For a nuclear spin of **I**, there are $21+1$ levels in total, and the way in which these are arranged depends on whether **I** is half-integral or integral. By far the majority of quadrupolar nuclei have half-integral spin, in which case. the energy levels occur in $\mathbf{I} + {}^1/_2$ sets of degenerate pairs. irrespective of the value of η. For $I = 3/2$, for example. as in ^{35}Cl or ^{79}Br, two degenerate levels are obtained (as in Fig. 1a), and just one transition is observed of frequency:

$$\nu_Q = 1/2\ (e^2qQ/h)(1 + \eta^2/3)^{\frac{1}{2}} \quad (6)$$

according to the selection rule $\Delta m_I = \pm 1$, where m_I is the nuclear magnetic quantum number. It is customary to classify the two levels in terms of the two sets of degenerate values of m_I, namely, $\pm {}^1/_2$ and $\pm 3/2$. but strictly speaking, this distinction is only correct when $\eta = 0$. When this is not the case. the eigenfunctions of $_Q$ are linear combinations of $|+{}^1/_2\rangle$ with $|-3/2\rangle$ and $|-{}^1/_2\rangle$ with $|+3/2\rangle$, which are mixed because of the last term on the right-hand side of Eq. 5. For $I = 3/2$, the quadrupole coupling constant cannot, therefore, be derived unless η is

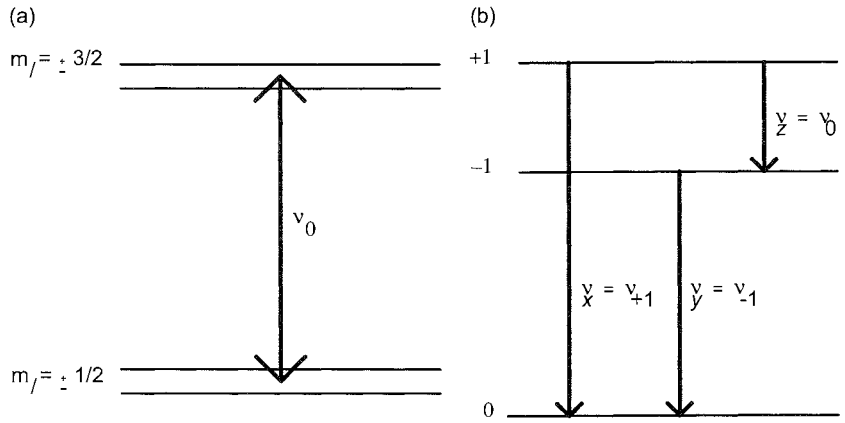

Fig. 1 Quadrupolar energy levels for (a) $I=3/2$ and (b) $I=1$.

known: the latter, however. can be obtained by experiments in weak magnetic fields or by quadrupole nutation spectroscopy.[4] For higher half-integral values of I, three or more sets of degenerate energy levels are obtained, and the existence of two or more allowed transitions following the selection rule $\Delta m_I=\pm 1$ means that values of the quadrupole coupling constant and asymmetry parameter can be separately derived by direct solution of the secular equation or by the use of tables listing frequency ratios as a function of η. In fact. because of the admixture of states when η is nonzero, transitions following the selection rule $\Delta m_I=\pm 2$ can also be weakly observed. In all cases. however, the sign of the quadrupole coupling constant is not usually derived. because changing its sign simply inverts the order of the energy levels. The sign can be obtained if other couplings of known sign, such as dipolar interactions. are present in the spectrum; alternatively, one can work at low temperatures [e.g., 100 μK for ^{45}Sc ($I=7/2$) in scandium metal],[5] when the substantial differences in populations cause deviations in the intensity ratios of adjacent transitions. For these higher-spin nuclei, when η is zero, the higher frequencies are all harmonics of the lowest, $\pm 1/2 \rightarrow \pm 312$. which equals 3/20 ($e^2qQ/h$) for spin 512, 1/14 ($e^2qQ/h$) for 712. and 1124 ($e^2qQ/h$) for 912. Thus, in $[Co(C_5H_5)_2]^+ ClO_4^-$ at room temperature. the three ^{59}Co frequencies expected for a spin −712 nucleus are detected near 12, 24. and 36 MHz, showing that the cobalticinium ion has axial symmetry and that the ^{59}Co quadrupole coupling constant is close to 170 MHz.

