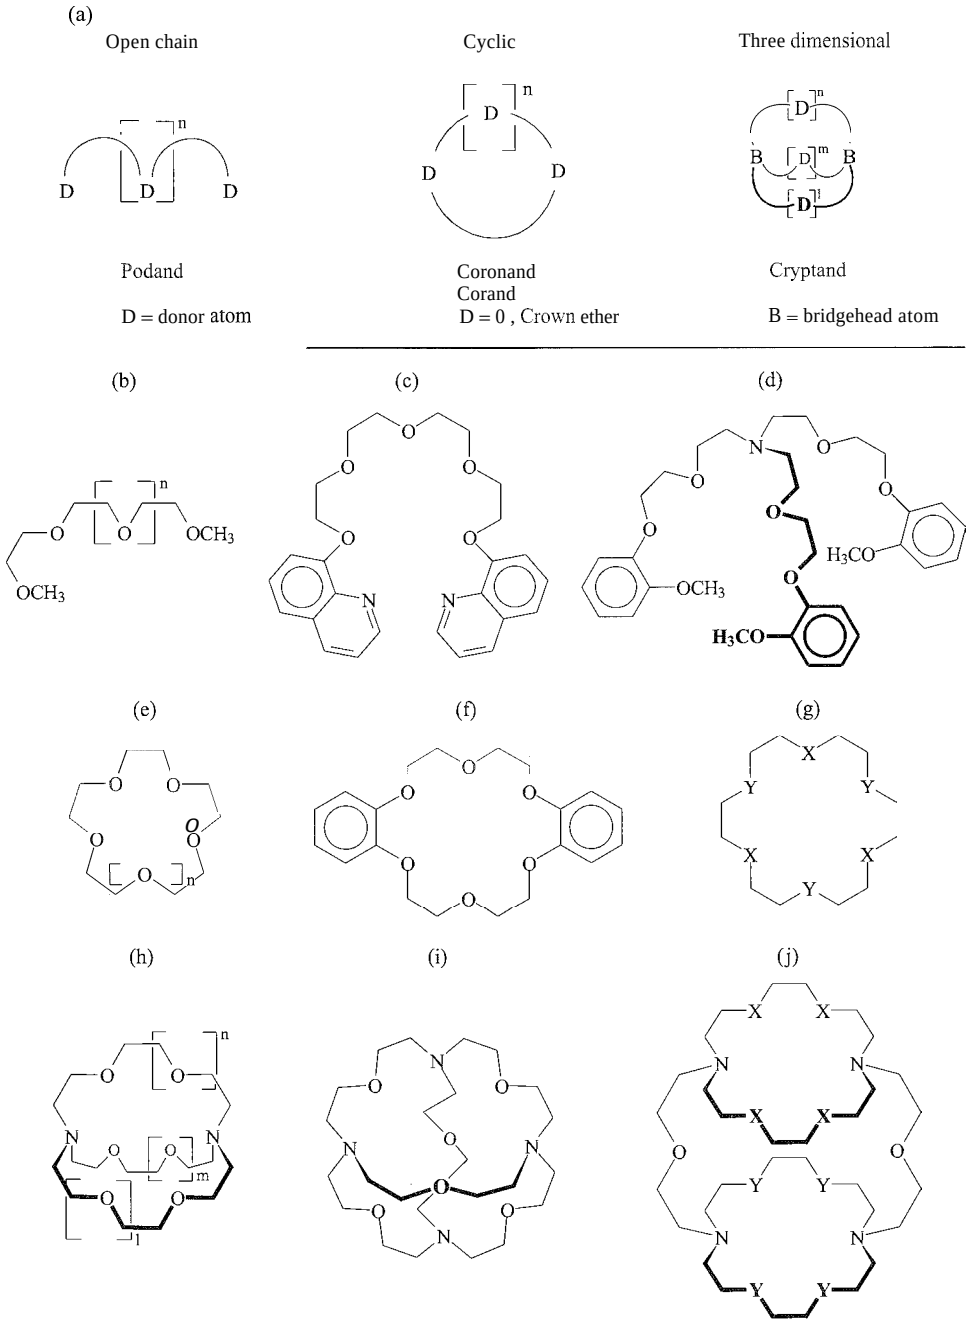

Fig. *3* Crown-type and cryptand hosts: (a) Class specification: (b)–(j) representative cases of compounds: (b,c) linear (n = 0, 1. 2. etc.) and (d) tripodal podands: (e,f) crown ethers (n = 0. 1. 2. etc.). and (g) coronand/corand (X = NH. S): (h) bicyclic (l, m, n = 0. 1. 2). (i) tricyclic spherical. and (j) tricyclic cylindrical cryptands (x = O, S).

All of these host molecules (ligands) were synthesized with the inclusion or complexation of guest species in mind, mostly of metal ions. Thus. transformation from the free host molecule to the host–guest complex changes the ending of the host name from "-and" to "-ate" or "-plex" (podate or podaplex, coronate or coraplex, etc.: see Table 1).[17,21,22]

Enforced Cavity Hosts

The features shared by all of the host molecules of this category are a high degree of structural rigidity coupled with multipoint binding, thus leading to rigid preorganization of the host for accommodation and binding of the guest[21,22] (Fig. 4). While the usual flexible podands have

a low degree of preorganization, the rigid molecular clefts (Fig. 4a) and tweezers (Fig. 4b) are much more organized in this respect.[31–33] In a sense, they may therefore be understood as highly preorganized podands. Similarly, the hemispherands, spherands (Fig. 4c), and cryptaspherands, showing enforced spherical arrangement of donor atoms, with increasing preorganization in this order, are the preorganized analogues of crown compounds and cryptands, respectively.[9,10,21] Typical of their rigid backbone are the ortho-connected anisyl units replacing the flexible ethyleneoxy fragments in the conventional crown compounds and cryptands. The stable inclusion complexes formed of the spherands are mostly called "spheraplexes."

Actually, these aromatic groups containing spherands fall under the extensive range of cyclophane hosts."] By definition, a cyclophane host must contain at least one macrocyclic ring comprising a bridged aromatic unit. This has been realized in numerous structural types (cf. Fig. 4d–g) that can be grouped to different compound classes, including the above cavitands (in a more specific sense) and carcerands, mostly having a rigid cyclophane-type framework and being generally termed container molecules.[35] The difference between the two species lies in the fact that the molecular cavity of the cavitands is usually open at one end (cf. Fig. 4f), while the carcerand (Fig. 4g) is defined as a closed molecular container or capsule without portals of significant size through which guests can enter or leave. Guest species within a carcerand to yield a carceplex are, therefore, permanently trapped or intercarcerated within the internal volume, unless covalent bond breaking within the host occurs.[36] Other individual cyclophane-type hosts making use of a characteristic kind of building block are the "calixarenes"[37,38] They are macrocycles formed from the condensation of a *p*-substituted phenol (e.g., *p*-tert-butylphenol) with formaldehyde. The most common calixarene is the cyclic tetramer derived from these components (Fig. 4h). The descriptive name "calixarene" for the whole family of compounds is indicative of the bowl-shaped conformatioil of the smaller calixarenes resembling a Greek vase called a "calix crater". Hybrid calixarenes such as calix-crowns, -cryptands, or -spherands are also known.[37,38] Closely related to the calixarenes are the resorcarenes or calixresorcarenes, which are derived in similar fashion by condensation of resorcinol with aldehydes[37,38] (Fig. 4i). Calixarenes and resorcarenes form cavitates. The torands and the kohnkene (named after his creator) are toroidal-shaped, rigid host cornpounds featming a macrocycle of condensed six-membered rings, while the characteristic curved molecular building block for the formation of cryptophanes (Fig. 4j) is cyclotriveratrylene (CTV).[2,33] These capsular hosts were given the name cryptophanes by analogy with the cryptands, while the ending "–phane" comes from membership in the class of cyclophanes. From another view, the cryptophanes fail under the class of "hemicarcerands" (closed molecular containers allowing guests enter to and exit), thus yielding hemicarceplexes on inclusion of a guest species.[36]

However, using linked aromatic rings of cyclophane type is not the only way to introduce rigidity into a host design. The most common, most studied and cheapest commercially available hosts, the cyclodextrins (CDs), are fully saturated cyclic oligosaccharides comprising usually six to eight D-glucopyranoside units, linked by a 1,4-glycosidic bond[39] (Fig. 4k). The name comes from dextrose, an early synonym for glucose. The shape of a cyclodextrin is often represented as a tapering torus or truncated funnel, making available a hydrophobic cavity into which guests can be included."[40] Another well-known host compound based on the fully saturated rigid glycoluril building block is cucurbituril[41] (Fig. 41). This barrel-shaped compound is named because of the resemblance to a gourd or pumpkin of the Cucurbitaceae family. The inclusion compounds formed of cucurbituril are of cavitate type with a likeness to a hemicarceplex.

Self-Assembling Inclusion Hosts

While the above host compounds were obtained by conventional covalent synthesis, formation of the present type of host compounds is based on a so-called self-assembling process: as a synthetic ltey step, i.e., programmed molecular components or tectons (from the Greek meaning "builder") come together spontaneously, in a well-defined way, to give noncovalent assemblies that are stable in solution.[42–44] Thus, the host assembly as such is already a supermolecule constituting the first level of hierarchy in the construction completed by formation of the inclusion compound, which is the second level of supramolecular construction. Characteristic examples of this class of host compounds are the self-assembling tennis ball and softball capsules formed of two self-complementary building blocks (see Fig. 5a) or the so-called giant capsules, being larger self-assembling cavity systems."[45] A different approach than assembling closed capsules via hydrogen bonding, as above, is to form self-assembling coordination compounds, where transition metals as structural components are used in the construction of containers. This was realized by a range of supramolecular triangles, squares, spheres, and boxes composed of different coordinatively effective building units and metal centers or partly protected metal fragments[46] (see Fig. 5b). In analogy to the conventional coronands and cryptands, the terms "metallacoronands," "metallacryptands," etc. (metallacoronates, rnetallacryptates for the inclusions) are in use for this type of supramolecular compound.[44]

Moving away from closed capsules. a number of rack, ladder. and grid structures were produced via metal-directed self-assembly using multidentate bridging ligands of different geometries to yield two- and three-dimensional synthetic receptors'"' (see Fig. 5c). From a more general point of view. this type of self-assembling metal arrays, also specified as open structures or porous systems. fa11 under the class of "coordination polymer~," an active field. Early types of coordination polyiners to be mentioned here are the Hofmann compounds and Werner clathrates, that are also classified into the below family of solid-state inclusion hosts.'"'

Interlocked and Interwoven Systems

Typical exainples of this category of supramolecular structures are the catenanes,[48] consisting of two or more rings that are interlocked mechanically without any chemical interaction between the two except nonbonding interaction (see Fig. 5d). Generally. the rings cannot be separated without breaking a chemical bond. A particular case of catenane being composed of five interlocked rings. such as in the international Olympic Games symbol. is dubbed ''olympiadane.''[49] In circumstances where the interlocked ring system is capable of acting as a ligand, the terms "catenate.' for the complex apply.[2] Compounds related to the catenanes are the rotaxanes.[48] They consist of a long. fairly linear molecule threaded through a macrocyclic ring with the linear part of the molecule terminated by bulky groups preventing slip out (see Fig. 5e). Rotaxanes without such physical barriers that can take apart are called pseudorotaxanes. They are frequently necessary precursors to rotaxanes and catenanes. The self-assembling double-helical structure of DNA provided the inspiration for a further area of supramolecular compounds called helicates.[50] Usually. they consist of extended. multidentate bridging ligands (helicands. a particular type of podands) capable of chelating different metal centers that gives rise to helical coordination complexes (see Fig. 5f). but hydrogen bonding analogues of such helical assemblies and much higher complex interwoven systems are also known.[42,43,47]

Solid-State Inclusion Hosts

The previous hosts produced host–guest compounds that usually exist in solution and in the solid state. By way of contrast; inclusion compounds of a so-called solid-state host are only in existence in the solid state. As stated above. host–guest compounds of this type are generally termed clathrates.[17,18] Although, here, a distinction between host and guest is sometimes subjective, because there are prototypes of organic and inorganic structures of host compounds following particular lines of molecular construction and concepts taken up in the trivial names.[2,47,51,52] In the first place. a distinction can be made between host molecules that feature strong mutual interactions (mostly via hydrogen bonding: see Fig. 5g,h), and those that have remarkable frames (specifically curved or propeller-type backbone, or a kind of awkward shape: see Fig. 5i,j). They result in an inefficient filling of space when host molecules are packed together in the crystalline form. thus providing voids.

The mutually interacting hosts can be simple molecules, such as water, on the inorganic and urea or thiourea on the organic side of compounds. The inclusions of ice are usually called clathrate hydrates or gas hydrates.[16] Trimesic acid (Fig. 5g) and derivatives, Dianin's compound (named after the creator), and other phenols. including hydroquinone, are further exainples of this particular compound type. Derivatives of cyclotriphosphazene. tri-o-thymotide, cyclotriveratrylene (CTV; Fig. 5i), perhydrotriphenylene (PMTP) and tetraphenylene are exempiary cases for the second category of host compounds characteristic of a curved or propeller-like framework structure. The host molecules typical of an awkward shape include all kinds of triarylmethanols and their derivatives. as well as molecular frameworks resembling a pair of scissors (Fig. 5h), a roof. or a wheel-and-axle shape[47,51,52] (Fig. 5j). Other design strategies leading to hexahosts (six-armed derivatives of benzene) or piedfort analogues (two trisubstituted aromatic rings juxtaposed: the term comes from a special coin stuck) were also successfully developed.[16,18,47] The most general approach to designing a solid structure (diamondiod network. rosette, tape motif. etc.) including host–guest systems. however. is to make use of the supramolecular synthon and crystal engineering concepts,[53–55]

Finally. the layered solids and intercalates of inorganic clay minerals and graphite as well as the zeolites as porous aluminosilicates have to be quoted here.[47]

SPECIFIED NOMENCLATURE

Due to their complex structure, systematic names of supramolecular compounds are cumbersome in use. This has given rise to many trivial names and descriptive

Fig. 4 Exemplary cases of enforced cavity hosts and their supramolecular compounds (guests symbolized in broken rings): (a) Cleft-type: (b) tweezer-type: (c) spherand; (d) cyclophane (monocyclic): (e) cyclophane ibicyclic): (f) cavitand; (g) carcerand; (h) calixarene (calix[4]arene); (i) resorcarene; (j) cryptophane; (k) cyclodextrin (β-cyclodextrin); and (l) cucurbituril.

terms. as shown above. On the other nand. systems of more detailed terminology were established for particular classes of compounds in order to make smooth yet sufficiently precise expert conversation possible.

Seen from this point of view, the naming of crown ether compounds is relatively simple.[3–5,24] The first number in the crown name designates the number of atoms in the ring and is usually given in square brackets. The second number

following the class specification crown gives the number of oxygen atoms involved. Substituents or condensations are denoted with a prefix such as benzo-. dicyclohexano-, and so on. For example, [18]crown-6 (Fig. 3e, n = 2) is a crown ether with an 18-membered macrocyclic ring containing six oxygen atoms, and dibenzo[18]crown-6 is an analogue with two benzo condensations (Fig. 3f). These are sometimes modified to 18-crown-6 and dibenz(en)o-18-crown-6 (abbreviations: 18C6 and DB18C6). Although this kind of notation is cotnmonly accepted. it gives only a rough characterization of the structure and is not clearly defined (positions of *O* atoms and substituents). In an improved notation system,[26] the name [18]crown-6 (cf. Fig. 3f) becomes 18⟨$O_6$2$_6$-coronand-6⟩, meaning an 18-membered monocyclic compound containing six oxygen atoms linked by six spacers containing two carbon atorns each to give a total of six donor atoms. Similarly, a corresponding azacoronand (azacorand) compound containing alternate oxygen and nitrogen atoms (Fig. 3g; X = O,Y = NH) is callen triaza[18]crown-6, 18⟨O_3N_3-2$_6$-coronand-6) or 18⟨$(ON)_3$-2$_6$-coronand-6⟩ showing upward precision in naming. Especially for coronands containing multiple nitrogen or sulphur donors. a notation based on the suffix ''-ane,'' along with numbers denoting the ring size and donor atorns. is in use.[30] Thus. the hexaaza analogue of 18C6, 18⟨$N_6$2$_6$-coronand-6⟩ (Fig. 3g: X.Y = NK). is denoted [18]ane-N_6, and its sulfur analogue (Fig. 3g; X,Y = S) [18]ane-S_6.

The spherical cryptands have a somewhat different nomenclature.[6–8,24] Each host is denoted by a series of numbers, given in square brackets, followed by the class name "cryptand". The numbers in square brackets and separated by dots indicate the number of donor atoms in each of the bridges between the bridgehead atoms. Thus. the most common cryptand (Fig. 3h) is termed [2.2.2] cryptand. sometimes abbreviated [2.2.2]. in accordance, the analogous compound with sulfur atorns in the bridges is designated [2$_S$.2$_S$.2$_S$]. A more specific nomenclature as for the coronands was also been developed for the cryptands but is only scarcely in use.[26] Commercially, the cryptands are sold under the trade name Kryptofix®.

By way of contrast, the podands cannot refer to a simple notation system for naming,[26] except for the glymes (e.g., gyme-6: Fig. 3b, n = 3) where the number following the class name denotes the number of oxygen atoms connected to the ethylene glycol linkages.[27,28]

Regarding the big family of enforced cavity hosts. a more specific nomenclature than class names is more or less in use only for the calixarenes and cyciodextrins. In case of the calixarenes, the number of phenolic residues is denoted by a number in square brackets.[37,38] Thus. the most common cyclic tetramer with *p-t*-butyl substituents (Fig. 4h) is termed *p-t*-butyl-calix[4]arene. When using the cyclophane nomenclature,[56] the calix[4]arene would go by the name of [1.1.1] metacyclophane. The other cyclophane-type hosts, if not too complex in structure, are named correspondingly. The three most important members of the cyclodextrin family are α-, β-, and γ-cyclodextrin (sometimes abbreviated to *r*-. β-, and ;/-CD), which possess, respectively, six. seven. and eight glucopyranoside units. Thus. the Greek letters serve to distinguish the different ring sizes of the homologous series and are essentially historical in nature.'''' Numbers in square brackets of a nomenclature rnay still have another meaning than mentioned above. In catenanes[2,48] these denote numbers of interlocked rings, e.g., a [2]catenane consists of two interlocked rings (Fig. 5d), and in the case of the helicates,[2,50] they denote the binding sites of the helicand used for coordination of a metal ion. e.g., [4 + 4]helicate for the structure shown in Fig. 5f.

While a distinction between the free host (ligand) and the host–guest compound (inclusion complex) is easy to make for all hosts ending their name with "-and." simply by changing the ending to ''-ate'' or ''-plex'' for the host–guest compound[17,21,22] (Table 1), the other hosts cannot be treated in a similar way. e.g., the calixarenes or cyclodextrins. Here, paraphrastic wording may be used for specification of the host–guest compound. However. there is also the possibility of using formula terms denoted by the mathematical symbol ⊂, meaning "part of the set of.''[15] Thus. the coronand 18-crown-6, when including a metal ion M^+, forms the corollate [M^+⊂18C6], or β-cyclodextrin including benzene gives the cavitate [benzene ⊂ β-cyclodextrin].

CONCLUSION

Due to the fast growth in the number of supramolecular compounds, assemblies, or materials. it becomes difficult to distinguish between the different chemical species. It is true that. in principle, naming by using the systematic nomenclature could help in telling the species apart, but most of the compounds under discussion are so complex in structure that systematic names are cumbersome and thus impracticable in common use. This is the reason for the many trivial names, mostly of high pictorial nature, that have been coined. However, this is anything but a solution to the problem. because new trivial names constantly have to be found. On ihe other hand, efforts have been undertaken to find a generalized system of nomenclature for all supramolecular compounds. or at least for the host–guest compounds.[17,26] As shown, this is possible up to a point. but naming also tends become intricate and thus relatively troublesome. The main problem, however. is more complicated. owing to the noncovalent binding type a supramolecular compound rests upon. Interactions of this kind are not contained in the conventional nomenclature

systems that are designed only for covalent-bonded molecules or ions. Another insurmountable problem met with the naming of solid supramolecular compounds is connected with the phenomenon of polymorphism,[53] i.e., the ability of a compound to crystallize in different crystal arrangements. Thus, at present. it is more or less impossible to unambiguously name a moderately complex supramolecular compound using the existing nomenclature. In a way, the circuinstances are similar to the single compound nomenclature used somewhere near the end of the nineteenth century. A glimmer of hope might come from the so-called "supramolecular synthons"[54,55] to lay the foundation for a new system of nomenclature. They are related to the functional groups on the molecular level that. as known, are the bases of conventional nomenclature. Apart from this potential approach, a long-dated solution of the problem is not in the offering, although this would be profitable for the development of the whole field.

To summarize, it can be said that basic classification of supramolecular compounds has been developed using several criteria, of which the type of interaction and topological considerations are most important. On the other hand, a strict systematic nomenclature for any type of supramolecular compounds is lacking. Instead, a number of trivial names, notations. and semi-systematic names are presently in use.

Clathrate Hydrates

John A. Ripmeester
Christopher I. Ratcliffe

National Research Council Canada, Ottawa, Ontario, Canada

INTRODUCTION

A clathrate hydrate is a crystalline inclusion compound in which small guest molecules. usually hydrophobic. are trapped in polyhedral cages formed by hydrogen-bonded water molecules.[1] True clathrates are formed by guests that interact with the hydrate lattice only by weak, nondirectional forces. In such cases. the water molecules form a completely hydrogen-bonded network, and the inaterials effectively are ices. A number of structures are known for true clathrate hydrates. including the three major families of clathrate hydrate structures[2] that will be discussed later.

Clathrate hydrates are of interest today for a number of reasons. It probably is fair to say that they were the first-recognized suprarnolecular coinpounds. with a history going back 200 years. Scientifically. they are of interest as perhaps the best-understood class of inclusion compounds, and they serve as the archetypal model for hydrophobic hydration. Technically, hydrates proved to be a hazard in the exploration and transport of hydrocarbon resources because of solid plug formation in pipelines.[3] Last. the existence of naturally occurring hydrates sparked an interest in their roles in the geosphere, especially pertaining to their possible roles as agents of climate change. as sources of clean-burning methane gas, and as geohazards.[4] The last features are related to the fact that a hydrate is an extremely efficient storage medium for gases. as each volume of Structure I hydrate, for example, is known to hold $\sim$160 volumes of gas at standard temperature and pressure (STP).

Several classes of materials closely related to clathrates are known as well, generally classified as semiclathrates, and ionic or salt hydrates.[3] Semiclathrates are crystalline hydrates formed mainly by amine guests, where there is some interaction between guest and host. This often takes the form of hydrogen bonding between the guest molecule and host lattices. which leaves some water molecules incompletely incorporated in the hydrogen-bonded clathrate framework. There is a large variety of structures. some of which are related to the true clathrates.

The ionic clathrates are formed by onium salts MR^+_4 and SR^+_3 (M = N, P. and R = C_1-isoC_5), where the anions can be inorganic or organic ions.[2] For these structures, it is also possible to substitute NH_4F for some of the water molecules. As well, acids such as perchloric, tetrafluoroboric, and HXF_6 (X = P, As. Sb). form clathrate structures with the anion in a hydrate cage and the proton incorporated into the hydrate lattice. Again, some substitution of lattice water molecules is possible for these compounds with HF. Oxides with formula R_3NO, R_3PO, and R_3AsO, where $R = C_4H_9$, isoC_5H_{11}, also form clathrate hydrates.

HISTORICAL PERSPECTIVE

Although some researchers claim that the initial observation of a clathrate hydrate took place in the eighteenth century. it is generally accepted that the first official report was made by Davy to the Royal Society and published in 1811.[5] He reported that a compound of muriatic oxide (chlorine) and water had a melting point higher than that of ice, and Faraday measured its composition to be $Cl_2.10H_2O$ in 1823.[6] Thus, clathrate science is. in fact, older than the concepts of modern chemistry. It can also be said that the clathrate hydrates often did not obey the general rules that were being discovered for chemical compounds. and until the first structure was determined in the early 1950s, remained somewhat of a mystery. Many eminent scientists contributed to clathrate science. developing a number of general concepts.[7] For instance. clathrates formed definite compounds. but their components could be recovered unchanged on decomposition: they were generally nonstoichiometric with fractional hydration numbers; and mixtures of guests often gave coinpounds as readily as pure guests.

The observation that solid hydrates of hydrocarbons might more easily form blockages in gas pipelines than ice[8] was the impetus for a vigorous research program with the aim of predicting hydrate formation conditions and preventing blockages, an effort that continues today. The early work led to a comprehensive package of practical knowledge on phase equilibria of gases and gas mixtures. either in the presence or absence of hydrate inhibitors. such as methanol and salt.[9]

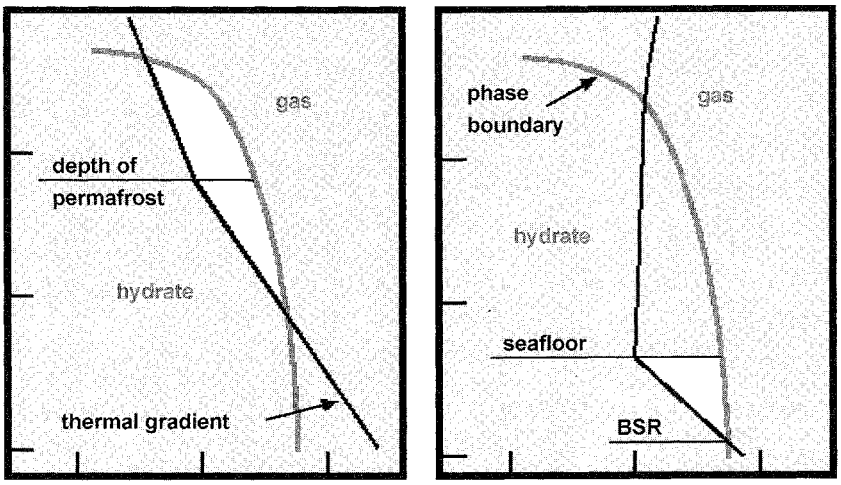

Fig. 1 Methane hydrate. which is stable belou· and to the left of the phase boundary line. Also shown is the geothermal gradient in permafrost as well as marine environments. Where the curves intersect, natural methane hydrate is stable. Natural methane hydrates are found in the lightly shaded region. BSR labels the "bottorn-simulating reflector." an unexpected interface found by sonic exploration techniques and usually associated with the interface between sediments with and without hydrate. (*View this art in color at www.dekker.com.*)

The first crystal structures for the clathrate hydrates now known as Structures I and II were published in the early 1950s, giving answers to many of the questions raised during the previous 150 years of hydrate work.[10–14] They were seen to fit the class of materials known as "clathrates." a term coined a few years earlier by Powell[15] to describe inclusion compounds of quinol and trapped guests. The knowledge of structural information and compositional data on clathrates. including the hydrates. led van der Waals and Platteeuw to propose their elegant "solid-solution" theory for clathrates,[16] still the basis for much of the predictive modeling of clathrate stability conditions today.

Interest in clathrate hydrates was sparked again when it was realized that hydrates might exist naturally in the geosphere. and when this hypothesis was subsequently confirmed. This includes "air" hydrates deep inside glaciers[17] and natural gas hydrates, both under the permafrost[18,19] and offshore on the continental margins (see Fig. 1).[20] On a more speculative note. it was also conjectured that gas hydrates exist on the outer planets and in comets.[21,22]

In the last 30 years or so. clathrate science has blossomed. with the reports of many new guests, a new hydrate structural family, a complete revision of the structure–size relationships. new approaches for hydrate characterization. refined models for hydrate stability prediction, high-level calculations and computational work on hydrate physical properties, experimental work and models for kinetic processes, etc.

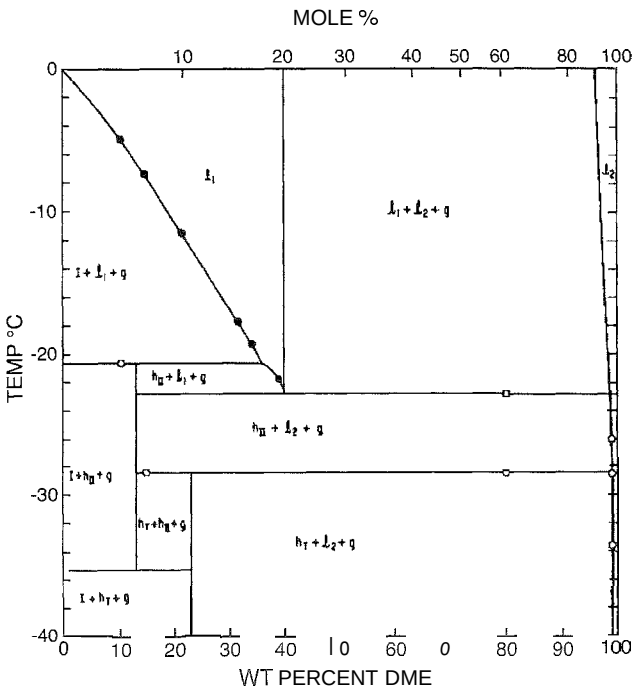

Fig. 2 Temperature–composition diagram for the water–dimethyl ether system. The two hydrates that form at −12 and 22 Wt% DME are Structure II ($DME.17H_2O$) and Structure T (DME.8 2/3 H_2O hydrates. respectively), Both decompose incongruently. (S.L. Miller, S.R. Gough, D.W. Davidson. J. Phys. Chem. 1977. *81,* 2154: K.A. Udachin. C.I. Ratcliffe. and J.A. Ripmeester, Angew. Chem. Int. Ed. 2001. *113.* 1343.)

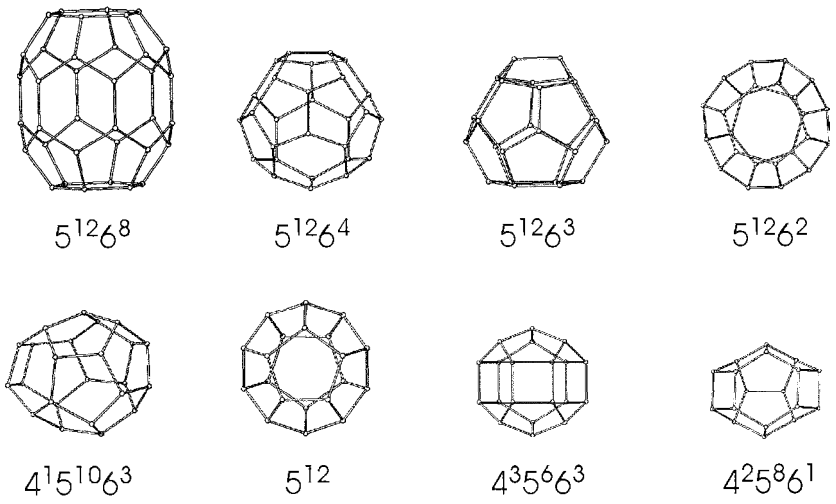

Fig. 3 Polyhedra present in the true clathrate hydrates

STRUCTURES

The true clathrates can be classified as belonging to three major families. commonly known as Structures I, II[1,2] and H,[23,24] and several unique structures formed by bromine,[25] dimethyl ether (see Fig. 2),[26] and *tert*-butylamine.[27] The polyhedra that make up these various structures are shown in Fig. 3. In contrast to Ice Ih, in which hexagonal rings of hydrogen-bonded water molecules occur exclusively. Fig. 3 and Table 1 show that pentagonal rings predominate in the clathrate hydrates. although hexagonal and, sometimes, square rings are necessary in order to give space-filling frameworks. The polyhedra, which must comply with Euler's relationship, F + V = E + 2 (where *F*, V. and *E* are the number of faces. vertices, and edges. respectively), stack together by sharing faces to fill three-dimensional space. They are usually described by the descriptor n^m, where *m* is the number of faces with *n* edges. Of the hydrate cages, the pentagonal dodecahedron (5^{12}), also referred to as "nature's second favorite structure",[26] is the only polyhedron that can have equal edges and interedge angles while maintaining planar faces. The cages of various types stack together to fill three-dimensional space. as shown in Fig. 4.

Table 1 Hydrate structure types. unit cell contents. and cage types

Structure type	Unit cell content *Space group*	Cage	Symmetry of cages
Structure I	$2D \cdot 6T \cdot 46H_2O$	5^{12}(D)	m3
	Pm3n	$5^{12}6^2$(T)	$\bar{4}$2m
Structure II	$16D \cdot 8H \cdot 136H_20$	5^{12}(D)	3m
	Fd3m	$5^{12}6^4$(H)	$\bar{4}$3m
Structure H	$E \cdot 3D \cdot 2D' \cdot 34H_2O$	5^{12}(D)	mmm
	P6/mmm	$4^35^66^3$(D)	$\bar{6}$m2
		$5^{12}6^8$(E)	6/mmm
Structure II/H polytype (ideal form)	$3E\ 12H \cdot 6D' \cdot 33D \cdot 306H_2O$	5^{12}(D)	3. 3m
	R-3m	$4^35^66^3$(D′)	3m
		$5^{12}6^4$(H)	3m, 3ln
		$5^{12}6^8$(E)	3m
Structure T	$12U \cdot 12T\ 24T'\ 12P\ 348H_2O$	$4^25^86^1$(U)	2. 2. 1
	P321	$5^{12}6^2$(T)	2, 2, 1
		$5^{12}6^3$(P)	32, 3, 2
		$4^15^{10}6^3$(T)	1, 1, 1, 1
Bromine hydrate	$2D_A \cdot 8D_B \cdot 8T_A \cdot 8T_B \cdot 4P \cdot 172H_2O$	5^{12} (D)	1
	$P4_2/mmm$	$5^{12}6^2$ (T)	m, m
		$5^{12}6^3$ (P)	m

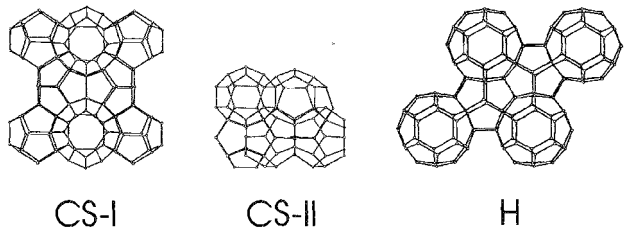

Fig. 4 Clathrate hydrate structures. Hydrates of cubic Structures I, II. and hexagonal Structure H are illustrated to indicate the stacking of the polyhedra.

As well. a summary of the structural details and the cages in each structure is given in Table 1.

Suitable guest materials for true clathrate hydrates vary widely in size and chemical nature and number well over a hundred. The main criterion is that the guest molecule should not interact too strongly with water, as in the solid hydrates, the guest and host must interaci hydrophobically. Thus. the classes of hydrate formers include monatomic (Ar. Kr, Xe), diatomics (N_2, O_2, CO, Br_2, Cl_2), other inorganics [H_2S, H_2Se, CO_2, COS, PH_3, NF_3, ClO_3F, SO_2F_2, MF_6 (M=S, Se, Te)], organic hydrocarbons (aliphatic. alicyclic. olefinic, acetylenic, aromatic). and substituted organics (halides. including CFCs HCFCs, sulfides. mercaptans, ethers, ketones, some alcohols. aldehydes, and acids). Size limits (van der Waals' diameter) on the guests vary from 4–8 A (Ar to ~dimethylcyclohexane). On the basis of high-pressure experiments. it was suggested that Ne, He, and H_2 are also able to form classical hydrate structures.[28]

The actual hydrate structure that forms is usually determined by the size of the guest. In two-phase systems, the relationship between guest size and structure is reasonably straightforward. When there is more than one guest type, the relationship is far more complex. as shown in Fig. 5.

PREPARATION AND PHYSICAL PROPERTIES

Pure hydrates are crystalline ice-like solids usually prepared from water or ice and an appropriate guest species. Hydrates of water-soluble guests have well-defined phase diagrams characteristic of two-phase systems with compound formation.".'' If the hydrate melts congruently, it is simply a matter of freezing a solution of the correct composition to obtain the hydrate. For systems that melt incongruently, the aqueous solution must be quenched below the peritectic temperature and conditioned so that the crystalline hydrate can form on annealing the frozen mixture. In cases where the guest species is a poorly water-soluble liquid or gas, hydrates can be made by contacting powdered ice with the guest in a sealed tube or in a pressure vessel and leaving the sample for periods of several days to weeks. Often it helps to cycle the temperature through 0°C in order to promote

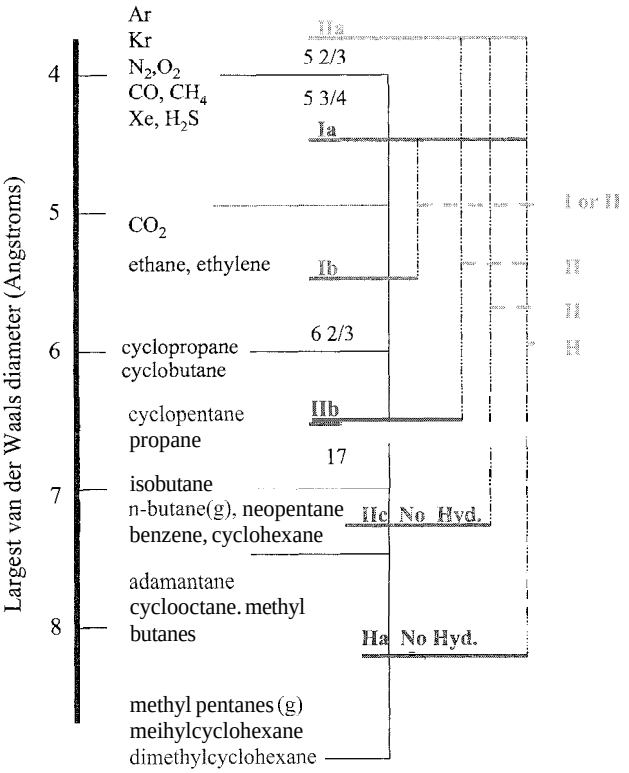

Fig. 5 Structure–sire relationships. A number of representative guests are shown at their largest van der Waals' diameters. Guests are classified as I and II. those being the structures formed if a single guest of that type were present. The **a.** b, c letters classify different subgroups, with the guest size of a smaller than that of b. which, in turn. is smaller than that classified as c. Also indicated are the ideal hydration numbers: 5 213 for guests of IIa. 5 3/4 for Ia if all cages are full. For guests ot Ia and Ib, some of the small cages are empty. so that hydration numbers tend toward 6 2/3 as the guest size increases. For guests of IIb, the small cages are empty. so that the hydration number is 17 Some guests at the Ib–IIb boundary can gıve either Structure I or IT Guests ın Groups IIc and Ha are not known to form hydrates by themselves but need small help gas molecules (trorn Groups Ia. IIa, some hom IIb) If guest types from Ia or IIa are present together with guests from Group Pb. Structures I or II maq occur depending on P.T conditions and relative concentrations. Guests of Type IIa. Ia. or Ib together with IIb or IIc give double hydrates of Structure II, and guests of Type Ia. IIa, or Ib with Ha give structure H. (J.A. Ripmeester. Ann. N. Y. Acad. Sciences 2000. *912*. 1.) (*View this art in color at www.*

hydrate formation, and continuous grinding of the reaction mixture has also been used effectively.

On the other hand, it is also possible to react water with liquid or gaseous guest in bulk. However, the hydrate usually forms at the interface, and agitation is needed in order to produce significant amounts of hydrate. The pressure of a gaseous guest must be maintained within the P–T range of stability for the hydrate, and usually a significant overpressure is needed in order to nucleate hydrate initially. For the clathrates with gaseous guests, it is difficult to form a "pure" hydrate in which there is neither ice nor hydrate former in excess. This is especially difficult if the hydrate is to be homogeneous in terms of composition. as it needs to be made under fom-phase equilibrium (usually water–liquid guest–hydrate–gas or water–ice–hydrate–gas) conditions.

Because hydrates are nonstoichiometric, the determination of the composition, especially for gaseous guests. has been a challenge.[1,3] This determination can be done by direct measurement of water and guests for samples known to be pure hydrate, or more generally by a variety of wet chemistry techniques. One of these is the application of the Clausius–Clapeyron equation to P–T data for the hydrate–liquid–gas and hydrate–ice–gas equilibria in systems of water plus one guest component, which yields the heats of forination for these two reactions, H_l and H_s. The difference divided by the molar heat of fusion of ice then gives an estimate of the number of moles of water in the hydrate. Because natural hydrates often occur in the presence of sediment and excess water. there is a strong interest in developing instrumental techniques that will allow the determination of composition in situ or in the presence of impurities.

THERMODYNAMIC DESCRIPTION

The best simple description of clathrate hydrates is the solid solution model of van der Waals and Platteeuw.[16] It assumes that there is an hypothetical empty hydrate lattice that is metastable with respect to ice, and that the lattice is stabilized by the presence of the guest molecules. Further assumption5 are that there is single occupancy of hydrate cages, and that guest–guest interactions can be neglected. Then, for a single-guest component at the quadruple point (hydrate, ice, water. gas), the hydrate will have the minimum cage occupancy for lattice stability. and the chemical potential difference $\Delta\mu$ between the hypothetical empty lattice and ice can be expressed in terms of the fractional cage occupancies θ_i as:

$$\Delta\mu = RT\Sigma_i[n_i \ln(1 - \theta_i)]/N \quad (1)$$

where n_i is the number of cages of type i, and N is the number of water molecules per unit cell, respectively. For Structure I hydrate, the best estimate of $\Delta\mu$ is 1297 J/m, which means that for guests such as methane and xenon. the large cages are essentially full and the small cages are $\sim$75% occupied, giving hydration numbers of 6–6.2. The thermodynamics of clathrates were recently reviewed.[29]

CHARACTERIZATION OF HYDRATES

A complete description of a hydrate requires knowing the detailed structure; including the distribution of the guest molecules over the cages. which then fixes the composition. and its phase diagram (P–T-composition, or a two-dimensional cross section thereof).[1–3,29] Other important parameters. especially for engineering and geophysical applications, include the thermal parameters, such as the various hears of reaction. the heat capacity, and physical properties. such as the dielectric permittivity, the thermal conductivity, the speed of sound. and the refractive index.

As for other crystalline solids, the primary method for determining hydrate structure is by diffraction techniques. High-quality single-crystal x-ray data obtained on a modern diffractometer can be good enough to determine the framework structure and the highly disordered guest positions. Refinement of the data with the cage occupancy as a variable can then be used to determine the composition of the hydrate.[30] Powder data (x-ray or neutron) can be refined by Rietveldt analysis, although the coupling of parameters tends to preclude a completely independent determination of structure and composition.[31]

Other techniques for the characterization of hydrates[32,33] include calorimetry, dielectric measurements. and spectroscopic techniques such as NMR,[34] Raman,[35,36] and IR spectroscopy.[37] These techniques depend on providing a structure-dependent spectral signature. In NMR spectroscopy. isotropic chemical shifts of the guests are affected by the size of the cages. As well. the anisotropic chemical shifts or quadrupolar coupling constants observed for the guests reflect the guest dynamics and the symmetry of the cages. Quantitative information can yield relative cage occupancies, which through expression I can be related to the hydration number. In vibrational spectroscopy. the size of the cage affects some of the vibrational modes of the guests. again allowing for identification of guests in different cages. However. there is evidence of guest–guest coupling. suggesting that intensity information needs to be treated with caution. especially in Raman spectroscopy, where the intensities depend on the polarizability tensor at the guest site.[35,36]

CONCLUSION

Gas hydrates continue to challenge researchers in scientific and technical areas. There is much current interest in understanding and controlling nucleation and kinetic processes; in discovering new hydrate phases, especially at high pressures; in viewing the nature of the hydrate in natural settings; in determining the location and extent of natural hydrate deposits and their roles in the geosphere: and in determining the feasibility of producing gas from natural deposits.

Over time, various applications were demonstrated on laboratory or pilot plant scale, including the fractionation of gases, the concentration of aqueous solutions. the desalination of water, cool energy storage, and the storage and transport of natural gas. All of these await future developments of commercially viable technologies.

Clathrate Hydrates: Occurrence, Uses, and Problems

Christopher I. Ratcliffe
John A. Ripmeester
National Research Council Canada, Ottawa, Ontario, Canada

INTRODUCTION

Clathrate hydrates are supramolecular framework materials in which guest molecules are physically trapped inside cages made of hydrogen-bonded water molecules. Naturally occurring hydrocarbon gas hydrates constitute a vast untapped energy resource, generally little known by the layman, though receiving increasing attention in the media. Ice-like in appearance, methane hydrate can generate about 160 times its own volume of gas at standard temperature and pressure (STP). Gas hydrates already have a huge impact on industry, as the cause of numerous problems for the oil and gas industry, but they also have a few specialized beneficial applications. and they have potential for use in a number of other areas. This review will be rather eclectic. because the study of hydrates cuts across many sciences, from the basic physics and chemistry of hydrates to their involvement in biological systerns, in geological processes, in astronomy. and in climatology. They even have a place as a source of entertainment. The sources for much of the current information, especially regarding natural gas hydrates, are a number of books. reviews, and conference proceedings, to which the interested reader may refer.[1–15]

First, we will present a little history and basic science. Although gas hydrates have been known to scientists since the early nineteenth century, with the work of Davy (in 1811) and Faraday (in 1823) on chlorine hydrate, their true nature as clathrates was not demonstrated until the advent of x-ray crystallographic studies in the 1950s. Gas hydrates began to gain more attention when their potential for causing blockages in natural gas pipelines was first noted in 1933. Their existence as natural deposits in permafrost regions of the Earth was recognized in Siberia in 1965 and in Canada in 1974. Off-shore deposits were found with the advent of the Deep Sea Drilling Project, with the first indications of hydrate recorded around 1972 and the first samples recovered around 1983.

The detailed physical science of hydrates can be found in a number of reviews.[2,4–9] Three principal crystal structures are known: Structures I and II, which are cubic, and Structure H. which is hexagonal. All have small cages together with cages of increasing size (in the order I, II, H) that can accommodate larger guest molecules. They are nonstoichiometric, and their stabilities depend on the particular guest molecules and the pressure (P) and temperature (T) conditions. Stability models are based on the statistical thermodynamic description formulated by van der Waals and Platteeuw.[16] Many hydrates can exist above the melting point of ice, some up to 28°C under pressure. Because the guest does not have any chemical bonds to the host. it has considerable translational and rotational freedom within its cage. Resonant coupling between these guest motions and the low-frequency lattice vibrational modes results in a thermal conductivity for hydrates that is considerably lower than that in ice. Many different techniques have been applied to study hydrate compositions and physical properties. The most reliable methods for determining structure type are x-ray diffraction, solid-state nuclear magnetic resonance (NMR), and (to a lesser extent) Raman spectroscopy.

OCCURRENCE

Hydrates can and will occur wherever the components exist in sufficient concentrations and the conditions of temperature and pressure are right for stability of the hydrate relative to ice (or water) and the particular encaged gas molecules.

Natural Gas Hydrates on Earth

Naturally occurring hydrocarbon hydrates occur in permafrost regions, i.e., in the north of Canada. Alaska, and Russia (Siberia), in marine deposits on the continental margins (probably everywhere around the globe), and in the beds of smaller seas and large deep lakes (Black Sea, Caspian Sea. Sea of Okhotsk, Lake Baikal. Gulf of Mexico) (Fig. 1). The most widespread gas hydrates (permafrost and continental margins) appear to be largely of Structure I type. with methane as the principal component, though other gases that form clathrate hydrates are usually present in much smaller amounts, e.g., H_2S, CO_2, and some hydrocarbons. However, hydrates associated with major marine oil and gas deposits and seeps. as in the Gulf of Mexico. are more often of

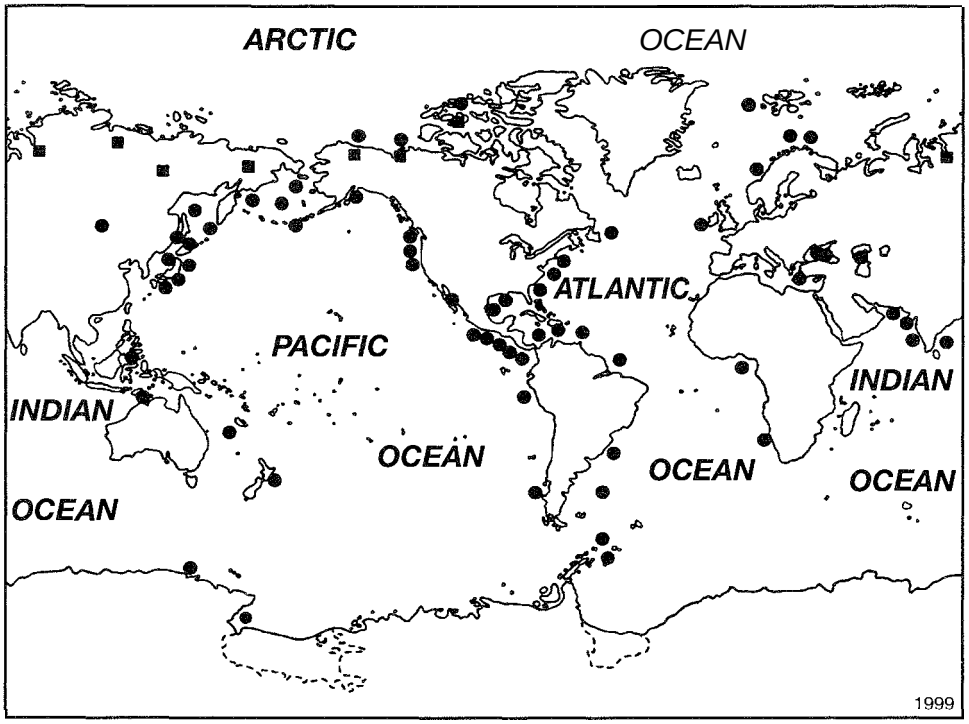

Fig. 1 Gas hydrate locations around the world. (Courtesy of K. Kvenvolden, U.S. Geological Survey. from Ref. [13], p. 18.)

Structure II *type because of the high content of the higher hydrocarbons' propane and butane. which are too large to form Structure* I. *There is even a suggestion that Structure* H *(first* discovered *in laboratory preparations in* 1987[17]) *may also occur naturally in the Gulf of Mexico* deposits:[18,19] Isopentane *is* found *to be excluded from the Structure* II *hydrate beds (this molecule is too large for Structure* II), *but it remains in quantity in the surrounding sediments. Thus. the coexistence of Structure* II *and Structure* H *at petroleum seep sites is postulated. and the* Structure HH *hybrid recently discovered in the lab* may *also be* relevant in *this* context.[20] *Structures* II *and* H *can contain the smaller gas molecules, including* CH_4, *in their small cages, and, in fact, Structure* H is *only known to exist* when *such* small *help gases are present. Double hydrates involving methane are quite likely to occur.*

"Massive" hydrate deposits outcropping on the sea floor have been found in the Gulf of Mexico and off the West coast of Canada. In *the latter* case, *geolo,gists were alerted to their existence when large frothing chunks were pulled* up *in a fishing net.*

On the continental *slopes, gas hydrates typically occur below* 500 *m water depth and within the upper* 700 *m of sediment. though they can go significantly deeper.* In *the permafrost regions. the zones can range between 100* m *(in places in Siberia) and as deep as* 2000 *m. The exact conditions of stability depend on the composition of the hydrate. The zones where they are found depend on the heat* flux *from* below *and the temperatures above.* Thus, *the bottom of* the *hydrate zone occurs where the temperature is just too high for stability at the local pressure (Fig. 2).* Large *quantities of gas can accumulate beneath the hydrate zone. There are also relict deposits, reflecting all earlier enlarged zone of hydrate stability, presumably still present because of self-preservation (a state in which hydrate particles develop a coat of ice that prevents further decomposition).*

Much effort is expended in making assessments of these geological occurrences; exploratory drilling often produces fizzing cores. and numerous other down-well sensor logging techniques are used. Besides these direct probe techniques, much use has been inade of seismic exploration. Bottom-simulating reflectors (BSRs) *are sound reflectors (they depend* on *a discontinuity in sediment density) that follow the contours of the sea floor, usually cutting through the bedding planes of the sediments* in *which they occur. The* BSR's *images are generally taken to indicate the presence of gas hydrates. and thus have been* very useful *in mapping potential hydrate areas. Follow-up drilling has confirmed the presence of hydrates in many instances, though* BSRs *are not an* 100% *reliable indicator.*

The origin of the gases that form the hydrates can be biogenic. involving the natural breakdown of organic detritus and bacterial action. or thermogenic, involving thermal fractionation of oil sediments. The latter usually generates the higher hydrocarbons and. thus, is *usually the*

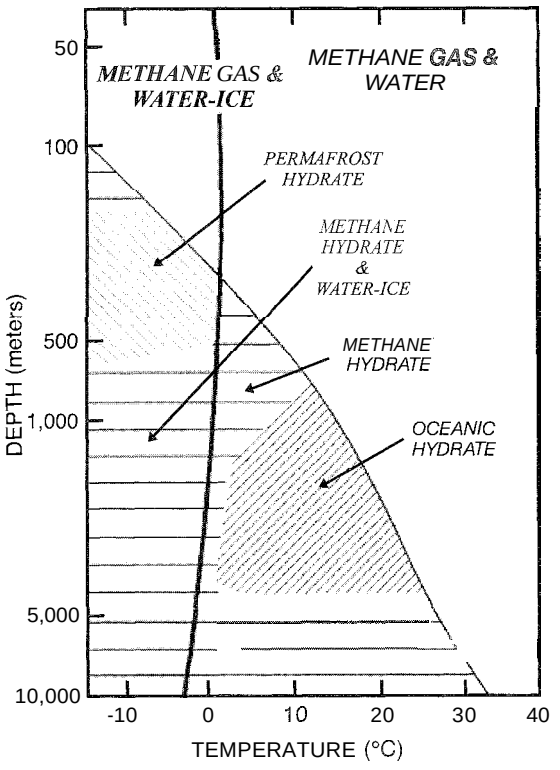

Fig. 2 Pressure (depth) versus ternperature stability diagram for methane hydrate. (From "Oceanic Gas Hydrate Research and Activities Review." U.S. Department of the Interior. Minerals Management Service. Gulf of Mexico OCS Region. OCS Report MMS 2000-017.)

source for Structure II *(or* H*) hydrate deposits. Carbon isotope analysis is* used *to distinguish between hydrocarbons of these different origins.*

Natural hydrates of air have been found in *ice cores obtained from the deep ice caps of Greenland and the Antarctic. Because the main guests are nitrogen and oxygen molecules. the* material *is of* Structure II *type, and considerable pressures and. hence. depths are required for their stability.* In *these environments. the temperatures are* low. -20 *to* $-28°C$, *for which* minimum *depths for air hydrates are* 800–700 m. respectively.[21] *These have been studied principally by microscopy,* Raman *spectroscopy, and powder x-ray diffraction.*

Artificial Hydrates

Laboratory production

There are a number of laboratories *around the world where hydrates are produced artificially for* study. *The* bulk *of our knowledge of the structures and properties of gas hydrates emerged from such synthetic materials.* Additionally, many *hydrates with* unusual *guest species that are unlikely to be* found *in nature have been* studied *in this* way. *Structural types. usually specific to one or two particular guest molecules, beyond the* major *Structures* I. *11. and H. have also been found. Recently.* a *Structure IT* H_2 *hydrate with multiple cage* occupancy[22] *and new hydrate forms of methane*[1] *''' were discovered by work* at *very high pressures. These high-pressure forms have relevance to* extraterrestrial *hydrates.*

In *laboratory prepared samples. if air* is *not excluded during the formation of the hydrate, then* O_2 *and* N_2 *can end up in the cages not occupied by* the *main guest. This shows up as extra electron density in x-ray diffraction single-crystal structural studies, and paramagnetic* O_2 *molecules cause relaxation effects and line-shape distortions in* NMR *spectra.*

Incidental production

Of *course, there are situations in which hydrates* can *form where they are not wanted, for instance, in gas and oil pipelines and in* tank *cars used for transporting liquid hydrocarbons. These will be discussed in more detail as* problem *areas.*

Extraterrestrial Gas Hydrates

It is thought to be highly *probable that gas hydrates exist elsewhere in the solar system and beyond, wherever the right conditions prevail,* e.g., *in the gaseous giant planets and on many of their* moons. *The crust of the Jovian satellite Europa* probably *contains clathrate hydrates in* abundance,[24] *and* it *was postulated that* CO_2 *hydrate exists* on *Mars.*

Much attention has recently been given *to the possibility of vast amounts of methane hydrate and high-pressure structural forms of methane hydrate existing on Titan, the largest* moon *of Saturn. Previously. it was thought that methane hydrate would phase separate into* methane *and ice at very high pressures, and that. consequently. Titan would have lost most of its methane.* However. *the discovery of the new high-pressure structures*[23] initiated *major revisions of* models *of the geology and* atmosphere *of Titan.*

Hydrates may also be involved in the outgassing from cornets. which are often described as dirty snowballs, as they warm during their *close approach to the sun.*

USES

Hydrocarbon and Energy Source

The natural *gas hydrates constitute a vast hydrocarbon and energy resource. Though the* numbers *are constantly* revised as exploration *and* measurements *of hydrate*

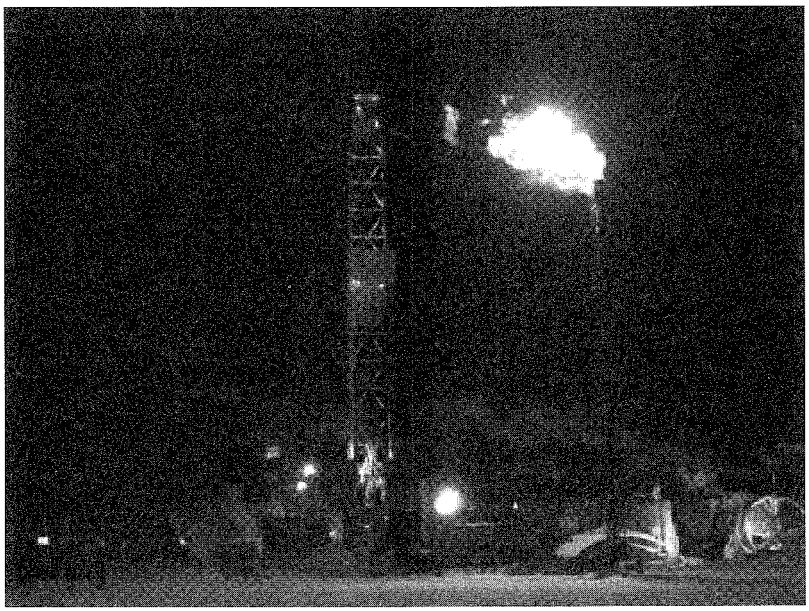

Fig. 3 Flaring of natural gas produced by thermal stimulation of gas hydrates at the Mallik 5L-38 production research well located in the Mackenzie Delta of Canada's Northwest Territories. (Photo provided courtesy of the Geological Survey of Canada from the Mallik 2002 field program.) *(View this art in color at www.dekker.com.)*

content in different deposits are made, there have been estimates suggesting that the world has 5.6×10^{18} m^3 of methane stored as hydrate, though more conservative current estimates suggest somewhere on the order of $1–50 \times 10^{15}$ m^3. On land, gas was obtained for years from hydrate beds in Messoyakha in Siberia, and gas was successfully generated and flared from hydrate buried under the permafrost at the exprimental well at Mallik in Canada in 2002 (Fig. 3). There was drilling into marine hydrate deposits in the Nankai trough off Japan in 1999–2000, and further drilling is planned to recover usable methane.

Gas Storage and Transport

Because a hydrate can contain, volume for volume, a large amount of gas, this is potentially a useful solid storage and transport medium, though it has to compete economically with liquefied gas. There is active research to find storage systems that will work at pressures less than 1 MP, involving "additives" to give double hydrates that are more stable.

CO_2 Sequestration

There has been considerable interest in the possibility of disposing of industrial CO_2 waste as hydrate in the deep ocean trenches. There have even been experiments conducted with liquid CO_2 on the ocean floor using submersibles to demonstrate the formation of hydrate from seawater. While this would remove a greenhouse gas, its disposal in this form raises other environmental concerns.

Gas Separation

Some gas mixtures can be separated by exploiting the different stability conditions for their hydrates, e.g., have been hydrofluorocarbons (HFCs) have been separated from nitrogen by forming the HFC hydrate that requires much less pressure than N_2 hydrate.

Desalination

This involves producing a hydrate from cold seawater (deeper ocean temperatures are close to 2–4°C around the world) and a guest that does not require much pressure for stability and then recovering and draining the saltwater. The hydrate can then be decomposed to obtain fresh water, and the hydrate former can be recycled.

Sludge Remediation

This can be effected by producing hydrates that remove excess water and thus concentrate the sludge.

Cold Energy Storage

Storage systems have been produced that make use of cheap off-peak electricity to produce hydrates. Then. at peak demand periods, the hydrate is used for air-conditioning.

Hydrogen Storage

The new high-pressure hydrogen hydrate[22] has been touted as a potential hydrogen storage medium, with implications for fuel cell applications and the "Hydrogen Economy," because it appears that it can be recovered at atmospheric pressures at liquid nitrogen temperature. With $4H_2$ in tne large cages and $2H_2$ in the small cages. a filled hydrate would have a substantial 4.97 wt% of hydrogen.

A Role in Anesthesia?

Hydrates enjoyed a period in the spotlight many years ago. when Pauling suggested chat they might have a mechanistic role in anesthesia. because many gases that cause anesthesia will also form clathrate hydrates. However, with our current knowledge of the stability conditions of these gases, it is not likely that such hydrates can exist in the body at normal body temperature and pressure. Nevertheless, this theory may have an element of truth, because clathrate hydrate-like structures involving other materials. such as amines, are stable at higher temperatures and normal pressures, or perhaps hybrid hydrate–organic structures could develop.

Hydrates and Biological Systems

It has been found over the last few years that there are marine ecosystems that depend on the existence of methane hydrates. There are certain methane-consuming archaea and bacteria associated with methane hydrate deposits in temperature and pressure regions where the hydrate is close to its decomposition threshold.[25–27] In one system studied, the archaea interact symbiotically with sulfate-reducing bacteria. with the net result that methane is oxidized and sulfate is reduced:

$$CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O$$

The sulfide produced is then processed by communities of sulfide-based organisms also found around the hydrate deposits. All of these organisms, in turn. provide a food source for the aptly named "ice worms." a new species recently discovered apparently feeding on the surfaces of exposed massive gas hydrate outcrops on the sea floor[28] (Fig. 4).

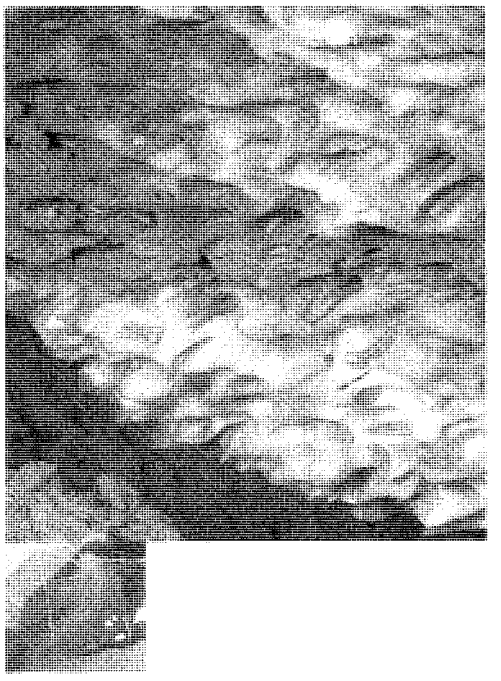

Fig. 4 "Ice worms'' in their natural habitat. The white ice-like material is gas hydrate. (From Ref. [28] and Fisher, C., Penn. State Eberly College of Science. Web site: www.science.psu.edu/iceworms/iceworms.html.) (Inset) Detailed view of an ice worm. (From MacDonald, I.R.; Joye. S.. Quarterdeck 1997. 5(3), TAMU. Department of Oceanography. Web site: www-ocean.tamu.edu/Quarterdeck/QD5.3/macdonald.html.) (*View this art in color at www.dekker.com.*)

It has been inferred that the waters of Lake Vostok and numerous other subglacial Antarctic lakes contain oxygen sufficient to support life in an unique ecosystem. at 350 atm and −3°C. in permanent darkness. Though the lake water has not been sampled for fear of introducing bacteria from above. oxygen is found in the refrozen lake water just above the lake. The oxygen comes from the decomposition of air hydrates present in the ice overburden.[29]

As a Source of Entertainment

There has been recurring media interest in gas hydrates ever since it was postulated by McIvor that they might be the cause of mysterious events in the Bermuda Triangle.[30] The notion is that ships might sink from loss of buoyancy, and aircraft could stall from lack of oxygen, due to large-volume gas release when a hydrate cap cracks or slides and the gas reservoir below bursts to the surface. While it is probably safe to say that this suggestion regarding the folklore of the Triangle now has little

credence in the scientific community, especially since the discovery of deposits all around the globe. the science regarding disturbances of hydrate deposits has relevance in the context of hydrate "problems.' discussed later.

Gas hydrates were used inadvertently as a plot theme in the movie "Total Recall," (starring O_2 hydrate). Set on Mars at a mining colony, it transpires that the whole interior of Mars is "ice." and that 0.5 M years ago, an alien race constructed machinery in huge underground caverns, which when set in motion sends huge heaters plunging into the "ice," which melts, generating vast amounts of water vapor and oxygen and creating a breathable atmosphere on Mars. From a scientific viewpoint, the implication is that the atmosphere was stored or trapped as air hydrate, and hence, it must have been of Structure II type.

Submarine hydrates feature prominently in the recent novel "Fire Ice'' (by Clive Cussler with Paul Kemprecos). in which a scheme is developed by a megalomaniac Russian tycoon to explode methane hydrate deposits off the East coast of the United States, creating destructive tidal waves.

The "burning snowball" is an often-repeated pyrotechnic demonstration (Fig. 5). Methane hydrate is allowed to warm to the point where the surface begins to decompose. and the evolved methane can be ignited (methane hydrate requires 26 atmospheres pressure of methane at 273 K to keep it stable). The burning snowball is self-sustaining until all the hydrate decomposes and the methane is consumed.

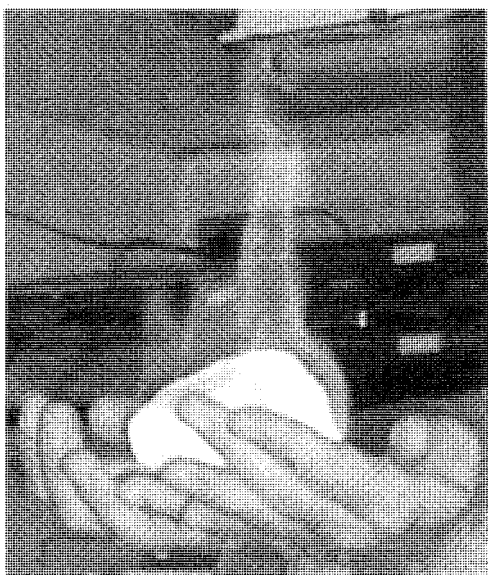

Fig. 5 The "burning snowball." Methane hydrate decomposing to gas, which is burning, and water. (Photo courtesy of the GEOMAR Research Center, Kiel. Germany.) *(View* this *art in* color *at www.dekker.com.)*

PROBLEMS

Pipeline Blockages

In the oil and gas industry. the occurrence and deterrence of gas hydrate plugs in pipelines has a tremendous cost. for example, on one occasion, the gas supply to all major users in Melbourne was shut down for 3 days because of a hydrate plug in a 30-inch pipeline. It is estimated that roughly $1 billion USD is spent annually to prevent and remove hydrate plugs. Consequently, there is great interest in both the formation and inhibition of gas hydrates. Water can be removed where possible, but from subaquatic sources especially, this is not feasible. Instead, large quantities of chemical additives are used, such as methanol or ethylene glycol, which act as thermodynamic inhibitors, shifting the stability conditions. Kinetic inhibitors, such as poly(*N*-vinylpyrrolidone), delay nucleation and slow the growth of hydrates. Quaternary ion salts can act as emulsifiers and antiagglornerants; any hydrates that form remain as small particles that are carried away in the flow. When plugs occur, attempts to unblock by releasing pressure on one side of the plug can be hazardous, because the plug tends to decompose from the outside in. Then, when it releases from the sides of the pipe. the high pressure on the other side turns the hydrate slug into a high-velocity projectile, until it meets a restriction or turn in the pipeline, with predictably disastrous consequences; i.e.. failure and rupture of the pipeline at the point of impact. Consequently, it is recommended that the pressure be released on both sides of the plug.

Methane Hydrate and the Global Environment

As a greenhouse gas. CH_4 is more than 10 times worse than CO_2, and as such. may be an important factor in climate change.[31] Concerns have been raised that its rapid release from hydrates due to increased global temperatures may exacerbate the greenhouse problem. causing runaway warming. It has been suggested that CH_4 released from gas fields and hydrate deposits caused two sudden strong warming pulses at the end of the last glaciation episode. Hydrates have also been associated with other prehistoric sudden warming episodes in the Jurassic (183 million years ago) and the Late Palaeocene (55.5 million years ago) periods.[32,33] But, at the same time, hydrate plays a role in the global carbon cycle, acting like a great carbon–methane capacitor (a source or a sink).

Marine Geohazard

There is a great deal of geological evidence linking hydrate destabilization with massive submarine slides and slumps. Such slides can run large distances. and the huge masses displaced create destructive tsunamis.[10,13,30,34]

Drilling and Construction Hazards

Drilling and production through hydrate formations above oil and gas reservoirs can cause dissociation and well blowouts. Similarly, the possible instability of the sea floor sediments over hydrate deposits where oil and gas is extracted raises concerns over the collapse and loss of engineering structures.

Tanker Car Explosions in Cold Climates

Though there do not seem to be any generally available technical reports. there are genuine stories of explosions and burn accidents caused by the inadvertent formation and subsequent decomposition of hydrates of hydrocarbons in railway tank cars in the cold climate of Canada. Incidents occurred due to the practice of washing ''empty'' tank carr following their use for transporting liquid hydrocarbons. In a cold winter climate, it is possible to form hydrates with small amounts of hydrocarbon residues. which later decompose when the tank car warms up, e.g., when exposed to sunshine. For example, the clathrate hydrate of isobutene (2-methyl-propene, b.p. $-6.9^{\circ}C$) needs only 1.12 bar at 273 K to be stable. Precautions were not taken around such nominally "clean and empty" tankers, and exposure to sparks or naked flames led to flash fires and explosions. While the main content of the tankers was butane, other hydrocarbons were present. In another kind of industrial accident, a worker was killed by H_2S gas liberated from H_2S hydrate residue in a heavy water production plant. during a shutdown for maintenance.

Problems in the Sense of Insufficient Knowledge

Prediction

The phase stability diagrams for natural source hydrates can become very complicated. especially when there are several guest components. This poses a major problem when assessing the quantity of gas, stability zones, structural types, etc. Also, the delicate physical balances determining structural types means that very small changes in the relative amount of a third component may trigger a structural transformation.

Exploitation

The exploitation of gas from natural hydrates poses many problems in terms of the technology needed to mine or extract them, environmental impact. and economics. One noble idea is to replace CH_4 with CO_2, and although lab experiments show that the physical exchange is possible, whether it can be done in situ in natural hydrate beds is another question.

Hydrate formation

The mechanisms of hydrate formation are still somewhat of a mystery. as neither component is soluble enough in the other to convert bulk material completely.

CONCLUSION

Clathrate hydrates are seen to be widespread in Nature wherever the stability conditions are met, occurring in vast. hidden quantities. It is surprising that these materials with such far-reaching potential and consequences for mankind have received so little attention beyond the oil and gas industries and the scientific community. But that must surely change in the coming decade and as conventional hydrocarbon sources decline. In closing. let us not forget that the amazing universe of clathrate hydrates and associated systems ultimately depends on one of the pillars of supramolecular chemistry. namely. the hydrogen bond, which in this case provides the glue for the assembly of clathrate hydrate frameworks.

Clathrate Inclusion Compounds, Phase Transitions in

C

Takasuke Matsuo
Osaka University, Osaka, Japan

INTRODUCTION

Interaction between guest molecules is a weak secondary energy compared with the primary host–guest interaction, and it contributes a small additional stabilization to the formation of the supramolecular system. However, in some inclusion compounds. the anisotropic part of the guest–guest interation plays a decisive role in determining their structures and properties, especially the temperature dependence of these characteristics. This occurs in disordered clathrate crystals for which the entropy is the important thermodynamic parameter underlying the occurrence of phase transitions. In this article. we discuss phase transitions arising from the guest–guest interactions in inclusion coinpounds based on urea, thiourea. and hydroquinone hosts and in clathrate hydrates and several other supramolecular systems from the structural and thermodynamic point of view.

PHASE TRANSITIONS

Phase transition is a general term meaning change of the physical state of matter. It includes melting. vaporization, sublimation, and the changes opposite these. In solid state and condensed matter. appearance and disappearance of ferromagnetistn. ferroelectricity, superconductivity. superfluidity, and liquid crystalline phases are among the important phase transitions. Phase transitions in clathrate inclusion compounds are structural phase transitions. The term "structural" means that the crystal structure (rather than the electronic states or spin states) changes in the transition.

The symmetry of the crystal changes as it undergoes a phase transition. Here, the symmetry is that of the distribution of atoms and molecules in the crystals. For an ordered crystal, it is simply the symmetry of the periodic structure; whereas. for a disordered crystal. it is the symmetry of the positions of the atoms and molecules averaged over space and time. Thus, the symmetry is that of the distribution functions of the atoms and molecules in the crystal. It is generally believed that two phases separated by a phase boundary in a phase diagram have different symmetries[1] (such as characterized by the presence or lack of an inversion symmetry). even if their actual space group symmetries are not known or have not been studied. A notable exception of this general statement is the vaporization: the liquid and the vapor of a substance have the same uniform distribution of molecules in the two phases. Also, there are several exceptional phase transitions. known as isomorphous transitions, where the symmetries of the distribution of the molecules in the two phases involved are the same, but the degree of the order of the atomic positions changes discontinuously.

The discussion based on symmetry becomes less clear when we consider modulated and incommensurate phases. In some crystals (notably thiourea), the crystal structure does not repeat Itself precisely with the periodicity of an ordinary crystal lattice but is modulated with a longer periodicity of several unit cells. The periodicity is, in general, not an integral multiple of the original lattice. Hence, the modulated structure is incommensurate with the basic structure. The symmetry of such a crystal cannot be described by one of the 230 space groups. although the space group representation theory copes with modulated structures and phase transitions involving them. Incommensurate phases can be identified by single-crystal diffraction experiments and are relevant to phase transitions in clathrate crystals.

Another important characteristic of a phase transition is the occurrence of discontinuities or singularities in the thermodynainic properties as functions of temperature, pressure. and other parameters. In the Ehrenfest classification,['.''] a phase transition is of the nth order if the free energy of the substance changes in such a manner that its nth derivative with respect to an independent variable (e.g., the temperature) is discontinuous at the transition point. Thus, a phase transition is of the first order if it is accompanied by a latent heat, because the entropy, one of the first derivatives of the free energy. is discontinuous at the transition point. This classification forms the basis of the Ehrenfest relations connecting the slope of the phase boundaries with the magnitude of the discontinuities in thermodynamic quantities.[2,3] However, the Ehrenfest classification is not general enough to cover all types of phase transitions. Important classes of phase transitions in which various the modynamic derivatives, such as the heat capacity. diverge to infinity are not included. The singularites in such cases are dealt with by the Pippard

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012841

relation in thermodynamics and by critical exponent formulations in statistical mechanics.[2,3]

There are two major types of structural phase transitions: order–disorder and displacive.[2,3] An order–disorder phase transition is characterized by disorder of the atoms or molecules in the structure of one of the phases. Sometimes both phases are disordered in different degrees. The disordered (or more disordered) phase is more symmetric. because disorder makes the average distribution of atoms more even. Most of the phase transitions in clathrate crystals are of this type.

In a displacive phase transition. the positions of atoms are ordered in both phases. but the position changes from a less symmetric site to a more symmetric one as the crystal undergoes the phase transition. Order–disorder transitions are distinguished from displacive transitions by, among other properties, a large entropy of phase transition. dielectric dispersion at low frequencies. and directly, by crystal structure revealing two or more sites fractionally occupied by the same atom.

Phase transitions are often accompanied by changes in the mobility of molecules. Nuclear magnetic resonance (NMR) is a sensitive technique used to detect the occurrence of phase transitions and to determine the type, magnitude, and timescale of the molecular motion involved in the phase transition. Neutron scattering also gives quantitative knowledge about the molecular motion involved in phase transitions. On account of the large scattering power of protons to a neutron beam. this is especially useful if the substance being studied contains hydrogen. a condition readily met in organic clathrate compounds.

Phase transitions in clathrate inclusion compounds are of interest in the general viewpoint of phase transition study because of the structural peculiarity of inclusion compounds that distinguishes them from ordinary molecular crystals. Phase transitions occur in clathrate inclusion compounds as a result of interactions between the guest molecules. (Clathrate hydrates are exceptional in that the host lattice is also disordered.) Host–guest interaction is not sufficient for the occurrence of a phase transition. however strong it may be. Thus. occurrence of a phase transition shows that there are strong enough interactions between the second nearest pair of molecules in the crystal. The first neighbor interaction is, of course, the host–guest interaction. The guest–guest interaction thus deduced from the phase transition also contributes to the stability of the clathrate crystal to some extent.

UREA AND THIOUREA INCLUSION COMPOUNDS

Long-chain hydrocarbons such as decane. dodecane, hexadecane, and eicosane form channel-type inclusion coinpounds with urea. Low-temperature calorimetry on these compounds reported in 1965[4] appears to be the first work that introduced inclusion compounds into the study of phase transitions. The hexagonal space group $P6_122$ requires that the guest molecules in the all-*trans* conformation be disordered, with their molecular planes lying in one of the three equivalent orientations. The phase transitions occur at temperatures between 100–200 K. depending on the chain length of the guest molecules. For the urea–hexadecane inclusion compound. the low-temperature phase stable below 150 K is orthorhombic, belonging to the space group $P2_12_12_1$. The transition entropies are consistent with the threefold disorder of the molecular plane in the hexagonal phase and its ordering in the orthorhombic structure at low temperature.[4] Because the length of the hydrocarbon chain is not always an integral multiple of the repeating unit of the host lattice; the structure may be incommensurate.[5,6] This complicates the structure analysis. For smaller guest molecules such as trioxane, the stoichiometry $(urea)_3G$ suggests a commensurate structure.[7] These stoichiometric inclusion compounds also undergo phase transitions. Deuteron magnetic resonance gives detailed knowledge about the reorientation of the guest molecules in the high-temperature phase. Undecane-1,11-dicarboxylic acid and dodecane-1,12-dicarboxylic acid form similar inclusion compounds with urea. They also undergo phase transitions at low temperatures arising from the order–disorder mechanism.[8]

Thiourea forms channel-type inclusion compounds with globular molecules.[9] This is partly because the space group $R\bar{3}c$ lacks a screw axis that the space group of the urea inclusion compounds $P6_122$ possesses. The larger diameter of the channel than in the urea compounds accommodates cyclohexane and monosubstituted cyclohexane as well as carbon tetrachloride and hexachloroethane in the channel. With these more or less spherical molecules as the guest species. thiourea inclusion compounds are rich in their polymorphism. most undergoing two or more phase transitions below room temperature.

The thiourea–cyclohexane inclusion compound undergoes phase transition at 127 K and 148 K.[10] The reorientational motion of the guest molecule approaches the spherical rotation at a higher temperature. with discontinuous increase of its rate at these temperatures. as detected by deuteron magnetic resonance.[10] Neutron scattering was used to study the molecular motion in space and time, simultaneously giving detailed knowledge of geometry and time rate of the reorientation.[11]

The thiourea–CCl_4 compound shows that a rigid molecule can also form an inclusion compound with thiourea.[9,12] It undergoes phase transitions of an order–disorder type. as the entropy change and the crystal structure suggest.[13,14] The $CBrCl_3$ forms a similar

compound with thiourea. The heat capacity reproduced in Fig. 1 shows the two thermal anomalies due to first-order (84 K) and second-order (92 K) phase transitions. The former is characterized by a Δ-function peak, whereas the latter is characterized by a discontinuous decrease of the heat capacity, exemplifying the first two cases of the Ehrenfest classification of phase transitions.[2,3] Interestingly, the orientational disorder corresponding to the exchange of Br and Cl atoms persists in the low-temperature phase and ultimately becomes frozen in a glass transition at 20 K (see the reference given in the caption of Fig. 1). Persistence of the residual disorder down to 4 K was also deduced from nuclear quadrupole resonance of the Cl nuclei. The high sensitivity of this technique contributed to detection and quantification of the critical properties of the phase transition in the CCl_4–clathrate compound.[15,16] This was achieved by studying the temperature dependence of the electric field gradient at the nitrogen nucleus in the host molecule, arising from disordering of the guest species.

A recent development in this area is the finding of an incommensurate structure in the thiourea–C_2C_6 compound,[17] a contribution from clathrate research to the general solid-state physics of incommensurate crystals. The stoichiometry of this compound is 2.95:1. The slight deviation from the ideal ratio 3:1 arises from discommensuration over several unit cells, where the location of the guest molecules does not mesh with the host structure, alternating with nearly commensurate regions persisting over several tens of the unit cells. The compound is disordered above 96 K, where a phase transition occurs, accompanied by an entropy change of 6.57 $JK^{-1}mol^{-1}$.[18] The soliton, another name of discommensuration, becomes less mobile at low temperature and finally freezes into a glassy state at 59 K.[18,19]

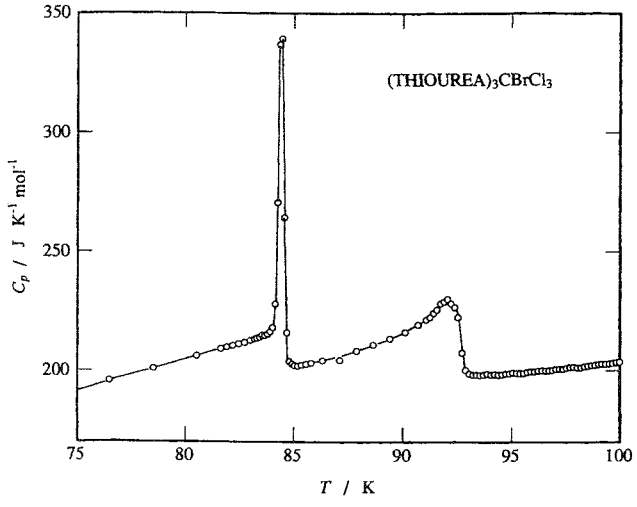

Fig. 1 The heat capacity of $(thiourea)_3CBrCl_3$ in the temperature range of the phase transitions. [From T. Matsuo and O. Yamamuro, *Supramolec. Chem.*, **6** (1995) 103.]

In the thiourea 1,1,2,2-tetrachloroethane compound, phase transitions occur at 224 K and 248 K with much larger transition entropies (28.1 and 11.3 $J K^{-1} mol^{-1}$[20]). This is related to the lower symmetry of the guest molecule than C_2Cl_6, giving a larger number of equivalent and distinguishable orientations of the guest molecule in the high-temperature phase. The ordered structure was not studied.

HYDROQUINONE–CLATHRATE COMPOUNDS

In hydroquinone–clathrate compounds, the host molecules form nearly spherical cavities in which small guest molecules reside. This structure, determined by x-ray diffraction in 1947 and the first recognized as such, was the starting point of clathrate research.[21] The phase transition in $(hydroquinone)_3MeOH$ was found in 1967 by heat capacity measurement at low temperature.[22] The entropy of transition (comparable with the molar gas constant for a mole of the guest molecule) suggested an order–disorder mechanism. The Debye-type dielectric loss (occurring above the transition temperature 67 K) is an important characteristic of an order–disorder mechanism involving motion of a polar molecule. Other hydroquinone clathrate compounds formed by small polar molecules also undergo phase transitions. Polarity of the guest molecule is necessary for a phase transition to take place in hydroquinone–clathrate compounds, because the mutually orienting interactions essential for an ordering phase transition are possible only with long-range electrostatic forces. In fact, the temperatures of the phase transitions of hydroquinone clathrate compounds correlate well with the square of the dipole moment of the guest molecule, as shown in Fig. 2. The figure includes recent data (on HCl and CH_3CN) added to the original plot on H_2S, CH_3OH, and HCN. The slope of this correlation line T_{trs} versus μ^2, related to the dipole lattice sum and electrostatic shielding factor of the host lattice, is also of the correct magnitude. However, actual ordering patterns are complicated, as shown by x-ray diffraction[23] and NMR[24] for the methanol clathrate. Macroscopic measurements (dielectric constant and spontaneous polarization) and vibrational spectroscopy are also useful for this purpose. Energy calculation, molecular dynamics, and comprehensive statistical mechanical calculations were performed with an important result about the stabilization of nonstoichiometric clathrates.[25]

The transition temperatures 7–15 K of hydroquinone–clathrate compounds containing very small polar molecules (HCl and H_2S) are comparable with the separation

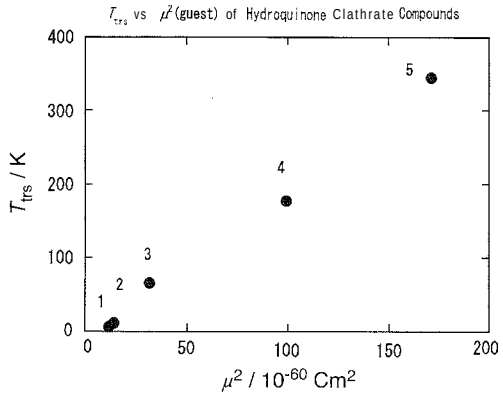

Fig. 2 Transition temperatures of hydroquinone clathrate compounds plotted against the electric dipole moment of the guest molecule: 1: H_2S, 2: HCl, 3: MeOH, 4: HCN, and 5: CH_3CN. [The original plot from T. Matsuo and H. Suga, **J.** *Inclus. Phenom.*, *2* (1984) 49, was extended with recent experimental data from Refs. [26] and [29].]

between the rotational energy levels of the guest species in the gaseous state. Far infrared absorption and neutron scattering showed the unusually high rotational mobility of these guest molecules at very low temperatures.[26] Quantum mechanical effects may be important in these compounds. as discussed in a quantum version of the mean field theory.[27]

The nonstoichiometric property of this compound presents a new type of cooperative behavior of the guest molecules. At lower concentrations of the guest MeOH, the transition temperature is lower. because the effective ordering energy is smaller. However, the reorientation rate of the guest molecule in the cavity decreases faster than the ordering temperature. This results in strong short-range correlation of the guest orientation. while the crystal remains in the high-temperature phase. Eventually. this leads to the freezing of the guest orientation in a spin-glass-like state.[28]

CLATHRATE–HYDRATE CRYSTALS

The guest molecules in clathrate hydrates are confined in nearly spherical cavities. The symmetry of the cavities is high, most having fourfold. threefold, inversion, or other symmetry elements and their combinations.[29] Therefore, the guest molecules of low symmetry (e.g., polar molecules) have several equivalent orientations in the cavity and, hence, are disordered. The disorder persists to 4.2 K, as dielectric and NMR measurements show for, e.g., dimethyl ether in a Structure II hydrate.[29] A phase transition to ail ordered phase may be expected to occur. as we saw in hydroquinone compounds discussed above. In fact, in trimethylene oxide hydrate; the ordering of orientation of the guest occurs in a phase transition at 105 K.[30] In other clathrate hydrates, it appears that the guest molecules remain disordered, even at low enough temperatures where the ordering is expected to take place from the thermodynamic point of view. Interestingly, the guest molecules reorient themselves fast. even at the lowest temperature (4 K) examined. Slow kinetics is thus excluded as the reason for the absence of ordering.

It was pointed out that the ordering is inhibited by the random electric field due to the disorder in the host lattice. The host lattice formed by tetrahedraily hydrogen-bonded water molecules has the same local structure as in ice *Ih* and has the same disorder as to the position of hydrogen atoms. Ice *Ih* becomes ordered below 72 K when doped with KOH (see the reference cited in the caption of Fig. 3). The dopant is effective even at concentrations less than 0.1 mole %. Clathrate hydrates undergo similar ordering transitions under the action of doped KOH. In Fig. 3, the heat capacities of tetrahydrofuran (THF) hydrate samples (pure and KOH-doped) are shown. Pure THF hydrate undergoes a glass transition at 85 K, and doped THF hydrate undergoes a phase transition at 61.9 K. The transition entropy includes contributions from the host lattice

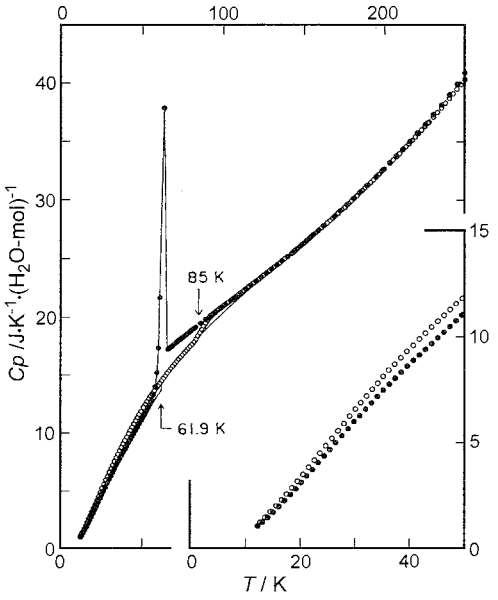

Fig. **3** The heat capacity curves of tetrahydrofuran clathrate hydrate (open circles) and tetrahydrofuran clathrate hydrate doped with KOH (mole fraction 1.8×10^{-4}, filled circles). showing the glass transition at 85 K for the former and phase transition at 61.9 K for the latter. [From O. Yamamuro, M. Oguni. T. Matsuo and H. Suga, **J.** *Phys. Chem. Solids.* 49 (1988) 425. See also O. Yamamuro and H. Suga, **J.** *Thermal Analysis, 35* (1989) *2025.1*

and guest molecules. The dielectric permittivity showed that the guest inolecules are disordered above 61.9 K and are ordered below. Other clathrate hydrates behave in a similar way. undergoing phase transitions when doped with KOH. For these, see the references given in Fig. 3.

OTHER CLATHRATE INCLUSION COMPOUNDS UNDERGOING PHASE TRANSITIONS

Phase transitions were reported in other clathrate systems. Although these were not studied systematically, they are important as indications of generality of phase transitions in supramolecular systems. Some are of interest because of the transition mechanism. others are of interest for molecular recognition involving cooperative effects, and still others are for potential use in practical applications.

In the toluene clathrate of *t*-butylcalix[4]arene, disorder of the molecules is suspected from the crystal structure. The NMR nieasurements showed that the spectrum changes at 248 K.[30,31] The more complicated spectrum recorded at a lower temperature is evidence for ordering of the host and guest molecules. Disorder of the guest molecule appears to also be involved in the phase transitions of the Werner clathrate compound containing p-xylene, studied by low-temperature calorimetry. Removal of xylene from the crystal does not destroy the crystal, but the peaks (at 45 K and 75 K) in the heat capacity curve disappear.[32] They are most likely ordering transitions arising from the guest molecules: though there were no structural studies of this compound at low temperatures.

β-Cyclodextrin undecahydrate undergoes a first-order transition at 226 K. accompanied by an entropy change of 45 $JK^{-1}mol^{-1}$.[33] The large transition entropy is related to disorder of the water molecules in the channel of cyclodextrin. Disorder of the water molecules is also involved in a clathrate-like hydrate crystal $[H_{31}O_{14}][CdCu_2(CN)_7]$ studied by calorimetry and dielectric measurement.[34]

CONCLUSION

The most interesting aspect of phase transitions in clathrate compounds is probably the cooperativity among the guest molecules that underlies their ordering. This arises from guest–guest interactions that are weak secondary interactions. usually disregarded in comparison with host–guest interactions. Despite the weak energy involved, guest–guest interactions can generate long-range cooperative effects that determine even macroscopic properties and the symmetry of the compound. Various clathrate systems undergoing phase transitions have so far been studied mostly for the purely theoretical purpose of understanding the basic mechanism of cooperativity. Clathrate systems will continue to provide actual cheinical compounds in which we will be given new aspects of cooperativity. They will include equilibrium as well as time-dependent cooperative phenomena. Nonstoichiometry, an original defining property of a clathrate compound[21] (but not stressed in recent years), offers the possibility of uniformly random cooperative systems.

Molecular recognition. as understood now, is a local concept meaning preferential stabilization of a pair of molecules in a specific mutual configuration. It appears that molecular recognition may be generalized to include cooperativity extending over a large distance. There is actually cooperative molecular recognition in the simplest clathrate crystal. When a hydroquinone acetonitrile clathrate crystal grows in acetonitrile solution, acetonitrile molecules enter the crystal lattice exactly in the orientation dictated by the guest molecules already in the crystal lattice. In the crystal thus formed. all the guest molecules recognize their own orientation relative to the orientations of their neighbors. Hence, cooperative molecular recognition. Although the hydroquinone clathrate is too rigid to be of use in actual application, the cooperative molecular recognition enunciated by this case may be a useful concept arising from phase transitions in clathrate compounds.

Collagens

Jean-Yves Exposito
Centre National de la Recherche Scientifique, Lyon, France

INTRODUCTION

Collagens are a family of extracellular matrix proteins that represents up to one-third of protein mass in higher animals. They are often associated with the emergence and evolution of metazoa. By definition, collagens are proteins that contain at least one triple-helical domain and that form supramolecular aggregates in the extracellular matrix. The triple-helical domain results from the conformational association of three polypeptides consisting of Gly–X–Y triplets and has to be considered as one of the multiple modules used to build multimodular proteins. Collagens were first known as the key elements of the extracellular matrix, providing the structural integrity of tissues, and ultimately, of animals. Involvement of many collagens in human diseases and their numerous interactions with neighboring extracellular components and cellular receptors clearly support their functional importance in developmental processes and tissue remodeling. Their roles in these functions are closely related to their ability to oligomerize and to create multivalent supramolecular networks.

COLLAGEN DEFINITION

In mammals. collagen is the most abundant protein (about 30%) and was first known as gelatin, which corresponds to heat-denatured collagen. A useful history of collagens was presented by van der Rest and Garrone.[1] The word collagen came from the properties of some connective tissues to give glue or gelatin after boiling (from the Greek; κολλα, glue, and γενοξ, birth). During the last century. biochemical and molecular investigations led to a clearer definition of this family of proteins. Collagens are extracellular matrix proteins that contain at least one collagenous domain or triple helix and that form supramolecular networks. More recently. biological activities other than their involvement in the structural integrity of organisms were demonstrated for collagens. Consequently. their fundamental role in developmental and biological processes such as cell behavior should be included in a current definition of collagens. In this article, we will describe collagens in terms of structure. metazoan evolution, and function.

THE COLLAGEN TRIPLE HELIX

The triple helix is a hallmark of collagens. which are trimeric molecules. This structural motif corresponds to a right-handed super helix and represents the conformation resulting from the association of three left-handed polyproline-11-like polypeptide a chains (Fig. 1). The sequence involved in this left-handed conformation consists of the repetition of Gly–X–Y triplets. where X and *Y* are often proline and 4-hydroxyproline, respectively. The imino acids stabilize the triple helix. while the sterically small glycine residue is the only amino acid that can fit into the central position of the three intertwining helices that are closely packed (1.5 nm in diameter). Within the triple helix, the neighboring α chains are staggered by one amino acid. During the last decades. diffraction and x-ray crystal structure analyses of collagen and synthetic peptides improved the knowledge of this supercoiled protein motif. The main conclusion is that the triple-helical structure is dependent on the collagen sequence[i3] Hence, the triple-helical twist is smaller in imino-acid-rich regions, but there are generally 3.33 residues per helical turn, with a rise of 2.86 Å per residue (see Fig. 1).

COLLAGEN AND COLLAGEN-LIKE FAMILIES

Collagen-hike Proteins

A collagenous domain is not peculiar to collagens and is present in proteins that are not implicated in extracellular matrix structure.[''''] Some of the collagen-like proteins are involved in host defense, and for this reason, they were called defense collagens.[6] In this group of proteins are the collectins that possess a short collagenous domain. connected to a C-type (calcium-dependent) lectin via an α-helical coiled neck region; the ficolins. which are structurally similar to collectins but with the lectin region replaced with a fibrinogen-like module: the complement C1q and adiponectin. which both consist of a carboxyl-terminal C1q domain connected to a collagenous region: and membrane-associated Type-II proteins, including three isoforms of the macrophage scavenger receptor and the so-called macrophage receptor MARCO. noncollagenous proteins possessing a triple helix are emilins, the collagen tail of acetyl cholinesterase, and the Type II transmembrane protein, ectodysplasin.

Human Collagens

Collagens are present in organisms from the sponge to a human.[5,7] In humans, 27 types were characterized, and their sequences are available online (Ref. [4]). Collagens are made by the association of three identical α-chains for homotrimeric molecules or by the association of two or three genetically distinct α-chains for heterotrimeric molecules. The collagen nomenclature results mostly from the order of characterization of the collagen types (I, II, III...). More precisely, an α*n*(*Y*) collagen polypeptide corresponds to the α chain *n* of type *Y*, where *n* and Yare Arabic and Roman numerals, respectively. Collagens can be divided into several subfamilies according to their primary structures and their resulting supramolecular structures. The first and best known are the so-called fibrillar collagens (Types I–III, V, and XI) that generate cross-striated fibrils. The procollagen procursors of all fibrillar α-chains present the same overall structure, i.e., a central uninterrupted triple helix of approximately 338 Gly–X–Y triplets flanked by two noncollagenous doinains, the amino- and carboxyl-propeptides (Fig. 2A). Other subfamilies are known as nonfibrillar collagens, because they present short interruptions in their collagenous domains. Among them, Type IV collagen is specific to basement membranes and is a network-forming collagen. Other nonfibrillar collagen subfamilies include the fibril-associated collagens with interrupted triple helices or FACITs (Types IX, XII, XIV, XX, XXI); the FACIT-related collagens (Types XVI and XIX); collagens that form beaded filaments and hexagonal networks (Type VI); Type VII, which is the major component of anchoring

Table 1 Fibrillar collagens

Type	Molecule	Tissue distribution	Disease
I			
α1(I) α2(I)	$(\alpha1)_2$, α2	Ubiquitous skin. tendon bone etc	Osteogenesis imperfecta, Ehlers–Danlos syndrome (arthrochalasia), osteoporosis
	$(\alpha1)_3$ (minor form)	Dentin. tumors, skin	
II			
α1(II)	$(\alpha1)_3$	Hyaline cartilage, vitreous body	Chondrodysplasia (severe to mild disease) osteodrthrosis
III			
α1(III)	$(\alpha1)_3$	Skin, blocd vessels intestine	Ehlers–Danlos syndrome (vascular)
V			
α1(V), α2(V), α3(V)	$(\alpha1)_2$ α2 (major form)	Same as Type I	Ehlers–Danlos syndrome (classical)
	$(\alpha1)_3$	Hamster lung cell culture	
	α1 α2. α3	Placenta. Synovial membranes	
		V/XI heterotypic molecules	
XI			
α1(XI), α2(XI), α3(XI)	α1. 22. α3	Hyaline cartilage	Chondrodyslasia (mild disease). osteoarthrosis no-syndromic hearing loss

The α3(XI) chain appears to be a posttranslationally modified form of the α1(II) collagen chain.

fibrils that participate in the attachment of basement membranes to the underlying extracellular matrix; and short-chain collagens forming hexagonal networks (Types VIII and X). Finally, the latest families include Type II transmembrane collagens (Types XIII. XVII. XXIII, and XXV); multiplexins (collagens including multiple collagenous domains and interruptions. Types XV and XVIII); and the newly characterized Type XXVI.

COLLAGEN BIOSYNTHESIS

In the extracellular matrix, collagens form supramolecular organizations. To follow the different steps leading to these structures. we will focus our attention on fibrillar collagens for which most of the work was done. Illustrated in Fig. 2B are the fates of fibrillar collagen chains from their syntheses to their incorporations into fibrils. The first step is the translation of collagen mRNA in the rough endoplasmic reticulum on membrane-bound polysomes. Concornitant with the translocation of the nascent procollagen chain into the lumen of the endoplasmic reticulum, cotranslational events occur. These include the hydroxylation of some proline and lysine residues by prolyl and lysyl hydroxylases. respectively. Modified prolines are 3-hydroxyproline and 4-hydroxyproline in the X and *Y* positions. respectively. Other cotranslational modifications are the glycosylation of certain hydroxylysines by galactosyltransferase or glucosyltransferase, the addition of mannose-rich oligosaccharides to the W-linked oligosaccharide attachment site in one or both propeptides, and the formation of disulfide bonds in the *C*-propeptide. mediated by the protein disulfide isomerase (PDI). After complete translocation of the procollagen chain and removal of the signal peptide, the formation of procollagen molecules begins. As indicated in Table I. not all of the possible molecular compositions are produced indeed—one cell can synthesize different types of fibrillar collagen. It was demonstrated that a short sequence located in the C-propeptide is involved in the recognition of relevant pro-α chains.[8] Interestingly, this sequence is absent in all the invertebrate fibrillar α-chains characterized to date.[7] The formation of the procollagen molecules begins by the recognition and association of the C-propeptides, this structure being stabilized by intra- and interdisulfide bridges. At this point, the formation of the triple helix is propagated from the C-terminus toward the amino-terminus. Even though a triple-helical conformation can be formed in the absence of the C-propeptide, proper α-chain recruitment and correct register of the collagenous regions requires this domain. The next step is the transfer of the procollagen molecules into the Golgi without leaving the lumen of the cisternae.[9] During cisternal maturation, procollagen is laterally aggregated. The final step is the secretion of these aggregates from vesicles. During ail of these processes, several chaperone

proteins are involved in the proper folding. the retention of unfolded molecules. and the vesicular trafficking of collagen molecules.[10] In addition to being involved in the hydroxylation of proline residues in position *Y*. prolyl-4 hydroxylase (P4-H) also acts as a chaperone by interacting with the correctly folded monomeric triple helix. The PDI is the enzyme used in the formation of disulfide bridges in the C-propeptides, but it is also involved in quality control of collagens in the endoplasmic reticulum. Hence, PDH mediates retention in the endoplasmic reticulum of unassembled procollagen C-propeptides. The Hsp47 is an endoplasmic reticulum collagen chaperone that seems to prevent the lateral aggregation of collagen molecules before their transfer to the golgi. An in vitro study indicated that Type I collagen is thermally unstable at body temperature.''' As indicated by Persikov and Brodsky,[12] the collagen triple helix is more stable in cells, and an increase in collagen stability might be correlated with the interaction between chaperones and the triple helix.

After secretion, the soluble aggregated procollagen molecules are generally processed by amino and carboxyl proteinases, leading to the formation of insoluble collagen molecules ready to be incorporated into fibrils. The mature collagen molecule consists of a central triple helix flanked by two shori noncollagenous extensions, the N- and the *C*-telopeptides. In fibrils, collagen molecules, approximately 300 nm or 4.4 D in length. are aligned in parallel. with a *D*-stagger, including a gap zone and an overlap region (see Fig. 2B). This molecular staggering explains the striated appearance of negatively stained fibrils as revealed by transmission microscopy (Fig. 2C). How are the fibrils organized and how can we explain the shape heterogeneity of fibrils? Although numerous studies and models were made from structural analyses, these questions were not completely answered. In this article, we will present data concerning heterotypic fibrils in cornea composed of Types I and V collagens. Corneal stroma fibrils are uniformly thin and are arranged into a highly ordered lattice-like structure. This orthogonal structure was postulated to be of importance in the transparency of cornea. Holmes et al.[13] used automated eiectron tomography to analyze the structures of corneal fibrils. The authors indicated that these fibrils are composed of microfibril units (five collagen molecules). which are tilted by 15° with respect to the long axis of the fibrils in a right-handed helix. Moreover. the microfibrils exhibit an ordered lateral arrangement at the boundaries of the overlap regions (*N*- and *C*-telopeptides) and in a region of the gap zone. Disordered arrangements were observed in other regions of the *D*-period. The *N*- and *C*-telopeptide regions are involved in intermolecular cross-linking in fibrils. Moreover, their presence improves fibril formation: as revealed by in vitro fibrillogenesis experiments. Analyses of these heterofibrils reveal that macromolecules are located at their surfaces in regions exhibiting a relatively ordered arrangement. These macromolecules might be the *N*-propeptide of Type V collagen that is not fully processed in mature fibrils. Linsenmayer et al.[14] suggested that the retention of Type V *N*-propeptide at the surface of the fibrils prevents, by sterical hindrance, the addition of new collagen molecules and permits the formation of thin fibrils of regular diameters. Other macromolecules are the small leucine-rich repeat proteoglycans such as lumican. Lumican-null mice present an opacification of the cornea and a disorganization of the fibril network.'''' The presence of lumican in normal mice seems to prevent the lateral fusion of collagen fibrils. Hence. different parameters might explain variations in fibril shape, including the collagen types involved and their ratios, retention of the *N*-propeptide, interaction with neighboring components such as the small leucine-rich repeat proteoglycans or the FACIT collagens, and the intrinsic sequence of the triple

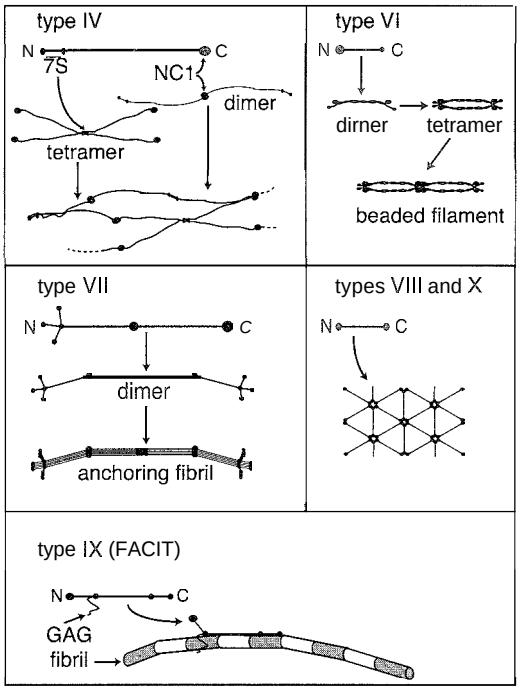

Fig. *3* Supramolecular organizations of some nonfibrillar collagens. The steps leading to the formation of supramolecular structures from monomeric molecules. helix. To complete this section. the supramolecular organizations of some nonfibrillar collagens are illustrated in Fig. 3.

EVOLUTION OF COLLAGENS

From the first multicellular animals, sponge and hydra. to humans, only two classes of collagens seem to be maintained to date: the fibrillar and the basement-membrane Type IV collagens. For fibrillar collagens, their absence was demonstrated in a few species such as *Drosophila melanogaster* and *Caenorhabditis elegans*. It was suggested that flies and nematodes do not need the mechanical resistance produced by fibrillar collagens, because they have a chitinous or a cuticular exoskeleton, respectively.[5,16] The complete genome sequences of these two protostome animals are available, and subsequent analyses indicated that in addition to Type IV collagen. only a vertebrate collagen ortholog, Type XVIII, is present in these animals. Collagens that appear to be unique to some invertebrate phyla were characterized. We can cite the cuticular collagens of nematodes. These short-chain collagens are encoded by a large family of genes and are involved in part in the physical properties of the cuticle.[17] Another family of short-chain exocollagens (collagens outside the animal) was described in sponges.[18] These collagens are termed spongin and play two major roles. One is to attach the animal to its substratum, while it can also act as cement between the spicules forming the sponge skeleton. Hence. in the well-known bath sponge, spongin collagen replaces the inorganic skeleton. Other invertebrate collagens described to date are the collagen from mussel bysus, hydra minicollagens, and the cuticle collagen of annelid.[''''] From the diversity of collagen and collagen-like proteins and the presence of this structural motif in prokaryotes. several questions come to mind. How old is collagen? How should the triple helix be perceived? From sequence and fossil analyses. its metazoan origin was dated to approximately 600 to 1000 million years ago.[20] Environmental changes. such as the increases in oxygen in the late proteozomic, were postulated to be involved in the burst of metazoan radiation during the Vendian–Cambrian period. Oxygen is important for animal respiration and for the evolution of metabolic processes in animals.[21] Moreover. through its involvement in the posttranslational hydroxylation of proline and lysine residues. the increase of oxygen can also be considered a key step favoring the synthesis of coilagen. which can be considered an hallmark of metazoans. En fact. collagen and collagen-like molecules were also described in plants and prokaryotes. In metazoans, extracellular matrix proteins and the extracellular region of transmembrane proteins are composed of modules. By definition, a module should be present in multiple copies in one protein or in otherwise unrelated proteins,[22] it should be able to fold independently, and it is generally encoded by one exon. Several authors indicated that the triple helix might be considered a module.[5,23] From its short repeating primary motif (Gly–X–Y), the size of this module can easily be changed. Hence. in fibrillar collagen genes, most of the exons encoding the triple helix are 54 bp or 45 bp long. In Type VI gene, there is a prevalence of 63 bp exons. Another important function of the triple helix is its involvement in oligomerization. a structural function permitting the formation of inultivalent supramolecular networks.

FUNCTIONS OF COLLAGENS

The structural and biological importance of collagens is clearly demonstrated by the study of human genetic diseases resulting from mutations in genes encoding collagens or enzymes involved in their posttranslational modification. The catalog of human diseases is available in a recent review[''] and is indicated in Table 1 for the fibrillar collagens. Natural disease and knock-out experiments in mice confirmed the human data and also permitted the identification of other potential genetic diseases. In this article; we will focus on the Ehlers–Danlos syndrome. This syndrome is divided into several subtypes, but it is generally associated with joint hypermobility and skin fragility. The genes involved in this syndrome encode Type I and III collagens, and the α1 and α2 chains of Type V collagen. lysyl hydroxylase and, more recently identified, tenascin-X.[24] Tenascin-X is also an extracellular matrix protein detected at the surface of fibrils in the skin that interacts with decorin, a small leucine-rich repeat proteoglycan.[25] Decorin interacts with Type I collagen and tenascin via its core protein and its dermatan sulfate chains. respectively. Moreover, decorin-null mice present a phenotype related to the Ehlers–Danlos syndrome.[26] Altogether, these data clearly show that maintainance of the supramolecular fibrillar network is important for the structural integrity of skin.

The functional importance of collagens in biological activities can be considered on two levels. The first results from the triple-helical sequence. Hence, as previously indicated[i1]] and shown in Fig. 1. residues X and Y are exposed at the surface of the triple helix and are available for lateral interactions. Ligands of the triple helix were characterized. such as several integrins and proteoglycans. The second level concerns the noncollagenous domains of collagen. One of the best known is endostatin, which represents the C-terminal region of collagen XVIII, a component of endothelial and epithelial basement membranes. Endostatin is the major molecular form in

several tissues. Functions associated with this protein are the inhibition of endothelial cell proliferation, migration, and angiogenesis.[27] Another function is the reduction of tumor growth in animal models. Actually, different modules form the noncollagenous domains of collagens, and some of their putative functions might be suggested from their obvious biological importance in other extracellular matrix proteins. Hence, chordin, which possesses several cysteine-rich modules (Tsp-2), is involved in dorsal-ventral patterning. Chordin interacts with different bone morphogenetic proteins (BMPs).[28] Type IIA collagen includes a Tsp-2 module in its N-propeptide. The dorsalizing activity of Type IIA collagen was shown by injecting Type IIA mRNA in *Xenopus* embryos.[29] The Tsp-2 module of Type IIA collagen, which is required for this activity, binds to TGF-β1 and BMP-2.[30] Hence; the retention and the concentration of growth factors or cytokines might be some of the nonstructural functions of collagen fibrils. The availability of these sequestering molecules during remodeling or tissue differentiation might be realized by the action of different metalloproteinases.

CONCLUSION

The metazoan extracellular matrix is composed of large supramolecular networks that involve modular glycoproteins and proteoglycans. Structural elements (coiled-coil motif, triple helix) permitting oligomerization are of importance in generating these networks. The triple-helical structure. the common structural element of collagens. allows the formation of trimeric molecules. This first structural order is often associated with higher oligomerization levels involving the self-association of the triple helix or multimerization from the noncollagenous domains of these molecules. Networks including collagens are implicated in the structural properties of tissues. The best known are the collagen fibril networks that provide protection against mechanical constraints in skin and tendon. However, collagens are also important in numerous physiological events. Future directions in the collagen Geld will include dissecting their functions during development, tissue remodeling, and tumor invasion. Their use in biomedical applications will also be explored. Hence. from their biological properties, collagens are of use in several biomedical applications (hemostatic sponges. surgical sutures, sponges for burns and wounds, etc.). Private companies and academic institutes used different systems (plant, yeast. mammalian cells) to produce recombinant collagens. Improvements in production in terms of quality, quantity, and cost will be considered in the future. This approach will be further improved with a better understanding of the biological functions of the noncollagenous domains. Actually. future progress will come in the understanding of collagens, not as an individual component of an extracellular matrix but as one of the elements of the extracellular macroaggregates. Mow do these macromolecular networks influence cell signaling events and what are the roles of the extracellular matrix on the control of distinct morphogenetic processes. are some of the questions that will mobilize laboratories working in the collagen field during the next few years.

Complexation of Fullerenes

Colin L. Raston
University of Western Australia, Crawley, Perth, Australia

INTRODUCTION

Complexation of fullerenes covers a diverse range of interactions and structural types. ranging from simple host–guest complexes through to oligomeric structures and continuous arrays, and structures with covalent metal-fullerene interplay.[1–5] The later organometallic chemistry is extensive and beyond the scope of this article,[6] except where the complexes show supramolecular interactions, such as in the complexation with silver nitrate, where the fullerene effectively templates a curved silver nitrate network.'" Accordingly, the focus of this article is on the host–guest chernistry of fullerenes and higher complexity supramolecular chemistry based on organization of fullerenes with one or more other synthons.

GENERAL CONSIDERATIONS

Fullerenes are electron-deficient molecules comprised exclusively of carbon, collectively representing a new allotropic form of carbon. for which C_{60} is the most abundant, smallest. and most widely studied. having a truncated icosahedral structure 10.0 A in diameter at the van der Waals limit. They can undergo addition organic reactions that have been extensively mapped out for C_{60}; the addition is across the 6,6′-position ring junction of two six-membered rings. which is consistent with the double bonds *in* the fullerene avoiding the five-membered rings of the polyhedran, an area reviewed by Diederich and Gomez-Lopez.[4] Recent advances *in* the supramolecular chemistry of such modified fullerenes include the organization of the potassium salt of a penta-substituted fullerene into −17 nm spherical bilayer vesicles,[8] assembling fullerenes on surfaces,[9] and binding porphyrins.[10] In general. surface assembly of fullerenes on continuous flat surfaces and on the surface of nanoparticles is possible and includes the use of aza-crown ether to complex C_{60} at air–water interfaces. and the assembly of 64 C_{60}^- anions on the surface of a dendimer with terminal ferricinium moieties.[11] Dendrimers can also bind fullerenes within their internal cavities,[12,13] and this includes porphyrin-containing systems.[14,15] In addition, self-assembly processes can stabilize nanoparticles of fullerenes, such as a diblock polymer shrouding 10^{10} fullerene molecules.[16]

In embracing the principles of supramolecular chemistry, the goal is to encourage the interplay of fullerene molecules, or reduced fullerenes, noting that they can be readily reduced, in the case of C_{60} this is reversible to C_{60}^{n-}, $n = 1$ to 6. with other synthons in an organized way. This chemistry is inherently complicated by the tendency of fullerenes to aggregate at the van der Waals limit in the presence of other synthons, but this offers potential for building new arrays and materials based on both types of interactions. i.e., host–guest and interfullerene. Optimizing complementarity of curvature of fullerenes with host molecules, such as bowl-shaped cavitands and saddle-shaped molecules was a successful but not essential strategy for host–guest chemistry, as was the choice of solvent. which can tip the balance from complexation to coinplexation with aggregation of the fullerenes, through to little or no complexation. Summarized in Fig. 1 are the main types of host molecules, including cavitands 1–4. 7,[17] and 9:[18] saddle-shaped molecules, 5: porphyrins, 6: siloxanes, 8: curved-face tryptophanes. 10;[19] and β,γ-cyclodextrins, 11. Where complexation is not prevalent. the addition of other synthons can be effective. Group 1 ions. for example. bind to modified calixarenes (R' =ester) and now results in complexation of C_{60}.[20] Seemingly most molecules with aromatic ring systems and electroll-rich moieties can form complexes with fullerenes. including benzene and extended aromatic systems and tetrathiafulvalenes,[4,21] but the conditions to effect complexation are varied. Essentially planar porphydns. 6. form a myriad of complexes. despite the lack of complementarity of curvature with fullerenes. The synthesis of fullerene complexes is often simple. for example, the mixing of equimolar amounts of the two components usually in toluene, or with an excess of the "host," with the complex crystallizing over several hours or sometimes days. Only where special conditions are required, is this discussed below for specific synthons.

Fullerenes can also be taken up in the pores of mesoporous silica, with aggregation of the fullerenes in the presence of cavitand molecules such as 1–4. This is a qualitative test for host–guest chemistry between the

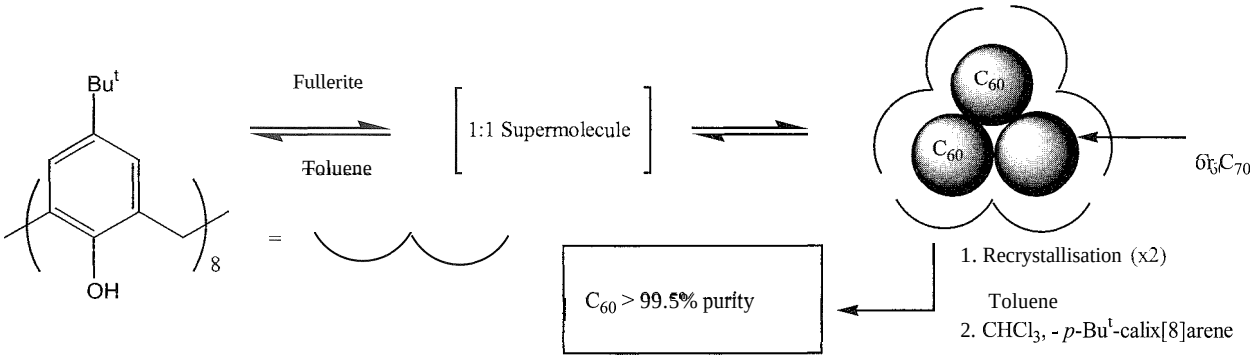
HOST–GUEST COMPLEXES

Calixarenes and Related Molecules

Calix[8]arenes, **1**, $n = 8$

Historically, complexation *of* fullerenes with *p*-Bu^t-calix[8]arene, **1**, $R = Bu^t$, $R' = H$, *was an important development in the field, independently reported in 1994 by* Atwood *et al. and Shinkai et al.. although there was an earlier report on the* binding *of a water-soluble calixarene bearing sulfonate groups on* the *lower* rim.[1,21] *p*-Bu^t-calix[8]arene *is effective in retrieving high-purity* C_{60} *from toluene solutions of* fullerite, *which is a mixture of* all *the* toluene-soluble *fullerenes in carbon soot. This involves recrystallization of the precipitate from toluene followed by* decomposition *of the* 1:1 *complex when added to chlorinated hydrocarbons* in *which the fullerene* is *only sparingly soluble (Scheme* 1). *Significant advances were made in understanding the nature of the host–guest*



Scheme 1 Purification of C_{60} by complexation

complex,[2] albeit with some conflicting reports. The *p*-Bu^t-calix[8]arene/C_{60} complex has a resonant inter-fullerene molecular transition at 470 nm, similar to that observed in thin films of C_{60}.[2] Formation of the cornplex is thought to involve a monomeric 1:1 transient intermediate that may be a genera! phenomenon for complexation of the fullerene with other host molecules. The proposed structure of the final complex is a triangular arrangement of three fullerenes surrounded by a sheath of three calixarenes in the double-cone conformation. [$(C_{60})_3$(*p*-Bu^t-calix[8]arene)$_3$] (Scheme 1). In contrast. the vibrational spectrum of the complex was probed, using Raman. IR. and neutron scattering,'" with the results consistent with the C_{60} molecules being almost isolated. suggesting that any fullerene–fullerene interactions are weak.

The electrochemistry of the *p*-Bu^t-calix[8]arene/C_{60} complex was extensively studied with the complex breaking apart on reduction (at 400 mV more negative potential).'" Other calix[8]arene complexes were reported, **1**, $n=8$. R = Pr^i and Et, R′ = H,[25] but they also were not structurally authenticated.

Fullerene C_{70} does not form a complex with the same calixarene in toluene. but it does so in benzene. crystallizing as the 2:1 complex, $(C_{70})_2$(*p*-Bu^t-calix[8]arene) (structme unknown).[25] The same fullerene also forms a 2:1 complex with *p*-Bu^t-calix[6]arene, and its precipitation from toluene solutions can be used to retrieve 87% purity C_{70} from C_{60}-depleted fullerite.[26]

Calix[6]arenes, **1**, $n=6$

The fullerene-rich calix[6]arene complexes. (C_{60} or $C_{70})_2$calix[6]arene, were structurally authenticated as isomorphous complexes,[2] showing the calixarene in the double-cone conformation with a fullerene perched in each of the shallow cavities. resembling the jaws of a pincer acting on two adjacent cage molecules; the extended structures have continuous three-dimensional interplay of the fullerenes close to the van der Waals limit (Fig. 2j). In the case of the C_{70} complex, the principle axis of the fullerene is aligned such that the end of the fullerene close to this axis, where the curvature of the cage is similar to that of C_{60}, resides in the cavity. Calix[6]-arenes bearing *N*,*N*-dialkylaniline or m-phenylenediamine units also form complexes of C_{60} in toluene solution (ill defined).

Calix[5]arenes, **1**, $n=5$

These can be grouped with oxacalix[3]arenes (see below), because they have single-cone conformations. at least for R' = H, which have a cyclic hydrogen bond array, and they have good complementarity of curvature with fullerene C_{60}.[2] In addition, there is the potential for "symmetry matching," whereby the fullerene lines up with the C_5 or C_3 symmetry axis of the cavitand, thereby optimizing π...π overlap between the synthons. For both calixarenes, there is little or no preorganizational requirement prior to forming host–guest interactions; unlike for the more flexible. larger-ring systems for calix[6,8]arenes.

Calix[5]arene, **1.** $n=5$, R = R′ = H, forms a complicated 4:5 complex with C_{60},[27] where the fullerenes assemble into five closed packed columns in a Z-arrangement. surrounded by a sheath of calixarenes (Fig. 2g). Initially. the complex was thought to be a 1:1 complex, and in this context, care needs to be exercised in establishing the stoichiometry of fullerene host–guest complexes. Moreover, the presence of otiher fullerenes and other globular molecules in solution dramatically changes the nature of the crystalline complex. In the presence of C_{70}, which is the other major fullerene in fullerite, a 1:1 calixarene:C_{60} complex forms with NO C_{70} incorporated in the structure, which is now comprised of a single zigzag array of fullerenes surrounded by a sheath of calixarenes

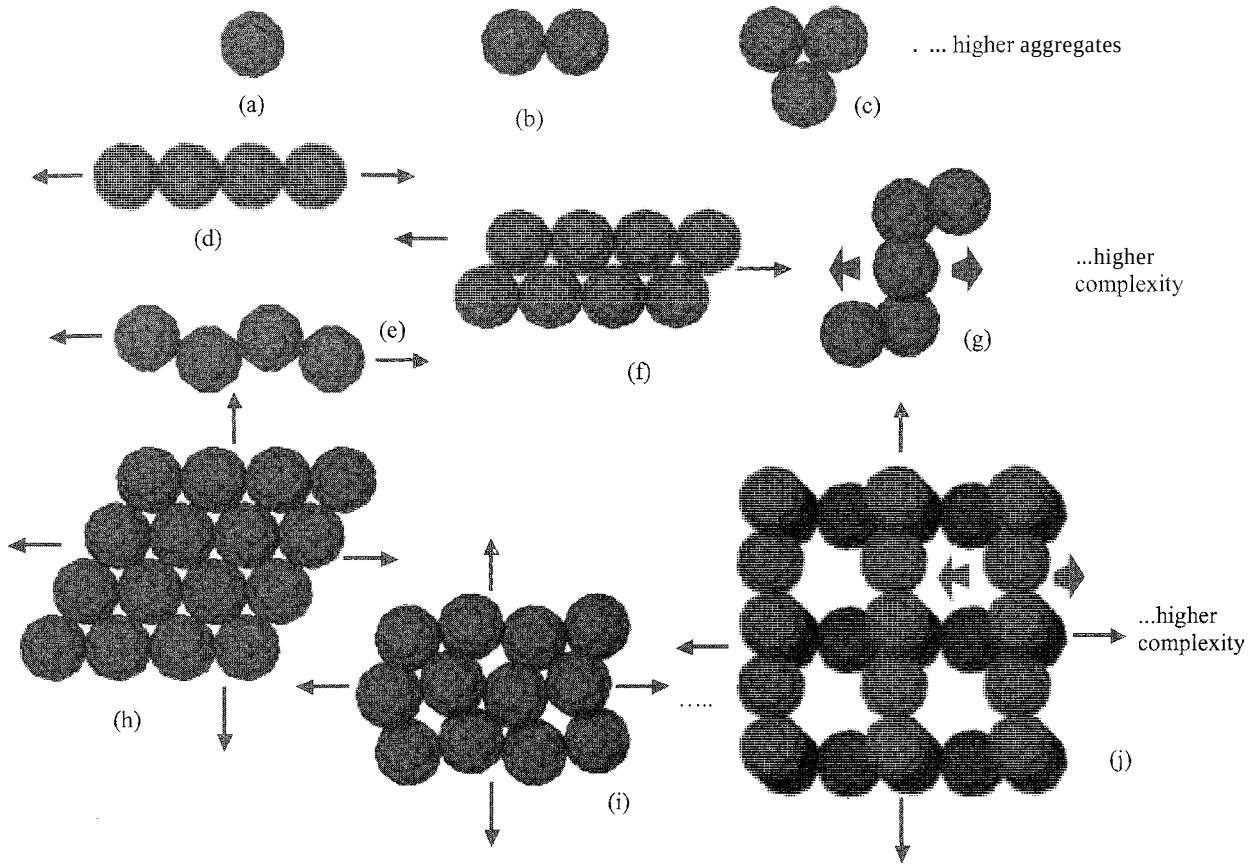


Fig. 2 The types of arrangements of fullerenes (van der Waals contacts) in their host–guest complexes (host molecules not shown). These cover finite structures. (a) monomeric (encapsulated). (b) dimeric. and (c) the proposed trimeric complex involving *p*-Bu^t-calixa[8]arene,[2] and higher aggregates. and continuous structures, all of which were established in parts (d–j),[2,27] with scope for structures of higher complexity. (*View* this *art in* color at *www.dekker.com.*)

(Fig. 2e). This is despite solution-binding constants favoring C_{70} complexation of C_{60}, and thus crystal-packing forces are important. The same 1:1 complex also forms in the presence of C_{84} and 1.2-dicarborane (1,2-$C_2B_{10}H_{12}$), an icosahedral molecule that is independently drawn into the cavity of the calixarene.[2]

p-Benzylcalix[5]arene forms 2:1 complexes with C_{60}. The fullerene is shrouded by two staggered *trans*-host molecules that are in the cone conformations with dangling benzyl groups (Figs. 2a and 3).[2,28] There is alignment of the symmetry axis of the calixarene with a C_5 symmetry element of C_{60}. However, in the case of *p*-phenylcalix[5]arene,[29] the rigid extended arms interdigitate on one hemisphere of the 2:1 supermolecule such that symmetry matching for both calixarenes is not possible. and interestingly. the fullerene here is now completely disordered.[''''] Other authenticated structures with C_{60} encapsulated by two calix[5]arenes, hence precluding

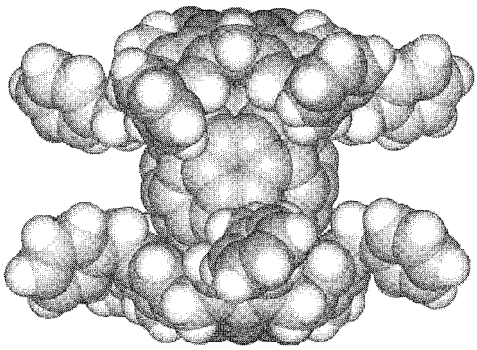

Fig. 3 Space-filling arrangement of the 2:1 supermolecules in [C_{60}⊂(*p*-benzylcalix[5]arene)2].8(toluene). (From Ref. [2].) (*View* ***this*** art *in* color *at www.dekker.com.*)

interfullerene contacts, is a calix[5]arene complex with three methyl and two iodo groups (1,3 disposition) in the p-positions of the upper rim.[2]

Solutions studies on complexation of **1**, R = benzyl, R' = H, with C_{60} in toluene gives a high K_1 association constant (2800 ± 200 dm^{3}mol^{-1}) and a relatively low K_2 (230 ± 50 dm^{3}mol^{-1}). This is consistent with the initial formation of a 1:1 complex [$C_{60} \subset$ (**1**)] (*cf* calix[8]arene intermediate. Scheme 1), followed by the formation of a 2:1 supermolecule, [$C_{60} \subset (\mathbf{1})_2$], and is in agreement with densitometry studies.[2] Similar UV/Vis studies involving 2, R = benzyl. R' = H, suggest the presence of more than one species in solution. In contrast, Fuji et al. obtained a 1:1 association constant of 35.6 dm'mol' for a related oxacalixarene (*R*= Bu^t, *2)* (or 64 ± 5 dm^{3}mol^{-1} for an independent study); and obtained 1:1 complexes rather than a 2:1 complex in the solid state, showing interfullerene interactions.[2] Other solution studies on calix[5]arenes were also reported.[27] including the electrochemical behavior of C_{60} with *p*-Bu^t-calix[5]arene[2] and *p*-benzylcalix[5]arene (solution and solid state).[28] Two calixarenes covalently linked show exceptional affinity for binding fullerenes (Fig. 4). One such system has a space between the calixarenes capable of binding metal ions (Fig. 4), and metal complexation triggers complexation of the fullerene, selectively for C_{70}.[30] Hydrogen bonding through urea moieties of single substituted calix[5]arene is another approach to entrap C_{60}, which can be retrieved under acidic conditions. The coinplexation proceeds via a 1:1 supermolecule that then takes up a second functionalized calixarene (association constants 450 and 110 dm'mol', respectively). The findings have major implications in the separation of fullerenes.[31] Elaborate monofunctionalized metal-complexed calix[5]arenes and bis-calixarenes (Fig. 4) can act as highly selective sensors for the detection of C_{60} and C_{70}.[32]

Calix[4]arenes and calix[4]resorcinarenes

The cavity of these calixarenes is usually too small to accommodate fullerenes, and is confirmed by solution, unless they have extended cavity walls as in calix[4]-naphthalenes.[27] Nevertheless, some calix[4]arenes were shown to form stable crystalline complexes with C_{60} with the fullerene eno- to the calixarene cavity. and they include *p*-Ph-calix[4]arene, which has a toluene molecule in the cavity, the overall structure dominated by fullerene–fullerene and eso-calixarene fullerene interactions;[2] *p*-Br-calix[4]arene propyl ether, the structure showing very close interfullerene contacts in a columnar structure (Fig. 2d), which most likely results in opposing induced dipoles from the unidirectionally aligned calixarenes;[34] and *p*-I-calix[4]arene benzyl ether. where the fullerenes are ordered without appreciable interfullerene interactions.[27] There is also a calix[4]resorcinarene, $R = CH_2CH_2Ph$, **3**, which has a molecular capsule derived from head-to-head hydrogen bonding of two resorcinarenes and propan-2-01 molecules, with the fullerenes also

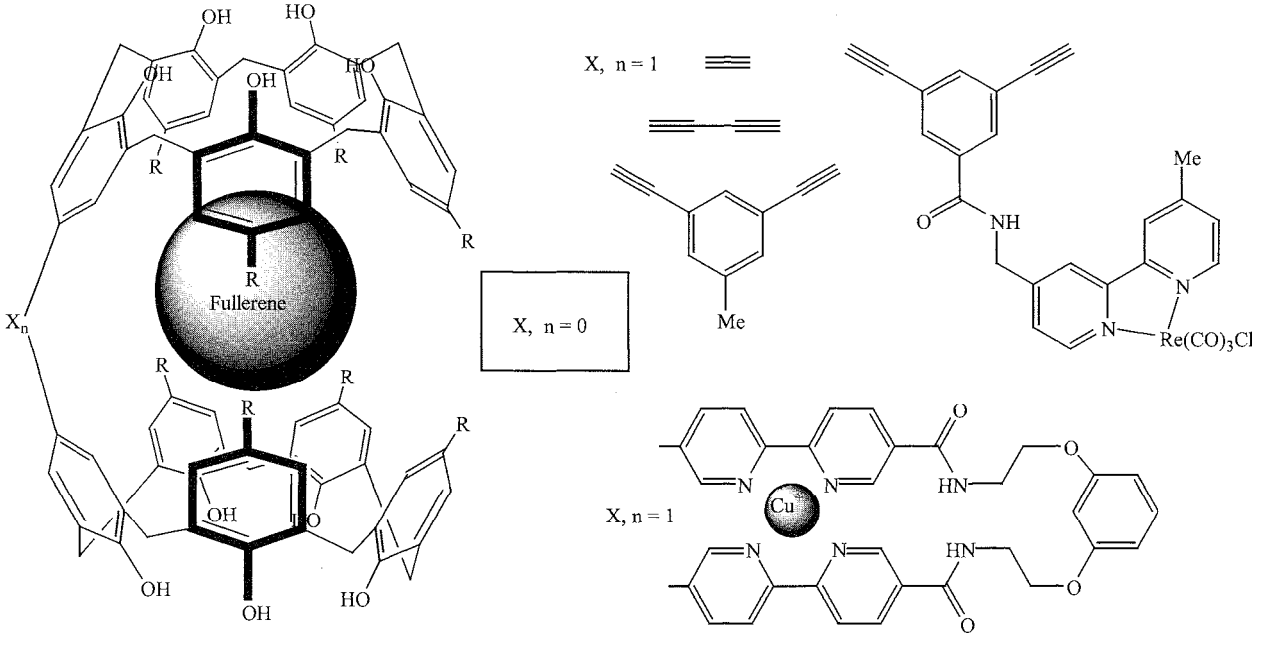

Fig. 4 Encapsulation of fullerenes by bridged calix[5]arenes. (From Refs. [30,32].)

arranged in columns.[2] A *bis*-calix[4]resorcinarene is effective in binding C_{60} (cf. his-calixarenes; Fig. 4),[35] and calix[4]resorcinarenes bearing dithiocarbamate groups between the oxo group, R = alkyl chains, and with methylene groups between adjacent 0x0-groups, 3, form torus-shaped complexes comprised of three calixarenes with divalent cadmium and zinc ions, which effectively bind C_{60}.[36]

The four-fold symmetry of calixarenes and resorcinarenes relates to complexation of the siloxane. 8, with C_{60} in toluene.[2] Here the fullerenes are arranged in double columnar arrays shrouded by edge on siloxanes (Fig. 2f), the siloxanes interlocking by one of the phenyl groups of one molecule residing in the cavity of another.

Oxacalix[3]arenes 2

These calixarenes form 2:1 complexes with C_{60} and include R = benzyl. R' = H, for which the complex was structurally authenticated (see above);''' R = 4-pyridyl, R' = $CH_2C(O)OEt$, which can be assembled with Pd^{2+} via pyridyl complexation into hexacationic capsules confining C_{60} (NMR studies);'''' and R = Bu^t, R' = water-solubilizing $CH_2C(O)N(H)(CH_2)_3NMe_3^+$.[38] Here the hexacationic capsules assemble as a monolayer on anion-coated gold surfaces and indium tin oxide surfaces. For the structure including R = benzyl. the benzyl groups are edge-on to the fullerene with C-H...fullerene interactions rather than face-on for n...π interactions.

Cyclotriveratrylene, 4

Complexation of C_{60} in toluene solutions of CTV. 4, R = R' = Me, results in poiymeric structures in the solid. either a fullerene-rich phase $(C_{60})_{1.5}$(CTV) or a 1:1 phase (C_{60})(CTV),[2,39] both complexes being studied electrocheinically (solution and solid state). The structures are dominated by fullerene–fullerene interactions, and each CTV has a C_{60} associated within the cavity of the CTV as a ''ball and socket'' nanostructure. For $(C_{60})_{1.5}$(CTV), the fullerenes collectively comprise a two-dimensional close-packed array with half of the fullerenes devoid of CTV (Fig. 2h).[2] Solvated host–guest species, [(CTV)(C_{60})], are formed first in solution. This results in polarization of the fullerene promoting aggregation, which is evident by a resonant interfullerene transition band as 475 nm. The substituted analogue 4. R = Me, R = allyl, with C_{60} shows only solvated host–guest species. C_{70} does not form an isolable complex with CTV. yet remarkably in the presence of 1.2-dicarborane, a ternary complex results with each fullerene in the cavity of a CTV. and each of these supermolecules is linked by bifurcated H-bonding to two carborane molecules. forming a helical arrangement. Thus. additional synthons can encourage host–guest chemistry.[2]

The incorporation of aromatic pendant arms on CTV leads to strong binding of C_{60}, that of *N*-methylpyrrole showing the highest association constant, 48×10^3 dm^3mol^{-1} in benzene. With six benzoyl arms. a 1:1 complex forms in the solid state. with two host molecules surrounding one fullerene, with a second ''bare'' C_{60} in the lattice.[2] The host molecule, R = benzoyl, 4. can be used to retrieve C_{60} from fullerite A planar analogue of CTV with a central six-membered ring (without the bridging methylene units of CTV) forms a 1 2 complex in the solid state. with isolated fullerenes surrounded by four planar molecules.[40]

Metal Macrocycles

Nonaromatic macrocycles 5

These have two divergent concave surfaces in a saddle-shape arrangement that arises from the otherwise unfavorable interactions between the methyl groups and the adjacent H-atoms on the aromatic rings. It can act as a divergent heterotopic receptor toward C_{60}. In the structure of (C_{60})Ni(TMTAA) (5, R = H, R' = R'' = Me), two host molecules shroud the fullerene such that a fullerene is in the saddle of one Ni(TMTAA) molecule with the methyl groups directed toward it and in the opposite saddle of another Ni(TMTAA) molecule, the overall host–guest contacts form a continuous zigzag array. with the fullerenes forming a corrugated two-dimensional sheet (Fig. 2i).[2] Cu(II) and Zn(II) TMTAA molecules similarly bind C_{60} and are isostructural with the Ni(II) analogue. For R = Me, **5**, (=OMTAA), a 1:1 complex is formed with C_{60} with the extended supramolecular array based on linear chains of close contact C_{60} molecules, and linear chains of n-stacked alternating molecules of C_{60} and Ni(OMTAA), with adjacent chains running in opposite directions and thus cancelling out dipole moments. The same macrocycle forms a 1:1 complex with C_{70}, which is isostructural with the C_{60} complex of Ni(TMTAA). In all of these Ni(II) macrocycle structures, there are no significant contacts between the metal centers and the fullerenes. As in other systems, there is evidence for the formation of 1:1 solvated supermolecules in solution. which then go on to form micelle-like species.''' The unsymmetrical macrocycle, **5**. R = H. R' = Me, R'' = Ph, also forms a 1:1 complex with C_{60}.[41]

Porphyrins, 6

Strong complexes form between n-curved surfaces of fullerenes. including C_{60}, C_{70}, Kr@C_{60}, NSc_3@C_{80}, and Er_2@C_{82}, and the airnost-planar π-surface of porphyrins,

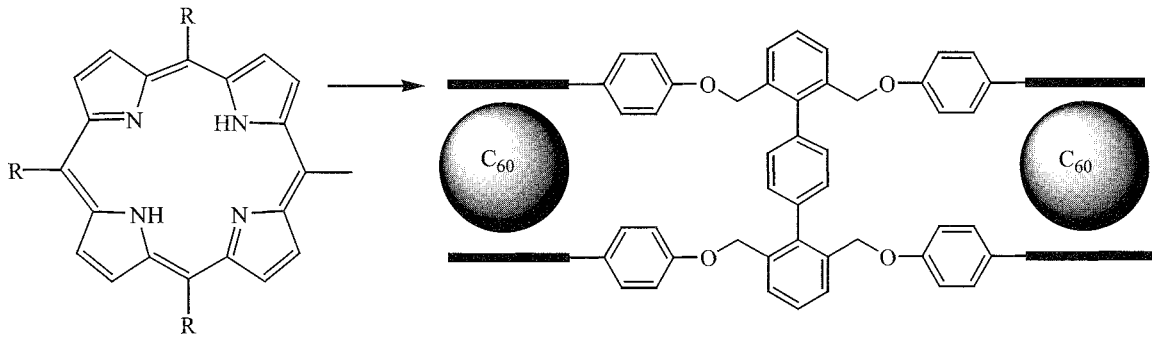

Fig. 5 A tertaporphyrin host designed for cooperative binding of C_{60} molecules (From Ref [47])

6. The most widely studied porphyrins are 6, $R = Et$, $R' = H$ (OEP), for M = Zn, Ru(CO), Pd, Cu, Ag, Ni, VO, Co, and Fe, with much of the work covered in a recent review article.[3] The complexes fall into two types: The first type includes ethyl groups in the *syn*-form, with the alkyl groups directed toward the fullerene, either one or two porphyrins associated with each fullerene (includes endohedral fullerenes).'''' and in the latter case, they almost shroud the fullerene. The second type includes four adjacent ethyl groups in either side of the porphyrin plane (*anti*-form), allowing slipped porphyrin–porphyrin contacts (includes endohedral fullerenes),[43] in structures where fullerene–fullerene contacts prevail.

Bulky groups incorporated into the porphyrin. 6, $R = H$. $R' = C_6H_3$-3,5-$(Bu^t)_2$, result in a 1:1 complex with C_{60}, but there is a fullerene on either side of the porphyrin, such that the continuous structure has the fullerene encapsulated. In the case of C_{70} complexes, the fullerene lies side-on to the principle axis, which maximizes $\pi\ldots\pi$ interactions with the flat porphyrin.[44] Amino-substituted porphyrins. 6, $R = NMe_2$, $R' = H$, M = Ni or Cu, or where the porphyrin is metal free, show a variety of structural types.[45] More elaborate porphyrin ligands were developed, including covalently linking two units to shroud a fullerene,[46] and attaching four units around a terphenyl axis (Fig. 5),[47] and assembling two porphyrins via metal complexation to form a "jaws porphyrin" host.[48] In this context, dendritic porphyrins strongly bind fullerenes.[14,15] A silica-supported zinc(II) tetraphenylporphyrin is effective in separating metallofullerenes from C_{60} and higher fullerenes (HPLC).[2]

CONCLUSION

The original work focused mainly on the larger -!-cyclodextrin, **11.** $n = 8$,[49] associated with solubilizing fullerenes in aqueous media, which was achieved for more hydrophobic cavitands, namely, lower-rim sulfonated calix[8]arenes[2] and amine-substituted oxacalix[3]arenes.[40] which are of interest in the separation of fullerenes as well as in biomedical applications. Earlier work used heterogeneous reaction to effect complexation, and here there is no binding with α- or β-cyclodextrins, **11,** $n = 6$ and 7, respectively. This was thought to be a consequence of the smaller cavity size of these cyclodextrins.[50] However, by using a mixed DMF/toluene solvent system, now as a homogeneous reaction, a 2:1 complex results, and the isolated complex is water soluble, 4 gL^{-1}. Covalently attaching fullerenes to cyclodextrins also results in binding in the cavity of two β-cyclodextrins, also as a water-soluble complex.[51]

Concave Reagents

Ulrich Lüning
Universitat Kiel, Kiel, Germany

INTRODUCTION

The selectivity of enzymatic reactions is mainly caused by the concave shielding of the active site. However. enzymes do not exist for all purposes. For some substrates and reactions, no enzymes have yet been found. Furthermore, most enzymes do not survive extreme reaction conditions (high temperatures, concentrated salt solutions, extreme pH, nonaqueous solvents). Therefore, the concave geometry of enzymes has been combined with artificial reagents. Standard organic reagents and catalysts have been placed in a concave environment in order to amplify or alter selectivities. Such concave molecules need not be made from amino acids. Almost any building block of organic chemistry may be used. Therefore, the structural components can be varied broadly. In addition, if compared to enzymes. the molecular weights of concave reagents will be reduced, because no large amino acid backbone is necessary to build up the concave structure.

The key feature of these new synthetic tools is the concave shielding of the functional group. In order to guarantee a concave geometry, the concave reagents or concave catalysts" have to be very rigid (see cleft molecules) or the potential rotational freedom has to be limited to avoid the functional group from turning to the convex outside. This can be achieved by incorporating the functional group into a polymacrocycle (cavity molecules). In the latter case. the overall geometry of such a concave reagent can be compared to a lightbulb in a lamp shade: the lamp shade is the concave shielding. and the lightbulb is the reactive functionality. Several classes of such concave reagents have been realized. and the most prominent classes will be discussed below.

In principle, all functional groups of organic chemistry can be incorporated into a concave structure. Especially acids, bases. and transition metal ions have been investigated in detail. Shown in Fig. 1 are important examples of concave reagents.

[a]In the context of this article. the term concave reagent will not differentiate between reagents and catalysts.

SYNTHESES

Before any concave reagent can be employed in a reaction. it has to be synthesized in acceptable quantities. For the translation of the structure "lightbulb in a lamp shade" into molecular dimensions, one conceivable geometrical form is a bimacrocycle. In a concave reagent. the rim must be large enough to let a molecule or a part of a molecule pass for a contact with the lightbulb. Therefore. it must be macrocyclic. This macrocycle must then be spanned by a bridge that carries the functional group, the lightbulb. Therefore, at least bimacrocycles must be synthesized. Such a synthesis is not necessarily trivial. Nevertheless, for bimacrocyclic concave pyridines **1** and concave 1.10-phenanthrolines 2, cyclization methods have been established with more than 50% overall yield for the cyclization steps. For other classes. the yields are not yet optimized.

Kinetically and thermodynamically controlled macrocyclizations have been used. A kinetically controlled reaction has the advantage in that once a macrocycle is formed; it remains a macrocycle. In contrast. the products of a thermodynamically controlled equilibrium may be interconverted into one another. If the desired macrocycle is the most stable molecule. potential side products will be transformed into the desired bimacrocycle.

Among the "library" of potential macrocycles, oligo- and polymers, the concave 1,10-phenanthrolines **2b** are the thermodynamically most stable products and can be formed by ring-closing metathesis of the tetra-alkenylated precursors 4 (see Fig. 2) in excellent yields (>70–92% for a double macrocyclization).[7] In contrast, the first macrocyclization in the synthesis of the concave pyridines **1**. the formation of the macrocyclic diimines **7**, can only be realized using a thermodynamical approach if a stabilizing template ion is added. When mixing a dialdehyde **5** and one or more diamines 6, a huge variety of possible products is or can be formed. and only the addition of a suitable template ion. an earth alkaline ion in this case, will shift the equilibrium to one macrocycle **7.** The final stable macrocyclic dianiines **8** can be isolated after reduction. If the iibrary is large and contains several diamines 6, then the addition of more than one template ion can give more than one inacrocyclic diamine 8 in good yields (>70%) in parallel.[8]

Fig. 1 Important classes of concave reagents: concave pyridines **1**[1–3] and concave 1,10-phenanthrolines **2**[4,5] and **3**.[6] which may complex transition metal ions.

But in most macrocyclizations, thermodynamic control is not yet possible. These macrocyclizations have therefore been carried out under kinetic control, often using high dilution conditions. Typical reactions are the formation of lactams, for instance. in the second macrocyclization during the synthesis of concave pyridines **1** by reaction of the macrocyclic diamines **8** with diacid dichlorides,[1–3] or the reaction of calix[6]arene with dibromides to give A,D-bridged calix[6]arenes like **3** by a double substitution reaction.[11,12]

Not only cavity-containing molecules can be employed as concave reagents, but also, cleft molecules have been realized. The necessary stiffness usually is realized by an aryl-aryl backbone (Fig. 3). In particular, two classes of concave reagents have been successfully employed to enhance selectivities: concave reagents based on 2′-substituted *m*-terphenyls **10**[13–18] and 2,9-diaryl-1,10-phenanthroline-derived transition metal ion complexes **2c**·M^{n+}.[4,5,7,19,20] The key synthetic steps are the formation of the aryl–aryl bonds. The synthesis of *m*-terphenyls **10** uses the addition of Grignard compounds to dichloroiodoarenes like **9**.[13–18] The resulting 2′-magnesium function in the m-terphenyl **10** can then be transformed into a broad variety of other functional groups like Hal. Li, COOH (and its esters), CHO (and its acetals), CH=NOH, CH_2OH, $CH{=}CH_2$, SO_2Cl, SO_3H, SO_2H, SH, SAc, and H.[13–18] The stiff *m*-terphenyl moiety has been used successfully for these cleft molecules and also in bimacrocyclic concave reagents.[13–15] Due to its special geometry. the stabilization of less stable fiinctional groups like selenic and sulfenic acids is allowed.[21] 2,9-Disubstituted 1,10-phenanthrolines like **2c** or 4 can be obtained either by adding aryl lithium compounds to 1,10-phenanthroline and following with rearomatization[4,5] or by Suzuki coupling of areneboronic acids with 2,9-dihalogeno-1,10-phenanthrolines.[22]

REACTIONS

Three different classes of reactions have been investigated using concave reagents:

1. Stoichiometric use of concave reagents in protonations.
2. Base catalyses.
3. Catalyses by transition metal ions.

Protonations

All concave reagents carrying a proton within the cavity can be used as concave acids. This includes protonated concave bases. If a proton is delivered directly from the proton source to the substrate (general protonation[b]) and the protonation is irreversible, the concave shielding will

[b]The term general and specific protonation is used in the same sense as the terms general and specific acid catalyses are used: specific means that a specific protonated solvent molecule is the reacting species. while general means that in general, all acids in solution contribute to the reaction.

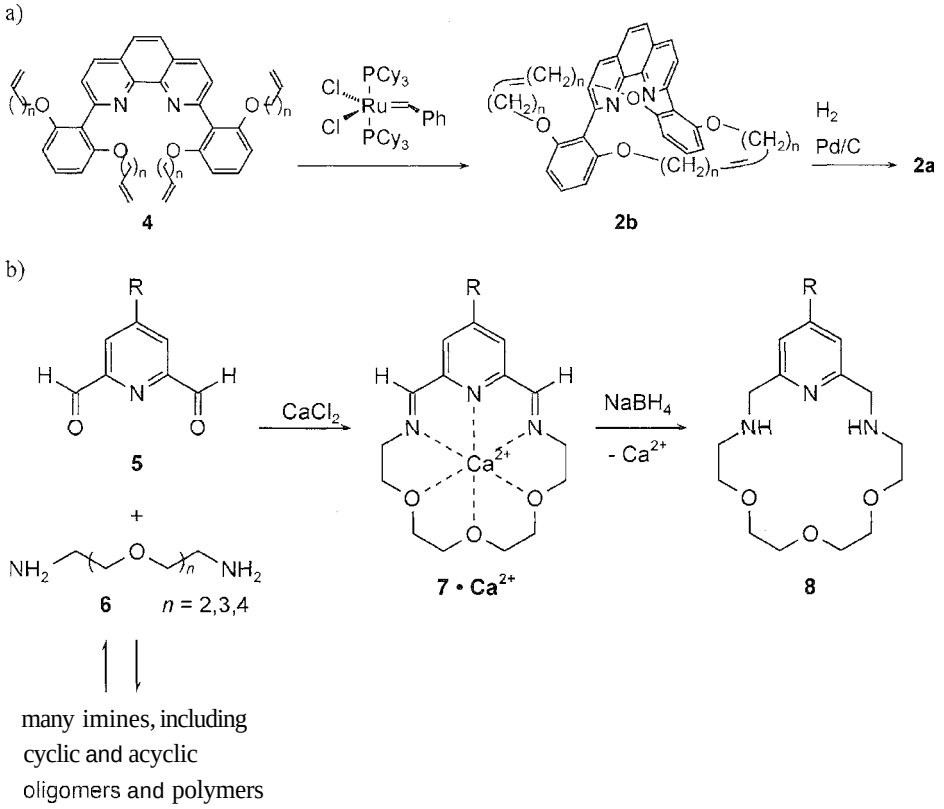

Fig. *2* Efficient syntheses of macrocycles for concave reagents using thermodynamic control for macrocyclizations: (a) Formation of concave 1,10-phenanthrolines 2 by ring-closing metathesis; (b) selection of niacrocyclic diimines **7** from a dynamic combinatorial library with the help of transition metal ions as templates and subsequent reduction to 8. here: formation of an 18-membered macrocycle by using Ca^{2+}.

influence the selectivity of the protonation (see Fig. 4a). Such a selective protonation would be extremely useful. especially if carried out stereoselectively, because most asymmetrically substituted carbon atoms carry a hydrogen atom as one of the four different substituents. But if

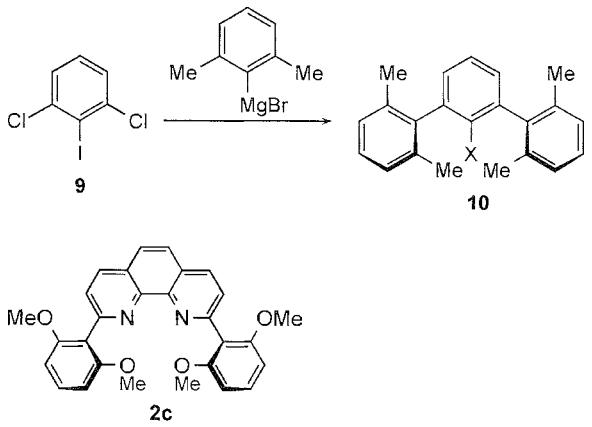

Fig. *3* Cleft molecules based on 2′-substituted *m*-terphenyls **10** (for X see text) and 2.9-diaryl-1,10-phenanthrolines like **2c**.

the acid protonates a solvent molecule first (k_{solv}), and this then transports the proton to the substrate (specific protonation[b]), then all proton sources will exhibit the same selectivity. Also. if the protonation is reversible (k_{deprot}), no influence of the proton source will be detectable, because the thermodynamical stability of the products would determine the selectivity. In order to avoid the equilibrium, the conjugate base of the acid should not be too basic, and the acid should not be too strong to avoid the protonation of the solvent. These limitations only allow a small window of acidities and basicities. and therefore, not too many examples for a selective kinetically controlled general protonation exist to date. However, some concave acids have been successfully employed in selective protonations.[23–25]

These selective protonations include the "soft Nef reaction" (Nef reaction in buffers at high pH), in which a nitronate ion is selectively protonated (proper buffer) to form the aci-nitro compound *aci*-**11** that ultimatively gives the corresponding carbonyl compound **12**.[26,27] Due to the steric shielding of the protons in the concave reagents. the competing C-protonation to give the nitro compound **11** is much slower (Fig. 4b).

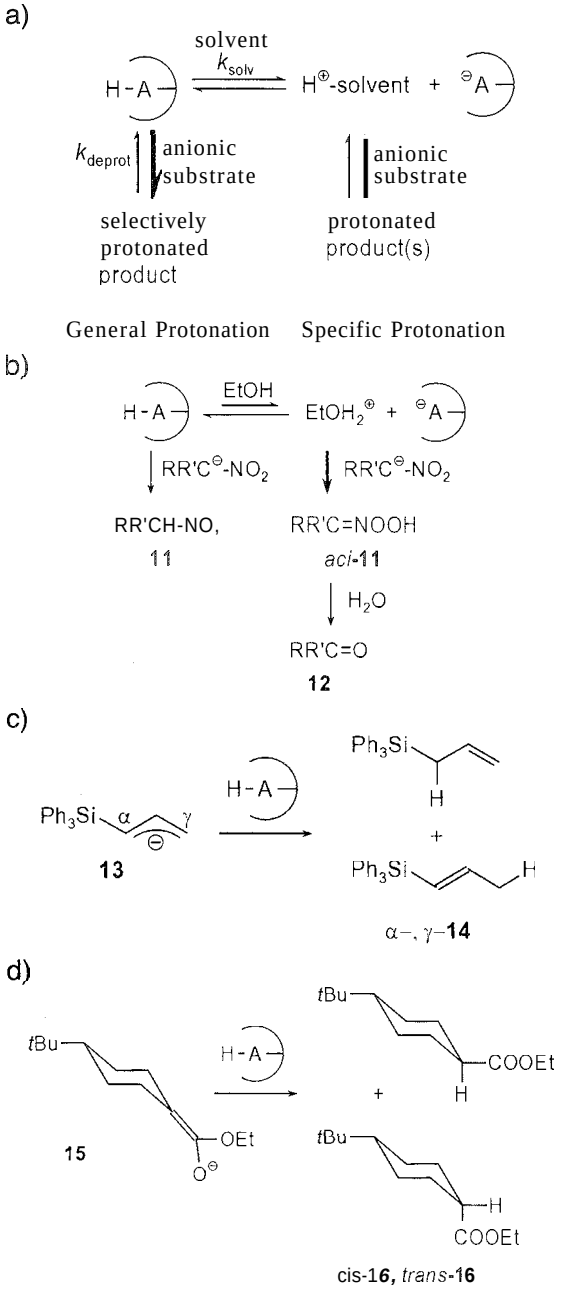

Fig. 4 (a) The change of the structure of an acid can enhance the selectivity of a protonation only in a kinetically controlled general protonation. (b) in the "soft Nef reaction,"[26,27] (c) in regioselective protonations of allyl anions.[25] and (d) in stereoselective protonations.[25]

A regioselective protonation (of allyl anions 13[25]) is also possible (Fig. 4c), as is the stereorelective protonation of esterenolates like 15 (Fig. 4d)[25] In the latter case, a contrathermodynamical diastereoselectivity (*cis/trans* for **15** or *threo/erythro* for noncyclic substrates) was observed, which was explained by a concave wrapping of the protons in the concave reagent. In the transition state, the wrapped proton is very large, while in the product. the transferred proton is the smallest substituent.

Base Catalyses

Pyridine is well known as a catalyst in organic reactions. However, in a large number of reactions, only pyridine is reactive. α-substitution diminishes the reaction rates considerably, because it hinders the reaction of pyridine as a nucleophile. The formation of hydrogen bonds to the nitrogen atom of a pyridine is also hindered by α-substitution but only if these substituents are huge (for example tert-butyl). Therefore, concave pyridines 1 also form hydrogen bonds, and they thus can be used, for instance, to enhance the nucleophilicity of hydroxyl groups. This has been exploited for the addition of alcohols to ketenes. and rate enhancements with several concave pyridines have been measured[28–30] (see Fig. 5).

In competition experiments, the relative rates for the addition of various hydroxyl groups to diphenylketene have been determined, and selectivity improvements have been found for inter- and intramolecular competitions.[28–30] Steric factors are dominant. and primary alcohols are added much faster than secondary ones. But by variation of the concave base. some concave pyridines could be identified that were able to differentiate even between similar secondary hydroxyl groups within one molecule. The glucose derivative 19 possesses two secondary. equatorial alcohol functions. Nevertheless. the 2-OH group can be acylated exclusively by using the concave pyridine 1a and diphenylketene.[31] With 2% of the catalyst and 85% conversion, only the 2-acylated carbohydrate 20 (not 3-acylated or doubly functionalized sugar) could be found. Also. a chinovose derivative could be acylated to give one out of seven conceivable products with 60% selectivity.[32]

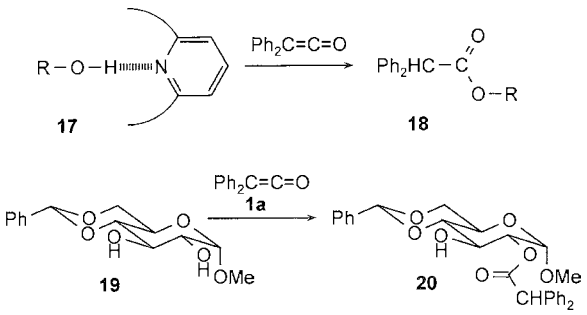

Fig. 5 Base-catalyzed addition of alcohols to diphenylketene. Formation of a complex 17 between a concave pyridine and an alcohol activates the OH group and facilitates the formation of the ester 18. When the concave pyridine Pa is used, the carbohydrate 19 can be acylated exclusively in 2-position to give 20.

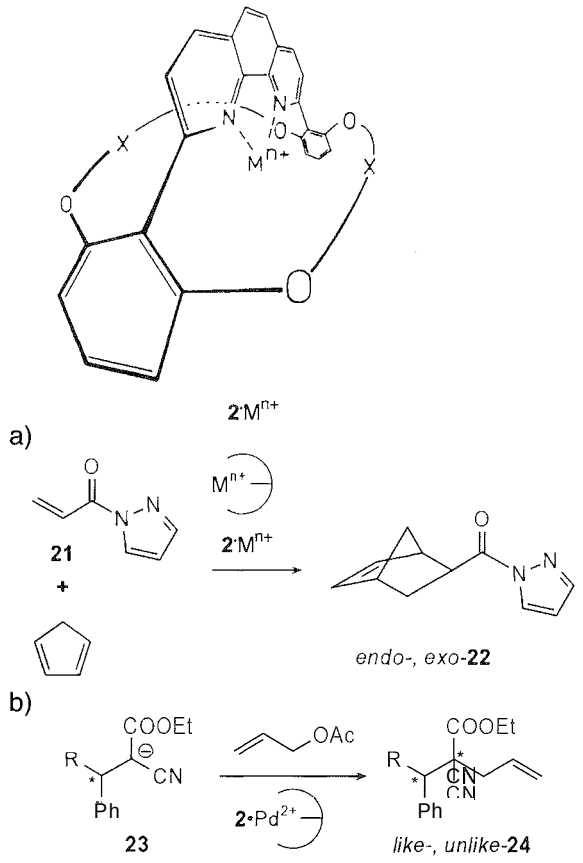

Fig. 6 (a) Transition metal ion complexes of concave 1,10-phenanthrolines $2{\cdot}M^{n+}$ can enhance the *exo*-selectivity of Lewis-acid-catalyzed Diels–Alder reactions. (b) The use of concave 1,10-phenanthrolines 2 as ligands can enhance the diastereoselectivity of palladium-catalyzed allylations.

Complexes of Concave 1,10-Phenanthrolines 2 and 3 with Transition Metal Ions

In *organic chemistry (and in enzymes),* many *reactions and especially catalyses take place at a transition metal ion. Concave* 1,10-phenanthrolines *2* and *3 offer two nitrogen atoms that can bind a metal ion in a bidentate fashion. In complexes such as* $2{\cdot}M^{n+}$, the *concave shielding ensures a* 1:1 *sioichiometry. leaving coordination* sites *open* for *the binding of substrates. Numerous* complexes *have* been investigated,[19,20] *and in many cases; these complexes are catalytically active. Then* the *selectivity of the catalyses can be determined by the shape of the concave shielding.*

For instance. the exo/endo-selectivity *of Lewis-acid-catalyzed Diels–Alder reactions can be shifted toward exo-products by incorporating* the metal *ion into a concave* 1,10*-phenanthroline 2* (Fig. 6a).[20]

Palladium-catalyzed allylations *can be carried out in the presence of a concave ligand* **2**[33] *(Fig.* 6b). *Due to the square-planar orientation of all ligands at the palladium center. non-macrocyclic and bimacrocyclic* 1,10-phenanthrolines **2a**, **2b**, *and* **2c** *do not differ much in their selectivity. The* 2,9-*bis*-aryl-substitution *is the* important *feature for this catalysis.*

In copper(I)-catalyzed *cyclopropanations of cyclic or noncyclic alkenes 25 with diazoacetates, two classes of* bimacrocyclic 1,10-phenanthrolines *2 and 3 have been checked (see* Fig. 7).[34–36] *Surprisingly. bath ligands are reactive and selective but give complementary anti/syn-selectivities* (*exo/endo or trans/cis for cyclic or* noncyclic alkenes *25, respectively). While the bimacrocyciic* diaryl-phenanthrolines *2 showed a strong arzti-selectivity* (e.g., up *to 140:*1 *with indene),* 1,10-phenanthroline-*bridged* calix[6]arenes *3 led to the syn*-cyclopropanes *26* (e.g., *up to* 14:86 *with indene). With 2, the selectivity was better when large residues* R′ *at the diazoacetate were used, while in the latter case. using 3, the smallest* substituent R′, *the* methyl substituent, *gave the* best *syn-selectivity.* Responsible *for this striking difference is the*

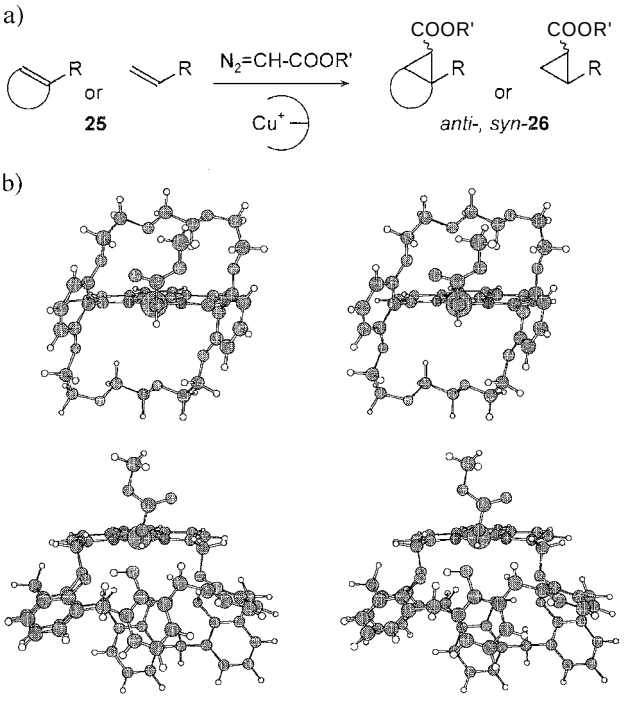

Fig. 7 (a) Copper(I)-catalyzed cyclopropanation of alltenes 25 with diazoacetates. (b) Explanation of the different *anti/syn*-selectivities of the cyclopropanation of alltenes 25 by diazoacetates in the presence of either concave diaryl-1, 10-phenanthrolines 2 or of A,D-1,10-phenanthroline-bridged calix[6]arenes **3:** stereopictures of the copper(I)-bound carbenoide iiitermediates. For details see text. (*View this art in* color *at www.dekker.com.*)

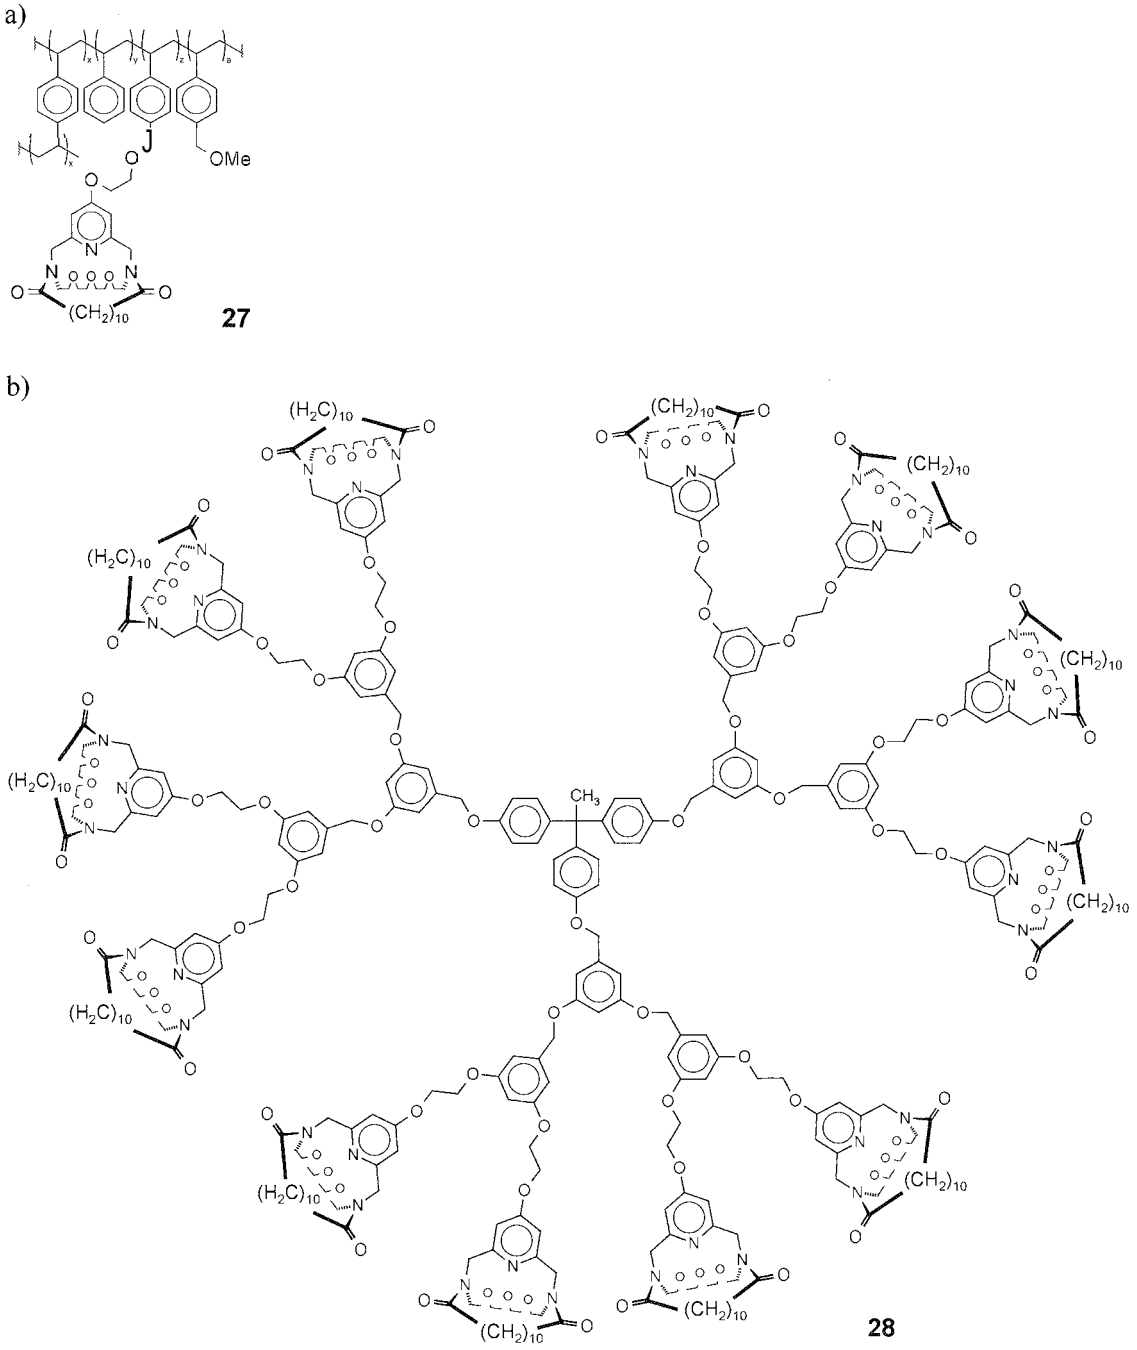

Fig. 8 (a) Polymer and (b) dendrimer fixed concave pyridines **27** and 28.

flexibility of the two ligands. In the case of the diaryl-1,10-phenanthrolines **2**. only a slight twist along the aryl-1.10-phenanthroline bonds is possible. Therefore, the overall geometry cannot be much different from the concave structure found in x-ray analyses. In the selectivity determining step. the carbene moiety transfered to the alkene 25 is attached to the copper ion that is bound to the concave ligand 2. In the resulting intermediate, the concave reaction site is partly covered by the ester substituent of the carbene moieiy. allowing the approach of an alkene only *anti* to this group. The validity of these intermediates has been investigated by calculations, and Fig. 7b shows a stereopicture of the minimized structure based on the x-ray geometry of a ligand **2a**.

In contrast to the diaryl-1,10-phenanthrolines **2**. the calix[6]arene derivatives **3** contain an oxygen atom and a methylene group between the aryl bridgehead and the 1,10-phenanthroline. This allows twists within the

bimacrocycle and leads to a structure in which the 1,10-*phenanthroline bridge is tilted against the vertical on the calixarene plane. This was proven by x-ray* analyses[37] and *by !ow-temperature NMR experiments.* A *complexed metal ion is still strongly shielded but is accessible from another direction if compared to the stiff* complexes *of 2. When a carbene moiety is bound to the* copper(I) *ion in the calixarene ligand 3, the ester group receives a strong sterical repulsion by the calixarene macrocycle that also forces the copper atom to leave the plane of the* 1,10-*phenanthroline a little bit (see Fig. 7b). An incoming* alkene can *now have two possible orientations: syn to the ester substituent of the former diazoacetate and thus anti to the calixarene, or* vice *versa. This difference is largest in* the *case of the small methyl group. which explains the finding* of *the highest syn-*selectivity for *methyl diazoacetate.*

Thus. with two classes of concave ligands. 2 and 3, respectively. which *only differ a little in* their *flexibility, opposing* selectivities *are accessible. Modification of each class of ligands with* chiral *substituents shall now allow these reactions to be carried out enantioselectively.*

RECYCLING

To justify the synthetic efforts for the synthesis of concave reagents, the gain in selectivity must be combined with an easy recovery. Usually. polymer fixation allows easy recycling, and therefore. the concave pyridine 1a has been attached to a Merrifield resin (27, see Fig. 8a).[38,39] *Indeed, the polymeric material 27 was able to catalyze the alcohol addition to diphenylketene comparably to the soluble concave pyridine* **1a**, *but complications may exist due to swelling of the resin and substrate depletion deep within the polymer. Therefore. soluble polymers loaded* with *the concave pyridine 1a have also been synthesized. However, this material behaved unreproducibly, especially because side reactions led to cross-polymerized insoluble material. Furthermore. due to reptation (leakage through membrane), an easy separation of product and catalyst would* not *be possible by ultrafiltration.*

Dendritic *compounds avoid such a reptation due to their branched structure. Thus, the concave pyridine 1a was incorporated into* Fréchet-type *dendrimers by a convergent synthesis (see Fig.* 8b).[40,41] *The resulting products like 28 can be retained by nanofiltration.*

CONCLUSION

A variety *of concave reagents and catalysts is now accessible In* protonations, *base catalyses and metal- on-assisted catalyses. they* have *been successfully* employed *enabling chemo-. regio-, and stereoselectivity. By introducing chirality into the* concave *structures. the* problem *of enantioselectivity shall be tackled next. The class of concave 1.10-phenanthrolines (and related molecules)* seems *to be especially promising for other* selective *reactions. which have not been investigated yet. because different concave catalysts can be provided by binding different metal ions to one given concave* 1,10-phenanthroline.

Concepts in Crystal Engineering

Andrew D. Burrows
University of Bath, Bath, United Kingdom

INTRODUCTION

Crystal engineering involves the design and synthesis of solid-state structures with desired properties, based on an understanding and exploitation of intermolecular interactions. The two main strategies currently in use for crystal engineering. based on hydrogen bonds and coordination bonds respectively, are discussed together with key concepts such as those of the supramolecular synthon and the secondary building unit.

CRYSTAL ENGINEERING

Crystal engineering is a rapidly expanding discipline, as witnessed by the steady increase of publications in the area over the past 6 years (Fig. 1) and the recent inauguration of several international journals in which the topic plays a major role, including *Crystal Engineering*, *CrystEngComm*, and *Crystal Growth and Design*.

The term "crystal engineering'. was first used in 1971 by Schmidt'" in connection with photodimerization reactions in crystalline cinnamic acids. Since this initial use, the meaning of the term has broadened considerably to include many aspects of solid-state supramolecular chemistry. A useful modern definition is that provided by Desiraju. who defined crystal engineering as ''*the understanding of intermolecular interactions in the context of crystal packing and the utilisation of such understanding in the design of new solids with desired physical and chemical properties*''.[2] Since many of the bulk properties of molecular materials are dictated by the manner in which the molecules are ordered in the solid state, it is clear that an ability to control this ordering would afford control over these properties.

MOLECULAR RECOGNITION AND SUPRAMOLECULAR SYNTHONS

Crystal engineering relies on noncovalent forces to achieve the organization of molecules and ions in the solid state. Much of the initial work on purely organic systems focused on the use of hydrogen bonds. though with the more recent extension to inorganic systems, the coordination bond has also emerged as a powerful tool. Other intermolecular forces such as π···π. halogen···halo-halogen, and Au···Au interactions have all been exploited in crystal engineering studies. and ionic interactions can also be important. However, the two most commonly used strategies in crystal engineering exploit hydrogen bonds'"."] and coordination bonds.[5]

Molecular recognition lies at the heart of crystal engineering, with the molecular recognition event typically involving an interaction between complementary hydi-ogen-bonding faces or a metal and a ligand. By analogy with the retrosynthetic approach to organic synthesis, Desiraju coined the term "supramolecular synthon" to describe building blocks that are common to many structures and hence can be used to order specific groups in the solid state.'" The carboxylic acid dimer (Fig. 2a) represents a simple supramolecular synthon, though in practice this is only observed in approximately 30% of crystal structures in which it is possible.[7] The alternative catemer (Fig. 2b) avoids the unfavorable secondary interactions present in the dimer (vide infra). The Cambridge Structural Database (CSD)[8] provides an excellent tool for assessing the efficiency of particular synthons. The supramolecular synthon approach has been successfully applied in the synthesis of one-dimensional tapes. two-dimensional sheets. and three-dimensional structures.

CRYSTAL ENGINEERING USING HYDROGEN BONDS

Examples of supramolecular synthons based on hydrogen bonds that have been used in crystal engineering studies are shown in Fig. 2. In an X—H···Y hydrogen bond. the X—H group is referred to as a hydrogen bond donor and the Y group a hydrogen bond acceptor. It might be expected that the greater the number of hydrogen bond donors and acceptors on each face. the greater would be both the degree and the specificity of the inte actions between the faces. This is true to some extent. though in systems containing multiple hydrogen bonds, secondary interactions are also important.[9] Hydrogen bonds are mainly electrostatic in origin. and secondary interactions

DOI: 10.1081/E-ESMC 120012750

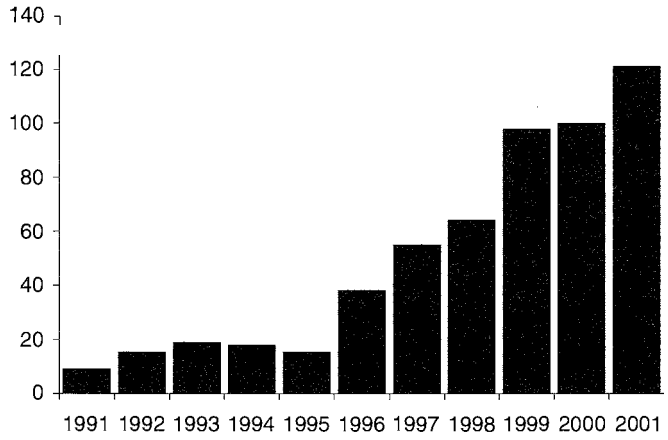

Fig. 1 The number of publications per year including the term "crystal engineering" in the title. keywords, or abstract from 1991 to 2001. Source: ISI Web of Science.

arise from the electrostatic interactions between those hydrogen-bonding groups on the two faces that are not hydrogen bonded together. Thus, in a synthon that contains two hydrogen bond donors on one face and two hydrogen bond acceptors on the other. denoted DD:AA (Fig. 2d), the secondary interactions are attractive, whereas in a synthon in which each face contains one donor and one acceptor, denoted DA:AD (Fig. 2a), the secondary interactions are repulsive. Since each secondary interaction has been calculated at approximately one-third the energy of a hydrogen bond. synthons based on DD:AA interactions would be expected to be more robust than those based on DA:AD interactions, a prediction borne out by theoretical studies, NMR experiments, and an analysis of the CSD.

One of the most highly studied hydrogen bond systems is that based on the triple hydrogen bond interaction between melamine and cyanuric acid. Melamine possesses three DAD faces, whereas cyanuric acid possesses three complementary ADA faces (Fig. 3a). The two molecules cocrystallize to form hexagonal two-dimensional sheets in which all hydrogen bond donors and acceptors are satisfied. a fact that despite earlier predictions was only

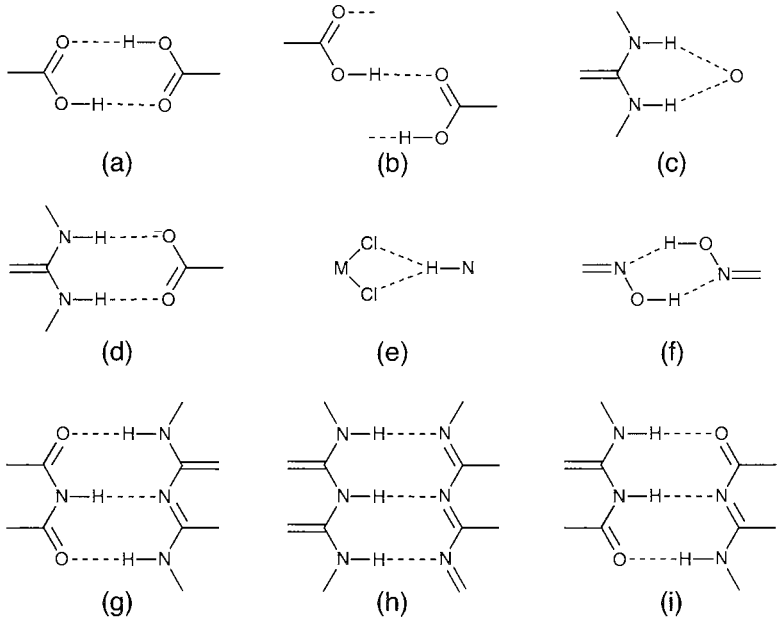

Fig. 2 Supramolecular synthons based on hydrogen bonds that have been used in crystal engineering studies. (From Refs. [3,4].)

confirmed crystallographically in 1999 (Fig. 3a).[10] Whitesides[11] and Lehn[12] and their respective coworkers showed that by introducing substituents onto the two components, they could reduce the number of hydrogen-bonding faces on each molecule, which reduces the dimensionality of the resultant aggregate forming either one-dimensional tapes (Fig. 3b) or discrete rosettes, depending on the steric demands of the substituents.

Guanidinium sulfonates form similar hexagonal two-dimensional sheet structures. though because each guanidinium cation contains three hydrogen-bonding faces bearing two hydrogen bond donors and each sulfonate anion contains three hydrogen-bonding faces bearing two hydrogen bond acceptors, in this case, charge-augmented DD:AA interactions serve to link the ions into the sheets. Ward and coworkers studied the influence of the sulfonate alkyl or aryl substituent on the structure[13] and demonstrated that use of a disulfonate enables the guanidinium sulfonate sheets to be linked together to form pillared structures capable of including guest molecules.[14]

Bifunctional ligands containing metal-binding and hydrogen-bonding faces are used in crystal engineering studies.[15] A metal center can serve to orientate the hydrogen-bonding faces in a predetermined direction, such as in the square-planar cation *trans*-[Ni{SC(NH_2)($NHNH_2$)-κ^2*S,N*}$_2$]$^{2+}$, which contains two DD hydrogen-bonding faces directed at 180° from each other and forms tapes with dicarboxyiate anions.[16] Unlike organochlorine compounds, metal-bound chloride can act as a hydrogen bond acceptor (Fig. 2e). This has been exploited in the formation of tapes based on protonated amine cations and polychiorometallate anions. typified by [4,4′-H_2bipy][$PtCl_4$].[17]

Hydrogen bonding in the solid state can also serve to bring reagents together. Hydrogen bonds between pyridyl-substituted alkenes and a resorcinol template have been used to orient the alkene double bonds into appropriate positions for solid-state photoreaction to occur, giving much higher yields of the [2 + 2] cycloaddition product than is observed in solution.[18]

Although most of the synthetic strategies employing hydrogen bonds use relatively strong interactions, weaker hydrogen bonds such as C—H···O and C—H···π interactions are also important. The recognition of the frequent occurrence of multiple phenyl embraces involving combinations of C—H···π and π···π interactions is particularly noteworthy, as the total energy of interactions between two triphenyl moieties can be as high as 80 kJ mol^{-1}.[19]

CRYSTAL ENGINEERING USING COORDINATION BONDS

The use of bridging di-or polyeopic ligands in conjunction with metal centers to construct predictable one-, two-, or three-dimensional coordination networks has received

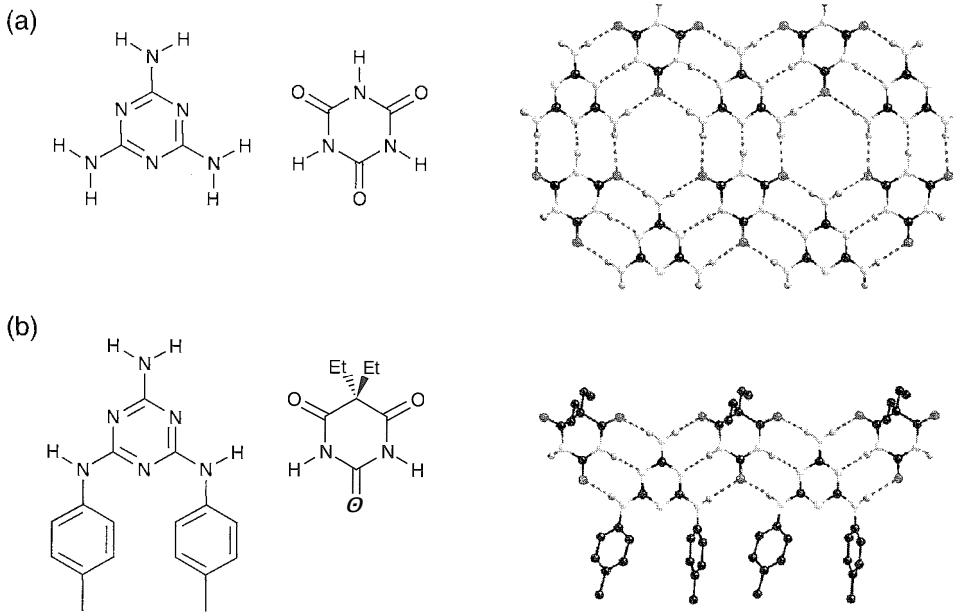

Fig. 3 (a) The structures of melamine and cyanuric acid and the hydrogen-bonded sheet formed by a 1:1 combination of them. (b) The structures of *N,N′-bis*(*p*-tolyl)melamine and 5.5-diethylbarbituric acid. and the hydrogen-bonded tape formed by a 1:1 combination of them. (From Ref. [11].) (*View this art* in *color at www.dekker.com.*)

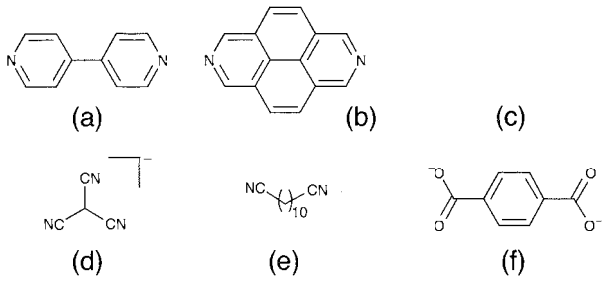

Fig. 4 Ditopic bridging ligands that have been used in crystal engineering studies involving coordination bonds. (From Refs. [5,20].)

considerable atiention recently.[20] The predictability arises from knowledge of the relative orientation of the ligand donor sites and the preferred metal ion coordination geometries, though variations in counterion and solvent can sometimes have unexpected effects. Examples of bridging ligands used in crystal engineering studies are shown in Fig. 4.