The situation is simpler for integral-spin nuclei, for which the degeneracy of the $2I+1$ levels is always resolved, except when η is zero. Typical examples are the spin-1 nuclei ^{2}H and ^{14}N, which in the general case, have three observed transitions. as in Fig. 1b, one of which is the sum of the other two, facilitating assignments when all three can be observed. The quadrupole coupling constant and asymmetry parameter can be separately determined from any pair of the three transitions. correctly assigned. from the following equations:

$$\begin{aligned} \nu_x &= \nu_+ = 3/4\ (e^2qQ/h)(1 + \eta/3) \\ \nu_y &= \nu_- = 3/4\ (e^2qQ/h)(1 - \eta/3) \\ \nu_z &= \nu_0 = 1/2\eta(e^2qQ/h) \end{aligned} \tag{7}$$

Many of the comments in the previous sections apply equally to single crystals as to polycrystalline samples, hut the advantage of the former is that they also allow the direction cosines of the quadrupole tensor to be determined. For spin-312 nuclei, such as ^{35}Cl or ^{79}Br, a weak magnetic field. B_0, is usually needed, which splits the $\pm 1/2$ and $\pm 3/2$ levels in Fig. 1 into a doublet and a quadruplet. respectively. Four transitions are now observed, symmetrically located about the original resonance frequency, the inner pair labeled α and the outer β. Their splitting varies with the orientation of the crystal with respect to B_0; the locus of zero splitting of the α doublet defines a geometric shape from which η and the direction cosines of V_{zz} and V_{xx} with respect to the crystal axes can be determined. Such measurements are relatively uncommon: the increasing use of high-field NMR spectrometers enables similar measurements to be made, often with a higher sensitivity and smaller single crystals. provided. of course. that the quadrupole splitting frequencies are considerably smaller than the NMK frequency.

EXPERIMENTAL METHODS

Experimentally, NQR measurements may be conducted on essentially the same instruments used for solid-state NMR, except that no static magnetic field is needed.

Unfortunately, the frequency range required is extremely large, stretching from less than 100 kHz or so for ^{2}H to 600 MHz or more for the high-frequency lines of heavy nuclei such as ^{127}I. A variety of RF probes has been designed to cover this range, from simple RF coils at low frequencies to butterfly capacitors and transmission lines up to and above 300 MHz. Because no static magnetic field is necessary, NQR experiments can be conducted with samples located inside much larger volumes of up to 600 liters or more, or in remote locations, tens of centimeters away from the RF antenna.[6] Most modern spectrometers use pulsed-RF techniques, which have the advantage of measuring relaxation times as well as frequencies. Whereas the latter give information on molecular structure and electron distribution, the former are an important source of information on molecular dynamics. Noise or stochastic excitation can also be used to observe spectra and has the advantage of requiring considerably smaller RF powers than conventional pulsed techniques used for solids.[7]

An advantage of pulse techniques is that they allow ready measurement of the quadrupole relaxation times, which are important in the investigation of molecular motion in solids. One useful quantity is the spin-lattice relaxation time. T_1, which as in NMR governs the time taken for the spin system to return to equilibrium following an RF pulse, and which can be measured, for example, by a pulsed steady-state sequence, in which a string of 90° RF pulses of variable spacing τ is applied to the sample, the signals being detected between pulses (the term 90° refers to that pulse width that generates the maximum signal). As τ is lengthened from values much less than T_1 to much longer, the recovered signal between pulses increases exponentially according to T_1, eventually reaching its equilibrium value.

The probes for pulsed RF spectrometers are usually difficult to tune over a sufficiently wide range to be suitable for searching for new resonances. Variable frequency continuous wave or superregenerative oscillator spectrometers are better adapted for this purpose, but they give little information on relaxation times. The same is true of NMR methods, which, however, may give problems when the solid to be studied contains several nonequivalent nuclei with different quadrupole parameters. Double-resonance techniques based on magnetic field cycling are also useful. provided the solid contains suitable magnetic nuclei, such as ^{1}H. with strong NMR signals.[8] However, if the structure of the solid is known, e.g., from x-ray or neutron diffraction, theoretical calculations can be employed to give a good estimate of the magnitudes and signs of the quadrupole parameters. Essentially, they are one-electron properties of the ground electronic state of the molecule; their significance can be understood from Fig. 2, which represents a volume