A 1:1 mixture of $AgBF_4$ and the linear spacer ligand 4,4′-bipyridine (4,4′-bipy, Fig. 4a) gives the one-dimensional coordination polymer $\{[Ag(4,4'\text{-bipy})]BF_4\}_n$ containing linear two-coordinate silver(I) centers.[20] Square-grid coordination polymers represent a common class of two-dimensional network. These structures are based upon a 1:2 ratio of metal centers containing square-planar coordination sites and linear spacer ligands such as 4,4′-bipy.[21]

Robson pioneered a net-based approach to the generation of three-dimensional coordination networks.[22] A net is a collection of nodes with clearly defined connectivity or topology.[23] The strategy involves identifying molecular building blocks with the functionality and stereochemistry appropriate to a particular target net. For example. the rutile net consists of octahedral and trigonal nodes in 1:2 ratio, and in rutile the titanium centers are octahedral and the oxides trigonal. The tricyanomethanide ion $[C(CN)_3]^-$ (Fig. 4d) contains trigonally arranged nitrogen donors, and the structures of $M[C(CN)_3]$ (M=Cr, Mn,Fe,Co,Ni,Cu,Zn,Cd, or Hg) all contain two interpenetrating rutile networks (Fig. 5).[24]

Interpenetration is a common phenomenon when networks contain large channels. It occurs when the channeis created by one framework are filled with one or more independent networks that may or may not be identical to the first. By using 1,12-dodecanedinitrile (Fig. 4e), interpenetration of as many as 10 independent networks has been observed.[25] Intel-penetration may be problematic when using coordination networks to prepare porous materials. though there is evidence it can lead to the strengthening of network structures.[26]

In some Instances, more than one structuie may be possible for a given set of molecular components. and such structures can be described as supramolecular isomers For example, three forms of $[Co_2(NO_3)_4\{1,2\text{-}bis(4\text{-pyridyl})ethane\}_3]_n$ have been structurally characterized with different network structures This results from the conformational freedom of 1,2-*bis*(4-pyridyl)ethane (Fig 4c), which unlike 4,4-bipy can adopt *gauche* or *anti* conformations [27]

SYNTHETIC STRATEGIES FOR CRYSTAL ENGINEERING

Crystal engineering requires information on intermolecular interactions in the solid state, which necessitates crystal structure determinations. Despite the increasing importance of structure solution using powder diffraction data, this generally implies a need for single crystals. Recent developments in diffractometer technology and access to synchrotron radiation have afforded the opportunity to obtain information using crystals of smaller size and poorer quality than previously possible. and on a vastly greater scale. However, the need for single crystals remains. Many elaborate experiments have been devised in order to ensure slow mixing of reagents and enhance the likelihood of growing single crystals. This is particularly important in coordination-based systems in which the product is usually insoluble. The reversibility of hydrogen bond and coordination bond formation is likely to be crucial in the formation of single crystals.

Two-component systems typically use cocrystallization or metathesis techniques. and in these experiments. the solvent needs to be chosen carefully to prevent the components from crystallizing separately. Grinding the components together can also be used sometimes to prepare cocrystalline compounds.[28]

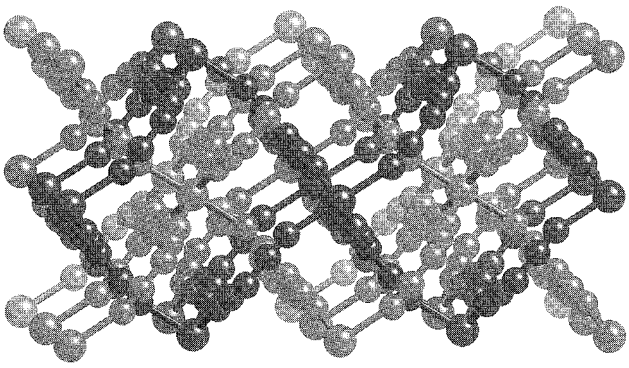

Fig. 5 The structure of $Cr[C(CN)_3]_2$, which is based on two interpenetrating nets with the rutile topology. (From Refs. [22,24].) (*View this art in color at www.dekker.com.*)

STRUCTURE–PROPERTY RELATIONSHIPS

Much of the crystal engineering literature is concerned with attempts to dictate organization in the solid state through control of intermolecular interactions. A criticism occasionally leveled at crystal engineering is that this can easily become a simple data gathering exercise. Although it can be argued with some validity that the discipline is at a stage where its tools are still being evaluated, it is clear that future progress will focus predominantly on function.[29] Many properties of materials are related to the manner in which the component molecules or ions pack. Thus. for example, for second-order nonlinear optical activity, the components need to be arranged in a noncentrosymmetric manner, whereas for magnetism. the components need to be organized so that communication between spins is possible. For porous materials that can be used for separations or gas storage, close-packing and interpenetration need to be prevented. Yaghi and coworkers have prepared a range of highly porous materials using the concept of the secondary building unit (SBU).[30]

The secondary building units utilized by Yaghi and others are metal carboxylate clusters such as copper acetate [$Cu_2(\mu\text{-}OAc)_4$], and basic zinc acetate [$Zn_4(\mu_4\text{-}O)(\mu\text{-}OAc)_6$], shown in Fig. 4. The bridging coordination mode of the carboxylates in these compounds imparts rigidity, and these SBUs can be linked together into two- or three-dimensional structures (Fig. 6) by use of dicarboxylates such as terephthalate (Fig. 4f) instead of acetate. Unlike many coordination networks. the resulting structures are maintained when the solvent is removed. The compound in which $Zn_4(\mu_4\text{-}O)$ units are linked by triphenyldicarboxylate dianions is, following removal of the solvent, the least dense crystalline material currently known, with a calculated crystal density of 0.21 gcm^{-3} and a free volume of 91.1%. The series of compounds prepared by linking $Zn_4(\mu_4\text{-}O)$ units by linear dicarboxylates shows reversible isotherm behavior characteristic of microporous materials.[31]

CONCLUSION

Although concerned with the design and synthesis of one-, two-. and three-dimensional structures, crystal engineering is not synonymous with crystal structure prediction. which is a far more precise and complex task. Crystal engineering at the current time also cannot seek to control. in anything but a very imprecise way. the factors involved in crystal nucleation and growth, though these obviously impact heavily upon the results obtained.

Crystal engineering is. however. a truly interdisciplinary area, coinbining organic and inorganic synthesis with material science. Much progress has been made over the past few years in the design and synthesis of new materials and, although much more work is needed before crystal engineering can be considered a mature area, it is clear that the discipline has a very promising future.

Crown Ethers

George W. Gokel
Washington University School of Medicine,
St. Louis, Missouri, U.S.A.

INTRODUCTION

Crown ethers are organic ring compounds, typically larger than 12 atoms in the cycle, that contain oxygen. nitrogen, sulfur: or other heteroatoms. These heteroatoms alternate with carbon bridges that may be ethylene (CH_2CH_2) units, or they may be part of more complex structures. One example of such an element is catechol (1,2-dihydroxybenzene), which may be thought of as an O-C-C-O unit fused to a benzene ring. The key property of crown ethers on which interest has centered for decades is their ability to complex various ions. Initially; studies were focused on such alkali metal ions as sodium and potassium, but ammonium ion, diazonium ion, transition metals, and even neutral species were complexed by these versatile macrocycles. Their applications in modern supramolecular chemistry now extend to their uses as functional elements or structural scaffolds in even more complex structures.

THE DISCOVERY OF CROWN ETHERS

Crown ethers were known as structural types as early as the 1950s, when 12-crown-4 was prepared and patented. As a class, however, the discovery is credited to Charles Pedersen, who obtained dibenzo-18-crown-6 serendipitously, while attempting to prepare open-chained complexing agents for vanadium cations that he planned to use as polymerization catalysts.[1,2] The target structures had phenolic hydroxyl groups that could readily be deprotonated and interact with a metal ion. The cyclic compound that was isolated had no detectable hydroxyl group. but an interaction with a metal ion was still apparent. Pedersen deduced that the cyclic. rather than open-chained, compound was formed. He then undertook an extensive and systematic study of macrocycles in which ring size, heteroatoms. and substructural elements were all varied. For this discovery, Pedersen shared the 1987 Nobel Prize in Chemistry.

DEFINING FEATURES OF CROWNS

Structural Features of **Crown** Ethers

Thousands of different macrocycles that fall under the general description "crown ether" are now known. It is, therefore, impossible to define the structural features beyond the presence of a macrocyclic ring (generally, but not always: considered to be $\geq$12 members), in which heteroatoms (generally $\geq$4) are separated by a carbon-containing unit of two or more atoms. Oxygen is probably the predominant heteroatom in macrocycles intended to bind alkali metals. Nitrogen is often incorporated into these structures and may predominate when binding to transition metals is the object. Likewise, crowns containing sulfur atoms in the donor array favor transition over alkali metal ions.

The two-carbon unit that separates heteroatoms may be part of an aromatic system (e.g., benzene, naphthalene, pyridine). In the case of a heteroaromatic component such as furan or pyridine. the subcyclic unit may contribute a heteroatom to the donor array. In aliphatic crown ethers, the preference for ethyleneoxy units (OCH_2CH_2) results from chemical and practical considerations. Repeating ethyleneoxy units are readily available by polymerization of ethylene oxide (oxirane). Construction of a crown from such a simple and readily available starting material is economical. Use of the ethyleneoxy unit also means that every third atom is a donor, so the macrocycle's interior void is electron rich. A higher concentration of donors would be possible if methyleneoxy (OCH_2) chains were used, but the acetal (OCH_2O) linkage is hydrolytically unstable. Fewer donors would be available in the same size of macroring if propyleneoxy ($OCH_2CH_2CH_2$) units were used for construction of the macrocycle. A problem in the latter case is that unfavorable conformational interactions would occur. Rotation about the ethylene linkage is facile when oxygens occupy the 1,2-positions (i.e., O-CH_2CH_2-O). The corresponding O-CH_2CH_2-CH_2 interaction is energetically less favorable. The conformation

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012703

problem increases with the number of carbons between the heteroatoms.

Grown Ether Nomenclature

A macrocycle comprised of six ethyleneoxy units $[(CH_2CH_2O)_6]$ is named 1,4,7,10,13,16-hexaoxacyclooctadecane Alternate heteroatoms and other structural elements consrderably complicate this already cumbersome nomenclature Because of the appearance of their molecular models and the fact that these macrocycles "crowned" cations. Pedersen suggested the family name "crown ether ' He called $(CH_2CH_2O)_6$ 18-crown-6 The analogs $(CH_2CH_2O)_4$ and $(CH_2CH_2O)_5$ are named 12-crown-4 and 15-crown-5. respectively When the ethyleneoxy unit is part of the arene catechol, the compound is named as a benzo-3*n*-crown-*n* in which "3*n*" is the total number of atoms in the macroring, and "*n*" is the number of heteroatoms In Fig 1. 14 clown ethers are illustrated along with their semi-systematic names

Problems with the nomenclature will be immediately apparent The naming system assumes the presence of two-carbon spacers. This is clearly impossible for 20-crown-6. but the relative positions of the 3-carbon bridges are not revealed by the name. This lack of clarity is also a problem wlienever more than one substituent is present. The two cyclohexane rings of dicyclohexano-18-crown-6 may be adjacent, separated by one ethyleneoxy unit, or as illustrated. This ambiguity applies as well to the dibenzo and dipyrido crowns. Because the systematic names are so cumbersome, structures are typically expressed by a combination of an illustration and a short name.

Crown Ether Toxicity

Early studies conducted at Dow Chemical Company showed that 12-crown-4 caused testicular atrophy in test animals.[3] Pedersen also found in early studies that at least one of his macrocycles was an irritant in the eyes of a dog.[4] These observations and a variety of anecdotal evidence gave crown ethers a reputation for toxicity. Later studies showed that for some macrocycles. toxicity was low.[5] In particular. the lethal dose for rats of 18-crown-6 and aspirin is similar. Of course, crown ethers should be

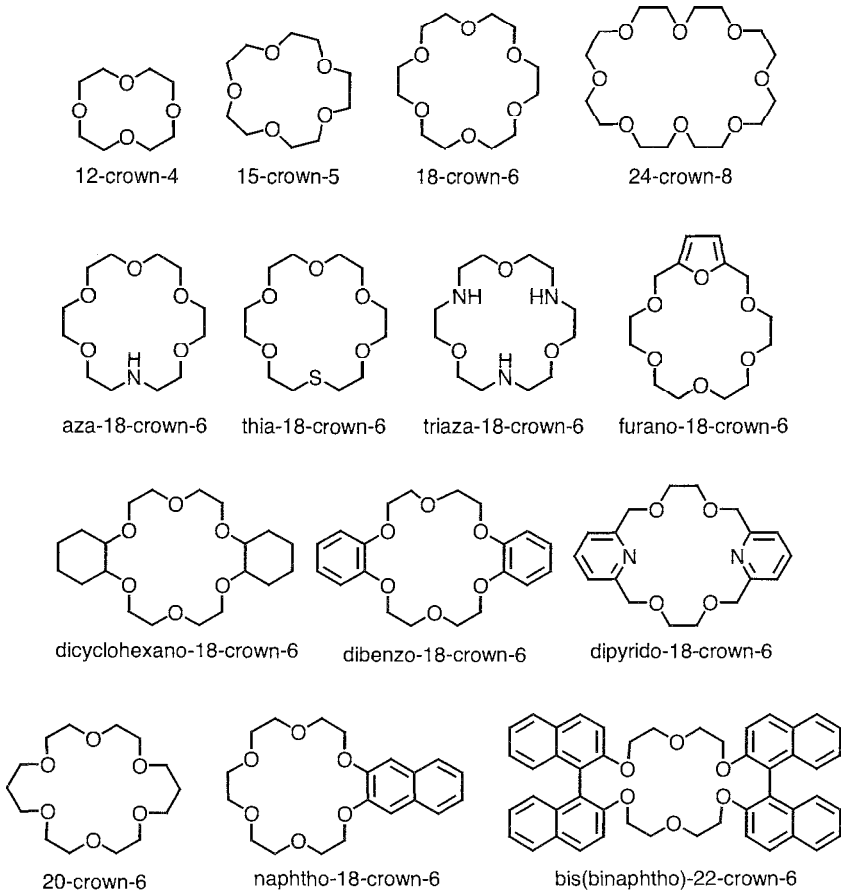

Fig. 1 Representative crown ethers and their semi-systematic names.

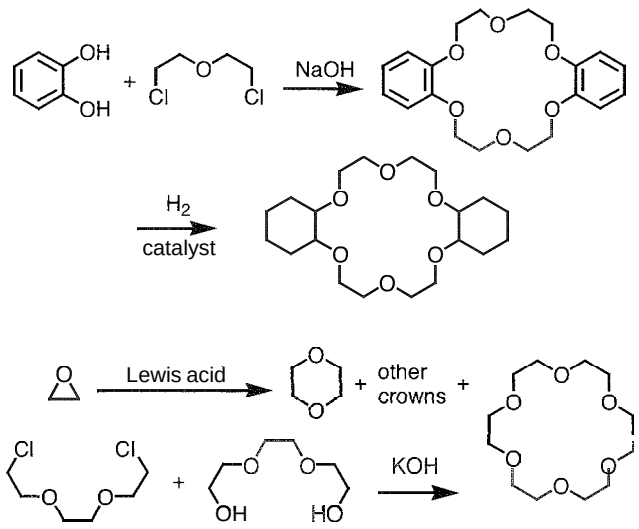

Pig. 2 Schemes depicting synthetic access to dibenzo-18-crown-6 dicyclohexano-18-crown-6, and 18-crown-6

handled with care. and all chemicals for which biological data are not available should be treated as potentially toxic.

STRUCTURAL TYPES AND SYNTHETIC ACCESS

Synthetic Methods

Unsubstituted crowns such as 15-crown-5 or 21-crown-7 may be prepared by cyclooligomerization of ethylene oxide (oxirane) under Lewis acidic conditions.[6] The products form in a mixture and must be separated by distillation. The predominant product of the reaction is dioxane, but the distribution of crowns may be influenced by the addition of alkali metal cations of different diameters. Unsubstituted crowns may also be formed by reaction of a diol fragment with a complementary fragment activated for substitution by dihalide or ditosylate. Reaction of $Cl(CH_2CH_2O)_2CH_2CH_2Cl$ with $H(OCH_2CH_2)_3OH$ in the presence of KOH can result in 18-crown-6 being obtained.[7,8] The crown is obtained by distillation and is further purified by forming a crystalline acetonitrile solvate (Fig. 2). Preparation of 15-crown-5 can be done similarly, by reaction of $Cl(CH_2CH_2O)_2CH_2CH_2Cl$ with $H(OCH_2CH_2)_2OH$ or $ClCH_2CH_2OCH_2CH_2Cl$ with $H(OCH_2CH_2)_3OH$. A difficulty with the approach in this case is that the leaving groups may exchange; leading to mixtures of 9- and 18-membered rings contaminating the desired 15-crown-5.

Pedersen's original preparation of dibenzo-18-crown-6 involved the reaction of $ClCH_2CH_2OCH_2CH_2Cl$ and catechol (1.2-dihydroxybenzene) with NaOH in *n*-butanol solution. The macrocycle was isolated as a white solid. Hydrogenation produced dicyclohexano-18-crown-6 as a mixture of stereoisomers.[4] Compounds such as dipyrido-18-crown-6 (see Fig. 1) may be produced by a similar 2+2 strategy. In this case, either 2,6-*bis*(chloromethyl)pyridine and ethylene glycol or 2,6-*bis*(hydroxymethyl)pyridine and ethylene glycol ditosylate must be used. When a compound that includes a single subcyclic unit is desired, it may be produced from the diol and an appropriately sized dihalide or ditosylate. For example, the reaction of 2,5-*bis*(hydroxymethyl)furan and pentaethylene glycol ditosylate will give furano-18-crown-6, shown in Fig. 1.

Macrocycles. especially azacrowns, were prepared by reaction at high dilution between diamines and diacid chlorides. The cyclic *bis*(amide) is then reduced (e.g., $LiAlH_4$) to afford the cyclic diamine. Other general and compound-specific inethods were developed (Fig. 3).[9,10]

The Template Effect

Crown ethers complex cations. as discussed later in this article. Conversely, cations can organize the reactive partners to form the macrocyclic products. In the absence of some organizing principle. the formation of large rings is an improbable process. The reaction of triethylene glycol with triethylene glycol dichloride in the presence of KOH. for example, begins with ether formation:

$$H(OCH_2CH_2)_3OK + ClCH_2CH_2(OCH_2CH_2)_2Cl$$
$$\rightarrow H(OCH_2CH_2)_3OCH_2CH_2(OCH_2CH_2)_2Cl$$
$$\equiv H(OCH_2CH_2)_6Cl$$

The next step in this process is likely to be a further extension of this intermediate to form the next longer

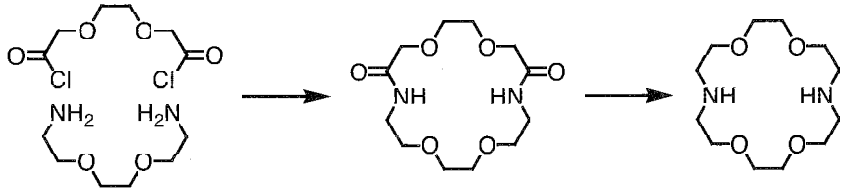

Fig. 3 A cyclization-reduction synthesis of 4,13-diaza-18-crown-6.

analog, $H(OCH_2CH_2)_9OH$. In addition, two inolecules of $H(OCH_2CH_2)_6Cl$ may combine to give $H(OCH_2CH_2)_{12}Cl$. This is a polymerization process. and many chain lengths will be formed. The process is favored because it is more likely that one molecule will find a second one with which to react than to find its other end. The latter can be made more probable by working at high dilution (i.e., low concentration). In that case. the odds of finding the other end are not increased, but finding another molecule is made more difficult.

There are two notions implicit in the idea of a "template effect." as discussed by Greene in reactions to form 18-crown-6.[11] The first is that the two reactive ends of the crown precursor are brought together by what is tantamount to a complexation phenomenon. This is illustrated in Fig. 4. Mandolini and Masci studied the template effect in a cyclization that formed benzo-18-crown-6.[12] The presence and absence of cations demonstrated that the presence of an organizing cation was beneficial. These reactions are illustrated in Fig. 4.

The second concept inherent in the template effect is that cations of different sizes favor the formation of different ring sizes. In the cyclooligomerization of ethylene oxide reported by Dale et al.[6] relatively more 15-crown-5 was formed in the presence of Na^+ and more 18-crown-6 was formed when K^+ was added to the reaction mixture. When the reacting components are triethylene glycol and triethylene glycol dichloride, the possibilities are the formation of rings having sizes of 9.

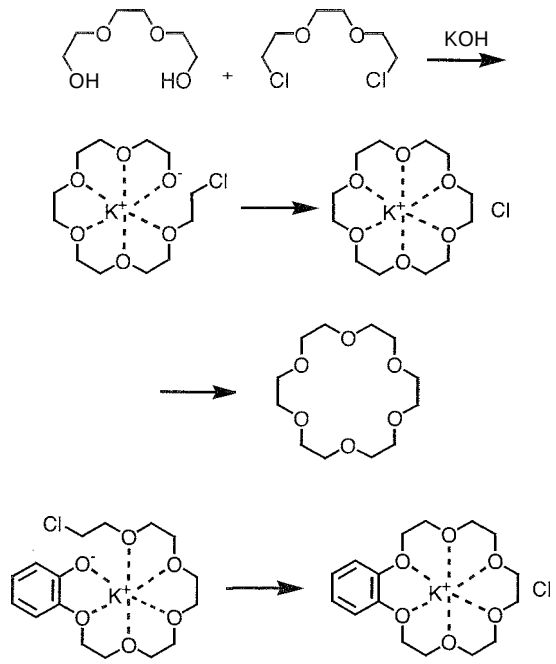

Fig. **4** Cyclization to form crown ethers assisted by cation complexation.

18. 27. etc. Cram showed that a 27-membered ring was favored by the large cationic template—guanidinium ion.[13] Often, though, the differences in the reaction products are subtle. and the demonstration of a clear template effect is problematic.

COMPLEXATION

The earliest and most studied properties of crown ethers concern their ability to cornplex cations.[14–16] A crown ether is, in a sense, a unirnolecular solvation gradient. The exterior of the macrocycle (alkyl) is lipophilic (hydrophobic), and the interior (heteroatoms) is hydrophilic (lipophobic). An 18-crown-6 may be likened structurally to a doughnut. An appropriately sized cation may fit in the "hole" to give a complex. The question of appropriate size is complicated. When the macroring hole and the cation diameter are identical, the cation is typically ernbedded within the ring. When the ring is larger than the cation, the ring may pucker so that donor-group-to-ion contacts are of appropriate length and geometry. When the cation is larger than the ring. the cation may "perch" on the ring or be "sandwiched" between two rings. Other geometric arrangements are also possible.

Organic cations may also bind to crown ethers. In particular. the macroring oxygen atoms may function as PI-bond acceptors. Alternate oxygen atoms in 18-crown-6 are positioned to form three $N—H\cdots O$ bonds with an ammonium ion. Hydronium ion. H_3O^+, has nearly the same geometry as $R—NH_3^+$ and forms a similar complex.

Shown in Fig. 5 are several complex structures. The top row illustrates typical alkali metal complexation. A sphere and the macrocycle structure represent the complex between 15-crown-5 and Na^+. This type of illustration is also used for the K^+ structure of 18-crown-6, shown in structural form in the center. The middle row illustrates H-bond complexes of an ammonium ion, a hydronium ion,[17–19] and a water complex of a protonated aza-crown.[20] The left-hand structure shown in the third row is a so-called "second-sphere" complex. The Pt—N bond renders the nitrogen atom partially positive, so the $Pt—NH_3$ structure is like $R—N^+H_3$. At the right is shown an arenediazonium cation complex.

Complexation sf Anions

The "bole" of a crown ether is lined with electronegative atoms. This nicely complements cations but repels anions. Complexation of anions proved to be possible. however. for azacrowns, protonated azacrowns, and related species. In these cases. the complex is stabilized by multiple hydrogen bonds. Although the anion complexation field is

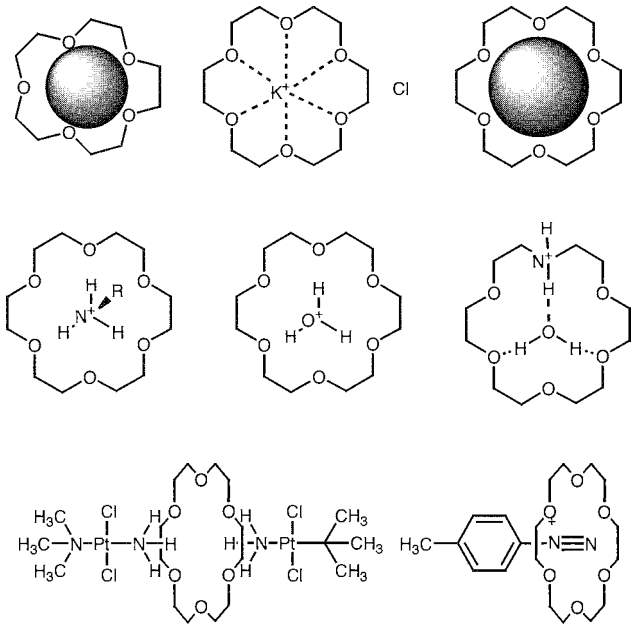

Fig. *5* Crown ether coinplexation of a range of cationic guests (see text for details).

growing rapidly,[21] the number of examples is dwarfed by the literature on cation complexation.

Methods to Detect and Measure Cation Complexation

The complexation of ions by crown ethers can be detected in solution, but evidence was also obtained by studies in gas and solid phases. Most complexation chemistry is conducted in solution. Complexation reactions can be expressed generally by the equilibrium:

$$\text{host} + \text{guest} = \text{complex}$$

The critical requirement is. therefore, to detect the complex quantitatively. From the amount of complex formed; the position of the equilibrium and, therefore, the equilibrium constant will be known. at least under the conditions of the measurement.

At an early stage. Frensdorff, a colleague of Pedersen's at Dupont, developed a useful method for determining the equilibrium complexation constant in solution.[22,23] The method required the use of ion-selective electrodes and an appropriate voltmeter. Calorimetric methods were applied early in the development of crown ethers by Arnett and by Izatt and Christensen and their coworkers.[24,25] The latter group reported extensive solution calorimetric studies of complexation involving metal and organic guest molecules with a variety of hosts. Considerable data on cation binding by macrocycles may be found in the literature.[14–16]

Cram and coworkers developed a convenient extraction method that they used to assess the structural factors that influence cornplexation of metal ions and protonated amino acids.[26–28] (For a review of chiral complexation see Ref. [29].) The method was used extensively enough to merit a description here. An aqueous solution of, for example, sodium picrate, is prepared. The solution is yellow owing to the trinitrophenoxide anion. A potential host molecule is dissolved in $CHCl_3$, and the two phases are shaken together. If successful, the host molecule will extract the cation picrate salt into the organic phase. The extent of the extraction can be quantitated by UV spectroscopy, based on the assumption that the amount of picrate anion observed corresponds to the amount of cation extracted. For obvious reasons, this method is called the ''picrate extraction technique.'' For comparisons to be made between data sets obtained by this method, solvents, volumes. concentrations. temperatures, etc., must be controlled. The influence of the anion on complexation was also studied.[30]

Enantioselective complexation between chiral host molecules and racemic guests was also achieved.[29] One enantiomer of phenylethylammonium cation can be selectively complexed by optically pure *bis*(binaphtho)-22-crown-6.[26–29] The racemic ammonium salt, dissolved in water. and the chiral crown, dissolved in an immiscible solvent such as $CHCl_3$, are shaken together. If one of the two diastereomeric complexes is favored, it can be detected (e.g., by NMR) or separated. When the chiral macrocycle is bound to a resin. a multi-plate, chiral organic separation is possible.

Solid-state complexes

Modern chemistry is aided profoundly by the advancement of x-ray techniques. and crown ether chemistry is no exception. Our understanding of solution coinplexaiion has been augmented by numerous solid-state structures. Among the earliest crown ether complexes to appear were those reported by Truter and Bush.[31] Numerous other contributions to this area were reviewed by Dobler.[32] In brief, many crown ethers are solid and form regular crystals. Because they possess an empty central space, one or more methylene residues typically turns inward to fill the molecular void. When complexation of a cation occurs, the methylene rotates outward so that the bound cation will be accessible to all of the macroring donors.

Shown clearly by solid-state structures is that crowns are versatile binders. Although the fit between K^+ and 18-crown-6 is nearly perfect. this host can complex numerous other cations. In addition, other crowns can complex K^+, even if the host is larger or smaller than the guest. For

example, 15-crown-5 forms a 2:1 "sandwich" complex with K^+. Likewise. 14-crown-4 forms a 2:1 sandwich complex with Na^+. The structure of $Na^+ \cdot$18-crown-6 shows that the macroring contracts so that the $O—Na^+$ distances are optimized for five donors. essentially in a plane. The sixth oxygen puckers upward but also coordinates the cation. A complex was also reported in which two Na^+ ions are complexed within a 24-crown-8 macroring. Literally hundreds of solid-state structures are known for crown ethers with cations and molecular species. and these may be found in the Cambridge Structural Database.

Six structures are shown in Fig. 6. Unbound 12-crown-4 is shown in panel (a). It is shown complexed in panel (b), along with 18-crown-6, in an unsymmetrical sandwich. Two additional molecules of 18-crown-6 are present in the unit cell but do not bind the cation. Note that because 10 oxygen donors are present. K^+ is not in the 18-crown-6 macroring's plane. Potassium cation is in the plane in (c), (d). and (e). The ClO_4^- ion is shown in contact with the cation in (d). The counterions are not shown for (c) and (e) (*N*-heptylaza-15-crown-5). The molecular complex between 18-crown-6 and acetonitrile is shown in panel (f).

Complex detection by mass spectrometry

The advent of such low-fragmentation techniques as fast-atom bombardinent (FAB) and electrospray ionization (ESI) permitted the direct observation of crown ether complexes in the gas phase. Complexation of a species such as $(18\text{-crown-6} \cdot Na)^+$ is readily detectable as a species having mlz (264 + 23) = 287. The corresponding K^+ complex would have a mass of 303. Selectivities were inferred by comparing peak intensities. The mass spectrometric method is of great value, but comparisons between gas, solution. and solid phases should be made with appropriate circumspection.[33]

APPLICATIONS

The applications of crown ethers in modern chemistry could fill many volumes. Initially, they were used to complex metal ions. This was expanded to organic ions and molecular species. Eventually, crowns became scaffolds upon which other. more ambitious structures were built. This section presents a limited number of these interesting and important applications and in only the briefest outline.

Dye and coworkers formed complexes of the type $M^+ \cdot \text{crown} \cdot M^-$. A cryptand complex of Na^+ permitted the first observation of Na^-. This work was extended from alkalides to cation complexes having an electron ("electride") as counterion.[34,35]

Chromophoric groups can be appended to or integrated with crown ethers. If absorption of light induces a conformational change in the macrocycle, complexation selectivity may be controlled and switched. This was recognized almost simultaneously by Misumi,[36] Vögtle,[37] Takagi,[38] and Shinkai,[39] who all reported "crown ether dyes" or photoresponsive crown ethers. Another means of altering the conformation is to use a redox reaction. Shinkai used oxidative formation of a disulfide linkage to achieve this end.[40] Another means of "switching" is to vary the electron density rather than the conformation. If this can be accomplished electrochemically. it is a convenient and reversible process. Enhancement of electron density by reduction of appended nitroaromatic residues in crown ethers was reported by Maifer. Echegoyen, and Gokel.[41–43] During the past decade, numerous and diverse applications were made for crown ethers. These include the formation of rotaxanes. catenanes, and knots,[44,45] membrane[46–49] and monolayer[50] formation, and ion channels.[51–53] They were used as fluorescent probes[54–56] and to demonstrate cation–π interactions.[57]

CONCLUSION

The original concept and report of crown ethers is now more than three decades old. Even so, the field remains vital. and many applications in modern science are found for crowns. They are used as complexing agents and as substructural elements in complex chemical architectures. The number of literature reports involving crown ethers continues to increase, and undiscovered applications are still ahead.

Cryptands

Bernard Dietrich
ISIS—Université Louis Pasteur, Strasbourg, France

INTRODUCTION

Shortly after the discovery of crown ethers by Pedersen in 1967. Lehn designed the first cryptand. and the synthesis of this compound was achieved in the fall of 1968.[1,2] Thus, at the end of the 1960s, one of the largest fields of research was opened by these two classes of compounds, and the origin of supramolecular chemistry goes back to that time. Not often mentioned in the foundation of this large field are the cyclodextrins. Nevertheless, credit should be given to the pioneer workers in this area, since as early as 1952, "Einschlussverbindungen" (inclusion compounds) were studied by F. Cramer.[3] Some of the numerous achievements of cryptand chemistry will be presented after a brief historical introduction.

HISTORY

In the mid-1960s. Jean-Marie Lehn developed interest in the process occurring in the nervous system, in particular, in the fact that the electrical events in nerve cells rest on changes in the distribution of sodium and potassium ions across the membrane. Around the same period, several research groups established that some natural macrocyclic antibiotics (nonactin, valinomycin) have a complexing ability toward alkali cations, and the first x-ray investigation on the K'-nonactin complex revealed the efficient surrounding of the cation by eight oxygen atoms of the macrocyclic ligand. Thus, when Charles Pedersen reported the cation binding properties of crown ether. Lehn rapidly realized that the recognition of a spherical species (an alkali cation) would be much more efficient if the ligand has a sphericai three-diinensional (3D) cavity instead of the circular two-dimensional (2D) surrounding of the cation observed with the crown ether.[4] This idea led to the synthesis of the first cryptand **1** (Fig. 1) that forms a stable potassium complex 2 (Fig. 2), named "cryptate." In addition to the high stability. the ligand also has a large selectivity for the potassium cation versus the smaller (Na^+) and the larger (Rb^+) cations. The crystal structure determination confirmed the inclusion of the cation in the 3D cavity and the perfect matching between size of cation and size of cavity.

CRYPTATES OF METAL CATIONS

This first synthesis was followed by the modification of the cavity size by altering the length of the bridging chains. This led to a series of cryptands exhibiting high selectivity of complexation toward almost all cations of Groups I and II. For example, the smaller cryptands **3** and 4 (Figs. 3 and 4) are selective for Li^+ and Na^+, respectively. Cryptands incorporating other donor atoms (nitrogen, sulfur) or heterocyclic rings were also synthesized (Figs. 5–7). These ligands present attractive coordination chemistry features: depending on their specific structures. they can bind transition metal ions, heavy metals, or lanthanides cations. Thus, most of the cations of the periodic table can be complexed with variable stabilities and selectivities. In addition, by virtue of molecular design. a tuned ligand exhibiting specific properties may be obtained by making appropriate modifications of an existing ligand.

A further step in complexity was accomplished by designing ligands able to complex more than one cation: cryptand **8** (Fig. 8), for example. forms a homodinuclear complex with silver or copper.[5] The crystal structure of the dinuclear Cu(I) complex formed with the hexaimine macrobicycle **8** shows the inclusion of the two copper ions, which are tetracoordinated at each end of the cavity. the Cu...Cu distance being very large (11.07 A). The small hexaimine macrobicycle **9** (Fig. 9) forms a Cu(I) dinuclear complex in which the Cu(I)...Cu(I) distance is short (2.45 A). In the reduced ligand **10** (Fig. 10), the Cu(I) is not stable, and only the $[Cu_2(\mathbf{10})]^{3+}$ cryptate was obtained. The Cu...Cu distance in this complex is 2.42 Å, and on the basis of ESW measurements, an average redox state (di $Cu^{1.5}$) was postulated rather than a Cu(I)...Cu(II) dinuclear complex.[6]

Mention has to be given to the synthetic aspects of cryptands. It is obvious that after the intellectual process of ligand design and despite the various new (efficient) modelization tools found for the computer. the necessity still exists to obtain the actual compound. Numerous methods were developed over the years.[7] Many symmetrical cryptands can be obtained in a few steps and with high yields. For the more elaborate cryptands, synthesis is usually more cumbersome. and the number of steps is high.

Encyclopedia of Supramolecular Chemistry

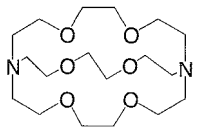

Fig. 1 1: Diazahexaoxa macrobicycle cryptand [2.2.2]

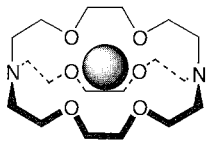

Fig. 2 2: Potassium coinplex of cryptand **1**. An example of cryptate.

The nomenclature used to describe the simplest cryptands is simple, it is formed by three numbers, each designing the numbers of oxygen atoms in each chain For example 1 is called [2 2 2]

PROTON CRYPTATES

The small cryptand 11 (Fig. 11) was obtained with difficulty. because the major compound obtained was a macrotricyclic tetraarnide resulting from a dimerization reaction. It was observed that stable proton cryptates of 11 can be obtained. The [1.1.1] bicycle binds one or two protons inside its intramolecular cavity. The diprotonated cryptate 11, $2H^+$, has a high resistance to deprotonation. The monoprotonated cryptate may be obtained with difficulty; but this latter species cannot be fully deprotonated by base to afford the free cryptand.[8] Smaller analogues of **11** containing only carbon atoms in the three chains were also described. They present similar behavior toward the proton.'" Another class of cryptands able to strongly bind the proton was developed more recently.

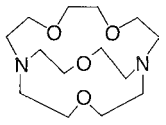

Fig. **3** **3:** Cryptand [2.1.1].

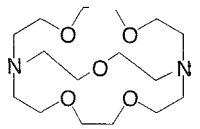

Fig. 4 4: Cryptand [2.2.1]

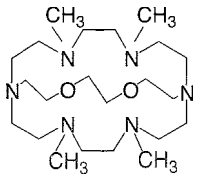

Fig. **5** **5:** Wexaazadioxa macrobicycle

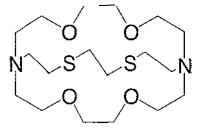

Fig. 6 6: Diazatetraoxa-dithia macrobicycle

The tetraazamacrotricycle 12 (Fig. 12) is an example of this type of cryptand. The name adamanzane was proposed for these compounds. As for the cryptands described above, in this new type of "proton sponge," one can observe the same inertness of the inside coordinated proton toward strong bases.[10] The simplicity of the synthesis of this class of compounds will allow for the preparation of many new representatives.

CRYPTATES OF AMMONIUM AND ORGANIC CATIONS

The binding by cryptand 1 of the nonspherical ammonium cation was observed. but not surprisingly, the receptor–substrate binding complementarity is poor. and therefore.

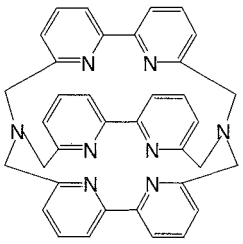

Fig. 7 7: Ti-is-bipyridine cryptand.

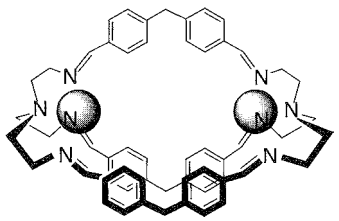

Fig. 8 Homodinuclear complex of the hexaimine cryptand 8 containing a diphenylmethane spacer

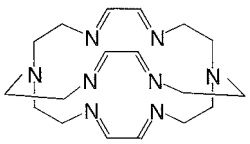

Fig. 9 9: Hexaimine cryptand

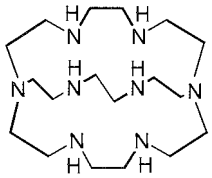

Fig. 10 10: Octaazacryptand

the stability constant of the coinplex [$NH_4^+ \subset$ 2.2.2] is in the medium range. By contrast, the macrotricyclic cryptand **13** (Fig. 13) forms a stable ammonium cryptate. The cation is held inside the cavity by a tetrahedral array of N–H^+...N hydrogen bonds with the four bridgehead nitrogen atoms. The binding is completed by electrostatic interaction between the partial charges on the NH_4^+ hydrogens and the remaining heteroatoms of the ligand.[4]

A new approach for efficient binding of the ammonium cation was postulated. It relies on the use of cation–π interactions in addition to hydrogen bonding. The ligand 14 (Fig. 14) was synthesized, and the binding of NH_4^+ was studied. The x-ray investigations revealed that the benzene rings are positioned at an appropriate distance from the cation so as to allow efficient cation–π interactions.[11]

The above-described spherical macrotricyclic cryptand 13 was designed for the ammonium cation, whereas the series of cylindrical macrotricycles **15** (Fig. 15) was

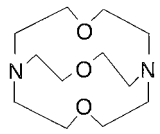

Fig. 11 11: Cryptand [1.1.1].

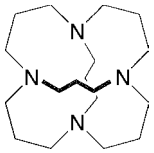

Fig. 12 12: Tetraazatricyclo cryptand

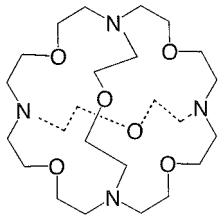

Fig. 13 13: Tetraaza-hexaoxamacrotricyclic cryptand.

synthesized for the linear recognition of diammonium salts $^+H_3N(CH_2)_n–NH_3^+$. The various bridges (R) allow specific binding of the substrate of complementarity length (n=2–12). Definitive proof that these molecular complexes display cryptate-like behavior was obtained by x-ray structure analysis of the complex [$^+H_3N(CH_2)_5–NH_3^+ \subset$**15b**].[12]

ANION CRYPTATES

Compared to cations. the field of anion coordination was developed more recently. but due to the efforts realized over the years in several laboratories, the area of anion complexation is by now a full member of the supramolecular chemistry family. The delayed exploration of the field can be mainly ascribed to the limited choices of appropriate binding sites for anions. The most studied are the ammonium binding sites that present. unfortunately, an intrinsic drawback: their positively charged status is pH dependent (except for the tetraalkylammonium derivatives). Nevertheless. many polyammonium macrocycles were synthesized and studied. These ligands exhibit good binding properties toward large poiyatomic anions (phosphates, sulfates, adenosine phosphates. tartrates, etc.). For the smaller spherical halide anions. efficient binding requires macrobicyclic structures. Thus, the octaaza analogue of the [2.2.2] cryptand, compound **10**. binds in its hexaprotonated form the F^- halide, with a high stability constant and a sharp F^-/Cl^- selectivity (>10^8).[13] The slightly larger macrobicycle **16** (Fig. 16) binds well the

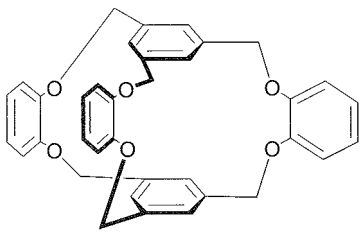

Fig. 14 14: Cage-type receptor for NH_4^+. In the top and bottom benzene rings, the 2.4.6 ethyl substituents are omitted for clarity.

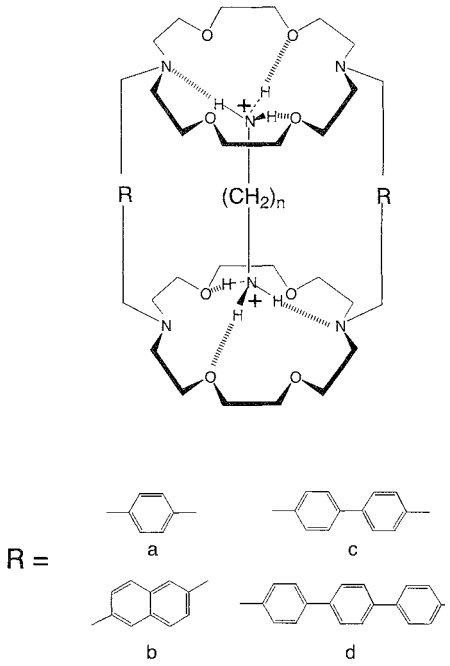

Fig. 15 15: Cylindrical macrotricyclic ligands.

Cl^- *anion. X-ray investigations confirm the inclusion of the anion in the macrobicyclic cavity.* Ligand *13 described above for the ammonium cation* complexation *is able to complex, in its tetraprotonated form. the* Cl^- *anion, a high* Cl^-/Br^- *selectivity being observed for this compound. An x-ray structure of the complex* [Cl^- *C* 13–$4H^+$] *confirmed the anion* inclusion *in the cavity and also the binding* of the *anion by a tetrahedral array of* four *ionic hydrogen bonds.*

Successful anion complexation *was also achieved with larger* macrobicyclic *ligands. Thus, the macrobicycle* 17 *(Fig. 17).6H' binds halide anions and the linear triatomic azide anion with a* very *high stability constant. The x-ray structure revealed an efficient shape and size complementarity between* N_3^- *and the* cavity.[14] *A whole series of* polyazacryptands *was obtained in high yields by a simple* Schiff *base* [2 + 3] *condensation between the* triaminotriethylamine *(tren) and various* dicarboxaldehydes. *The hexaimine macrobicycles prepared by this* way *lead, after reduction, to the polyaza cryptands, which* in

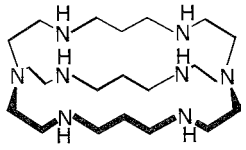

Fig. 16 16: Octaazacryptand containing a propyl spacer.

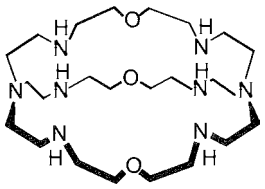

Fig. 17 17: Octaaza-trioxa cryptand.

their hexaprotonated form were shown to complex numerous polyatomic *anions. The examples presented here were characterized by x-ray structures: terephtalate anion by* cryptand 18 (Fig. 18), $6H^+$,[15] *perchlorate and nitrate by* 19 *(Fig.* 19), $6H^+$, *and 20 (Fig.* 20), $6H^+$.[16] *Encapsulation of two nitrates by the latter compound was also observed. and the x-ray structure revealed that the two planar nitrate anions were maintained inside the cavity by hydrogen-bonding interactions between the protonated amine* functions *and the* anions.[17]

The large cavity of cryptand 17 *allows another approach to anion coordination, the "cascade anion binding." In a first step, the ligand binds by* its *tren subunits two* Cu(II) *cations. In a second step.* the *axial vacant hollow between the two already bound* Cu(II) *cations* will *allow the binding of an anion. An early example was based on* computer *analysis of potentiometric titrations data, and the efficientbinding of* the *chloride anion by the dicopper complex of* 17 *was* postulated.[18] *Many other bis-tren-type figands were studied, and the cascade binding of anions such as Br , OH , N_3^-, WCO . etc. was demonstrated. Many x-ray structures confirm the location of the anions between the various metal* cations.[6,19]

An interesting novel approach to anion binding is the use of NH–π *hydrogen bonds. It has to be emphasized that this type of receptor rests on neutral hydrogen bonding, a seldom-encountered situation in the field of anion coordination. In Compound* 21 *(Fig.* 21). *it can be seen that the amide hydrogens are orientated toward the inside of the cavity and are* able *to* interact with *the* π *electron system of an anion. Crystal structure of the acetate coniplex reveals that the anion* is *bound within the* cavity.[20]

APPLICATIONS OF CRYPTANDS

The development of the cryptand field has been rapid for two major reasons. First. a few years after the first publication on cryptands syntheses. several representatives became commercially available, allowing subsequent wide inquiries into numerous areas. A second explanation for rapid multifield developments rests on the large number of researchers in various fields who immediately realized the potentialities of cryptands in their ow11 spheres of expertise.

Few examples will illustrate the revolution introduced in some domains by the cryptands. In 1974. J. L. Dye published the first x-ray structure of an alkalide. a new species containing a sodium anion (Na^-) (a rather offensive discovery for a traditional trained chemist in the 1970s) as counterion of the sodium cryptate of cryptand [2.2.2]. The cryptate has a stabilizing effect on the fairly unstable anion. and by using this procedure, a large number of alkalides were isolated. A further step was the isolation of electrides species in which the counterion of the cryptate is an electron.[21,22] The field of polyanionic clusters was largely studied by J. D. Corbett, and many of these systems could be isolated owing to the stabilization of the polyanion by the associated alkali cation cryptand.[23,24] Other interesting new species were generated by L. Echegoyen using the electroreductive crystallization of the sodium cryptate of ligand 7. This process leads to a neutral entity formed by the positively charged cation cryptate and one electron located on one of the bipy units of the cryptand. The name cryptatium was proposed

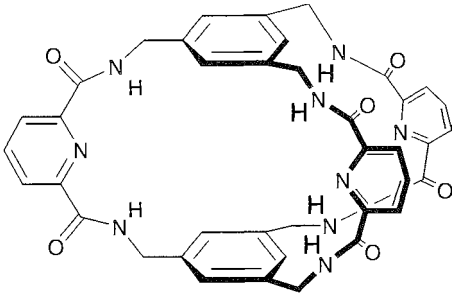

Fig. 21 21: Cage-type receptor for anion. In the top and bottom benzene rings. the 2.4.6 ethyl substituents are omitted for clarity.

for this new class of compounds.[25] The Eu^{3+} cryptate formed with cryptand **7** showed attractive luminescent properties,[26] and practical applications in fluoroimmunoassays were realized.

Other areas of interest include stabilization of noncommon oxidation states, solvent extraction of cations. transfer of cations through membranes, isotopic separation, detoxification of harmful and radioactive metals, metal recovery, metal trace analysis. ion chromatography on polymer-supported cryptands, and chromo- and fluoroionophores. More organic-chemistry-orientated applications can be mentioned, including enhancement of metal salt solubility in organic solvents, anion activation, phase-transfer catalysis. and anionic polymerization. Many of these applications are covered in other articles in this encyclopedia as well as in the literature.[27]

CONCLUSION

In this short presentation, the author tried to give a short survey of this enormous field. There was not enough room to mention many other types of cryptands, like the metallocene-containing cryptands. the sepulchrate and sarcophagine cage complexes, the photocleavable cryptands, the borocryptands, the phosphorus cryptands, and the macrobicyclic polyethers with carbon atoms bridgehead. to cite just a few. Concerning the future. there is no doubt that the design of new cryptands displaying specific properiies will remain a major challenge for the people active in this area. Improvements of already existing compounds[12''] and new trials[29] will lead to new achievements and progress.

Cryptophanes: Molecular Containers

K. Travis Holman
Georgetown University, Washington, District of Columbia, U.S.A

INTRODUCTION

In the past few decades, we have witnessed the profusion in synthetic chemical systems that highlight an elegance of design in the field of supramolecuiar chemistry, with many examples arising as models that help to deconvolute the supramolecular operations of biological systems. To this end. a large variety of molecules appeared possessing concave hydrophobic surfaces that can serve as binding sites for convex substrates. Cryptophanes hold a special place in this historical context. First reported by Collet and coworliers in 1981,[1] they are among the first examples of synthetic "container molecules"—that is, closed-surface macrocycles that possess the defining ability to completely encapsulate molecule-sized substrates.[2–5] Molecules of this unusual form, including such members as the (hemi)carcerands and self-assembled capsules. immediately bring to mind poiential applications as microreaction vessels, sensors. molecular delivery devices, and separations agents. to name but a few possibilities. Research is ongoing in these areas, and technological applications based upon the remarkable recognition cheinistry that is characteristic of these container-like species appear to be forthcoming.

The defining features of the cryptophanes are structural. They are composed of two cup-shaped. C_3-symmetric, [1.1.1]orthocyclophane units, connected by three bridges (Y, Fig. 1). This construction effectively ensures that. with appropriate bridges. cryptophanes possess enclosed (or nearly so) elliptical cavities with interior volumes on the size-scale of individual small molecules. The closed-surface nature of the cryptophanes is exemplified by a space-fill rendition of the so-called cryptophane-E, a well-studied member of the cryptophane family (Fig. 1). Enforced cavities make these molecules exceptionally well suited for molecular recognition studies—particularly. the sort that shed light on the nature of substrate binding within a generally hydrophobic pocket. The existence of two diastereomeric forms of these compounds (*syn* and *anti*, Fig. 1). together with chemical variety in the bridging (Y) and peripheral substituents (R), makes available a large number of cryptophanes with readily adjustable cavity volumes. aperture sizes, solubilities, and, ultimately, recognition properties.

The remarkable recognition properties displayed by the cryptophanes have attracted a great deal of attention. In this article, an attempt will be made to provide general insights into the supramolecular chemistry of these remarkable hosts by highlighting selected studies in the context of the field. Collet, the late father of cryptophane chemistry. provided more in-depth reviews elsewhere.[6]

CRYPTOPHANE STRUCTURE AND SYNTHESIS

As the details of cryptophane structure greatly affect the molecular recognition properties of these hosts. some discussion of structure and synthesis is pertinent. The construction of a cryptophane skeleton can be accomplished via any of three basic methods: (i)the "template" method. (ii)the "two-step" method, or (iii)a "capping" method. These approaches are generalized in Fig. 2. Each relies. at some stage. on a cyclization reaction that leads to the formation of the trimeric [1.1.1]-orthocyclophane moiety that provides the critical element of curvature to the cryptophane structure. This electrophilic aromatic substitution reaction is made regioselective, promoting C_3-symmetric trimeric products, by employing an appropriately 3,4-disubstituted benzyl alcohol as a starting material. For obvious reasons, the choice of substituents is limited. To achieve reasonable yields. the R substituent is almost exclusively limited to the strongly activating methoxy group. The identity of the X substituent is less important; typically. X needs only to be activating (e.g., -OR. -SR, NHCOR), but some limitations exist. These synthetic limitations dictate that functionalization of the peripheral substituents (R), which ultimately define the apertures of the cryptophane cavity. usually occurs after the critical cup-forming steps.

The C_3 symmetry of the cup-lilie trimers indicates that they are chiral. typically being formed as a racemate. In some cases, the cups are resolvable via suitable diastereomers. as the enantiomers are somewhat stable to racemization via conformational inversion of the nine-membered cyclophane ring ($\Delta G^{\ddagger}_{298}$ = 110–115 kJ/mol). Chirality in the cup-shaped units implies that two types of cryptophanes exist. Joining two cups of opposite

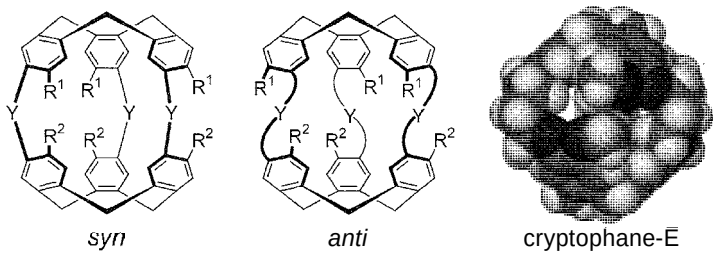

Fig. 1 Cryptophane structure.

handedness; as defined by the arrangement of the bridging *Y* substituents, results in a cryptophane, where the R substituents display a *syn* relationship. Alternatively, joining two cups of the same handedness results in a chiral *anti* cryptophane (only one enantiomer is depicted in Fig. 1). If $R^1 = R^2$, the *syn* diastereomer will be the achiral *meso* form, with C_{3h} symmetry, whereas the anti diastereomer will be chiral, possessing D_3 symmetry. Fortunately, most cryptophane *syn* and *anti* diastereomers can be readily separated, but unambiguous assignment of their identity can be more difficult. Additionally, if the top and bottom cups differ with respect to their peripheral substituents ($R^1 \neq R^2$), the *syn* and *anti* forms will both be chiral (C_3). It is relatively straightforward to impart top/bottom asymmetry in the cryptophanes, but only recently have lower-symmetry C_2 varieties, bearing different Y bridges. been achieved."]

Method (i), the "template method," was the first employed by Collet for the synthesis of cryptophanes.[1] A suitably substituted benzyl alcohol is first cyclized to form a trimeric cup. Additional benzyl alcohol substituents are then appended via a bridging Y group, and these groups are then subjected to an intramolecular cyclization to yield the corresponding cryptophanes. The initially fonned C_3-cup thus serves as a template for the second cup-forming reaction, with the reaction typically proceeding in good yields (often > 60%) and with appreciable diastereoselectivity. Though this method normally requires high dilution conditions (10^{-4} M in formic acid), it provides distinct advantages in some respects. This approach. for instance, allows the synthesis of cryptophanes that are asymmetric with respect to the peripheral substituents attached to the top and the bottom cups ($R^1 \neq R^2$). Second, provided that the initially formed trirner can be resolved, this route can be employed to provide optically active *anti* cryptophanes of known absolute configuration.

Method (ii), known as Collet's ''two step'' synthesis, yields suitable cryptophanes in only two synthetic steps from readily available vanillyl alcohol (R = OCH_3, X = OH).[8] In this approach. a monomer possessing two vanillyl alcohol residues is synthesized and then cyclized directly, under acidic conditions, to the con-esponding

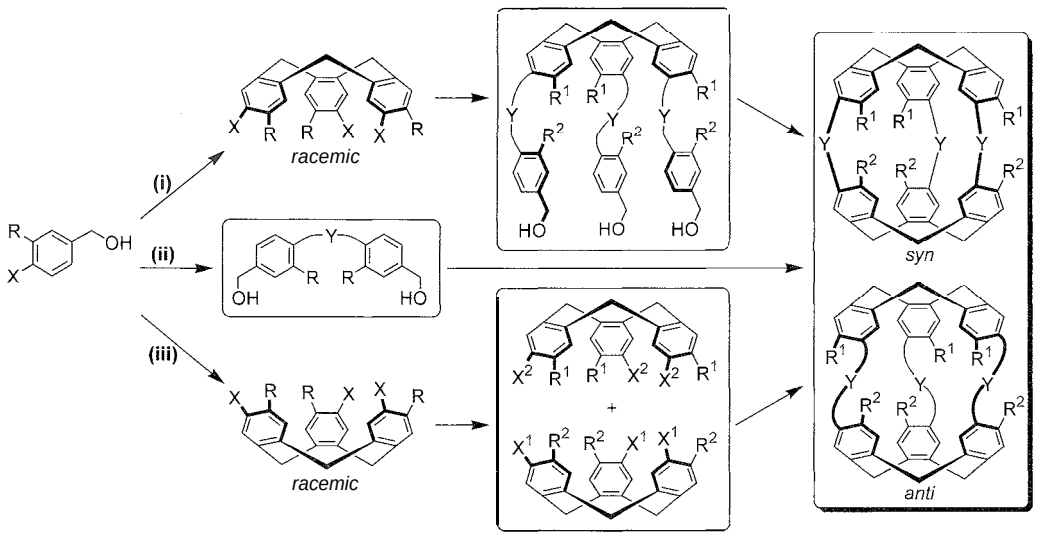

Fig. 2 Synthesis of cryptophanes.

cryptophanes. The reaction entails the formation of both orthocyclophane cups in a single pot and. although the yields are generally low (< 20%), gram quantities of cryptophanes can be readily prepared by this convenient approach. Notably, this reaction tends to display diastereoselectivity in favor of the chiral anti cryptophanes: making available some chiral *anti* cryptophanes that give low yields by the "template" method.

Cram and coworkers demonstrated that Method (iii). the "capping" of one preformed C_3-trimer with another. is also viable.[9] Though Cram's synthesis involved the oxidative coupling of two identical cups possessing terminal acetylenic groups (R = CH_3; X = $OCH_2C{\equiv}CH$), "capping" one C_3-trimer with a dissimilar trimer can also be envisaged ($R^1 \neq R^2$ or $X^1 \neq X^2$). Though the yields of cryptophanes synthesized by the "capping" method were low (< 15%), lessons learned from similar approaches toward the syntheses of (hemi)carcerand molecular containers suggest that it may be possible to improve yields by employing suitable guest templates.[10]

To date, several dozen cryptophanes have been synthesized. A detailed list of these is beyond the scope of this short review; but most cryptophanes are of the form where the bridging Y substituents are simple oxyhydrocarbons {e.g., Y = –OZO-: Z = $(CH_2)_n$ [n = 2–10], CH_2ArCH_2, $CH_2CH{=}CHCH_2$, $CH_2C{\equiv}CCH_2$, $OCH_2C{\equiv}CC{\equiv}CCH_2O$, $(OCH_2CH_2)_2O$}.[6] Moreover, the peripheral R substituents of as-synthesized cryptophanes are often methoxy groups, but these may be selectively cleaved to the phenol, providing a synthetic entry point to cryptophanes with varying peripheral R substituents. Interestingly, there are two examples of cryptophanes that were synthesized in effectively quantitative yields via supramolecular self-assembly. These examples highlight the growing importance of self-assembly as a synthetic approach toward increasingly complex macrocycles.[11,12]

CRYPTOPHANE COMPLEXES

Of the 70 or so cryptophanes that have been reported, relatively few were characterized with respect to their supramolecular chemistry. Listed in Table 1 are those examples that were shown to display some kind of complex-forming behavior. As the IUPAC names for cryptophanes are exceedingly complex, an alphabetical system based simply on the chronology of synthesis was used and, as much as possible. will be adopted here.

Discovery

The cryptophane story begins in 1981 with Collet's template-directed synthesis of the first and smallest known cryptophane, the so-called cryptophane-A (*anti*; $Y = O(CH_2)_2O$; $R^1 = R^2 = OCH_3$).[1] At the time. the field of supramolecular or host–guest chemistry was entering

Table I Cryptophanes *possessing demonstrated complex-forming* abilities

its developing stages. and, though many examples of synthetic molecules capable of the selective binding of cations (or even anions) were known. nonnatural systems. wherein complexes persist in solution between uncharged apolar host, and similar, uncharged apolar guests, were essentially unknown. Though naturally occurring cyclodextrins had long been observed to complex uncharged molecules in aqueous solution via their hydrophobic cavities. the question remained whether the design of synthetic molecules for such purposes could be achieved. It was generally recognized, however, that synthetic hosts capable of discriminatory binding according to size. shape; and especially chirality. could prove useful for a variety of technologies.

Examination of space-filling models of cryptophane-A indicated it to be an effectively closed surface container. suggesting that it would be exceedingly difficult for certain solvent molecules. such as $CHCl_3$, to enter the cavity through the methoxy-guarded apertures. Accordingly. $CDCl_3$ was originally chosen as a noncompetitive solvent to initiate complexation studies. but the evidence showed that substrates like CH_2Cl_2 were only weakly bound under these conditions. It was thought. therefore. that the cryptophane-A cavity may be too well guarded, and that the cavity apertures needed to be enlarged in order to allow potential substrates access to the cavity. Collet and coworkers thus synthesized cryptophanes-**C** and -**D**, the anti and *syn* cousins of cryptophane-A, wherein one of the two cups was absent the methoxy substituents.[16,17] Despite similar cavity sizes, the ^{1}H-NMR spectrum in $CDCl_3$ showed cryptophane-C to complex CH_2Cl_2 more effectively than cryptophane-A, though the association was modest ($K_a = 1.8\ M^{-1}$). Further studies showed that CH_2ClBr ($K_a \approx 0.9\ M^{-1}$) and CH_2Br_2 ($K_a \approx 0.15\ M^{-1}$) were also weakly bound by cryptophane-**C** under these conditions, and effective size discrimination was clearly operative. Remarkably, the *syn* diastereomer, cryptophane-D, forms complexes with the same guests. but the association constants are an order of magnitude smaller.

In 1985, Collet and coworkers demonstrated the first example of enantioselective recognition by a cryptophane. Optically pure cryptophane-**C** was used as an ^{1}H-NMR shift reagent for the analytical resolution and first experimental determination of the maximum rotation of bromochlorofluoromethane (CHFClBr), one of the simplest chiral molecules.'''' At *332* K, the difference in association constants (in $CDCl_3$) between the diastereomeric conipiexes ($K_a = 0.22\ M^{-1}$ and $0.30\ M^{-1}$) were sufficient to effect the separation of the fast exchange resonances of the guest, and the enantiomeric excess of a weakly resolved sample could be determined; thus yielding the maximum rotation as $[\alpha]^{25}_D = 1.7 \pm 0.5°$—data that were sought for nearly a century. The (*R*)-(−) absolute configuration of the haloform was later assigned with the aid of corroborating molecular dynamics simulations and Raman optical activity spectra of the cryptophane-**C**⊙CHFClBr complexes.[26 27]

Lessons in Molecular Recognition

Given the modest association constants. it originaliy appeared that thermodynamic driving forces for the formation of cryptophane complexes were destined to be extremely small. Binding of CH_2Cl_2 by cryptophane-A, for instance, was immeasurably weak in chloroforin solution. As experiments progressed, however, it became clear that, contrary to earlier beliefs, the chloroform solvent was, in fact. a significant competitor for the cryptophane cavity. In $(CDCl_2)_2$, a much larger solvent, the binding of CH_2Cl_2 by cryptophane-A is strong ($K_a = 475\ M^{-1}$ at 300 K). Moreover, under these conditions. the strong affinity of cryptophane-A for chloroform also became apparent ($K_a = 230\ M^{-1}$).[14] Binding of CH_2Cl_2 by cryptophane-**C** was observable in chloroform, not because the apertures of the cryptophane cavity are larger, but because chloroform does not compete as effectively for the cavity of cryptophane-C [$K_a = 10\ M^{-1}$ at 300 **K** in $(CDCl_2)_2$].

These results highlight a general caveat in supramolecular chemistry: the significance of complexation behavior must always be interpreted in the context of the solvent. In special cases where the solvent is bound by the host in competition with the intended guest. the observed association constant is only an apparent association constant (K_{app}). Thus, K_{app} will be comparable to the "true" association constant, K_a, only when the binding of the solvent, K_s, is extremely weak ($K_s < 10^{-2}$–10^{-3}). This considered, molecular recognition studies involving container compounds are typically performed in less conventional solvent systems, where the solvent is usually too large to be accommodated by the cavity (e.g., mesitylene. phenyl ether, hexachloroacetone, 1,1,2,2-tetrachloroethane) or has a poor affinity for the, typically hydrophobic, cavity (e.g., water).

The subtleties of the molecular recognition properties exhibited by cryptophanes are best appreciated by comparing a series of structurally similar cryptophanes in a common solvent system. In this respect, the binding of neutral guests by cryptophanes-**A**, -**C**, and -**E** (*anti*, $Y = O(CH_2)_3O$, $R^1 = R^2 = OCH_3$) are directly comparable in $(CDCl_2)_2$, as this solvent is sufficiently large that it cannot compete with the guests. Depicted in Fig. *3* are the free energies of association, at *300* K, as a function of guest volume for a series of neutral molecules that are bound by these three cryptophanes.[6,14,18] The identities of selected guests are indicated. The most notable feature of this plot is the sharp size discrimination displayed by all

of all of the cryptophanes and particularly for cryptophanes-C and -E. The intrinsic thermodynainic driving forces for complexation of optimal guests ($-\Delta G_i^0$) range from 15–21 kJmol^{-1}, meaning that these hosts will effectively. scavenge complementary guests. even in the absence of solvophobic effects. The optimal guest volume increases smoothly with increasing cryptophane cavity size: Xe, CH_2Cl_2, and $CHCl_3$ for -**A**. -**C**. and -E. respectively. Guests smaller or larger than the experimental optimal volume are bound less effectively; and those that, according to molecular models. are too large to occupy a particular cryptophane cavity are simply not complexed. Notably, the cryptophanes can effectively differentiate guests on the basis of subtle volume differences (< 5%). Cryptophane-C, for instance, discriminates between CH_2Cl_2 and CH_2ClBr by 1.5 kJmol^{-1}. Similarly, cryptophane-E discriminates between $CHCl_3$ and $CHCl_2Br$ by 1.2 kJmol^{-1}. In terms of shape recognition. guests of roughly tetrahedral or elliptical shape tend to be bound more effectively than planar or linear guests. Isobutane, for example, is bound more strongly by cryptophane-E than is *n*-butane ($\Delta\Delta G^0 = 6.0$ kJmol^{-1}). Additionally. the cryptophanes tend to have a low affinity for fluorinated guests. Cryptophane-A, for example. has almost no affinity for CHF_2Cl, though the size and shape of this guest would suggest that it should be bound strongly.

Cryptophanes also readily bind and recognize suitable cations in organic solvents.[20] The free energies of association, at 300 K in $(CD_2Cl_2)_2$, between cryptophane-E and alkyl ammonium cations ranging in size from Me_3NH^+ to Me_3PrN^+ are plotted in Fig. 3. along with the corresponding data for the binding of neutral molecules by the same host. A similarly sharp size selectivity profile is observed for the binding of these cations. with Me_4N^+ being the most strongly bound. The K_a of cryptophane-E binding to Me_4N^+ (2.25×10^5 M^{-1}), however, is three orders of magnitude greater than that of the most favored neutral molecule complex (cryptophane-E⊙$CHCl_3$), reflecting the strong preference of the cation for the electron-rich. aryl-lined cryptophane cavity as compared to the halogenated solvent. Moreover. Me_4N^+ is 33% larger than $CHCl_3$. Remarkably, neutral molecules of this size are essentially unbound under the same experimental conditions. and these results raise some serious questions concerning the criteria by which one defines inolecular "size."

Collet and coworkers also synthesized cryptophanes of a water-soluble variety. Cryptophanes-A3, E3. and **O3** are water-soluble derivatives of cryptophanes-A, **C**. and **O**. possessing six pendant ionizable –OCH_2COOH groups in place of the methoxy groups.[15,20,21] As expected, the stability of the neutral molecule cryptophane complexes is increased on moving to aqueous solvent due to the hydrophobic effect. and the stabilizing effect is more pronounced as the size of the guest increases. Notably. the larger cryptophane-03 displays an affinity for comparatively larger guests (Me_4Sn, Et_4Ge, Me_4Pb), an observation in accord with expectations. The water-soluble cryptophanes are far less effective at binding small alkyl ammonium cations in aqueous solution than their parent cryptophanes in organic solvents, though

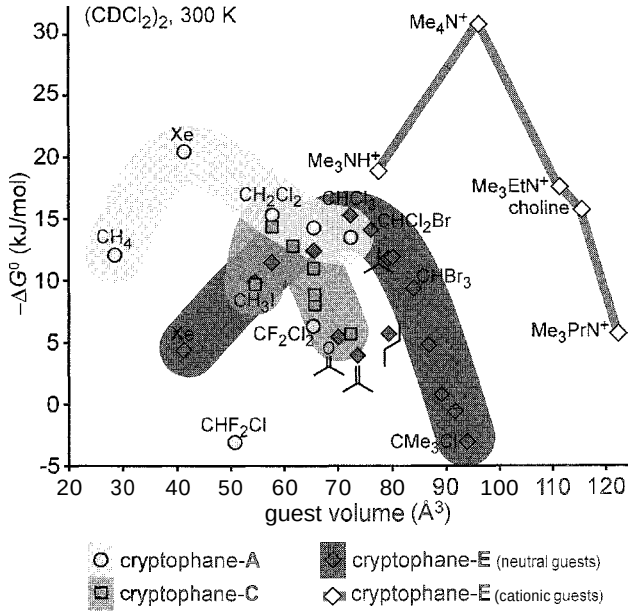

Fig. 3 Gibb's molar free energies of complexation for various cryptophane⊙guest complexes in $(CDCl_2)_2$ at 300 K.

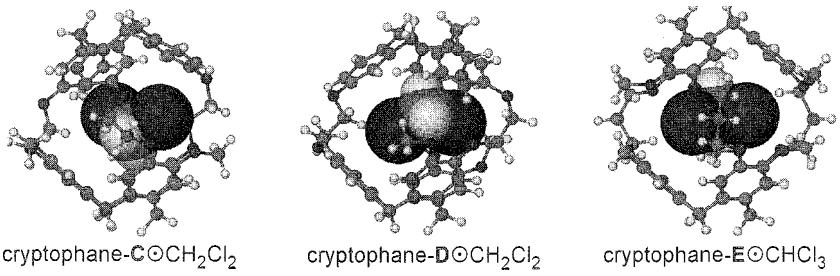

Fig. 4 Crystal structures of well-resolved cryptophane⊙guest complexes.

similar trends are observed with respect to size selectivity. The K_a for the binding of Me_4N^+ by cryptophane-E3, for example. is only 320 M^{-1}, as compared to the aforementioned K_a of 2.25 x 10^5 M^{-1} for the cryptophane-E⊙Me_4N^+ complex in $(CD_2Cl_2)_2$. Lower association constants are attributable to the hydrophilic nature of the small alkyl ammonium cations. As the size of an alkyl ammonium ion is increased, however. it tends to become more hydrophobic. Thus, the larger cryptophane-03 forms a complex with acetylcholine that is of comparable stability to that of acetylcholine esterase.

Variable temperature studies allow deconstruction of the free energy of association into the enthalpic and entropic contributions.[6] Though complex formation is typically favored from an enthalpy standpoint, these studies show that complex formation may also be entropically favored. The binding of CH_2Cl_2 by cryptophane-E. for instance, is driven strictly by entropy, with values for ΔH^0 and ΔS^0 equal to 4.2 kJmol^{-1} and 25 Jmol^{-1}K^{-1}, respectively. Similarly. the binding of methane by cryptophane-A is both enthalpically (AN" = – 6.7 kJmol^{-1}) and entropically (ΔS^0 = 17 Jmol^{-1}K^{-1}) favored. Moreover, Cram and Rebek observed similar results for hemicarceplexes and self-assembled capsules. respectiv e~~.These extraordinary observations are counterintuitive for an association of two molecules, in an apolar solvent, wherein the motions of the molecules would be anticipated to be relatively restricted. Collet and coworkers rationalized these observations by pointing out that the guest molecules of such entropy-favored complexes often do not efficiently fill the volume of the host cavities, suggesting that in such cases, the cryptophane interiors may best be described as a supercritical fluid and the guests may readily disorder within the host. The methane molecule of the cryptophane-A⊙CH_4 complex, for example, occupies a mere 35% of the cavity volume. Cram used related arguments to make the case for a ''new phase of matter'' within carcerand interiors and pointed out the entropic benefits of diluting empty space on complex formation.[4] Additionally, it should be considered that complexation may release somewhat organized solvent molecules from the solvation sphere of the guest, a factor that is known to assist complex formation in aqueous solutions.

The crystal structures of only a few well-defined cryptophane complexes were reported. The complexes cryptophane-C⊙CH_2Cl_2,[16] cryptophane-D⊙CH_2Cl_2,[17] and cryptophane-E⊙$CHCl_3$[19] are depicted in Fig. 4. Each depicts an arrangement wherein the guest is completely encapsulated by the pseudo-C_3 symmetric cryptophane.

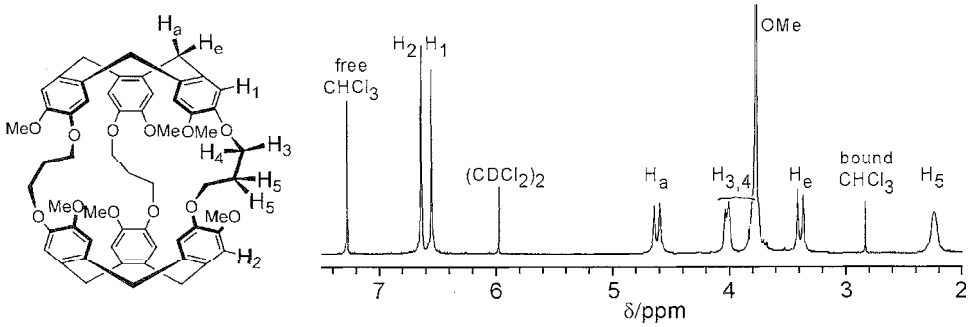

Fig. 5 Slow exchange binding of $CHCl_3$ by cryptophane-E in $(CDCl_2)_2$ as revealed by ^{1}H-NMR.

The two CH_2Cl_2 complexes possess ordered guest molecules This ıs ın accord with a negative entropy of complexation for the cryptophane-C complex (ΔS° = -4 $Jmol^{-1}K^{-1}$) and the fact that the guest can occupy roughly 70% of the available cavıty volume, a value sımılar to the packing fraction of close-packed crystals

Constrictive binding: the "container effect"

In an appropriate solvent. guests encapsulated by cryptophanes typically exchange slowly, with many complexes exhibiting half-lives on the order of milliseconds-seconds at room temperature. Thus, in a typical NMR experiment, separate signals for free and complexed guest species can often be observed simultaneously. Fig. 5 depicts the room temperature 300 MHz ^{1}H-NMR spectrum of cryptophane-E in $(CDCl_2)_2$ in the presence of four equivalents of $CHCl_3$. The peaks at δ 7.28 and δ 2.84 correspond to free and cryptophane-bound $CHCl_3$, respectively. The dramatic upfield shifts ($\Delta\delta \approx 4$ ppm) for encapsulated species are consistent with the close proximity to the shielding regions of the aryl rings of the host. Similar spectroscopic signatures were noted for guests encapsulated within other container molecules.

Observation of slow exchange in these systems is remarkable. considering that the negative free energies for complexation of neutral molecules rarely exceed 15 $kJmol^{-1}$. The activation barriers for dissociation. $\Delta G_d^{\ddagger}$, were measured by line shape analysis for some cryptophane complexes of uncharged substrates.[6] The $\Delta G_d^{\ddagger}$ for complexes of cryptophane-E are found to be nearly independent of the guest identity, ranging only from 66-71 $kJmol^{-1}$ for a relatively wide range of guests. Cram and coworkers recognized similar behavior for hemicarceplexes and put forth the notion of a container effect. termed constrictive binding, as an explanation.'" Constrictive binding ($\Delta G_c^{\ddagger}$) is a manifestation of the physical consequences of encapsulation and is defined as the activation free energy for host–guest association or. alternatively, the activation free energy of dissociation ($\Delta G_d^{\ddagger}$) less the intrinsic thermodynamic driving force for complexation, $-\Delta G_i^0$ (Fig. 4). As for some hemicarceplexes. the constrictive binding energy for cryptophane-E [$\Delta G_c^{\ddagger} = \Delta G_d^{\ddagger} - (-\Delta G_i^0) \approx 56$ $kJmol^{-1}$] remains relatively constant for a series of guests, implying that exchange of guests is governed by a (somewhat costly) conformational gating by the host. As a result. complexes of relatively Iow intrinsic thermodynamic stability (e.g., $\Delta G_i^0 \approx 15$ $kJmol^{-1}$) can display impressive kinetic stabilities (upwards of $\Delta G_d^{\ddagger} > 70$ $kJmol^{-1}$), a feature that should be regarded as a defining trait for true molecular containers. This concept is illustrated schematically in Fig. 6 by cornparing the binding behavior of container molecules with that of related cup-shaped cavitands. which display similar values for $-\Delta G_i^0$ but differ greatly with respect to their ability to constrictively bind guests via encapsulation. McCammon and coworkers performed molecular dynamics simulations on some cryptophane complexes and found that the conformational sampling of the host can depend on the identity of the encapsulated guest.[28,29] In related work. Houk and coworkers performed gas-phase calculations on several members from the hemicarcerand family and identified two operative mechanisms. termed "French door*' and "sliding door,.' responsible for the gating of encapsulated guests.[30] Taken together, the experimental and computational findings suggest opportunities to finely tune the kinetics of complexation by modifying the cavity-guarding periphery, without appreciably affecting the thermodynamics. It is clear that more insight can be gained from continued complementary computational and experimental work.

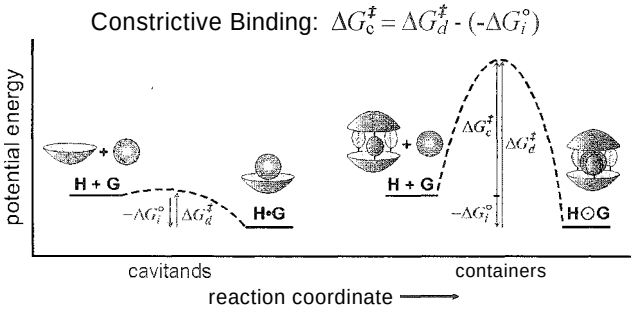

Fig. 6 Constrictive binding via encapsulation results in complexes with relatively high kinetic stabilities.

CONCLUSION

The study of cryptophanes has led to a greater understanding of molecular recognition phenomena. and particularly that which occurs within a hydrophobic binding site. Moreover, the ability of these and other molecular containers to discriminate between small molecule substrates on the basis of size. shape, chirality. and electronic characteristics is extraordinary. and the feasibility of practical applications derived from these characteristics is clear, though much work remains to be done. The development of higher-yield synthetic procedures or efficient optical resolutions, for instance. would increase availability and promote the use of cryptophanes for practical, recognition-based technologies. Additionally. much remains to be learned about the relationship between the kinetics and thermodynamics of complexation, the mechanisms by which these hosts select their guests,

and the properties of materials that might be derived from these remarkable compounds. Moreover, larger cryptophane-like molecular containers should be able to encapsulate larger or even greater numbers of substrates, opening the door for use as delivery devices or miniature reaction chambers. To be sure, much remains to be written in the story of container molecule chemistry.

Crystal Deconstruction

Fabrizia Grepioni
Università di Sassari, Sassari, Italy

Università degli Studi di Bologna, Bologna, Italy

INTRODUCTION

Crystal deconstruction is the process that leads backwards. in a reverse ''aufbau'' process. from the structure of a molecular crystal to the component molecules or ions. Crystal deconstruction allows one to focus on the interactions that are more relevant for crystal structure cohesion. The objective of the deconstruction process is also that of learning about the factors responsible for molecular/ionic recognition and self-assembly in the solid state. Insights into crystal polymorphism can be gained by comparing the different distributions of intermolecular interactions associated with the existence of different crystal forms of the same molecular species.

FROM BONDS BETWEEN ATOMS TO BONDS BETWEEN MOLECULES

Understanding the interactions that control molecular or ion recognition and self-assembly is one of the most relevant chemical problems of our time. with implications in all areas of chemistry, from biochemistry to organic, organometallic, and physical chemistry, to encompass inaterials chemistry. The interest in the bonds between molecules is paradigmatic of supramolecular chemistry.[1,2] This perception is shared with molecular crystal engineering[3,4] if the concept of bonds between molecules is convoluted with the translational symmetry of a molecular crystal (see Fig. I).

Molecular crystals can. in fact, be viewed as periodical supermolecules, in which a large number of molecules or ions interact via noncovalent interactions, generating collective physical and chemical properties.[5] According to the same reasoning. polymorphic modifications of a molecular crystal. i.e., different crystals of the same constituent molecule/ions,[6–9] can be regarded as periodical supramolecular isomers, differing in distribution of the noncovalent bonds.

In the context of this article, we will use the term ''*intermolecular*'' as a synonym of noncovalent. with this encompassing all types of secondary interionic or intermolecular interactions, e.g., electrostatic, hydrogen bonds, and van der Waals interactions. which do not imply two-electron σ-bonds. Accordingly, it is useful to identify neutral molecules and molecular ions (e.g., those formed by an ensemble of covalently bonded atoms) as molecular systems.

INTERNAL VERSUS EXTERNAL INTERACTIONS

The assembling of molecules to form stable three-dimensional aggregates is the quintessence of the self-recognition and self-aggregation processes that are behind the construction of any supramolecular system. The understanding of these processes requires a profound knowledge of the interactions among molecules and ions in the solid state.[10]

Crystal deconstruction is a logical process that allows one to "decode" the crystal structure organization of a given molecular or ionic crystal by sifting out those interactions. that are relevant to supramolecular recognition and to crystal cohesion.[11]

Supramolecular recognition is a process that applies when two different or identical entities (two molecules. two ions) approach each other in the vacuum or in a solvent medium to form a stable aggregate. In the absence of directing interactions, such as those resulting, for example, from the presence of strong dipoles or hydrogen-bonding donor–acceptor groups, the recognition process will be controlled by the outer shape of the molecule and by the nature of the peripheral atoms. The formation of a stable dimolecular aggregate. whether formed by the same molecule, i.e., *AA*, or by two different molecules/ions, i.e., AB, or $A^{+/-}B^{-/+}$, will depend primarily on the complementarity of shape. This concept was put forward by Linus Pauling long ago:[12]

> ...in order to achieve the maximum stability, the two molecules must have complementary surfaces. like die and coin. and also a complementary distribution of active

Encyclopedia of Supramolecular Chemistry
DOJ: 10.1081/E-ESMC 120012751

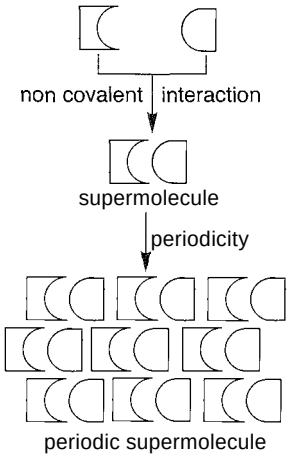

Fig. I The relationship between an aggregate at the molecular level—a supermolecule—and an aggregate at the crystal level—a periodic supermolecule.

groups. The case might occur in which the two complementary structure5 happened to be identical: however. in this case also the stability of the complex of two molecules would be due to their complementariness rather than their identity.

The pairwise approach of two molecules is the most elementary aggregation step in the nucleation of a crystal. This first nucleus will respond to the need to optimize the pairwise interaction; possibly in competition with the solvation/desolvation process. However, as the first nucleus begins to grow. with molecules/ions clinging to it one after the other, the cohesion of the overall aggregate becomes more important, to the extent that an optimum pairwise interaction may be sacrificed in favor of a more stable multicomponent aggregation. In other words. the construction of the crystal responds to a process of global energy minimization. which has to compromise between various factors in order to optimize the following:

I. Pairwise atoni–atom interactions between first neighbors (strong "local" repulsions are not tolerated).
2. Cohesive energy of the crystal aggregate (with its trillions of molecules).
3. Conformational energy for the isolated molecules. (This term is relevant in the case of flexible. structurally nonrigid molecules/ions.)

In addition. the temperature of the system must be taken into account, because molecules in thermal motion or undergoing low-energy reorientational/fluxional processes have temperature-dependent shapes and geometries. It should not be surprising, therefore. that there is no unique answer to the optimization process. and that different compromises between internal and external energy terms (both of enthalpic and entropic natures) may be reached for a given species. This inay well be the fundamental reason for the existence of polymorphic modifications of the same substance or for the occurrence of solid-state processes, such as solid-to-solid phase transitions between enantiotropic forms, order–disorder transitions, temperature-dependent isomerization in the solid state, etc. Crystal deconstruction is also useful for exploring the different distributions of intermolecular interactions that are consequences of crystal polymorphism.

ANALOGIC CRYSTAL DECODING

The crystal structure formed by neutral molecules or by molecular ions can be efficiently decoded by focusing on the number and distribution of the nearest neighbors around the reference molecule or ion in the crystal, the so-called molecular "enclosure shell" (ES) approach.[13] The ES approach avoids the strictness of translational and point symmetry and affords a direct appreciation of the most relevant interinolecular interactions involving the molecule of interest. One commences from the known molecular structure to study how the observed crystal can be reconstructed. This logical process recalls Kitaigorodsky's molecular ''aufbau'' process.'[14] In general, if possible, it is useful to first prepare a "one-dimensional" crystal by linking molecules to form a inolecular row. then a "two-dimensional" system by coupling molecular rows. and finally. a three-dimensional crystal by stacking molecular layers as depicted in Fig. 2. The decoding process can be carried out by using computer-aided graphic programs exploiting atomic coordinates determined by x-ray diffraction.

A practical application of the decoding process is afforded by the investigation of the crystal structure of two chemically different molecular systems. namely. benzene and *bis*benzenechromium,[13] compared in Fig. 3. The analogy between the two crystals is remarkable. even though the two molecules greatly differ in terms of chemistry. This is because the periphery of most organometallic molecules and coordination complexes is "organic" in nature.'''' while the metal centers are mostly situated in the molecular cores and are shielded from neighboring molecules. Because the surface atoms. besides determining the outer shape of the molecules/ions, are crucial in determining the nature and extent of intermolecular interactions, the packing problem of most molecular organometallic compounds reduces to the organic case. Under this viewpoint. it should be no surprise that the structures of benzene and *bis*benzenechromium are topologically similar. The peripheral.

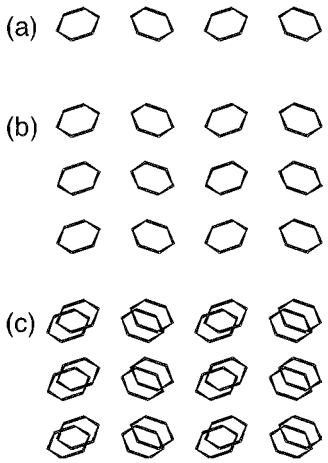

Fig. 2 The "crystal construction" process. Formation of (a) a one-dimensional crystal by linking molecules to form a molecular row: (b) a two-dimensional system by coupling molecular rows: and finally. (c) a three-dimensional crystal by stacking molecular layers.

crystal-structure-determining features of the two molecules are the same. with discoid. aromatic C_6H_6 moieties. which are able to form C–H· · ·π interactions.[15,16]

A more complex application of the deconstruction algorithm is provided by a prototypical transition metal carbonyl cluster molecule. $Ru_3(CO)_{12}$.[17] In this crystal. a row of molecules forming the crystal backbone is obtained by inserting of one axial CO-ligand into a tetragona! cavity — formed by two axial and two radial COs—on a next neighboring. equally oriented molecule (see Fig. 4). This intermolecular interaction is responsible for deviation of the molecular symmetry from the

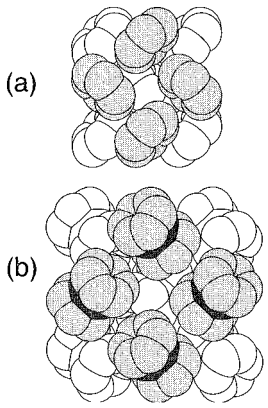

Fig. **3** Space-filling representation of the crystal structures of benzene (a) and *bis*benzenechromium (b). showing the similarity between the two packing arrangements.[12] The H atoms were omitted for clarity.

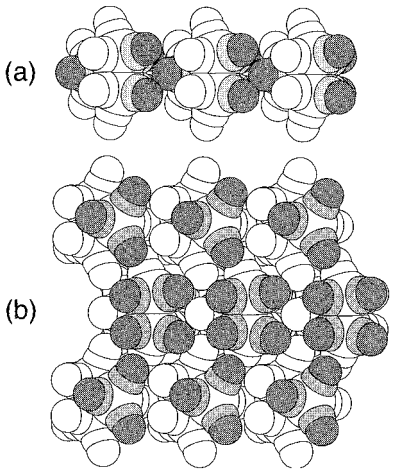

Fig. **4** Deconstruction of crystalline $Ru_3(CO)_{12}$: (a) a row of molecules constituting the crystal backbone is obtained by inserting one axial CO-ligand into a tetragonal cavity. formed by two axial and two radial COs on a next neighboring. equally oriented molecule: (b) a molecular layer is obtained by placing other rows on both sides of the central one. uith the $(CO)_3$ and $(CO)_4$ units protruding from the surface affording a "Velcro"-type interaction for the incoming molecular layers. (From Ref. [17].)

idealized D_{3h} symmetry. Once a row of $Ru_3(CO)_{12}$ molecules is formed. a molecular layer is obtained by placing other rows on both sides of the central one. The layer presents $(CO)_3$ and $(CO)_4$ units protruding from the surface. These units afford a ''Velcro''-type interaction between molecular layers, which can then pile up. generating a three-dimensional stacking. viz. the observed crystal structure.[18]

An example of crystal deconstruction is provided by Dance's study[19] of the packing of molecules containing PPh_3 peripheral groups. Dance showed that molecules with multiple PPh_3 ligands recurrently form one-. two-, and three-dimensional supramolecular networks. based on

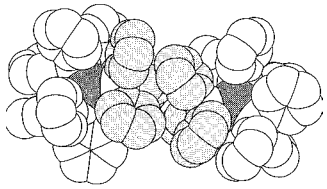

Fig. **5** A sixfold phenyl embrace involving two PPh_3 ligands on adjacent $Ni(PPH_3)_3$ molecules. The remaining PPh_3 ligands are participating in analogous interactions in the crystal. thus originating an extended network.[18,19] The H atoms were omitted for clarity.

a precise supramolecular packing motif, called multiple phenyl embrace. This packing motif is transferable from crystal to crystal and possesses clear directionality (topological) features. An example, reported in Dance's paper. of a sixfold phenyl embrace is shown in Fig. 5. It can be seen that three phenyl rings on each of two PPh_3 ligands belonging to adjacent $Ni(PPH_3)_3$[20] molecules form a dimer. which is part of an extended network of similar interactions.

ATOM–ATOM POTENTIAL ENERGY CALCULATIONS: A VALUABLE TOOL FOR PACKING DECODING

The examples discussed above show the importance of analogic crystal deconstruction. Clearly, this is not the only means by which to investigate crystal packings. Computational methods can also be used. For example, the atom–atom potential energy method, in use for more than 50 years in the organic solid-state chemistry field[14,21,22] has proven to be a valuable tool with which to estimate noncovalent interactions of the van der Waals type incrystals. The most commonly used expression for the empirical estimate of the packing potential energy (PPE) of a molecul ar crystal is the 6-exp-l potential, with $PPE = \Sigma_i\Sigma_j Ae^{-Brij} - Cr_{ij}^{-6} + q_i q_j r_{ij}^{-1}$.[21,22] In this expression. index *i* runs over all atoms of a molecule taken as reference in the lattice: index *j* runs over the atoms of the surrounding molecules distributed according to crystallographic symmetry; r_{ij} is an atom–atom intermolecular distance; and q_i and q_j are the formal atomic charges if a coulombic term is included in the calculations. The basic assumption underlying the use of most atom–atom potential calculations is that only central forces operate between pairs of atoms. and chat the total interaction energy is the sum of the interactions between all atomic pairs. Repulsions arising from short contacts between atoms belonging to different molecules are taken into account by the exponential function. A number of independent tabulations for the coefficients to be used in each type of atom–atom contact for organic substances, including hydrogen-bonded ones, are available in the literature.[23,24] They are obtained by fitting observed crystal properties (heat of sublimation and known crystal structures) or via ab initio calculations of the intermolecular potential energy.[25]

The atom–atom method is extraordinarily flexible and transferable and can be applied to a great variety of molecular crysialiine systems. including metal-containing materials.[''''] Rather than use the atom–atom potential energy method to obtain (more or less reliable) estimates of the enthalpy of the crystal. the method can be used as a computational tool to explore the ES. i.e., the surroundings of a molecule within an observed crystal structure. For the pu pose of crystal deconstruction. the lack of suitable parameters for the metal atoms does not seriously affect the calculations; the metal atoms, in fact. are usually deeply embedded in a sheath of ligands and screened from the surroundings, to the extent that their contribution to crystal cohesion is often minor, if not negligible. The molecules forming the first-neighbor shell of the one chosen for reference can be selected and ranked on a relative scale of pairwise van der Waals energy.[27,28]

COMPARISON OF PACKINGS CAN BE USEFUL TO UNDERSTAND PHASE TRANSITIONS AND CRYSTAL TRANSFORMATIONS

It was amply demonstrated in studies of organic solids that little differences in free energy are sufficient to yield alternative packing modes, and that, in the absence of highly directional forces; there is no unique way to organize the complex web of intermolecular interactions responsible for the choice of packing arrangement. This is at the basis of the phenomenon of crystal polymorphism.[6–9] One way to tackle this problem is to computationally generate theoretical crystal structures, which often goes under the epithet of crystal structure prediction.[29–32] This is an important area of research, but it falls outside the scope of this article and will not be discussed.

A crystal deconstruction application of the atom–atom potential energy method to tackle a problem of conformational polymorphism is provided by ferrocene.[33] for which a disordered monoclinic phase is stable at room temperature and to 163.9 K. below which it forms an ordered triclinic phase. An orthorhombic phase can also be grown by seeding at low temperature with crystals of orthorhombic ruthenocene. At the crystal level, the three phases differ in the relative orientation of the molecules (see Fig. 6). which. in turn, possess different relative conformations of the cyclopentadienyl ligands. In terms of van der Waals energy, it was shown that the difference between the various phases is small (of the order of 1 kcal . mol^{-1}), and that the phase transition behavior can be understood as a need to alleviate interatomic repulsions as the temperature is decreased and the hydrogen atoms at the periphery are brought in to closer contact.[34] Crystal deconstruction also allows for the modeling of the transition between the orthorhombic and the monoclinic phases as the temperature is increased;[34] as it can be appreciated on comparing Figs. 6b and 6c, a relatively simple geared motion in the plane of the drawings can lead from one phase to the other.

CRYSTAL CONSTRUCTION WITH VAN DER WAALS INTERACTIONS

In van der Waals solids. the attractive forces acting between molecules. regarded as ensembles of atoms, are not particularly sensitive to molecular shape. rather they depend on the distance and fall off rapidly ($E \propto r^{-6}$). Repulsions are effective at very short distances and are dependent on the nature of the peripheral atoms. In this way, the bulk of the molecule provides attraction, while surface atoms determine recognition. optimum relative orientation, and interlocking of molecules in the solid state. In general, a given supramolecular arrangement in the solid state can be seen as the result of the minimization of short-range repulsions rather than the optimization of attractions. Therefore. it is important, when considering a van der Waals solid. to focus on the relationship between molecular shape and nature of the peripheral atoms.

An example is provided by the work of Hosseini and collaborators, who designed one-dimensional van der Waals networks by joining calix[4]arene derivatives, bearing two receptor cavities arranged in a divergent fashion. by means of neutral molecules employed as linear connectors.[35,36] The example in Fig. 7 shows the result of utilizing symmetrical calix[4]arenes obtained from the double fusion of two different calix[4]arenes by silicon atoms. The koilands so formed are joined together with hexadyine. which acts as a symmetrical connector.[''''] The resulting one-dimensional network, or koilate, is obtained by translating the assembling core defined by the inclusion connector into the cavity of the receptor. Recognition. self-assembly, and cohesion of the solid-state networks are based on van der Waals interactions.

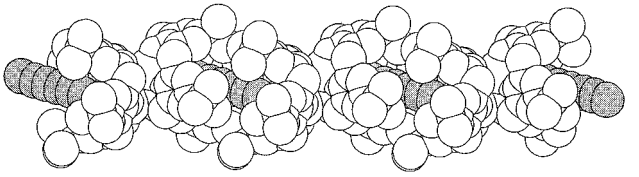

Fig. 7 Space-filling representation of the koilate (one-dimensional molecular array) formed between a symmetrical calix[4]-arene derivative and hexadyine as a connector.[''''] The H atoms were omitted for clarity.

CRYSTAL DECONSTRUCTION IN CRYSTALLINE SALTS

When dealing with molecular ions, the nature of the interactions changes considerably. The energies involved when ions are present are greater by at least an order of magnitude with respect to molecular neutral crystals. The dispersion energies are always attractive at long distances. while coulombic terms depend on the sign of the interaction. The evaluation of the crystal energetics. even on an empirical basis, becomes more difficult when large polyatomic anions or cations are involved. The packing of molecular ions has to fulfill the same requirements for optimization of next-neighbors interlocking and of pairwise interactions with the additional, not trivial, constraint of minimizing the sum of repulsive interactions

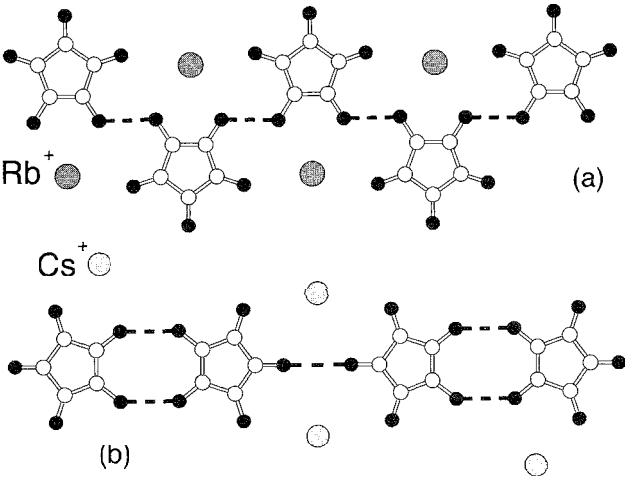

Fig. 8 Hydrogen croconate anions joined in chains (a) and ring dimers (b) in crystalline $RbHC_5O_5$ and $CsHC_5O_5$, respectively. (From Ref. [36].)

between like charges and maximizing the attraction between ions of opposite signs.

The crystals of $RbHC_5O_5$ and $CsHC_5O_5$ are good examples of the relationship between directional hydrogen-bonding interactions and ionic charges[37] (see Fig. 8). The structure of the rubidium salt contains chains of hydrogen croconate anions, while the cesium salt is characterized by the presence of ring dimers (Fig. 8b). An ab initio computational analysis provides the notion that the $^{(-)}O—H\cdots O^{(-)}$ hydrogen-bonding interactions between like ions are not sufficient to bind the ions together, as the stability is provided by attractive next-neighbor anion. . ·cation interactions, which largely overcompensate for the combined effect of next-neighbor anion . ·anion and cation. . ·cation repulsions. These observations lead to the recognition that $^{(-)}O—H\ldots O^{(-)}$ interactions are not energetically determinant in the cohesion of these salts, while they are responsible for the spatial organization of the anions. The $^{(-)}O—H\cdots O^{(-)}$ interactions contribute to cohesion by reducing interanion repulsions.

Another example is afforded by potassium croconate $K_2C_5O_5$, which was isolated and characterized as $K_2C_5O_5 \cdot 2H_2O$ by Dunitz[38] and subsequently by us.[39] The coordination around the potassium cation is depicted in Fig. 9a. The croconate dianions form columns. extending parallel to the c-axis. completely surrounded by cations and water molecules, with these latter acting as "pinchers" on the dianions (see Fig. 9b.c). The short interplanar separation (3.30 Å) is thus a result of the external interactions that "compress" the anions together.

The deconstruction of the potassium croconate crystal allows us to recognize the analogies with another member of the family of oxocarbon anions, rubidium rodizhonate $Rb_2C_6O_6$.[40] The crystals possess some remarkable

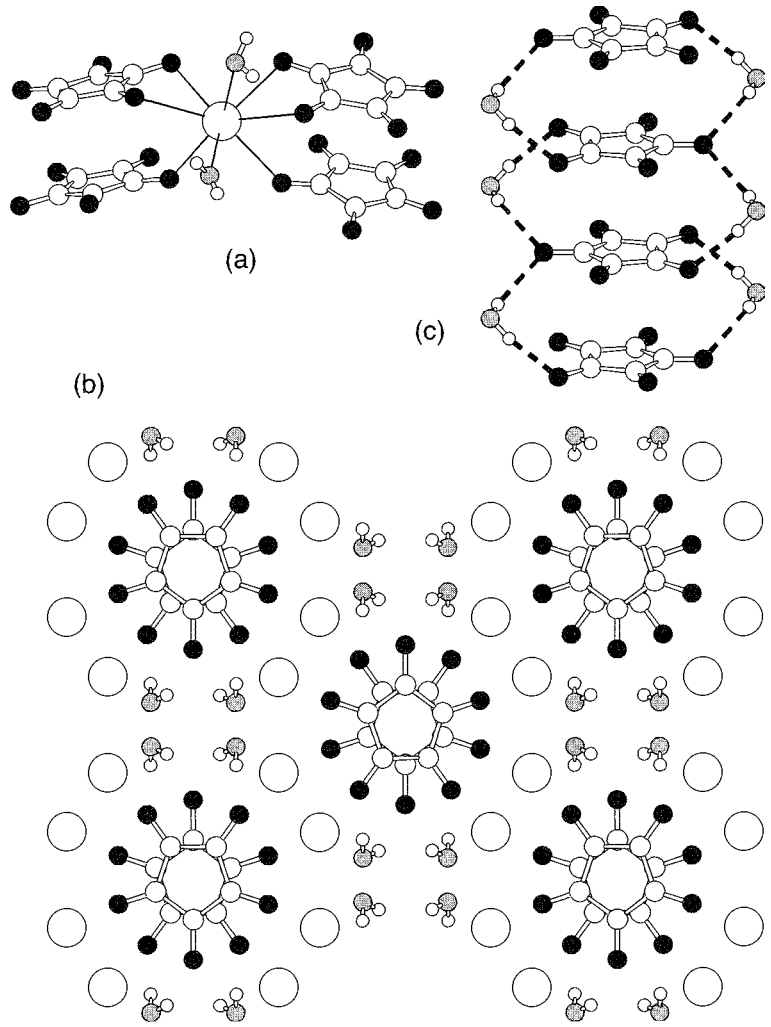

Fig. 9 Crystal deconstruction in $K_2C_5O_5 \cdot 2H_2O$: (a) the coordination of two water molecules and four croconate dianions around the K^+ cation in crystalline; (b) the dianions are stacked in columns surrounded by the cations and the water molecules (b); the latter act as ''pinchers'' along the columns (c). (From Refs. [37,38].)

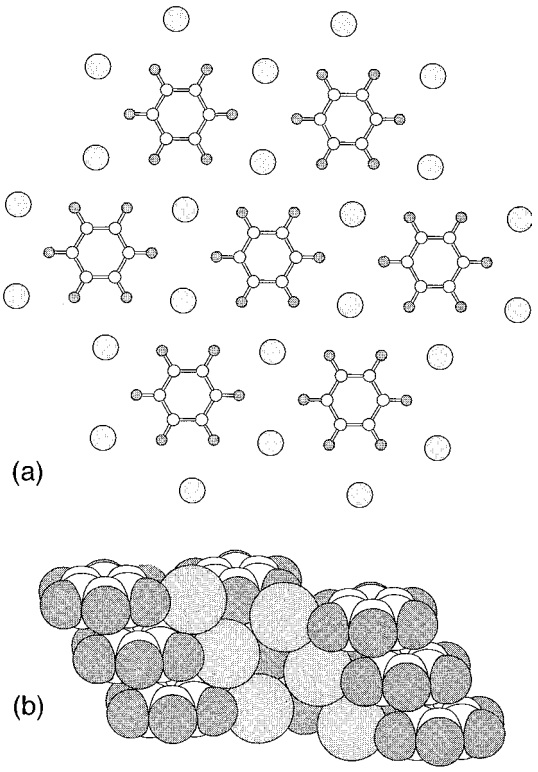

Fig. 10 (a) The pseudosixfold symmetry of $C_6O_6^{2-}$ dianions and Rb^+ cations in a layer of crystalline $Rb_2C_6O_6$; and (b) the stacking of layers. showing how the dianions are shifted and the Rb^+ ions are in close contact. forming cationic piles. (From Ref. [39].)

features: I) there are layers of rhodizonate dianions $C_6O_6^{2-}$ organized with pseudosixfold symmetry within the layer (see Fig. 10a), and the $C_6O_6^{2-}$ units lie flat on each other at an interplanar distance of 3.30 Å; and 2) the Rb^+ ions form cationic rows in between the rhodizonate units (see Fig. 10b).

CONCLUSION

The design of solids starting from molecular and ionic building blocks with predefined shapes and functions has become the forefront of molecular assembly and recognition studies. as well as of materials chemistry research. This is witnessed by the rapidly increasing number of publications that deal specifically with intermolecular interactions in molecular solids. A great contribution to these studies came from the development of structural databases, in particular, the CSD (Cambridge Structu e Database), and, to a smaller extent, the ICSD (Inorganic Crystallographic Structural Database),[41,42] which permitted statistical evaluation of the topology of noncovalent interactions on a large basis. The "quest for intermolecular interactions" afforded remarkable insight into ihe factors responsible for recognition and cohesion. Some cautionary words are. however. in order. It is argued that it is dangerous to focus exclusively on pairwise interactions. as one may forget that it is the overall balance of interactions. some acting at short range only, some acting at very long range, that accounts for cohesion in molecular crystals. At the same time, very weak interactions. falling in the fluctuations of the crystal structure energetics (due, for instance: to motion of atoms or atomic groups), may be useless in design strategies, because they are too feeble to control crystal construction. Only strong pairwise interactions (e.g., an O—H···O bond) may stand out of the noise and act as true packing directors. Because interactions of this type are often already present in solution; nucleation and crystal growth occur around preformed long-living aggregates. On the other hand. crystallization of structurally nonrigid molecules often requires complicated compromises between intra-and intermolecular interactions. The dynamic behavior of molecules or ions in the solid state (from libration, to large amplitude and reorientational motions, and fluxionality) will also be controlled by intermolecular interactions and by the way these will convolute with the internal energy barriers to structural rearrangement.[7,9] Insights into the relationship between size. shape, and charge of the component molecules and the molecular organization in the crystal can be obtained by decoding observed crystal packings by means of empirical packing potential energy calculations and computer graphics.

ACKNOWLEDGMENTS

We acknowledge useful discussions with a number of scientists through the years: including A. Gavezzotti, H.-B. Bürgi, and J. Dunitz. This research work was possible thanks to financial support through the years from MIUR and CNR and from the universities of Bologna and Sassari.

Crystal Engineering with Hydrogen Bonds

Dario Braga
Università degli Studi di Bologna, Bologna, Italy

Fabrizia Grepioni
Università di Sassari, Sassari, Italy

INTRODUCTION

Molecular crystal engineering is the bottom-up construction of functional *materials, starting from molecular or ionic building blocks assembled by means of noncovalent interactions. The hydrogen bond (MB)is the interaction of choice, because it* combines *strength and directionality. These properties guarantee* materials *cohesion and stability as* well *as reproducibility of crystal-directed syntheses.*

THE INTERACTION OF CHOICE IN MOLECULAR CRYSTAL ENGINEERING—THE HYDROGEN BOND

Molecular *crystal engineering can be viewed as the area of supramolecular* chemistry[1,2] *devoted to the controlled design of* crystalline materials.[3] *As noncovalent interactions are responsible for the existence and functioning of* supermolecules, *intermolecular and interionic interactions are responsible for crystal cohesion and solid-state properties. The* HB *is the interaction of choice in molecular crystal engineering, because it combines strength and* directionality.[4,5] *Strength* is *a synonym of cohesion and stability. while directionality implies topological control and selectivity, which guarantee reproducibility to the* supramolecular *assembly process. These properties are quintessential for an interaction to be useful in crystal engineering. A* nondirectional, i.e., *nonselective, intermolecular interaction wili not possess specific topological properties, and its performance within different structural environments will not always be predictable.*

Strength *deserves a more subtle comment, because it brings about the definition of the hydrogen bond. What is a* hydrogen *bond? The answer to this question is controversial and depends on the objective of the investigator. For* the *purpose of crystal engineering, however, Etter's elaboration*[6] *of the* Linus Pauling *definition of a* bond[7] is *probably the* most *appropriate:*

> A hydrogen bond is an interaction that directs the association of a covalently bound hydrogen atom with one or more other atoms, groups of atoms. or molecules into an aggregate structure that is sufficiently stable to make it convenient for the chemist to consider it as an independent chemical species.

The focus is on *the concept of "directed"* association *and of stability. The existence of an* intermolecular *bond is* conceptually *associated with the energetic stability of the aggregate.*

For most purposes, *however. the HB can be described as a stable interaction of essentially electrostatic nature between an X-H donor and an* Y *acceptor, being X- and* Y-electronegative *atoms or electron-rich* groups.[8] *The HB interaction is* generally *stronger than the strongest van der Waals* interaction. *The* H···Y *and* X···Y *separations are shorter than van der Waals contact distances, and* X—H···Y *angles that tend to linearity are* considered *diagnostic of the presence of strong* HBs.[9] The *same topological rules are followed by hydrogen-bonding interactions between ions,* even *though the energetic scale is* different.[10] In *the case of* HB *interactions between neutral molecules. the* length/strength *analogy is believed to hold.* i.e., *the shorter the acceptor–donor distance.* the *stronger the bond. This relationship. however, fails to apply satisfactorily in the case of weak and very weak HB interactions,"" where the electrostatic* component *is active at a distance larger than van der Waals contacts: and in the case of HB interactions between ions. where the* dominant *energetic terms come from* coulombic *attractions and* repulsions.[12] *This latter aspect. in particular, is often overlooked.*

In terms of energy, HB interactions span a large interval. ranging from tiny energies (ca. *10* kJ/mol *in the case of* C—H···O, *vide infra) to large values* when *the acceptor is an anion (ca. 120–130* kJ/mol *in the case of* O—H···$O^{(-)}$). *Negatively charge-assisted."" positively charge-assisted."" as well as* resonance-assisted[15] HBs *were identified. Metal atoms* can *also be directly involved in* HB formation.[16]

A *discussion of the energetics of the HB is beyond the scope of this article. What* is *relevant for crystal engineering is the* notion *that the strongest of weak hydrogen bonds are comparable to the weakest of strong hydrogen*

DOI: 10.1081/E-ESMC 120012752

bonds (−20 kJ/mol) and. in terms of crystal structure directing effects. there seems to be little difference between these two categories. As in conventional covalent bonding, there is a continuum of energy, and the distinction between strong and weak HBs is, often, only conventional. It is essential. however, to know the exact nature of the interactions one is trying to control. If discrimination needs to be made. this is between noncovalent interactions in ionic and neutral crystalline materials because of the differencesin physical properties (solubility, melting point, behavior under mechanical stress. etc.) arising from the presence of ions or neutral molecules.

In general. strong donor/acceptor groups such as -COOH and -OH systems. as well as primary -$CONH_2$ and secondary -CONHR amido groups, form essentially the same type of HB interactions, whether as part of organic molecules or of metal coordinated ligands. This is not surprising. as HBs formed by such strong donor and acceptor groups are at least one order of magnitude stronger than most noncovalent interactions and are most often already present in solution. For the purposes of crystal construction, the utilization of a single very strong interaction; as the O—H···$O^{(-)}$ mentioned above, is not necessarily the best or only way to provide cohesion. The "Gulliver effect" can also be exploited: the collective strength of weaker bonds may be equivalent. in terms of cohesion. to the strength of a single bond, although the directionality component may be lost or greatly diminished with respect to that of single strong bonds, e.g., O—H···O or N—H···O. etc.

HYDROGEN BONDING AND CRYSTAL ENGINEERING INVOLVING NEUTRAL MOLECULES

Some examples of utilization of HB in crystal engineering strategies are presented in the following. The reader is referred to the entries on crystal engineering and to those on the hydrogen bond for more details. The selection of examples is clearly arbitrary and cannot do justice to the number of scientific groups involved in this booming field of research."""

An early entry into the crystal engineering of organic crystals using strong O—H···O bonds is provided by the work of Etter.[18] The molecuie 1,3-cyclohexanedione, [$C_6H_8O_2$], capable of forming O—H···O HB interactions, can be crystallized from THF in linear chains (Fig. 1a) or in hexarneric units (Fig. 1b) when the solvent is benzene. which acts as a templating unit through the self-assembly of the dione molecules. We were later able to mimic such behavior by replacing benzene with his-benzene chromium (vide infra).[19]

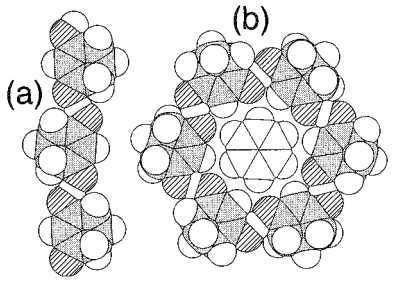

Fig. 1 Etter's example of crystal engineering with O—H···O hydrogen bonds: (a) a space-filling representation of the chain of O—H···O bonded 1.3-cyclohexanedione molecules, crystallized from THF; and (b) the cyclamer formed by 1.3-cyclohexanedione with benzene—note how the benzene molecule is surrounded by six neutral molecules linked by O—H···O interactions.

Hanessian utilized N—H···O interactions between *trans*-1,2-diaminocyclohexane and 1,2-diols to construct supramolecular helicate structures that, depending on the chirality of the diols. can be left-handed or right-handed.[20] An example is given in Fig. 2. which shows the left-handed helical structure formed by the self-assembly of (R,R)-1,2-diaminocyclohexane with (R,R)-2,3-butanediol via N—H···O hydrogen bonds.

Crystal engineering endeavors based on weak HBs are less frequent for the reasons given above. One may wonder if weak HBs are "good enough" to direct molecular recognition and crystal packing. While there is consensus on the relevance of C—H···O bonds in crystals, C—H···N bonds have not been investigated to the same extent. Boese showed that C—H···N bonds can be used likewise for producing predictable patterns. For instance. C—H···N bonds can be used between sp^2 CH groups and nitrogen atoms in pyrazines and methyl-substituted pyrazines[21] to form layered structures (see Fig. 3): the methyl groups are involved in sp^3 C—H···π interactions and govern the interlayer packing.

Combining coordination bonds with hydrogen bonds is another attractive crystal engineering perspective. Brammer and collaborators elaborated the idea of incorporating transition metals into the design of hydrogen-bonded crystalline solids.[22–24] The metal centers can be used to provide a directing influence upon the hydrogen-bonded links between neighboring building blocks (Fig. 4a)[22] or are appended as a potentially functional group to the parent hydrogen-bonded organic network, as in π-bonded organometallic systems (Fig. 4b).[23] Coordination of halide ligands to transition metals leads to good HB-acceptor capability. New supramolecular hydrogen-bonding motifs, such as N—H···X_3M and N—H···X_2M, that have no precedents in organic crystal engineering were used to construct hydrogen-bonded assemblies using ammonium salts of perhalometallate ions.[24]

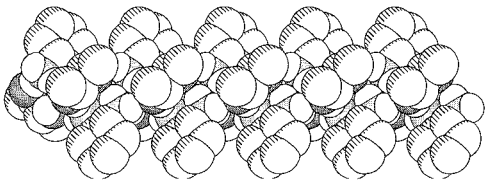

Fig. 2 Space-filling representation of the left-handed helical structure formed by self-assembly of (R,R)-1,2-diaminocyclohexane with (R,R)-2,3-butanediol via N—H···O hydrogen bonds.[20] For clarity. H_{CH} atoms are not shown.

Aakeröy and collaborators[25,26] elaborated a strategy based on the assembly of inorganiclorganic architectures through a combination of copper(I) coordination polymers and self-complementary hydrogen bonds. The design strategy yields lamellar inorganiclorganic hybrid materials (see Fig. 5). Infinite copper(I) halide coordination polymers provide robust one-dimensional building blocks, and these are subsequently linked into two-dimensional layers by attaching one pyridine ligand to each metal ion. The ligand, which carries a self-complementary hydrogen-bond moiety (e.g., carboxylic acid. carboxamide, oxime). provides a noncovalent directional tool for connecting neighboring coordination polymers into an extended two-dimensional network.

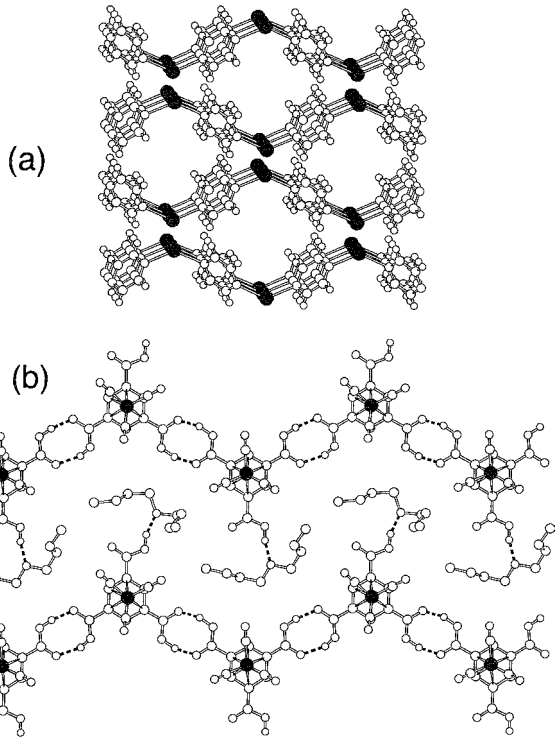

Fig. 4 Examples of hydrogen bonds combined with coordination chemistry: (a) stacking of adjacent layers (anions omitted) in crystalline $Ag(O_2CCF_3)L$ (*L*=pyrazine); and (b) zigzag tapes of $[Cr(CO)_3(\eta^6\text{-TMA})]$ with Bu_2O hydrogen bonded in channels.

HYDROGEN-BONDING INTERACTIONS BETWEEN IONS

A practical instrument in devising new solids is afforded by the possibility of combining ionic charges and HB interactions. Because the HB has a fundamentally electrostatic nature, the presence of ionic charges on the building blocks can be exploited to strengthen the interaction. Charge assistance to HB is the enhancement of the polarity of donor and acceptor systems by utilizing cationic

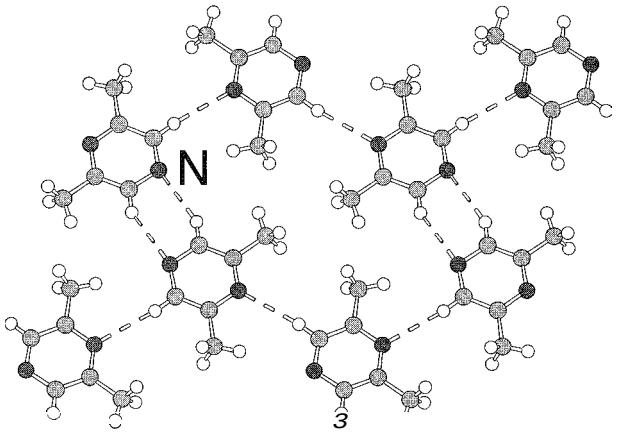

Fig. 3 The use of C—H N hydrogen bonds allows for formation of a layered structure in 2,6-dimethylpyrazine The methyl groups are involved ın sp^3 C—H π ınteractıons (not shonn) and govern the interlayer packing

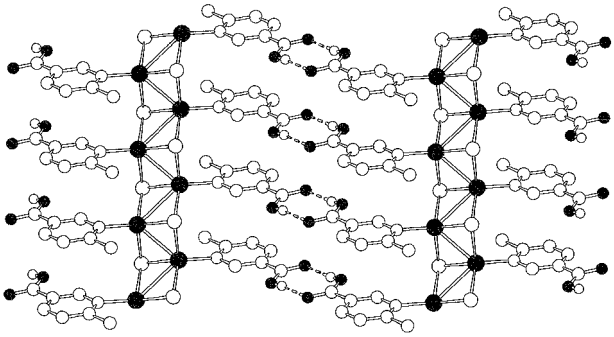

Fig. 5 Pyridine ligands carrying a self-complementary hydrogen-bond moiety (carboxylic acid. in this example) provide a noncovalent directional tool for connecting infinite copper(I) chloride coordination polymers into an extended two-dimensional network.

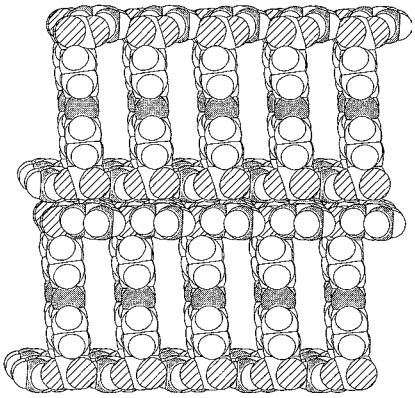

Fig. 6 An example of guanidinium–sulfonate superstructures. The fundamental interaction responsible for robustness and flexibility is the charge-assisted $^{(+)}N—H\cdots O^{(-)}$ hydrogen bonding between the guanidinium cations and the sulfonate anions, which can be varied in shape and length.

donors and anionic acceptors instead of neutral systems, i.e., $X—H^{(+)}\cdots Y^{(-)}$ rather than $X—H\cdots Y$. The favorable location of ionic charges enhances proton acidity and acceptor basicity in the solid state. Hydrogen-bonding interactions between ions need to occupy a special place in the library of noncovalent interactions of interest to supramolecular chemists and crystal engineers. because they optimally convolute the strength of the coulombic field generated by the ions with the high level of directionality afforded by the $X—H\cdots Y$ interaction.

Interionic hydrogen-bonding interactions are easily accessed via homogeneous or heterogeneous acid–base reactions. By choosing the number of potential donor/acceptor groups on the building block and the acid–base stoichiometric ratio, one can control the formation of homo- or heteroionic interactions. For example. partially deprotonated polyprotic acids possess "loaded" and "unloaded" hydrogen-bonding donor groups. i.e., COOH and $COO^{(-)}$, that can take part in the formation of heteroionic bridges with competing donors. This fairly comrnon situation arises when the base participates in the HB interactions. This is the case, for instance, of nitrogen-containing bases (ainines. amidines, etc.) that are protonated upon reaction with acid molecules. e.g., $RCOOH+NR_3\rightarrow RCOO^{(-)}\cdots{}^{(+)}HNR_3$, leading to anion–cation pairing in the solid state. and hence, to formation of $^{(+)}N—H\cdots O^{(-)}$ charge-assisted interactions.[27]

With an analogous approach, "soft" molecular host networks were developed by Ward et al. They combine two relatively simple structural units: layers of guanidinium cations spaced by pillars of sulfonate anions (see Fig. 6).[28] The $^{(+)}N—H\cdots O^{(-)}$ interactions between guanidinium cations and sulfonate anions render the superstructures robust and adaptable to the guest requirements, while the porosity can be tuned by changing the length of the pillars. These properties were exploited in several applications, such as shape-selective separation of molecular isomers.

A less common situation is observed when the counterion cannot form HB interactions with the acid moiety. as in the case of the reaction with inorganic or organometallic hydroxides.[29]

Partially deprotonated polyprotic acids. possessing COOH and $COO^{(-)}$ HB donor groups. can thus take part in the formation of homoionic bridges with themselves.

This strategy was applied, rather unawarely, when 1,3-cyclohexanedione, $[C_6H_8O_2]$ was reacted with bis-benzene chromium.[19] The reaction afforded the pseudocyclamer formed by two $[Cr^I(C_6H_6)_2][(C_6H_8O_2)_3(C_6H_7O_2)]$ units held together by $O—H\cdots O$ and $C—H\cdots O$ interactions (Fig. 7). The product differs substantially from Etter's compound mentioned above: the reaction between the acidic molecule and $[Cr(C_6H_6)_2]$ leads to the oxidation product $[Cr^I(\eta^6\text{-}C_6H_6)_2]^+$ and to partial deprotonation of the dione.

A recent example of engineering a supramolecular arrangement with target magnetic properties is provided by crystalline $[Cr^I(\eta^6\text{-}C_6H_6)_2][HC_4O_4]$, obtained by reacting squaric acid (3,4-dihydroxy-3-cyclobutene-1,2-dione, $H_2C_4O_4$) with $[Cr(\eta^6\text{-}C_6H_6)_2]$.[30] The intercalation of the hydrogen squarate chains between the sandwich cations leads to the formation of one-dimensional $D^+A^-D^+A^-$ structures comprised of alternating cation donors (D) and anion acceptors (A). The presence of a charge-transfer transition was detected in the reflectance spectrum, while magnetic measurements showed that the weak, but appreciable, antifersomagnetic interaction between the S=1/2 of the $[Cr^I(\eta^6\text{-}C_6H_6)_2]^+$ cations could be attributed to the anion–cation π-stacking interaction.

Orpen and collaborators developed the use of salts of perhalometallate complexes $[MX_n]^{m-}$(X=Cl, Br, etc.:

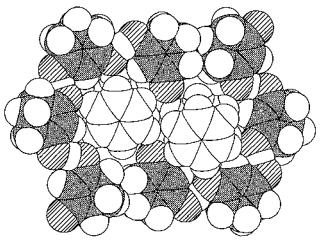

Fig. 7 An organometallic mimic of Etter's cyclamer (see Fig. 1b): space-filling representation of the pseudocyclamer formed by two $[Cr^I(C_6H_6)_2][(C_6H_8O_2)_3(C_6H_7O_2)]$.

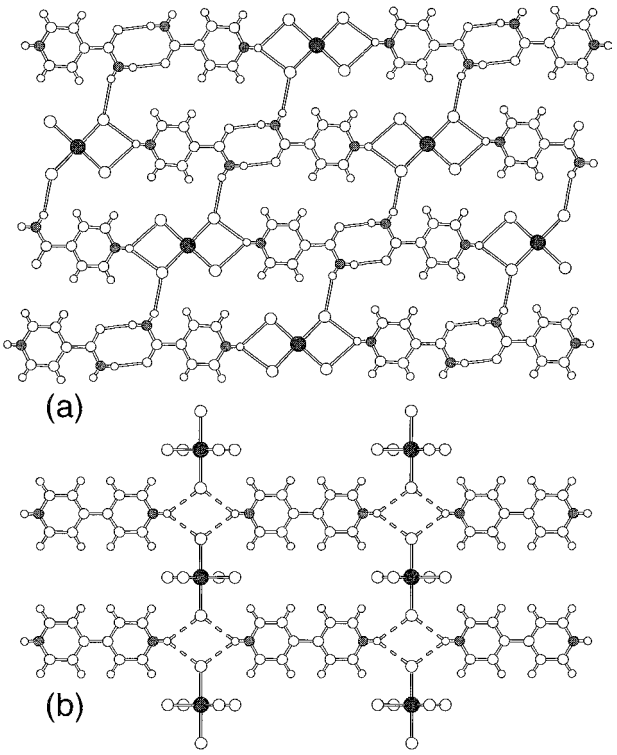

Fig. 8 Hydrogen-bonding networks in salts of perhalometallate complexes $[MX_n]^{m-}$ (X=Cl, Br. etc.; M=Pt, Zn, Mn. Pb. etc.) with organic cations possessing N—H hydrogen-bond donor functionality.

M=Pt, Zn, Mn, Pb, etc.) with organic cations possessing N—H HB-donor functionality (Fig. 8).[31,32] These systems are modular and robust and offer the opportunity to exploit the shape, charge, and functional groups of the ions in order to control the crystal structures they form and. in particular. the HB networks they contain.

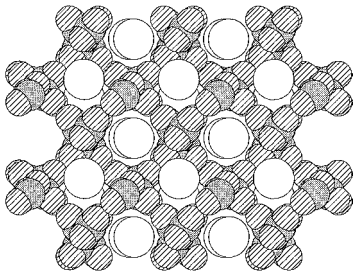

Fig. 9 Space-filling representation of the L-tartaric acid framework in crystalline $[Co^{III}(\eta^5\text{-}C_5H_5)_2]$[L-hydrogentartrate], with the $[Co^{III}(\eta^5\text{-}C_5H_5)_2]^+$ cations (represented as large spheres) occupying the channels.

Chiral crystals based on hydrogen L-malate anions were assembled via $^{(-)}O—H\cdots O^{(-)}$ bridges in anionic layers.[33] Because the two-dimensional network is highly reproducible, it can be transferred from crystal to crystal, inducing noncentrosymmetry, a target on the route to materials for a second-harmonic generation. We used analogous strategy to self-assemble chiral frameworks around organometallic cations (Fig. 9).[29]

Lehn et al. used interionic hydrogen bridges to direct the recognition and self-aggregation of metal complexes carrying terpyridine-derived ligands joined by intercation $^{(+)}N—H\cdots N^{(+)}$ bridges.'''' The solid-state arrangement of the $Co(terpy)_2^{2+}$ complex is highly dependent on the choice of counterion: in the $[PF_6]^-$ salt, a two-dimensional infinite network is formed via pairs of N—H···N interactions. while in the $[BF_4]^-$ salt. a broken network is observed (Fig. 10). This provides an example of competition between formation of N—H···N interactions and optimization of the coulombic interactions that. in turn. depend on the size of the ions.

The possibility of switching between neutral hydrogen-bonded systems and charged systems is at the basis of the reversible gas-trap system obtained on reacting the cobalticinium zwitterion $[Co^{III}(\eta^5\text{-}C_5H_4COOH)(\eta^5\text{-}C_5H_4COO)]$ with acid and base vapors (HCl, CF_3COOH, HBF_4, and NH_3, NH_2Me, NMe_3).[35,36] The salts resulting from the heterogeneous reaction contain the organometallic moiety in its fully protonated form $[Co^{III}(\eta^5\text{-}C_5H_4COOH)_2]^+$ (in the reaction with acids) or in its fully deprotonated form $[Co^{III}(\eta^5\text{-}C_5H_4COO)_2]^-$ (in the reaction with bases), as shown in Fig. 11. The two types

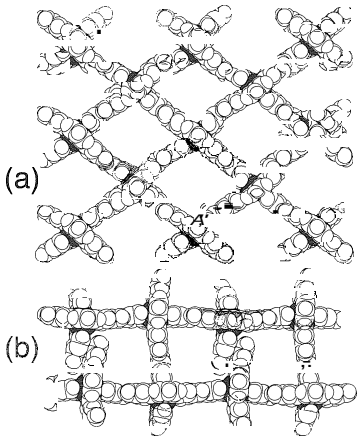

Fig. 10 A two-dimensional infinite netuork is formed via pairs of $^{(+)}N—H\cdots N^{(+)}$ interactions in the $[PF_6]^-$ salt of the cobalt complex $Co(terpy)_2^{2+}$ (a), while a quarter of the potential hydrogen-bond interactions are not formed. leading to a broken network in the case of the $[BF_4]^-$ salt (b).

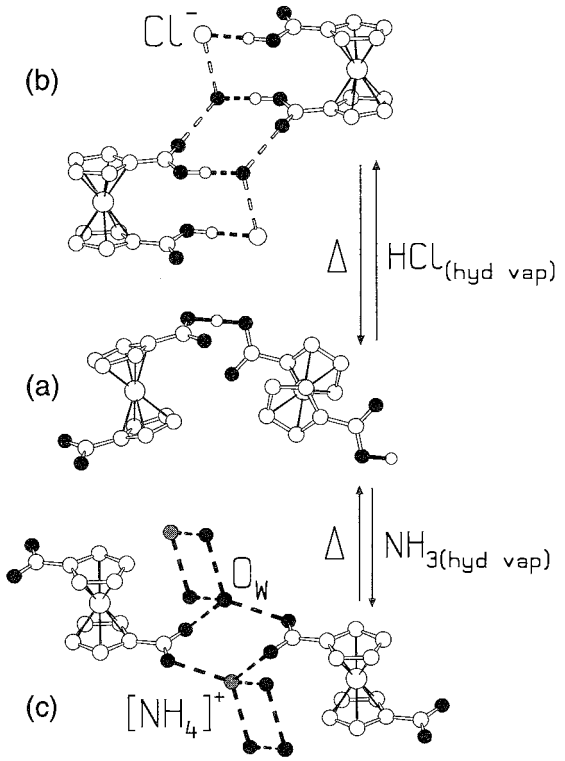

Fig. 11 The zwitterion $[Co^{III}(\eta^5\text{-}C_5H_4COOH)(\eta^5\text{-}C_5H_4COO)]$ (a) reacts reversibly with HCl (b) and NH_3 (c) hydrated vapors to give the corresponding salts.

of reactions imply the interconversion between neutral O—H . ·O hydrogen-bonding interactions and $^{(+)}$O—H- . . .X and $^{(-)}$O· . ·H—N$^{(+)}$ interactions. respectively.

CONCLUSION

Molecular crystal engineering is supramolecular solid-state chemistry. Crystal engineers concentrate their efforts on developing synthetic strategies aimed at the preparation of periodic supermolecules. Engineering implies function-oriented design of the superstructure. selection of the building blocks (on the basis of their chemical and physical stabilities and of their extramolecular bonding capacity), their assembly and characterization. to end with evaluation of the properties of the resulting supramolecular aggregate. In order to be satisfactory, a supramolecular/crystal engineering synthetic strategy should be reproducible. Hence. the utilization of interactions that are strong and, at the same time. highly directional, such as hydrogen bonding; are favored for the assembly of molecular components. These interactions are transferable from crystal to crystal and retain the same assembly-directing capacity, even on changing the nature of the forces holding the building blocks together in the crystal. For these reasons, the hydrogen bond is the interaction of choice in the engineering of molecular and ionic crystals constructed from neutral molecules or molecular ions.

Crystal Growth Mechanisms

Nicholas Blagden
Bradford University, Bradford, United Kingdom

INTRODUCTION

Crystal growth in a synthetic or suprarnolecular chemistry context is usually from solution and is undertaken to purify a material or is used as a synthesis step in a crystal engineering strategy. The process of crystal growth may have a great effect on the final form and cornposition of the targeted crystalline material. An objective of this contribution is to contrast the classical descriptions and the molecular recognition description of how molecules self-assemble into crystals from solution in order to describe the core mechanism and processes of crystal growth. In the classical interpretation. the vehicle for this process is the growth unit: for suprarnolecular chemists. the comparable vehicle is the synthon. Both perspectives rely on a hierarchical description of overall assembly directed by the Sunctionality inherent to the crystallizing species. This process naturally forms the basis for understanding how the growth units assemble (crystal graph. for crystal growth or motif, for crystal engineer). Such an understanding of the molecular assembly at the crystallographic level is widely used to describe the functionality and stereochemistry inherent in the bulk and surface of the crystal, and this information can be utilized to direct crystal growth.

GROWTH THEORIES

Two aspects of crystal growth".'' will be covered: One aspect pertains to surface processes and the second to transport processes at the growing crystal face. However. it is first necessary to describe the nature and mechanism of a crystal face capturing growth units from solution. According to Hartman and Perdock,[3] for a three-dimensional crystal face. the capture of growth units can be classified according to how many contacts form between the adsorbed growth unit and the crystal surface. If three orientations of surface contacts are involved, then incorporation is at a kinked face: if two orientations of surface contacts are involved. then incorporation is at a stepped face: and if one surface contact is involved. then incorporation is at a flat face (Fig. 1). According to Temkin.[4] (for any of the above incorporation steps). the energy change occurring when a solvated flat surface is roughened by the transfer of a solvated growth block from one layer of the surface to form a new layer can be expressed as the overall calculated energy of dissolution. then adsorption, and is given by Eq. 1:

$$\Delta E = 4\Phi_{sf} - 2\Phi_{ss} - 2\Phi_{ff} \quad (1)$$

where Φ is a binding energy of a growth unit, and the subscripts indicate the type of binding interaction: *ss* for solid-to-solid binding. *ff* for fluid-to-fluid binding, and sf for solid-to-fluid binding.

According to Jackson.[5] which growth mechanism a crystallographic unique face obeys depends on the magnitude of the surface roughing factor, α. which is a function of $\Delta E/kT$. Human et al.[6] modified the Jackson α-factor function to include paramaters that account for the supersaturation contribution and the contribution arising from the binding energy of the crystallographic plane and crystal lattice under consideration. E_{ss}^{face} and $E_{ss}^{crystal}$. respectively, see Eq. 2:

$$\alpha = E_{ss}^{face}/E_{ss}^{crystal}[\Delta E/kT - \ln\Omega] \quad (2)$$

where Ω=solubility relative to the density of the crystallizing solute.

In this scheme (the respective growth processes are illustrated in Fig. 2), as supersaturation decreases, a region occurs where $\alpha<2$–3. This range is where the growth process is without a layer mechanism and grows without any crystallographically defined orientation. If $3>\alpha>5$, then the system moves to growth dominated by nucleation with subsequent layer growth. When $\alpha>6$. then sequential layer growth occurs. and this is when the supersaturation reaches the metastable zone on the solubility curve.[7]

In general. at low supersaturation, the growth is via flat faces according to the solubility modified α-factor. In addition. the general analysis of α indicates that if ΔE is a kinked, stepped. or flat face, the energy change decreases according to the following inequality:

$$kinked < stepped < flat$$

and thus indicates that a flat face is the energetically most unfavorable. So. growth via a flat face requires an energetically cheap mechanism for the growth process.

Crystal growth theories aim to describe how an energetically unfavorable flat faces grows and how a set

Encyclopedia of Supramolecular Chemistry

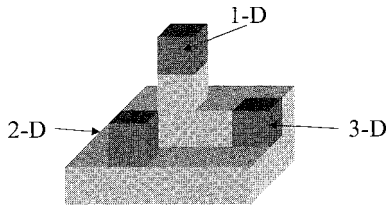

Fig. I The classification of surface contacts according to Hartman and Perdock: 1-D—flat. one contact: 2-D—step, two contacts: 3-D—kink. three contacts. (View *this* art *in* color *at www.dekker.com.*)

of possible flat faces may grow relative to each other. It was Cabrerra, Burton, and Frank[8] who first proposed that the energetically cheap process that enables a flat surface to grow is mediated by the presence of the screw dislocation lattice defect. In this model of how a lattice surface grows. the growth rate for a flat surface is described by a complex product of the flux of growth units entering kink sites: the step velocity (v_{step}); the density of kink sites (ρ_{step}); and the height of the step (h_{step}). The theoretical expression for the rate of a crystal surface growing (G_{sdl}) is described by an involved set of paraineters for a flat surface. using screw dislocation lattice defects. but can be simply put according to Eq. 3.

$$G_{sdl} = v_{step}^{x} h_{step}^{y} \rho_{step}^{z} \tag{3}$$

The complexity of each variable arises as the flux of growth units entering a kink site is determined by a function describing the diffusion of growth units to the kink sites. The density of steps is related to the spiral curvature. which is a function of supersaturation: the height of the step depends on the initial number of defects in the nucleating crystal. The exact form of Eq. 3 can be found in the literature.[7–9]

For moderate supersaturation, the mechanism of growth is described by a site nucleation process. followed by growth from this nucleation center.[10,12] In this process. the growth rate is determined by a complex product of nucleation rate N_s, step height H_s, and step velocity V_s. Again. the theoretical expression for the rate of a crystal surface growth (G_{ns}) is described by an involved set of parameters for nucleation and spread mechanism but can be simply put according to Eq. 4.

$$G_{ns} = N_s H_s V_s \tag{4}$$

The nucleation rate N_s is determined by a function that relates the surface energetics of the nucleation process and the supersaturation. The step height H_s describes the number of growth sites available from the nucleation center. and it is determined by the type of growth site, which is also a function of supersaturation. Step velocity V_s is determined by a function that describes the rate of the diffusion of growth units over the surface from the nucleation center.

At high supersaturation, a surface is deemed to contain a large number of kinks and steps. The surface diffusion step that describes how a growth unit finds a growth site depends on supersaturation only. In this situation. it is assumed that all growth units find a growth site. and under this mechanism, the growth rate takes on a simple form.[1,2] as shown in Eq. 5.

$$G_c = K\sigma \tag{5}$$

To describe the bulk growth of crystals in solution where the solvent is in excess, the growth rate G is described by two contributions. These are the mass transport to the particle surface and the reaction or integration step, the process whereby incoming growth units incorporate into the crystal surface. Again. the quantities involved are complex, and the details are to be found elsewhere.'''' Shown in Eq. 6 is the bulk growth rate expression. G, derived using first-order kinetics:

$$G = \frac{k_I k_d}{k_I + k_d}\sigma \tag{6}$$

where σ is the supersaturation and represents the difference between the concentration in solution: k, and k_d represent the rates of incorporation and diffusion. respectively. at the incorporating interface. See Fig. 3 for an overall schematic representation of the mass transport

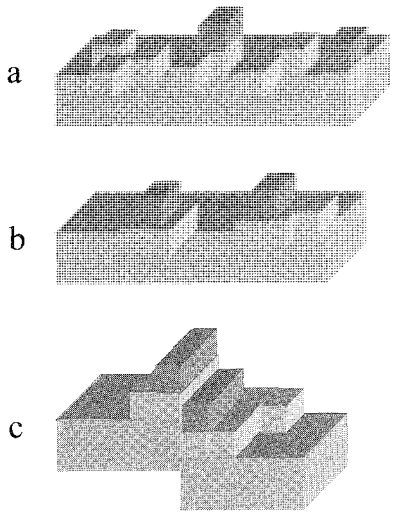

Fig. *2* The classification of the crystal growth process according to Jackson α-factor: (a) rough growth; (b) island growth (nucleation and spread): and (c) spiral growth. (*View this* nrt in color *at www.dekker.com.*)

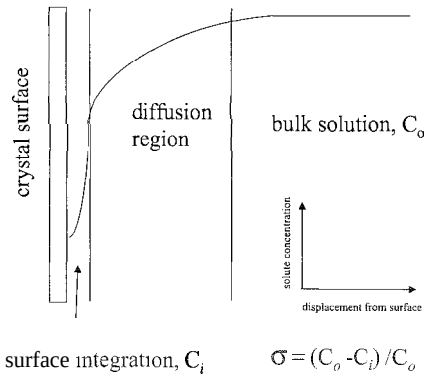

Fig. 3 The diffusion model of crystal growth. (*View this art in color at www.dekker.com.*)

process. Over the range of supersaturation and *differing* k_I and k_d, *three regimes of growth are usually observed. When* $k_I < k_d$, *then the integration step dominates growth: if* $k_d < k_I$, *then the diffusion step* dominates *the growth; and* when $k_d = k_I$, *then the growth process is a cornbination of both processes.*

In summary. whichever *mechanism appropriately describes the mechanism of crystal growth from solution. crystal growth is the balance between adsorption and desorption processes* at *the solid–liquid interface.* Conse*quentiy. temperature,* supersaturation, *surface process, diffusion process. and the energy transfer associated with incorporation* contribute *to the description of the overall crystal growth process.*

CRYSTAL GROWTH AND CRYSTAL HABIT

It is the overall relative growth rates of crystal faces described by the internai structure of the crystalline inaterial under consideration that *determine the observed* equilibrium *morphology of crystal.* referred *to as* habit.[12,13] Gibbs *and* Wulf[14] *described the attainment of an equilibrium* form *acco ding to surface free-energy sums being* minimized, *later relating* the *dominance of a face to the distance a face* was *from* a *growth center. according to the relative surface-energy* contribution *of each possible face. An* implication is *that the relative growth rate of faces defines the final shape of* the *crystal. As flat faces are the slowest growing faces. then the habit is defined by the relative gron-th rate of these flat faces (see* Fig. *4). In addition. if spiral growth conditions hold. the enerpetics of the process can be written* in terms *of a sequential lattice layer concept of face formation. With these two criteria, the habit of a crystal* is *defined by a set of expressed faces based upon relating face growth to* the *individual surface energy of each plane in* the *set of crystallographic planes defining the crystal. In order to do this, two* assumptions *are made, which are reviewed in the* literature:[15,16]

1. *Crystals* grow *by the addition of complete* layers *of* thickness d_{hkl} *that* have *the same crystal structure* as *the bulk, as* given *by the crystal structure. taking* into *account* systematic *absences.*
2. *The energy* released *per* mole *of layer—the so-called attachment energy.* E_{att}, is *directly proportional to the growth rate of the face.*

The introduction *and* use *of these* assumptions *are often attributed to the pioneering* work *of* Hartman *and Perdok in the* 1950s.[9] *In* making *these assumptions,* they *extended* the *treatment of crystal* morphology *described by* Gibbs *and* Wulf. *In this system of analysis of expressed faces. the faces* that *bound a crystal will be those with the* more *positive* E_{att} *consistent with the point group* symmetry. *Additional assumptions are made* that *relate to fluid–fluid contributions and fluid–solid contributions. These are assumed to be isotropic interactions. in that they are nonface specific,* and *that the anisotropic contribution* from *the solid–solid interaction* is *the critical* quantity *describing* E_{att}. *For this to be* valid, *the assumption* is *made that there is no differentiation between bulk and interface interactions.* In *conclusion, of the factors that affectcrystal habit, the morphology is dominated by the slowest growing faces, with the exact habit described by the relative growth rates of all flat faces. As we will see. modern theories* attempt *to account for the process* at *a molecular level.*

HABIT MODELING THEORY

Various approaches exist for predicting crystal habit. The basic concepts of those commonly *used will be described.*

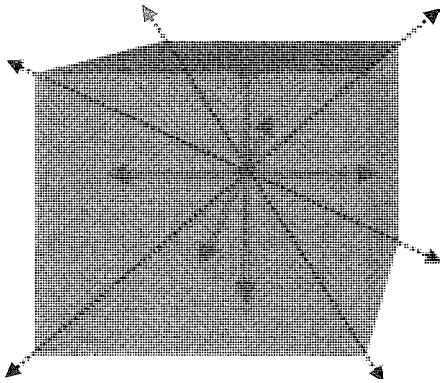

Fig. 4 The relationship between habit and the relative growth rates of faces: the faces are defined by the weakest interactions and slowest growth: and the edge defined by the strongest interactions and the fastest growth. (*View this urt in color at www.dekker.com.*)

The methods. as described. are not able to accommodate modifications to deal with solvent or impurity effects. How these effects might be included in the model will be discussed later. The following are three commonly used approaches:

1. The Donnay Harker[17] approach — The attachment energy is assumed to be inversely proportional to the interplanar spacing. Thus, the relative growth rates of faces in a series can be assessed purely on the basis of their structures.
2. The Hartman and Perdok[9] approach — An examination of the crystal structure is undertaken. in order to identify molecular chains within the crystal structure (referred to as the crystal graph). For each molecular chain identified, the intermolecular interactions within the molecular chains are classified. The weakest intermolecular contacts within these chains are identified and are taken to be the molecular contacts that determine the growth rate of that particular chain. These points are then used to identify sets in the crystallographic plane that describe the crystal (the crystal net) and are taken as the flat growth face that defines the habit. It is from this work chat the importance of attachment energy in describing rate of growth of a specific crystal face in low supersaturation was made.
3. The attachment energy approach—Bennema[18] and coworkers initially, and more recently Docherty and Roberts (HABIT code)[19] and Berkovitch-Yellin,[20] utilized the attachment energy as derived from differences between the lattice energy (the potential energy summation derived from a central inolecule to all other molecules in the lattice) and the slice energy. The slice energy is defined as the potential energy summation from the central molecule along the direction of a Miller plane that characterizes a set of lattice planes that describe a specific face. Parameterized Leonard-Jones-type potentials are commonly used, and a pairwise summation of all the nonbond interactions and an Ewald summation for either point charges or multipole contributions to the electrostatic interactions are used in the calculations. As with all calculations of this type. the calculated morphology obtained is sensitive to the combination of charge treatment and potential set used.

SOLVENT AND IMPURITY EFFECT ON CRYSTAL GROWTH

As stated earlier. the internal structure controls the energetics of a molecule or ion attachment to the cryrtal surface. For different crystal surfaces, the energetics vary. and it is this variation that differentiates between the growth rates of respective faces.[21] External factors, such as the levels of supersaturation, solvent. and impurities, may contribute additional influences on the attachment energy for a set of growing faces, with the result that a modification to the overall habit is observed as the growth conditions are varied. In particular, because crystal growth is a surface-specific process, with the distinct feature that if a recognition process between a crystal face and impurity or solvent occurs, then a dramatic influence on crystal habit is achievable.

A problematic area is how to ratify the effect of solvent or impurities. When analyzing the effect of solvent or impurities on crystal habit. two factors are essential to understanding the process.

The first is the process of solvent or impurity inclusion at the growth site. Here, attachment energy calculations are used to assess the effect. Two parameters are used to evaluate the impact of inclusion. One parameter is the binding affinity of the solvent or impurity to a specific lattice plane. this is used to characterize the affinity of the solvent or impurity for a specific face. The second key parameter is the inclusion effect on the attachment energy. What must be envisaged in this process is that the habit is altered as a result of an impurity or solvent molecule blocking a growth site. such as a kink, and so reducing the growth rate of one face relative to the others. i.e., increasing the attachment energy. As the binding affinity increases, the probability of incorporation increases. This approach to the mechanism of impurities and solvent is effective, because the concentration of active growth sites on the surface is low, and an impurity or solvent may be specific to one particular face.

The second factor in quantifying the influence of solvents or impurities is the effect of solvent or additive on the growth mechanism. particularly when solubility is affected. Because solubility defines supersaturation, any change in supersaturation can cause the growth mechanism to move from screw dislocation to surface nucleation and eventually to continuous growth. This is the change in growth behavior as previously discussed. Predicting the transition of the growth process from one of continuous growth to one of spiral growth requires detailed calculations that include surface diffusion, collision, and exchange processes at the growth interface. The transition of the growth process that includes the above phenomena is usually modeled using an Ising Net and Monte Carlo simulation techniques.

It is important to note that the comparison of experimental morphologies to calculations is also problematic. due to the effect of solvent. It is usual to compare the habit of a crystal grown by sublimation with those generated by varying the solvent. For example, when the

calculated sublimation and solvent-grown crystal morphologies of succinic are compared, the role of the solvent becomes clear. As morphology and binding modeling indicate, the presence of water results in the rhomb morphology elongating. as the water molecule has a preference for the (100) faces and, with the presence of 2-propanol. has a preference for the (010) faces, resulting in needle morphology.

CRYSTAL GROWTH: ADDITIVES AND HABIT MODIFICATION

If solvents or impurities are added to produce a specific effect on morphology, they are referred to as "tailor-made additives." In recent years, the principle of selecting a molecule to selectively disrupt or block the growth of specific faces and, consequently, to modify the habit or inhibit growth has been widely applied. Which process occurs depends on the additive loading and to what degree the additive blocks the subsequent growth layer. This work was guided by the habit calculations using attachment energies. In many cases, the choice of additive is made purely on considerations of surface geometry.

In all cases. the objective is to identify additives that will either cap a growing face and thus act as a blocker to growth from the target face or that will maintain the ability to support the next face layer but distort the attachment of the next layer, thus acting as a disrupter to growth from the target face (see Fig. 5). The reason for modifying crystal morphology relates to the effect of particle geometry on the physical properties, such as particle flow, filtration characteristics, or optical properties.

Some examples of the attachment energy calculation approach to additive effects can be found in the Clydesdale, Roberts. and Docherty article on HABIT 95[23,27] and Davey, Polywka, and Magin.[22] For instance; the effect of benzoic acid on the growth of benzamide and the impact of biphenyl on the growth of naphthalene were modeled and analyzed in these articles. An example in which laboratory experiments and calculations were used is the work on the disruptive additive benzoic acid on benzamide.[23] Pure benzamide grows in needle-plate geometry. but in the presence of benzoic acid. the morphology changes to a rhombohedra1 plate. In this system. the aim was to block the formation of the hydrogen-bond ribbon characteristic of the structure along the [010] axis.[26] This was achieved using benzoic acid, as the incorporation of this molecule into the hydrogen-bond ribbon disrupts the attachment of the next incoming layer, as no -H–O- contact is available for benzamide attaching to benzoic acid incorporated in the chain. Consequently, the (010) faces dominate the habit. and the crystal elongates along the [100] axis.

Calculations are not always carried out; often, a geometric approach is used. Again. there are many examples to be found in the literature: one example is the selective inhibition of prochiral faces (viz. when a pair of faces are described by lattice planes that are mirror images of each other). for glycine[24] by chiral additives, such as *L*- or R- serine. Here, the solution was doped with either the L- or *R*- form of the amino acid serine. Both forms of the amino acid cause the glycine crystal to grow as a pyramid. instead of growing as the usual bipyrainid. This occurs as glycine posseses a prochiral axis along [010]. This prochiral axis arises as the glycine molecules form two antipolar sets (the relative mirror orientation of the molecule within prochiral lattices gives rise to alternating pairs of lattices within the structure) within the structure and lie perpendicular to the orientation of prochiral lattice planes. The habit modification was rationalized in terms of the R-serine being specific for the (010) face only and the L-serine being specific for the (0-10) face only. The overall habit arises as the antipolar set typifies the plane intersecting the bipyramid, and each component of the antipolar set characterizes one of the respective top faces of the bipyramid.

A variation of the principles of habit modification is the inhibition or retardation of crystal growth. In this strategy, the additive is selected to mimic and block the fastest-growing face of the crystalline material under study. This has led to additives, which control encrustation, fouling the surfaces in many industrial situations, i.e. barium sulfate precipitation in oil wells.[25]

A common theme for all of these examples is the application of an impurity that partially mimics the stereochemistry of the next incoming growth layer of a specific lattice plane, and in doing so, manipulates the significance of the targeted faces in the overall morphology. Not only is the crystal engineered to express a specific morphology. but influences on size are also observed.

To conclude the discussion of habit modification by additives, additive choice is based either on a geometrical

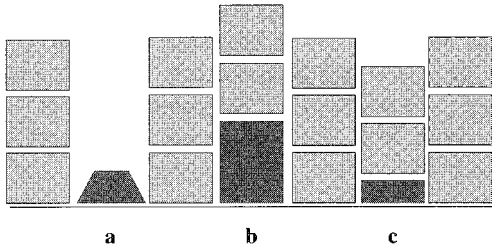

Fig. 5 Additive strategies for habit modification: (a) capping of a growth layer site; (b) disruption of contacts due to an additive larger than the site: (c) disruption of contacts due to an additive smaller than the site. (*View this art in color at www.dekker.coin.)*

match between the additive geometry and the host site or on calculations. Calculations are used to determine the affinity of the additive for the surface, and the influence of the additives on the energetics of the growth process. In certain cases, the choice is based on a guess using derivatives of the molecule under study.

CRYSTAL GROWTH AND POLYMORPH SELECTION

A variation on the application of impurities, which affect the crystal growth process, has been the selection of polymorphs[26,27] grown from solutions using solvents and additives. In this area, the route to polymorph selection and stabilization is to employ additives or solvents (impurities) that have the ability to inhibit or to interfere with the fastest growth directions of a stable polymorph over that of the metastable form exhibited by the system. Such studies highlight the subtle role growth conditions play in crystallization and have direct ramifications for the supramolecular chemist engaged in crystal engineering. as such work highlights the effects kinetics and growth conditions may have on the durability of a synthon to generate a particular architecture. This arises. as such systems are subject to the issue of the growth of one form over another, which is described by Ostwald's rule of stages,[28] which states:

> "...when a change in phase occurs. the transformation proceeds not directly to the most stable phase but to the next stable...."

Consequently. for solution crystallization, polymorphism adds a kinetic dimension to crystal growth, whereby the kinetics requires that the transformation of one phase (G_I) to another (G_{II}) in solution is dependeat on the dissolution (k_d)of the metastable phase (as stated in Eq 7). driving the supersaturation of the growth of the stable phase (k_g) (as stated in Eq 8)

$$G_I = -k_d(\sigma - \sigma_{(i-ii)}) \tag{7}$$

$$G_{II} = k_g(\sigma_{(i-ii)}) \tag{8}$$

Experimentally. this process can be verified using time-lapse micrographs of a polymorphic system crystallizing. and this is illustrated for dimorphic system L-glutainic in Fig. 6. In this figure. a series of time-sequence micrographs clearly show the dissolution of the metastable rhomb phase (I) and the growth of the stable needle phase

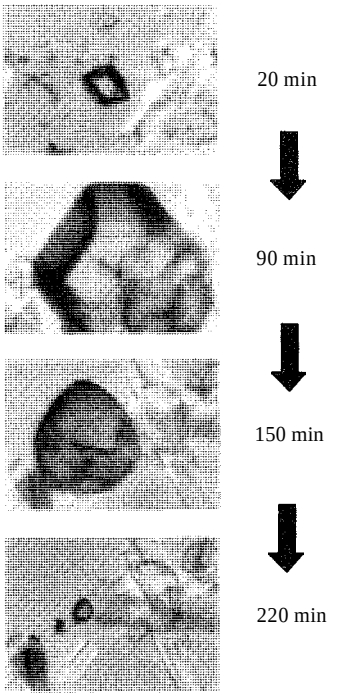

Fig. 6 Dissolution and growth process of polymorphic transformations in solution of L-glutamic acid from Form I to Form II. (*View this art in color at www.dekker.com.*)

(II). Such a description of the transforination kinetics suggests that the stabilization of the metastable form using an impurity would require the impurity to affect the growth kinetics of the stable phase. In the case of glutamic acid, the impurity used was trimesic acid, as this impurity is a conformational mimic of glutamic acid in the stable form. Consequently, an impurity of this type will disrupt the growth of the stable form of glutamic acid via disruption of the fastest growth direction, and this arises as the trimesic acid possesses a larger volume than the host site within the fastest growth direction, thus disrupting the next incoming layer.

CONCLUSION

Selectivity of crystal growth processes based on a firm understanding of the mechanism of crystal growth should enable the practitioner to manipulate the habit: isomer, or polymorph of a molecular solid grown from solution. Also. the suprainolecular chemist. as a crystal engineer. will be able to make better use of the underlying crystallographic principles that govern crystal growth to better understand the appearance of habit or polymorph variation.

Crystal Structure Prediction

Sarah L. Price
University College London, London, United Kingdom

INTRODUCTION

Programs are available for the computational prediction of organic crystal structures. usually based on searching for the most thermodynamically stable unit cell. Such programs will generally predict any dominant supramolecular motif and are often successful at predicting the complete crystal structure for simple organic molecules in common space groups. Although there have been successful predictions, even under blind test conditions, no method is yet reliable for any type of organic molecule. The methods will become more widely useful as accurate quantitative models for the intermolecular and intramolecular forces are developed and the range of possible crystal structures covered in the searches is extended. Nevertheless, there is a fundamental limitation when: as is often found. the search generates more energetically feasible crystal structures than experimentally known polyinorphs. In such cases, the kinetics of nucleation and crystal growth will determine which of these crystal structures are observed. Work on incorporating kinetic factors into crystal structure prediction is only just beginning.

WHAT IS CRYSTAL STRUCTURE PREDICTION?

Crystal structure prediction can simply mean using a computer to predict the crystal structure of an organic molecule from its chemical diagram. The aim is to predict the space group, cell dimensions, and atomic fractional coordinates that will be observed should the molecule be successfully synthesized and crystals obtained that allow the structure to be solved by diffraction methods. Such a computational method would be practically valuable in the development of molecular materials, where the crystal structure as well as the molecule affect the property of industrial or scientific interest. For example, a molecule with a high nonlinear optical coefficient will only produce an active material if it crystallizes in a noncentrosymmetric space group. Crystal structure predictions could also reduce synthetic effort in the development of energetic materials and pigments.

Crystal structure prediction is considerably complicated by polymorphism. When a inolecule can adopt more than one crystal structure. we want to be able to predict all the crystal structures that are likely to be found and the conditions to control the form produced. This would benefit the pharmaceutical industry, where the unexpected appearance of a new polyinorphic form is a disaster. However, until there is an experimental screening method that reliably establishes all the polymorphs that could exist for a given molecule. it is impossible to conclude with certainty that a crystal structure prediction study was completely successful. A predicted polymorph may yet be found. A known crystal structure could be thermodynamically metastable, but there may be no kinetically feasible route to forming the more stable form. Hence, the development of crystal structure prediction is intrinsically linked with progress in demystifying polymorphism.

Thus. crystal structure prediction is a forinidable problem and a major test of our quantitative ability to model the details of supramolecular recognition. The answer to the question as to whether crystal structures are predictable has only recently advanced from an emphatic "no" to a ''maybe''.[1] Experience in this field is still relatively limited.[2] Although there have been cases where the crystal structure of a molecule was genuinely predicted just from the chemical diagram, it is certainly not yet possible to predict ab initio the crystal structures of any organic molecule. Indeed. it is not yet possible to define the molecules for which current methods are likely to be adequate.

The distinction that crystal structure prediction should completely predict an unknown crystal structure makes it intrinsically more precise and difficult than crystal engineering, which seeks to predict broad structural patterns and motifs. For example. crystal structure prediction may indicate that a molecule has a strong preference for a certain hydrogen-bonding motif. for example, forming a sheet. If this sheet was observed in all polymorphs. then the prediction would be a success for crystal engineering. However. it would only be deemed a successful crystal structure prediction if the stacking of the sheets was accurately predicted to give the correct space group and cell dimensions.

The emphasis on no prior experimental knowledge is important in distinguishing crystal structure prediction from methods of solving crystal structures using known unit cell parameters. For most fairly rigid organic molecules. the problem is much simpler when the unit cell parameters are known, as seen by recent progress in solving crystal structures from x-ray ponder diffraction.

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012751

However. a set of computed feasible crystal structures can be useful in solving structures from x-ray powder data when the pattern cannot be indexed to give the cell dimensions. This only requires that a set of feasible crystal structures. containing one with a simulated powder pattern close enough that it can act as a starting point for refinement: be generated by the prediction.

Thus, there will be many practical uses for a reliable computational method of predicting the crystal structures of organic molecules. It is a fundamental challenge that underpins crystal engineering. We cannot claim to understand crystallization until we can at least predict the crystal structures that will be observed. It is probable that a reliable method of crystal structure prediction will have to represent in a quantitative way the factors that control crystallization.

THE BASIC ASSUMPTION OF CRYSTAL STRUCTURE PREDICTION

Most crystal structure prediction methods are based on the assumption that the observed crystal structure will correspond to the global minimum of the Iattice energy. This is essentially assuming thermodynamic control of crystallization. It also simplifies the calculation of the thermodynamics by neglecting all temperature. pressure, and quantum effects and by replacing the appropriate free energy by the lattice energy. the classical energy at 0 K. According to this zero-order assumption, any local minima in the lattice energy that are sufficiently close to the global minimum may be potential polymorphs.

Implementing this crude assumption requires a method of evaluating the lattice energy and of searching through the wide range of possible crystal structures. Quantifying inter - and intramolecular forces and global optimization are all major research fields, and so many alternative schemes were developed. Many of the programs[3–16] developed for crystal structure prediction based on lattice energy minimization are listed in Table 1. The main features of the search methods were reviewed[''' and compared.[17,18] Their limitations in terms of the techniques used in molecular crystal modeling,[''' particularly in the types of intermolecular and intramolecular potentials that can be used. usually reflect the type of organic molecules that were the main focus of the developmental work.

SEARCH METHOD

Even for a simple rigid organic molecule, the number of variables required to define the crystal structure presents a major search problem. and the search is limited to the most probable space groups. Some programs[8,14] use information on most likely packing modes within each space group. Most methods are. in practice; confined to considering just one molecule in the asymmetric unit ($Z'=1$) of the most common space groups for organic molecules. So, consideration of $P2_1/c$, $P\bar{1}$, and $P2_12_12_1$ is routine, and most programs can consider many others, such as $P1$ (as trivial), $P2_1$, $Pna2_1$, $Pca2_1$, $Pbca$, $C2/c$, Cc, $C2$, etc., though the computing time increases with the number of molecules in the unit celi (Z). During a search in a given space group. minimization could place molecular symmetry elements so as to generate a higher symmetry space group. Similarly; a stationary point found by minimizing within a space group symmetry could be a transition state between lower-symmetry structures. and reducing the symmetry in these cases can generate a minimized structure with more than one crystallographically independent molecule in the unit cell ($Z'>1$). Searches in $P1$ with varying numbers of independent molecules in the unit cell may become more effective in the future. However, to date, only in one published study. of hydrates of pyranoses and alcohols,[''' was the search explicitly for structures with more than one independent molecular unit in the cell. though this extension is urgently required for considering salts and solvates.

Crystal structure prediction only really started in the 1990s, when the increases in computer power made it possible to consider even this limited range of possible types of crystal structures. Some methods sample the potential energy landscape systematically. relying on efficiently eliminating impossible structures where ihe molecules overlap significantly. or use other criteria, such as the density of pseudo-hard sphere packing or the interaction energy of symmetry-constrained nuclei, to select a more limited number of structures for starting points for lattice energy minimization. Other methods use Monte Carlo simulated annealing or molecular dynamics to search for minima. repeating the runs to overcome the random element. However, all methods are extremely computer intensive. involving some sort of consideration of millions of hypothetical structures to span the potential energy surfaces and resulting in at least thousands of lattice energy minimizations. The problem is difficult because of the complex shape of the potential energy hypersurface: the energy barriers for converting between different approximately close-packed structures are high, and so only a small range of the surface will minimize to the global minimum. A key practical issue is in how to cluster similar hypothetical crystal structures, in the process of being relaxed or as minima. The clustering must remove structures that would correspond to the same

Table 1 Overview of programs developed for organic crystal structure prediction by searching for minima in the lattice energy. The types of molecules for which the program was originally developed are given. though all programs with emboldened names were used in the blind tests and so have been used for a wider range of systems (Fig. 4).

Program	Type of molecules used in development (Ref.)	Search type
Chin	Crystal engineering—diketopiperazines[3]	Monte Carlo simulated annealing with hydrogen-bonding bias
CRYSTALG	Rigid organics — amides, bases[4]	Self-consistent basin-to-deformed-basin mapping global optimization
CRYSCA	Pigments. organometallics[5]	Random search with steepest descent
ICE9	Rigid hydrocarbons[6]	Systematic grid search to generate close-packed structures
MDCP	Small rigid[7]	Constant pressure molecular dynamics to find crude structures
MOLPAK	Energetic materials. rigid[8]	Systematic search for high-density
(and DMAREL)	Rigid polar and hydrogen bonded[9]	structures in common coordination types
MPA, extended to Mpg	Small rigid[10]	Lattman systematic, or random generation of expanded trial unit cell
Perlstein	Moderate sized. semiflexible organics[11]	Aufbau search for low-energy one-dimensional and two-dimensional aggregates. primarily for monolayer predictions
PMC	Hydrocarbons[12]	Symmetry-adapted grid systematic
Polymorph Predictor	Flexible organics, including	Monte Carlo simulated annealing with intemediate clustering
PROMET	Rigid hydrocarbons[14]	Selecting cohesive dimer, ribbons and layer substructures of partial space-group
SySe and PP	Pigments[15]	Grid-based systematic
UPACK	Sugars and alcohols[16]	Systematic grid or random search. with intermediate clustering

observed crystal structure, while ensuring that minima that correspond to two closely related polymorphs are not eliminated.

Thus, a crystal structure prediction search will generate many hundreds to thousands of different lattice energy minima. The example in Fig. 1 shows the distinct minima obtained from about 1500 MOLPAK-generated starting points for a rigid nonplanar molecule with a CH-CO-NH-CO-CH functional group. The low-energy structures include hydrogen-bonded dimers and catemers and cover a range of distinct structures with relatively little difference in densities. Such crystal structure prediction results, where the energy gap separating the global from other minima is very small. and there are many distinct minima within the energy range of possible polymorphism. currently appear to be common. Examples where the known structure is found at the global minimum. with a sufficient energy separation from hypothetical structures to rule out polymorphism, are rare. The number of energetically feasible minima will obviously depend on the search method and force field. However. the main determinant is the molecule, as there is considerable similarity[18] between the low-energy hypothetical structures found by different methods with different force fields.

TREATMENT OF MOLECULAR FLEXIBILITY

The number of variables that need optimizing severely limits the degree of conformational flexibility in the types of molecules that can be studied. Many workers restrict their studies to molecules that can be reasonably assumed to be rigid. The gas-phase molecular structure is estimated by ab initio optimization, or sometimes molecular mechanics methods, and this molecular structure is kept fixed during the lattice energy minimizations. The molecular model can be taken from x-ray diffraction results, with suitable adjustment for the errors in locating the hydrogen atoms. for developing crystal structure prediction methodologies. However, the distortions in the molecular structure caused by the crystal environment will bias the calculated lattice energies toward the crystal structure used. It is clear[19]

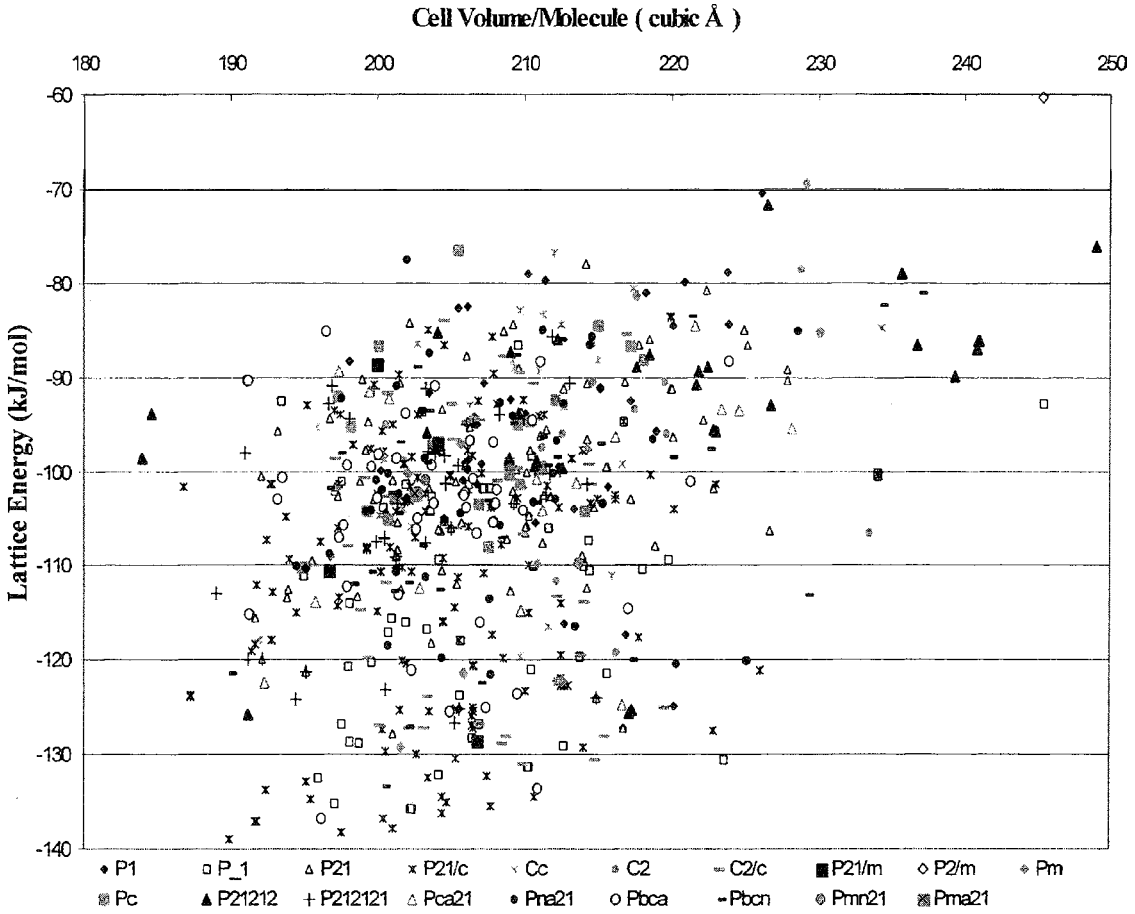

Fig. 1 A plot of the lattice energy minima found in the crystal structure prediction search for the rigid CHNO molecule in the 2001 blind test[18] (Fig. 4). in the search by Price. This diagram illustrates the plurality of distinct minima in different space groups found in a relatively sparse search. which did not locate the experimental structure.

that even minor distortions of the molecular structure, arising from crystal packing or experimental uncertainties, can change the calculated lattice energies significantly, compared with the lattice energy differences associated with polymorphism.

The other alternative is to use an intramolecular force field that allows the molecular structure to change torsion and bond angles and bond lengths in the course of the minimization. This is essential for considering flexible molecules like sugars. In this case, the lattice energy being optimized has to accurately represent the balance between the energetic cost for distorting the molecule and the intermolecular energy gain from, for example, improving the hydrogen bond geometry. In order to treat systems where conformational polymorphism is possible (i.e., there are low-energy molecular conformations with distinctly different molecular shapes), it is often prudent to start a search with each conformer, as the search/minimization procedure may not cross the intramolecular energy barrier effectively. Thus. crystal structure predictions for molecules with only one or two degrees of conformational freedom are currently considered challenging, but this will change with increasing computer power.

THE INTERMOLECULAR POTENTIAL

For all molecules, the reliability of the relative lattice energies for different hypothetical crystal structures depends on the accuracy of the intermolecular potential, and this is the key factor in the generation of the energetically feasible crystal structures. The range of molecules with crystal structures that can be predicted by lattice energy minimization is therefore limited to the ones for which a sufficient:~reliable potential is available. This is dependent

on the functional groups within the molecule. The lattice energies of different hypothetical crystal structures may be balancing van der Waals forces in different orientations with the energy differences between different types and orientations of hydrogen bonds and π – n stacking. A crystal structure can only be predicted as accurately as the lattice energy minimum closest to the experimental structure, which even with the best potentials. is likely to be only within a few percent in the cell dimensions because of the neglect of thermal effects. Because in most crystal structure prediction studies there are many structures within the energy range of possible polymorphism (c.f. Fig. 1), the desired accuracy in the relative lattice energies is often only a fraction of a kJ/mol. This provides a major challenge to the development of intermolecular potentials.[21,22] Empirically fitted model atom–atom potentials are often used, and the confidence in their accuracy increases with the number of crystal structures used in the fitting and testing. Because the accuracy of such empirical potentials is limited by the transferability of the parameters between different molecules, the parameters should be specific to the functional groups. For polar and hydrogen-bonding molecules. where the electrostatic contribution dominates the lattice energy and its orientation dependence, then the most accurate representations of the molecular charge distribution. such as distributed multipoles[21] or models with explicit lone pair or π electron point charges. are theoretically more reliable. The requirements of crystal structure prediction for accurate intermolecular and intermolecular potential are driving the development of increasingly accurate. elaborate, and computationally intensive methods of evaluating the inter-and intramolecular forces.[22] Improvements are envisaged even on the most elaborate force fields combined with ab initio intramolecular energies developed for sugars.''''

WHAT AWE THE RESULTS LIKE?

A survey[2] of ail the published crystal structure prediction papers in approximately the first decade of significant activity in this area reveals a considerable degree of success for lattice energy minimization methods over a range of types of molecules (Fig. 2). In approximately 250 searches for a particular polymorphic form, there was only a 10% reported failure rate to locate the structure: with the experimental structure being located as the global minimum in approximately half the cases (Fig. 3). However. these published studies were generally aimed at developing the methodology for specific types of molecules. and so the reported failures were generally within a

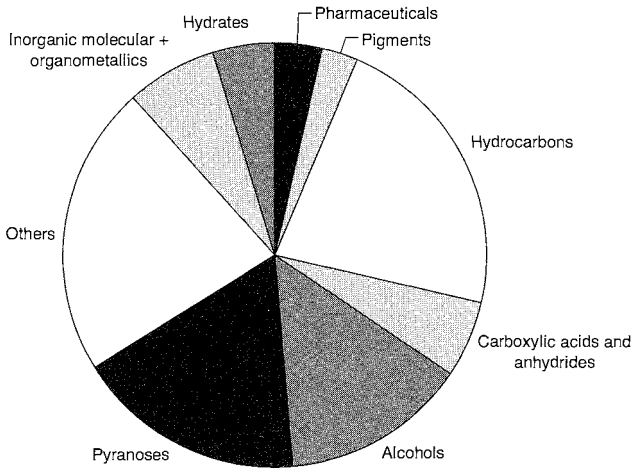

Fig. 2 The types of molecules studied in the first decade of crystal structure prediction. as derived from a survey of published lattice energy minimisation based studies.[2] Within each category, the molecules are generally the smaller and more rigid molecules whose published crystal structures are in common space groups with Z'=1.

sample of chemically similar molecules or in locating a particular polymorph. This literature will also not reflect the use of crystal structure prediction methods in industry. where predictions of feasible crystal structures for more complex molecules may be required to help solve particular problems in conjunction with experimental data. Suggested by Fig. 3 is that the ''global minimum'' assumption is useful but far from reliable, but this may reflect the makeup of the small sample as well as force field inadequacies. The molecules studied contained a large proportion of hydrocarbons and sugars, with nearly 30 known polymorphic systems, and hence, a low proportion of molecules that would be considered easy to predict or suitable for use in crystal engineering. It may be that more complex molecules, with irregular shapes and a well-defined hierarchy of functional group interactions may be more readily predicted as having a unique thermodynamically favored structure. For example, Pigment Yellow 74 (Hansa-Brillantgelb 5GX), which has two phenyl rings and a variety of nitrogen and oxygen functional groups producing four intramolecular hydrogen bonds, had its known experimental structure correctly predicted[1''''] as the global minimum. over 12 kJ/mol more stable than any hypothetical structures. Various syntheses and recrystallizations confirmed this prediction that no other polymorphic form is energetically feasible.

A more meaningful test of whether an arbitrary molecule can be genuinely predicted from its chemical diagram

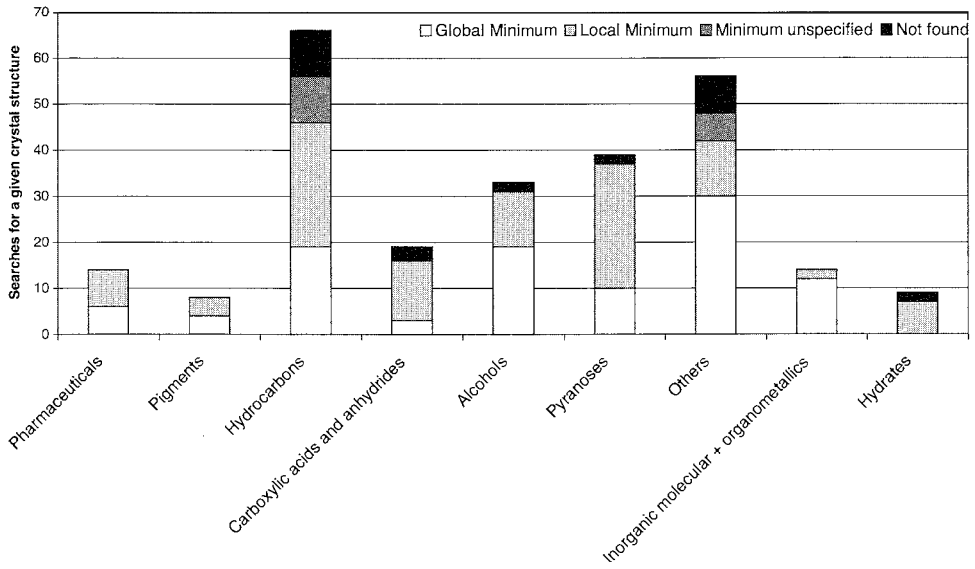

Fig. **3** The success rate of searches for a given crystal structure by lattice energy minimization, as derived from a survey of published studies.[2] The results are distinguished as to whether the known structure was found as the global or local minimum or not found. The number of searches significantly exceeds the 189 molecules categorized in Fig. 2. because of searches for polymorphic systems (where one structure is necessarily a local minimum) and where different groups have published a search for the same molecule.

is provided by the blind tests in 1999[17] and 2001,[18] organized by the Cambridge Crystallographic Data Centre. The participants were sent the chemical diagrams of the molecules. as in Fig. 4, which although arbitrarily chosen by an independent referee. fell into three categories within the capabilities of at least some of the programs. and thus illustrate the current limitations. One molecule was to be rigid with only C, H, N. or O atoms. another also rigid but allowing a wider range of atomic types as a test of force field development, and the third had a limited degree of conformational flexibility. The participants were allowed to submit up to three predictions per molecule of the crystal structure for comparison with the unpublished crystal structures. The success rate shown in Fig. 4 indicates that genuine crystal structure prediction is possible. However; the overall success rate was low. and might have seemed discouraging had a metastable polymorph not been characterized in 1999. It must be stressed that most of the participants correctly indicated a low level of confidence in their predictions, particularly when the search gave results such as in Fig. 1, where the energetic discrimination between different structures was very small compared with the expected accuracy of the force field.

It is. of course; possible to analyze the reasons for failure of a crystal structure prediction study using the experimental structure. The search is inadequate if it does not find the minimum obtained starting from the experimental structure, using the same force field. If this

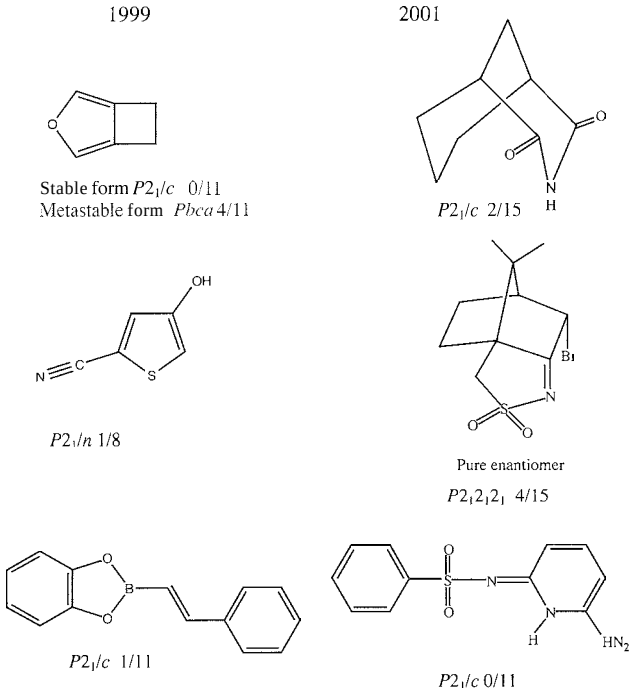

Fig. 4 The molecules used in the blind tests of crystal structure prediction, organized by the Cambridge Crystallographic Data Centre in 1999[17] and 2001.[18] For each molecule. the success rate is given as *x*/*y*, where *x* is the number of successful predictions, and *y* is the number of groups that submitted (usually) three guesses for the crystal structure.

minimum is not a good approximation to the experimental structure or is found to be considerably less stable than the global minimum, then the force field is inadequate. However. when this minimum is found among a plurality of minima within a few kcal/mol of the global minimum, then the observed polymorph could be metastable. In this case, it is probably a fundamental problem that there are more energetically feasible polymorphs than known structures. Improvements in the calculation of the relative thermodynamic stabilities of hypothetical crystal structures, and expansions of the search procedures, are definitely required. Some progress has been made in estimating entropic and zero-point energy contributions to the relative free energies of the crystal, using calculations of the lattice dynamical frequencies. Although the differences in these entropic terms are small, they may re-order structures that are approximately equi-energetic on lattice energy.[25] Further advances are anticipated in the future. However, the more fundamental problem is the limitations of the basic assumption that the observed crystal structure will correspond to the global minimum in the lattice energy.

BEYOND LATTICE ENERGY MIMIMIBIZATION—KINETIC EFFECTS

The phenomenon of polymorphism demonstrates that metastable crystal structures are observed, and it is not always obvious that such crystal structures are metastable. The energy differences between different polymorphs crystallized out of different solvent are small, and those between concomitant polymorphs presumably are very small. Kinetics must play a major role in determining which of the approximately equi-energetic hypothetical crystal structures are actually observed. How do the kinetics of nucleation and growth, and the variations with crystallization conditions. affect which thermodynamically feasible crystal structures are actually seen? How can this be incorporated in the crystal structure prediction model to produce a polymorph prediction model?

One approach is to assume that these kinetic factors are in some way represented in experimental crystal structures. Thus, analyses using the information in the Cambridge Structural Database were developed.[26,27] Although there have yet to be successful independent predictions by this method in the blind tests. this approach holds promise for discriminating among the hypothetical crystal structures within the energy range of potential polymorphism and force field uncertainty.

An alternative approach is to develop methods of calculating relative nucleation and growth rates, and their solvent dependence, for the hypothetical structures that are energetically feasible lattice energy minima. Thus, crystal structure prediction is pushing for further development of computational models. Preliminary attempts include estimating the mechanical properties of the hypothetical structures. Crystal structures that have an unphysically low resistance to shear can be eliminated as unlikely to be able to grow in competition with more mechanically stable crystallites.[9] The relative growth rates of the faces of the different hypothetical structures, as used to predict the morphologies of the crystals when the growing from the vapor by a birth and spread crystal growth mechanism, can be used to eliminate particularly slow-growing structures from being plausible polymorphs.[9] When there is a distinction in predicted growth rate among the low-energy structures, as observed for paracetamol[9] and pyridine,[25] the observed structures are favored. However. calculations on the kinetics of the crystal structure can only distinguish between the structures that readily nucleate. Thus, a method of predicting which crystal structures correspond to readily formed nuclei in different solvents would be a major step forward in polymorph prediction.

CONCLUSION

Crystal structure prediction is a technique that is in the relatively early stages of development. It is unlikely to become a reliabie method of predicting crystal structures, and particularly polymorphism, until our fundamental understanding of crystallization considerably improves. However, the methodology for generating energetically feasible hypothetical crystal structures for a molecule is well-developed, and foreseeable improvements in force fields and computational resources will allow such studies to be applied to an increasing range of molecules. When this extends to more of the molecules of interest in supramolecular chemistry. it may be found that when the molecular recognition is sufficiently strong, there will be one well-defined global minimum in the lattice energy. and the crystal structure will therefore be readily predictable.

Crystal structure prediction is already sufficiently mature to show the more subtle interplay between the nature and disposition of functional groups that determines which recognition motifs are feasible. For example, it demonstrates that the smaller carboxylic acids have low-energy minima corresponding to catemer and dimer structures, whereas benzoic acid has a significant energy preference for dimes-based structures. 5-Azauracil has a marked energy preference for forming a layer structure. which produces a more stable crystal[30] than is possible for 6-azauracil. where a variety of a three-dimensional

hydrogen-bonded networks are almost equi-energetic. The ability to generate a set of energetically feasible crystal structures will often be useful in understanding a given system. Although the ambitious goals of crystal structure prediction are only sometimes achieved. the calculations have the potential to be a valuable tool in developing supramolecular chemistry.

ACKNOWLEDGMENTS

Crystalline Microporous Silicas

Hermann Gies
Bernd Marler
Ruhr-Universität Bochum, Bochum, Germany

INTRODUCTION

Crystalline microporous silicas, the porosils, are a family of materials based on [TO_4] units with tetrahedral densities below 21 T-atoms per 1000 $Å^3$, which are synthesized in the presence of teinplating guest molecules. Their silica host frameworks are three-dimensionally four-connected, and in their calcined form, they belong to the large family of silica polymorphs. Porosils with pore openings too small to let the occluded guest molecules out are called clathrasils; porosils in which the guests can be removed are called zeosils.

In the course of synthesis, the template molecules act as structure-directing agents. Size and shape of the ternplate determines the geometry of the pore. During crystallization. the amphiphilic nature of the template (mainly organic amines) allows for molecular interaction between the aqueous silicate solution and the growing hydrophobic silica framework. Thermodynamic analyses suggest that the kinetics of nucleation are the most important factors in the crystallization process.

Experiments employing model systems show that nanoblocks of ~10 Å organize to macroscopic crystals in a second stage. However, there is still no deep understanding of the synthesis of crystalline microporous silicas.

The impact of computer modeling on development in the field is increasing. Databases store all possible tetrahedral frameworks. More detailed analyses allow for the optimization of the host–guest interaction for the synthesis of new materials. Finally, molecular dynamic calculations potentially show the molecular details of the nucleation and crystallization of micropoi-ous crystals. This article lists the most important geometric and crystallographic properties, points out possible applications of microporous silicas, summarizes the recent developments; and presents ideas for future progress in the field.