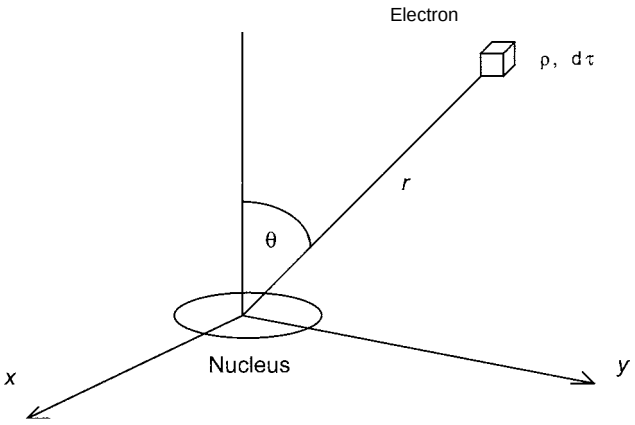

Fig. 2 A volume element, $d\tau$. of charge density p, distance r from the nucleus at the origin.

element $d\tau$ of the molecular charge density p (including sign) generating at the origin the electric potential:

$$V = \rho d\tau/\{(4\pi\varepsilon_0)r\} \tag{8}$$

where ε_0 is the vacuum permittivity, from which it is easy to show that

$$\partial V/\partial z = -\rho(4\pi\varepsilon_0)^{-1}(z/r^3)d\tau$$
$$= -\rho(4\pi\varepsilon_0)^{-1}(\cos\theta/r^2)d\tau$$

and

$$q_{zz} = \partial^2 V/\partial z^2 = \rho(4\pi\varepsilon_0)^{-1}(\{3\cos^2\theta - 1\}/r^3)d\tau \tag{9}$$

Separating out the nuclear charge contribution of nuclei at a distance R_i from the nucleus under study (which behave as point charges) and replacing ρ for the electrons by the product $\psi\psi^*$ gives the following equation for eq:

$$eq = V_{zz} = (4\pi\varepsilon_0)^{-1}\{-e\int \psi^*([3\cos^2\theta - 1]/r^3)\psi d\tau + \sum Z_i e([3\cos^2\theta_i - 1]/R_i^3)\} \tag{10}$$

To evaluate the first term on the right-hand side of Eq. 10 one needs good ground-state wave functions. for the second one needs the molecular geometry or crystal structure. Similar equations can be used to calculate the asymmetry parameter η from V_{xx} and V„. Modern, a priori, programs that include all electrons are now being used[9] and give quadrupole parameters that agree with experiment to better than 20%. They do not. however. always include corrections for vibrational and translational motions of the atoms and molecules in the solid state, which are largely responsible for the observed temperature variation of the quadrupole parameters.

There are several approximate methods often useful in understanding the trends in the quadrupole parameters in a related series of molecules containing the same quadrupolar nucleus. One. due to Townes and Dailey,[10] *is essentially a localized orbital approach. in which attention is focused on changes in the orbital populations of the atom containing the quadrupolar nucleus. and polarization of the core electrons (the so-called Sternheimer polarization factor) is assumed to vary negligibly from one molecule to another. In the case of* ^{14}N, *for example, the* $2p$ *electron distribution is the dominant factor; in a molecule such as* NH_3, *the lone pair is the major contributor, so that* q_{zz} *lies along the lone pair direction, the electronic term from Eq. 9 is negative. and because* Q *is positive (Table* I), *the quadrupole coupling constant is negative. Donation of the* N *lone pair, as in coordination to an electron acceptor, reduces the* $2p$ *lone-pair population* and *hence makes the quadrupole coupling constant less negative. Such a model, however. contains many approximations; it neglects, for example. changes in the H–N–H angle that may occur on coordination.*