MICROPOROSITY IN FRAMEWORK SILICAS

The highly covalent nature of the Si—O bond in silicas, SiO_2, with tetrahedral silicon coordinated by oxygen, [SiO_4], leads to open, three-dimensional bonding networks. Silica polymorphs with high densities have Si in octahedral coordination and are natural or synthetic high-pressure phases with oxygen in close-packed arrangements. As an example, the crystal structure of stishovite. one of the densest naturally occurring silica minerals, can be seen as distorted hexagonally close-packed array of O atoms with Si in octahedral interstices. Its density is $\rho=4.28$. The naturally occurring silica minerals quartz. cristobalite, etc.. are crystalline solids with tetrahedrally coordinated Si, and they have densities of less than 60% compared to high-pressure phases. There are also the microcrystalline silicas, like opals, chalcedon. etc., and the amorphous silicas. such as lechatelierite, hyalite, and opal AG (gemstone opal), the latter two containing water. which possess three-dimensional bonding networks with densities even below that of tridymite. the least dense natural crystalline polymorph of silica ($\rho=2.27$). Their density is $p-2.1$, which corresponds to approximately 21 tetrahedral units [SiO_4] per 1000 $Å^3$. The composition independent value was introduced as framework density. FD. However, none of these silicas is porous in the sense of having accessible pore space. By definition, porous structures have framework densities below 21 T-atoms (T=tetrahedral) per 1000 Å', which leads to open space within the silica framework wide enough for the incorporation of guest molecules. If the size of the pore opening in these materials is less than 20 A, they are microporous; in the range between 20 and 1000 Å. they are mesoporous; and finally. above 1000 Å, the macropore regime begins. The crystalline porous silicas, the topic of this article, typically are microporous and contain guest molecules as templates for their pores in the as-made form. which can be exchanged or removed by thermal treatment to render all-silica porous framework structures, the porosils. A compilation of all crystalline and noncrystalline silicas is given in Table 1.[1,2]

The crystalline microporous silicas. [SiO_2]·(template), (Tables 2a and 2b) are considered solid solution end members of aluminosilicate zeolites, $(cation)^{x+}[Al_xSi_{1-x}O_2]^{x-}$ (nonframework constitutents). The topology of the host framework is the same. however, the composition and, with it. the properties, are distinct for every material. A

#$[4^2 5^8 6^2 8^4]$ is a 16-hedron built by two 4-membered rings. eight 5-mernhered rings. two 6-membered rings and four 8-membered rings.
(From Refs. [3,4].)

composition materials that are otherwise not accessible. For reasons of systematics, those are not included in this compilation.

Recently, a mathematical, rigorous enumeration of all possible tetrahedral networks (three-dimensional four-connected nets) in three-dimensional space was presented.[6] This included all existing and hypothetical porosil framework structure types. Geometrically feasible models are potential candidates for new framework structure types, provided a suitable SDA can be made.

Clathrasils

The silica frameworks of the clathrasil family are built from cage-like polyhedral structural subunits containing the guest molecules (Fig. 1). The cages are bound by

Table 2b Structural properties of zeosils

Zeosil	Zeolite framework type	Framework density*	Composition per unit cell	Type of channel	Approx. cross section of the limiting pore [Å]	Dimensionality of the pore system

*Number of Si atoms per 1000 Å^3 based on idealized cell constants.
[§]PxMR = channel like void with a cross section which is defined by an x-membered ring of $[TO]_4$ units.
(From Refs. [3,4].)

polygons with 4-, 5-. or 6-tetrahedral $[SiO]_4$ units. i.e., 4, 5, or 6 MR. With the exception of silica sodalite (SOD), all clathrasils known so far are composed of more than one type of cage (Table 2a). In general, the biggest cage contains as template the SDA, whereas the smaller cages are occupied by help guest species (e.g., N_2, Ar) or are empty. The size and shape of the cage reflect the size and shape of the SDA. Because of the electroneutral nature of the silica framework, the interaction with the SDA is weak, at least in the completed structure. Among the clathrasil structures, the smallest cage containing a SDA is the $[5^{12}]$ cage, the pentagonal dodecahedron. with 90 Å^3:

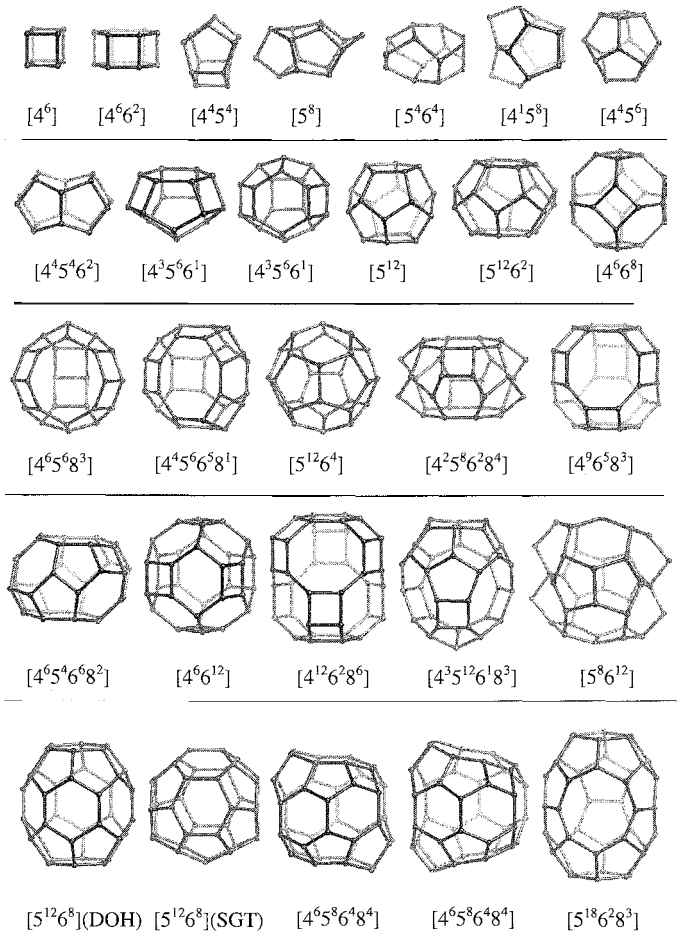

Fig. 1 Compilation of cage-like voids observed in clathrasils. For more information on the cage properties and the symbols used see Table 2a. (*View this art in color at www.dekker.com.*)

the biggest found so *far is the* $[5^{18}6^2 8^3]$, *with 560* Å^3 *as free cage volume in the framework of* DD3H. *The silica* framework *of* the *clathrasils* is *thermally stable,* e.g., *dodecasil 3C (MTN) was held for more than 3 months at* 950°C. *In* DTA *analyses. the framework breakdown was observed above 1000°C for melanophlogite, dodecasil 3C. dodecasil* 1H, *and decadodecasil 3R when heating with a* 5°/min *heating rate. Because of* the *high thermal resistance. all clathrasils* were *calcined successfully and obtained as* pure porous *silicas. This leads* to *a reduction of* the symmetry *caused by distortion of the silica framework through cooperatively tilting the rigid* $[SiO_4]$ *unit for* melanophlogite, *sodalite, and dodecasil* 3C, *whereas no lowering of the space group symmetry was observed for the other clathrasils. At higher* tempertures, *the distorted silica frameworks undergo a* displacive *phase transition to the highest possible space group symmetry for* the given *framework topology. Surprisingly. the silica frameworks of all clathrasiis in their highest symmetry forms contract when raising the temperature above the phase-transition temperature. The thermal* contraction *is* in the *order of* $\alpha \sim -1*10^{-6}$ *over a wide* temperature *range. in the case of dodecasil 3C. between 100°C* and 1000°C, *before an expansion of the* unit *cell sets in* again.[7]

The study of the morphology of the clathrasils shows that ail materials *synthesized so far crystallize with a typical crystal morphology. Because the crystal growth faces developed grow slowest;* they *are indicative for the rate-determining step* in *crystal growth. All* morphologies *studied so far show* dominant *faces, ivhere the cage containing the SDA* is *involved in high concentration. This indicates that the trapping of the SDA on the respective growth face is the rate-limiting* step *for the progress of crystal* growth.[8]

Zeosils

The typical structural feature of a zeosil is *channel-like voids in the silica framework that extend in one* dimension *or intersect to* two- *or* three-dimensional *channel*

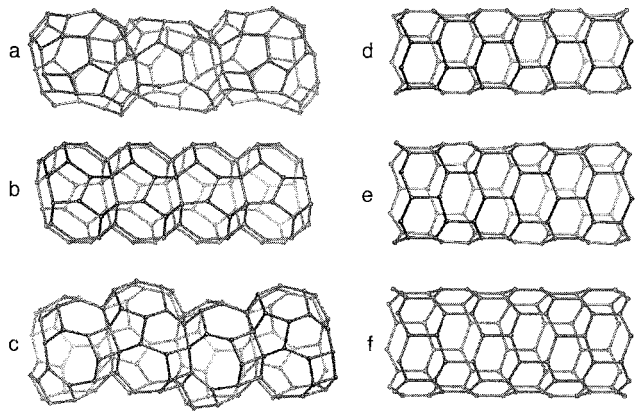

Fig. 2 Typical channel-like voids observed in zeosils of different framework structure type. The channel-like voids possess pore openings limited by n-membered rings (nMR) a) 7MR of the STT type, b) 8MR of the RTE type, c) 9MR of the STT type. d) 10MR of the Silica ZSM-48, e) 12MR of the AFI type. f) 14MR of the DON type. (*View this art in color at www.dekker.com.*)

systems Fig. 2). The channel opening is confined by 7 MR (2.4 * 3.5 A. SSZ-23) at least. The widest channel has 14 tetrahedral units. with a free diameter of ~8.2 Å for UTD-1. The typical SDAs for zeosils are molecules that extend in one or two dimensions. As for the clathrasils, the pore geometry reflects the molecular shape of the SDA. After calcination at moderate temperatures, the channel pores are accessible for suitable sorbate molecules. In general, the physical and chemical properties of porosils are comparable to those of clathrasils—they are transparent. colorless, hard, thermally resistant, have negative thermal expansion coefficients in a wide temperature regime, and show typical crystal morphologies. As an example, zeosils with a one-dimensional channel system always crystallize in a needle morphology. with the needle axis parallel to the channel pore. As already discussed for clathrasils. the growth-limiting step is the formation of a new channel by trapping the SDA along the needle axis.[8]

In contrast to zeolites. which are porous aluminosilicates. water does not enter the zeosil pore; however. hydrophobic molecules of appropriate size are readily taken up. The hydrophobicity index characterizes this property. The materials are useful for the separation of hydrophobic, nonpolar, or aprotic molecules in the presence of water in the liquid and gaseous states. As an example. the zeosil DD3R was a candidate for the separation of CO_2 in the presence of moisture for air-conditioning in spacecrafts.

The accessibility of the pore space of zeosils was also used for the encapsulation of functional molecules inside the silica matrix. Because the channels are anisotropic and provide a mold for molecules with polar properties, they are ideally suited as supports. Dipolar molecules will line up inside the channel, create polar symmetry, and might imprint interesting properties on the composite material, e.g., nonlinear optical properties. Dye molecules can be arranged within the silica matrix in favorable distances. so that their dipolar interactions can be used for light harvesting, and magnetic nanocrystals might be deposited inside zeosil matrix in well-defined sites.[9]

Silica is a material with a low dielectric constant of k—4.0. In order to increase the packing density between multilevel interconnects, new. ultralow-k inaterials are needed. Because k decreases with decreasing density, crystalline and noncrystalline porous silicas with DK as low as $k<2.0$ were introduced to replace the current wire insulators in microelectronics for multilayer devices. Because of their low density, ordered mesoporous materials are used for practical purposes.[10]

SYNTHESIS OF POROSILS

Mechanism of Porosil Synthesis

Porosils are synthesized using hydrothermal techniques in the typical temperature range of 140–200°C in the presence of SDA. Here. the SDA act as templates for the formation of the pores in the silica framework.'"] Therefore. the as-synthesized porosil is not porous but is a composite material that contains molecular or ionic species inside a crystalline silica framework. The bonding interaction between host and guest is of van der Waals type and is weak. Although research on crystalline porous materials, including porosils, is more than 50 years old. and there are several hundreds of examples of host–guest pairs for porosils only, the principles of the early stages of formation are poorly understood. From the thermodynamic standpoint, the porous silica frameworks are between 4–14 kJ/mol SiO_2 metastable with respect to quartz and similar to amorphous silica and silica glasses.[12] The thermal energy at 150°C, a typical synthesis temperature. is 3.5 kJ/mol, so the formation of crystalline porous silicas from amorphous silica sources is not generally hindered. However. in order to understand the details of the nucleation process. the interaction of solvent. silica, and organic template must be taken into account. The analysis shows that the seif-assembly process depends upon a delicate interplay between a large number of weak interactions. The thermodynamic analysis suggests that the kinetic factors are of major importance, and the kinetics of nucleation are likely to be the critical factors in determining the material obtained from a particular preparation."[3,14]

It is difficult to experimentally identify the molecular structure of the critical species from which crystal growth continues to bulk dimensions. One approach is to use the crystal structure analysis of the as-made material. including the guest species, as a protocol of the synthesis process. Using fragments of the structure as building blocks from which the porosil framework can be made, a rational model can be developed and tested against experimental evidence from syntheses experience. This concept was used to enumerate so-called secondary building units (SBU),[3] from which a particular structure can be built entirely. However, the building blocks are not framework-specific, and one SBU-type can be used to construct different porosil structures. Recently. a number of studies on the nucleation, seed formation. and crystal growth of silicalite were presented.[15–17] Over several orders of magnitude, starting from the species in solutions until the coherently scattering crystals, the formation of the silicate framework was monitored. Under the conditions of a clear. homogeneous starting solution. the formation of nanoblocks of $\sim$10 Å under synthesis conditions was postulated. These nanoblocks then assemble to three-dimensional periodic crystals.[17] The model as the general mechanism of nucleation is discussed controversially. However, for the specific synthesis conditions of the model system, nanoblocks containing the templating species play a crucial role in the development of the extended silicate framework.

On the other hand. silicate oligomers in aqueous solution were analyzed for their potentials as structure precursors.[18] The multitude of silicate species in solution and the complicated equilibrium between different oligomers, however, make it impossible to unambiguously identify those species involved in seed formation. In an attempt to identify silicate species attached to SDA molecules in solution. it was shown that there is no distinct structural entity as an SDA/silicate complex, but silicate oligomers segregate close to the organic guest species. matching the charge, size, and shape of the template.[19]

Computer modeling also offers the opportunity to investigate the nucleation process. A new approach was described.[20] Instead of starting with structural subunits typical for porous silicas. a random arrangement of silicate monomers and solvent describing the synthesis solution was observed over time, however, without the template present. For temperature and pressure conditions typical for silicate synthesis and using Monte Carlo techniques. the silicate cluster forination was studied. The analysis showed that condensation reaction in the computational procedure was sensitive to pH and silica concentration. which is in agreement with the experiment. Critical clusters were calculated to have 25–50 Si atoms. In addition. the geometrical analysis of the cluster showed a close relationship to structural units of dense silicas. In the future, it is hoped that the calculations. run in the presence of templates. will yield clusters that resemble subunits of zeolite framework structures.

Synthesis Rules for Porosil Synthesis

Based on wide experimental experience, a set of rules for porosil synthesis was established that characterizes the fundamental relation of host and guest in a descriptive and intuitive way. There are general physical and chemical properties an SDA must possess. It must be stable under the conditions of synthesis. physically and chemically. Because the solvent for synthesis is water, the SDA should be soluble. however, it must not hydrolyze. Most guest molecules are rigid or have a limited nuinber of conformer states. The basic organic amines and ammonium coinpounds comprise the group of molecules most successfully used as SDA. They are soluble in water, stable under the conditions of synthesis. and because of their basicity. dissolve silicates. If used as ammonium fluorides. the anion. in addition, acts as a help species in a multifunctional way. Fluoride is a common mineralizer and enhances the solubility of silicates. In the presence of fluoride, porosils were synthesized even in acidic conditions. In addition, the anion has properties of an SDA or help species, because it is often incorporated in the small cavities of porosils (Fig. 3a). leading to the stabilization of materials otherwise not accessible. The characteristic property of organic amines as SDA is their amphiphilic nature. They are hydrophilic at the N-carrying head group and hydrophobic at the hydrocarbon tail. This specific property. the positive ionic charge in the protonated form. and the basicity of the SDA lead to pairwise interaction with the anionic silicate species in solution responsible for the nucleation process. Once the critical size of the nucleus is reached, growth determines the progress of crystallization. The amphiphilic property of the SDA matches the dominant growth faces of the porosils. because they consist of hydrophobic parts, e.g., half-complete cavities and channels where the internal silica surface is already complete, and of hydrophilic parts where silanol groups terminate the growing host framework. The role of the SDA now is to fill the developing pore with the hydrophobic tail and to interact with the solvent. the silicate species in solution, and the silanol groups of the silicate framework. At the interface between framework and solution. the N-carrying head group of the amine that can easily be protonated and deprotonated, probably acts as a catalyst for the condensation of the silicate species in solution and the

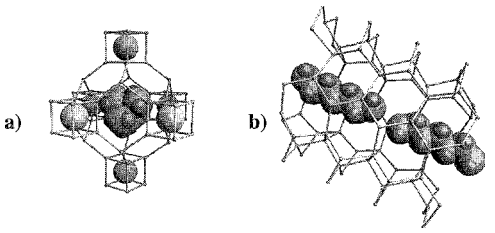

Fig. 3 a) Section of the structure of octadecasil (zeolite framework type: AST) showing the isometric tetramethylammonium cation as the guest species occluded in the $[4^6 6^{12}]$-cage and the fluoride anion occupying the small $[4^6]$-cage. b) The channel-like void of Silica-theta-I (zeolite framework type: TON) possessing a LO-membered ring pore opening and being occupied by a chain-like amine. (*View this art in color- at www.dekker.com.*)

silanol groups of the framework. The continuing condensation process of the silicate species finally traps the SDA inside the pore. In a series of AFM studies of zeolite crystal growth, this picture is convincingly supported. On growth surfaces, terrace steps are observed that are higher than one atomic layer but are of the same height as the characteristic, SDA-containing structural subunits.[''']

SDA for Clathrasils

As explained above. most clathrasils are built from several types of cages with different volumes. The SDA occupies the cage characteristic for a framework structure type: the framework-specific cage. The cage-like voids of the clathrasils require isometric SDA of appropriate size and shape (Fig. 3a).[11] Size and shape are the dominant attributes of tlte SDA. In general, the SDA interacts as a template only weakly with the host framework through van der Waals forces. Therefore. different SDA function as templates for one framework structure type. e.g., there are 26 SDA known for the synthesis of dodecasil 3C (Fig. 4a). On the other hand. a number of SDA stabilize different framework structure types (Fig. 4b) under different conditions of synthesis; occupying cages of different volumes. At lower synthesis temperature and higher pressures. the cage volume of the framework-specific cage is smaller for the SDA than at a higher synthesis temperature and lower pressure, respectively. Although there are a large number of hypothetical framework structure types. with bonding geometries comparable with the known clathrasil phases, only a limited selection was synthesized. Despite all efforts with computer modeling, combinatorial synthesis. and high-throughput experimentation, none of the framework structure types was "tailor made" but was discovered by systematically varying SDA and synthesis conditions. This shows that the process of nucleation is not well understood and that energy differences between various nuclei are small, which makes predictions from modeling difficult.

Another important factor influencing the product in clathrasil synthesis is the active concentration of the SDA. For some SDA, high concentrations lead to frameworks with higher densities of framework-specific cages. Pyrrolidine, for example, gives silica sodalite (2.9 cages per 1000 A') at high concentrations of SDA. whereas RUB-10 (2.0 per 1000 $Å^3$) and dodecasil 3C (1.1 per 1000 $Å^3$) form at lower concentrations.

SDA for Zeosils

The characteristic feature of a zeosil is channel-like pores wide enough for the exchange of SDA with sorbate molecules. The ring size must be larger than six and is typically eight and more. Some zeosils have spacious. cage-like voids, however. the interconnecting pore windows are much smaller (Fig. 2a–c). As an example. decadodecasil 3R (DDR) contains 1-aminoadamantane

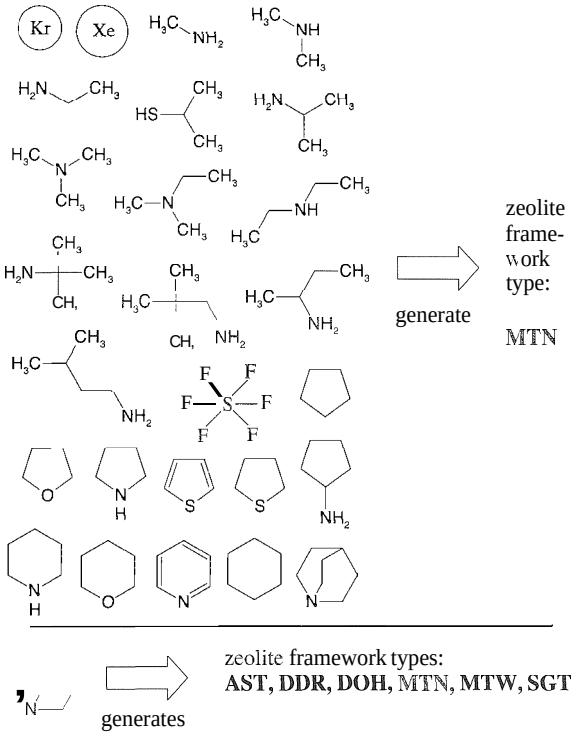

Fig. 4 top) Compilation of structure directing agents (SDA) which all lead to the formation of MTN-type materials. bottom) Zeolite framework types obtained with quinuclidine as SDA under different synthesis conditions.

as SDA in the as-synthesized form and is a typical clathrasil. After calcination and the removal of the decomposition fragments, a two-dimensional channels system becomes accessible through the 8 MR.

The typical zeosils have channel-like voids that extend in one dimension or are interconnected to two- and three-dimensional channel systems, respectively. The channels are bound by 10, 12. or 14 MR housing the SDA (Fig. 2d–f). As for clathrasils. the sizes and shapes of the SDA are imprinted on the host framework. Chain-like amines, polyazacompounds, and di- and trialkylamines are typical SDA for zeosils with 10 MR (Fig. 3b).[11] Here. the di- and trialkylamines create intersecting channel systems. In order to obtain the larger 12 MR pore. bulkier SDA. such as phenyl groups containing templates. are needed. For the even larger 14 MR zeosils. the diameter of the SDA is further increased. However. the SDA for the large-pore zeosils show only limited conformationa! freedom. The geometries of tricyclic molecules or metal–organic compounds are almost rigid. Because the channel cross section is the only characteristic feature of zeosil host framework structures that reflect SDA geometry, a number of different SDA can be used for the synthesis of every zeosi? framework structure type. As already mentioned for the clathrasils. there are many hypothetical framework structure types derived from existing models and through rigorous mathematical enumerations. However. modeling calculations with the aim of identifying specific SDA for new host framework structure types has not been successful so far.

Help guest species

In recent years, the fluoride route[i]**.*'' was successfully used for the synthesis of a series of new framework structure types. Often. SDA are ion pairs with a quarternary ammonium cation and fluoride anions as constituents. The structure-directing influence of the fluoride anion is such that the framework structure type forms only in its presence. The ammonium cation yields a different framework structure type. This finding led to a new direction in the research of the synthesis of porosils, the use of combinations of SDA for different structural subunits. Whereas the ammonium cation occupies the major void in the host framework. the fluoride anion resides in small cages that are rigid. Typical cages are the cube, [4^6] cage (Fig. 3a), and the [5^8] cage. Therefore. the fluoride-containing cages are the backbones for the otherwise open host framework. Careful calcination also removes the fluoride anion and leads to porous silicas. The influence of help species on the structure-directing effect of guest species was also reported for atmospheric gases in combination with pyrroiidine as SDA.[24]

CONCLUSION

Developing new directions in the synthesis of porosils includes all of the possibilities outlined above. The design of new and the modification of existing SDA was successful until now. Attempts to use nonaqueous solvents and dry gels were intensively researched for some time. however. without a major breakthrough. The use of mixtures of SDA, in particular, the combination of small and spacious molecules. was promising in the recent past. High-throughput experimentation will increase the efficiency of experiments and help to explore the vast parameter space in porosil synthesis. The fact that we know all possible porosil framework structure types and that computational chemistry has the power to calculate the SDA–host framework interaction should provide powerful tools for the synthetic chemist.[25] This combination of database knowledge. computer modeling, and experimental synthesis has not yet been exploited, or. at least, there is no successful example of the beneficial collaboration of the different disciplines in a joint effort. However. modern and successful synthesis research on porosils must include these disciplines in order to achieve the long-awaited goal of tailored synthesis of porous silicas.

INTRODUCTION

Cucurbituril (cucurbit[6]uril, or CB[6]) is a hexameric macrocyclic compound self-assembled from an acid-catalyzed condensation reaction of glycoluril and formaldehyde (Scheme 1). Although its synthesis was first reported by Behrend and coworkers in 1905,[1] its chemical nature and structure were unknown until they were revealed by Mock and coworkers in 1981.[2] CB[6] has a cavity of ~ 5.5 Å diameter, accessible from the exterior by two carbonyl-laced portals of ~ 4 Å diameter. Although the size of the cavity is similar to that of a-cyclodextrin (!-CD), the highly symmetrical structure with two identical openings distinguishes CB[6] from α-CD. In a similar way to CDs, the hydrophobic interior of CB[6] provides a potential site for inclusion of hydrocarbon molecules. Unlike CDs, however, the polar carbonyl groups at the portals allow CB[6] to bind ions and molecules through charge-dipole and hydrogen-bonding interactions. The rigid structure and capability of forming complexes with molecules make CB[6] attractive as a synthetic receptor[3,4] and as a building block for the construction of supramolecular architectures.[5] Recent syntheses of cucurbituril homologues (cucurbit[*n*]uril) and derivatives opened up new opportunities in supramolecular chemistry of cucurbituril. In this entry, we briefly survey recent developments of supramolecular chemistry based on cucurbituril, its homologues and derivatives.

CUCURBITURIL (CUCURBIT[6]URIL)

Host–Guest Chemistry with Organic Molecules

Host–guest chemistry using CB[6] as a host has been studied mostly in strongly acidic aqueous solution, typically a 1:1 mixture of formic acid and water, because CB[6] is sparingly soluble in virtually any solvent except strongly acidic aqueous solution. Thus, early studies on the host–guest chemistry of CB[6] were mainly focused on the complexation with alkyl amines or diamines, which exist as ammonium ions in acidic solution.[6] The thermodynamics and kinetics of the binding were investigated.[7] The binding affinities of selected amines are summarized in Table 1 and a more extensive collection of such data is available.[4] Charge–dipole interaction as well as hydrogen bonding between the protonated amine group of the guest and the carbonyl groups at the entrance of CB[6] is responsible for the high affinity of these substrates. In addition, hydrophobic interactions between the alkyl group and the inside wall of the cavity contribute to the stability of these host–guest complexes. Shape-selectivity associated with the inclusion phenomenon is demonstrated by the fact that par-a-substituted benzene rings are able to access the cavity, whereas *ortho-* and ineta-substituted counterparts are not included (Table 1). Complex formation between CB[6] and other organic substrates, including alcohols. acids. nitriles. nonionic surfactants. and polyethylene glycols was recently studied by calorimetric titration in aqueous formic acid (50 vol%) solution.[7]

The kinetics of the host–guest complexation between cyclohexylmethylamine and CB[6] was recently investigated in a wide range of pH.[8] Interestingly. the rate of inclusion is related not to the thermodynamics of complexation but to the degree of protonation of the guest. The ingress of the protonated guest is retarded by the formation of an association complex. while the unprotonated guest can enter the cavity directly with a 20-fold larger rate.

Despite the poor solubility of CB[6] in pure, neutral water, it dissolves appreciably in neutral aqueous solutions containing alkali metal ions in high concentration. For example, $\sim 6.6 \times 10^{-2}$ mol of CB[6] dissolves in 1/L of 0.2 M Na_2SO_4 solution.[9] The markedly increased solubility has been ascribed to binding of alkali metal ions to the carbonyl groups at the portal. The X-ray structure of CB[6] crystallized from Na_2SO_4 solution reveals that two sodium ions are coordinated to each portal, and these ions along with water molecules cover each portal of CB[6] like "a lid on a barrel." Encapsulation of simple organic molecules such as tetrahydrofuran (THF), cyclopentanone, furan. and benzene in the cavity of CB[6] in alkali metal ion solutions was studied.[9] The inclusion of xenon into CB[6] dissolved in aqueous Na_2SO_4 solution was also investigated by ^{129}Xe- and 'H-NMR spectroscopy.[10] Xenon is reversibly trapped into

Encyclopedia of Supramolecular Chemistry

the cavity to form a 1:1 host–guest complex. The exchange between the free and the complexed xenon is slow on the ^{129}Xe-NMR time scale but fast on the ^{1}H-NMR time scale.

Fluorescence enhancement of 2-anilinonaphthalene-6-sulfonate (2,6-ANS) in aqueous Na_2SO_4 solution caused by the complexation with CB[6] was reported.[11] In addition. a solid precipitate formed from aqueous Na_2SO_4 solution containing 1-anilino-8-naphthalenesulfonate (1,8-ANS) and CB[6] is highly fluorescent.[12] The X-ray crystal structure of the fluorescent solid revealed that 1,8-ANS molecules are clathrated in the lattice of CB[6] molecules with an overall 1,8-ANS/CB[6] stoichiometry of 2:1.[12]

Sorption of Organic Dyes for Water Treatment

Potential applications of CB[6] for the treatment of waste water containing organic dyes from the textile industry were investigated. In general. the solubility of CB[6] decreases significantly when dyes are present. Buschmann and coworkers measured stability constants for the complexation of some organic dyes by CB[6] in formic acid/water solution.[13] Karcher et al. also investigated the sorption of reactive dyes by CB[6] and effects of metal salt concentration. pH, and temperature on the dye sorption.[14]

Quantitative Studies of Metal Ion Binding

The two carbonyl-fringed portals of CB[6] are potential binding sites for metal ions. Buschmann and coworkers investigated the binding of alkali metal ions and other cations ($<5 \times 10^{-4}$ M) to CB[6] in aqueous solution by UV/Vis spectroscopy.[15] Assuming that CB[6] binds metal ions in a 1:2 stoichiometry and K_1 and K_2 are equal, they reported stability constants of Na^+ and K^+ complexes with log K of 3.69 and 3.96. respectively. Later. the metal ion binding was studied by calorimetry in a 50% formic acid/water solution where 1:1 complexes were observed.[16] The complexation of CB[6] with some transition metal ions was also reported.[17]

Reactions Inside CB[6]

Mock et al. reported that 1.3-dipolar cycloaddition of alkynes with alkyl azides, both substituted with a terminal amine group, yielding triazoles. is catalyzed by CB[6] in aqueous acid solutions.[18] The reaction proceeds with

large rate acceleration by a factor of 10^5 and high regiospecificity, yielding only 1,4-disubstituted triazoles, via formation of a ternary host–guest complex with CB[6] in solution.

Mechanically Interlocked Molecules and Their Supramolecular Assemblies

CB[6] has been used as a molecular bead to synthesize mechanically interlocked molecules such as rotaxanes and catenanes.[5] The first rotaxane containing CB[6] was synthesized by Kim and coworkers.[19] The highly efficient, one-pot synthesis involves the threading of CB[6] with sperminc followed by attaching a dinitrophenyl group to each end of the spcrmine unit to prevent dethreading. They also developed a novel strategy to polyrotaxane using metal-ion-directed self-assembly. It involves threading a CB[6] "bead" with a short "string" to form a stable pseudorotaxane, followed by joining the pseudorotaxanes with transition or lanthanide metal ions such as Cu^{2+},[20] Ag^{+} (Fig. 1a),[21] or Tb^{3+}[22] as "linkers" to organize into a polyrotaxane. A wide variety of one-dimensional (1D), 2D, and 3D polyrotaxanes were synthesized, and their structures wcre characterized by single-crystal X-ray crystallography.[23] This strategy was extended to the synthesis of molecular necklaces, in which a number of small rings arc threaded onto a large ring. In the synthesis of molecular necklaces, however, a metal complex with *cis* "vacant" coordination sites such as $Pt(en)(NO_3)_2$ (en = ethylenediamine), instead of simple metal salt, is used as a "90 degree angle connector." Molecular necklaces [4]MN (Fig. Ib) and [5]MN having three and four CB[6] beads threaded on trianglar and square frameworks, respectively, were synthesized.[24] Reaction between a prcorganized L-shaped pscudorotaxane, in which two molecular beads arc already in place, and metal ions or metal complexes, produced a molecular necklace [5]MN containing four molecular beads.[25]

(Pseudo)polyrotaxanes containing CB[6] thrcaded on organic: polymers wcrc also reported. Such (pseudo)polyrotaxanes were synthesized by interfacial polymerization of CB[6]/polyamine pseudorotaxane with diacid chlorides such as 1,6-hexanedioyl chloride (adipoyl chloride).[26] Steinke and coworkers recently reported a novel way to produce polyrotaxanes utilizing 1,3-dipolar cycloaddition between azide and alkyne inside the cavity of CB[6].[27] They also synthesized pseudopolyrotaxanes by threading CB[6] onto poly(iminohexamcthylene chloride).[28]

Dendrimcrs with terminal groups that are modified with pseudorotaxanes were reported.[29] Kim et al. attached diaminobutane units at the terminals of polypropylimine (PPT) dendrimers (G1–G5), and then threaded CB[6] onto the diaminobutane terminals to produce pseudorotaxane-terminated dendrimers. The structures and properties of the dendrimers can be reversibly changed by threading and dethreading CB[6].

Interaction of (pseudo)rotaxanes containing CB[6]/polyamine with DNA was investigated by Nakamura and Kim.[30] Pscudorotaxancs containing a CB[6] bead threaded on polyamines with an acridinc terminal bind to DNA strongly. Furthermore, the activities of polyamines, such as spermine and spermidine, which are known to accelerate transcription and nuclcasc activities, are greatly affected by their formation of pseudorotaxanes with CB[6].

Molecular Switches and Machines

One of the potential applications of mechanically interlocked molecules is construction of molecular-scale devices such as molecular machines and switches. [2](Pseudo)rotaxanes containing CB[6] were studied along

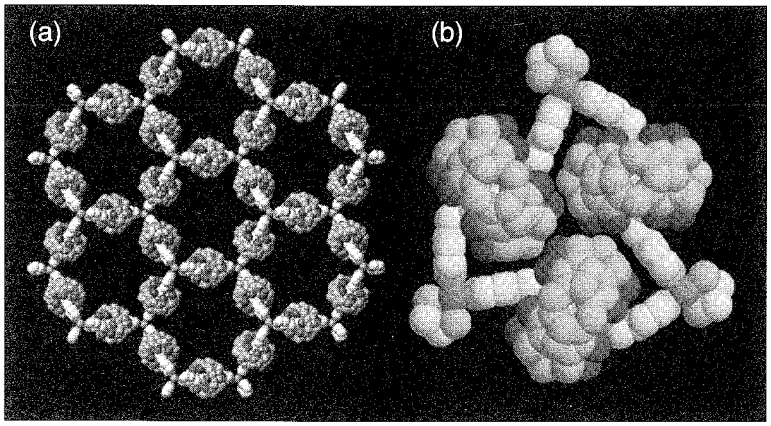

Fig. 1 X-ray crystal structures of a two-dimensional polyrotaxane (a) and a molecular necklace [4]MN (b). (*View this art in color at www.dekker.com.*)

this line. In 1990. Mock reported a pseudorotaxane-based molecular switch consisting of a CB[6] "bead" and a triamine "string" $PhNH(CH_2)_6NH(CH_2)_4NH_2$.[31] At low pH, the "bead" resides at the protonated diaminohexane site. because CB[6] forms a more stable complex with diprotonated diaminohexane than with diprotonated diaminobutane. Upon deprotonation of the aniline nitrogen (pK_a = 6.7). however, the "bead" migrates to the diprotonated diaminobutane site, because binding with the monoprotonated diaminohexane is weaker. Recently, Kim et al. extended this work to design a fluorescent molecular switch that can signal the change in the "bead" position by color and fluorescence changes.[32] They also reported another bistable [2]rotaxane containing CB[6] that behaves as a kinetically controlled switch.[33]

Other Supramolecular Assemblies Formed with CB[6] end Metal Ions or Metal Complexes

CB[6] and K^+ or Rb^+ ion form a columnar one-dimensional coordination polymer in the solid state, in which CB[6] molecules stack atop one another through coordination of their carbonyl groups to K^+ or Rb^+ ions in between. In the case of Rb^+, the coordination polymer chains are arranged in such a way as to produce a honeycomb-like structure with large. linear hexagonal channels parallel to the polymer chains.[34] Supramolecular assemblies of CB[6] and transition metal ion clusters were investigated. For example, an infinite one-dimensional chain structure was reported, in which a double cube cluster cation $\{[M_3E_4(H_2O)_7Cl_2]_2Hg\}^{4+}$ (M = Mo, W; E = S. Se) is sandwiched between two CB[6] units via hydrogen bonds.[35]

CUCURBITURIL HOMOLOGUES

Syntheses, Structures, and General Properties

Cucurbituril homologues having glycoluril units fewer or greater than six were recently reported by Kim and coworkers.[36] The cyclization at lower temperatures (75–90°C) compared to that (> 110°C) employed in the conventional synthesis of CB[6] allows formation of significant amounts of other CB homologues besides CB[6] (Scheme 1). The homologues (cucurbit[*n*]uril or CB[*n*], *n* = 5–8) can be isolated by a series of fractional crystallizations. The higher homologues (CB[*n*], *n* = 9–11) were also detected by mass spectrometry, although they have not yet been isolated due to the very low level of production. Recently. Day and coworkers examined a wide range of reaction conditions. including acid type. acid concentration, reactant concentrations. and temperature to probe the mechanism as well as to optimize the yield of individual CB homologues.[37]

The CB homologues CB[5], CB[7], and CB[8] were fully characterized by various spectroscopic methods. including x-ray crystallography (Fig. 2).[36] Compared in Table 2 are some structural parameters of the CB homologues. As we go from CB[5] to CB[8], the mean diameter of the internal cavity increases progressively from ~ 4.4 to ~ 8.8 Å. Likewise, the oxygen-bounded portal increases its mean diameter from ~ 2.4 to ~ 6.9 Å. In terms of cavity size, CB[6], CB[7], and CB[8] are close to α, β, and γ-CDs, respectively. The different cavity size of the CB homologues is manifested in their host–guest chemistry. Protonated 2,6-*bis*(4,5-dihydro-1*H*-imidazol-2-yl)naphthalene is too large to be included in CB[6] but forms a 1:1 host–guest complex with CB[7] and a 1:2 complex with CB[8].[36]

Similar to CB[6], solubility of CB homologues. except CB[7], is extremely low in common solvents. including water. However, CB[7] has a moderate solubility in water (3×10^{-2} M),[38] which is comparable to that of β-CD. All CB homologues (n = 5–8) have high thermal stability in the solid state. No decomposition is observed up to 420°C for CB[n] (n = 5, 6, and 8), although CB[7] starts decomposing at a somewhat lower temperature (370°C).[38,39] Prolonged heating of CB[8] in concentrated HCl at 100°C produces the smaller hornologues. while smaller CB homologues do not show interconversion or detectable decomposition.[37]

Cucurbit[5]uril

Although cucurbit[5]uril (CB[5]) became available only recently, along with other CB homologues. its derivative decamethylcucurbit[5]uril (Me-CB[5])[40] was known since 1992, and its chemistry was studied (see *Cucurbituril Derivatives*). Because CB[5] and Me-CB[5] have essentially identical cavity structures, their chemistry is also expected to be the same.

Cucurbit[7]uril

Nau and Marquez examined the photophysicai properties of 2,3-diazabicyclo-[2,2,2]oct-2-ene (DBO) inside CB[7] to characterize the chemical environment of the CB[7] cavity.[41] The encapsulation of DBO by CB[7] strongly affects the photophysical properties of DBO. Interestingly, the polarizability inside CB[7] cavity is even lower than that in perfluorohexane, and thus, the environment of the cavity inside CB[7] is closer to the gas phase than the solution phase.

Kim et al. discovered that CB[7] forms a stable 1:1 inclusion complex with methylviologen dication (MV^{2+};

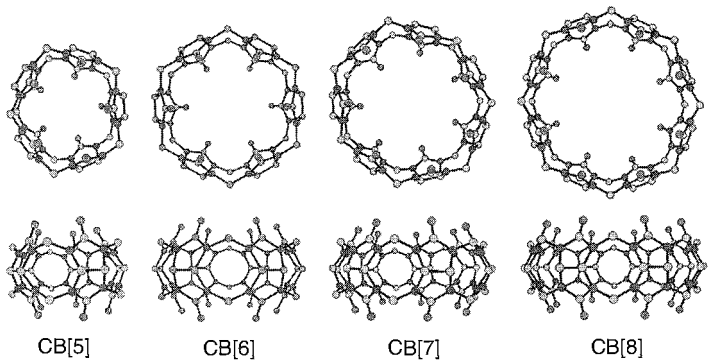

Fig. 2 X-ray crystal structures of cucurbit[*n*]uril (*n* = 5–8)

log K = 5.30).[42] It is in sharp contrast to the fact that β-cyclodextrin, which has a similar cavity size, does not bind MV^{2+} appreciably. Unusual electrochemical behavior of the inclusion complex was also observed. Inclusion of o-carborane in CB[7] was recently reported.[43]

Cucurbit[8]uril

The selective inclusion of a hetero-guest pair in CB[8] driven by charge–transfer interaction between the electron-rich and electron-deficient guests. such as methylviologen and 2,6-dihydroxynaphthalene or 1.4-dihydroxybenzene was reported (Fig. 3a).[44] The 1:1:1 ternary complexes exhibit largely red-shifted charge–transfer absorptions with a concomitant high increase in intensity and the strong fluorescence quenching of 2.6-dihydroxynaphthalene compared to those of a 1:1 mixture of the guest molecules in the absence of CB[8].

Macrocycles within macrocycles were synthesized; where tetraazamacrocycles and their metal complexes are encapsulated within CB[8].[45] The 1:1 inclusion complexes cyclen·4HCl-CB[8], cyclam·4HCl-CB[8], and [Cu(cyclen)(H_2O)](NO_3)$_2$-CB[8] (Fig. 3b) were characterized by X-ray crystallography. An electrochemical study shows that the encapsulation of Cu(cyclen) in CB[8] increases the stability of the Cu(I) state but considerably slows the electron transfer between the electrode and the redox center.

The synthetic utility of CB[8] as a reaction vessel was also demonstrated. The [2 + 2] photoreaction of *trans*-diarninostilbene dihydrochloride proceeds with large rate acceleration and high stereoselectivity via formation of a stable 1:2 host–guest complex with CB[8] in solution.[46]

Table 2 Structural parameters for cucurbit[*n*]uril (*n* = 5–8).[a]

	CB[5]	CB[6][b]	CB[7]	CB[8]
Portal diameter (Å)	2.4	3.9	5.4	6.9

CUCURBITURIL DERIVATIVES

Decamethylcucurbit[5]uril

The first cucurbituril derivative decamethylcucurbit[5]uril (Me-CB[5]) (Chart I) was synthesized from dimethylglycoluril and formaldehyde in 1992.[40] The X-ray structural analysis shows a cavity of 4 Å in diameter and two identical portals of ~ 2.5 A in diameter. Bradshaw and coworkers studied complexation of Me-CB[5] with metal ions in 50% formic acid/water solution by calorimetric and potentiometric methods.[47] Me-CB[5] binds most metal ions in a 1:1 stoichiometry in the acidic solution. Interestingly, Me-CB[5] shows exceptionally high affinity for Pb^{2+} ion (log K > 9). which is mainly due to the size match between Pb^{2+} and Me-CB[5] portals. The pK_a value (9.56) for protonation of Me-CB[5] indicates that Me-CB[5] behaves as a base in an aqueous solution.

The encapsulation of small molecules, such as N_2, O_2, methanol, or acetonitrile in ammonium ion complexed Me-CB[5] in the gas phase. was observed using electrospray ionization Fourier transform mass spectrometry.[48] The guest is released in the gas phase upon removing an ammonium ion "lid" using 18-crown-6. The rate of guest release depends on the size of the guest molecules.

Cyclohexanocucurbit[*n*]uril (*n* = 5 and 6)

Cyclohexanocucurbit[*n*]uril (n = 5 and 6: CB*[5] and CB*[6]) (Chart 1) were recently synthesized from

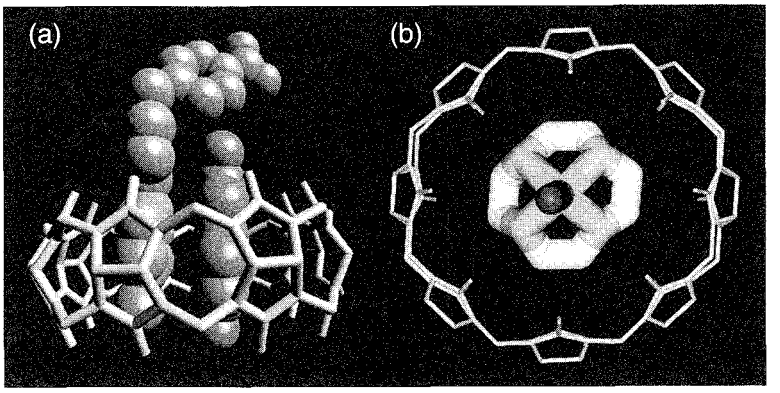

Fig. 3 X-ray crystal structures of inclusion complexes of a hetero-guest pair (a) and Cu(cyclen) (b) in CB[8]. (View this art *in* color *at www.dekker.com.*)

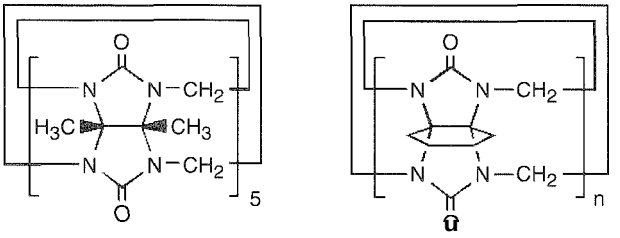
cyclohexanoglycoluril and formaldehyde.[49] Their X-ray crystal structures reveal 5 and 6 fused cyclohexane rings, respectively, decorating outside the "equators" of CB[n] (n = 5 and 6). The portal and cavity sizes of CB*[5] and CB*[6] are essentially the same as those of CB[5] and CB[6], respectively.

Remarkably, the new CB derivatives CB*[5] and CB*[6] are soluble in common solvents, such as water, methanol, and DMSO, and moderately soluble in ethanol, DMF, and acetonitrile. They are both more soluble in water ($\sim 2 \times 10^{-1}$ mol L^{-1}) than in organic solvents ($\sim 3 \times 10^{-2}$ mol L^{-1} or less) despite the presence of the equator-decorating fused cyclohexane units. The solubility of CB*[6] in water is comparable to that of x-CD.

A study of the complex formation of CB*[5] with K^+ ion in neutral water using titration calorimetry showed that CB*[5] binds K^+ ion in a 1:2 stoichiometry. The utility of water-soluble CB*[6] was also illustrated by formation of a stable 1:1 host–guest complex with acetylcholine in neutral water. The good solubilities of CB*[5] and CB*[6] in organic solvents make their applications in ion-selective electrodes (ISEs) possible. Membrane electrodes prepared with CB*[5] and CB*[6] behave as ISEs for sensing Pb^{2+} ion and acetylcholine, respectively, with good sensitivity and selectivity.



Decamethylcucurbit[5]uril (Me-CB[5])

Cyclohexanocucurbit[n]uril (CB*[n]; n = 5 and 6)

Chart 1.

CONCLUSION

Cucurbit[6]uril is attractive not only as a synthetic receptor but also as a building block for supramolecular assemblies. Recent syntheses of its homologues and derivatives further broadened the scope of cucurbituril chemistry.[50] Many challenges remain, including direct functioualization of CB[n] and synthesis of CB analogues, particularly chiral ones. Considering what has been done with cyclodextrins, nevertheless, we believe that the CB homologues and derivatives provide new opportunities in many areas of supramolecular chemistry, including recognition, catalysis, separation, transport, and many others.

Cyclodextrins

József Szejtli
CYCLOLAB, Cyclodextrin Research and Development Laboratory Ltd., Budapest, Hungary

INTRODUCTION

Cyclodextrins (CD) are the most widely used molecules that form host–guest-type inclusion complexes. Although as recently as the 1970s these long-known molecules were merely scientific curiosities. available only as expensive fine chemicals. by the end of the twentieth century, they we e produced and used industrially in thousand-tons amounts.

The spectacular development of CD technology relies on a series of reasons:

- They are seminatural products. produced from a renewable natural material (starch) by employing a relatively simple enzymic conversion.
- They are produced in thousand ton/year amounts by environment-friendly technologies.
- Their initially high prices have dropped to levels where they become acceptable for most industrial purposes. Through their inclusion complex-forming ability. important properties of the complexed substances can be modified significantly. This unprecedented "molecular encapsulation'' is widely utilized in many industrial products. technologies, and analytical methods. Their toxic effects are of secondary character and can be eliminated by selecting the appropriate CD type or derivative or mode of application.
- They can be consumed by humans as ingredients of drugs. foods, or cosmetics.

STRUCTURAL FEATURES OF CYCLODEXTRINS

Cyclodextrins comprise a family of three well-known industrially produced major. and several rare. minor cyclic oligosaccharides. The three major cyclodextrins are crystalline, homogeneous. nonhygroscopic substances. which are torus-like macro-rings built up from glucopyranose units. The α-cyclodextrin (Schardinger's α-dextrin, cyclomaltohexaose. cyclohexaglucan, cyclohexaamylose, αCD, ACD, C6A) comprises six glucopyranose units, βCD (Schardinger's β-dextrin, cyclornaltoheptaose, cycloheptaglucan, cycloheptaamylose, βCD, BCD. C7A) comprises seven such units, and γCD (Schardinger's y-dextrin. cyclomaltooctaose, cyclooctaglucan, cyclooctaamylose. γCD, GCD, CXA) comprises eight such units (Fig. 1). The most important characteristics of the CDs are summarized in Table 1.

The nomenclature of CDs is not exact. Maltose is a disaccharide. i.e., a cyclomaltopentaose could be interpreted as a 10-glucopyranose-containing cyclic oligosaccharide. Otherwise. this is the five-membered pre-αCD. How would a four-membered CD be named?

Fortunately, the practically important. industrially produced CDs are the E-, p-, and γCDs. Their names are unambiguous and need not be changed. A complete and unanimous nomenclature was suggested by Lichtenthaler and Immel,[1] e.g., the pre-αCD is named cyclo-α(1 → 4)-glucopentaoside. This nomeilclature is recommended for the so-called minor CDs as well as for any other cyclic oligosaccharides.

As a consequence of the $^4C_1$ conformation of the glucopyranose units. all seconclary hydroxyl groups are situated on one of the two edges of the ring, whereas all the primary ones are placed on the other edge. The ring, in reality. is a cylinder, or better said. a conical cylinder. which is frequently characterized as a doughnut or wreath-shaped truncated cone. The cavity is lined by the hydrogen atoms and the glycosidic oxygen bridges. respectively. The nonbonding electron pairs of the glycosidic–oxygen bridges are directed toward the inside of the cavity. producing a high electron density there and lending to it some Lewis-base characteristics.

The C–2–OH group of one glucopyranoside unit can form a hydrogen bond with the C–3–OH group of the adjacent glucopyranose unit. In the βCD molecule, a complete secondary belt is formed by these H-bonds. and therefore, the βCD is a rigid structure. This intramolecular hydrogen-bond formation is probably the explanation for the observation that βCD has the lowest water solubility of all CDs.

The hydrogen-bond belt is incomplete in the αCD molecule. because one glucopyranose unit is in a distorted position. Consequently. instead of the six possible H-bonds. only four can be established simultaneosly. The γCD is a noncoplanar, more flexible structure. and therefore. it is the more soluble of the three CDs.[2–8]

Shown in Fig. 2 is a sketch of the characteristic structural features of CDs. On the side where the secondary

hydroxy! groups are situated, the cavity is wider than on the other side, where free rotation of the primary *hydroxyls reduces the effective diameter of the cavity.*

For a *long time.* only *the three parent (or major)* CDs (α-, β-, *and* γCD) *were known and well characterized.*

In *the* 1990s, *a series of larger* CDs *was* isolated *and studied. For example. the nine-membered* δCD *was isolated from the* commercially *available CD-conversion mixture by chromatography. The 6CD has greater aqueous solubility than the* βCD *but less than that of* α- *and* γCD. *It was the least stable* among *the* CDs *known at that time; their acidic hydrolysis* rate *increases in the order of* αCD<βCD<γCD<δCD. *The* δCD *did not show significant solubilization effect on slightly soluble drugs* in *water. except in the cases of some large guest molecules, like spironolactone and digitoxin.*

The larger CDs *are not regular cylinder-shaped structures. They are collapsed. and their real cavity is* even smaller *than that in* the γCD. *The proposed principal driving force of the complex formation, the substitution of the high-enthalpy water molecules in the CD-cavity, is weaker in the case of larger* CDs, *and therefore. their utilization as inclusion-complexing agents will probably* remain *restricted.*

PRODUCTION OF CDS

The cyclodextrin glucosyl *transferase enzyme (CGT-ase)* is *produced by a large number of microorganisms, like Bacillus macerans, Klebsiella oxytoca, Bacillus circulans. Alkalophylic bacillus No. 38-2. etc. Genetic engineering provided more active enzymes, and probably, in the future. these enzymes will be used for industrial* CD *production.*[7]

The first step in CD *production is the liquefaction of starch at an elevated temperature. To reduce the viscosity of the concentrated (around 30% dry weight) starch solution, it has to be hydrolyzed to an optimum degree. The prehydrolyzed starch* must *not contain glucose, or low-molecular oligosaccharides, because they strongly reduce the yield of the* CDs *formed. After cooling to the optimum temperature, the* CGT-ase enzyme *is added to the starch solution. In the so-called nonsolvent technology, the* α-, β-, *and* γCDs *formed have to be separated from the complicated partially hydrolyzed mixture.* In *the case of solvent technology. an appropriate* complex-*forming agent is added to the* conversion *mixture. If toluene is added to this system. the* toluene–βCD-formed *complex is separated immediately. and the conversion is shifted toward the formation of* βCD. *If n-*decanol *is added to the conversion mixture. mainly* αCD *will be produced. while in the case of cyclohexadecenol. the main product is* γCD. *Various other complex-forming agents can be used. The selection depends on price, toxicity. and explosivity,* and most *importantly, on the efficiency of the removal of the solvents* from *the crystalline end product. The insoluble complexes are separated from the conversion mixture by filtration. The removal of the solvents from the filtered and washed complex is generally* made *after suspending it in water by distillation or extraction. The aqueous solution obtained after removal of the* complexing *solvent is treated with activated carbon and then filtered. The cyclodextrins are then separated* from *this solution by crystallization and filtration. The* homogeneity *of the industrially produced cyclodextrins* is *generally better than 99%.*

CYCLODEXTRIN DERIVATIVES

For many reasons *(price. availability. approval status, cavity dimensions, etc.).* βCD *is the* most *widely used and*

Table 1 Characteristics of α-, β-, and γCD

	a	β	γ

Adiabatic compressibility in aqueous solutions ml.mol^{-1} bar^{-1}.10^4	7.2	0.4	−5.0

represents at least 95% of all CDs produced and consumed. It is used for many purposes; however. its anomalous low aqueous solubility (and the low solubility of most of its complexes) is a serious barrier in its wider utilization. Fortunately by chemical or enzymatic modifications. the solubility of all CDs can be strongly improved, and instead of the 18 g/L aqueous βCD solutions 500 g (or more)/L aqueous βCD derivative solutions can easily be prepared.

In the cyclodextrins. every glucopyranose unit has three free hydroxyl groups that differ in their functions and reactivity. The relative reactivities of C(2) and C(3) secondary, and the C(6) primary hydroxyls, depend on the reaction conditions (pH. temperature, reagents). In βCD, 21 hydroxyl groups can be modified by substituting the hydrogen atom or the hydroxyl group with a large variety of substituting groups (like alkyl-, hydroxyalkyl-. carboxyalkyl-, amino-. thio-. tosyl-, glucosyl-, maltosyl-, etc., groups). And. thousands of ethers. esters. anhydro- deoxy-, acidic, basic. etc.. derivatives can be prepared by chemical or enzymatic reactions.[110] The aim of such derivatizations may be as follows:

To improve the solubility of the CD derivative (and its complexes).
- To improve the fitting. or the association between the CD and its guest, with concomitant stabilization of the guest, reducing its reactivity and mobility.
- To attach specific (catalytic) groups to the binding site (e.g., in enzyme modeling).

To form insoluble, immobilized CD-containing structures, polymers. e.g., for chromatographic purposes.

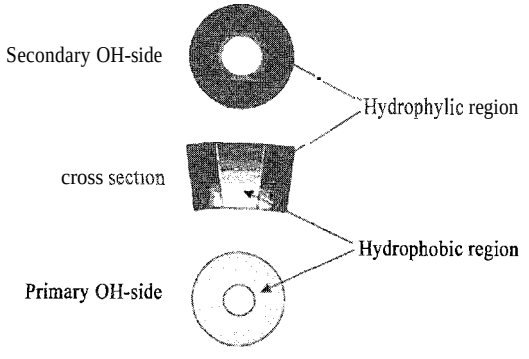

Fig. 2 Schematic representation of the hydrophilic/hydrophobic regions of a CD molecule. (*View this* art *in color at www. dekker.com.*)

From the thousands of CD derivatives described in hundreds of scientific papers and patents, only a few can be taken into consideration for industrial-scale synthesis and utilization. Complicated muitistep reactions, using expensive. toxic. environment-polluting reagents, and purification of the products by chromatography are feasible for preparing derivatives only on laboratory scale. To produce tons, at an acceptable price. only about a dozen of the known CD derivatives can be taken into consideration.

Among industrially produced. standardized, and available (even in ton amounts) βCD derivatives. the most important are the heterogeneous, amorphous. highly water-soluble methylated βCD and 2-hydroxypropylated βCDs. Due to their heterogeneity, these products cannot be crystallized, which is an important advantage (e.g., at

producing liquid drug formulations). More important. however. is that these derivatives cannot form crystalline cholesterol complexes; because the nonmodified βCD has a particularly high affinity to cholesterol. If administered parenterally, it is not metabolized in the organism but forms insoluble cholesterol complex crystals in the kidneys, resulting in nephrotoxicity.

The first hydroxypropyl-βCD and hydropropyl-γCD to contain drug formulations are already approved and marketed in several countries.

A methylated βCD is more hydrophobic than the βCD, therefore, it forms a more stable (but soluble) complex with cholesterol. Its affinity to cholesterol is so strong that it extracts cholesterol from the blood cell membranes: resulting in hemolysis in around 1 mg/mL concentration.

A particular inethylated βCD, the heptakis (2,6-di-*O*-methyl-βCD, called DIMEB) is a crystalline product. It is extremely soluble in cold water but insoluble in hot water, therefore, its purification, and also the isolation, of its complexes is technically simple. Up to now, no better solubilizer was found among the CDs. It is available in better than 95% isomeric purity for injectable drug formulation. but for widespread industrial application, the cheaper randomly methylated βCD (called RAMEB) is produced and marketed.

Reacting βCD with starch in the presence of pullulanase enzyme results in the attachment of one or two maltosyl or glycosyl groups to the primary side of the CD ring with α-1,6 glycosidic linkage. The product is the so-called "branched" CD (mono- or dimaltosyl or mono- or diglucosyl CD). which is very soluble in water, being a heterogeneous, noncrystallizable substance. It is produced and used in the food industry, mainly in Japan. for example, for production of stable flavor-powders.

There is also increasing interest in the per-acyl-CDs. All acetylated CDs from per-acetyl to per-octanoyl esters were studied partly as retard drug carriers (to retard the drug release for absorption from its pharmaceutical formulation). partly as bioadhesive, film-forming substances to be used in transdermal drug delivery systems.

The heptakis-(sulfobutyl)-βCD is very soluble in water. noncrystallizable. and even at extremely high doses seems to be free from any toxic side effects. It can be used as a chiral separating agent in capillary zone electrophoresis. But, the aim of intensive research is to develop it as a parenteral drug carrier, for preparation of aqueous injectable solutions of poorly soluble drugs.

The GD sulfates possesses many similar properties as heparin. without its anticoagulating effect. Apparently, they can reduce the blood supply of tumor tissues through inhibiting the formation of new arteries.

The monochloro-triazinyl βCD is produced on industrial scale from CDs and cyanuric chloride. It is reactive with cellulose fibers in alkaline medium (see the entry *Cyclodextrins: Applications).*

To elongate the actual CD cavity, substituents are attached to the primary or secondary side. This elongation may be hydrophylic, in which case: hydroxyalkyl groups are attached to the ring, or it might be hydrophobic, for example, by substituting the primary hydroxyl groups with long fatty-acid chains: "medusa"-like molecules can be prepared. These molecules behave as detergents while retaining their complex-forming ability. In the coming years. it will be decided how these derivatives may be utilized.

The chair conformation of the CD ring can be modified by inverting the position of some hydroxyl groups. For example, eliminating the tosyl group in alkaline medium from a CD-tosyl derivative, 2,3-anhydro derivatives can be prepared. When opening the anhydro ring, one hydroxyl group will take up an inverted position, and in this way, cycloaltrins are formed. By eliminating an appropriate leaving group from the primary side, 3,6-anhydro-CDs are formed. Because of the twisted conformation of the anhydro-glucopyranose unit, the properties of CDs (for example, their solubility) are strongly changed.

It is possible to close one side of the CD cavity, for example, by overbridging the primary or secondary side with an appropriate bifunctional substituent. It is expected that these overbridged CDs will form more stable complexes with certain guests.

The essence of photodynamic tumor therapy is that particular compounds have to be delivered to the tumor tissues. which upon the effects of strong light, become toxic through isomerization or splitting, etc. In this case, upon strong light irradiation, the photosensitive molecules will become toxic just for the tumor cells. For such targeting of the drug, very stable (10^5–10^7 M^{-1}) complexes are needed. The duplex homo- or heterodimers of CDs (constructed only from one or two different CDs) form complexes that are more stable by orders of magnitude than those of the single CDs. By interconnecting two CDs with appropriate bridges, such duplex CD derivatives were prepared that can form stable complexes with photosensitive posphyrinoid structures and transport them to the target organs.

In "antennae"-bearing CDs, receptor-specific oligosaccharide units are attached to the CDs, which will bond only to specific receptors in the living organisms. The aim of these efforts is to synthesize a receptor-targeting carrier, that is, the drug complexed with an antenna-bearing duplex CD would transport the specific drug solely to the target organ.

The most complicated CD derivatives are synthesized for enzyme-modeling experiments. By dimerizing amino acid CD derivatives. hydrolase enzyme models were prepared. that approximate the activity of natural enzymes.

A dozen CD derivatives of various types are used in gas chromatography. liquid chromatography: and capillary zone electrophoresis.

For other industrial purposes where toxicological demands do not play a decisive role, epichlorohydrin crosslinked. hydroxyethylated, or sometimes apparently fancy (but justified by their usefulness) mixed ethers–esters, like heptakis (2,6-di-*O*-methyl)-3-*O*-trifluoracetyl-βCD and similar derivatives are produced and utilized.

It seems to be probable that for drug carrier purposes, four or five different CDs will be developed and produced in the future, because no one of them alone is able to fulfill all of the strict requirements, which are usual in case of a parenteral drug carrier.

For other industrial purposes. the production of hundreds of tons of alkylated, hydroxyalkylated, and acylated CDs is forecast by the end of the first decade of the twentieth century.

CYCLODEXTRIN COMPLEXES

In an aqueous solution, the slightly apolar cyclodextrin cavity is occupied by water molecules that are energetically unfavored (polar–apolar interaction) and, therefore, can be readily substituted by appropriate "guest molecules" that are less polar than water (Fig. 3). The dissolved cyclodextrin is the ''host'' molecule. and part of the "driving force" of the complex formation is the substitution of the high-enthalpy water molecules by an appropriate "guest" molecule. One, two. or three cyclodextrin molecules contain one or more entrapped "guest" molecules. Frequently, the host:guest ratio is 1:1. This is the essence of "molecular encapsulation."

This is the simplest and most frequent case. However 2:1, 1:2, 2:2, or even more complicated associations, and higher-order equilibria exist, almost always simultaneously.

The inclusion complexes formed can be isolated as stable crystalline substances. Upon dissolving these complexes, an equilibrium is established between dissociated and associated species. and this is expressed by the complex stability constant K_a. The association of the CD and guest (D) molecules, and the dissociation of the CD/guest complex formed is governed by a thermodynamic equilibrium:

$$\mathrm{CD} + \mathrm{D} \rightleftharpoons \mathrm{CD.D} \tag{1}$$

$$K_{1:1} = \frac{[CD.D]}{[CD][D]} \tag{2}$$

The most important primary consequences of the interaction between a poorly soluble guest and a CD in aqueous solution are as follows:

1. The concentration of the guest in the dissolved phase increases significantly, while the concentration of the dissolved free CD decreases. In case of ionized guests or hydrogen-bond-establishing (e.g., phenolic) guest molecules. the solubility of the CD increases. After reaching the solubility limit of the complex, its precipitation begins.
2. The spectral properties of the guest are modified. For example, the chemical shifts of the anisotropically shielded atoms are modified in the NMR spectra. Also. when achiral guests are inserted into the chiral CD cavity. they become optically active and show strong induced Cotton effects on the circular dichroism spectra. Sometimes the maxima of the UV spectra are shifted by several nm, and fluorescence is strongly improved, because the fluorescing molecule is transferred from the aqueous milieu into an apolar surrounding.
3. The reactivity of the included molecule is modified. In most cases. the reactivity decreases. i.e., the guest is stabilized. but in many cases, the CD behaves as an

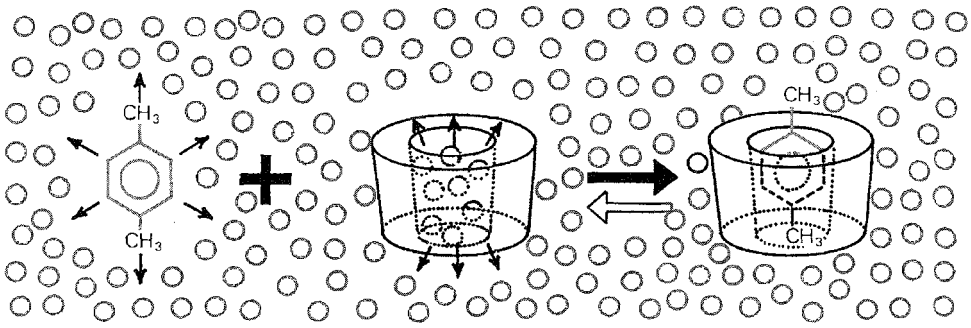

Fig. **3** CD inclusion complex formation. p-Xylene is the guest molecule. and the small circles represent the water molecules. (*View this art in color at www.dekker.com.*)

artificial enzyme. accelerating various reactions and modifying the reaction pathway.
4. The diffusion and volatility (in case of volatile substances) of the included guest decrease strongly.
5. The formerly hydrophobic guest, upon complexation. becomes hydrophilic, and therefore. its chromatographic mobility is modified.
6. In the solid state. the complexed substance is molecularly dispersed in a carbohydrate matrix forming a microcrystalline or amorphous powder, even with gaseous guest molecules.
7. The complexed substance in the solid state is effectively protected against any type of reaction, except that with the CD hydroxyls or reactions catalyzed by them.
8. Sublimation and volatility in the solid state are reduced to a low level.
9. The complex in the solid state is hydrophilic, easily wettable, and rapidly soluble.

When, in an aqueous system, the formation of the CD-inclusion coinplex can be detected, e.g., by NMR or circular dichroism or through a catalytic effect, this does not necessarily mean that a well-defined crystalline inclusion complex can be isolated. The two main components of the driving force of the inclusion process are the repulsive forces between the included water molecules and the apolar CD cavity on the one hand, and between the bulk water and the apolar guest, on the other hand. This second factor does not exist in the crystalline (dry) state. Therefore. it is common to find that the complex formation is convincingly proven in solution, but the isolated product is only a very fine dispersion of the CD and the guest.

The absolute majority of all practical applications of CDs (see *Cyclodextrins:* Applications) is based on their inclusion complex-forming capacity.

THE CD LITERATURE [REF. 9]*

By the end of 2003, the number of CD-related publications will be more than 26,000, representing more than 160,000 printed pages.

The only way to exploit the enormous potential hidden in the vast amount of literature is to summarize it in specific, well-limited critical reviews. More than 450 reviews were published on cyclodextrins. Less than 10% can be considered "critical evaluations." The majority comprise an uncritical compilation of that literature that the author was able to find and read (frequently only as an abstract), mixing significant, industrially important observations and products with unfounded speculations and nonfeasible ideas. While 30 years ago about four to five CD papers were published monthly, in 2002 just that many are published daily.

About 16% of all CD-relevant publications are dedicated to the fundamentals of cyclodextrin chemistry and technology, i.e., the physical and chemical properties of cyclodextrins, their enzymology, toxicology, production. and derivatives. This section also includes the numerous review articles on CDs.

Nearly 22% of the publications are dedicated to studies of the CD-inclusion phenomena. These works are generally not directly practice-oriented, dealing with energetics and kinetics of inclusion, x-ray, FT-IR, liquid- and solid-phase NMR, EPR, circular dichroism, Raman spectroscopy, enhancement of luminescence and phosphorescence. thermal analysis, interaction of CDs, with specific guest types, enzyme modeling with CDs and CD derivatives, preparation, analysis of cyclodextrin complexes, etc. These methods, as well as the correlation between the complexation and various structural and external parameters. form the basis for all practical applications of CDs.

The largest group of CD papers, nearly 25%, is dedicated to the pharmaceutical applications of CDs. The large number (nearly 5000) of drug/CD-related papers and patents is misleading, because many authors publish the same results in different journals under different titles but with virtually identical content. Rediscoveries are published frequently, simply because the authors did not read the earlier literature: in essence, they discovered something that was published earlier. Because of the many repetitions and the nonfeasible ideas. only about 30% of the published papers disclose new and significant results. Actually. only 7% of the CD-related papers are dedicated directly to the food, cosmetic, and toiletry applications of CDs, but at the same time, about 70% of all cyclodextrins produced are used in this field. The approval process for CD-containing products in this field is much simpler and faster than in the case of the drug/CD formulations. The amount of CD used in a cosmetic or toiletry product might be larger, by orders of magnitude, than the amount used in a drug.

Presently, about 11% of the CD literature is dedicated to the application of CDs in the chemical and biotechnological industries.

Approximately 25% of the CD literature involves the applications of cyclodextrins in analytical chemistry and diagnostic preparations. The analytical applications of CDs refer mainly to the application of cyclodextrins in gas chromatography. in high-performance liquid

*The most comprehensive source of CD literature is the *Cyclodextrin-News*, published monthly, since 1986.

chromatography. and in capillary zone electrophoresis. but some research was dedicated to thin-layer chromatography. to enhancement of UV-Vis absorption. luminescence/phosphorescence by CDs, and to increasing the sensitivity of the related analytical methods. Apparently. it is difficult to find a separation problem on an analytical scale that could not be solved by using the appropriate CD.

CONCLUSION

Cyclodextrins are, by far. the most important organic host molecules. The raw material for their production is starch: available, cheap. and its conversion to cyclodextrin is a relatively simple enzymatic process. A continuous, steady increase in production is expected in the following decade. both for CDs and their derivatives.

Cyclodextrins: Applications

József Szejtli
CYCLOLAB, Cyclodextrin Research and Development Laboratory Ltd., Budapest, Hungary

INTRODUCTION

The vast majority of cyclodextrin (CD) applications involve the formation of inclusion complexes between CDs and appropriate guest molecules. The complex formed (Fig. 1) may be used as follows:

Might be isolated as a solid inicrocrystalline or amorphous powder.

- Might be utilized in (mostly) aqueous solutions to modify solubility. spectral properties, reactivity, etc., of the guest.
- Complex formation might be utilized only as a transient, discriminating operation, as in catalysis or in chromatographic separation processes.

The actual arid potential uses of CDs in products and technologies seem to be inexhaustible.

The amount of relevant literature keeps steadily growing. An incoinplete list of relevant papers and patents would consist of at least 15 thousand references. which grows, at least in the next few years, by at least 1000 new entries per year. Therefore, the following few pages can give only a superficial impression of the enormous versatility of CD applications.

CYCLODEXTRINS IN DRUGS

The complexation of a drug molecule with a CD (Fig. 2) is generally considered in the following cases:

The drug is poorly soluble, and therefore, its bioavailability (upon oral, dermal. pulmonar, mucosal, etc.. applications) is incomplete or irregular.
The time to reach the effective blood level of the orally administered drug is too long because of the low dissolution rate. even in case of a complete absorption.

- There is no aqueous eye drop or injectable solution or other liquid formulation that can be prepared because of the low solubility.
The drug is chemically unstable. Because of its autodecomposition, polymerization, or degradation by atmospheric oxygen, absorbed humidity. light, etc., no marketable formulation with satisfactory shelf-life can be produced.
- The drug is physically unstable. Volatilization or sublimation results in losses. By migration. the originally homogeneous product becomes heterogeneous. or on account of its hygroscopicity, it liquifies by atmospheric humidity.
The acceptability of the drug is bad. because of bad smell, bitter, astringent, or irritating taste.
- The drug is a liquid, but its preferred pharmaceutical form would be a stable tablet. powder, aqueous spray, etc.
- The dose of the lipid(-like) poorly homogenizable drug is extremely low, and therefore. content uniformity of the product is problematic.
The drug is incompatible with other components of the formulation.
The relief of serious side effects (throat, eye, skin, or stomach ill-itation) is required.
- The extremely high biological activity (in case of drugs, requires extremely low doses) makes working with such powder dangerous.

The advantageous results of CD complexation of (CD-complexable) drugs are as follows:

Improved bioavailability from solid or semisolid formulations.
Enhanced stability and prolonged shelf life.
Reduced side-effects.
Uniform, easy-to-handle powders. even from liquids.
Aqueous. injectable solutions from poorly soluble drugs can be prepared (Fig. 3).

Speaking only of the numerous advantages of drug/CD complexation can be misleading, because there are just as many limiting factors that restrict the applicability of CDs to certain types of drugs. In addition. not all drugs are suitable for CD complexation. Many compounds cannot be complexed. or complexation results in no essential advantages. Inorganic compounds generally are not suitable for CD complexation. The exceptions include nondissociated acids (HCl, HI. H_3PO_4, etc.) halogens. and gases (CO_2, C_2H_4, Kr, Xe, etc.). Inorganic salts such as KCl, Fe-salts. etc., cannot be complexed.

General preconditions (which are not without exceptions) to form a medicinally useful CD complex of a drug molecule include characteristics such as a need for more

DOI: 10.1081/E-ESMC 120012796

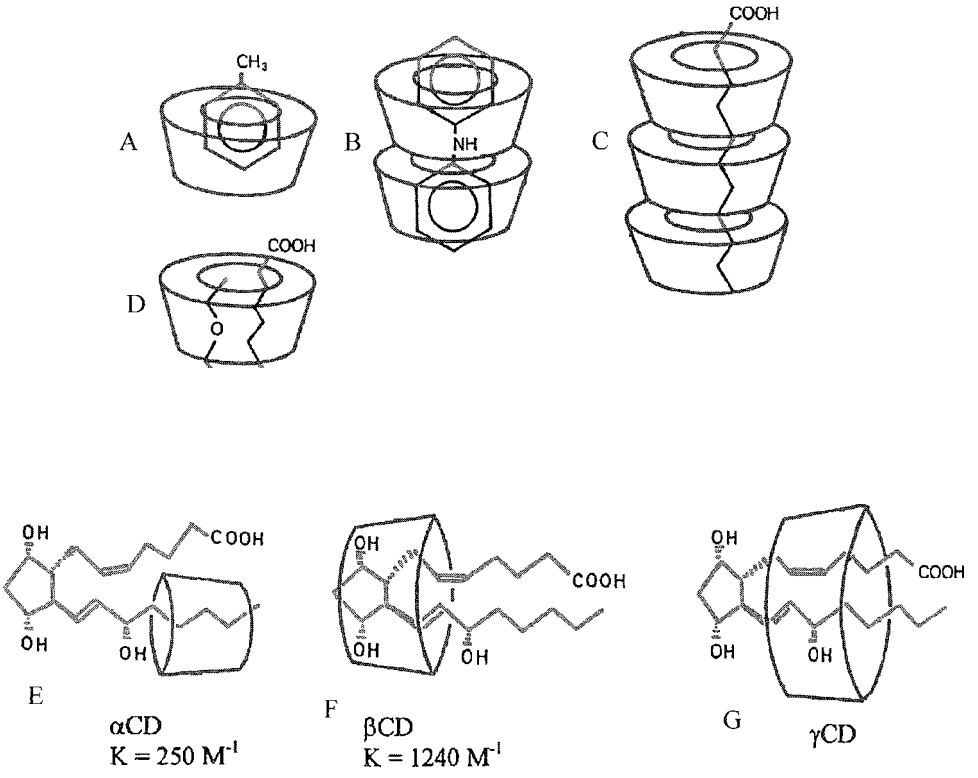

Fig. 1 Structures of various CD complexes. Toluene fits well into a βCD cavity. for diphenylamine, two βCDs form a "capsule." A long-chain fatty acid can take up three or more αCDs. A short-chain fatty acid and diethylether form a stable ternary complex. In the case of prostaglandin E_1 the αCD accomodates only the aliphatic chain of the unsaturated cyclic hydroxy-fatty acid. but it is enough to convert it into a water-soluble complex. The βCD can accomodate the cyclopentane moiety. but γCD is too wide for this guest. (*View this art in color. at www.dekker.com.*)

than five atoms (C, P, S, N) to form the skeleton of the drug molecule:a solubility in water of less than 10 mg/ml; a melting point temperature below 250°C (otherwise the cohesive forces between the molecules are too strong); a inolecule that consists of less than five condensed rings; and a molecular weight between 100 and 400 (with smaller molecules, the drug content of the complex is too low, and large molecules do not fit the CD cavity).

Strongly hydrophilic and moiecules that are too small or too large, such as peptides, proteins, enzymes, sugars. polysaccharides. etc., generally cannot be complexed. Nevertheless, when large water-soluble molecules contain appropriate complex-forming side chains, e.g., an aromatic amino acid in a polypeptide. they will react with CDs in aqueous solutions, resulting in modified solubility and stability. (For example, the stability of an aqueous solution of insulin, or many other peptides, proteins, hormones. and enzymes, is significantly improved in the presence of an appropriate CD.)

An unavoidable limiting factor in selecting the drug for complexation is the dose of the complex that has to be administered. A fundamental requirement is that the mass of a tablet should not exceed 500 mg. Because the drugs to be complexed have molecular weights between 100400, and the CDs have large molecular weights (972. 1132, and 1297 for α-, β-, and γCDs, respectively), a 100 mg complex contains only about 5–25 mg of active ingredient. If the single dose of a drug is not more than 25 mg. then even a complex of 5% active substance content can carry the necessary dose in a single tablet of 500 mg weight, otherwise the possibility of a powder sachet or sparkling-tablet formulation has to be taken into consideration. Thus, in the case of complex-forming drugs. the relationship of the required dose and the molecular weight determines the feasibility of oral administration in CD-complexed form.

Similarly, the volume of an injection should be less than 5 inl, or even better, not more than 2–3 ml, i.e., sufficient to dissolve the necessary amount of drug in 2–3 ml of 40% HPBCD (=2-hydroxypropyl-β-cyclodextrin) solution—800–1200 mg HPBCD can be used. In liquid formulations: the use of CD derivatives in excess is possible. In the case of Prostavasin injection, the molar ratio of prostaglandin E_1 to αCD is 1:11 (20 μg

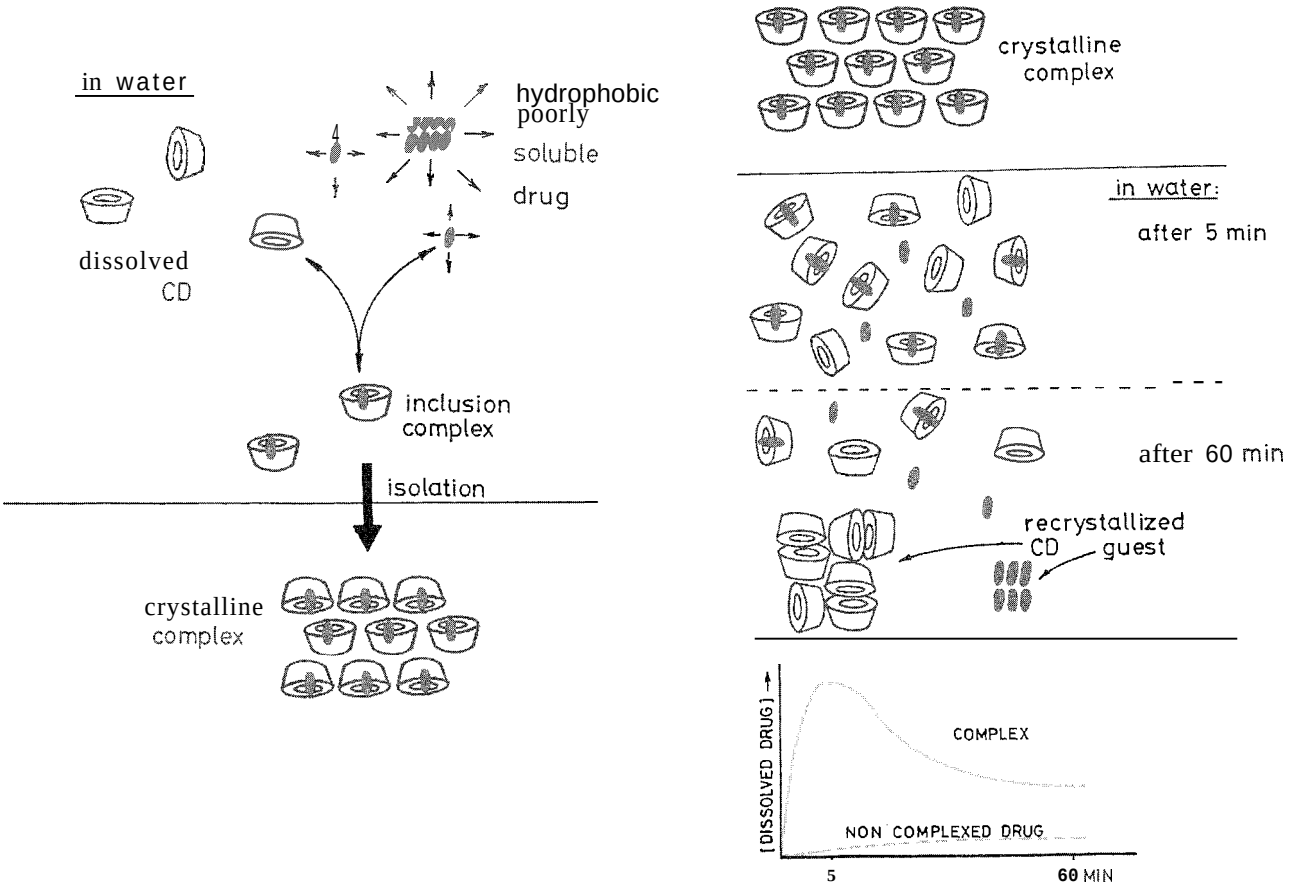

Fig. *2* Preparation and redissolution of a drug/CD complex. (Left) The poorly soluble drug is dissolved in an aqueous CD solution. The formed complex is isolated by cooling or removing the water by freeze-drying. spray-drying, or evaporating to dryness as a microcrystalline or amorphous powder. (Right) The drug/CD complex (e.g., compressed to tablet) in water. In gastric juice, the complex is dissolved within seconds. resulting in an oversaturated solution. Both recrystallization (separation) of the host (CD) and the guest (drug) and absorption of the drug begin immediately. Dissolving the complex results in a much higher dissolved level of the drug than in case of the plain drug. (*View this art* in color *at www.dekker.com.*)

PGE_1 + 646 μg αCD/dose). In slow infusion. the parenteral administration of several grams of a noncrystallizable CD derivative is possible. for example, in a liquid itraconazole formulation; the weight ratio of the drug to hydroxypropyl βCD is 1:40.

A 3000 I.U. D_3-vitamin tablet contains only 0.075 mg cholecalciferol; a Prostarmon-E tablet contains only 0.5 mg PGE_2; the active ingredient content of a nitroglycerin tablet is 0.5–4 mg—these and similar drugs are ideal for CD complexation, but even the 20 mg piroxicam containing BREXIN tablet is a widely marketed successful product.

If the K_a stability constant of a complex is low (less than 10^2 mol^{-1}), the existence of the complex can be demonstrated in solution. but on removing the water, the product obtained is often only a mixture (e.g., a coprecipitate) that contains the host and guest in a fine dispersion. Also, on removing the water, an important component of the driving force for complexation is eliminated: the repulsive forces between water and the hydrophobic drug. Upon contact with water, the complex formation is an instantaneous process, i.e., in solution, the guest is included in the CD cavity, and the dissociation–association equilibrium is reached within seconds.

In such cases. the guest is not protected against external destructive factors, like oxygen or humidity. but if the guest is stable enough. and only its low solubility is problematic, such intimate mixtures can be utilized for preparation. e.g., solid formulations of improved bioavailability. If. however. the guest is unstable, then only full complexation. even in the anhydrous state, can be of use.

In cases of extremely high complex stability constants (over about 10^4 M^{-1}), the bioavailability of a drug can be reduced. The complex is practically not absorbed and actively arises only from the free, molecularly dispersed (dissolved) drug molecules. In such cases, the

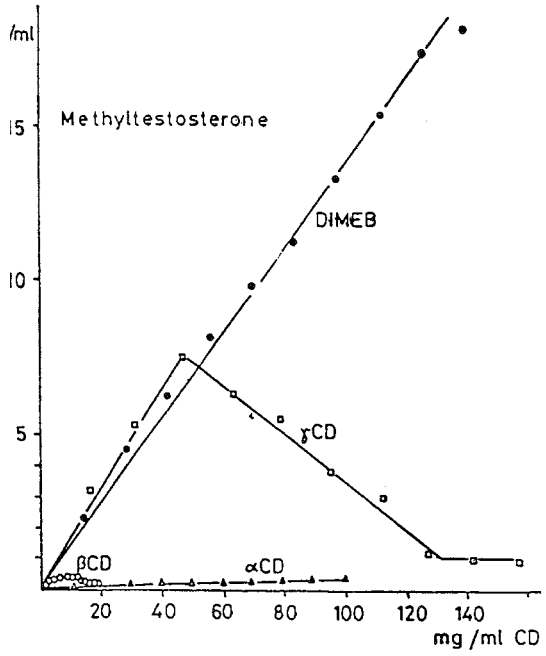

Fig. *3* In aqueous solutions of crystallizable CDs. depending on their concentrations. the solubility of poorly soluble compounds is increased. When reaching the solubility limit of the formed inclusion complex, the concentration dissolved drug reaches a plateau or even drops back. In the case of non-crystallizable CD derivatives, no such limit is attained, therefore. to form practically water-insoluble steroid. 10 or 20 or even more mg substances can be dissolved in the 1 ml solution of an appropriate CD derivative.

coadministration of a better complex-forming competitor molecule (e.g., phenylalanine) can help.

Hundreds of published examples illustrate the stabilizing, solubilizing and bioavailability enhancing, side-effect reducing, and advantageous technological effects of CD complexation of unstable. poorly soluble, locally irritating drugs. Illustrated in Table 1 is a selection of CD-containing drugs that are approved and marketed in various countries.

CYCLODEXTRINS IN **COSMETICS** AND TOILETRIES

Many active principles of interest in cosmetics were complexed with cyclodextrins. achieving positive and interesting results. For instance, the inclusion of retinol in hydroxypropyl-β-cyclodextrin leads to a water-soluble product, sufficiently stable, of higher bioavailability and lower toxicity compared to free retinol. Similarly, it is possible to include almost all vitamins in cyclodextrins. with unquestionable advantages with regard to their stability and bioavailability (Table 2). The main advantages of using CD complexes in functional dermocosmetics are similar to those in pharmaceutical formulations:

- Increase in the bioavailability of incosporated active components(vitamins, hormones. glycolic acid, depigmenting agents, etc.).
- Protection from oxidation (vitamin A. retinol, hydroquinone, arbutin, DHA, etc.).
- Reduction of toxicity and aggressivity (glycolic acid, hydroquinone. essential oils, fragrances, etc.).
- Formation of hydrosoluble complexes, even if the incorporated molecule is liposoluble.
- Increased stability of emulsion and gel products.
- Easy formulation: the complex is added to the final formulation, dispersing it in the aqueous phase at 35–40°C.
  No preservatives added.

Some special advantages were observed for sunscreen agent/CD complexes:

- Increased stability (photostability) of cream formulations.
- Decreared cytotoxicity.
  Increased/improved functional activity.
- Reduced smell.
  Reduced fabric staining.

Thus, the markedly increased photostability is associated with decreased phototoxicity and photosensitization risk coming from the production of free radicals primed by solar photochemical attack on the filter molecule.

Cyclodextrins are suitable for skin treatment products and for the formulation of makeup cosmetics. which are to stay on the face and skin for a number of hours (up to one day).

CD complexation can be used to stabilize emulsion and color, perfume, or aroma. For instance, most perfume concentrates. such as rose oil, citral, and citronella1 can form complexes and can be used in any solid preparation. such as powdered detergents: the collateral irritant effect caused by a scent in a shampoo can be reduced through the use of CD complexes: a solution of iodine-βCD can be used as deodorant for the body. for baths, or as a refresher for the oral cavity; a CD complex with detergent molecules can act as antifoam agents: etc.

CYCLODEXTRINS IN FOODS

Flavor substances are generally volatile and easily deteriorate. Most (e.g., tespenoids and phenylpropan derivatives) form stable complexes with CDs, and in dry

Table 1 Some approved and marketed CD-containing pharmaceutical products

Drug	*Trade name*	*Indication*	Formulation	Company/country
PGE_2/βCD	Prostarmon E	Induction of labor	Sublingual tablet	Ono, Japan
PGE_1/αCD 20 μg/amp	Prostavasin	Chronic arterial occlusive disease	Intraarterial	Ono, Japan: Schwarz. Germany
PGE_1/αCD 500 μg/amp	Prostadin 500	Controlled hypotension during surgery	Infusion	Ono. Japan
OP-1206/γCD	Opalmon	Buerger's disease	Tablet	Ono. Japan

Nicotine/βCD	Nicorette		Chewing gum	Pharmacia Upjohn, Sweden
Cetrizine/βCD	Cetrizin	Antiallergic		Losan Pharma. Germany
Voriconazole/sulfobutyl-βCD	VFEND®	Antimycotic	Tablet	Pfizer. USA
Mitomycin/HPβCD	MitoExtra	Antiinflammatory	Infusion	Novartis. Switzerland
Diclofenac Na/HPγCD	Voltaren ophtha	Nonsteroid antiinflammatory	Eye drop	Novartis. Switzerland
Omeprazole/βCD	Omebeta	Proton pump inhibitor	Tablet	Betapharm. Germany

complexed form remain stable for a long time, without further protection, at room temperature. Such powder-flavors are approved, produced. and used in several countries. like France. Japan, and Hungary. For example, lemon-peel oil/βCD complex mixed with powdered sugar is used in pastries: spice–flavor mixtures are complexed with CDs in the preparation of canned meat, and sausages: peppermint oil/βCD complex is used in chewing gum. etc. In Germany, the garlic-oil/βCD complex is marketed as odorless dragées (to substitute garlic. and a number of unstable garlic preparations. consumed to reduce blood cholesterol levels). The βCD cannot be considered tasteless. and its sweetness cannot be ignored. Its taste threshold value is lower than that of sucrose (detection: 0.039% c.f. 0.27%: recognition: 0.11% c.f. 0.25%). An aqueous solution of a 0.5% βCD proved to be as sweet

Table 2 Examples of CD-containing cosmetic products

Product name	Type	Produces
KLORANE	Dry shampoo	Klorane Laboratories
L EAU D ISSEY	Deodorant	Issei Miyake
EXCEPTIONAL	Lipstick	Elisabeth Arden
SELF ACTION TANNING CREME	Creme	Estée Lauder
ADVANCED SUN CARE	Sun protection	Estee Lauder
AKTIV COMPLEX PLUS	Sun protecting	AOK

EUCERIN Q10 ACTIVE	Q10 vitamin creme	Beierisdorf
EUCERIN VITAL RETINOL	Vitamin A creme	Beiersdorf

as a 0.5% aqueous solution of sucrose, and a 2.5% solution was proven as sweet as a 1.71% sucrose solution. When βCD is used in food processing. its sweetness cannot be ignored. Sucrose sweetness and βCD sweetness are additive.

Emulsion stability, water retention, and storability can be improved in many cases by adding cyclodextrins to the food component or food. A solid composition containing sugars and amino acids for food or pharmaceutical purposes is known to undergo browning and caking. This can be prevented by incorporating in such a composition at least 40% of an oligo- or polysaccharide. such as dextrin, starch. or CD, with a water content of not more than 3%. For example, adding 20% βCD to a powdered juice consisting of anhydrous glucose: sodium L-aspartate. DL-alanine, citric acid. and inorganic salts, resulted in a product of excellent stability. After 30 days at 40°C, there was no apparent discoloration or caking. The control, without βCD, began to cake on the second day and to turn brown on the fourth day.

The CD can be utilized for preparing stable water-in-oil emulsions, such as mayonnaise and salad dressing. Natural food-coloring components in tomato ketchup can be stabilized by adding 0.2% βCD. The ketchup thus prepared did not discolor on heating at 100°C for 2 h, whereas the control did. The addition of CDs to emulsified foods or cheese can increase the water retention and the shelf life. In processed meat products. CD improves water retention and texture.

In Belgium. low-cholesterol butter is produced. The molten butter is mixed with βCD, which does not react with triglicerides but forms complexes with cholesterol. The βCD complex is easily removable from the butter. More than 90% of the choleste ol can be removed in one step. The butter does not retain any CD. Other low-cholesterol milk products, like cheese, cream. and even low-cholesterol eggs. are produced by this technology.

CYCLODEXTRINS IN CHEMICAL PRODUCTS AND TECHNOLOGIES

It is impossible to list all products that contain CDs. In the following, only a few examples will be given to illustrate the possibilities of CD utilization.

Binding CD to textile fibers chemically or by adsorption opens new ways for the preparation of perfumed textiles, with slow release of the perfume. The immobilized (wash-fast) cyclodextrin can be loaded with perfumes, or insect repellents, which will be released only slowly as a result of th reaction of body heat and released humidity (perspiration). Simultaneously. these hosts can bind distasteful smelling components of perspiration (deodorizing effect).

By mixing CD or CD-polymer fragrance complexes to a melt mixture of synthetic fiber polymers (e.g., polyester) and weaving fabric from such fibers. wash-fast fragrant fabrics can be produced.

The CDs represent a new class of auxiliary substances for the textile industry. It is important that their chemical oxygen demand (in wastewater) is lower than that of the usual textile auxiliary substances. While the chemical oxygen demand (in mg/g) for the widely used tensides NP10 is 2020, Uniperol O is 1930, and Gisapon 1555 is 2290. for βCD this value is only 1060.

For coloration of polyester fibers, so-called dispersion dyes are used, which are poorly soluble in water (0.1–10 mg/l). Without using solubility-enhancing agents, such as tensides. uniform dyeing is not possible. However; CDs can substitute tensides. e.g., 0.3 g/l conversion mixture (which contains three cyclic and noncyclic dextrins) proved to be about equivalent to 1 g/l Eevegal HTN (a nonionic tenside).

Fragrant paper or paper containing protective substances can be prepared using CD complexes of perfumes, insecticides, rust inhibitors, mold- and mildew-proofing

agents. fungicides. and bactericides. For example. the fenitrothion βCD complex sprayed on a wet paper web, passed between drying rollers heated to 100°C, and wound to give insecticide-containing paper, was shown to be effective for more than 6 months.

Silane resins are made using a 1,5-cyclooctadieneplatinum catalyst. Once the catalyst is added, the reaction proceeds. On complexing the catalyst with βCD, it became possible to produce a single-component heat-curable silicone with a shelf life exceeding 7 months. because complexation prevented immediate catalysis and reaction. No gelation occurred at ambient temperature. Gelation began only when the mixture was heated to 150°C.

The conservation of wooden products, which are prone to attack by microorganisms. like the frames of windows, doors. and buildings constructed from wood; was usually done by impregnating, the wood with fungicides, which are generally water insoluble and therefore had to be dissolved in organic solvents. After impregnation, the solvents escape into the atmosphere. A new process dissolves the fungicides in aqueous CD solutions, and thus, the impregnation and conservation of the wood can be carried out without using organic solvents.

Emulsion-type coatings (paints) contain emulsion polymer binders to give. after drying, a resistant. continuous protecting film on the coated surface. To ensure the formation of a good film, the applied layer has to contain various coinpatible components, like solvent, pigment, thickener, and binder. The rheological properties of the paint are determined by the thickener. which is usually a hydrophobically modified polymer. like polyurethanes. polyacrylamides, cellulose ethers, etc. To avoid a concomittant excessive viscosity (which makes the formation of uniform coating on the surface to be covered difficult). viscosity suppressors have to be added to the emulsion. On adding CDs to this emulsion. the CD molecules will associate with the hydrophobic sites of the polymer and, being strongly hydrated. inhibit the association of the macromolecules, resulting in a strong reduction of the viscosity.

The CD complexes are compatible with thermoplastic resins. Mixing a dry pulverized CD complex of a perfume, for example, a geraniol αCD complex. with a thermoplastic resin (polyethylene), and molding it, yielded plastic products with a long-lasting (at least 6 months) fragrance. Rapid loss of the perfume by volatility and thermal decomposition can be avoided in this way.

Mixing CD complexes of thymol, eugeneol, isobutylquinoline, etc., to inolten PVC. a natural leather odor-emitting (leather-like) material. was prepared. e.g., for automobile door internal coverings.

Important properties, such as the relative sensitivity and fog of silver halide containing photographic materials can be improved by adding CDs to the light-sensitive photographic gelatin layers.

Additives, dyes, stabilizers, and fog inhibitors used in the photographic industry should be fixed to a certain layer of the film or photo paper. This can be achieved by using derivatives with "heavy" side chains. It seems to be more convenient to prepare water-soluble polymer complexes of these substances. In complexed form, their mobility is markedly reduced, and they become fixed to the layer required. A diminished diffusion can be observed either on preparing, processing, or storing the film. Another advantage of the soluble polymer complex is that poorly soluble or even water-insoluble stabilizers can be applied to the film in aqueous solutions. The CD–gelatin composition as in the photographic layer shows lower water absorption and accelerated diffusion of the developing agents.

The biological remediation of carcinogenic polyaromatic hydrocarbon polluted soils is a slow process. because the dangerous polluting hydrocarbons are adhered strongly to the soil particles, and hence, they are not available for the soil microorganisms. Adding CDs (for example. randomly methlyated βCD) to such soils results in mobilization of the hydrocarbons by the CD, which makes them available for the microorganisms. resulting in an accelerated remediation of the soil.

Explosive substances, like nitroglycerine, or isosorbide-dinitrate. when complexed, can be handled without any danger. The pernitro-γCD complex of the extremely explosive nitramine can be used as a controlled missile propellant.

Incorporated into food packaging plastic films, CDs effectively reduce the loss of aroma substances. Incorporating fungicide CD complexes into films, for example, packaging of hard cheeses, significantly elongates the shelf life of the product by inhibiting the rapid development of mold colonies on the surface of the packaged cheese.

CYCLODEXTRINS IN BIOTECHNOLOGY

The application of cyclodextrins in biotechnology began only in the 1980s. but rapid development is expected in this field.

The majority of biotechnology processes constitute an enzyme-catalyzed transformation of a substrate in aqueour media. The main difficulties that used to arise include the following:

- The substrate is hydrophobic and sparingly (or hardly) soluble in water.
  The enzyme or the enzyme-producing microbial cells are sensitive to the toxic effects of the substrate or to inhibitors that can be the product of the transformation.

- The substrate or the product is unstable under the conditions of the enzymatic transformation.
- Isolation of the product from the heterogeneous system is difficult.

Cyclodextrins and their derivatives enhance the solubility of complexed substrates in aqueous media and reduce their toxicity. but they do not damage the microbial cells or the enzymes. As a result, the enzymatic conversion of lipophilic substrates can be intensified (accelerated. or performed at higher substrate concentrations) in industrial processes and in diagnostic reagents, the yield of product-inhibited fermentation can be improved, organic toxic compounds can be tolerated and metabolized by microbial cells at higher concentrations, and compounds in small amounts can be isolated simply and economically from complicated mixtures.

Examples illustrate the rapidly-growing and promising uses of cyclodextrins in various operations: the intensification of the conversion of hydrocortisone to prednisolone, the improvement in the yield of fermentation of lankacidine and podophyllotoxin, the stereoselective reduction of benzaldehyde to L-phenylacetyl carbinol, and the reduction in toxicity of vanillin to yeast, or organic toxic substances to detoxificating microorganisms. In the presence of an appropriate cyclodextrin derivative (e.g., 2,6-dimethyl-β-cyclodextrin), lipid-like inhibitor substances are complexed. The propagation of *Bordatella pertussis* and the production of pertussis toxin therefore increases up to hundred-fold. Cyclodextrins and their fatty acid complexes can substitute for mammalian serum in tissue cultures.

Until recent years, the *Leprae bacillus* (Mycobacterium leprae) was considered not to be cultivable under in vitro conditions. The most important energy source for the bacillus is palmitic (or stearic) acid, which, however, cannot penetrate the thick. strongly hydrophobic shell of the mycobacterium. On solubilizing, the fatty acids (or fatty alcohols) with dimethyl-β-cyclodextrin, however, the Mycobacterium can be cultivated in vitro, on synthetic media. This discovery will facilitate the screening of drugs against similar difficultly-to-cultivate microorganisms.

MISCELLANEOUS USES

The active ingredients of pesticides (insecticides. fungicides. herbicides, etc.) can be complexed with the same technologies and same consequences as drug molecules.

The selectivity of an insecticide can be improved. For example, by complexing. the insecticide that kills the herbivorous insect will not be toxic for the honeybee. The stability against sunlight-accelerated decomposition of pyrethroids can be improved, ensuring a longer-lasting insecticidal effect. Wettability or solubility of poorly-soluble benzimidazole-type antifungicides can be improved. allowing reduction of the dose and reducing the pollution of the environment. The possibilities of utilization of CD in pesticide formulations were elucidated in numerous scientific papers; however, until the last years, the price of βCD did not allow for its application in such fields, because the pesticide industry is cost sensitive. By end of the twentieth century, the price of βCD dropped to such a low level that the price was no longer a restricting factor.

In medicinal diagnostic kits, a frequent problem is the limited, uncertain solubility of some essential component and the stability and storability of the kit. On complexing. the typical components with such problems can be

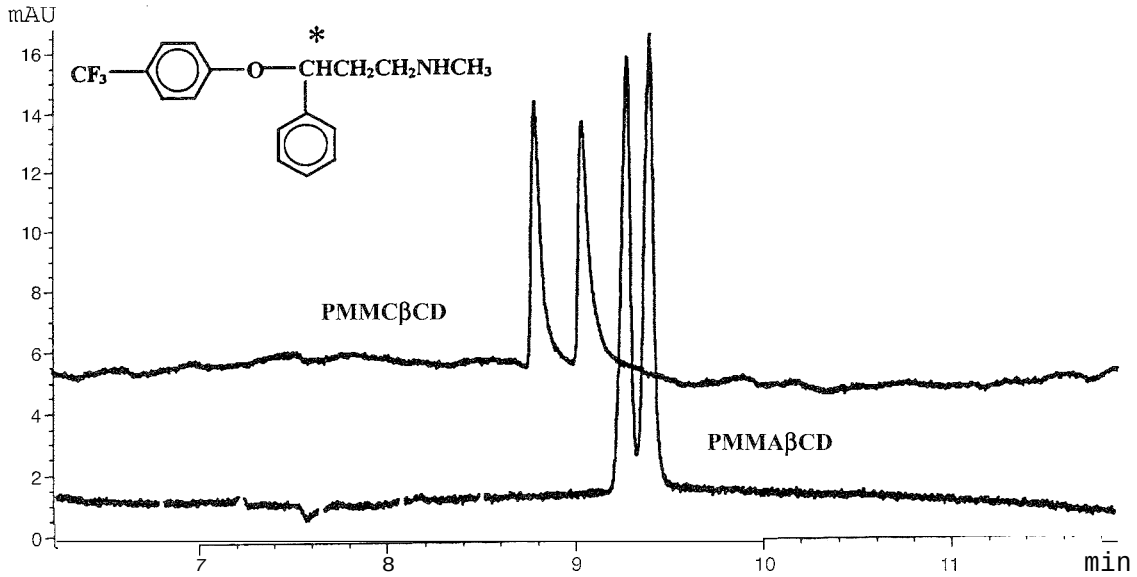

Fig. 4 Enantioseparation of Fluoxetine by capillary zone electrophoresis using permethyl-monodeoxy-monocarboxy-βCD or permethyl-monodeoxy-monoamino-βCD as chiral selector (10 mmol CD derivate pH 3.0 or 3.9).

eliminated. Also, frequently, the intensity of color reactions or of fluorescence can be significantly enhanced by the presence of CDs, resulting in higher sensitivity of the method.

There are some cases when the human taste and smell sensors cannot be substituted, even by the most sophisticated analytical instruments. In an organoleptic evaluation (comparison of identical food products of different origins, for example, beers), the dosing of extremely small but exactly known amounts of flavor components (for example, ppm amounts of mercaptanes. butyric acid, hydrogen sulfide, etc.) is necessary. To store and dose these volatile. unstable substances becomes simple when they are complexed with CDs, diluted with inert excipient to the appropriate grade, and filled in known amounts into hard gelatin capsules. By adding the content of one or more capsules of different flavors to the sample during sensoric "titration," the differences between the products can be expressed unambiguously and numerically.

In chromatographic separations, CDs and mainly specific derivatives are used widely. In the years 1990–2000, about 25 papers monthly were published on successful application of some CD in gas or liquid chromatography. In gas chromatography, CDs are used only in the stationary phase, while in HPLC, the CD is used either dissolved in the mobile phase. or bound to a surface in the stationary phase. In capillary zone electrophoresis. the most used chiral selectors are CDs. as their anionic: cationic. or alkylated derivatives (Fig. 4).

CONCLUSION

It is difficult to find an industry in which CDs are not or cannot be applied. In steadily increasing amounts, in the drug. food. cosmetic, textile. plastic, paper. pesticide, wood. toiletry; etc., industries, and in analytical chemistry. diagnostic. environment protection, packaging material production, etc.. CDs and CD derivatives are being used. Extrapolating the trends of the applications of CDs observed during the last two decades, no leveling-off is expected in the upcoming decades.

Cyclophanes: Definition and Scope

Carlo Thilgen
Vladimir A. Azov
ETH Zürich, Zürich, Switzerland

INTRODUCTION

The beginning of the more than centenarian history of cyclophane chemistry[1–4] can be related to the preparation of [2.2]metacyclophane (**1**, Fig. 1) by Pellegrin in 1899.[5] The ''modern age'' of cyclophanes started in 1951 when Cram and Steinberg reported a rational synthesis for the isomer **2**.[6,7] In the following decades, such ''small'' or strained cyclophanes were extensively used to study intramolecular interactions between braced arenes held in close proximity with defined relative orientation. The gained insights provided a strong basis for the understanding of weak intermolecular interactions involving aromatic rings.[8] Together with the exploitation of the restricted conformational flexibility of arene-based building blocks, this knowledge spurred the creation of highly preorganized macrocyclic cyclophane receptors and self-assembled superstructures, thus contributing significantly to the exuberant development of supramolecular chemistry during the last 30 years.

DEFINITION

Cram and Steinberg proposed the class name *paracyclophane*s for compounds in which two benzene rings are rigidly held in a face-to-face orientation by methylene bridges in the *para* positions,[6,7] the term *cyclophane* constituting a contraction of ''*cyclophe*nylene alk*ane*.'' The concept was subsequently systematized by Smith[1] and extended to a broader range of structural elements by Vögtle and Neumann, who designated as ''*phane*'' every molecule containing at least one aromatic nucleus and at least one n-membered bridge with $n \geq 0$.[3] A recent recommendation of the IUPAC defines *cyclophanes* as compounds having (i) mancude (*ma*ximum number of *n*on*cu*mulative *d*ouble bonds)-ring systems, or assemblies of mancude-ring systems, and (ii) atoms and/or saturated or unsaturated chains as alternate components of a large ring.[9]

NOMENCLATURE

According to the commonly used nomenclature of Vögtle and Neumann, two sets of numbers precede the components of the name that carries the suffix *-phane*: numbers in brackets indicate the length(s) of the bridge(s), starting with the longest one, and numbers in parentheses define the substitution pattern of the aromatic moieties (**1–5**, Fig. 1).[3] For multibridged arenes, the number of equal bridges can be indicated as a subscript to the number of *C*-atoms they contain (**1–3**).

The IUPAC recently published recommendations on phane nomenclature, representing a new approach for building names of complex organic structures.[10,11] In principle, each arene is collapsed to a ''superatom'' that, together with the remaining backbone, is named and numbered as an alicyclic system, the typical *-ne* ending being replaced by *-phane* (**5a,b**). Superatoms are cited as prefixes derived from the names of the corresponding arenes by changing their terminal *-e* to *-a*, e.g., *benzena*. These prefixes are incorporated in the name in analogy to heteroatoms in replacement (''a'') nomenclature. Arene positions that are connected to the remainder of the cyclophane backbone are indicated within parentheses, following the locants for superatoms. As an example, the simplified skeleton for cyclophane **5a** corresponds to ''cycloheptaphane'' **5b** with two superatoms in positions 1 and 4; the amplified full name is 1(2,7)-naphthalena-4(1,3)-benzenacycloheptaphane.

SYNTHESIS

In line with the immense structural diversity of cyclophanes, the synthetic approaches are extremely heterogeneous[1–3,12] and cannot be reviewed in a short synopsis. Progress in the preparation of cyclophanes is closely associated with the development of synthetic methodology for ring closure and ring contraction. Three principles of general importance in cyclophane synthesis should be mentioned.

Molecular Building Block Principle

A common aspect of many cyclophane syntheses is the modular assembly of simple structural subunits.[12] Macrocyclization can involve one or several components. The

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012737

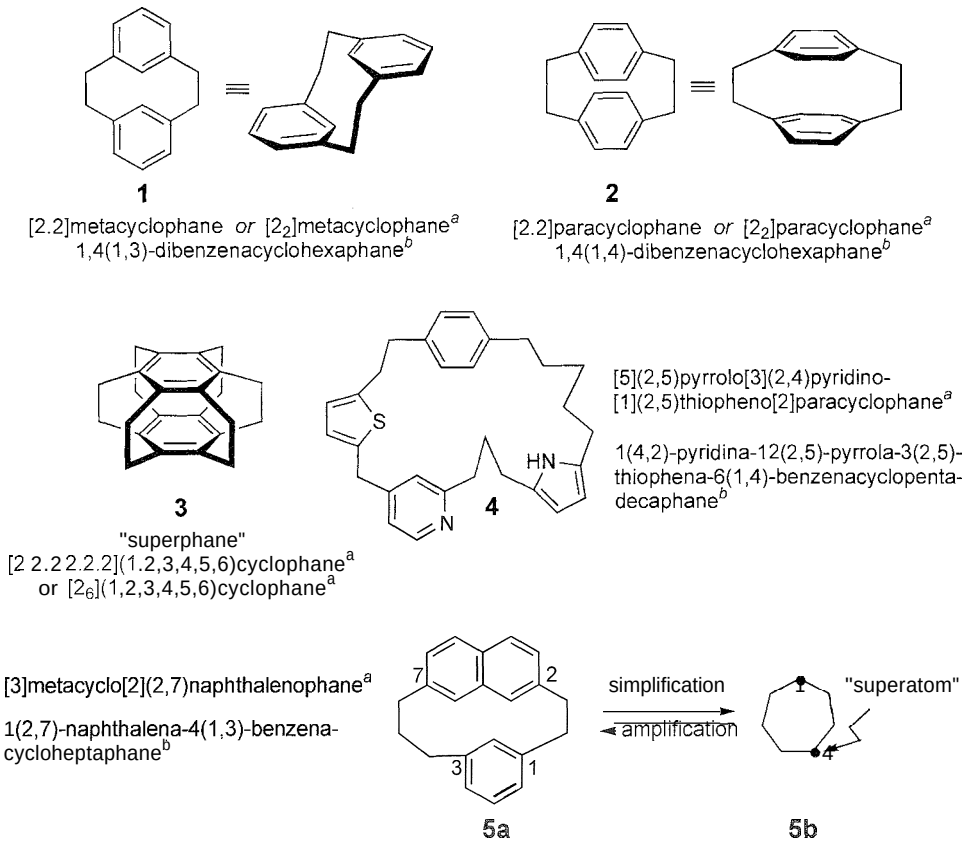

Fig. 1 Selected cyclophane structures and their nomenclature according to *Vögtle/Neumann*[a] and to IUPAC[b]

fewer bond formations it comprises, the higher the yields, in general. On the other hand, the synthesis of more elaborate precursors requires a higher number of steps. In practice, a compromise is made between synthetic effort and cyclization yield. The most important approaches to promote cyclization versus polymerization make use of the dilution principle and the template effect.

Dilution Principle

Cyclizations typically start from cornpounds with two or more reactive centers. Whereas the ring-closure is an intramolecular first-order reaction. intermolecular second-order reactions lead to undesired oligo- or polymerization. To favor cyclization over polymerization, reactions should be run at low concentration, a principle referred to as Ruggli's dilution principle.[13] However, in multicomponent syntheses including bimolecular steps prior to cyclization. the total reaction rate becomes too low at extreme dilution, and component concentrations between 5 and 50 mM are generally recommended. These can be achieved by slow addition of the starting materials to the reaction flask, for example, using syringe pumps.

Template Effect

Molecular templates are control elements leading to predominant or exclusive formation of a specific product from reactant5 that can, in principle, assemble in different wayc [''' They are often used to favor the formation of cycles over oligomers or of cycles of a certain size through specific interactions with the components during the assembly process.

'"SMALL" CYCLOPHANES

Small and, therefore, often strained cyclophanes encompass an enormous structural diversity (**1–13**, Figs. 1 and 2) that was reviewed in detail.[1–3] Their preparation initiated studies of weak noncovalent interactions between chromophores fixed in a rigid. geometrically defined arrangement. and thus, contributed substantially to paving the way for the development of supramolecular chemistry.

The "bent and battered''[6,7] arene rings of many cyclophanes with short bridges, e.g., **1** and **2**, or the *ansa* (lat.: handle) compounds [6]paracyclophane (6) (Jones)

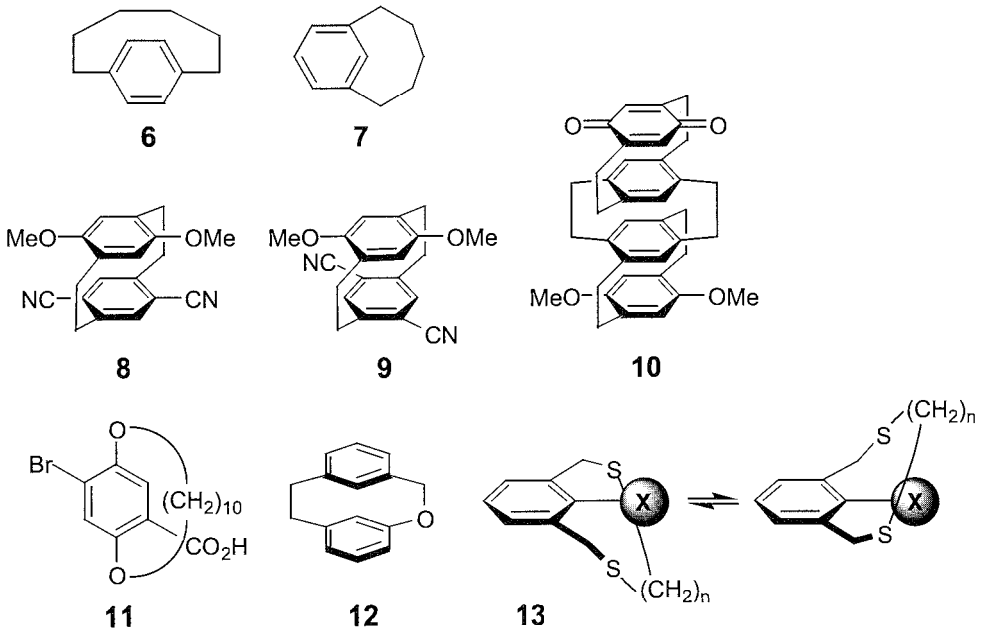

Fig. 2 "Small" cyclophanes with interesting structural, optical, and stereochemical properties.

and [5]metacyclophane (7) (Bickelhaupt),[3] deviate strongly from planarity. Together with transannular effects, the corresponding π-system distortions significantly affect chemical reactivity and spectroscopic properties.

Small cyclophanes generally exhibit an enhanced reactivity compared to the constituent arenes.[6,7,15] In [2_n]cyclophanes, for example, electrophilic aromatic substitution is facilitated by transannular interactions with the n-basic second deck; furthermore, Lewis-basic substituents direct a substitution in the second ring predominantly to the pseudogeminal position. Strain relief plays an important role in reactions like catalytic hydrogenation, cycloadditions, and cleavage or rearrangement of bridges.

Transannular interactions between arenes held in defined proximity and orientation within a cyclophane are easily detected in their electronic absorption or emission spectra, as shown by the groups of Staab, Haenel, and Misumi.[4] In combination with the deviation from planarity, these interactions result in a loss of fine structure and the appearance of a new long-wavelength transition centered around 300 nm in the UV/Vis spectrum of [2.2]paracyclophane, when compared to an open-chain reference.[6,7] Likewise, cyclophanes served as models for intermolecular excimers and exciplexes: most show a red-shifted, poorly structured fluorescence, reflecting the typical binding energy of an excimer or exciplex as well as the repulsion energy of the corresponding ground state. In an elegant study with donor–acceptor cyclophanes such as 8 and 9, Staab and coworkers investigated the orientation and distance dependence of charge–transfer interactions.[3] Typically. the pseudogeminal derivative (8) gave a red-shifted and more intense charge–transfer band compared to the pseudoortho isomer (9). Such interactions are effective even over several stacked chromophores, for example, in 10.

The incorporation of arenes in small cyclophanes hinders rotation around certain bonds and can afford isolable enantiomers with appropriately substituted backbones, e.g., planar-chiral 11 (Liittringhaus) or helical-chiral 12 (Vögtle).[1,16] Studies of the dynamic properties of small cyclophanes with intraannular substituents X (13) provided insight into the space occupancy of atoms or functional groups.[3]

CYCLOPHANE RECEPTORS

During the rapid development of supramolecular chemistry over the last two to three decades, a great variety of synthetic hosts was designed, many of them with a cyclophane backbone.[4,17–21] Aromatic building blocks confer a certain rigidity to cyclophanes and, if connected appropriately, span a preorganized cavity that can act as a binding site for guests.

The aromatic "walls" or spacers delimiting the cavity can participate in nondirectional binding through disperrion (van der Waals) interactions that are inherently weak but can add up to considerable values for large surfaces. Depending on the nature of the substrate and the

functionalization of the receptor, other possible interactions include aromatic π–π stacking and edge-to-face interactions, cation–π interactions: ion pairing (Coulomb interactions), ion–dipole and dipole–dipole interactions, and hydrogen bonding.[4,8,21] Binding selectivity: on the other hand, relies on size and shape of the cavity. and, most importantly, on directional interactions such as hydrogen bonding between appropriate functional groups of host and guest.

Extracavity functionalization is often required to make the inherently apolar cyciophanes soluble in polar solvents. Water solubility, in particular, may be desirable to take advantage of the hydrophobic effect as a strong driving force in the complexation of apolar guests.'''."]

Cyclophanes for Apolar Binding

Apolar binding plays a key role in the complexation by cyclophanes and will be discussed in some detail before specific classes of receptors are reviewed. Apolar complexation is mostly studied in water or polar organic solvents, because binding energies. largely determined by dispersion interactions and the desolvation of hydrophobic surfaces, are highest in these solvents. Polar functional groups that may be present are favorably solvated in the unbound receptor or substrate. To avoid a strong reduction in binding free enthalpy, full solvation must be maintained upon complexation or replaced by energetically equivalent host–guest interactions.[4,21]

In 1980, Koga and coworkers reported the inclusion complexation of benzene and naphthalene derivatives by 14 (Fig. 3) in aqueous HCl.[2] To inspect the driving forces for inclusion complexation by completely lipophilic cavities in detail. Diederich and coworkers investigated a series of cyclophanes (**15a–c**) displaying the following features:[4]

- The diphenylmethane moieties open and preorganize a cavity lined by benzene rings that are nearly orthogonal to the mean molecular plane.

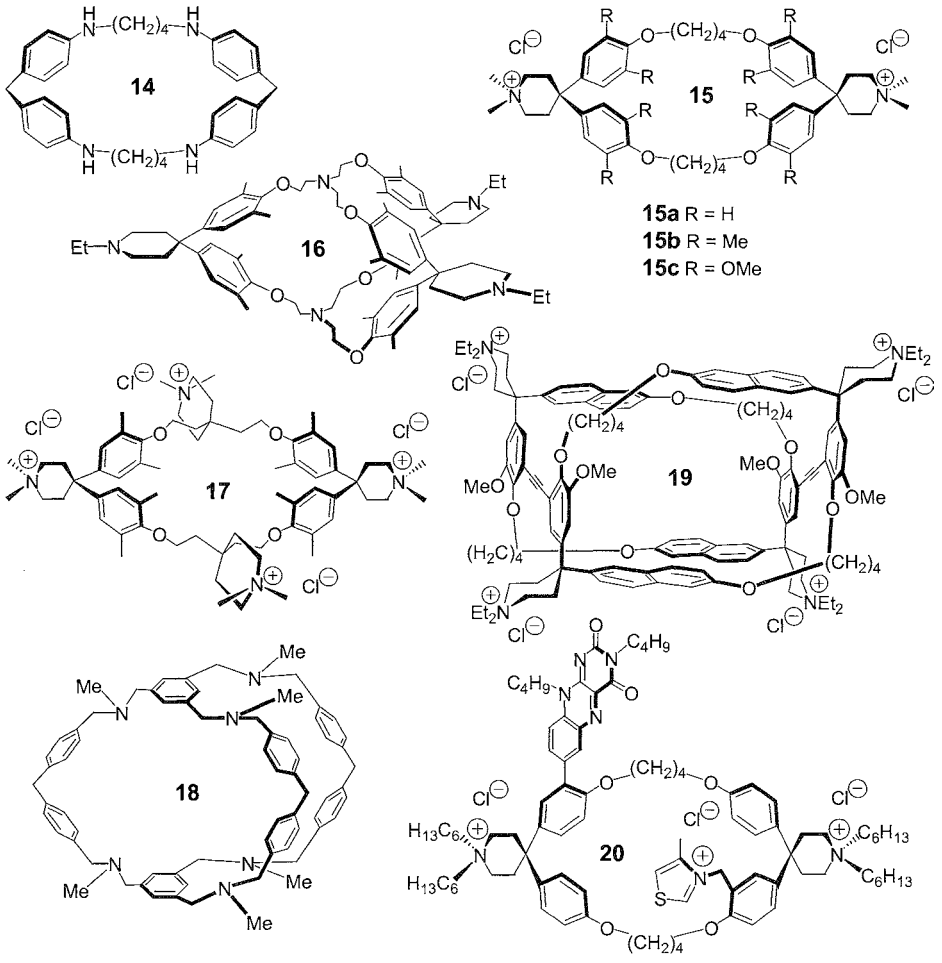

Fig. *3 Cyclophanes for apolar* complexation.

The length of the chains between the diphenylinethane substructures determines the size of the cavity. Careful conformational analysis of flexible units is crucial for succesful host design.

- The depth of the cavity is influenced by substituents on the benzene rings.

  The quaternary ammonium ions provide water solubility. Being remote from the binding site, they do not influence its polarity or solvation.
- In the absence of guests, the cavity is filled with solvent.

A coinplexation study (CD_3OD) of **15b** with 2,6-disubstituted naphthalenes carrying donor or acceptor substituents revealed that relative binding strength is controlled by polar effects that can also be considered donor–acceptor interactions:[4,21] increasing acceptor strength of the guest substituents enhances π–π-stacking interactions with the electron-rich benzene rings of the host and $C–H_{guest} \cdots \pi_{host}$ edge-to-face interactions.[8]

The thermodynamics of tight complexation of *para*-disubstituted benzene derivatives by **15c** in water are in conflict with the classical hydrophobic effect. i.e., large favorable entropy change. small enthalpy change. and large negative change in heat capacity. Deeper insight into the enthalpic driving force for apolar complexation and the role of the solvent was provided by calorimetric investigation of the coinplexation between **16** and pyrene in a series of solvents ranging from H_2O to CS_2.[4,21] Tight apolar colnplexation is mostly enthalpy driven and increases from apolar over dipolar aprotic to protic solvents with water at one end of the scale but in accord with the entire series. The main enthalpic contributions appear to be favorable changes in solvent cohesive interactions and gain in dispersion interactions (nonclassical hydrophobic effect).

Cyclophane **17** undergoes strong colnplexation with polycylic aromatic hydrocarbons (PAHs) of complementary size and shape in water.[4,21] Peryiene. with its large surface providing significant dispersion interactions and releasing many H_2O molecules into the bulk solvent, shows the strongest binding that may benefit also from ammonium ion–π interactions. For naphthalene derivatives with ionic substituents, ion-pairing interactions lead to extraordinary substrate selectivity. Cyclophane **17** can act as a carrier for the passive transport of PAHs between two hexane phases across an aqueous interphase. Another strong size-and shape-selective receptor for PAHs in acidic aqueous medium is hexaamine 18. reported by Vögtle and coworkers.[3,17]

Thanks to their modular design. cyclophanes are easily adjusted to bind target substrates. Thus, when the cavity of 15c was enlarged by replacing two benzene by naphthalene units and deepened by .'stacking" two macrocycles on top of each other. the resulting D_2-symmetrical double-decker cyclophane 19 was suitably shaped and preorganized for inclusion of steroids such as cholesterol.[21]

Water-soluble cyclophanes are also studied as possible catalysts or artificial enzymes: the hydrophobic cavitiy serves as substrate binding site while appended functional groups act as cofactors. The pyruvate oxidase mimic 20 performed remarkably in the oxidation of aromatic aldehydes to the cossesponding esters (MeOH/H_2O), and it displayed Michaelis–Menten kinetics comparable to those of natural enzymes.''' The encapsulation of cyclophanes in dendrimers creates binding sites within microenvironments. resembling those existing in protein superstructures.

Calixarenes, Resorcinarenes, and Cavitands

Calixarenes (**21**) and resorcinarenes (22) (Fig. 4)[22] are condensation products of phenol or resorcinol (benzene-1.3-diol) and aldehydes. Depending on the reaction conditions and the substitution of the starting benzenols. size and shape (conforination) of the cyclooligomers and, therefore. of their basket-shaped cavities can be varied. They can be further modified by functionalization of the hydroxy groups or the benzene rings. This modular concept makes them versatile receptors with regard to structure and function.

The bridging of vicinal arene units of resorcinarenes via their hydroxy functions leads to deeper and more rigid cavities in cavitands (23 and **24**).[23] Quinoxaline-2.3-diyl-bridged cavitands (24) can be switched between the so-called *vase* and *kite* conformers as a function of temperature or pH. Whereas the *vase*, predominant at higher temperature or lower pH, possesses a deeper cavity, the *kite* displays an extended, relatively flat surface.

Carcerands and Hemicarcerands

Carcerands are large, closed molecular containers that are assembled by fourfold interconnection of two cavitands (**25**).[23] They irreversibly incarcerate substrates, for example, solvent molecules, that are required as necessary templates for the assembly and cannot escape the cage for steric reasons unless it is destroyed. Hemicarcerands (26), on the other hand. include fewer or longer linkers. thus containing portals large enough for guests to get in and out at elevated temperatures. This allowed highly reactive species, such as cyclobutadiene and benzyne. to be generated from appropriate entrapped precursors and to be characterized in the ''inner phase'' at ambient temperature.

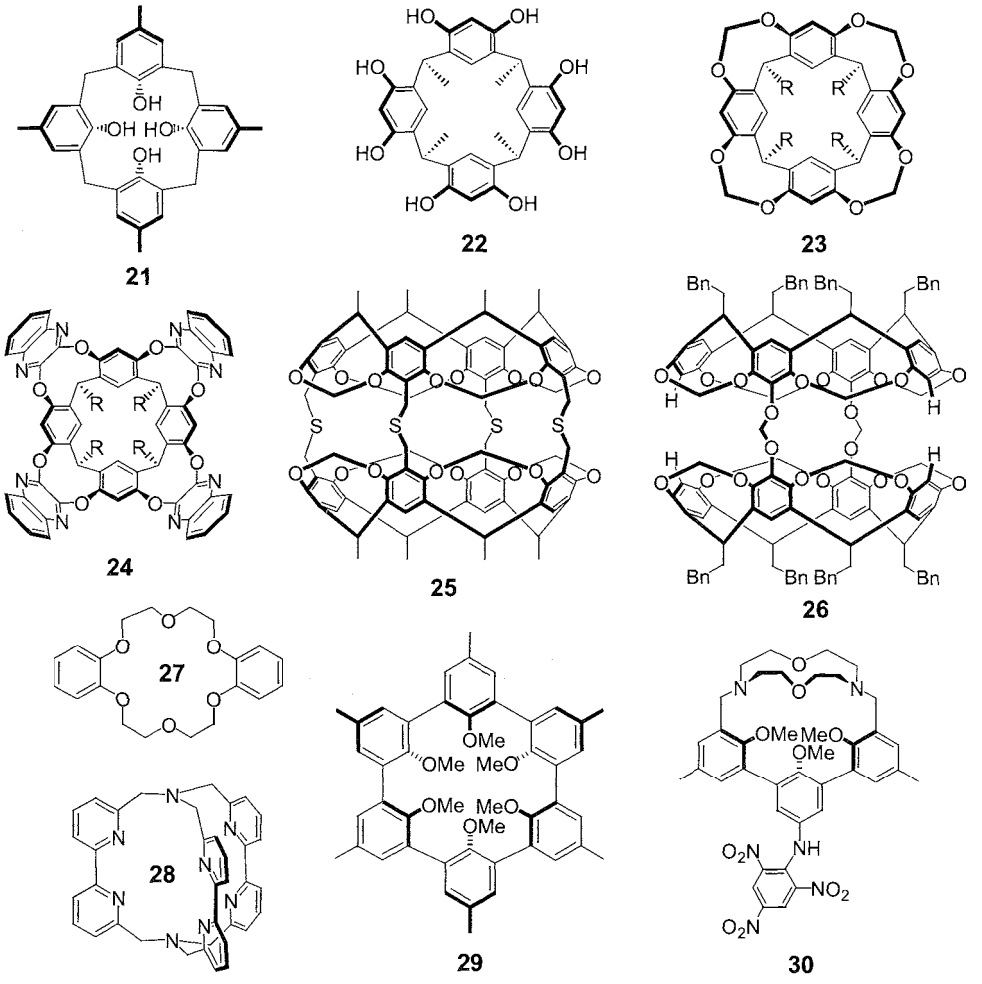

Fig. 4 Representatives of typical cyclophane host families calixarene (21), resorcinarene (22), cavitands **(23,** 24), cdrcerand (25). hemicarcerand (26), crown ether (27), cryptand (28), spherand **(29).** and hemispherand (30)

Fullerenes also represent container molecules that are able to Incarcerate metals, noble gases, or extremely reactive species such as *N*-atoms

Cyclophane-Type Ionophores

Compared to chemically similar individual ligands. macrocyclic cyclophanes with several donor centers may be potent complexing agents for metal ions. Next to the chelate effect, this is often related to a productive preorganization of convergent donor functionality providing favorable coordination sites.

Although many crown ethers are entirely alicyclic, the first representative. obtained by Pedersen in 1967, was a cyclophane (**27**).[24] Generally, the fusion of arenes to crown ethers and cryptands[25] makes the ionophores more lipophilic and confers a handle for functionalization. Also, the cyclophane backbone may include heterocycles that simultaneously provide the donor atoms for complexation. as illustrated by cryptand 28 (Lehn).[3,17]

Spherands[23] are typically derived from a hexa-*m*-phenylene backbone with donor substituents converging toward the center of the macrocycle (29). The close proximity forces the donor atoms to line a small and extremely preorganized cavity appropriate for very strong and specific binding of metal ions. As a consequence of the exceptional preorganization, decomplexation kinetics are exceedingly slow. Hemispherands (30) have a more flexible structure that reduces binding strength to some extent, but selectivities can still be very high. This has led to their incorporation into chromoionophores used for the determination of Na^+ (30) or K' in blood serum.[23]

Macrobicyclic cyclophanes with three highly preorganized catechol units were prepared by the groups of Vogtle and Raymond.[3,17] As an example. 31 (Fig. 5)

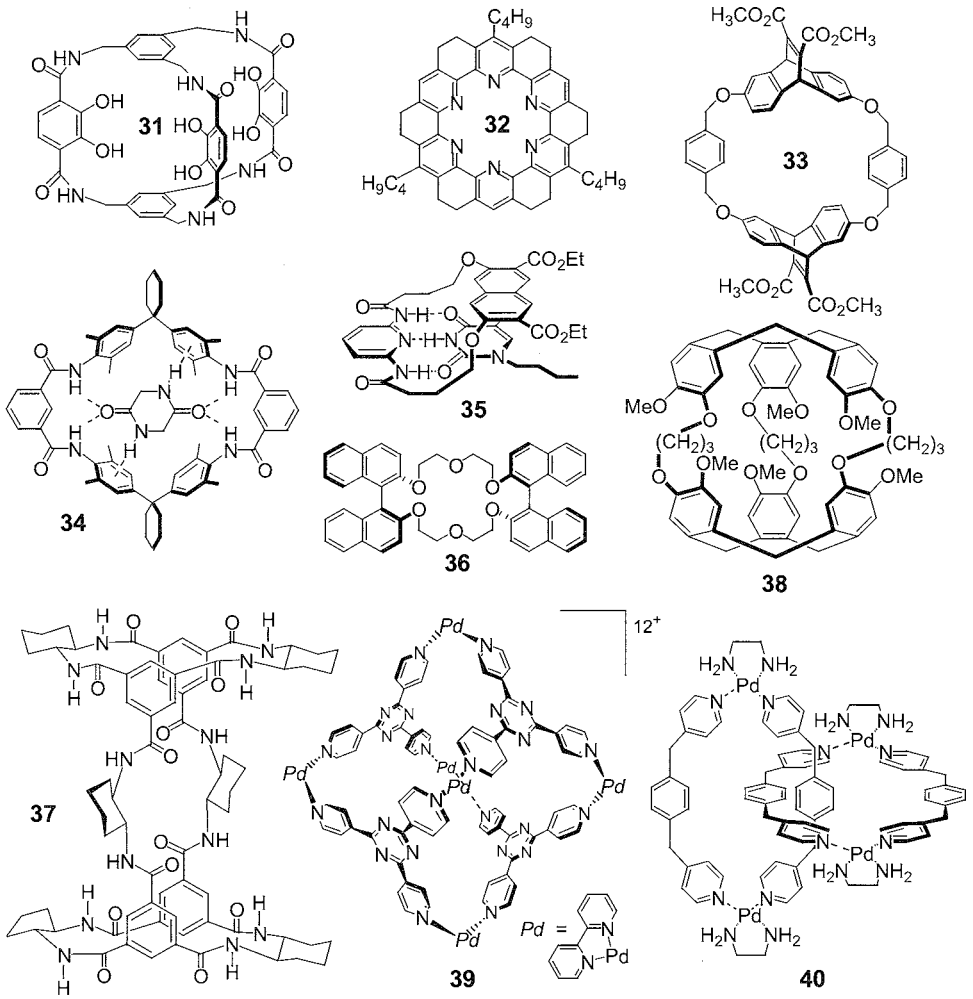

Fig. 5 Typical cyclophane receptors for metal ion complexation (siderophore 31. torand 32, crown ether 36), onium ion-π interactions (33, crpptophane 38). hydrogen bonding interactions (34–37), and chiral recognition (36–38). Self-assembled cyclophanes 39 and 40.

displays extremely strong complexation of Fe(III) upon deprotonation. exceeding that of the related natural siderophore enterobactin. Other well preorganized cyclophane-type ionophores include torands (Bell), e.g., 32 and a multitude of bridged and unbridged porphyrins.[3]

Cation–π interactions

While studying the coinplexation of ammonium ions by cyclophanes, Dougherty and coworkers recognized the interaction between cations and the electron-rich, polarizable π-systems of arenes.[26] Receptor 33 thus encapsulates *N*-methylquinolinium ions ($CDCl_3$) but not quinoline. Furthermore. complexation-induced changes in ^{1}H-NMR chemical shifts of the bound adamantyltrimethylammonium ion demonstrated that the ionic rather than the hydrocarbon moiety is included in the cavity. Cation–π interactions[18] play an important role in many natural systems such as proteins.

Hydrogen Bonding and Binding Selectivity

The directionality of hydrogen bonding makes cyclophanes with hydrogen-bond donor or acceptor sites very selective hosts for guests with a complementary hydrogen-bonding pattern. and high association constants are usually observed in noncompetitive solvents. Receptor 34, prepared by Hunter and coworkers,[27] strongly binds cyclo-diglycine ($CDCl_3$): in addition to the H-bonding between N–H groups of the cyclophane and the C=O groups of the guest, $N–H_{guest}\cdots\pi_{host}$ interactions[18] became evident by x-ray crystallography. In the complex of 35 with *n*-butylthymine, hydrogen-bonding interactions are complemented by π–π stacking which, as shown by

Hamilton and coworkers, is controlled by partial charge complementarity between the stacked naphthalene and heterocycle moieties.[28]

A number of cyclophanes with acidic NW groups, often belonging to pyrroles or amide functions, are suitable for anion binding.

Cyclophane Receptors for Chiral Recognition

Enantioselective recognition between chiral hosts and guests is of great interest. The required difference in stability between diastereoisomeric complexes often relies on three-point interactions between a well-preorganized receptor and the substrate. Hydrogen bonding as a directional interaction is of particular importance in this context, often in combination with steric host–guest complementarity.

Early reports from the groups of Cram[23] and Prelog[29] describe the use of chiral crown ethers derived from binaphthalene *(36)*and spirobifluorene. respectively, for the recognition, among others, of ammonium salts of D- or L-amino-acid esters. A model was proposed for the observed chiral recognition by *36*, and it was tested as a carrier in a machine for the preparative resolution of guest enantiomers by differential passive transport through a liquid membrane. However, developing back transport limited separations to "initial transport rate" conditions, thus hampering large-scale applications.

Still and coworkers prepared the highly selective, D_2-symmetric receptor 37 for amino acids and small peptides by simple condensation of (*R*,*R*)-cyclohexane-1,2-diamine and trimesic acid.[30] Complexes are held together by four intermolecular hydrogen bonds and resemble a peptidic three-strand β-sheet. A further, enantiomer-discriminating interaction is based on steric complementarity between the amino acid side chain and the cleft-type cavity of the receptor.

The aesthetically pleasing cryptophanes reported by Collet et al. include two cyclotriveratrylene (CTV) units

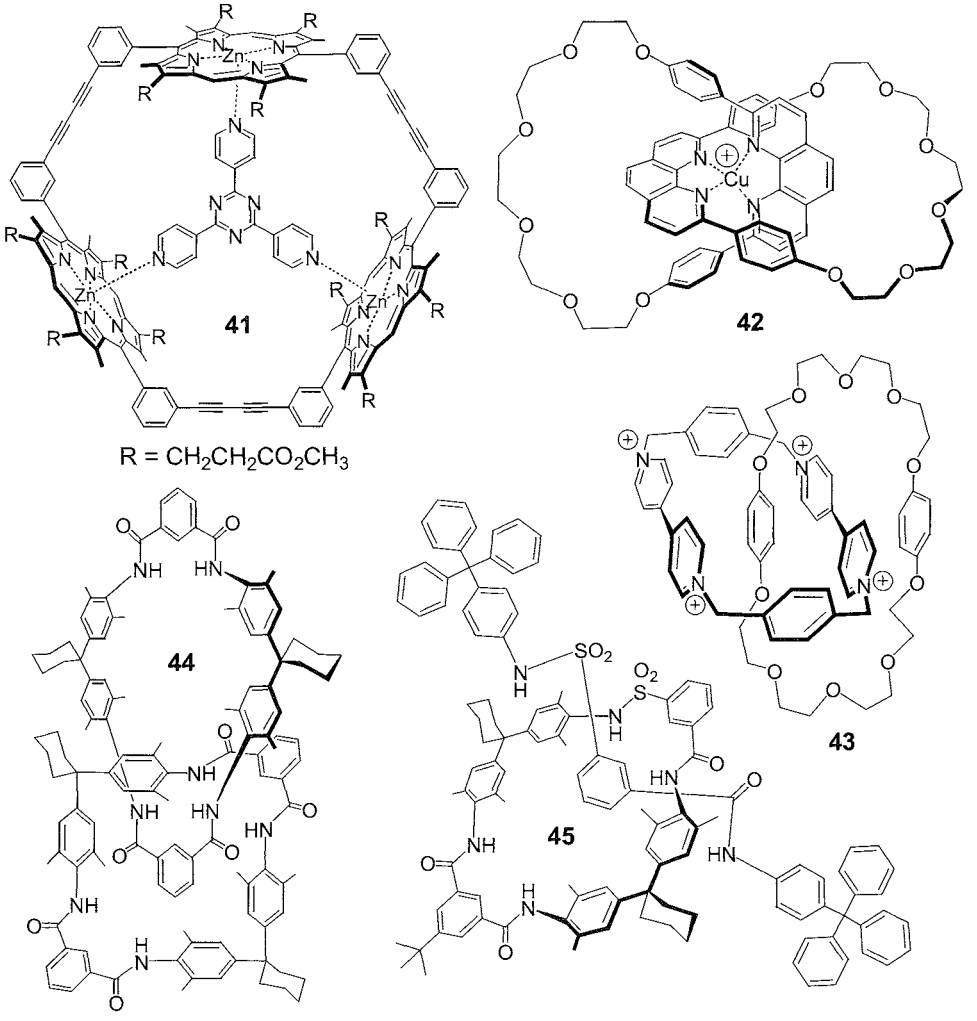

Fig. *6* Cyclophanes obtained by templated synthesis or self-assembly.

with a chiral substitution pattern, interlinked by three aliphatic chains.[31] Depending on the configuration of the CTV moieties, either an achiral (*meso* form) or a chiral cryptophane. e.g., **38**, results. The latter forms inclusion complexes with small apolar methane derivatives and onium ions [$CHCl_3$, $(H_3C)_4N^+$, etc.] in $CD_2Cl–CD_2Cl$. Nonracemic cryptophanes allowed the first chiral recognition, defined enantiomeric enrichment and configurational assignment of CHBrClF.

TEMPLATED SYNTHESIS AND SELF-ASSEMBLY OF CYCLOPHANES [REF. 203]

Based on coordinational preferences and the resulting spatial arrangement of ligands. certain transition-metal ions were used. sometimes in combination with covalent bond formation: as structural building blocks for rational self-assembly of molecular components into well-defined cyclophanes. The groups of Stang and Fujita thus exploited the coordination of ligands containing pyridine units to Pd and Pt to obtain some remarkable square cyclophanes. cage-type receptors (**39**), or catenanes (**40**).[32–34]

The metal-ion-mediated template effect was widely used in crown ether synthesis. Templated syntheses of cyclophanes such as **41** (Fig. 6) (Sanders)'''' are generally impressive by their efficacy and selectivity. Besides, they made structures such as rotaxanes, catenanes. and knots easily accessible for the first time. Sauvage and coworkers. taking advantage of a Cu(I)-mediated preorganization of phenanthroline building blocks. reported the first efficient rotaxane and catenane (**42**) syntheses and the first preparation of a molecular knot.[33,34] A strategy developed by Stoddart and coworkers for the synthesis of rotaxanes and catenanes, e.g., **43**, uses interactions between electron-deficient *N*-alkylated 4.4'-bipyridine units and electron-rich dialkoxyarene-based crown ethers.[33,34] The modular architectures were investigated in great detail and extended to interlocked multicomponent structures and functional systems on the way to molecular machines and motors. An efficient synthesis of macrotetralactam-based catenanes such as **44**, relying on templated self-assembly mediated through hydrogen bonding and, to a lesser extent, aromatic π–π-stacking, was reported by the groups of Hunter and Vögtle.[33,34] By subtly varying the structure and the combination of building blocks. the latter group was able to prepare unusual interlocked structures, including topologically chiral knots. catenanes, and rotaxanes (**45**). The cycloenantiomerism associated with the latter two compound families is a consequence of the directionality originating from asymmetric atom sequences within the macrocycles and the dumbbell component.

CONCLUSION

The building block principle applied successfully to the synthesis of cyclophane receptors allows for an enormous structural diversity with regard to shape and function. In combination with template-directed synthesis. self-ascembly, and other recent advances in macrocyclization methodology. it is hard to imagine limits as to the potential of cyclophane hosts in the foreseeable future. Similarly and despite the ''old age'' of small and nonhost-type cyclophanes, aesthetically pleasing, stereochemically remarkable, and extremely strained new structures are still being created.

ACKNOWLEDGMENT

We thank Prof. Dr. F. Diederich for providing a number of structural drawings.

Cyclophanes: Endoacidic, Endobasic, and Endolipophilic Cavities

Andrew C. Benniston
University of Newcastle, Newcastle upon Tyne, United Kingdom

INTRODUCTION

The name "cyclophane" is specific and literally means organic compound containing bridge aromatic ring."' However. as time has gone by, the generic term "cyclophane" has come into play, and scientists now use the name to encompass a multitude of molecular assemblies that have various cavities capable of binding guests. Indeed. some of the intricate and sophisticated molecules created today are a far cry from the first cyclophane chemistry started in 1899, when Pellegrin succeeded in preparing [2,2]-metacyclophane.[2] In this article. we will tie down a few specific examples and categorize the cavities of the cyclophanes according to the type of molecules they bind and the driving force for complexation. Why this is important will become clear later on, but it should not be forgotten that binding studies are carried out in solvents, and all entities in solution will be solvated to some extent. Hence. upon complexation. degrees of desolvation of the molecular species must occur so that binding is allowed to take place. Even this simplified picture does not explain the binding of certain cyclophane structures. because, for example, ion-pairing effects and solvotophobic effects play an important role in molecular association.

Over the last 10 years or so, numerous books (Diederich[3] and Vögtle[4] are particularly recommended) and chapters in books were published, covering many aspects of cyclophane chemistry.[5] Readers are pointed to a recent review on "Synthetic Receptors'' that also embraces many aspects of cyclophane chemistry.[6] It is the intention of this article in the *Encyclopedia* to focus on more recent developments toward the end of the last century and the turn of the new millennium. The examples chosen are in no way exhaustive but rather serve as pertinent examples to emphasize the types of cavities the cyclophane receptors possess and interactions that drive complexation. Where possible, the bioinimetic nature of the receptors will be discussed; because the ultimate goal in much of cyclophane work is to mimic nature's processes. It is hoped that the reader will see the cross-fertilization of cyclophane chemistry and how examples discussed in other articles on. for example, cyclodextrins, cryptophanes. cavitands, crown ethers, etc.. are just as relevant to this article.

ENDOACIDIC CYCLOPHANES

Endoacidic cyclophanes contain cavities with functional groups thai are acidic; and hence. they have the potential to bind cation guests such as metal ions. quaternary ammonium salts, positively charged species, and H-bonding solvents. Obvious acidic groups that could be part of the cyclophane skeleton structure include carboxylic acids, phenols, etc. In the general definition. we can also include cyclophane structures that are π-acidic (electron accepting) and use intimate donor–acceptor interactions to drive binding.

Cryptophanes comprise a class of compounds made up of two cone-shaped cyclotriveratrylene units attached to one another by three bridges. This feature leads to a highly preorganized three-dimensional enforced cavity suitable for accommodating organic substrates. In general. these classes of compounds contain, on the periphery, substituted methoxy groups, and examples are rare where substitution with ionizable groups was carried out. This situation was recently rectified by the group of Weber,[7] who successfully prepared the new cyclophane receptor **1** featuring three *endo*-carboxylic acid groups (Fig. 1). Complexation studies were performed using **1** in $CDCl_3$ and a range of alcohols (methanol, ethanol, and isopropanol). because proton donor–acceptor interactions were considered to operate. No binding to isopropanol was observed to take place, which is attributed to its inability to pass through the narrow openings of the cyclophane wall. The smaller alcohols were. however, found to navigate the passages. and binding constants for 1:1 complexation of methanol and ethanol were determined to be 7500 and 41 dm' mol ^{1}. respectively. Interestingly, small dipolar solvents with proton acceptor capabilities. such as acetonitrile, nitromethane, acetaldehyde, and acetone. also tested as guests. failed to form detectable complexes. Solvent extraction studies of metal ions were fortunately more rewarding and highlighted the capability of **1** to act as an ion carrier. Cyclophane **1** acts as an efficient transporter of highly charged. hard metal ions of matching size. including divalent alkaline earth metals (e.g., Ca^{2+}, Sr^{2+}) and trivalent lanthanide metal ions (e.g., Yb^{3+}).

it is worth noting that **1** represents the spherical analogue of the proposed *endo*-cyclophanes **2a** and **2b**

Encyclopedia of Supramolecular Chemistry

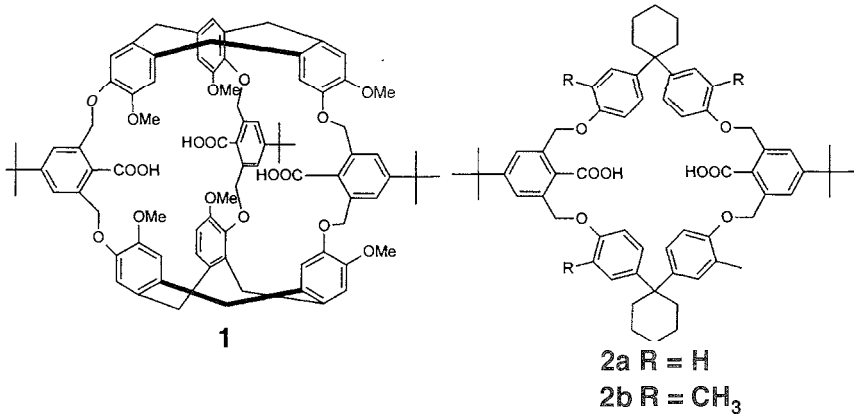

Fig. 1 Examples of endoacidic cyclophane hosts containing carboxylate binding sites.

prepared by the same group. which once again contain carboxylate moieties capable of convergent binding.[8] The cyclophane **2b** was found to be an excellent host for numerous solvents, where host:guest ratios vary from 1:1 (benzoquinone, benzene, cyclohexane, toluene: and DABCO) to 1:2 (DMSO, propionic acid, and methanol) to 1:4 (acetic acid. acetone). For these host–guest complexes, the structures of the adducts are not unique along the series. The single-crystal x-ray structure of **2b**.4 (acetic acid) $2H_2O$ (Fig. 2A) clearly demonstrates that the cavity is filled by methyl groups, thus forcing both the carboxylate units to an exo orientation. On the other hand, the carboxylate groups do not take an exo or *endo* orientation in the host–guest complex 2b.2 (propionic acid), as illustrated in Fig. 2B.

Without doubt, the most widely known *endo* π-acidic cyclophane is Stoddart's "blue-box" **3** that incorporates in the cyclic framework two electron-deficient (electron acceptor) *N,N'*-bipyridinium units.[9] The cavity size is consummate for binding a wide range of electron-rich (electron donor) aromatics in organic and aqueous solvents. The intimate interaction between donor and acceptor groups is evident, because a broad charge-transfer absorption band is observed in the visible spectral region. Because of the rigidity and highly beneficial photophysical properties of cyclophane **3**, and its host–guest complexes, many applications have emerged, including testing electron-transfer theory,[10] mimicking photosynthesis,[11] and light-activated devices,[12] to name a few. Since this pioneering work. new n-acceptor cyclophanes based on. and similar to, **3** emerged. by Stoddart and other groups as well.[13] The work of the group of Mallouk[14] is highlighted here, because they took the basic design of 3, incorporated extra recognition sites, and exchanged the cation electron-affinic groups with neutral electron acceptor units (Fig. 3). It could be argued that these cyclophanes cannot be considered as endoacidic cyclophanes, which to an extent is true, because other functional groups are added. Hopefully. the reader will see that there is a great deal of crossover when categorizing cyclophane structures; and many could be included in other sections.

The cyclophane 4 incorporating the tripeptide backbone was the first attempt at creating a chiral host for shape-selective molecular recognition. This group is mainly interested in intercalating host molecules into α-zirconium phosphate (α-ZrP) for applications in such areas as preparative-scale chiral separation. Although 4 displayed considerable promise in chiral recognition of racemic DOPA [3-(3,4-dihydroxyphenyl)-DL-alanine) in a water–acetone mixture, the same molecule embedded in (α-ZrP) was not an effective chiral separation agent. It was hypothesized that this lack of recognition was caused by reduction in the n-acidic nature of the cyclophane, caused by close association of the negative α-ZrP with the *N,N*-bipyridinium group. Cyclophanes **5**–**7** represent the next stage of development by Mallouk et al. to overcome this problem. An association constant (K) of 13 ± 1 dm^3 mol^{-1} was determined for **5** and indole in chloroform. Unfortunately, the low solubility of **6** and **7** in chloroform (the curse for all binding studies) meant that similar binding constants could not be obtained with indole. Even more disappointing was that no obvious binding of **6** and **7** with indole could be detected when the solvent was changed to DMSO. Why should this be the case, because indole is a good electron donor, and the aromatics used are recognized to be adequate electron acceptors? The strength of the cyciophane–guest interaction depends on several factors. The first is the stereoelectronic complementarity between host and guest. which leads to favorable donor–acceptor, hydrogen bonding, and other interactions. The second is the preorganization of the host, i.e.. the existence of a rigid binding pocket that does not require loss of entropy to accommodate the guest. The third. and often neglected, is the donor ability of the solvent. which determines how heavily solvated the separated molecular

species really are, i.e., association will only take place if it is favorable for the host and guest to bind rather than be solvated in solution. In this case. DMSO is a strong donor solvent and would solvate strongly the indole and cyclophanes. Other steric factors could also play a role. especially in cyclophane **7**, where molecular modeling shows that nitro groups sterically inhibit π-complexation.

ENDOBASIC CYCLOPHANES

The internal cavity of a cyclophane is endobasic if functional groups are present that are basic or electron donating: the most obvious groups include the ethers, pyridines, amines. and phosphorus-based donors. Cyclophanes in this category would be expected to bind metal ions and also promote H-bonding interactions within the cavity. Hence, in this section, crown ethers and azamacrocycles could easily be included. Under this heading, we can also

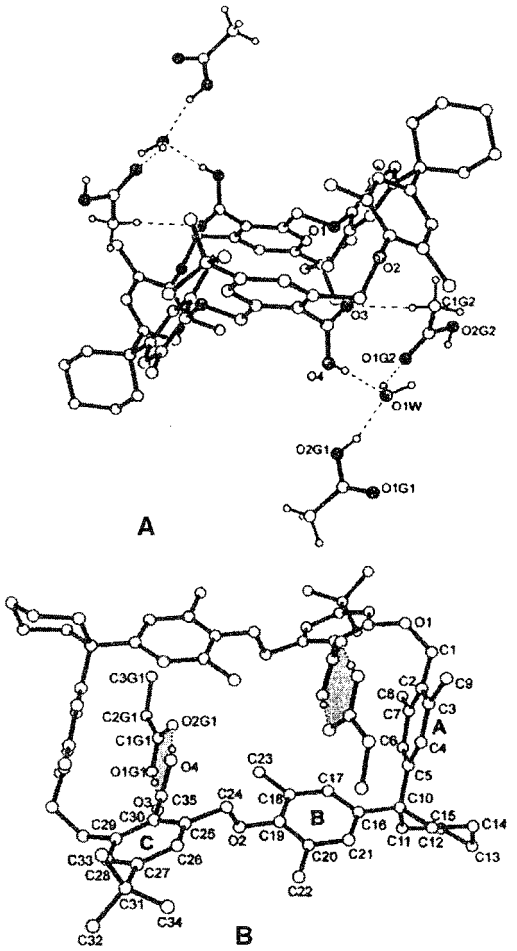

Fig. 2 Crystal structures of cyclophane complexes 2b.4 (acetic acid) $2H_2O$ (A) and **2b**.2 (propionic acid) (B).

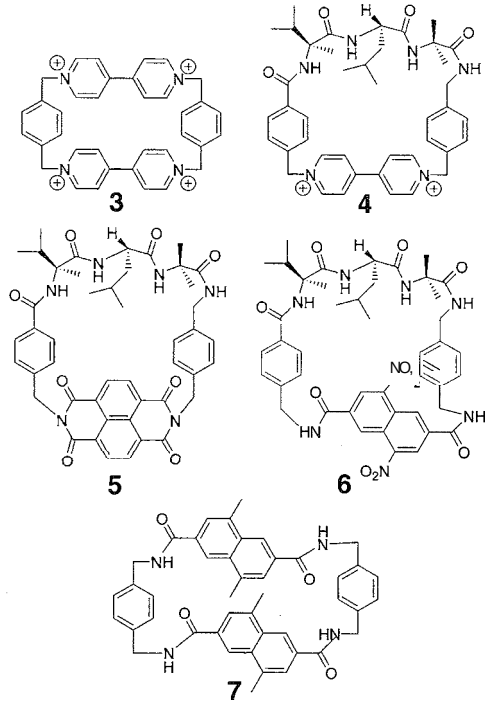

Fig. **3** The *endo* π-acidic cyclophanes incorporating cationic and neutral electron acceptors.

incorporate electron-rich aromatics, because n-donation to an electron acceptor will result in host–guest binding.

Collected in Fig. 4 are examples of cyclophanes containing the correct functional groups for inclusion in this section. The three-dimensional Structure *8* prepared by Takemura and coworkers[''''] incorporates four pyridine donor sites. as well as potential N and O donors as part of the connecting straps. The x-ray structure of the potassium adduct of **8** clearly established the *endo* binding nature of the pyridine. nitrogen. and oxygen atoms. The cyclophane cavity is consummate for host–guest complexation of other cations. Inclusion properties of the cyclophane were also carried out with varying anions (Cl^-, F , Br , I , BF_4^-) in 10% D_2SO_4; the protonated form of the cyclophane enhances binding because of favorable cation–anion interactions. A binding constant of 24 ± 2 dm^3 mol^{-1} for Cl^- complexation was determined, and thermodynamic data obtained by a van't Hoff plot afforded ΔH° (-2.9 kcal mol ') and AS" (-3.9 cal K^{-1} mol '). Larger anions Br^-, I , and BF_4^- were not complexed by the cyclophane.

Twistophanes **10** and **11** represent a new class of cyclophanes that recently emerged as the follow-up compounds to the endobasic host **9** first prepared by Baxter.[16] The cyclic structures comprise substituted 2,2′-bipyridyl groups linked via acetylinic linkers, and they are primarily developed as sensors for metal ions. For both

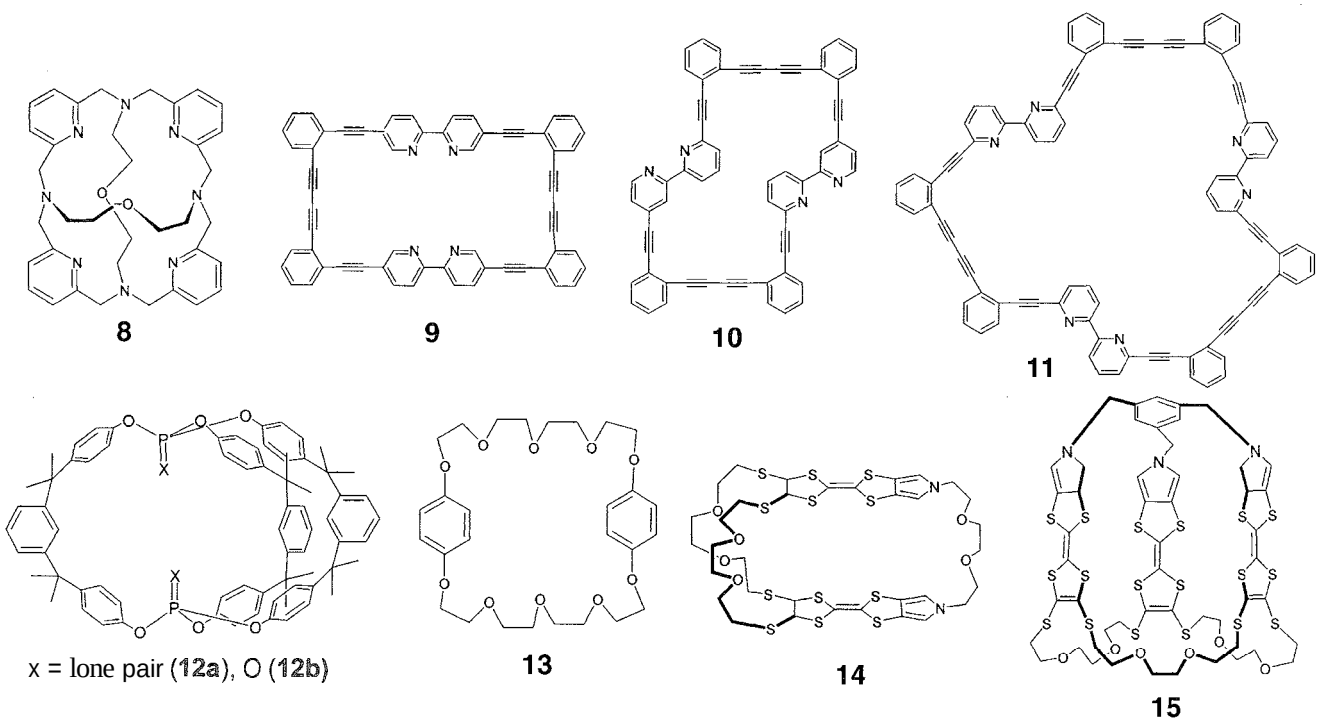

Fig. 4 Examples of multidimensional structures containing donor sites for molecular recognition.

bipyridine subunits of **9** to bind a single metal ion, the twisted carbon backbone must slightly unwind, thus permitting the bipyridine rings to rotate about the long axis and orient the four nitrogen lone pairs in an *endo* orientation. In this case, only a minimal change in conformation is required. So, a spectroscopic response from metal-ion binding originates only from electron distribution perturbations communicated through the bipyridine nitrogen lone pairs. The new cyclophanes 10 and **11**, however, must undergo larger structural alterations and, hence, more significant electronic perturbations upon metal ion binding. Ultraviolet-Visible spectroscopic studies revealed that **10** and **11** bind with dissimilar selectivities to the following metal ions: Cu(II), Ag(I), Hg(II), Th(I), and Pd(II). Fluorescence quenching observed for **10** and **11** (1: 2 $CHCl_3$/MeOH) in the presence of Cu(II) ions also support that these new twistophanes could be used as sensors. It is also worth noting that the cyclophanes function also as chromogenic fluorescence sensors for protons.

Endo-functionalized cyclophanes incorporating trivalent phosphorus are potentially interesting, because the soft donor site is perfect for binding soft transition metals that have applications in many catalysis reactions. Trivalent phosphorus atoms easily undergo oxidation to afford pentavalent species such as phosphoryl moieties. Thus, the phosphoryl oxygen can act as a hard donor site. which once again, can be used for metal ion binding, but also molecular recognition of H-bonding substrates such as biologically interesting amino acids. Cyclophane systems incorporating P-bridgehead atoms are not common, and reported assemblies show the expected *endo*/*exo* isomerism. A recent example of the synthesis of *endo*–*endo* P-based cyclophanes (**12a**/**12b**) was reported by Bauer and Habicher.[17] The x-ray structure of endo–endo **12a** shows two flat cyclic conformers with P–P distances of 4.5 Å and 5.3 Å, respectively.

In the previous article, the n-acidic "blue box" of Stoddart was introduced as a cyclophane capable of binding electron donor groups. Here. we introduce the reverse analogue of this cyclophane. 13, in which the donor groups form part of the cyclic structure, and hence, bind electron-deficient molecules.[18] Cyclophane 13 and its analogues now have a central role in the creation of more exotic structures such as rotaxanes[19] and catenanes.[20] More recently. a move toward tetrathiafulvalene-based cyclophanes was made because of their unique π-electron donor properties. Structures **14** and **15** represent two such examples prepared by the group of Becher.[21] The central cavity of cyclophane 14 is a little too small to accommodate electron-deficient guests such as 7,7,8,8-tetracycano-π-quinodimethane. Preliminary complexation studies with **15** and 1,3,5-trinitrobenzene have been more encouraging. The addition of one equivalent of 1,3,5-trinitrobenzene to a solution of 15 in chloroform resulted in a color change from orange to light green and the

appearance of a CT absorption band at 646 nm. The 'H-NMR evidence was also consistent with the formation of a 1:1 host–guest complex, presumably with the 1,3,5-trinitrobenzene moiety residing in the donor cage.

ENDOLIPOPHILIC CYCLOPHANES

The final category in this series is the endolipophilic cyclophanes that possess internal cavities that bind organic entities through $\pi-\pi$ stacking or other dispersive forces. This class of cyclophanes is probably the most extensive, and examples are numerous. Illustrated in Fig. 5 are just a handful of recent diverse examples from the literature. A common thread running in these examples is their biomimetic nature, in which host–guest chemistry involves the binding of biologically relevant molecules.

Cyclophane 16 represents a lipophilic host specifically prepared by Roelens and Bartoli,[22] as part of their continuing research effort. to ascertain the influence of cation–n interaction on the binding of numerous acetylcholine (Ac) derivatives and tetramethylammonium (TMA) salts.[23] Association constants were measured for 17 salts of commonly used anions; binding energies ($-\Delta G^{\circ}$) ranged from over 8 kJ mol^{-1} down to the limit of detection. Thermodynamic parameters ascertained for the association of 16 with TMA.picrate demonstrate that binding is enthalpic in origin, with a substantial enthalpy gain ($\Delta H^{\circ} = -16.7$ kJ mol^{-1}) and an unfavorable entropic contribution ($AS^{\circ} = -27.9$ J mol^{-1} K^{-1}). Interestingly. there is a good correlation between the ''goodness'' of anions as guest partners and the solubility of their salts. When the salts were converted to more charge-dispersed species such as dialkyltrichlorostannate salts. cation binding substantially improved, which indicates that charge dispersion is a main factor determining the influence of the anion on the cation–n interaction. Detailed high-level computational studies were also performed to ascertain the influence of the counterion on the binding free energy of TMA with Cyclophane 16. It was found that binding energies correlated with the electrostatic potential of the ion pair. In other words, the guest binding behavior is determined by the cation's

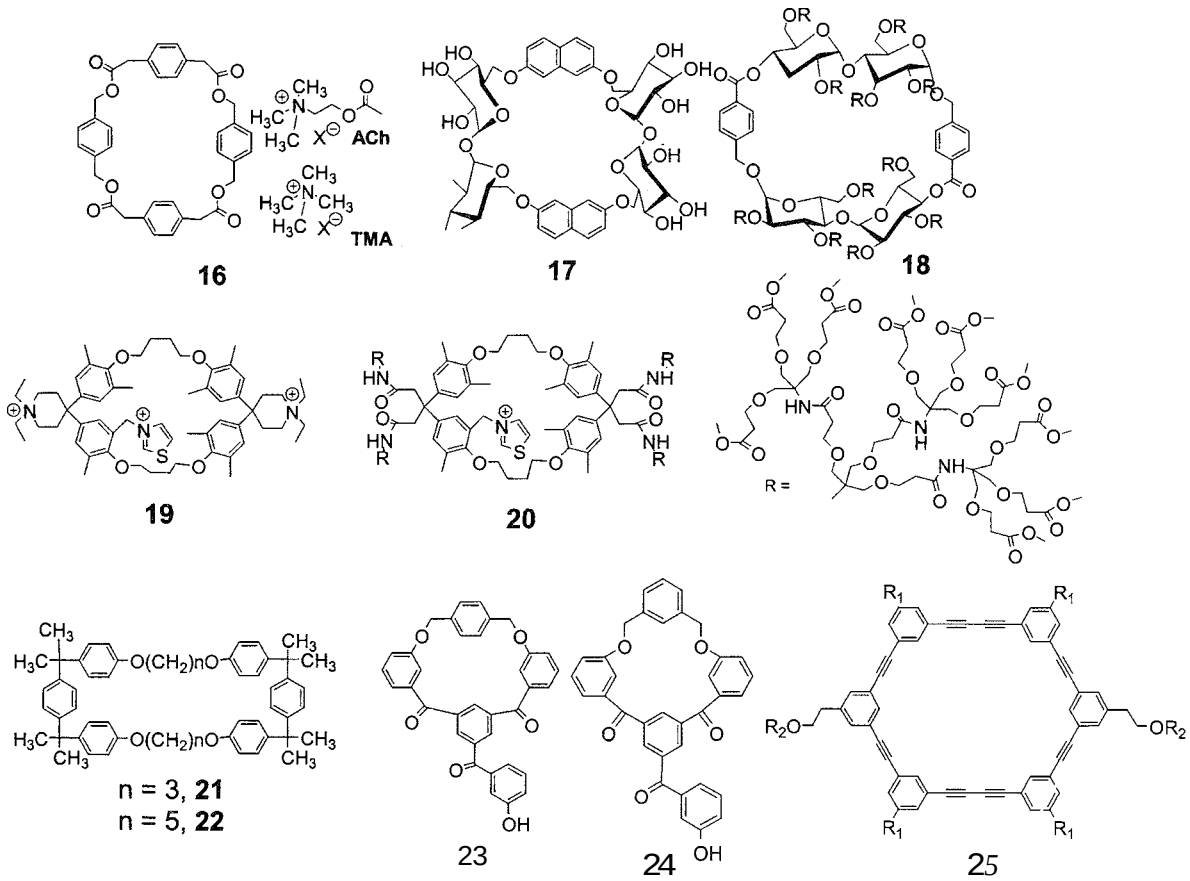

Fig. 5 A selection of endolipophilic cyclophanes for binding a range of guest molecules

charge density exposed to the receptor, which is determined by the anion's charge density by way of a polarization mechanism.

The cyclic sugar compounds cyclodextrins have long been recognized as water-soluble hosts for aromatics. The internal cavity is hydrophobic (or lipophilic), and complexation of aromatics is driven by solvotophobic response. Glycophanes represent a class of compounds incorporating sugar residues associated with cyclodextrins and aromatics more in fitting with cyclophanes; hence, the name glycophane. meaning cyclodextrin+cyclophane. The compounds **17** and **18** are two such examples reported by the group of Penadés.[24] Carbohydrate–carbohydrate interactions are recognized as important interactions that manipulate processes within cells. Hence. the two cyclophanes were developed to establish the strength of carbohydrate–carbohydrate interactions in water. Binding of **17** and **18** in water toward a series of 4-nitrophenyl glycosides with axial α-D-gluco(α-Glc), α-D-galacto (α-Gal), α-D-manno (αMan), β-L-arabino (βLAra), and α-L-fucopyranoside (αLFuc), plus equatorial β-D-gluco (βGlc), β-D-galacto (βGal), β-D-manno (βMan), z-L-arabino (αLAra), and β-L-fucopyranoside (βLFuc) configurations at the anomeric center were measured by ^{1}H-NMR spectroscopy. The overall findings of the work suggest that within glycophanes, carbohydrate–carbohydrate interactions in water contribute to the affinity of binding. Thus. the systems seem to reproduce the nonpolar interactions between lipophilic surfaces found in sugars binding to proteins.

Enzymes are nature's work horses. specifically designed for carrying out many essential transformations in biological systems. Small molecule mimics of enzymes based on cyclophanes are highly sought-after commodities in the supramolecular chemistry field. Compounds 19 and 20 are a class of thiazolio-based cyclophanes developed by Diederich et al.[25] for mimicking the action of thiamine diphosphate-dependent enzymes. Cyclophane 19 is a mimic of pyruvate oxidase and was shown to catalytically oxidize napthalene-2-carbaldehyde to methyl naphthalene-2-carboxylate, as illustrated in the cycle of Fig. 6. In basic MeOH. solution 19 is in equilibrium with the thiazolium ylide that reacts with bound aromatic aldehyde to afford an activated aldehyde. In the presence of an oxidant, the intermediate is transforined to the 2-acylthiazolium ion. The methyi ester is generated in a rapid reaction of the intermediate with the solvent. One outcome of this work was the understanding of how the microenvironment at the active site is critical for rate enhancement. That is, the large contribution to the catalytic behavior is the reduced polarity at the active site. Hence. the dendritic cyclophane *20* was designed and synthesized so as to alter the microenvironrnent at the active site. Unfortunately. **20** exhibited only a weak catalytic activity hypothesized to be due to steric hindrance of reaction transition states by the dendritic branches.

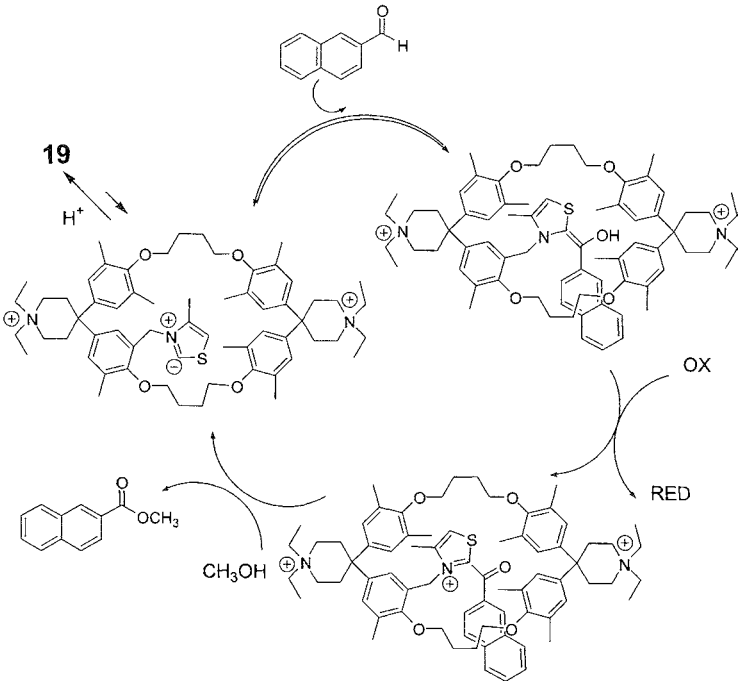

Fig. 6 Proposed catalytic oxidation cycle for conversion of napthalene-2-carbaldehyde to methyl naphthalene-2-carboxylate using a functionalized cyclophane

To conclude this final section. the cyclophanes 21–25 are illustrated as recent new additions to the host–guest arena. Bartsch and coworkers[26] recently reported the synthesis of the π-electron-rich hydrophobic cyclophanes 21–22 that are termed "corrals" because of the walled enclosure. The binding ability of 2%is limited, but the crystal structure of the anthracene adduct confirms that the cavity is consummate for binding, with edge-to-face π-interactions locking the guest in place. The linked aromatic motif is a popular approach in cyclophane construction. and 23–24 are two examples of Pigge et al.[27] constructed via an enaminone-directed benzannulation macrocyclization reaction. Although no binding studies were reported so far. x-ray crystal structures confirm that the cyclophanes adopt conformations suited for molecular association. The shape-persistent cyclophanes (SPCs) 25 (R_1=$OC_{12}H_{25}$, R_2=TBS; R_1=$COOC_{12}H_{25}$, R_2=TBS; R_1=$OC_{12}H_{25}$, R_2=H; R_1=$COOC_{12}H_{25}$, R_2=H) comprise an interesting class of compounds recently reported by Tour and Lin.[27] In a sense, the cavities in these compounds are not as important as their intermolecular π-stacking ability. The cyclophanes were shown to dimerize in solution using n-stacking and hydrogen-bonding interactions. Clearly. further oligomerization is eventually the goal so that well-defined suprainolecular assemblies (nanostructures) are generated containing internal cavities for aromatic encapsulation.

CONCLUSION

Cyclophane chemistry is flourishing and important field in the general area of supramolecular science. The hosts bind a multitude of species to varying degrees using a wide range of intermolecular noncovalent forces. In specific cases, they can help us understand the role these weak forces play in biological receptors. or offer the possibility of mimicking the enzyme reactions that nature uses so well. In an attempt to keep up with the most up-to-date advances in the field of cyclophanes, references to works were, where possible, taken from recent papers. However. the field is expanding so rapidly that new examples will be in the literature as this article is published.

Dendrimers

University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

From the time that chemists could characterize and manipulate molecular architecture, methods have been sought to enhance and modify molecular properties with an eye toward, among other attributes. intra- and intermolecular interactions based on covalent and noncovalent means. Evolution of the study of these properties and interactions has led to the supramolecular regime, whereby noncovalent molecular interplay produces effects and properties not ordinarily exhibited by the individual components.

This supramolecular tenant, defined by J.M. Lehn, is classically exhibited by the action of a micelle, whereby surfactant molecules aggregate into a globular motif that is capable of enhancing molecular guests' solubilities or acting as nanoscale reactors and transport vehicles, to mention but a few utilities. The micelle architecture, as well as the lipophilic-hydrophilic character, leads logically to the consideration of dendrimers as supramolecular components; this potential is herein chronicled.

Dendrimers are first examined with respect to their ability to soiubilize molecular guests in environments that, without added dendrirner. would exhibit unfavorable solubility properties. such as dissolution of water-insoluble molecules. Numerous dendritic architectures are highlighted with respect to this phenomenon.

The potential of dendrimers to encapsulate molecular species is further examined from the perspective of catalysis and the ability to improve reaction rates and yields. As well. their use as components facilitating chroinatographic separations is discussed. Finally, the use of dendrimers to effect noncovalent molecular ordering is examined.

MICELLAR ASPECTS

Consideration of the generally globular. or pseudo-spherical. 3-dimensional architecture of dendritic molecules".'' naturally leads to a comparison with the idealized concept of micellar organization and properties (Fig. I). From the perspective of classical, charged amphiphilic aggregation (1) above the critical micelle concentration (cmc). dendrimers (2) are structurally similar in that charged, or polar, surfaces connected to more lipophilic interior frameworks are readily attainable. Of course, reversible micellar characteristics (i.e., lipophilic exteriors and hydrophilic interiors) are also conceivable and have been demonstrated. Thus, to date, a structurally diverse array of nanoscopic-sized dendrirners has been shown to possess structural parameters comparable to that of supramolecular aggregates known as micelles.[3] Notably, even though in most cases monomer connectivity is covalent, the iterative nature of dendritic construction imparts an ordering to the building blocks that creates molecular characteristics inaccessible by a collection of simple unordered monomers.

However. it is not only from an architectural viewpoint that dendrirners can be contrasted to organized assemblies. but micellar stabilization and organization of species in uncharacteristic environments are also suggested. Thus. structural attributes of branched frameworks can be employed for such applications as aqueous solubilization of inherently water-insoluble species as well as molecular ordering based on noncovalent interactions, such as *H*-bonding and ionic associations. The advent and current status of several dendritic micelles are herein chronicled.

Internal Inclusion

With the beginning[4,5] of dendrirner chemistry in 1985, and the successful construction of branched, multifunctional architectures such as polyols **3** and 4 (Fig. 2), the logical application of supramolecular chemistry to this field was obvious, as noted by the original introduction[4] of the ierm ''unimolecular micelle.'' It would, however, be several years before the actual proof-of-concept for covalently connected surfactant moieties was unequivocally demonstrated[6,7] in the all-hydrocarbon micellane series;[8] this was the first example of a unimolecular micelle that incorporated the lipophilic/hydrophilic features of a classical micelle into a single molecule. Pivotal to its construction was access to monomers possessing

tetraalkyl-substituted quaternary carbon branching centers via the free radical-promoted replacement of a tertiary nitro *group with an electron-deficient alkene* (i.e., *acrylonitrile or an* alkyl *acrylate).*

Thus reaction of the tetrabromide core 5 *with four equivalents of the requisite terminal alkyne building block* 6 *via generation of the alkynide anion afforded the first generation polyalkyne; concomitant reduction and* deprotection *yielded the polyol. which was transformed to the corresponding polybromide for iteration. Following reduction and conversion of the periphery to carboxylic acid moieties, aqueous solubility was imparted by treatment with* $Me_4N^{[+]}OH^{[-]}$ to *form the* poly(ammonium *carboxylate)* 7.

Molecular inclusion was demonstrated by the aqueous solubilization and UV *and fluorescence analysis of the guest dyes phenol blue* (8), *pinacyanol chloride (9). chlortetracycline (10).and naphthalene (11).Fluorescence lifetime decay experiments using* 1,*6-diphenylhexatriene* (12) *as the probe further supported the host–guest relationship: while electron microscopy (EM)* corroborated *the single molecule. non-aggregated state. Calculated molecular modeling diameters of* 48 Å in *a fully extended conformation were also substantiated via EM.*

Prior to micellane construction, ca. 1989, *Tomalia and* coworkers[9] *examined the* $^{[13]}$C-NMR T_1 (spin-*lattice) relaxation times of* 2,4-dichlorophenoxyacetic

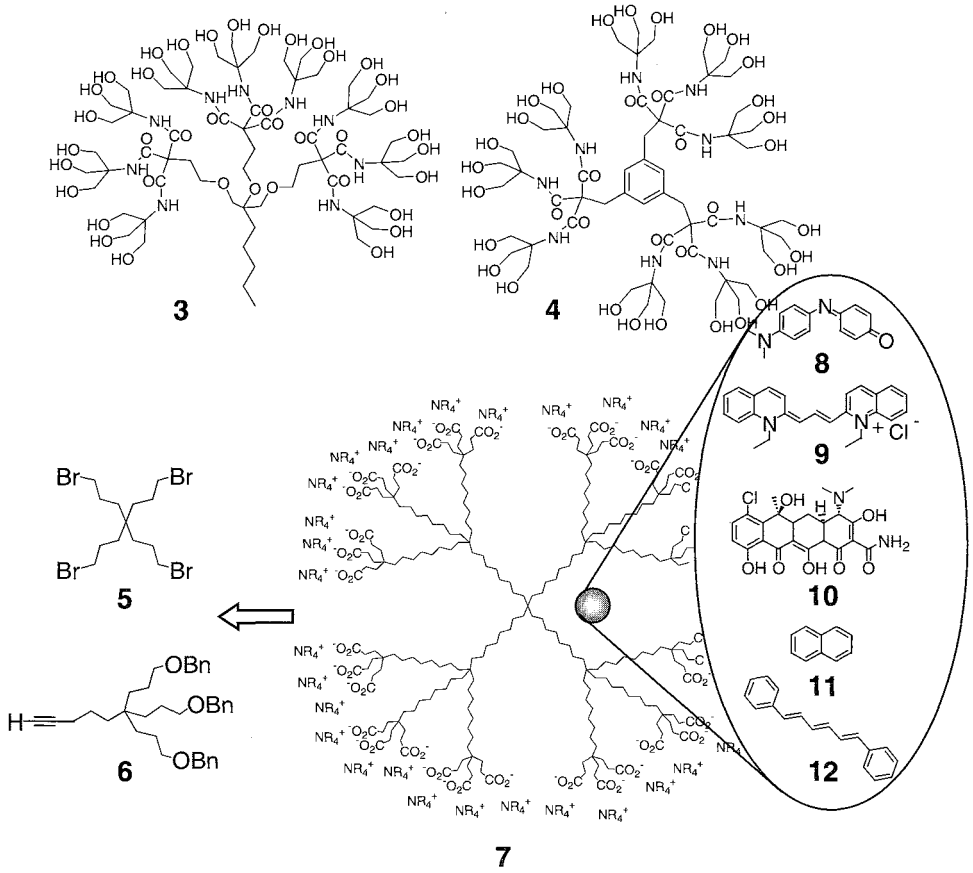

Fig. 2 Early *tris*-terminated, branched architectures (i.e., 3 and 4) were described as possessing micellar architecture and character: and study of the properties of nuinerous encapsulated molecular guests proved the micellar character of the first, all-alkyl hydrocarbon dendrimer 7.

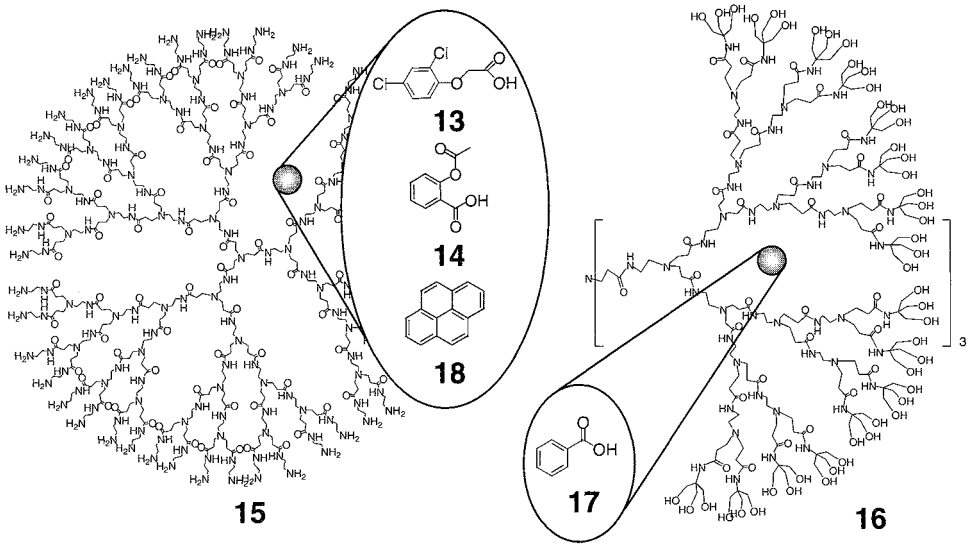

Fig. 3 [13]C-NMR spin-lattice (T_1) relaxation studies of guests, such as acetylsalisylic acid (14), encapsulated in polyamidoamine dendrimers (15) and the enhanced *aqueous* solubility of guests (i.e., 17) reveal the micellar nature of dendrimers.

acid (13) and acetylsalicylic acid (14) in the presence of PAMAM (polyamidoamine) *dendrimers* (15; *Fig. 3, prepared via repetition of two steps. exhaustive amine alkylation with methyl acrylate followed by amidation of the resulting ester* moieties with *1.2-diaminoethane to regenerate the* amine *surface) and in bulk solution alone. Relaxation* times *were found to be significantly* lower *with added host. suggesting molecular inclusion within the dendrimer. or a dendrimer aggregate, as noted by the authors.*

Other notable PAMAM-based host–guest studies have appeared. Tris(hydroxymethyl)aminomethane-(TRIS) *terminated* PAMAMs (16) *have been* created[10] *by reaction of* TRIS *with the ester groups on the surface. Inclusion complexes with, for example, benzoic acid* (17), *significantly increased guest aqueous solubility 300-fold at neutral pH; while the above* PAMAM *examples denote an acid–base interaction,* Turro *and* coworkers[11,12] *used pyrene* (18) *in* photoluminescent *experiments to evaluate internal hydophobicity and thereby corroborate a predicted morphology change* for *this family* [i.e., *changing* to *a* more *globular shape with a more closed and congested surface'" beyond generation* 3.5].