APPLICATIONS

Almost all quadrupolar nuclei in the Periodic Table have been studied experimentally in one or more of their compounds. A *current list of these results is available in a database published by the JAICI (Japan Association for International Chemical Information, Tokyo, Japan). Biennial International Symposia on nuclear quadrupole interactions are also excellent sources of the latest experimental and theoretical works. As an illustration of the kind of solid-state problems that may be studied, we give some recent examples of such investigations. Sensitivity. or signal-to-noise ratio (SNR) in WQR spectroscopy, as well as NMR, depends on the observed frequency, which in turn, depends, inter alia, on the value of* Q. *The lighter* elements *tend to have low values of Q and low NQR frequencies and low sensitivities.* ^{2}H, *for example. a spin-1 nucleus, has NQR frequencies less than 200* kHz, *and most measurements are therefore* made *by high-field* NMR *methods. The* ^{14}N, *another spin-I nucleus, resonates from below 0.4 to 6 MHz, an intermediate region where both NQR and NMR methods are used. Because they are governed predominantly by electric interactions. NQR frequencies and relaxation times are sensitive to phase changes and the numbers of lines to changes in the crystal symmetry. For example,* ^{14}*N-NQR was used*[i''] *to study the inclusion compound of thiourea and carbon tetrachloride, which undergoes a second-order phase transition near 67 K, the low-temperature phase having three signals for the* ν_+ *transition from the host, whereas above 67 K, only a singlet is observed. Over a range of about* 1 *K, signals can be observed from both phases near 2.5 MHz.*

At higher frequencies of 40–41 MHz, ^{35}Cl-NQR *signals can be* observed[12] *in the guest molecules, which show two resonance lines with an intensity ratio of* 1:3, *indicating that they lie at sites of threefold symmetry in the channels of the host. Above 27 K, the* ^{35}Cl *lines disappear, due to gross reorientation of the* CCl_4 *molecules. The favorable sensitivity at these higher* radio-*frequencies has led to a number of notable experiments, including NQR imaging and two-dimensional (2D) exchange spectroscopy. In the* former,[13] *the experiments were conducted at* 116 MHz, *the* ^{75}As-NQR *frequency in arsenolite. and the imaging technique was based on the* use *of gradients in the RF* B_1 *field (rotating-frame* NQR *imaging). Two cylinders of this material of diameter 3.5 cm, and placed* 5.5 cm *apart, were easily resolved in two* dimensional *images. In the latter. the phrase "exchange" should be interpreted in a general sense, to include not only chemical exchange of atoms or groups but also molecular rearrangements or rotation of atoms or groups within molecules. For example, a three-pulse, 2D sequence was used to study molecular rotation of the* $-CCl_3$ *group in p-*chlorobenzotrichloride.[14] *The first pulse excites all quadrupole resonances within the excitation* width *of the pulse. which are allowed to evolve in a time* t_1; *the second pulse restores some of the longitudinal magnetization, which now changes as the exchange process takes place. Finally,* a *third pulse generates the exchange-modified NQR signals that are sampled over a* time t_2. A *double Fourier transform with respect to* t_1 *and* t_2

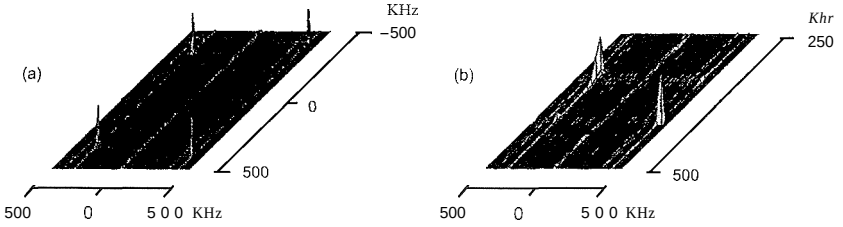

Fig. **3** A two-dimensional exchange ^{35}Cl-NQR spectrum of *p*-chlorobenzotrichloride at 208 K. (a) Whole spectrum and (b) lower part in more detail.

then generates a 2D spectrum in which the off-diagonal or cross peaks represent a transfer of magnetization at frequency coordinates corresponding to the sites between which exchange occurred. In the example selected, the ^{35}Cl-NQR spectrum of the $-CCl_3$ group consists of two lines at frequencies close to 38.07 and 38.82 MHz at 207 K (Fig. 3): the cross peaks on either side of the diagonal arise from hindered rotation of the $-CCl_3$ group. which interchanges the two sites of different frequencies. At a temperature of 201 K. jump times are of the order of a ms or so.