PAMAMs *constructed starting with lipophilic* C_{12} *cores have been exploited as hosts for studies using the dye Nile* red.[13] *Notably. aqueous fluorescence emission was significantly enhanced by the formation of a* dendrimer-surfactant *assembly upon amphiphile addition. Modification of* PAMAM *surfaces by* treatment *with* epoxyalkanes,[14] such *as* 1,2-epoxyhexane *and* 1,2-*epoxyoctane. produced* nanoscopic *container molecules that facilitated the solubilization of* $CuSO_4$ *in toluene when placed in contact with a 0.1 M aqueous solution.*

Meijer *and* coworkers[15] *provided a striking example of dendrimer-based. host–guest interaction (Fig. 4) by successfully sterically trapping 3-carboxyproxyl radicals (19).* 7,7,8,8-tetracyanoquinodimethane *(20:TCNQ), and the dye Rose Bengal* (21) *within the interior of fifth-generation* poly(propyleneimine) (PPIs; *accessed by repetitive terrninal* amine *alkylation* with *acrylonitrile and subsequent* nitrile reduction *to regenerate a set of new amines for further elaboration) dendrimers described as a dendritic box (22). A filled dendritic box was prepared by reacting the* amine *surface with an activated ester of a t-*BOC-protected *amino acid. such as phenylalanine, in the presence of encapsulated guests; notably, complete impermeability of the shell by trapped molecules was observed.*

The PPI *series has also been used to craft inverted* micelles[16] *via termini modification with long-chain* ($C_{5,9-15}$) *acid chlorides. Ethanol solutions of these dendrimers and Rose Bengal afforded second- and fifth-generation* unimolecular *micelles entrapping an average of one and seven (or eight) guests. respectively.* Dynamic *light scattering experiments supported single particle behavior. Also. coating the surface with palmitoyl chloride and subjecting to low pH gave rise to efficient anionic dye* extractors;[17] *however. higher* pH *environments* (i.e., >6), *afforded less-effective extractors. Similar materials have been* employed *for* oxyanion-*based extraction of pertechnetate, perrhenate, AMP. ADP, and* ATP.[18] *As well. host–guest binding constants using*

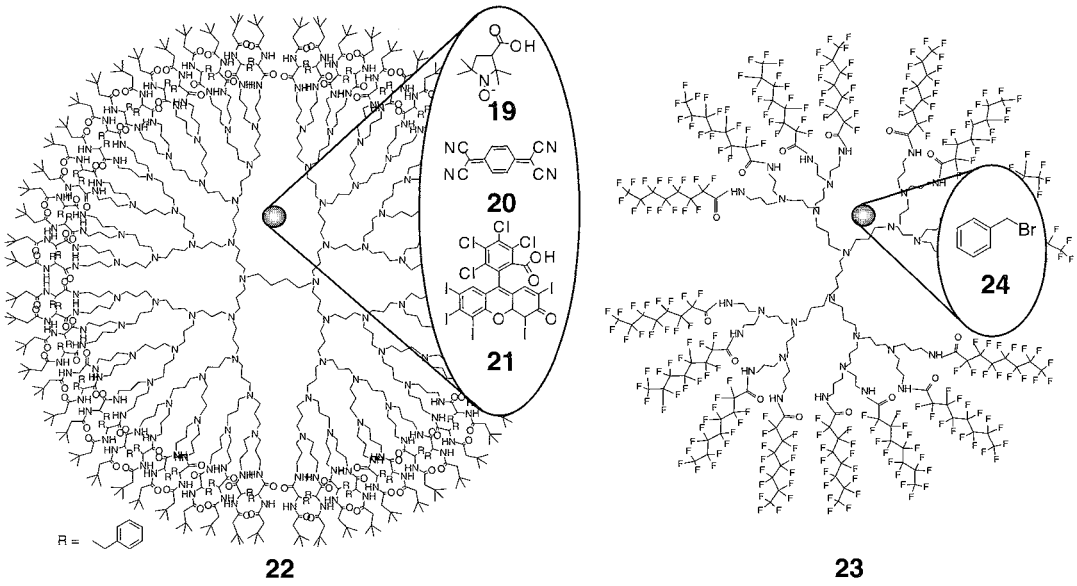

Fig. **4** A dendritic box has been shown to trap molecular guests (i.e., **22**), while fluorinated constructs (23) show promise as phase-transfer catalysts.

pyrene as the probe,[19] PPIs quaternized with glycidyltrimethylammonium chloride as pH-sensitive. controlled drug release systems,[20] and unimolecular micelles crafted by the preparation of oligo(ethyleneoxy)-terminated PPIs[21] have also been reported.

Researchers van der Broeke and coworkers[''' created perfluoro-functionalized poly(propyleneimine) dendrimers (23; Fig. 4) and demonstrated their potential as phase-transfer catalysts in supercritical carbon-dioxide–water mixtures and as anionic species extractants. The dendrimers were accessed via reaction of perfluorinated, linear alkyl acid chlorides with the terminal amines. Extraction of perinanganate or dichromate from aqueous to CO_2 solution was described as rather low, whereas their use as phase-transfer catalysts in a halogen exchange reaction [benzyl chloride to benzyi bromide (24)] resulted in high rates of conversion.

Dykes et al.[23] reported that peptide-coupled L-lysine amino-acid-based dendrimers solubilized proflavin hydrochloride and aurin tricarboxylic acid in CH_2Cl_2. The degree of dye solubilization increased as the degree of branching increased (i.e., at higher generations), with generation 4 incorporating up to 97% of suspended proflavin •HCl in the best case. Dye incorporation was enhanced by focal carboxylic acid or amine coordination with a proflavin-free amine or an aurin acid moiety, respectively. Control experiments with unbranched hosts. such as acetic acid, showed very little dye uptake, as expected, further suggesting that ''ddedritic branching does indeed play a key role in the dye solubilization process.''[23]

Soon after the introduction of convergent dendrimer synthesis,[24] hemispherical. aryl-ester-coated, benzyl ether-based dendrons were reported.[25] Attachment to a divalent core and conversion to the polycarboxylate 25 (Fig. 5) yielded dendriiners that facilitated a 200-fold increase in pyrene (26) solubility in water compared with that of pure water without the dendrirner. Notably, use of sodium dodecyl sulfate (SDS; above cmc: $9 \times 10^{[-3]}$ M) for pyrene encapsulation resulted in only an 100-fold enhancement.

Piotti et al.[26] reported the construction of Fréchet-type reverse unimolecular micelles possessing polar internal aryl methyl esters at each generation and linear C_{14} alkyl chains at the periphery. Construction began with reaction of 3,5-*bis*(tetradecylaryl ether)benzyl bromide (27) with the 3,5-dihydroxybenzene (28). Repetition of the standard benzyl alcohol to bromide conversion[24] followed by phenolic substitution of the benzylic halide produced fourth-generation wedges that were subsequently attached to a *tris*(phenolic) core to afford the desired architecture 29. The internal methyl aryl ester groups were also converted to alcohols via $LiAlH_4$ reduction. Micellar potential was demonstrated by use of these dendrimers as catalysts in elimination reactions of tertiary iodoalkanes. The greatest effect was observed for the transformation of 2-iodo-2-methylheptane (30), with a recorded 99% conversion to alkene (dendrimer to substrate ratio. 1:17,600), while the lowest observed conversion was 83%.

Acid-terminated, amide-based dendrimers (i.e., 31) have been shown to be effective surfactant substitutes in

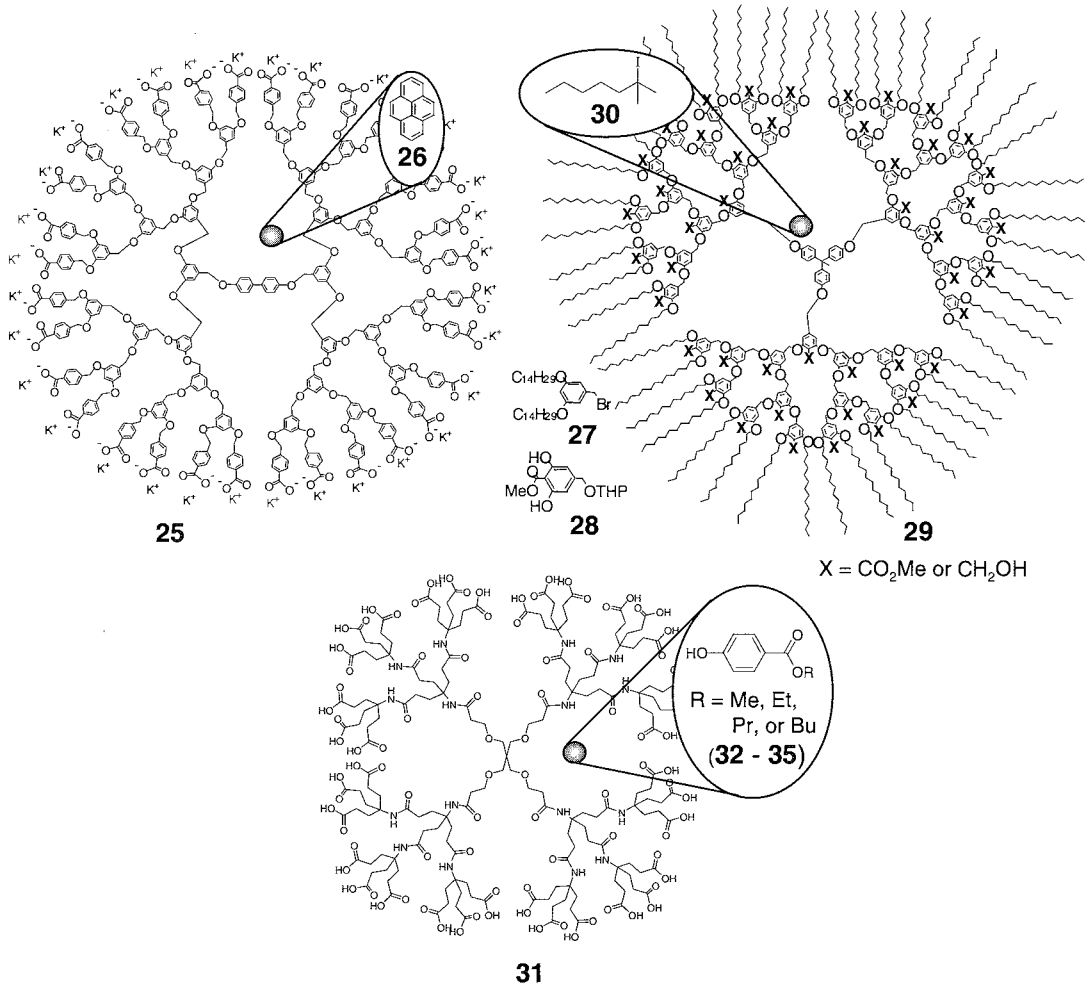

Fig. 5 A variety of architectures have been demonstrated to be useful aqueous solubility enhancements (**25**), catalysts for elimination reactions (**29**), and vehicles for chromatographic separations **(31).**

the analytical separation technique of micellar electrokinetic capillary chromatography (MECC).[27] The dendrimers were prepared by iterative peptide-type coupling followed by carboxylic acid deprotection using an amino*tris*(*tert*-butyl ester) building block: divergent synthesis began with a *tetrakis*(carboxylic acid) core. A series of alkyl parabens (methyl, ethyl, *n*-propyl, and *n*-butyl 4-hydroxybenzoate; **32–35)** were separated, employing first-, second-, and third-generation polyacids, with the higher construct affording the best results. Essentially, the greater the analyte:micellar (i.e., dendrimer) interaction, the longer the analyte retention time in the capillary. Thus, the observed order of elution started with the least lipophilic benzoate and progressed sucessively to the most lipophilic. Separations were shown to be strongly pH dependent, with acidic buffers yielding no results due to dendrimer interaction with the fused-silica capillary surface effectively stopping mobility. MECC has also been examined using PAMAM dendrimers as surfactant substitutes.[28]

Ordered Positioning

Whereas the majority of dendrimer-based lipophilic-hydrophilic inclusion phenomena discussed thus far results in random guest positioning on a branched framework. ordered interactions in supramolecular assemblies are also of interest. For example, González et al.[29] reported the surface modification of poly(propyleneimine)s with cobaltocenium groups that are easily reduced to Co(0). Reaction of the amine termini with 1-chlorocarbonylcobaltocenium afforded the metal-terminated dendrimers. The lipophilic, charge-neutral polycobaltocenes were rendered H_2O soluble via addition of β-cyclodextrin (36, β-CD) based on its cylindrical

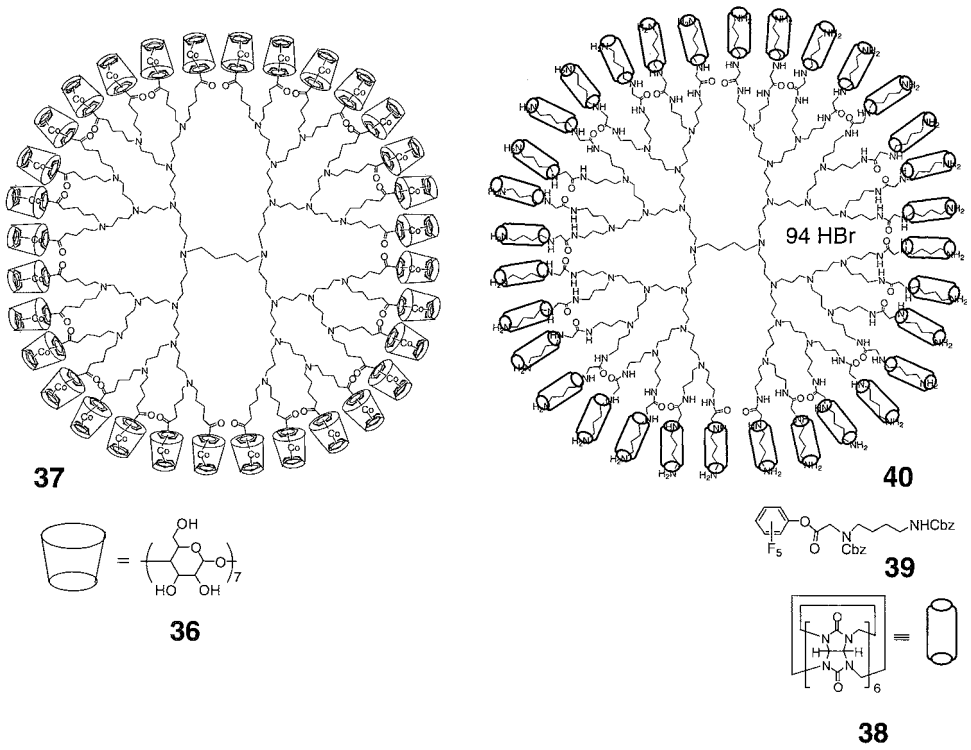

Fig. 6 Branched architectures have also demonstrated their utilitarian nature by facilitating supramolecular ordering on modified surfaces (i.e., 37 and 40).

encapsulation of the metallocene moieties (37; Fig. 6). Reversible electrochemical oxidation to the charged state afforded the uncomplexed dendrimer form. Similar ferrocenyl-terminated PPIs are also known.[30]

Kim and coworkers[31] adapted the periphery of PPIs for a similar, albeit more ionic, coordination with cylindrical cucurbituril (CB; 38) units to give a stable, poly(pseudorotaxane) architecture. The required *bis*(ammonium)-coated scaffolding was accessed via treatment of the dendriiner amine surface with the perfluorophenyl-activated ester of a *bis*(protected) diamine-modified acetate 39 followed by deprotection (HBr) of the diamine chains. Dissolution of the polyprotonated framework in H_2O followed by the addition of CB afforded the self-assembled product 40. Preliminary studies aimed at decomplexation via treatment with base yielded partial separation. T_1 (spin-lattice) relaxation experiments with the CB-dendrimer complex showed a sharp increase with higher generations, suggesting that the outer shell possessed attributes of a solid phase; such behavior has also been noted by Jansen et al.[15]

Newkome and coworkers[32] employed site-specific, *H*-bonding-based, molecular recognition on the interior of a branched framework for guest positioning. Incorporation of the binding sites was facilitated by a single-pot, three-component reaction, whereby 1,5-glutaryl dichloride was reacted with one equivalent of an amino-*tris*(*tert*-butyl ester) followed by treatment of an excess of 2,6-diaminopyridine to form an extended aminotriester useful in iteration. NMR titration experiments using glutarimide and 3'-azido-3'-deoxythimidine (AZT) revealed downfield shifts of the pyridyl diamide protons substantiating the dendrimer–guests complexes (e.g., 41).

Baars et al.[33] reported the peripheral amine modification of PPI frameworks with adamantane isocyanate to afforded terminal urea moieties. Supramolecular surface ordering of carboxylic acid-modified urea guests was achieved based on ionic-acid–base association at the outermost dendritic tertiary amine moieties and urea promoted H-bonding. T_1 relaxations were found to significantly increase at the complex surface verifying enhanced rigidity. Other assemblies of interest include PAMAM–fatty acid[12''] and PAMAM–surfactant''' mixtures.

CONCLUSION

Progress in supramolecular chemistry and nanotechnology is inherently linked to the building blocks that are available. Attributes of desirable building blocks include the potential to effect noncovalent molecular interactions

on their environment. Due to the modular and iterative features of branched. macromolecular architecture syntheses that facilitate the fine-tuning of physicochemical parameters. and from the perspective of multifunctional and multilevel interactions, dendrimers are uniquely and logically suited as supramolecular monomers.[36–58]

Osaka University, Osaka, Japan

INTRODUCTION

Deoxycholic, cholic, and apocholic acids were established to have abilities for including various organic compounds. They exhibit characteristic inclusion behaviors with different arrangements and hydrogen-bonding schemes. Their structures are equally the same but different in hydrogen-bonding groups. This prompts us to verify the other derivatives by simple modified the numbers of hydroxy groups with different locations and directions on the skeletons. as well as different side-chain length and functional groups on the side chains. This article will describe their inclusion compounds from the viewpoint of molecular assemblies and hydrogen-bond motifs.

ORIGIN OF BILE ACIDS

Bile acids are natural compounds that are produced in livers of vertebrate animals for digestion and absorption of fats and fat-soluble vitamins. Shown in Fig. 1 is the synthetic process of bile acids through cholesterol from isoprene. Cholesterol is converted to primary bile acids. such as cholic acid (CA). deoxycholic acid (DCA), chenodeoxychoiic acid (CDCA), and lithocholic acid (LCA).

FACIALLY AMPHIPHILIC AND ASYMMETRIC STRUCTURES OF BILE ACIDS

Bile acids are aliphatic compounds with unique structures. Shown in Fig. 2a is the molecular structure of **CA**. as compared to the turtle for simplicity. CA consists of large, rigid, facial skeletons as well as small, flexible, axial side chains. The skeletons accompany three hydroxyl groups and two methyl groups, which brings about facial amphiphilicity. The former groups point below the steroidal plane to form a hydrophilic face. while the latter groups point above the plane to form a lipophilic face. The facially asymmetric structure enables us to distinguish three axes of the skeletons. First, we call the hydrophilic and lipophilic sides "belly" and .'back." respectively. Second, we separate the small side chain as the "tail" and the reverse part of the skeleton as "head." Third, we discriminate the hydroxyl groups at carbon 7 and 12 positions as left and right. respectively.

HISTORICAL RESEARCH OF INCLUSION COMPOUNDS OF BILE ACIDS

Deoxycholic acid (DCA) is the first bile acid with inclusion ability that was established in a crystalline state."' So far, many research groups reported the inclusion compounds of DCA with various guest molecules, such as aliphatics. aromatics. alcohols, fatty acids, esters, ketones, and ethers. In mid-1980.~"Giglio overviewed the compounds and gave significant insight for flexible bilayer structures by means of energy calculation. Although DCA is a well-known host, there were no detailed reports on inclusion abilities of the related compounds. Only a little description is seen for apocholic acid (ACA). which has the same structure as DCA except for a double bond in the skeleton."' In 1986, Miyata and Miki et al. discovered lots of inclusion coinpounds of CA with channel structures."' This is the starting point at which to investigate inclusion phenomena of the other bile acids and their derivatives. Since then. several research groups dealt with their crystal structures and inclusion abilities. leading to the interpretation of comprehensive molecular recognition in size, shape. polarity. and chirality.

MODIFICATION OF BILE ACIDS AS HOST COMPOUNDS

The primary bile acids can be modified in many derivattves, as shown in Table 1 As for the side chains, we can change the carboxylic group to amide, hydroxyl, ester. and so on And we can decrease or increace the methylene number of the side chains Moreover, we can regulate the

direction of hydroxpl groups of the skeletons at axial or equatorial positions.

We usually search their inclusion abilities by using more than 100 organic compounds as guest candidates. The inclusion phenomena vary from one case to another. meaning that we do not always obtain their crystalline molecular assemblies. X-ray diffraction studies display that the steroidal hosts form various molecular assemblies such as monolayers. bilayers, helical tubes, and so on. In addition, we see diverse relationships among multiple host molecules and guest compounds. Such diversities originate from subtle differences on the hydrogen-bonding groups with respect to their positions and numbers. enabling us to compare hydrogen-bonding networks. molecular arrangements, inclusion behaviors, and so on, from a viewpoint of various donor–acceptor relationships between the hydrogen-bonding groups.

INCLUSION COMPOUNDS OF BILE ACIDS AND THEIR DERIVATIVES

Bile Acid Hosts

Deoxycholic acid (DCA)

DCA, one of the classical hosts, is known to form crystalline inclusion compounds with a wide range of organic substances. Craven and De Titta[5] reported the first crystal structure of DCA with acetic acid in 1972. Most of the crystals of DCA inclusion compounds belong to orchorhombic. and have cumulated bilayer structure5 with channels (Fig. 3a). The host molecules are arranged in a parallel fashion on the hydrophilic faces and in an antiparallel fashion on the lipophilic faces. as depicted in Fig. 2b. Also refer to the constant helical motif among hydrogen-bonding groups (see Fig. 6a).

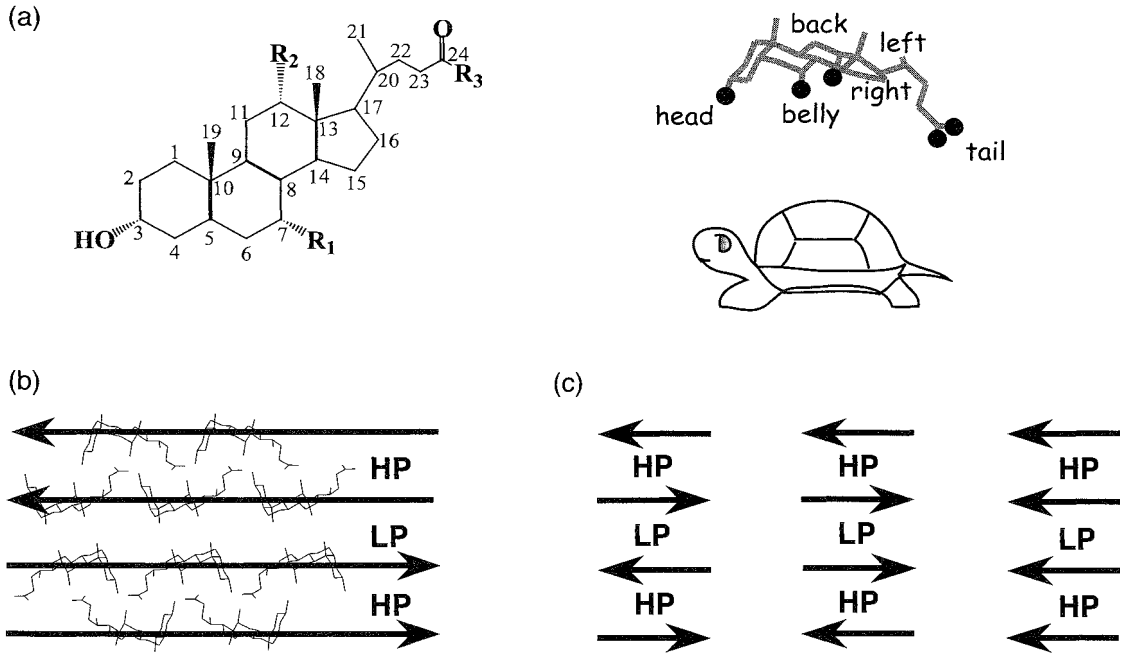

Fig. *2* (a) A facial amphiphilic and asymmetric structure of CA compared to turtle: (b) arrangements of the host molecules—parallel on the hydrophilic side (HP) and antiparallel on the lipophilic side (LP); and (c) three different arrangements in the bilayers.

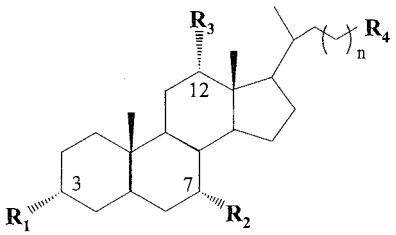

Table 1 Bile acid derivatives and their abbreviations used in this article

R_1	R_4	n	R_2 = α-H, R_3 = α-OH	R_2 = α-OH, R_3 = α-OH
N-OH	COOH	1	Deoxycholic acid (DCA)	Cholic acid (CA)
a-OH	$CONH_2$	1	Deoxycholamide (DCAM)	Cholamide (CAM)
x-OH	$CONHCH_3$	1	N-Methyldeoxycholamide (MDCAM)	N-Methylcholamide (MCAM)
α-OH	$CONHCH_2CH_3$	1	N-Ethyldeoxycholamide (EDCAM)	N-Ethylcholainide (ECAM)
α-OH	CH_2OH	1	3a.12a,24-Trihydroxy-5b-cholane (DCAtriol)	3a,7a,12a.24-Tetrahydroxy-5b-cholane (CAtetraol)
α-OH	$COOCH_3$	1	Methyl deoxycholate (MDC)	Methyl cholate (MC)
α-OH	COOH	0	Nordeoxycholic acid (NDCA)	Norcholic acid (NCA)
α-OH	COOH	2	Hoinodeoxycholic acid (WDCA)	Homocholic acid (HCA)
α-OH	COOH	3	Bishomodeoxycholic acid (BHDCA)	Bishomocholic acid (BHCA)
β-OH	COOH	1	3-Epideoxychol~cacid (3EDCA)	3-Epicholic acid (SECA)
	R_4	n	R_2 = α-OH, R_3 = α-H	R_2 = α-H, R_3 = α-H
α-OH	COOH	1	Chenodeoxycholic acid (CDCA)	Lithocholic acid (ECA)
α-OH	$CONH_2$	1	Chenodeoxycholamide (CDCAM)	Lithocholamide (ECAM)
α-OH	$CONHCH_3$	1	N-Methylchenodeoxycholamide (MCDCAM)	N-Methyllithocholamide (MLCAM)
α-OH	$CONHCH_2CH_3$	1	*N*-Ethylchenodeoxycholamide (ECDCAM)	N-Ethyllithocholamide (ELCAM)
α-OH	CH_2OH	1	3a,7a,24-Trihydroxy-5b-cholane (CDCAtriol)	3a,24-dihydroxy-5b-cholane (LCAdiol)
α-OH	$COOCH_3$	1	Methyl chenodeoxycholate (MCDC)	Methyl lithocholate (LMC)
α-OH	COOH	0	Norchenodeoxycholic acid (NCDCA)	Norlithocholic acid (NLCA)
α-OH	COOH	2	Homochenodeoxycholic acid (HCDCA)	Homolithocholic acid (HECA)
α-OH	COOH	3	Bishomochenodeoxycholic acid (BHCDCA)	Bishomolithocholic acid (BHLCA)
β-OH	COOH	1	3-Epichenodeoxycholic acid (3ECDCA)	3-Epilithocholic acid (3ELCA)

Apocholic acid (APA)

APA[3] has long been known to form the inclusion compounds similar to DCA. The crystal structures and inclusion abilities are nearly the same as shown in Fig. 4. They are served as hosts for inclusion polymerization. The former has larger channels than the latter.

Cholic acid (CA)

Inclusion compounds of CA with some alcohols were first reported by Mylius in 1887.[6] One hundred years later. Johnson and Schaefer[7] determined a crossing type of crystal structure for the inclusion compound of CA with ethanol. On the other hand, Miki et al. found a bilayer structure for the one with acetophenone.[8] Further studies made clear that CA forms various host frameworks to include different kinds of organic guest compounds. such as carboxylic acids, alcohols, nitriles. esters, aldehydes, ketones, and aromatic compounds. It is noteworthy that CA includes small alcohols such as methanol, ethanol, and propanol, in contrast to DCA. Shown in Fig. 5 are the guest-dependent crystal structures of CA. Small alcohols, carboxylic acids. as well as nitriles are incorporated in the crossing structure. On the other hand, aromatic compounds are done in the bilayer structure, where the host molecules are arranged in an antiparallel fashion on hydrophilic and lipophilic sides. CA has a cyclic hydrogen-bond network among four hydrogen-bonding groups of four different host molecules, which is different from the helical one of DCA. The versatile enclathration of CA comes from isomerization of the host frameworks on the basis of layer sliding on the lipophilic sides and conformational changes of the side chains.

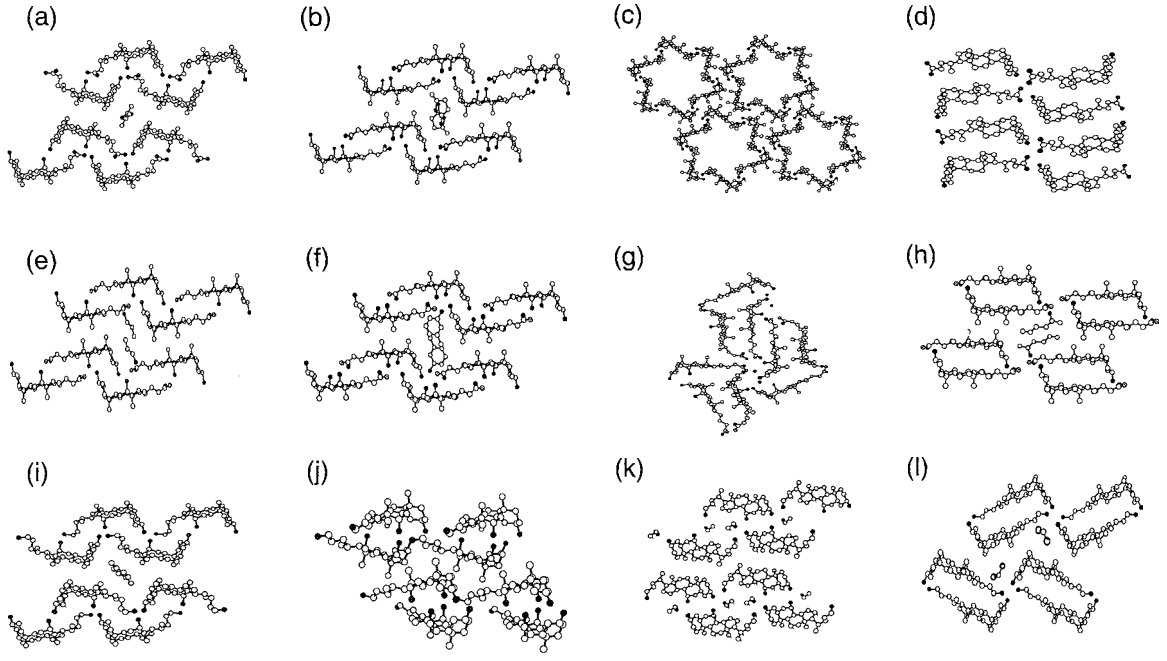

Fig. **3** Crystal structures of (a) DCA with acetone: (b) CA with γ-valerolactone; (c) guest-free crystal of CDCA: (d) guest-free crystal of LCA; (e) DCAM with 1-propanol; (f) CAM with *m*-cresol; (g) CDCAM with water; (h) LCAM with 2-hexanol; (i) DCAtriol with p-xylene: (j) guest free of CAtetraol; (k) CDCAtriol with ethanol: and (1) LCAdiol with dichloromethane.

Chenodeoxycholic acid (CDCA)

There are several reports[9–12] on the inclusion compounds of CDCA, despite many articles on those of DCA and CA. It is known that CDCA forms guest-free crystals (monoclinic $P2_1$)[9] as well as inclusion crystals with helical assemblies (hexagonal $P6_5$),[10] as depicted in Fig. 3c. The hexagonal type provides a large channel, where various guest compounds are included. Recently, Sada et al. succeeded in producing large crystals from the gel state, leading to the study on the intercalation and polymerization in the CDCA channels with retention of the crystalline state.[13]

Lithocholic acid (LCA)

It seems that LCA will not include any organic guests. as can be seen from the fact that only structures of guest-free and hydrate crystals are known[11] (Fig. 3d). In fact, we attempted to recrystallize LCA with over 100 organic compounds but inclusion compound still remains unknown.

MODIFICATION OF SIDE-CHAIN FUNCTIONAL GROUPS

Bile Amide Hosts

Replacement of the carboxyl group at the side chain to an amide group led to a great change of the inclusion abilities. One additional hydrogen-bond donor acts as a "hook" for catching a guest molecule with an hydrogen-bond acceptor. As a result, bile amide hosts can include many aliphatic alcohols in contrast to the original bile acids.

DCAM includes various types of organic compounds, regardless of their functional groups, and do not give

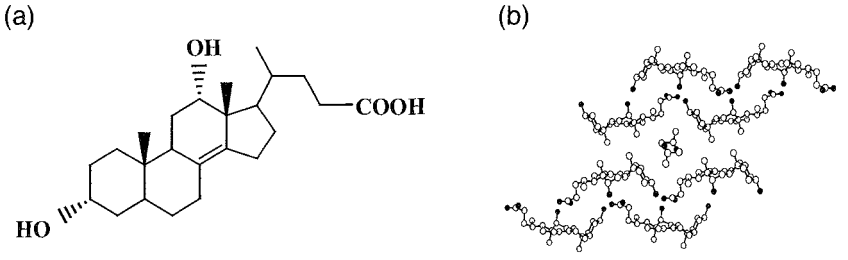

Fig. 4 (a) Molecular structure of APA and (b) crystal structure of APA with acetone.

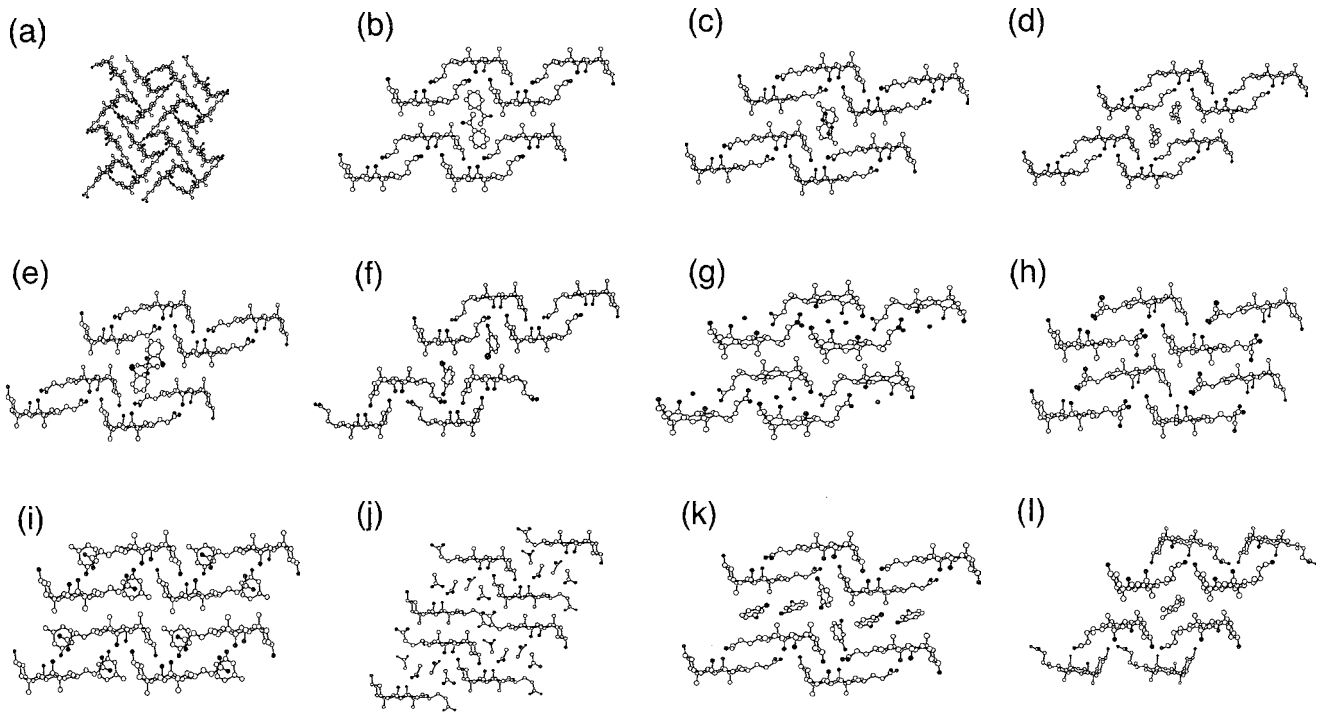

Fig. 5 Various host frameworks of CA with (a) methanol: (b) acetophenone: (c) γ-valerolactone; (d) ethylnylbenzene; (e) 2-fluoropropiophenone; (f) *m*-chloroaniline; (g) water: (h) acetonitrile; (i) 3-methylcyclohexanone; (j) acetic acid: (k) *m*-fluoroaniline; and (l) 1,2,3-trimethylbenzene.

guest-free crystals at all. It forms several host frameworks that depend on guests. In the case of small alcohols, the crystals have bilayer structures, where the host molecules are arranged in an antiparallel fashion on the hydrophilic and lipophilic sides as depicted in Fig. 3e. This arrangement is the same as that of CA. The hydroxyl groups of the guest molecules are inserted into the cyclic hydrogen-bond networks (Fig. 6e). On the other hand, in the case of large alcohols or aromatic compounds, DCAM employs the bilayer structure similar to DCA, where the host molecules are arranged in a parallel fashion on the hydrophilic sides and in an antiparallel fashion on the lipophilic sides. The guest molecules do not join the helical hydrogen-bond networks like DCA (Fig. 6f).

CAM forms the same bilayer structure as CA. Although the steric dimensions of the host cavities are identical. CAM has hydrogen-bond hooks on the wall of the channels for catching guest inolecules with hydrogen-bond acceptors. Therefore. CAM prefers to form inclusion compounds with guest molecules involving hydrogen-bonding groups.[15] Most of nonpolar guests do not give stable inclusion crystals, but CA has the opposite preference. For example. CAM forms the stable inclusion crystals with a wide range of alcohols, from methanol to decanol. The hydroxyl groups of the guest molecules are linked between two cyclic hydrogen-bond networks among the host molecules, as depicted in Fig. 6g.

CDCAM do not yield inclusion crystals with organic guest molecules but hydrate crystals, as shown in Fig. 3g. In contrast, LCAM constructs a bilayer structure with channels for including various organic molecules. LCAM tends to include aliphatic alcohols involving over five carbon atoms, while it does not include small alcohols, such as methanol, ethanol. and propanol.[16,17] LCAM forms flexible molecular assemblies due to the sliding of the bilayer as well as to the conformational change of the side chain. In the case of LCAM. replacement of the carboxyl group to amide leads to a change of the hydrogen-bond network from helical to ladder type,[16] as shown in Fig. 6h.

Bile Alcohol Hosts

DCAtriol prefers to form inclusion compounds with nonpolar guests. such as aromatic compounds. but not with polar guests, such as alcohols. The helical hydrogen-bond network of DCAtriol is similar to that of DCA. DCAtriol has a parallel arrangement on the hydrophilic side and an antiparallel one on the lipophilic side, as shown in Fig. 3i. However. in the benzene clathrate,[18] host molecules are arranged in the parallel fashion on hydrophilic and Iipophilic sides. Although DCAtriol includes various aromatic compounds: CAtetraol does not include organic guests and gives only guest-free

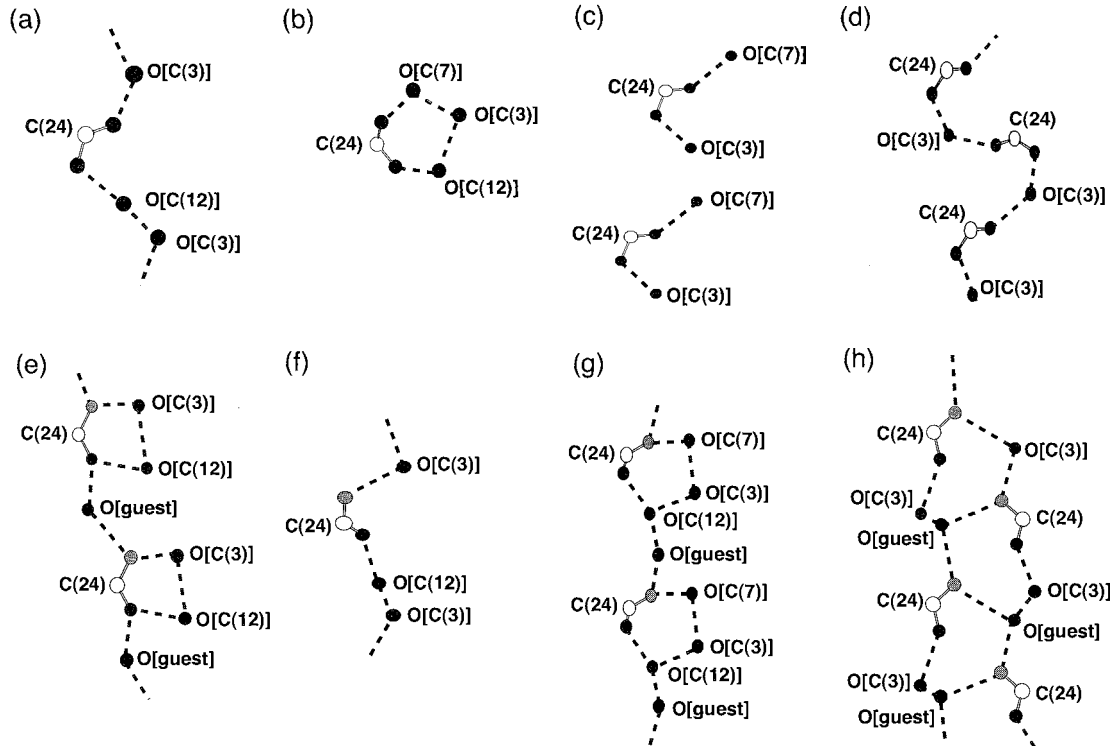

Fig. 6 Hydrogen-bonding networks of (a) DCA; (b) CA; (c) CDCA: (d) LCA; (e) DCAM with hydrogen-bond guest: (f) DCAM with nonhydrogen bond guest; (g) CAM; and (h) LCAM. Carbon. nitrogen. and oxygen atoms are represented by open, shadowed, and filled circles. respectively.

crystals,[19] as depicted in Fig. 3j. **CDCAtriol** constructs a bilayer structure. which is different from a tubular structure of CDCA. Small alcohols are included in the hydrophilic layers through hydrogen bonds between host and guest molecules. LCAdiol forms inclusion crystals with only small guests (Fig. 31).

Bile Ester Hosts

Esterification of the carboxylic acid decreases the number of hydrogen-bond donor group at the steroidal side chain, leading to a reduction of their inclusion abilities. MDC includes only methanol[20] and do not form the bilayer structure (Fig. 7a). MC includes only small polar guests, as shown in Fig. 7b, c. The inclusion compounds of MC with small nitriles have the same crystal structures as that of CA with acetonitrile.[21,22] Although there are no channels on the lipophilic sides, the guest molecules are held in the cavities between the pleated bilayers. No hydrogen bonds between the host and guest molecules are found. However. when the alcoholic guests are included, the side chains of the host molecules are leaned toward to the lipophilic face and do not form hydrogen bond.[23] The hydroxyl groups of alcoholic guests are inserted into the helical hydrogen-bond

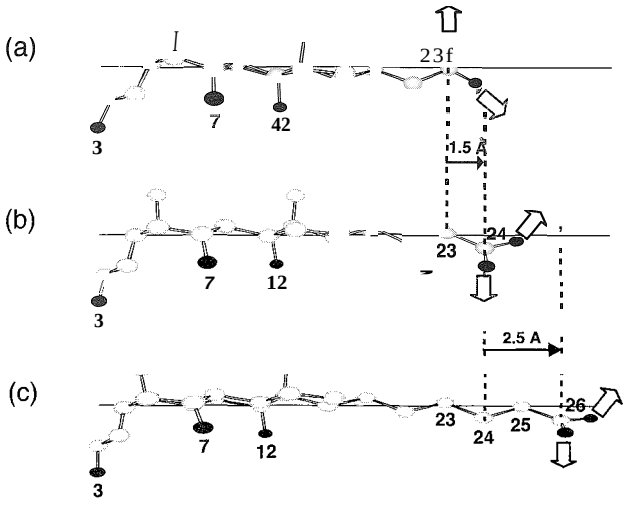

Fig. 8 Different distances and directions of carboxylic acid groups of (a) NCA; (b) **CA**; and (c) BHCA

networks. On the other hand, MCDC and **MLC** do not seem to include any organic compounds.

MODIFICATION OF THE SIDE-CHAIN LENGTH

Norbile Acids

Norbile acids have shorter side-chain lengths by one methylene unit than original bile acids. They form inclusion crystals with various organic substances.[24,25] Shortening the side-chain length brings about a change in the orientation of the carboxyl group and deforms the hydrogen-bonding motif, as shown in Fig. 8. The cyclic hydrogen-bond network is formed among two hydroxyl groups at the 3-position and two carboxyl groups at the side chains from four different host molecules. In Fig. 9, the crystal structures of four norbile acid, with acetone. They are all the same bilayer structures with cage-like cavities. Compare to the lack of inclusion abilities of LCA and **CDCA**, NLCA and NCDCA include a wide range of organic substances, as shown in Table 2.

Bishomobile Acids

The elongation of the side chain of CA gives rise to the expansion of the host cavity. BHCA. which have longer side-chain length by two methylene units than CA. was reported to form inclusion compounds with various guests[26] in a 1:1 host-to-guest ratio. X-ray crystallographic studies reveal that BHCA have two kinds of host frameworks: a bilayer structure and crossing structure, like CG. Larger aromatic compounds. such as 1-methylnaphthalene, are included in the former host framework with a cyclic hydrogen-bond motif among host molecules, while smaller aromatic compounds. nitriles. and alcohols. are included in the latter, with helical hydrogen-bond motif (as shown in Fig. 10a, b). In contrast, the other bishomobile acids do not tend to include any guest molecules and yield only guest-free crystals.

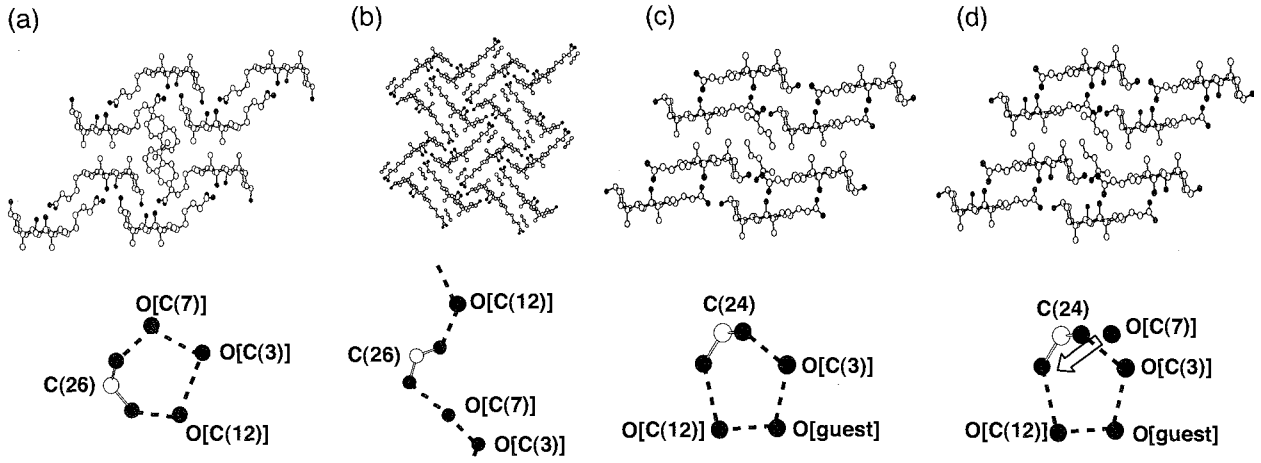

Fig. 10 Crystal structures and hydrogen-bonding networks of BNCA: (a) bilayer structure: (b) crossing structure: and epibile acids with 2-pentanol (c) 3EDCA: (d) 3ECA.

CHANGE OF DIRECTIONS OF HYDROXYL GROUPS OF THE SKELETONS

3-Epibile Acids

Change of direction of the hydroxyl groups at 3-position of the bile acids from α to β give 3-epibile acids. 3EDCA tends to include hydrophilic guests, such as alcohols and lactones, whereas DCA forms inclusion crystals with a wide range of organic compounds. except for alcohols. In Fig. 10c, the crystal structure of 3EDCA with 2-pentanol is shown. The host molecules arrange in an antiparallel fashion on hydrophilic and lipophilic sides. The hydroxyl groups of the guest molecules join the cyclic hydrogen-bond networks.

3ECA also gives the inclusion crystals with various aliphatic alcohols. Shown in Fig. 10d is a crystal structure of 3ECA with 2-pentanol, indicating the same bilayer structure in the case of CA. 3ECA forms a cyclic hydrogen-bond network, which is the same as that of 3EDCA. The extra hydroxyl group at 7-position is branched to the carboxylic group. because the direction change forces the hydroxy group at carbon 3-position to combine with carboxylic groups of the side chains. The alcoholic guest is inserted between the 3- and 12-positioned hpdroxy groups. as shown in Fig. 10c,d.

PACKING COEFFICIENT OF HOST CAVITY (*PCcavity*)

Key and lock mechanism has been established as a principle for molecular recognition. Steric and electronic complementary between guest molecules and host cavities play an important role for formation of the host–guest compounds. Only the guest molecules with steric size fitness to the host cavities are included as a result of size-selective binding. Guests that are too large or too small do not form stable inclusion complexes due to misfitting between guest and host cavities. Comparison of the volumes between the guest molecules and the host cavities may explain the size-selective guest recognition. In order to understand the steric fitness between guests and host cavities, we introduced the term; "packing coefficient of the host cavity" or *PCcavity* in the inclusion compounds of CA with monosubstituted benzenes.[27] *PCcavity* is the ratio between molecular volume of the guest molecules and free volume of the host cavities in a unit cell. This ratio is indicated by the equation shown below (see Eq. below):

The optimal *PCcavity* values are in the range of 55–70% (Table 3) for the complexes in which the guest molecules are included via steric complementation and no interaction between host and guest molecules. Complexes

$$PCcavity(\%) = \frac{\text{(Molecular volume of guest)} \times \text{(Number of guests in the unit cell)}}{\text{Volume of the host cavity}} \times 100$$

Table 3 Molecular volume of guests, host cavity, and *PCcavity* in the inclusion compounds of CA with monosubstituted benzenes

Guest	Molecular volume [Å^3]	*V*cavity [Å^3][a]	*PCcavity* (%)[b]
Benzene	83.4	298.1	56.0
Fluorobenzene	88.4	319.2	55.4
Aniline	95.8	336.0	57.0
Chlorobenzene	97.5	327.6	58.0
Toluene	100.8	334.5	60.3
Bromobenzene	101.8	318.9	63.8
Benzaldehyde	104.0	331.0	62.8
Iodobenzene	107.9	351.6	61.4
Nitrobenzene	109.6	326.4	67.2
Anisole	110.4	332.0	66.5
Styrene	111.2	345.7	64.3
Benzyl chloride	114.5	370.1	61.9
Ethylbenrene	117.7	386.1	61.0
Benzyl bromide	119.1	400.4	59.5
Acetophenone	120.9	344.9	70.1
Allylbenzene	127.9	393.9	64.9
Phenetol	128.1	389.2	65.8
Phenyl acetate	131.0	399.4	65.6

[a] *V*cavity is the volume of the cavity in the unit cell calculated with a 0.7 Å radius probe.
[b] *PCcavity* is the packing coefficient of the guest components in the host cavity: *PCcavity* = (molecular volume of guest molecule) x 2/*V*cavity x 100.

with *PCcavity* out of this range give rise to the isomerization of the host frameworks or change of the host-to-guest ratios due to steric misfit. However, the interaction between host and guest molecules, such as hydrogen bonds, could be expanding the range of the *PCcavity*. Calculations of the *PCcavity* should be helpful in estimating the boundary in changing the host framework as well as the host:guest ratio., and also in designing the included guests.

CONCLUSION

Designing the robust host molecules is one of the fascinating researches for future chemistry. In this article. we demonstrated that the bile acids and their derivatives serve as host molecules for various guest compounds. Each derivative exhibits individual characteristic that vary from one case to another. Finally, bile acids tell us their information and expression through their molecular assemblies. that we should listen from them.

The Diphenylmethane Moiety

Antonio García Martinez
José Osío Barcina
Universidad Complutense, Madrid, Spain

INTRODUCTION

Diphenylmethane (DPM) and some of its derivatives are often used as subunits in the design of supramolecular structures. One of the factors controlling the stability of the resulting complexes is the conforrnational flexibility of the host. Therefore. an entropic cost is paid upon complexation with DPM derivatives, because they must organize into a binding conformation. An efficient way to reduce this entropic cost is by stabilizing the gable conformation. This can be done by employing 7,7-diphenylnorbornane (DPN) as a building block.

THE DIPHENYLMETHANE MOIETY

The DPM moiety is easily recognized as a basic constituent of the most important cyclophanes (diphenylmethanophanes).[1] The supramolecular properties of these compounds cannot be understood without knowledge of the structure, energy. and molecular dynamics of DPM.

The complete potential energy surfaces (PES) of DPM were calculated with semiempirical, ab initio. and density functional theory (DFT) methods.[2,3] The stationary points correspond to the conforinations given in Scheme 1. Frequency calculations reveal that conformations **1–3** are transition states (one imaginary frequency was found). and 4 is the only minimum energy conformation.

For comparison, the relative total energy (BE) values computed for DPM with the semieinpirical (AM1), ab initio. and DFT methods are listed in Table 1, as well as geometrical data (torsional angles ϕ_A and ϕ_B and angle 0, Scheme 1 j.

All computed PES show a large flat minimum between 30" and 95° (ϕ_A or ϕ_B) with a C_2 minimum structure 4. The geometry of this structure is similar to the experimental C_1 conformation of DPM in the solid state (x-ray)[4] with ϕ_A=63.9°, ϕ_B=71.1°, and θ=112.5°. The results of the ab initio and DFT methods agree with the semiempirical AM1 method. with the exception of the relative energy of the gable conformation **2**.[3] There is also agreement with the PES computed with other semiempirical and molecular mechanics methods."' although some of them (e.g., PM3 and MM2) indicate a gable (2) ground state for the isolated molecule, but only 0.1–0.5 kcal/mol lower in energy than the helical conformation 4. Therefore, inexpensive semiempirical and molecular mechanics methods, especially AM1, seem to be useful for all problems related to the phenyl rotation.[3]

The bending angle θ depends on the dihedral angles ϕ_A and ϕ_B.[2] Typical examples are the conformers 2 and 3 (Table 1), where 8 varies from 113.6° to 116.4'. As expected, the angle 0 increases when the dihedral angles approach zero. Thus, the T-shaped conformation **3** is destabilized due to the repulsive short-range C—H···π interaction (vide infra). On the other hand, angle 8 of DPM determined by x-ray analysis (112.5") is significantly smaller than any other similar angle reported for ring-substituted DPM with electron-donor substituents.[2,4] Conformation 1 is expected to be unstable due to the short H.H distance of the o-hydrogen atoms. The steric repulsion between the filled π orbitals at the C_{ipso} atoms of conformation 2 causes its relative instability; which shows two aryl rings in an apical cofacial disposition (vide infra).[5] Conformation 4 seems to correspond to the equilibrium point between the π,π and C—H,π repulsions.

The relative population of each rotamer can be expressed quantitatively using the Boltzmann distribution:

$$N_A/N_B = e^{-\Delta G/RT} \quad (1)$$

where N_i represents the population of each conformation and AG the free energy difference associated to the rotation from A to *B* conformations. On the other hand. AG is given by the following equation:

$$\Delta G = \Delta H - T(\Delta S_R + \Delta S_V + \Delta S_T + \Delta S_L) - RT \ln \Delta\sigma \quad (2)$$

where AH is the difference in enthalpy [AE corrected by the work term (−RT)]. ΔS_i the differences in entropy (R = rotational. *V* = vibrational, *T* = translational, and *L* = librational), and $\Delta\sigma$ the difference in the symmetry numbers (degeneracy).[6–8]

The thermocheinical properties (H and *S*) arise from the energetics of vibrational frequencies obtained by frequency analysis of the wave functions of each conformation. The so-obtained ΔG values must be corrected by the entropy term $RT\ln\sigma$.

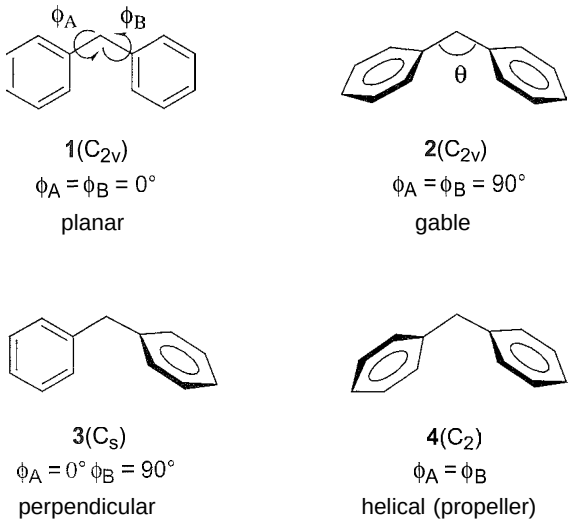

Scheme 1 Torsional angles (ϕ), point symmetry group. and name[***] of the conformations of DPM.

In supramolecular chemistry, separation of librational (configurational) entropy from the rest of the entropic contributions is often useful. The contribution of librational (torsional angle vibrations) modes to the configurational entropy can be calculated in a good approximation using Eq. 3:[9,10]

$$TS_L = RT\Sigma_i[(\theta_i/e^{\theta_i} - 1) + \ln(1/1 - e^{-\theta_i})] \quad (3)$$

where frequency θ_i is given by

$$\theta_i = h\omega_i c/RT \quad (4)$$

where h is Planck's constant. c the speed of light. and ω_i the wave number (in cm^{-1}) of the vibrations (ranging from 0–650 cm^{-1}).

Table 1 Computed AE values (in kcal/mol) for the conformations of DPM using several methods

	AM1*	HF/6-31G*	B3LYP/ 3-28G	B3LYP/ 6-31G*
1	8.89	—	10.48	—

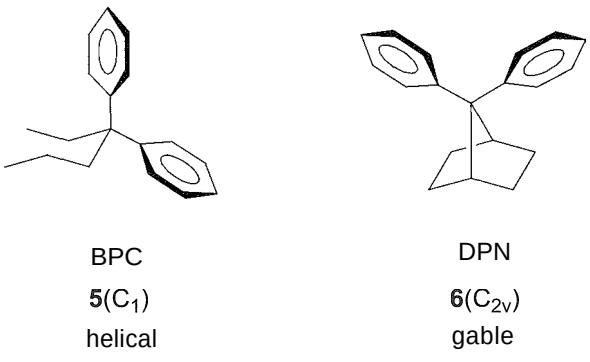
MOLECULAR DYNAMICS

In order to obtain information on the fluctuations in the DPM moiety, we performed molecular dynamics (MD) computations on DPM and 1,1-diphenylcyclohexane (5, DPC). often used as spacers in supramolecular chemistry, as well as on DPN 6 (Scheme 2).[11] The aryl rings of DPN are disposed in a gable conformation forced by the steric effect of the four exo-norbornylic C–H bonds.[***] In contrast to DPN, DPC adopts a helical conformation like DPM.[5]

The MD studies of DPM, DPC. and DPN were carried out with the MM2 force-field method implemented in CHEM3D.[13] Dynamic trajectories were generated for 20.0 ns at 300 K (target temperature), with 2.0 fs step interval, 10 fs frame interval, and a heating (cooling) rate of 1.0 kcal/atom/ps. The mean values of torsional angles (ϕ_m) and the corresponding standard deviations were calculated from the φ values of 60 frames (configurations) statistically sampled. During the whole equilibration time. the phenyl rings of DPM underwent five rotations. On the contrary, the aryl rings of DPC and DPN did not rotate but carried out librations, with amplitudes given in Table 2 as standard deviations of the mean torsional angle (ϕ_m). The ϕ_m values were similar (or identical) to the equilibrium values coinputed with the MM2 method. Noteworthy, the librational mobility of the equatorial (e) ring is higher than that of the axial *(a)* ring. As expected. the lowest librational amplitude corresponds to DPN.

The computed rotational barriers ($\Delta E^{\neq}$) using the AM1 method are given in Table 2. The C_{2v} symmetrical structure 2 of DPM is the lowest energy transition state between the C_2 symmetrical minimum 4 and its mirror image.[3] Hence. the racemization takes place according to the conrotatory two-ring-flip mechanism.[14,15] Conrotatory and disrotatory librations are allowed in the ground state of DPM[2] and its derivatives DPC and DPN. In the case of DPC, the perpendicular conformation is slightly more stable (by 0.24 kcal/mol) than the gable



Scheme 2 More stable conformations of DPC and DPN.

Table 2 AM1 rotational barriers ($\Delta E^{\neq}$, in kcallmol) and molecular dynamics of DPM. *DPC*. and *DPN* (MM2)

	DPM	DPC	DPN
$\Delta E^{\neq}$	0 01	0.43	12.5
φ_m	Rotor	$\phi_e=69\pm20°$	$\phi_A=93\pm15°$
		$\phi_a=67\pm30°$	
○	—	$\phi_e=69°$	$\phi_A=93°$
		$\phi_a=65°$	$\varphi_B=83°$

conformation, and the racemization takes place mainly according to a disrotatory one-ring-flip mechanism[14,15] through a C_s symmetrical structure similar to **3.** The amplitude of the librations in DPN is much higher than the deviations from the planarity ($\sim3°$). Therefore, DPN can be considered as a librating C_{2v} structure. On the contrary, according to the MD results, at 300 K, DPM and DPC can be described as a free rotator (propeller) and a high-amplitude librator. respectively. This has important consequences on the properties of both compounds. In the case of DPN, the gable conformation shows both phenyl rings in a disposition favorable for a π,π interaction, a kind that we named apical homoconjugated.[5] This repulsive interaction between filled orbitals gives place to new binding and antibinding MOs and, therefore, to new electronic transitions. Thus, the UV spectrum of DPN (in MeOH) shows a strong absorption at 228 nm ($\varepsilon=12.300$) that is not observed in the UV spectra of 2,2-diphenylpropane (DPP), that has phenyl rings arranged in a helical conformation. Besides this homoconjugation band (AHK band),[5] DPN shows the ^1L_b and the fine-structured ^1L_a bands (β and α bands, respectively). which are common to all DPM and alkylbenzenes,[16] due to intraannular transitions. However, methylene-bridged donor–acceptor systems exhibit weak intramolecular charge-transfer absorptions.[16] Intramolecular through-space donor–acceptor interactions are feasible even in the case of orthogonality of the donor and acceptor chromophores.[17] On the other hand. the orthogonality of donor and acceptor orbitals exclude an intramolecular through-bond ground-state interaction.[16]

Moreover, the second-order nonlinear susceptibility (β_z) of DPN derivatives is higher than the value of related DPM derivatives, due to the π–π interaction in the gable conformation.[18] Both transannular electronic transitions and hyperpoiarizability are Franck–Condon processes, which are favored in DPN, because the probability of a photon impacting the gable conformation in a free rotor is negligible.

The conformational instability of DPM is partially transmitted to derivatives that are important in supramolecular chemistry, such as cavitands.[19,20] Resorcarenes are conformationally mobile, with a $\Delta G^{\neq}$ for the rotation of one ring of 4.5 kcallmol for *p-n*-hexyl[4]resorcarene,[19] whereas the $\Delta G^{\neq}$ range for calixarenes is higher (15–16 kcallmol). The reason for this is the strong cyclic lower-rim intramolecular hydrogen bonding of the calixarenes in comparison to the analogous upper-rim interaction in resorcarenes. As a consequence, the cavities of calixarenes are relatively small and too conformationally mobile to offer significant solvophobic protection.

A inacrobicyclic cyclophane host containing three *N*-ethyl-4.4-diarylpiperidine units was the subject of MD simulations. At 300 K, no conformations with a collapsed or significant distorted cavity were observed.[20] However, a relatively high degree of flexibility is maintained in complexes of macrocyclic hosts containing two diarylmethane moieties bonded by isophthaloyl and phosphonate subunits, with one adrenaline molecule. despite the high binding enthalpies resulting from the combination of electrostatic interactions, hydrogen bonds, and van der Waals interactions.[21]

FORMATION **OF INCLUSION COMPLEXES**

The chemical equation for the reaction of formation of an inclusion complex between the gable conformation of DPM and a symmetrical guest G, is

$$\mathbf{2}(C_{2v}) + \mathrm{G} \leftrightarrows \mathbf{2}\ (C_{2v})\cdot\mathrm{G}$$

The thermochemistry is given by Eq. 2, where ΔH now represents the binding enthalpy and AS, the differences in entropy between the complex and the gable conformation $2\,(C_{2v})$. Only the stable conformations in equilibrium with the host conformation contribute to the term $\Delta\sigma$. Thus, in the case of DPM and DPC,[22] $\Delta\sigma=2$, and a loss of mixing entropy by $RT\ln2=0.41$ kcallmol (at 300 K) must be taken into account.

The computational packages usually calculate the ΔS_T using the Sackur–Tetrode equation. This equation predicts the entropy of monoatomic gases successfully. The ΔS_T values predicted with this equation in the liquid or solution phase are. however, significantly lower than the experimental ones.[23] These discrepancies can be corrected; considering the idea of free volume in condensed phases.[24]

The uncertainty regarding the value of AS_{m} in solution is low, because the value of rotational entropy in solution is, in most cases. the same as that in the gas phase. Thus, AS_{m} is predicted with reasonable accuracy using an existing model based on statistical mechanics.[24]

The changes in high-frequency harmonic vibration ΔS_V upon assembly are negligible. By contrast, the contribution of low-frequency vibrations associated with torsions about single bonds (librations), expressed by ΔS_L, is high.

Unlike high-frequency vibrations, low-frequency vibrations cannot be modeled as accurately as harmonic oscillations.[24,25]

A simple model for the determination of conformational entropy (ΔS_L) is based on the assumption that accessible conformational space has the same potential energy. From the classical (nonquantum mechanical) definition of the partition function, the conformational entropy is given by the following equation:

$$S_L = R \ln(V_{conf}/V_{mol}) \quad (5)$$

where V_{conf} is the available volume to a rigid molecule of volume V_{mol}.[24]

An interesting approach to the estimation of ΔS_L is offered by Eq. 3. The amplitude of the host librations decreases upon binding and implies a reduction of conformational entropy, because the frequency θ_i in Eq. 4 increases. Therefore, the complexation takes place with an additional entropy cost, which increases with the binding enthalpy. It is higher in the case of strongly bonded complexes and, for the same host, depending on the nature of the guest. Hence, it is to be expected that the loss in conformational entropy is accompanied by a compensatory enthalpy change. The decrease in librational amplitude leads to a better preorganized host structure. The configurational (conformational) entropy term, ΔS_L, can be considered as the entropic cost of the assembly of the conformations (microstates) that disappear upon binding, placed between the stable conformations.

The tightly bonded inclusion complexes in aqueous solution, between aromatic and aliphatic guests (steroids, among others) and cyclophane receptors with tetraoxa[*n*.1.n.1]paracyclophanes and quaternary ammonium cyclophanes is entropically unfavorable and strongly enthalpically driven.[26,27] The thermodynamic characteristics of tight inclusion complexes differ from those measured for weak apolar association processes, which are characterized by small enthalpic changes and favorable entropic terms. This is the usual interpretation of the so-called hydrophobic effect.[28]

The enthalpic contribution to ΔG of formation of a complex depends on the geometry. Sometimes. the DPM moiety in the cyclophane complex adopts a helical conformation, as observed in synthetic adrenaline receptor~,[~in' which the guest is placed outside the DPM cavity and undergoes double π-staking interactions with two DPM moieties. But, most of the cyclophane–arene complexes prefer a gable conformation of the DPM moiety,'''' because this geometry allows for a deeper docking of the arene guest in the cavity than does the helical conformation. Hence, DPM hosts are enthalpically favored in comparison to 2,2-diphenyl propane (DPP) or DPC hosts. because the ΔE between the gable and the helical conformation is lower. When the complex formation is enthalpically controlled. DPM hosts should be better receptors than DPP hosts. This was observed in the case of cyclophanes incorporating Troger's base and DPM or DPP moieties.[30,31] Thus, substituents at the methylene group of DPM influence the complex stability. However, the DPM derivatives used as building blocks in the design of hosts are often selected in order to increase only the solubility.

TOWARD THE REDUCTION OF CONFIGURATIONAL ENTROPY

The high configurational entropy of DPM is a serious disadvantage in its use as a building block in the construction of macrocyclic hosts,[10,21,24] although some flexibility is needed for a fast guest complexation.[32]

In order to decrease the configurational entropy, several strategies are possible. Thus, the introduction of *ortho* substituents causes an increase of the rotational barriers. A $\Delta G^{\neq}$ value of 16.4 kcallmol (323 K) for the conrotatory racemization of the helical conformation of *bis*(2-ethyl-6-methylphenyl)methane was determined by dynamic nuclear magnetic resonance (DNMR).[33] This result is in agreement with that calculated with the MM2 program (16.4 kcallmol for a zero-ring-flip mechanism).[34] However, according to our MD calculations, this compound shows the C_2 conformation ($\phi_B = 52 \pm 14°$) as the more stable and, therefore, is not preorganized for the formation of inclusion complexes.

Another improvement of the DPM rigidity and preorganization without alteration of the substitution pattern is the back-stabilization of the gable conformation. The 1.1-diphenylcyclopropane derivatives invariably show preference for the gable conformation. as revealed from x-ray data.[35] Also, in diarylmethane-bridged fullerenes, the gable disposition was described as the most stable conformation.[36] However, no experimental rotational barriers were reported until now.

The best approach reported to date to solve this problem is DPN,[5,12,18,22,37] with a gable conformation that is the most stable described until now (vide supra). From Eq. 2, using the RHF/STO-3G method for the computation of ΔE and AS, and taking into account the mixing entropy, the formation of inclusion complexes of DPN in the gable conformation should be disfavored by 2.27 kcallmol in comparison to complexes of DPN and the same guest.[22]

Interestingly, hosts containing the DPN moiety form complexes with isophthaloyl derivatives, which are only slightly more stable (by 0.29 kcal/mol) than analogous complexes with DPC hosts.[22] These results clearly show that DPC is in the helical conformation, with a small loss

of configurational (librational) entropy caused by the interaction with the guest. The entropic contribution to the energy of complexation with DPC hosts can be as high as 1 kcal/mol, a value that can be important in the determination of weak noncovalent interactions.[38,39] The entropy loss due to the configurational term becomes higher in the case of macrocyclic hosts.[10]

CONCLUSION

The DPM moiety is a convenient building block for the design of cyclophanes able to form inclusion complexes with neutral molecules. However, an entropic cost must be assumed due to the conformational flexibility of DPM and derivatives. The best way to reduce the conformational entropy is to stabilize the gable conforination by back substitution, just as carried out in the case of DPN.

Disorder and Diffuse Scattering

T. Richard Welberry
Australian National University, Canberra, Australia

INTRODUCTION

The strong sharp Bragg reflections that occur in diffraction patterns of all real crystals are used by conventional x-ray crystallography to deduce the average repetitive arrangements of atoms or molecules. Diffuse scattering. on the other hand, contains information about the deviations from the average (i.e., different types of disorder) and gives structural information on a scale that goes beyond that of the average unit cell and extends over a range of ~1 A–1000 A. In many important materials, it is this extended range of structural information that is crucial in determining the unique or novel properties of the material. rather than the average unit cell structure.

METHODS OF ANALYSIS

Despite potentially providing a rich source of information about local and nanoscale structural detail in materials and about hour atoms and molecules interact with each other to produce this structure, the development of methods to analyze diffuse scattering lagged well behind conventional average structure determination. There are two main reasons. First, diffuse scattering intensities are weak in comparison to Bragg peaks, making the experimental observation vastly more demanding and time consuming. Second, the sheer diversity of different types of disorder makes it difficult to formulate a solution strategy that will work for all problems.

The recent advent of intense synchrotron sources and various kinds of multidetectors has meant that even weak diffuse scattering can now be readily observed.[1,2] but the second problem remains. However. the ever-increasing power and decreasing cost of computers facilitated the development of model-building techniques that are beginning to bear fruit in terms of their use as aids in the interpretation and analysis of the scatte ing for an increasingly diverse range of materials.[3–5] In these methods. the basic aim is to construct a computer model of the disordered structure using suitably parameterized basic interatomic or intermolecular interactions and a prescription for the particular type of disorder. A diffraction pattern computed from this model can then be cornpared with the observed pattern. Following this comparison, the model parameters can be adjusted and the process repeated until satisfactory agreement is obtained. Although agreement between an observed pattern and a calculated pattern does not guarantee the correctness of a model, the fact that sound chemical and physical principles were built into it at the outset lends considerable confidence to its validity. A model giving poor agreement can certainly be rejected. This methodology can be applied to a wide range of disorder problems with equal facility.

In order to be able to construct such a computer model, it is necessary to be able to identify particular types of disorder and understand the basic diffraction theory that describes how these affect the diffraction pattern. Our aim in this article is to give a brief overview of the theory of diffraction from disordered crystals and then present a number of real example patterns that illustrate some of the important principles. These examples were chosen to illustrate the diversity of the patterns that can be encountered and the types of disorders that cause them. We do not attempt to present details of the modeling of these examples. which is beyond the scope of the present article. For this. the reader is referred to the original literature on these systems.

DISORDER INVOLVING OCCUPANCIES AND DISPLACEMENTS

General

A description of diffuse scattering that allows for short-range substitutional disorder and local atomic displacements that accompany the SRO can be obtained by expanding the exponential in the general diffraction equation in terms of powers of displacement [6,7]

$$\begin{aligned} I(\mathbf{k}) &= \sum_m \sum_{m'} f_m f_{m'} \exp(i\mathbf{k}\cdot(\mathbf{r}_m + \mathbf{u}_m - \mathbf{r}_{m'} - \mathbf{u}_{m'})) \\ &\approx \sum_m \sum_{m'} f_m f_{m'} \exp(i\mathbf{k}\cdot(\mathbf{r}_m - \mathbf{r}_{m'})) \\ &\quad \times \left\{ 1 + i\mathbf{k}\cdot(\mathbf{u}_m - \mathbf{u}_{m'}) - \frac{1}{2}[\mathbf{k}\cdot(\mathbf{u}_m - \mathbf{u}_{m'})]^2 \right. \\ &\quad \left. - i\frac{1}{6}[\mathbf{k}\cdot(\mathbf{u}_m - \mathbf{u}_{m'})]^3 + \ldots \right\} \end{aligned} \quad (1)$$

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012736

In this equation. f_m is the scattering factor of the atom m associated with the lattice site at the locator $\mathbf{r}_m$ and which is displaced from its mean position by a small amount $\mathbf{u}_m$. Expressed in Eq. 1 is the fact that the scattered intensity may be written as the sum of component intensities. The zero'th-order term is independent of the displacements. The first-order term is dependent on the first moment of displacements, the second-order term on the second moments, etc. If we carry out a reduction of Eq. 1 by separating terms into those corresponding to the average lattice and those corresponding to the deviations from the average, this separation into scattering components is preserved. We can then express the total intensity as follows:

$$I_{\text{Total}} = I_{\text{Bragg}} + I_0 + I_1 + I_2 + I_3 + \ldots \text{etc.} \tag{2}$$

I_{Bragg}, The Bragg Scattering Term

The term I_{Bragg} is the intensity due to the average lattice. This has a form that includes the Debye–Waller factor. $\exp(-2M)$, where $M = 8\pi^2\langle \mathbf{u}^2\rangle\lambda^2/\sin^2\theta$ (see Ref. [8]):

$$I_{\text{Bragg}}(\mathbf{k}) = (m_A f_A + m_B f_B)^2 \exp(-2M) \sum \exp(i\mathbf{k} \cdot \mathbf{r}_N) \tag{3}$$

The Debye–Waller factor takes account of the mean-square amplitude of displacements. (u^2). The equation describes how the Bragg peaks are still sharp, but their intensities are depressed at high angles.

I_0, The Short-Range Order Component

The term I_0 is known as the SRO component and may be expressed in the following general form:

$$I_0(h_1,h_2,h_3) = -N \sum_{i,j} \sum_{l,m,n} c_i\ c_j\ f_i\ f_j^* \times C_{lmn}^{ij} \cos(2\pi(h_1 l + h_2 m + h_3 n)) \tag{4}$$

The summation over i,j is over all atomic species and sublattices, and the summation over l,m,n represents all interatomic vectors. The N is the number of unit cells; c and f are the concentration and scattering factors for the species, respectively. The C_{lmn} are short-range order (SRO) parameters that may alternatively be called correlation coefficients.

The SRO parameters or correlation coefficients measure the degree of mutual dependence of the type of atom (or molecule) occupying a particular site in the crystal with that occupying another site. For $C_{lmn}=0$, there is no dependence, and the chance of finding an A-atom, say. in one site. is the same whether the second site contains either an A-atom or a B-atom. For $0 < C_{lmn} < 1$. the pair are more likely to be (A...A or B...B), and this is called positive correlation. For $0 > C_{lmn} > -1$, the pair is more likely to be (A...B or B...A), and this is called negative correlation. In a later section. we consider how a particular set of C_{lmn} might have arisen in a crystal or how in we might construct a model to contain such a set of values.

Note that presented in Eq. 4 is a summation over cosine functions so that the form of the diffuse scattering due to this component is symmetric about the Bragg peak positions.

I_1, The Size–Effect Component

The I_1 is the Warren size–effect term that takes account of the fact that interatomic vectors. $\mathbf{r}_N$, nominally all of equal length in the average lattice. have different lengths depending on whether the vector joins sites occupied by A–A, A–B, B–A, or B–B. This component includes all terms that are linear in the displacements $\mathbf{u}_m$. In contrast to I_0, therefore, the intensity for each term varies in reciprocal space relative to the displacement direction. If $\mathbf{k} = h_1\mathrm{a} + h_2\mathrm{b} + h_3\mathrm{c}$ and $\mathbf{r}_N = l\mathrm{a} + m\mathrm{b} + n\mathrm{c}$, then the size–effect intensity can be written in the following form:

$$I_1(h_1,h_2,h_3) = -2\pi N \sum_{ij} \sum_{lmn} c_i\ c_j\ f_i\ f_j^* (1 - C_{lmn}^{ij}) \times \sin(2\pi(h_1 l + h_2 m + h_3 n)) \times (h_1\langle X_{lmn}^{ij}\rangle + h_2\langle Y_{lmn}^{ij}\rangle + h_3\langle Z_{lmn}^{ij}\rangle) \tag{5}$$

The quantities in angle brackets are averages of various kinds of displacement. For example.

$$X_{lmn}^{ij} = u_{lmn}^{xj} - u_0^{xi}, \text{etc.} \tag{6}$$

Here u_{lmn}^{xj} is the displacement in the x direction of an atom with label j situated at the end of the vector $\mathbf{r}_{lmn}$ from the origin, where an atom with label i is displaced u_0^{xi}, also in the x direction. Note that Eq. 5 is a summation over sine functions so that the form of the diffuse scattering due to this component is antisymmetric about the Bragg peak positions. That is to say. it has the effect of transferring intensity from one side of the Bragg position to the other.

I_2, The Huang Scattering and First-Order TDS Component

The I_2 is the Huang scattering and first-order thermal diffuse scattering (TDS) component. It can be written in the following form:

$$\begin{aligned} I_2(h_1,h_2,h_3) = & -2\pi^2 N \sum_{ij} \sum_{lmn} c_i\ c_j\ f_i\ f_j^* (1 - C_{lmn}^{ij}) \\ & \times \cos(2\pi(h_1 l + h_2 m + h_3 n))[(h_1^2\langle (X_{lmn}^{ij})^2\rangle \\ & - (1 - C_{lmn}^{ij})^{-1}\langle (X_{\infty}^{ij})^2\rangle) + (h_2^2\langle (Y_{lmn}^{ij})^2\rangle \\ & - (1 - C_{lmn}^{ij})^{-1}\langle (Y_{\infty}^{ij})^2\rangle) + (h_3^2\langle (Z_{lmn}^{ij})^2\rangle \\ & - (1 - C_{lmn}^{ij})^{-1}\langle (Z_{\infty}^{ij})^2\rangle) \\ & + 2h_1 h_2\langle X_{lmn}^{ij} Y_{lmn}^{ij}\rangle + 2h_2 h_3\langle Y_{lmn}^{ij} Z_{lmn}^{ij}\rangle \\ & + 2h_1 h_3\langle X_{lmn}^{ij} Z_{lmn}^{ij}\rangle] \end{aligned} \tag{7}$$

Note that Eq. 7 is a summation over cosine functions so that the form of the diffuse scattering due to this component is again symmetric about the Bragg peak positions.

I_3, The Third-Order Sine–Effect Component

The expression for I_3 is even more complex than that for I_2. It involves averages of displacements, such as

$$\langle (X_{lmn}^{ij})^3 \rangle, \langle (X_{lmn}^{ij})^2 Y_{lmn}^{ij} \rangle, \langle X_{lmn}^{ij} Y_{lmn}^{ij} Z_{lmn}^{ij} \rangle, \text{etc.} \tag{8}$$

and the different terms are dependent on factors such as h_1^3, $h_1^2 h_2$, $h_1 h_2 h_3$, etc. This third component, in common with all odd components. is again the sum of sines. Consequently, scattering due to this component is antisymmetric about the Bragg peak positions. and it has the effect of transferring intensity from one side of the Bragg position to the other. The effect of this component is thus similar to that of the I_1 term. but it should be noted that it is of opposite sign. This and other higher-order component terins are usually negligible at low scattering angles but become increasingly important at large angles.

SOME PARTICULAR DISORDER MODELS

The theory outlined in the previous section shows how diffuse scattering can be described in terins of various kinds of lattice averages.''' These include simple occupancy correlations, averages involving atomic displacements; and cross terms where dispiacements are coupled with occupancy. In their most general form. the equations are not useful. because they contain many unknowns for each type of interatomic vector. However, the general form of the equations and the fact that the intensity can be broken into different components is of prime importance, because it allows different diffraction features to be identified. In any particular disorder problem. not all of the possible types of lattice average will be important, and correct identification of what is causing a particular pattern of diffuse scattering is the initial key question.

The Eqs. 4, 5. and 7 are general, and detailed elaboration of how these apply in particular systems is beyond the scope of the present article. In this section, we instead illustrate some aspects of the general problem by elaborating the form of particular terms in more detail for some important simple models.

One-Dimensional Occupancy Disorder

Nearest-neighbor Markov chain

The general problem in Eq. 4 is to consider how a particular set of C_{lmn} might have arisen in a crystal or how we might construct a model to contain such a set of values. In one dimension (1D), a simple way of constructing a disordered crystal is to use a simple Markov chain. We first choose an atom (or molecule) to be A or *B* at random and then add subsequent atoins one at a time using a probability that depends only on the previous one. If x_i is a (0.1) random variable, such that $x_i=1$ corresponds to an A-atom and a value $x_i=0$ corresponds to a B-atom, then a disordered sequence can be generated using the following simple expression:

$$P(x_i = 1/x_{i-1}) = \alpha + \beta x_{i-1} \tag{9}$$

Here. the expression $P(x_i=1/x_{i-1})$ means "the probability that x_i takes the value 1 given the value of x_{i-1}.'' This model can be shown to have the property that the fraction of atoms that are A, m_A, and the set of correlations, C_n, are simply related to the parameters α and β.

$$m_A = \alpha/(1-\beta) \text{ and } C_n = \beta^n \tag{10}$$

(note $C_1 = \beta$ and $C_0 = 1$)

It can then be shown that the diffuse intensity is entirely defined by these two parameters:

$$I(\mathbf{k})_{\text{diffuse}} = m_A m_B (f_A - f_B)^2 \times \left[1 + 2 \sum_{n=1}^{N-1} \beta^n \cos(\mathbf{k} \cdot n\mathbf{a}) \right] \tag{11}$$

As the number of atoms (or molecules), N. tends to infinity, the summation can be carried out to give

$$I(\mathbf{k})_{\text{diffuse}} = K \frac{1-\beta^2}{1+\beta^2-2\beta\cos(\mathbf{k}\cdot\mathbf{a})} \tag{12}$$

Here. K replaces the constant terms involving m_A and f_A, etc. In Fig. 1a, we show plots of this function for different values of the nearest-neighbor correlation coefficient $C_1=\beta$. Note that m_A only appears in the constant term and therefore affects only the overall intensity of the diffuse peaks and not their shapes. The shape is entirely dependent on β. Positive correlations produce a diffuse peak centered on the Bragg peak positions ($\mathbf{k}=0, 2\pi, 4\pi$, etc., if $a=1$), while negative correlations produce a peak midway between them ($\mathbf{k}=\pi, 3\pi$. etc.). The higher the absolute value of β, the sharper the diffuse peak. The geometrically decaying correlations seen in Eq. 11 and the corresponding diffuse peak shapes seen in Fig. 1a are characteristic of ID disorder.

Second-nearest-neighbor Markov chain

Eq. 9 can be readily extended to include second-nearest-neighbor (or higher) effects:

$$P(x_i = 1/x_{i-1}, x_{i-2}) = \alpha + \beta x_{i-1} + \gamma x_{i-2} \tag{13}$$

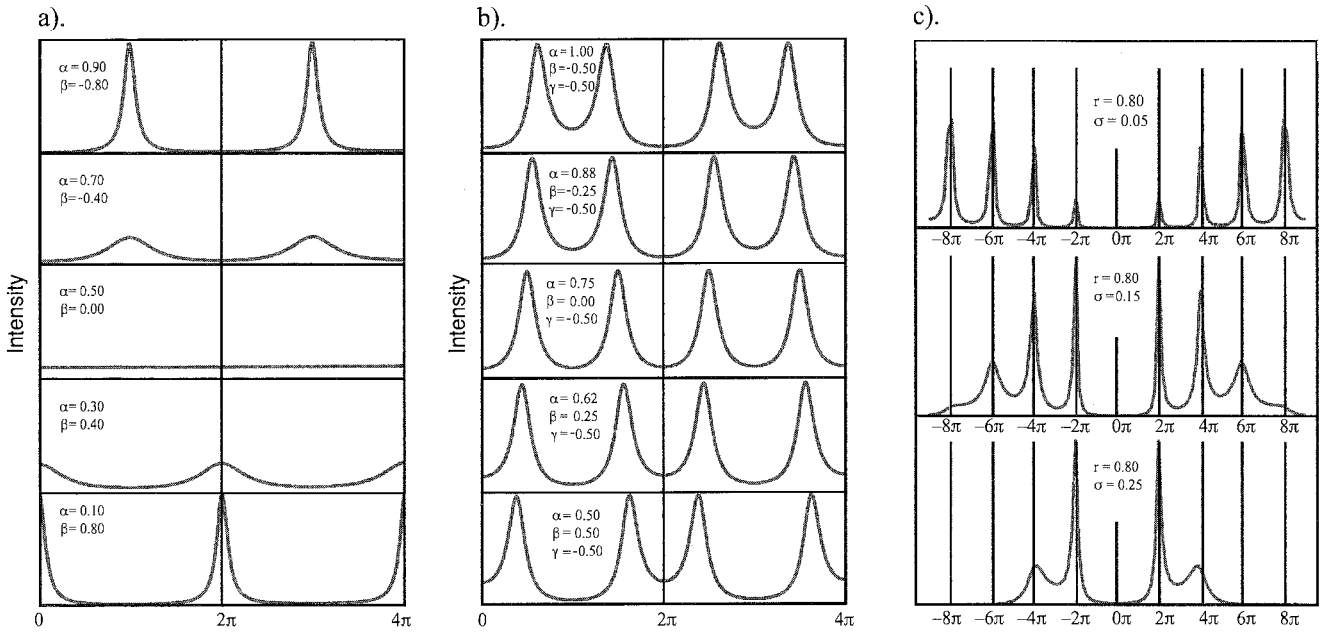

Fig. 1 Diffuse intensity plots for various 1D models discussed in the text. (a) The nearest-neighbor Markov chain. (b) The second-nearest-neighbor Markov chain. (c) The perturbed regular lattice. (See the text for details.) (*View this art in color at www.dekker.com.*)

This model can again be readily solved, and the diffuse intensity is now of the following form:

$$I(\mathbf{k})_{\text{diffuse}} = K\left(c_1\frac{1-\beta_1^2}{1+\beta_1^2-2\beta_1\cos(\mathbf{k}\cdot\mathbf{a})} + c_2\frac{1-\beta_2^2}{1+\beta_2^2-2\beta_2\cos(\mathbf{k}\cdot\mathbf{a})}\right) \tag{14}$$

Here, β_1, β_2 and c_1, c_2 depend on the parameters α, β, γ, and they may be complex. but $I(\mathbf{k})_{\text{diffuse}}$ is real. Example plots of this function are shown in Fig. 1b. It is seen that diffuse peaks may occur at positions other than k=O or $\mathbf{k}=\pi$. For the plots that have diffuse peaks at positions close to $\mathbf{k}=2\pi/3$ and $\mathbf{k}=4\pi/3$, the atom sequence tends to be *AABAABAAB*... or BBABBABBA..., while for ones with peaks close to $\mathbf{k}=2\pi/4$ and $\mathbf{k}=6\pi/4$, the sequences tend to be *AABBAABB*....

The second-neighbor Markov chain is the simplest system that gives rise to diffuse peaks at incommensurate positions. Incommensurate peaks occurring in real materials invariably arise from a competition between nearest-neighbor forces and some more distant force.

Ising models in 1D

Although at first sight they appear different, 1D Markov chain models are formally equivalent to Ising models. In the Ising formulation, it is more convenient to change from the x_i (0,1) variables to σ_i (−1, +1) variables, where $\sigma_i=2x_i-1$. In the simplest 1D Ising model, the random variables interact only with nearest-neighbor variables on either side. A given configuration of the lattice (a disordered sequence of As and Bs) is assumed to occur with a probability given by a Boltzmann partition:

$$P_{\text{config}} = \frac{\exp(-E_c/kT)}{\sum_c \exp(-E_c/kT)}$$

where the summation is over all configurations, c, and the interaction energy is given by

$$E_c = \sum J\sigma_i\sigma_{i-1} \tag{16}$$

This simple pair-interaction Ising model is equivalent to the Markov chain model of Eq. 9 for $m_A=0.5$. The interaction parameter J is related to the correlation β by the following:

$$\beta = \tanh(-J/kT) \tag{17}$$

1D Displacement Disorder

Perturbed regular lattice

We consider for simplicity the displacement equivalent of the simple 1D Markov chain model given in Eq. 9. We suppose that x_i is now a zero-mean normally distributed random variable that represents the longitudinal displacement of the site i from its regular position on a 1D lattice

of spacing **a.** The spacing d_i between the $(i-1)^{th}$ and ith points is $x_i - x_{i-1} + a$. We construct the distribution by choosing the position of the first point and then adding subsequent points using a conditional probability relation:

$$P(x_i/x_{i-1}) = K\exp\left(-\frac{1}{2\sigma_L^2}\frac{(d_i-\mathbf{a})^2}{2(1-r)}\right) \tag{18}$$

This produces a distribution that has the property that the probability distribution of the variables x, is a simple Gaussian function:

$$P(x_i) = K\exp\left(-\frac{x_i^2}{2\sigma_L^2}\right) \tag{19}$$

and the joint probability distribution of two neighboring points is also Gaussian:

$$P(x_i, x_{i-1}) = K\exp\left(-\frac{1}{2\sigma_L^2}\frac{(x_{i-1}^2 + x_i^2 - 2rx_{i-1}x_i)}{(1 \quad r^2)}\right) \tag{20}$$

Here r is a correlation coefficient with properties similar to the occupancy correlations discussed above. Positive values of r correspond to neighboring points tending to be displaced in the same direction and negative r to neighboring points tending to be displaced in opposite directions. The diffracted intensity for this model again consists of two parts: a Bragg intensity that comes from the average lattice and a diffuse component that comes from the differences from the average. It can be shown[9] that

$$I(\mathbf{k})_{\text{Bragg}} = \exp(-\mathbf{k}^2\sigma^2)\sum_n \exp(i\mathbf{k}\cdot n\mathbf{a}) \tag{21}$$

$$I(\mathbf{k})_{\text{Diffuse}} = \exp(-\mathbf{k}^2\sigma^2)\sum_{P=1}^{\infty}\frac{\exp(\mathbf{k}^2\sigma^2)^P}{P!} \times \frac{(1 - r^{2P})}{(1 + r^{2P} - 2r^P\cos(\mathbf{k}\,.\,\mathbf{a}))} \tag{22}$$

Some plots of this diffuse intensity function are shown in Fig. 1c. All plots use the same value of the correlation coefficient r. When the value of σ is a small fraction of the lattice spacing (n.b. typical values for thermal displacements may be $\sim$0.05), only the P=1 term in the summation is appreciable. In this case: the form of the diffuse scattering is practically the same as for substitution disorder (Eq. 12). However, here the overall intensity is zero at the origin and rises with k. As the value of a is increased. higher-angle diffuse peaks become broader as a result of the increasing contribution of the $P=2, P=3$, etc., terms in the summation. At the same time. the exponential before the summation (the Debye–Waller factor) reduces the overall intensity at high angles.

It should be noted that when σ reaches about 0.3 (of the repeat distance), the intensity of even the first Bragg peak is so small that it is virtually undetectable, and all the scattering can then be considered to be diffuse scattering. In this case, increasing the value of r to values > 0.95 will result in a scattering pattern consisting of moderately sharp diffuse peaks but no actual Bragg peaks.

Disorder in 3D

Although 1D models provide useful insight into the various concepts of correlation and disorder. and there are real systems for which 1D models are appropriate. for most purposes, it is necessary to consider the possibility of disorder in higher dimensions. Unfortunately, the change from 1D to higher dimensions is decidedly nontrivial. At the conclusion of his work on the 1D Ising model, Ising considered that the extension to higher dimensions would be a simple matter. It was not until 1944[10] that the 2D nearest-neighbor Ising model was solved. and there is still no analytical solution for the 3D model. The correlation coefficients, C_{lmn}, are now present on a fully 3D array. and the constraints and interdependencies of these are much more complex.

In general terms. it is easy to see why the extra complexity occurs. In ID, a given lattice site can be influenced by its neighbor only via a direct interaction. In 2D or 3D systems, there is a multitude of other indirect pathways that can transmit the interaction. This has a marked effect on the way in which correlations spread through a lattice. For the 1D models discussed earlier, it was seen that there was a geometric progression of the correlations with distance. For the corresponding 2D or 3D nearest-neighbor Ising model with the same value of the nearest-neighbor correlation coefficient β, the decay is much less rapid. The corresponding diffraction peaks have a profile that is correspondingly sharper than those seen for the 1D model in Fig, 1a.

Despite the difficulty in obtaining analytical solutions for higher-dimension Ising models, they are still simple to formulate, and realizations of them can readily be obtained via Monte Carlo simulation (although care must be taken. because there may be phase transitions present). Such models are routinely used in a wide range of different systems (see, e.g., Refs. [3–5,7,12,14]).

EXAMPLES

Example 1: The Molecular Crystal 1,3-dibromo-2,5-diethyl-4,6-dimethylbenzene

Shown in Fig. 2a is the $(0kl)$ section of the diffraction pattern from the pure molecular crystal 1.3-dibromo-2.