Pulsed NQR measurements of the spin-lattice relaxation time, T_1, also give detailed information on the mechanisms and dynamics of molecular motion in solids. For example, ^{14}N quadrupole relaxation times for solid triethylenediamine show a T_1 minimum at a temperature close to 260 K. when T_1 equals 0.048 s.[15] On either side of the minimum, T_1 depends exponentially on temperature, according to an Arrhenius-type equation with an activation energy of 34 kJ mol^{-1}. The mechanism of the relaxation is shown to be hindered rotation of the triethylenediamine molecule about its threefold symmetry axis, which modulates the dipolar coupling between ^{14}N and the adjacent CH_2 protons.

NQR can be used to study the electronic structure of a wide variety of inorganic compounds and complexes. As an example. ^{63}Cu and ^{65}Cu, both spin-312 nuclei, have been investigated in a variety of Cu(I) complexes.[16] In a number of halocuprate ions, for example, the ^{63}Cu-NQR frequencies lie between 26–31 MHz according to the halogen atoms (Cl. Br, I) attached to the Cu(I) atom: in such cases. by using the Townes–Dailey theory. it is possible to interpret the variation in terms of the 3*d*, 4s. and 4*p* orbital populations of the Cu atom in the complex.

Intercalated compounds can also be studied by WQR methods, typical examples being amine intercalates of the layered structures of CdI_2 and PbI_2,[17] in which the ^{127}I (I= 512) resonances lie close to 80 (112→312) to 90 (3/2→512) MHz for the former and 17 (112→312) to 75 (3/2→512) MHz for the latter. depending on the chemical nature of the amine intercalate and its chemical interaction with the host.

Finally. crystalline and amorphous phases can be studied by NQR methods, the expected distinction between the two being that much broader lines are encountered in the latter. Despite line widths of 1 MHz or more. NQR signals can still be seen. provided suitable frequency-swept pulse sequences are used. An example is ^{75}As-NQR in arsenic-chalcogen glasses, such as As_2S_3 and As_2Se_3, in which the resonance lines can be 8–10 MHz in width.[18] In Fig. 4, the dotted line shows ^{75}As-NQR in annealed glassy As_2S_3 in bulk, with the two lines at the top of the diagram denoting the experimental frequencies in crystalline As_2S_3. The triangles (dashed line) are for the fast-evaporated film. which shows new peaks close to 80 and 94 MHz, close to the ^{75}As-frequencies in crystalline As_4S_3. These new lines are attributed to the presence of As—As bonds in the film, which are broken when the sample is irradiated for 30 h with radiation of wavelength 5145 Å.

Two-dimensional NQR methods give further information on the broadening mechanisms by the use of 2D correlation methods.[19] In a coherence transfer experiment, for example, a pair of 90° pulses separated by a variable delay t_1 is applied to (say) one transition ν_1 of a half-integral spin nucleus (such as ^{123}Sb, for which $I=7/2$), followed by a 90°-τ-180° pulse pair at a second connected transition ν_2, the signal being detected at a time t_2 following the 180° pulse (a 180° pulse is approxiinately twice the width of a 90" pulse). A double Fourier transform with respect to t_1 and t_2 gives a 2D spectrum correlating the two transitions ν_1 and ν_2, from an analysis of which the individual broadening components of the electric field gradient tensor. Δq_{xx}, Δq_{yy}, Δq_{zz} can be derived, giving information on the anisotropy of the line-broadening mechanisms.