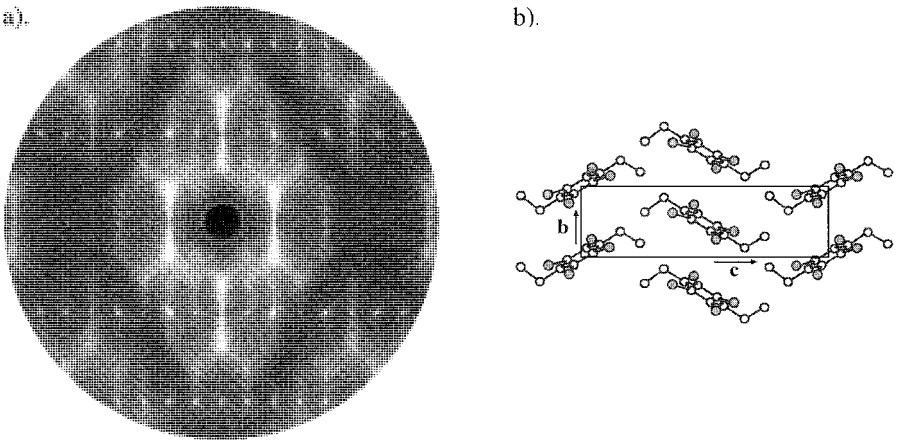

Fig. 2 (a) The (*0kl*) section of the diffraction pattern of 1,3-dibromo-2,5-diethyl-4,6-dimethylbenzene. (b) A corresponding projection of the average crystal structure. (*View this art in color. at www.dekker.com.*)

5-diethyl-4,6-dimethylbenzene recorded at low temperatures (100 K).[7] Shown in Fig. 2b is the corresponding projection of the average crystal structure. This material is disordered because of the similarity in size of the methyl- and bromo-substituents, and in the drawing. the atomic sites shaded in gray are revealed by conventional crystal structure determination to be occupied by 50% Br and 50% methyl.

Although the intensity distribution in Fig. 2a looks complex, it can be described purely in terms of substitutional disorder. in which there are two different possible molecular orientations A and *B* in each site and can be understood in terms of a small set of C_{lmn} intermolecular occupancy correlations. In addition. and most importantly. the overall form of the scattering is modulated by the difference of the molecular scattering factors, $|F_A - F_B|^2$. Because there are two different molecular sites (cell corners and cell centers), with different average orientations, some terms arise from pairs of molecules on a single sublattice (e.g., the cell corners). while others arise from pairs comprising a molecule on one sublattice (cell corner), with a molecule on the other sublattice (cell center).

Example 2: The Zeolite Material, Mordenite

Shown in Fig. 3a is part of the (*hk5*) section of the diffraction pattern of the zeolite mordenite." The origin of the reciprocal section is near the center at the top of the figure. Two different diffuse scattering features can be seen: narrow diffuse streaks emanating from the Bragg reflection positions and broad uniform diffuse regions each extending over several reciprocal lattice cells.

A schematic drawing of the structure is shown in Fig. 3b. This is made up of corner-connected SiO_4 tetrahedra that appear as triangles in this figure. The basic building blocks for the structure are the clusters of tetrahedra (eight triangles) shown in two different shades of gray. These form columns along the **c** (projection) direction. The origins of the light and dark columns differ by 0.5**c**. The perfect structure consists of alternating light and dark columns, as seen in the lower-right portion of the figure.

Two types of defects can occur. First. a single isolated column is able to slip by 0.5**c**. Such a slip of origin corresponds to a change of shading from dark to light or vice versa. Second, stacking faults can occur where one whole region of the structure slips 0.5**c** relative to the adjacent region. The dark line running diagonally across the figure indicates such a fault line. Note that the shading of columns on opposite sides of the fault is in antiphase.

For this example, the two different diffuse features can also be described purely in terms of substitutional disorder and understood in terms of sets of correlation parameters. For both types of defects, F_A and F_B represent the structural factors for the two different types of columns (one shifted 0.5**c** relative to the other). The difference between these $|F_A - F_B|^2$ gives a function with the broad areas of scattering that are seen. For isolated random defects, only the origin term C_0 is present: all other C_{lmn} are zero. This produces uniform (unmodulated) scattering in the noted broad areas.

The sharp streaks caused by the stacking faults involve strong correlations that modulate the scattering in the same broad regions. Parallel to the fault line, there is strong positive correlation, i.e., neighboring columns fol-

Fig. **3** (a) Part of the (*hk5*) section of the diffraction pattern of the zeolite mordenite. together with (b) a schematic plot of the structure illustrating the formation of a stacking fault. (See the text for details.) (*View this art in color at www.dekker.com.*)

low the perfect structure sequence. This gives the streaks their narrow widths. Normal to the fault line, there is also positive correlation, as neighboring sheets of structure still tend to conform to the perfect structure sequence, but depending on the faulting probability. the range of order is only moderate. This results in the streak being most intense at the Bragg position and diminishing away from it.

Example 3: Dibromodecane/Urea Inclusion Compound (BBD–Urea)

Shown in Fig 4a is the (*0kl*) section of the diffraction pattern from the DBD–Urea inclusion compound In urea inclusion compounds, the urea molecules form a hydrogen-bonded network containing hexagonal channels that run along the c-direction The channels can accommodate various kinds of long-chain molecules. of which DBD is an interesting example.[11,12] The DBD molecules pack end-to-end in an individual channel to form a pseudo-ID crystal, the repeat distance of which is not commensurate with the crystallographic repeat of the urea framework. At room temperature, the molecules are able to rotate about their long axes and are also able to slide along the channels. To a first approximation, the molecules in one channel are independent of those in neighboring channels. This is shown schematically in Fig. 4b. The average crystal structure obtained from the Bragg peaks reveals details of the urea framework, but little information is obtainable about the guest molecules' positions or orientations.

The vertical diffuse bands in Fig. 4a arise from the chains of molecules that form a pseudo-1D crystal along each urea channel. Each band is virtually uniform in intensity, because there are no correlations linking one

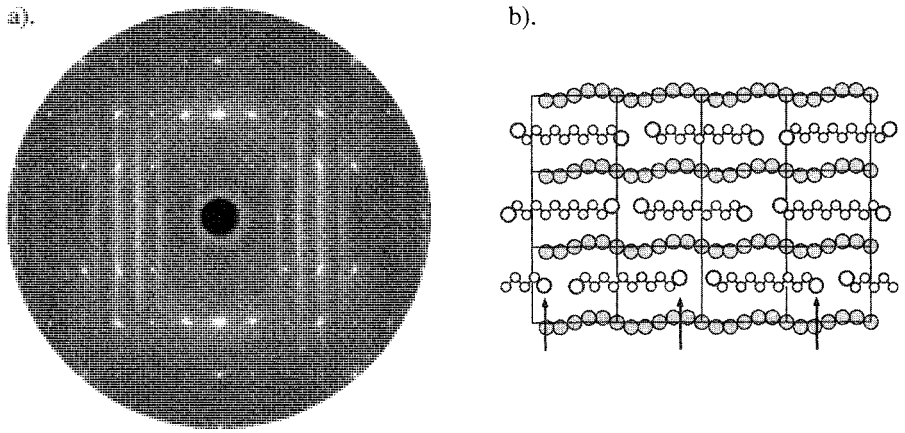

Fig. 4 (a) The (*0kl*) section of the diffraction pattern of the dibromodecane/urea inclusion compound, together with (b) a schematic diagram of the structure showing that the dibromodecane molecules form a pseudo-1D crystal within each channel of the urea host. Fig. 5 (a) The (*hk0.5*) section of the diffraction pattern of a calcia-stabilized cubic zirconia, together with (b) a schematic drawing of part of the structure showing how the cations move away from a vacancy in the oxygen lattice. The ''+'' signs in (a) mark the reciprocal points (4 0 0.5) and (0 4 0.5). The arrows are drawn to indicate pairs of diffuse spots refel-red to in the text. (*View this art* in *color at www.dekker.com.*)

channel with the next. It is seen that the firct diffuse band is narrow. but higher-order ones get progressively broader. This behavior is in accord with the 1D displacement model described by Eq. 22. Note also that the spacing of the bands is incommensurate with the Bragg peak spacing. [It should be noted that the second band is absent due to the particular form of the molecular structure factor (omitted from Eq. 22).]

Example 4: Calcia-Stabilized Cubic Zirconia (Ca-CSZ)

Shown in Fig. 5a is the *(hk0.5)* section of the diffraction pattern of a Ca-CSZ of composition. $Ca_{0.125}Zr_{0.875}O_{1.875}$.[13] CSZs have the fcc fluorite average structure, with all atoms in special positions. A drawing of part of the fluorite structure viewed down **c** is shown in Fig. 5b. Only two layers of anion sites are shown, together with the cations they contain. In CSZs, the cation sites are all occupied but are disordered; the anion sites have partial occupancy. Between two cations, there are two bridging oxygen sites, as shown in Fig. 5b, and the black circle near the center of the figure is drawn to represent a vacancy in one of these sites. The figure illustrates the proposed mechanism by which the cations are displaced away from a vacancy. This distortion mechanism accounts for the dark lines (indicated in Fig. 5a by the direction of the arrows) (see Ref. [7]).

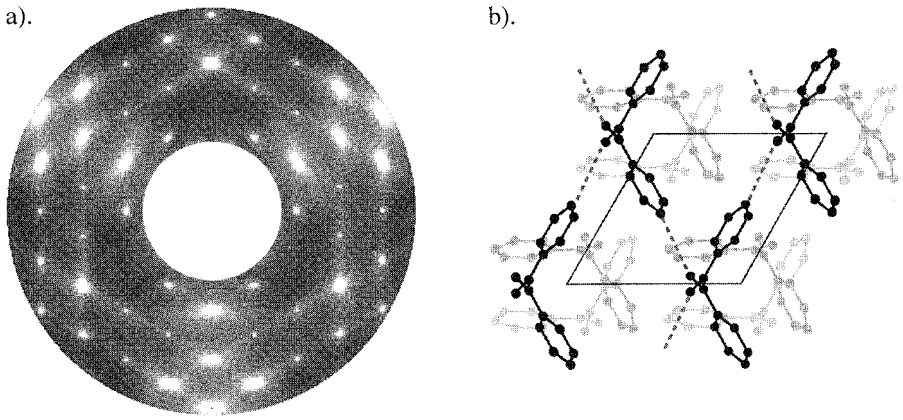

Fig. **6** (a) The (*hk2*) section of the diffraction pattern of benzil. $C_{14}H_{10}O_2$, together with (b) a plot of the corresponding projection of the structure (H atoms omitted). The structure consists of three symmetry-related molecular planes, two of which are drawn in light shading for clarity. The dashed line indicates the important vectors along which the internal motion of one molecule is coupled to its neighbors. (View *this art* in *color at www.dekker.com.*)

The second-neighbor Markov chain, described earlier, is the simplest system that gives rise to diffuse peaks at incommensurate positions. Incommensurate peaks occurring in real materials invariably arise in a similar way from a competition between nearest-neighbor forces and some more distant force. The CSZ example of Fig. 5 is one such system. It was recently shown[4] that the diffuse peaks in this system can be understood in terms of a competition between nearest-neighbor forces and a longer-range strain that builds up as the locally prefen-ed structure tries to fit into the average lattice.

The CSZ diffraction pattern shown in Fig. 5a also demonstrates the importance of the higher-order diffuse scattering components that involve interaction between occupancy and displacements. The diffuse spots mentioned above are due to the presence of occupancy correlations (i.e., the I_0 component), but their intensities are modified by the various other components. Each pair of spots spans a particular dark line, four of which are indicated by the directions of the arrows in Fig. 5a. The point of each arrow indicates a particular pair of spots. Of particular interest is the relative intensity of the two spots comprising each pair. At low diffraction angles, the lower-angle spot is stronger. but as the diffraction angle increases, the higher-angle spot progressively becomes stronger. The asymmetry of the spot intensity arises from the size-effect term; I_1, and the other odd higher-order components. such as I_3. At low angles, I_1 dominates. but at higher angles, the I_3 term becomes progressively more important. Because I_1 and I_3 are of opposite signs. the asymmetry switches the signs.

Example 5: The Molecular Crystal, Benzil

The $(hk2)$ section of the diffraction pattern of benzil is shown in Fig. 6a.[5] This is an example of a system where the scattering is purely TDS and does not involve any occupancy disorder. The molecule has internal degrees of flexibility, and the diffuse scattering results from motions in which the internal degrees of flexibility are coupled from molecule to molecule via intermolecular interactions. The corresponding c-axis projection of the structure and the most important intermolecular vectors are shown in Fig. 6b. These vectors run between the O atoms in the flexible bridge of one molecule to the C–H terminus of a neighboring molecule. This hydrogen-bond network enables the internal motions of molecules to be coupled over relatively large distances.

Because there is no occupational disorder, the diffuse scattering in Fig. 4a is essentially made up of terms from the second-order diffuse component I_2 (Eq. 7). Because this is a sum of cosine terms. the intensity is symmetric about Bragg peak positions. This is true for the strong anisotropic peaks that surround some strong Bragg peaks and for the narrow diffuse bands that run between them. The diffuse peaks that surround the Bragg peaks indicate that there are strong positive correlations between the displacements of atoms and molecules. The anisotropy of the peaks (relatively narrow on a radial vector and broader in directions normal to this) is indicative of the fact that correlations are stronger in directions parallel to the displacement direction and weaker in directions normal to the displacement direction. This information is present in the relative magnitudes of the different displacement averages that appear in Eq. 7.

CONCLUSION

In this article, we attempted to show, using a selection of real diffraction examples, the range and diversity of different types of disorder that occur in many materials. We also gave a brief survey of some important aspects of diffraction theory. an understanding of which enables the different disorder effects to be identified. Correct identification of the origins of a particular diffuse scattering pattern is a prerequisite to being able to correctly analyze it. This is particularly important, because the diffraction experiment can only give information concerning pair correlations and so there is always the possibility of ambiguity.

Perhaps of most importance to chemists is the last example of the molecular crystal benzil.[5] In this, the diffuse scattering arises entirely from thermal disorder and so is essentially similar to a whole range of molecular crystal systems that are nominally considered to be perfect. Whereas conventional crystal structure determination will provide such quantities as mean-square atomic displacement ellipsoids. the diffuse scattering analysis reveals details of how the molecules are interacting and moving. The analysis of benzil is indicative of the level of detail that can be obtained using current modeling techniques. The agreement between model calculations and the observed diffuse scattering is approaching the level that is routinely obtained for Bragg reflections. At this level of quantitative agreement, for example, it was possible to measure the torsional force constant for the internal degrees of flexibility in the benzil molecule. As the modeling methods develop and computers become ever more powerful, the future looks bright for this kind of detailed information to become routinely available.

DNA as a Supramolecular Scaffold

Alexandra L. Pickering
Leroy Cronin
The University of Glasgow, Glasgow, United Kingdom

INTRODUCTION

Since the elucidation of the structure of DNA in 1953, a revolution has occurred in molecular biology that recently culminated in the sequencing of the entire human genome. However, the properties that define DNA as a macromolecule with the most essential role in biology are also of tremendous importance in the design and understanding of DNA as a stnictural component in nanotechnology. After all. it could be argued that DNA is the ultimate supramolecular architecture. In this article, we describe the structural features of DNA that allow application as what promises to be one of the most fundamental supramolecular scaffolds. In describing this, we discuss the importance of molecular recognition and DNA binding in the design of synthetic DNA architectures. diagnostic agents, and the growth of new DNA-hybrid materials. The understanding of how DNA acts as a template, both to allow its own replication and to assemble cations; is also vital, as is an appreciation of topological concepts in the design of new materials. Finally, we describe how these ideas were applied to the design of DNA-based architectures for nanolithography, DNA machines. molecular wires, and as chiral memory devices.

DNA STRUCTURE

Considering its integral importance to life, the structural components of deoxyribose nucleic acid (DNA) are reinarkably simple. Each strand of DNA is a linear polymer comprising a constant backbone of alternating deoxyribose sugars and negatively charged phosphodiesters, and a selection of four heterocyclic bases (Fig. 1). The uniqueness of the DNA strand is defined purely in terms of the sequence of the bases.

Two polymeric nucleic acid strands are held together by Watson–Crick hydrogen bonds (2.8–3.0 Å) between two bases to form a double helix. Adenine and thymine base pairs hydrogen bond together via two interactions, and guanine and cytosine through three. The conformation of the base pairing defines the mutual positions of the two sugar–phosphate strands in DNA. Hydrophobic and van der Waals interactions as well as π stacking between sets of base pairs also contribute to the stability of the overall structure.

Although the individual bases are planar heterocycles. considerable flexibility is conferred upon the entire structure from a number of contributing factors. Base pairing, for example, can deviate from planarity by up to 35° to minimize steric interactions without appreciable loss of hydrogen-bonding energy.[1] Furthermore, there are 12 different torsion angles associated with the sugar–phosphate backbone that can adopt a range of values. and hence, can have significant effects on the overall structure of the oligonucleotide. Linking the bases to the deoxyribose sugars is a glycosidic bond. which can have a torsion angle (χ) dependent on the orientation of the base in relation to the sugar. The sugar has a nonplanar "puckered" conformation dependent on its five internal torsion angles (τ_0–τ_4). The relative populations of the conformations arise from the type of base attached, and in solution, it is possible for these to interconvert, which alters the orientation of the substituents and, hence, the backbone of the entire structure. The final six variable torsion angles (α–ζ) define the conformation of the phosphodiester backbone. Steric restrictions prevent large angular variations between 0–360°; however, many possible low-energy conformations of the oligonucleotide exist.[2]

As a function of both flexibility and restraint, the overall structure of DNA can adopt several polyrnorphs, including left- and right-handed helices. Four major secondary structures of DNA are known; A-DNA. B-DNA, and triple helices are right-handed. and Z-DNA structures are left-handed[i]" ((Fig. 2). The A-conformer is the most compact, being wider and having a helical rise of 1I bases (25.6 Å). Z-DNA is composed of alternating purine-pyrimidine nucleotides, giving the structure a zigzag appearance and has a rise of 12 bases (37 A). A triple helix, comprising one purine and two pyrimidine strands, results from a "base triplet" hydrogen-bonding system. Its dimensions are similar to those of A-DNA. with the second pyrimidine strand lying in the grooves formed by a pyrimidine and a purine strand.

B-DNA is the most common polymorph due to its chirality and geometry along the sugar–phosphate backbone. The overall width of the helix is approximately 20 Å and completes one turn every 10 bases (34 Å).[4] As with

each double helix. the asymmetry of the base pairs results in major *and minor grooves along the helical axis. with dimensions that are related to the distance and orientation of the base pairs in relation to the axis. The major groove is approximately 13* Å *wide and 8* Å *deep. whereas the minor groove is 4.5 A and 6* Å, *respectively. The minor groove has hydrophobic hydrogen* atoms *of the sugar groups forming its walls. The major groove is richer in base* substituents, *having the* O_6, N_6 *atoms of the purine moieties and the* N_6, O_4 *atoms of pyrimidines available.*

DNA BINDING

The two major ways in which DNA *interacts with other eniities can be classed as nonspecific covalent bonding via either the phosphodiesicr or sugar moieties or electrostatic dominated noncovalent bonding. Nonreversible covalent interactions are important when considering the cellular processing of many drugs, but it is the ability to form* noncovalent *interactions that defines* DNA *as the ultimate supramolecular building block.*

Fig. 2 *The common* polymorphs *of DNA. (View this art in color at www.dekker.com.)*

Noncovalent interactions *with* DNA *occur via two binding modes: groove binding and intercalation. Much research has been carried out* to *exploit the properties of DNA* in *the design of targeted intercalating and* groove-*binding drugs in such areas as anticancer. antibacterial. and antiviral agents. and in the postgenomic era, the* need *for a deeper understanding of how* DNA *interacts with other* molecules *is* becoming more *apparent. However. analyses of the integral features of the structure of* DNA *allow a much* more *comprehensive view of its noncellular potential.*

Conventionally. the structures of the molecules designed for each binding mode followed certain distinctive criteria."' Boundaries are now *being extended and* becoming *less clear. and an ever-increasing number of physical and chemical techniques are emerging to aid in the determination of the structures, sequence specificity. energies. and binding stoichiometries of these* noncova-*lent* interactions.[6] *The specific binding mode of interaction can now be determined by a combination of such techniques as x-ray crystallography, NMR. gel* footprint-*ing, circular* dichroism. and *fluorescence.* UV. IR, *and mass spectroscopy.*

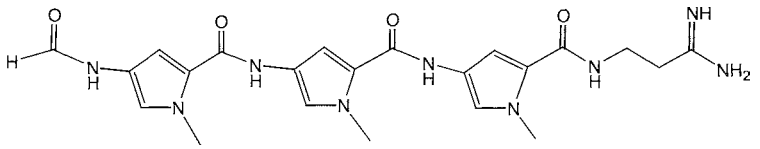
In the biological environment, it is *important to understand the processing of the genetic code stored in the* DNA. *The ability to stimulate or prevent this processing is of great importance in terms of molecular biology and drug design. and also in* terms *of* supramo-*lecular chemistry. as the noncovalent interactions* in-volved *in such "switching"* mechanisms *are of great interest. These mechanisms involve a variety of molecular tools in order to recognize the genetic code in a* sequence-*specific manner. Biology achieves this through the surface motifs of proteins. which are too large to fit into the minor*

groove and instead interact in or around the major groove.[7] This acts as a particularly attractive macroreceptor site for DNA recognition agents, as the dimensions of the major groove are dependent to a large extent on the base sequence and so can be seen as a molecular "lock" that is activated by a highly specific recognition "key." For example, distortion of the DNA backbone is activated by transcription regulators that incorporate cylindrical binding units such as α helices or zinc fingers that insert into the major groove.

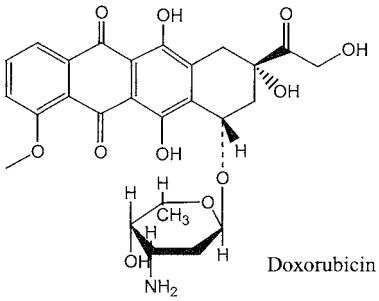
It is possible to mimic the biological mechanisms used to bind DNA. For example, oligonucleotides of natural and synthetic origins are capable of forming triplexes by sequence-specific binding to the major groove, and the area of metallosupramolecular assembly can provide cationic charge around the metallocenters, which confer a substantial electrostatic contribution by interactions with the anionic sugar–phosphate backbone.

Such large arrays of macromolecular recognition contrast sharply with the mode of *DNA* binding of small molecule recognition agents. Typically, cationic at physiological pH and much smaller than proteins. these agents are able to bind preferentially to the minor groove. where the electrostatic potential is negative, displacing the hydrogen-bonded water molecules. Strong electronic interactions along with the formation of significant van der Waals contacts make the complex stable, with dissociation constants in the order of 10^{-5} M^{-1}. The natural antibiotic distamycin *A* (Fig. 3) and its derivatives are well-established reversible minor-groove binding agents. It incorporates an oligopeptidic pyrrolic framework with a terminal amidino moiety and is highly selective for A·T-rich regions containing more than four A·T base pairs. Typical minor-groove binders include an extended ring syctem with unfused rings, although recent developments in sequence-dependent DNA binding included ligands with polyaromatic nuclei. These conjugated systems form strong hydrophobic contacts with the sugar-containing walls of the minor groove. Increased interactions can be introduced through hydrogen-bonding moieties to improve the affinity of the groove binders for G·C-rich regions. Derivatives of such groove binders as distamycin A can be used for alkylating and nonalkylating agents in anticancer therapeutics.[8] It is believed that the ability of small molecule recognition agents to alkylate DNA in a sequence-specific manner and modify the function of nucleic acids irreversibly will increase the specificity for target cells.

In general, groove binding effects only subtle changes in the overall structure by bending or kinking the DNA. Intercalation, on the other hand: has a much more dramatic structural effect in terms of helical twist and compression. Intercalators are typically polycyclic aromatic compounds that bind reversibly to the DNA double-helical structure by inserting into the central hydrophobic region of the helix between the stacked base pairs. These chromophores are conventionally two or three six-membered rings, for example, doxorubicin (Fig. 3), of approximately the same size as a base pair. This means that, in addition to π-stacking interactions between the intercalator and the adjacent base pairs, strong van der Waals contacts further contribute to the stability of the complex. There are also a number of intercalating agents containing side chains that play vital roles in both the stablization and sequence specificity of interactions with *DNA* by binding in the minor groove.[9]



Distamycin A



Doxorubicin

Fig. 3 Minor groove binder distamycin A and intercalator doxorubicin

The process of intercalation demands an alteration of the $\alpha-\zeta$ torsion angles along the sugar–phosphate backbone in order to accommodate the aromatic ring system. Rotation around these torsion angles results in a separation of the base pairs and a subsequent extension of the helical axis (approximately 3.4 Å per bound intercalator) and "unwinding" of the two DNA strands. The extent of the unwinding is dependent on the individual intercalator. Polyintercalators are well known,[10] containing two or more aromatic ring systems bridged by appropriate linker chains that facilitate simultaneous intercalation along the DNA strands and the potential for increased sequence specificity.

DNA AS A TEMPLATE

DNA as a helical anion can be viewed as a macromolecular template. The fact that DNA is comprised of two self-complementary strands of base pairs is responsible for its ability to replicate upon dissociation of these strands. In fact, the replication of DNA via a templating effect to form a coinpleinentary strand aided by Watson–Crick base pairing is linked to the central dogma of molecular biology.[11] By utilizing a self-complementary and "self-templating" molecule such as DNA, the emergence of life and the possibility for evolution was realized. This is because the use of a double helix of DNA, containing two identical copies of genetic information, allowed the development of an exquisite DNA repair mechanism. Furthermore, the supramolecular coiling of DNA in the chromosomes of a cell is the key to cellular development via protein expression; this is thought to occur through a kind of unwrapping process in which DNA is the key molecule.

The anionic nature of DNA also has important implications in the construction of virus capsids. in which the protective capsid is either assembled around the DNA from a large number of repeating protein building blocks or preformed for DNA insertion. This self-assembly process is partly responsible for the fast spread of viral infection, as many viruses can spontaneously assemble from a soup of DNA and protein-based building blocks.[12] The ability to manipulate the structure of the DNA duplex by altering the code should therefore affect the ability of DNA to coil in chromatin formation as well as gene therapy vector design and in the manipulation of virus structure. It was shown that DNA can also direct the assembly of small molecular units that can undergo a template-driven polymerization process.[13] The covalent casting of noncovalent architectures serves to determine large molecular constructs that express well-defined modes of aggregation. In the case of one-dimensional hydrogen-bonding motifs, covalent casting yields molecular strands that adopt a duplex mode of aggregation.

It is well known that nucleic acids are capable of promoting chemical reactions, and catalytic nucleic acids were found in nature or evolved through in vitro selection processes. Interestingly, it appears that the DNA acts in a similar manner to enzymes and promotes chemical reactions through spatial alignment of the reaction partners; i.e., via a template effect.[14] Recent reports reveal new facets of nucleic acid promoted chemistry and indicate that DNA strands are able to promote chemical reactions by bringing reaction partners into close proximity of each other rather than by precisely aligning the reactive groups. Therefore. it appears that DNA-templated synthesis is a phenomenon that applies to a remarkable variety of chemical reactions (Fig. 4). The ease of automated DNA synthesis. predictable binding, and established methods for nucleic acid amplification and sequence analysis render DNA a promising template for future developments.[15]

DNA TOPOLOGY

Research into the application of noncovalent metal–ligand interactions to direct self-assembly resulted in a number of interesting topological structures.[16] It is well established that DNA topology is a crucial factor in many biological processes. such as topoisomerism and DNA supercoiling. Highly ordered DNA topology is also of considerable interest with respect to the

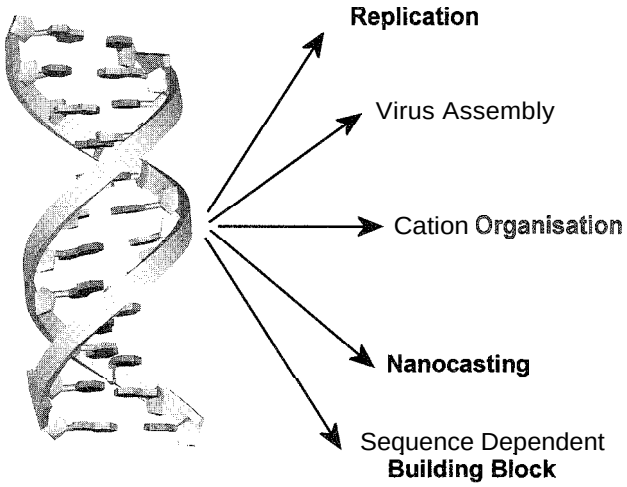


Fig. 4 Examples of DNA chemical reactions. (*View this art in color at www.dekker.com.*)

design of sequence-specific DNA binding agents, allowing targeted recognition and precise regioselectivity along the polymeric strands. The crystallographic motivation for such developments lies in the desire to organize DNA in a periodic array in order to provide a scaffold on which other macromolecules, which are difficult to crystallize by conventional methods, may be arranged.

The first-known topological polymorph of DNA, discovered in 1967,[17] was the DNA catenane consisting of two interlocked rings of circular DNA. It was recognized that these structures had important implications in the cellular functioning of DNA. If, during the replication of circular DNA. a catenane structure is formed upon the interlocking of parent and daughter molecules, continuation of the replication process is impeded. Topoisomerases are a class of enzymes capable of changing the topology of DNA by an incision and repair mechanism. Once the DNA strand is broken, another strand may pass through the rupture; and then repair mechanisms reseal the original strand. Type I topoisomerases effect topological transformations during the disruption of one DNA strand, and Type II topoisornerases are capable of breaking two strands.[18] The design of

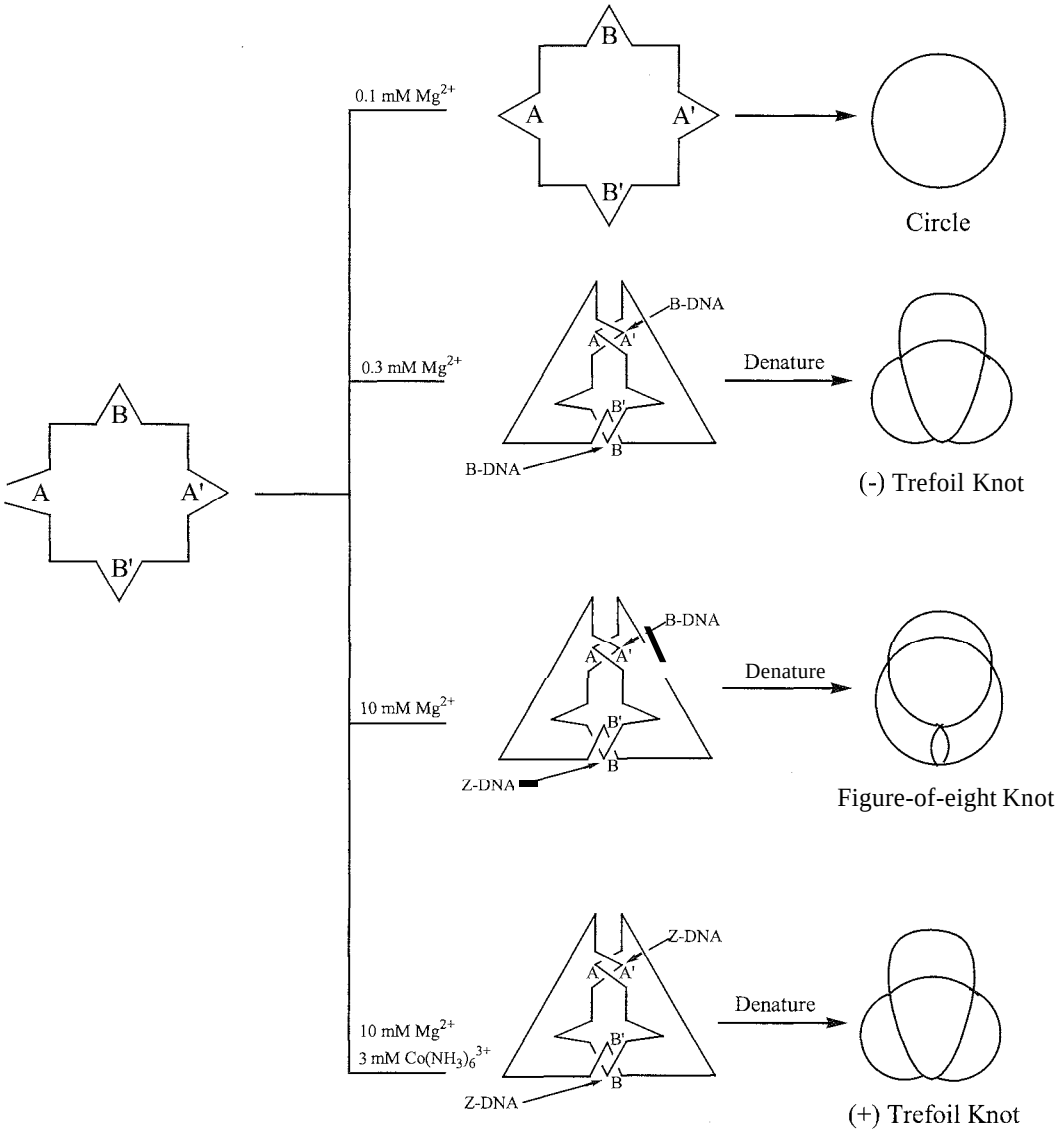

Fig. **5** Seeman's synthesis of DNA knots. (From Du. S.M.: Stollar, B.D.: Seeman, N.C. A synthetic DNA molecule in three knotted topologies. J. Am. Chem. Soc. 1995, *117*, 1194–1200.)

topoisomerase-inspired synthetic agents could provide a much desired control of highly ordered topology in the area of nanotechnology.

The replication of DNA is controlled by its topology in another vital process known as supercoiling. Topological isomers of circular double-stranded DNA can be made by incision of the duplex and twisting of the strands through 360° before repairing the incision. The overall three-dimensional structure of the DNA undergoes a significant change in the number of helical twists, and a compression along the helical axis in coinparison to the uncomplexed B-DNA is observed.

In addition to naturally occurring complex helical DNA topologies, it is also possible to design topologically interesting structures with linear DNA. The differences in chirality between right-handed B-DNA and left-handed Z-DNA duplex formation as well as engineered effects of specific base-pair complimentarity facilitate the formation of a number of molecular knots from a single-stranded DNA oligomer as a function of salt concentration (Fig. 5).[19,20]

Other remarkable complex structures were assembled from both single strands, for example, the DNA ''padlock,''[16] and multiple strands. such as the DNA cube[21] and a truncated octahedron.[22] The formation of a linear double-helical structure from two strands of oligodeoxyribonucleotides is the most energetically favorable, and as such, it would appear that other configurations are unlikely. However, the principles of genetic recombination. a biological process forming new genetic inaterial from the interaction of two pieces of DNA. can be applied to generate novel, topologically interesting architectures. A key structural intermediate in the recombination mechanism is the Holliday junction,[23] which joins four double helices in a branched molecule. The sequence of nucleotides that converge at the junction is generically twofold symmetric, which allows isomerization of the branch point to the region of symmetry. This is not, however. crucial to the forination of DNA branched molecules, and so it is possible to develop junction structures with fixed branch points.

DNA, MOLECULAR ARCHITECTURE, AND NANOTECHNOLOGY

A significant challenge faced in the use of nanoscale building blocks lies in developing parallel methods for interconnecting and patterning assemblies of the individual components. Molecular scaffolds based on the structure of DNA have the potential of preparing closely spaced, specifically arranged nanoscale assemblies. The ease in which DNA can be synthesized and manipulated means that it is an ideal building block for nanostructured materials.[24] Furthermore, the fact that DNA can interact with other molecular assemblies in a sequence-specific manner means that DNA is a perfect functional scaffold for application in nanotechnology as a molecular device.

The ability to cause DNA to branch is being used in the design of new molecular devices and materials. Such DNA branch junctions are often found in biology; they occur as ephemeral structures in cellular DNA metabolism, including the processes of replication and repair. A particularly significant structure in such systems is the four arm branched Holliday intermediate crucial to the process of genetic recombination.[23] It is fairly simple to design sequences of DNA molecules that lead to stable synthetic variants of Holliday junctions, branched molecules with varied numbers of arms. as well as more complex motifs; it is also elementary to synthesize their constituent strands and engineer subsequent self-assembly of target systems. The use of branched intermediates allows us to make N-connected objects from DNA as well as periodic and aperiodic arrays. Similarly, branched DNA motifs were the basis for several nanomechanical devices.[25]

Further applications of the DNA scaffold are as molecular wires in nanoelectronic circuits, facilitated by

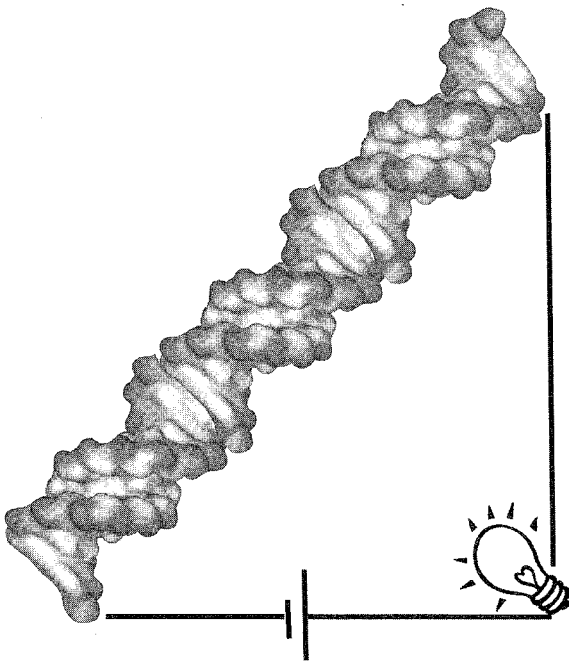

Fig. 6 DNA as a conducting molecular wire. *(View this art in color at www.dekker.com.)*

the fact that electron-transfer processes appear to be mediated by DNA via the π–π-stacked arrangements of the base pairs.[26] This idea, although still the subject of controversy, appears to be limited by recent observations that such events can only occur over small distances.[27] However, DNA has now been used as a template to provide a surface that can be coated with metal atoms to form a conducting or semiconducting sheath.[28] Therefore, should the conducting properties of the polymeric DNA be proven to be insignificant, it appears possible to use the linear framework as a scaffold to assemble or grow a conducting sheath (Fig. 6).

DNA can also be used as a template for the assembly of extended. close-packed nanoparticle structures. Electrostatic binding of ligand-stabilized nanoparticles to the DNA backbone results in extended linear polymers of ribbon-like structures composed of parallel nanoparticle chains and branched structures. Furthermore, the functionalization of DNA with gold nanoparticles led to the design of a DNA array detection method.[29] As such, DNA shows tremendous potential for a variation of biomolecular nanolithography. and the arrangement of nanoscale building blocks on biomolecular scaffolds is a viable approach to interconnecting individual devices into extended, close-packed assemblies.[30]

CONCLUSION

Perfected by nature, the cellular functioning of DNA is an important model for the design of binding agents and therapeutics. However. the potential of such a splendid example of supramolecular architecture as a prototype for the future development of advanced and functional supramolecular scaffolds is now being realized.

r

INTRODUCTION

DNA nanotechnology is a new area of research. It has many goals, but few of its practical aims have been achieved. Nevertheless. the results obtained to date are encouraging and suggest that the application targets of the endeavor are within reach. Before going into the specific aims that the field seems well-poised to accomplish, it might be useful to explain just what DNA nanotechnology is, and where its niche is likely to lie. We all know that DNA is the genetic material of living organisms. DNA nanotechnology utilizes the features of DNA that enable it to function in this role, but the field is not exclusively a biologically oriented enterprise. It seeks to control the a chitecture of matter on the nanometer scale. with the aims of creating well-defined two-dimensional (2D) and three-dimensional (3D) molecular arrangements.

The key to DNA's biological role lies in the specificity of the base pairing that holds the two strands of the double helix together: adenine (A) pairs with thymine (T). and guanine (G) pairs with cytosine (C). The familiar double helix that results from these complementary interactions is a linear molecule. in the topological sense that its axis is not branched. However, by designing appropriate sequences for synthetic molecules, it is possible to produce more complex molecular topologies from synthetic strands,[1,2] for example. the branched DNA molecule, termed a "junction." shown in Fig. 1. The sequence of this molecule has been optimized so that the likelihood of the four strands associating as shown is very high. In addition. twofold symmetry is forbidden about the branch point to prevent its relocation via an isomerizaiion known as branch migration.

DNA NANOTECHNOLOGY COMBINES BRANCHED DNA WITH INTERMOLECULAR COHESION THAT USES BASE PAIRING

Genetic engineers frequently produce their constructs by using DNA molecules that contain short overhangs on one end or the other of their double helices. These overhangs, known as sticky ends. will bind with their complements in solution to produce concatenated species that cohere by hydrogen bonding; if desired, DNA ligase can seal the nicks in these complexes to convert them to covalent molecules.[3] Thus, specific intermolecular associations between DNA components can be designed by the simple method of designing complementary sticky ends. It is important to recognize that sticky-ended cohesion is not merely a means of generating programmed affinity. Sticky ends form the classical B-DNA structure when they cohere; thus, the 3D structure near the point of cohesion is known, without need for further characterization.[" In this article, attention will be confined to those instances in which tight structural control of this sort is inherent to the molecular design.

DNA nanotechnology combines the two concepts of programmable intermolecular assembly using sticky ends with DNA topologies based on branched molecules. The addition of sticky ends to branched molecules produces components that can lead to association and ligation products more complex than could be obtained from linear DNA. These products include stick polyhedra, knots and catenanes, and devices and networks. A simple example is shown in Fig. 2, where four identical branched molecules containing sticky ends are assembled into a quadrilateral. The edges are double helical DNA, and the vertices correspond to the branch points. The quadrilateral has open valences on the outside, so the construct could be extended, in principle. to produce an infinite array. The arsay could be two-dimensional. as suggested by the drawing. or three-dimensional. The scale of DNA is important to keep in mind. The B-DNA double helix is about 20 Å wide. and its helical repeat is 10–10.6 nucleotide pairs for a pitch of 34–36 Å. Thus. constructions made from DNA will have features on the nanoscale.

DNA NANOTECHNOLOGY SEEKS TO BUILD USEFUL ARCHITECTURES ON THE NANOSCALE

What is the value of producing DNA objects, devices, and arrays'? Several applications have been suggested. The original motivation for the program was based on the

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012867

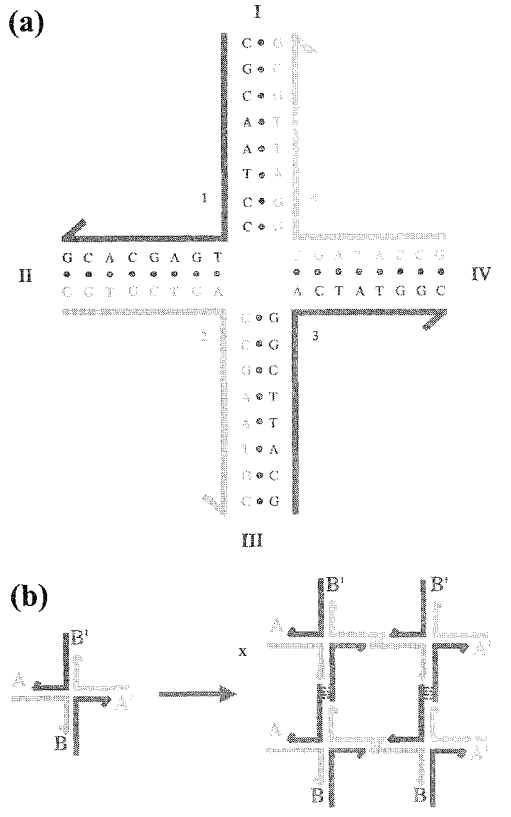

Fig. 1 (a) A branched molecule with four arms. The four strands labeled with Arabic numerals combine to produce four arms, labeled with Roman numerals. The branch point of this molecule is fixed by lack of twofold sequence symmetry. (b) Formation of a two-dimensional lattice from a four-arm junction with sticky ends. A is a sticky end, and A' is its complement. The same relationship exists between B and B'. Four of the monomeric junctions on the left are complexed in parallel orientation to yield the structure on the right. DNA ligase could close the gaps in the complex, Note that the complex could be extended by the addition of more monomers. (*View this art* in color *at www.dekker.com.*)

notion that spatially periodic networks are crystals.[1] The ability to build stick-figure crystalline cages on the nanometer scale could be used to orient other molecules as guests inside those cages, thereby rendering their structures tractable to diffraction analysis. as shown in Fig. 2a. Using the same logic, one could use the architectural properties of branched DNA to position and orient components of molecular electronic devices with nanometer-scale precision,[5] as shown in Fig. 2b. DNA nanomechanical devices will eventually lead to robotics on the nanometer scale. with applications in molecular fabrication and assembly. In addition. the motifs produced by DNA nanotechnology appear to be useful for DNA-based computation and the algorithmic assembly of materials.[9,10] Finally, DNA objects offer the possibility for self-replication, although the only route yet suggested to self-replicating branched DNA systems is somewhat oblique."[11]

THE REASONS TO USE DNA AS A MEDIUM FOR NANOARCHITECTURE

The key reason for using DNA to make nanoscale constructs is that DNA sticky ends provide the most predictable. diverse, reliable, and programmable set of intermolecular interactions available. In contrast to other molecules their scale. e.g., proteins, it is simple to program associations between specific molecules through

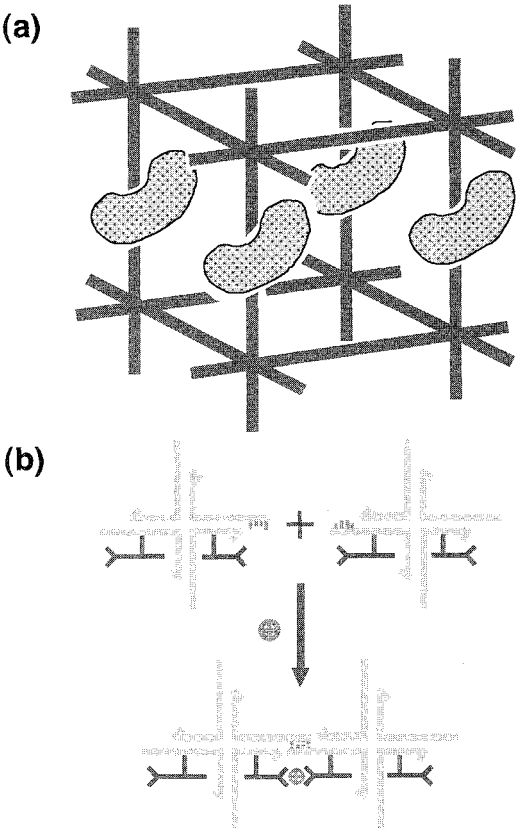

Fig. 2 Future applications of DNA nanotechnology. (a) A guest in a simple cubic lattice. The DNA lattice is drawn as a portion of simple cubic lattice made from 6-arm junctions. The guests are represented by the kidney-bean-shaped features in every unit cell. (b) DNA as scaffolding. Two branched junctions are shown. and a molecular wire is attached to them. When the two junctions cohere with each other. so does the molecular wire, which forms a synapse. (*View* this *art in* color *at www. dekker.com.*)

complementarity. In addition. convenient automated phosphoramidite chemistry[12] permits the assembly of arbitrary sequences containing 100 or more conventional or modified nucleotides. Likewise. it is key that DNA molecules can be manipulated by commercially available modifying enzymes. such as ligases. restriction endonucleases, exonucleases, or topoisomerases. The long persistence length of DNA (--500 A, or ~15 turns) ensures a stiff segment[13] when one uses lengths consisting of two to three double helical turns. DNA also contains an externally readable code''] that ultimately may be used to position and orient scaffolded molecules within arrays. Although most effort today is devoted to conventional DNA molecules. there are many variants that may be used ultimately in specific applications.[15] It is also worth noting that DNA has a very high density of functional groups: consequently, any given molecular motif may be decorated richly with derivatives.

MOTIF GENERATION

The key operation in generating motifs used in DNA nanotechnology is reciprocal exchange between two different strands.[2] This operation can be performed between strands of the same or different polarities, leading to parallel or antiparallel helices. These terms are derived from the biological recombination literature. but they really refer to the relative phasing between two adjacent helices. Illustrated in Fig. 3 is this operation at the top. and shown on the bottom are useful molecules derived from this operation. two double crossover (DX) molecules. a double crossover molecule with an extra junction (DX + J), and a triple crossover (TX) molecule.

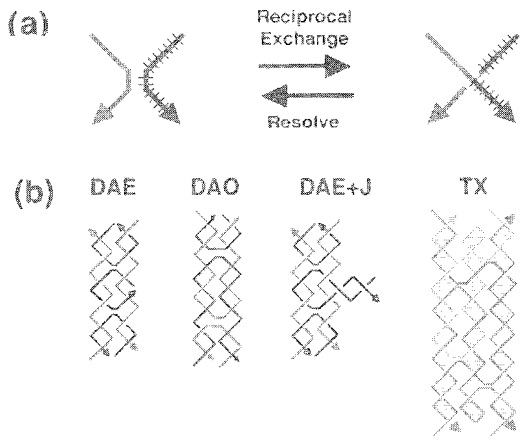

Fig. **3** Complex DNA Motifs. (a) Reciprocal exchange. Two strands are juxtaposed on the left. Arrowheads indicate their 3' ends. After reciprocal exchange, each resulting strand consists of a mixture of the two initial strands. (b) Rigid DNA motifs. The DAE and DAO motifs are generated by double reciprocal exchange between two helices. The separation of the crossover sites is an even number of half-turns in DAE and an odd number of half-turns in DAO. DAE + J contains an extra DNA domain: when this domain is oriented perpendicular to the plane of the other helix axes. it can be detected by the AFM. The base pairs are indicated in the triple crossover motif. (*View* this art in color *at www.dekker.com.*)

SEQUENCE SELECTION

We noted above the designing stable branch points requires avoiding twofold symmetry. In addition, the design of junction sequences entails the elimination of sequence symmetry among contiguous nucleotide groups. Sequences are divided into a series of overlapping 4–6 nucleotide elements, and repeated elements are forbidden during the sequence selection process; likewise. the complements to all elements flanking branch points are also avoided.''.''' This approach aims to eliminate all possible alternative structures that the system could assume: branched target molecules correspond to an excited state, and care must be taken to ensure that the excited product obtained is the one that is sought. The algorithm is a simplification of a more formal thermodynamic protocol,[17] and. with the motifs investigated so far, has proved remarkably successful in the design of DNA molecules containing branch points.

BRANCH FLEXIBILITY

The assembly of the quadrilateral product shown in Fig. 1b assumes not only that the sticky ends associate in a specific fashion. but also that the junctions maintain fixed angles between their double helical arms. Unfortunately, this assumption is not correct. Individual junctions have flexible angles around their branch points,[18,19] so rigid variants on simple branches must be used. The DX, DX + J, and TX molecules shown in Fig. 3 are systems in which this problem has been solved. They contain multiple branch points, with undistorted or minimally distorted helical domains. By contrast. control over the ligation products of single junctions is restricted to the topological level, and likewise, proof of synthesis is only topological and not geometrical. A group of single junctions with unique sticky ends can be joined to form discrete low-symmetry closed products, but rigid subunits

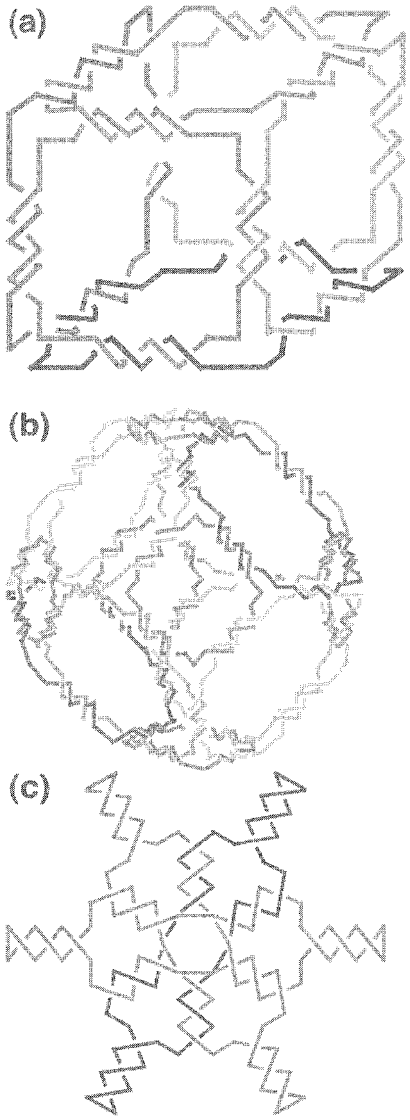

Fig. 4 Ligated linked products from flexible DNA components. (a) A stick cube and (b) a stick truncated octahedron. Each edge of the cube and the truncated octahedron contains two turns of double-helical DNA. The twisting is confined to the central portion of each edge for clarity. but it actually extends from vertex to vertex. (c) Borromean rings. Scission of any of the three rings shown results in the unlinking of the other two rings. (*View* ***this*** art *in color at www.dekker.com.*)

are necessary to form high-symmetry targets, such as periodic arrays.

POLYHEDRAL CATENANES AND KNOTS BUILT FROM SINGLE-BRANCH JUNCTIONS

Flexible single-branch junction building blocks have been used to construct a variety of topological targets. The first of these (Fig. 4a) is a DNA molecule with heiix axes connected like the edges of a cube or a rhombohedron.[20] Each edge contains two turns of double-helical DNA; as a consequence of this design, each face corresponds to a cyclic single strand. Each of these strands is linked twice to each of its neighbors, resulting in a complex hexacatenane. The topology has been demonstrated by designing a unique restriction site in each edge and then digesting the product at those sites to yield predicted subcatenanes. Illustrated in Fig. 4b is a more complex DNA molecule, a molecule with the connectivity of a truncated octahedron[21] that was built using a solid-support-based methodology.[22] This figure contains 14 faces, six squares, and eight hexagons. Each edge contains two turns of DNA. so this molecule is a complex 14-catenane; its topology has been demonstrated by techniques similar to those used to prove synthesis of the cube.

The half-turn of DNA corresponds to the fundamental unit of braiding topology. the node or a crossing seen when a topological figure is projected in two dimensions.[23] This feature makes branched DNA a particularly useful component with which to build complex topological figures. The half-turn of right-handed B-DNA produces negative nodes, and a half-turn of left-handed Z-DNA[24] produces positive nodes. Borromean rings consist of a set of linked circles that completely unlink upon the scission of any one of them. Combining a three-arm branched junction built from B-DNA and a three-arm branched junction built from Z-DNA produces the three-ring Borromean rings shown in Fig. 4c.[25]

The convenience of DNA as a topological synthon has been taken advantage of in constructing a variety of DNA

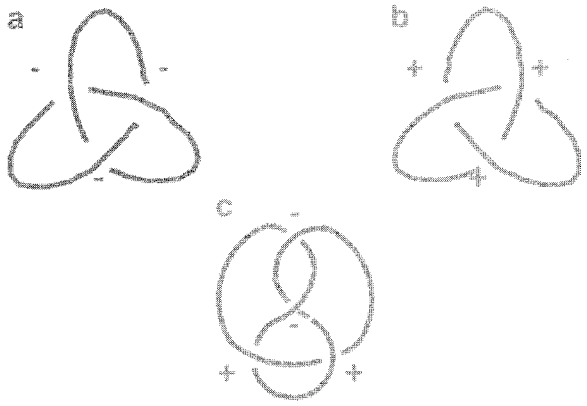

Fig. 5 Knots constructed from DNA. The signs of the nodes are indicated. A trefoil knot with negative nodes is shown in panel (a), a trefoil knot with positive nodes is shown on panel (b), and a figure-eight knot with two positive and two negative nodes is shown in panel (c). (*View this art in color at www.dekker.com.*)

knots. A trefoil knot with negative nodes is shown in Fig. 5a, and a trefoil knot with positive nodes is shown in Fig. 5b. An amphichiral figure-eight knot, with two positive and two negative nodes, has also been constructed: using B-DNA to produce the negative nodes and Z-DNA to produce the positive nodes (Fig. 5c). All of these knots can be produced from the same strand by varying conditions.[26] An RNA knot built similarly has been used to demonstrate that E. coli DNA topoisomerase III has an RNA topoisomerase activity.[27]

PERIODIC **ARRAYS** FROM **DNA MOTIFS**

The key goal of this system is to produce periodic (or aperiodic) assays from DNA motifs that can act as tiling elements in two or three dimensions. These tiles must be rigid components, because flexibility can lead to undesired structures. As noted above. the antiparallel DNA DX molecules. DAO and DAE and DAE + J (shown in Fig. 3b), have this property, as does the TX molecule shown there. Rigidity has been demonstrated experimentally for the DAF and DAE + J molecules[28] and inferred for the rest because of their successful use as tiling components. The two topological isomers of antiparallel DX molecules, DAO and DAE. differ by whether there are an odd (DAO) or even (DAE) number of double helical half-turns between crossover points. The DAE + J motif. consists of one or more bulged junctions positioned between the crossovers; the bulge consists of two nucleotides, with a presence that enables the stacking of the helix that is interrupted. The extra helix can act as a topographic marker in the atomic force microscope (AFM), when positioned so that it protrudes from the plane of the two DX helices.

Illustrated in Fig. 6 is a variety of two-dimensional arrays that have been formed from DNA tiles. Illustrated

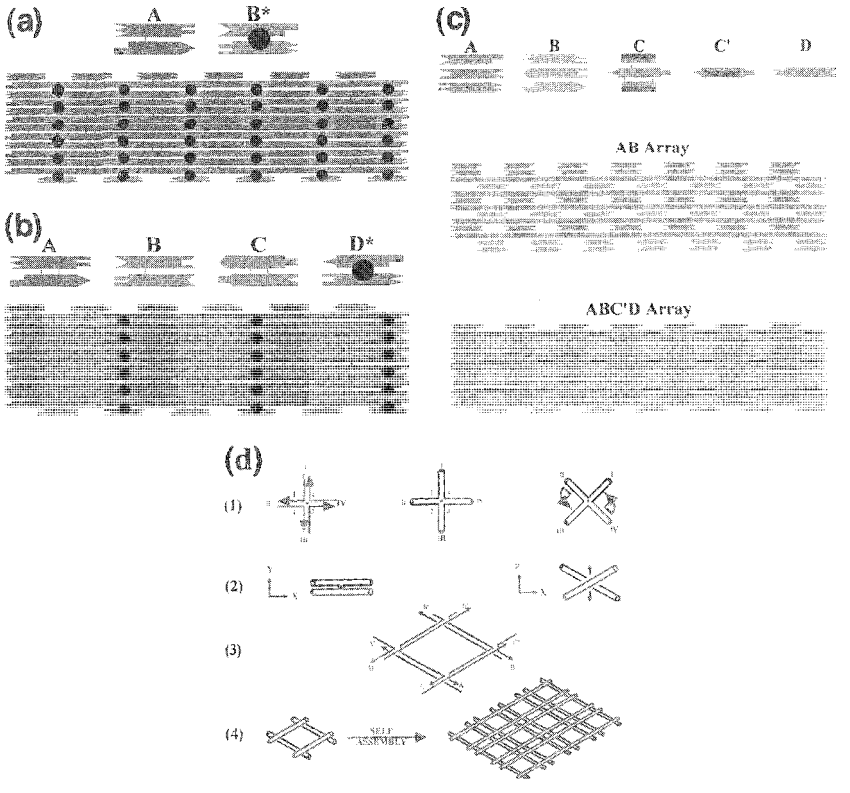

Fig. 6 Two-dimensional arrays assembled from DNA components. (a) A two-component array made from a DAE and a DAE + J motif. both 4 x 16 nm in this projection. where the extra domain is indicated by a filled black circle. Sticky ends are represented geometrically. (b) A four-component array. where the stripes occur every 64 nm. (c) An array made of two TX molecules (A and B), a rotated TX molecule (C'). and a double helix (D). (d) A four-arm junction can also be used to produce an array. (d.1) and (d.2) show that the four-arm junction assumes a two-domain structure, where the two domains are at an angle 60° to each other. Although flexible in its own right. four of them can produce a well-structured parallelogram (d.3) that can self-assemble into a 2D array (d.4). (*View this art in color at www.dekker.com.*)

in Figs. 6a and 6b are 2D arrays composed of DX and DX + J molecules. represented by A and **B***, respectively, in Fig. 6a; likewise, A. **B**, and **C** are DX molecules in Fig. 6b, whereas **D*** is a DX + **J** molecule. The dimensions of these tiles are about 4 nm x 16 nm, so the protruding stripe-like features on the DX + J tiles are separated by 32 nm in Fig. 6a and by 64 nm in Fig. 6b. Indeed. these features are readily apparent in AFM examination of these arrays.[29] These patterns may be modified by restriction. ligation, and hydrogen-bonded annealing.[30]

In Fig. 6c. patterns obtained from TX molecules are illustrated. At the top of the panel, one can see four molecules. A. B. **C**, and **D**. A and **B** are TX molecules that are connected 1–3 in the AB array illustrated below the individual molecules. This type of connection leads to gaps in the array. **D** is a simple double helix that can be fit into one of the gaps. **C** is another TX molecule, but it can be shifted by three nucleotide pairs from the phasing of A and B. This shift results in rotating it about 102°, nearly perpendicular to the array. This rotated molecule. called **C′**, can be fit into the gaps in the lattice that **D** does not fill. This arrangement provides a robust way of extending helices out of the A–B plane.[31]

In Fig. 6d, a different kind of array is illustrated—one made of DNA parallelograms. The single branch does not assume the conformation shown in Fig. 1 but rather folds, as illustrated in Figs. 6d.1 and 6d.2, to produce two stacking domains with an angle of about 60° between them. This angle is flexible, but when four of these junctions are assembled into a parallelogram. the angle focuses to its most favored value. These parallelograms yield an array containing cavities with sizes that can be tuned by design.[32]

ALGORITHMIC ARRAYS

The arrays described in the last section are all periodic arrays. Winfree suggested[9] that DNA molecules can be assembled in arrays based on algorithms more complex than simple periodicity. Thus, in principle, the self-assembly of DNA tiles can be used to generate complex arrangements, without using a unique tile for every component of the asyininetric unit. A preliminary test of this notion has been executed,[10] in which a one-dimensional cumulative exclusive OR (XOR) calculation was performed over four steps with high accuracy.

DNA NANOMECHANICAL DEVICES

DNA is not a static molecule. During its life cycle in the cell. it undergoes pairing, unpairing, cleavage. ligation. topoisomerization, branch migration, and changes of double helical structure. Hence. it seems reasonable to try to use DNA as the basis for nanomechanical systems. as well as fixed structural systems. The minimal mechanical device is a inolecule with a structure that switches between two alternatives in response to an external signal. Four such devices have been described to date. In the first, somewhat unwieldly system, the dimensions of a DNA cruciform were altered via branch migration, caused by the addition of ethidium to the solution.[33] Fhe first two-state device with a well defined structure is predicted on the B-Z transition of DNA.[34] Conventional DNA, known as B-DNA, is a right-handed molecule. However. there is another structure of DNA that is radically different from DNA, known as Z-DNA.[24] Z-DNA is a left-handed double helix. but it is not the mirror image of B-DNA. because it is also composed of sugars in the D-configuration. Two conditions must be met to obtain the Z-DNA structure: first is a sequence (called a proto-Z sequence) that can be converted from B-DNA to Z-DNA: the second is a solution environment that will promote the B → Z transition. The best-known of the proto-Z sequences contains alternating C and G [$(dCdG)_n$]. High ionic strength. and effectors such as $Co(NH_3)_6Cl_3$, can promote the B-Z transition.[24] The sequence requirement can be used to delimit the B-Z transition in space, and the environmental requirement can be used to delimit it in time. The device consists of two DAO molecules joined by a double-helical shaft that contains 20 nucleotide pairs capable of undergoing the B-Z transition. The operation of the B-Z device is illustrated in Fig. 7a.

Despite their appeal. the problem with both of the devices described above is that they are activated by small molecules. To approach nanorobotics succesfully. one needs many different devices incorporated into a larger matrix, such as the 2D arrays described above. However, both the cruciform and the B-Z devices are activated by small molecules. so that the action of these effectors could not be targeted easily to a specific device within the assay. Given the informational nature of DNA, it seems that sequence-dependent devices should be developed to fulfill this purpose. Two such devices have been developed, both based on the same principle of activation by strand addition and strand removal. This approach was pioneered by Yurke et al.[35] who developed molecular tweezers that were closed by adding a strand of DNA. The strand contained an unpaired segment and could be removed from the tweezers by the addition of its full complement; removal of the strand resulted in the tweezers relaxing to their open state.

A robust rotary device based on this principle has been developed using a new DNA motif, PX DNA, and one of its variants. JX_2 DNA. PX DNA consists of two parallel double helices, wherein crossovers occur at all possible sites:[36] two crossovers are absent in the JX_2 molecule.

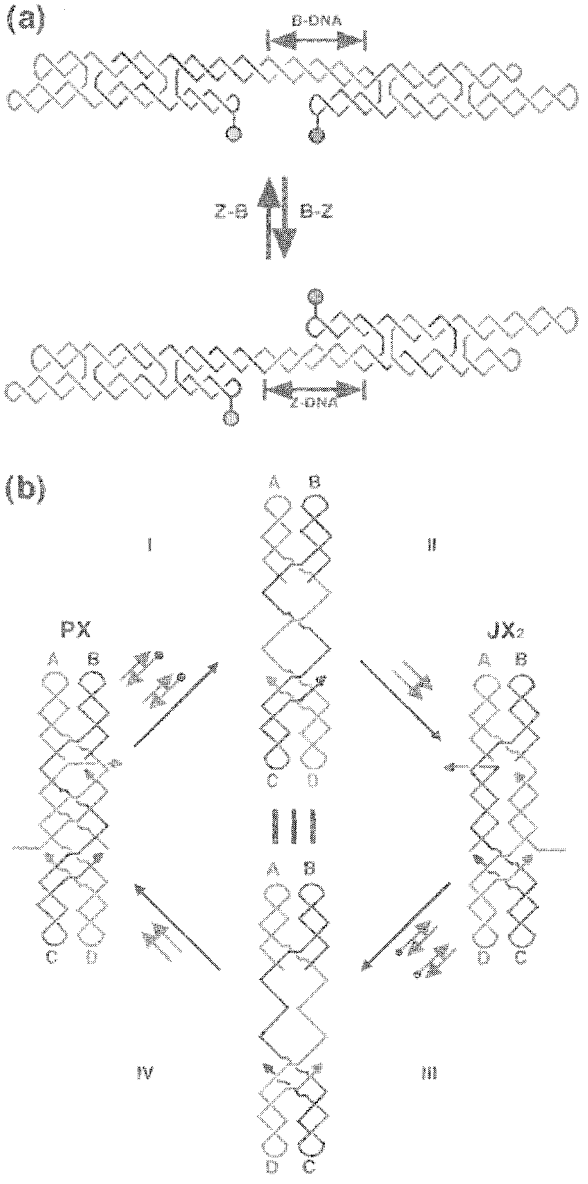

Fig. 7 DNA nanomechanical devices. (a) A device based on the B-Z transition. The device consists of two DNA DX molecules (DAO motif) connected by 4.5 turns of DNA between the nearest crossover points. The upper portion of the drawing illustrates the molecule constructed entirely from right-handed B-DNA. Fluorescent dyes are drawn schematically as filled (fluorescein) and unfilled (Cy3) circles attached to the free hairpins near the middle of the molecule. When this transition occurs. the two double crossover molecules change their relative positions. increasing the separation of the dyes. (b) A sequence-dependent device. This device uses two motifs. PX and JX_2. The labels A. B, C. and D on both show that there is a 180° difference between their total wrapping. There are two thick strands at the center of the PX motif. and two thin strands at the center of the JX_2 motif; in addition to the parts pairing to the larger motifs, each has an unpaired segment. These strands can be removed and inserted by the addition of their total cornplements (including the segments unpaired in the larger motifs) to the solution: these complements are shown in the processes I and III as strands with black dots (representing biotins) on their ends. Starting with the PX. one can add the complements strands (process I). to produce an unstructured intermediate. Adding the set strands in process II leads to the JX_2 structure. Removing them (III) and adding the PX set strands (IV) completes the machine cycle.

leading to a 180° rotation. These two motifs and the machine cycle are shown in Fig. 7b. The short strands at the centers of the PX and JX_2 molecules are set strands that set the state of the device. Starting from the PX device on the left, the addition of the complements to the set strands extracts them from the molecule, leading to an ill-defined intermediate at the top. The addition of the other set of strands puts the device in the JX_2 state, and return to PX is also available through the intermediate shown on the bottom. Many different groups of sequences can be used in the set strand regions. leading to many devices, all of which can be addressed individually.[36]

CONCLUSION

The experimental results described above augur well for the use of DNA self-assembly to produce structural targets on the nanometer scale. The resolution of control in this system is about an order of magnitude above the atomic scale; however, this is the scale on which the cell builds its structural components, and it is likely to be appropriate for biological goals, Among the challenges for DNA nanotechnology are to extend 2D periodic arrays to 3D. to extend algorithmic assembly to 2D and 3D systems, and to incorporate sequence-dependent DNA devices into those arrays. Although difficult. none of these goals seems to require chemistry beyond that already known for these systems. At some point. DNA must incorporate heterologous materials into the arrays, either biological macromolecular structures or nanoelectronic components. This incorporation will require further advances in the chemistry of these systems. DNA constructs appear potentially capable of self-replication, although the difficulties of combining branched systems with DNA polymerase are not likely to be simple.[37] Ultimately, DNA nanotechnology must advance from the biokleptic to the biomimetic, and from there to the abiological. This progression is likely to take some time, but the field appears to be gathering momentum, so the prospects are promising.

Drug Delivery

Saad A. M. Ali
Smith & Nephew Group Research Centre, York, United Kingdom

INTRODUCTION

The modes in which chemicals or drugs are administered have gained increasing attention in the past two decades. Normally, a *chemical is administered in a high dose at a given tiine only to have to repeat that dose several hours or days later. This is not economical and sometimes* results *in damaging side effects. As a consequence, increasing attention has been focused on* methods *of giving drugs continually for prolonged time periods and in a controlled manner. The primary method of accomplishing this controlled release has been through incorporating the chemicals within polymers. This technology now extends across many fields and includes pharmaceutical, food and* agricultural *applications, pesticides, cosmetics, and household products. In the pharmaceutical field; in addition to the importance of polymers, an understanding of the physiological barriers in the human body is also critical to developing appropriate* controlled-*release systems. The skin. the gastrointestinal tract, the lung, the nose, and the eye are of particular importance. Recent advances in genetic engineering produced numerous new polypeptide agents. Novel approaches for delivering and stabilizing these therapeutic molecules are being developed.*

BACKGROUND

Drug research has evolved and matured through several phases, beginning with the botanical phase of early human *civilization. through to the synthetic chemistry age in the middle of* the *20th century, and finally the biotechnology era* at *the dawn of the* 21st *century. Rapid developments in* molecular *biology, immunology, genetics. biochemistry, and information technology have converged and culminated* in *the deciphering of the human genome. Functional genomics and proteomics are likely to expand the therapeutic agents to incredible levels. once the gene–protein and protein–protein relationships are firmly established for the 5000–10.000 drug targets expected from the human genome map. In tandem. drug delivery has also progressed from conventional pills* to sustained/controlled *release and sophisticated* programmable *delivery systems. Meanwhile,* drug *delivery has also become more specific from* systemic *to organ and cellular targeting.*

Drug *discovery and development has* undergone *a paradigm shift from serendipity to a more rational approach. However, drug discovery remains a costly (US $400–650 million), time-consuming (10–15 years). and risky* process.[1] *As a consequence. new drug delivery systems have been developed at 20% of the cost and in half the time, which allows pharmaceutical companies to maximize the return on their investment, giving second life to old drugs, with better efficacy and patient* compliance.[2]

Since the formation of the pioneering companies in this area, Alza Corporation (U.S.A.) and Elan Corporation (Ireland), in the 1960s. more than 350 drug delivery and 1000 medical *device companies have come into existence, with worldwide drug delivery sales of US $22 billion.''' At the present rate of growth, the drug delivery market is expected to* comprise *20% of the total pharmaceutical market by* 2005.[2]

Novel drug delivery systems evolved over a period of time *to* improve *patient compliance and optimize the dosage regimen without* compromising *the therapeutic efficacy. The foundations were laid in 1952, with the introduction of the first sustained-release capsule of* Dexedrine.[4] Subsequently, *several concepts originated. including prolonged, timed, and extended release: and finally matured to controlled-release systems.*

MODES OF DELIVERY

Drug delivery covers a wide range of techniques used to deliver therapeutic agents into the human body. Many limitations have been recognized for the most widely used drug delivery techniques, those of the ingested tablet and *of the* intravenous/subcutaneous/intramuscular *injections. The ingested tablet delivers the drug into the blood only through the hepatic system. and hence; the amount in the bloodstream* may *be* much *lower than the amount formulated into the tablet, which results* in *low* bioavail-*ability;* furthermore, *liver damage is a side effect of many soluble tableted drugs. The injection mode of delivery can be used to deliver any size of drug molecules and* is *versatile in this regard, but it suffers from the disadvantages*

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012797

of being invasive and painful and the shortness of duration of residence for drugs with short half-lives.

To address some of these limitations. other modes of delivery of drugs into the body were investigated in the early 1970s. Transdermal (through the intact skin), transmucosal (through the intact mucosa of the mouth, intestine, rectum. vagina, or nose), transocular (through the eye), transalveolar (inhalation, through lung tissue). implantable (subcutaneous and deeper implants, delivery into surrounding tissue). and injectable (intramuscular or subcutaneous) modes of delivery have been investigated extensively over the last 30 years, with varying degrees of commercial and therapeutic success.

Two other modes of injectable drug delivery are receiving increased attention. One focuses on the use of nanoparticles for delivering DNA or genes to cells for transfection. These particles have the unique ability to be taken up by targeted cells via various transcellular entry mechanisms. Another mode is needleless (and hence, painless) injectables. which are being explored.

The common features underlying these delivery modes are increased therapeutic efficiency and increased patient compliance.

FORMULATION REQUIREMENTS

The polymeric component of the delivery device is required to perform a set of functions in order to address some of the shortcomings of the most widely used forms of drug delivery. i.e., oral tablets and intravenous injections. The most important shortcomings are the duration of action and its relationship to the controlled release needed to achieve the desired plasma profile for the drug. In addition, the alternative delivery system must be acceptable to the patient (noninvasive) and must increase the level of patient compliance. Thus, the polymeric component is required, in these alternative drug delivery approaches. to extend and control the release of the drug into the bloodstream via various portals of entry (skin, oral mucosa, etc.). The primary role of the polymer is diffusional control of active agents, and the secondary role is disintegration or dissolution control of the dosage form employed.

ORAL DELIVERY

Among all routes of administration, the oral route has been most widely used and successful. This is. in part, because of the inherent simplicity of the oral route and oral delivery systems. On the other hand. the oral route is constrained by short and variable gastrointestinal tract and the size of the system.

Dissolution-Controlled Release

Dissolution-controlled release can be achieved by slowing the dissolution rate of a drug in the gastrointestinal medium, incorporating the drug in an insoluble polymer, and coating drug particles or granules with polymeric materials of varying thicknesses. The rate-limiting step for dissolution of a drug is the diffusion across an aqueous boundary layer. The solubility of the drug provides the source of energy for drug release, which is countered by the stagnant-fluid diffusional boundary layer.

Drug delivery using rate of dissolution as a controlled release mechanism can be achieved by encapsulation of a drug-polymer matrix with a relatively insoluble polymeric membrane. The coated beads can be compressed into tablets or capsulated, as was done with the Spansule® products.[5] Because the time required for the membrane coat to dissolve is a function of membrane thickness, granules with varying thicknesses can be employed to achieve sustained release of the drug. Examples of drugs delivered in this manner include antispasmodic-sedative combinations,[6] phenothiazines,[7,8] and anticholinesterase agents.[9]

One of the most common approaches used to achieve sustained release is to incorporate a drug in a hydrophobic matrix, such as wax, polyethylene, polypropylene. and ethylcellulose. or in a hydrophilic matrix, such as hydroxypropylcellulose. hydroxypropylmethylcellulose, methylcellulose. and sodium carboxymethylcellulose. The rate of drug release is controlled by the rate of penetration of the dissolution fluid into the matrix.

Diffusion-Controlled Release

Diffusion of a drug molecule through a polymeric membrane forms the basis of these controlled drug delivery systems. Similar to the dissolution-controlled systems, the diffusion-controlled devices are manufactured by encapsulating the drug particle in a polymeric membrane or by dispersing the drug in a polymeric matrix. Unlike the dissolution-controlled systems, the drug is made available as a result of partitioning through the polymer.

Another configuration of diffusion-controlled systems includes matrix devices, which are common because of ease of fabrication. Diffusion control involves dispersion of drug in either a water-insoluble or a hydrophilic polymer.[10–13] For instance, bupropion hydrochloride (Zyban®, GlaxoSmithKline) is formulated using carnuba wax and hydroxypropylmethylcellulose.[13]

Osmotically-Controlled Release

Theeuwes et al.[14] developed an elementary osmotic pump to achieve controlled drug delivery. The delivery of

the drug from the system is controlled by solvent influx across a semipermeable membrane. which in turn carries the drug outside through a laser-drilled orifice. The osmotic and hydrostatic pressure differences on either side of the semipermeable membrane govern fluid transport into the system.

Oral controlled-release forms generally involve either dispersing the drug into a polymeric matrix or encapsulating the drug containing core or granules with a rate-controlling membrane. Several techniques, such as wet granulation. spray drying, or spray congealing, are being used in the manufacture of oral controlled-release products.[15]

Despite great strides in the development of successful commercial oral novel drug delivery systems for small molecules, delivery of macromolecules is still a remote goal. Nevertheless, there are a number of emerging approaches[16] to deliver macromolecules, which include stabilizing the macromolecules in the harsh environment of the gastrointestinal tract (GIT) and increasing the membrane permeability, either by using of sorption promoters or exploiting natural carrier systems in the GIT.[17,18] A promising strategy from Emisphere Technologies Inc. uses small synthetic molecules, consisting of both α and non-α amino acids capable of interacting reversibly with macromolecules and facilitating their membrane permeability.[19] Various prodrugs of peptides and proteins have been explored to improve the proteolytic stability as well as membrane permeability.[18] Efforts are also focused on oral gene delivery for both systemic and local action; however, there are several critical issues that need to be addressed to improve their bioavailabilities.[20]

NASAL DELIVERY

Of all the mucosal, nasal mucosa is considered to be the most permeable, offering tremendous scope for peptide delivery, particularly for vaccines (90% of pathogens invade via mucosa).[21,22] Already, several peptide formulations are on the market. and further developments will depend on clarifying the immunogenicity of bioactive agents on the nasal mucosa and the long-term effect of enhancers on the nasal mucociliary activity.

PULMONARY DELIVERY

The lung also offers an exciting opportunity for systemic delivery because of the enormous surface area and rich blood supply.[23] However, the major limitations are high-dose requirements and low efficiency of deposition on alveolar surfaces. Although it is possible to design aerosol particles of desired characteristics using supercritical fluid technology,[24] improved aerosol design awaits further progress. Unlike the pressurized metered dose inhalers. new dry powder inhalers are breath-activated, deriving the energy from the patient's inhalation.[25] However, the real commercial feasibility of the pulmonary route for macromolecules will only be realized when inhaled insulin reaches the market.

TRANSDERMAL DELIVERY

Because of significant obstacles posed by the oral route. focus has shifted to alternative routes of administration, of which the transdermal route has generated much interest, beginning with the introduction of the scopolamine patch in 1983. Since then, only eight drugs have been commercialized, with a market share of US $2 billion, indicating that drug delivery through the skin is also far from easy.[26] Chemical and physical enhancement techniques (iontophoresis. electroporation, sonophoresis, and high-speed powdered delivery) are under active investigation to expand the scope of drugs (in terms of size, lipophilicity, and charge) that can be delivered through the skin.[27] Iontophoresis, which uses a small electric current, offers promise for delivery of small peptides, but there are several developmental and skin-safety considerations that need to be resolved before reaching a stage of commercialization.[28] Newer approaches involving a synergistic combination of the above-mentioned enhancement techniques are evolving to deliver very large proteins, while at the same time overcoming the skin-toxicity issues.[29]

There are two designs in transdermal systems: membrane-controlled systems and matrix systems.[30] A brief discussion of the features of each is given below.

Membrane-Controlled Systems

This design consists of three major components: the drug reservoir. the rate-controlling membrane, and the adhesive. The drug permeates the membrane and the adhesive to reach the skin. The drug reservoir contains a solution of the drug and liquid excipients. One excipient used is an enhancer that permeates the layers to the skin, where it exerts its enhancing effects by modulating the skin permeability.

Matrix Systems

In this design, the adhesive performs the role of the drug reservoir. The drug and excipients are formulated into the adhesive, typically into adhesive solution, and the solvent is evaporated to yield the matrix film. The matrix-adhesive film is then laminated to a backing film.

The main factors limiting the progress of transdermal technology are the ability to push small molecules through the skin faster and the problems associated with sensitization from certain drug classes. Advancement will occur through the development of new enhancers. Co-administration of immune suppressants or modification of drug structure to an immunologically inert form may be required to address the issue of sensitization.

IMPLANTABLE DELIVERY SYSTEMS

Implantable drug delivery systems are defined as long-term (>30 days) implantable products that are resorbable or removable. The resorbable implants are injectables incorporating lyophilized microspheres. The removable version is typically a subcutaneous implant, requiring minor outpatient procedures for insertion and removal. The main commercialized product in this category is Norplant®, a contraceptive implant. Medtronic Corporation has two products in the implantable area that allow drug delivery into the intrathecal space (where the spinal fluid circulates). One of these products delivers baclofen for spasticity, and the other delivers anaesthetics for pain control. Both products utilize Medtronic's SynchroMed® infusion pump, which can be electronically programmed to deliver any type of preset dose.

MICROPARTICLE AND NANOPARTICLE DELIVERY SYSTEMS

Microparticles and nanoparticles incorporate drug in matrix or encapsulated form, delivered to the body via injection (intramuscular; intravenous. or subcutaneous), via the oral cavity or via the nose. For nasal or oral delivery. the particles are typically in the 20–100 μm size range, because smaller particles can be inhaled and may make their way to the lung for alveolar delivery. For injectable delivery, to achieve prolonged duration of effect, the particles tend to be in the 50–100 μm range. Nanoparticles are classified as having diameters below I μm and tend to be used specifically for targeted delivery, usually via the injectable route.

SYSTEMIC AND LOCAL DELIVERY

Parenteral administration (injection). which is the immediate option for orally undeliverable drugs. has advanced greatly in recent years for systemic and local drug delivery.[31] The novel drug delivery system has metamorphosed from simple polymer and antibody conjugates to sterically stabilized colloidal systems. Liposomes and nanoparticles can improve pharmacokinetic-pharmacodynamic profiles of antibiotics (e.g., aminoglycosides and fluoroquinolones) and antifungal agents with enhanced intracellular accumulation and activity against dormant forms.[32]

Now, it is possible to deliver antineoplastic agents, toxins, proteins and peptides, and antisense oligonucleotides by conjugating to polymers such as polyethylene glycol or hydroxypropyl methacrylate, or by entrapping them in colloidal carriers leading to a decrease in the clearance of drugs and offering protection against hostile plasma constituents. This passive targeting of antineoplastic agents to tumors is based on the leaky vasculature hydrodynamics and enhanced permeation and retention effect. On the basis of this principle, styrene maleic acid neocarzinostatin, a polymer conjugate, has been approved for the treatment of primary hepatoma.[33] Further. to augment targeted therapy of tumors, cytotoxic agents and radioisotopes can be conjugated to antibodies.[34]

Local delivery for cancer therapy is accomplished using biodegradable polymeric systems or infusion pumps, where the drug is distributed throughout the tumor by passive diffusion, leading to increased drug levels at the tumor site and thereby minimizing systemic burden.[35] FeRx Corporation is developing magnetic-targeted systems, which make use of elemental iron magnets with drug adsorbed to the surface of carriers. These carriers that localize within tumors because of the applied magnetic field are being developed for the treatment of metastatic liver cancer.[36] Delivery of drugs for treatment of central nervous system (CNS) disorders is challenging because of the significant barriers posed by the blood-brain barrier (BBB) and the blood cerebrospinal fluid barrier.[37] Drug delivery to the brain has been attempted by targeting drug-and growth-factor-conjugates/liposomal formulations to specific transporters in the BBB. The discovery of cell-penetrating peptides (penetratin, transportan) has opened the scope for cellular delivery of drugs and macromolecules across the BBB and other biological membranes.[38] Chemical approaches using retro-metabolic design (soft drug-and chemical-delivery systems) offer the promise of targeting drugs to the brain.[39] Gene therapy using viral (retrovirus and adenoviruses) and nonviral (cationic liposomes and DNA-ligand complexes) vectors is gaining momentum for the transfer of genetic information to target cells; enabling them to synthesize the protein encoded by the gene.[40]

SUPRAMOLECULAR STRUCTURES

Micelles self-assembled from amphiphilic block copolymers have attracted interest because of their ability to solubilize hydrophobic molecules in water.[41,42] Interest is particularly keen in the context of drug solubilization,

where many existing drugs and many new ones coming out of drug discovery lack water solubility. Efforts focused on the synthesis of micelle-forming block copolymers that can be safely administered to humans and that can adequately solubilize drugs.[43]

Nanocapsules for controlled drug delivery are being developed using supramolecular structures. These capsules are made from polyelectrolyte multilayers and are produced using a patented process called layer-by-layer deposition.[44] The building blocks are naturaily occurring charged polymers. such as pectins. gelatins, polyglutamic acid. chitosan, and hyaluronic acid. These are adsorbed around the drug particle in alternating layers of oppositely charged material. The supramolecular structure is held together electrostatically through the formation of complexes between the polycations and polyanions. The resulting capsules have a wall thickness of 10–40 nm and range from 20 nm–20 mm in diameter, with the exact size controlled via the production process. Their physical, chemical, and pharmacokinetic properties can be manipulated as required by varying the polymers used and incorporating other materials into the layer structure, including lipids, nanoparticles. and biological molecules. such as ligands or receptors. Drug particles can be carried in the lumen of the capsule or incorporated into the wall layers.

FUTURE PROSPECTS

One of the most recent developments is the use of microchips as controlled drug delivery devices.[''' This novel technology is based on tiny silicon or polymeric chips containing hundreds or thousands of microreservoirs, each of which can be filled with any combination of bioactive agents. In this way. complex release patterns can be achieved with programmed microprocessors.

CONCLUSION

Novel delivery strategies have begun to diversify outside the realm of mere drug delivery to tissue engineering and diagnostics. In tissue engineering, controlled-release concepts are being applied for the delivery of growth factors to nurture the cells encapsulated in biocompatible polymers so as to expedite tissue regeneration.[46] Diagnostic application can be exeinplified by the recent premarket approval granted by the U.S. Food and Drug Administration (US FDA) for a blood-glucose-monitoring device (Glucowatch™) that can extract glucose through skin using reverse iontophoresis coupled to an enzyme-based detection system.

INTRODUCTION

Computer-aided drug design is playing an increasing role in the development of pharmaceuticals. *Computers can now be used in* many *ways to aid the design of therapeutic drugs. Molecular graphics software running on powerful workstations can draw useful qualitative insights from the experimental structure of a receptor and its complex with ligands. Rapid advances in computer technology and computational chemistry facilitated the generation of quantitative data to help sort promising drug leads from real and virtual chemical libraries and to aid in rational drug design. These methods range from rigid structural models* employing simple *but easy-to-compute scoring functions to flexible structural models with sophisticated descriptions of intra- and intermolecular interactions. Structural predictions* programs *were developed to provide structural models of receptors when experimental structure is not yet available. Alternatively, useful insights into drug design can be obtained by conducting comparative analyses of a* number *of inhibitors that are known to bind to* a *receptor. This ligand-based approach can be used without knowledge of the three-dimensional structure of the receptor. Each approach has its pros and cons. and effective computer-aided drug design usually utilizes a* number *of methods. Mere, we give a* glimpse *of some of these approaches* with *a short selected list of references that aids interested readers in* further *exploring the subject.*

MOLECULAR MODELING

For a long time, *chemists learned and predicted the properties of molecules based on their structures. This has now gone beyond two* dimensions *to three and more, as the physical and* chemical *properties of a molecule obviously depend on how different* functional *groups of the molecule are presented in three-dimensional* (3D) *space at different* conformations. *These properties will; in turn, determine* whether *a* small *molecule binds favorably* to *a receptor and whether* the *molecule possesses drug-like characteristics. Molecular graphics help a drug designer visualize the three-dimensional structure of a receptor so that useful insight can be gained into what* molecules *may fit into a suitable pocket of the receptor so as to modulate its activity and achieve therapeutic effects. The receptor can be rendered in a variety of ways to aid in drug design. For example, molecular surfaces can be displayed to provide ideas of the shapes and sizes of different pockets. In addition, the surface can be colored according to the electrostatic potential to suggest where positively charged, negatively charged, and nonpolar groups of an inhibitor may fit into the receptor. Fast computers made it feasible to quickly obtain the electrostatic potentials surrounding a receptor by solving the Poisson–Boltzmann equation, taking into account the detailed shape of the* receptor,[1,2] *and to display the resulting potentials in high resolution. In Fig.* 1, *an* example *of the electrostatic potential calculated on the van der Waal surface of protein kinase* A *using the APBS program is given.''* Small *molecules can be displayed simultaneously and manually* docked *to different sites of a receptor, interactively. Molecular graphics also allows one to overlay structures of* similar *proteins on a graphics screen to facilitate comparison. Such visualization can provide useful insight into designing inhibitors that are selective toward the intended targets. A molecular editor embedded within a graphics* program *can be used to edit the inhibitor in a* receptor–*inhibitor complex to examine what modifications may be profitable in order to enhance interactions with the receptor. Based on the structural features of a binding pocket, one can also design three-dimensional* pharmaco*phore models*[i4,] *to help mine drug candidates from chemical libraries.*

Pharmacophore Model

A 3D *pharmacophore model contains features. arranged in 3D space, with which a* molecule *can act on a drug* target.[4] *These features include hydrogen-bond donors. hydrogen-bond acceptors, hydrophobic groups, and charged moieties. Knowing the structure of a suitable binding pocket of a receptor can generate such a pharmacophore* model *by putting suitable features near complementary groups on the receptor. One can then search a chemical database, which can be a virtual database containing cornpounds that have not yet been made, to find real or virtual molecules that match the*

pharmacophore model and therefore may be active toward the desired receptor. Usually, many conformations of each compound in a library need to be generated and examined for fit to a pharmacophore model. Modern computing power can now permit thousands of compounds to be screened within hours. Higher-quality pharmacophore models can be constructed when the crystal structure of the complex of a receptor with one of its ligands was determined, as the coordinates of the ligand can provide a precise definition of the features of a pharmacophore. However, the interplay among many factors can sometimes complicate the development of pharmacophore models relying on visual inspection of crystal structures. For example, the mere presence of a functional group in the ligand in the vicinity of an apparently complementary group does not necessarily imply that these groups interact to enhance binding. This is partly because the binding of a ligand to a receptor is accompanied by the desolvation of ligand functional groups and receptor residues. For example, it is not obvious whether the formation of an intermolecular hydrogen bond upon complex formation can overcome the penalty associated with the desolvation of the hydrogen-bond donor and acceptor before the complex is formed. Quantitative calculations can remove these ambiguities. For example, one can calculate the binding free energy using a suitable computational model (some are discussed below) and knock out parameters of different functional groups of the ligand to examine whether they affect binding.[4,5] The truly significant functional groups can then be selected to construct a pharmacophore model. Quantitative calculations also allow one to quantify the relative significance of different pharmacophoric features and assign them different weights in mining chemical databases. Methods that dock simple molecules to a receptor can also aid the placement of different features of a pharmacophore. For example, Monte Carlo docking of methanol molecules to HIV integrase revealed possible sites for placing hydrogen-bond donors.[7]

Structure and Ligand-Based Models

When the structure of a receptor has not yet been determined experimentally, structural modeling of receptors and ligand-based approaches can be used. If a protein has a similar amino acid sequence as one previously determined, homology modeling can be carried out to construct a structural model for the target protein from the known structures. Here, one usually starts with a sequence alignment of the target protein with the proteins with structures that were determined. This will direct how the sequence of the target protein will be threaded into a template structure. The backbone coordinates are usually built first by simply taking the corresponding coordinates from a known structure. When more than one template is available, a structural alignment of the known structures can first be done to get an idea of which parts of the proteins are structurally conserved. These parts do not vary significantly from one template structure to another and the target protein is likely to have similar structure in

these regions. These portions of the structural model can be constructed most reliably. The other parts of the backbone, loosely called the loops, can then be built. If the sequence of a loop of the target is similar to one or more of the templates, one may use the template coordinates to build the structure of the loops. If the sequence of the loop is different from the ones in the templates, two approaches are commonly used. One is a database approach in which one searches from a structural database of proteins for loops with N and C termini that have similar local structures as the anchoring points in the corresponding structural conserved regions. Those loops that also have high sequence similarity to the loop of the target can then be used to build models for the loop if they do not overlap with the backbone coordinates that were already built. Another approach is to carry out conformational samplings that give low-energy structures. The energy is calculated based on models similar to those described below. A side chain can be built by taking coordinates from the templates, if they contain similar amino acids. If the side chain contains groups that cannot be built from the templates. a structure from a rotamer library can be tried. Energy refinement can then be carried out to further improve the model. Different algorithms may work somewhat differently. But the above descriptions summarize some key features of homology modeling. Swiss-Model[8] is an example of a Web-accessible resource that helps researchers build homology models.

Homology modeling only works when the target sequence is more than about 30% homologous to proteins in a structural database. When it is difficult to find proteins with significant sequence identity with the target, one can use methods such as threading. In a threading experiment, one threads the sequence of the target into template structures in a structural database, and a scoring function is used to help determine which threaded structures are more likely. A scoring function can be derived from a database approach in which residue–pair interaction potentials. for example, are determined by their probability of being observed in the database. Empirical force fields (described below) commonly used in molecular simulations can also be used. Once a structural model of the receptor is determined, pharmacophore models can be constructed using methods such as those described above. A recent article[9] gives an overview of several structural prediction methods.

Another way to construct pharmacophore models when the structure of a receptor is not known is to use a ligand-based approach. Here, one does not try to predict the structure of the receptor but focuses on analyzing similar and dissimilar features among a number of ligands that are known to act on a receptor. A long-used qualitative method is to simply draw the structure of a number of inhibitors along with their measured activity levels. Common features shared among them are likely important for their activities. Such a qualitative study of the structure–activity relationship (SAR) can be quantified with mathematical models. For example, one can express the activity of a number of bioactive compounds in terms of a set of descriptors:

$$activity = A[\log(P_{o/w})] + B[\log(P_{o/w})]^2 + C\sigma + DS + \ldots \quad (1)$$