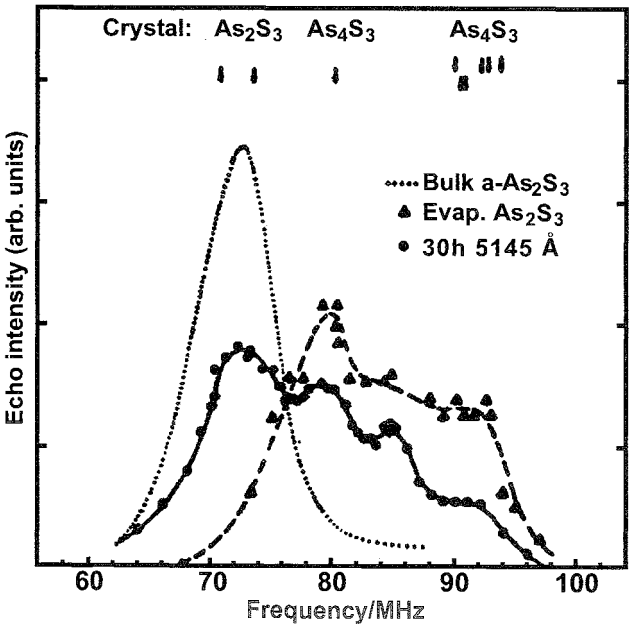

Fig. 4 ^{75}As-NQR in bulk glassy A_2S_3 (dotted line) and in rapidly evaporated film (dashed line). Irradiation for 30 h with light of wavelength 5145 Å produces the NQR response shown by the continuous line. The frequencies of ^{75}As-NQR signals in selected crystals are shown at the top of the figure.

CONCLUSION

NQR spectroscopy is a powerful method for studying the electronic structure of molecules and their dynamic

behavior in the solid state. A wide range of nuclei has an electric quadrupole moment and can be studied in crystalline and amorphous phases. The frequencies and relaxation times are related to the electronic structure and dynamic behavior, respectively, enabling the electron distribution in inorganic complexes. host and guest molecules in inclusion and intercalated compounds, and any molecular motion therein, such as chemical exchange and molecular rearrangements as well as phase changes, to be investigated. NQR spectra are usually inhomogeneously broadened, and experimental methods are available with which to study the magnitude and anisotropy of these effects. Illustrative examples are given of NQR studies in a range of materials containing one or more of the quadrupolar nuclei ^{14}N, ^{35}Cl, ^{59}Co, $^{63\,65}$Cu, ^{75}As, and ^{127}I.

INTRODUCTION

Since 1756, when the Swedish mineralogist Cronstedt described a group of silicate minerals as zeolites, this area developed immensely. In early times, observations were limited to the fact that these minerals lose water while heating (zeolithos: *steaming stones). An ever-increasing number of other properties are known today. Zeolites were found to show outstanding ion exchange and sorption properties for all kinds of small-diameter molecules.'" The most well known are topochemical applications for large-scale cracking of olefins. Essentially, zeolites are* somehow *porous materials. A great number of synthetic zeolite frames were synthesized over the years. Most of these structures are formed by use of a template and are obtained by kinetic control. Many inclusion compounds survive the removal of guest molecules upon heating and under vacuum conditions, although they are not* thermodynamically *stable thereafter. Recently, much effort was devoted to obtaining materials that feature zeolite properties, however, exclusively involving molecular units and supramolecular interactions in the solid* state.[2] *Although a tuning of pore sizes may give rise to materials featuring the potential of zeolites, a* main *drawback of molecular crystals may be that the chemical and thermal stabilities are inferior to inorganic counterparts. Impressively: at present. organic network structures can show porosity up to about 91% of the total* volume *and are capable of undergoing selective guest inclusion.'"* Such *supramolecular* materials *yield significantly more open space than classical inorganic* zeolites.[4,5]

A p omising strategy for assembling porous organic networks refers to the stability of some supramolecular *interactions. As a result of strong bonding by metal coordination or hydrogen bonding. some networks are robust enough to withstand the total removal of guests. All* kinds *of driving forces that can induce* self-assembly *to access zeolite-like organic compounds are thus of great interest.*

CRYSTAL DESIGN

Prediction of Porous Networks

The main molecular strategy to structure materials uses supramolecular synthons.[6]

Despite the effect of packing constraints given by molecular shape and symmetry, organic solids may be designed by using directional or anisotropic interactions (hydrogen bonding or halogen–halogen or metal–*ligand interactions).*

The Cambridge Structural Database (CSD) *is a comprehensive source for intermolecular motifs.* In *view of the fact that structural predictions became more* successful *in the last few years. open framework materials are nevertheless difficult to predict correctly, because they often represent thermodynamically nonstable states.*

The avoidance of close packing in *a crystal structure is thus a major aim in creating nanoporous organic materials.*

A *basic principle for the prediction of crystal structures was described by Kitaigorodskii:*

> We must first of all deduce all possible methods of constructing chains of molecules (formations extending in one dimension) and then demonstrate what layers are possible (formations extending in two dimensions). followed finally by considering layer stacking in the crystal (a formation extending in three dimensions).[7]

The occurrence of porosity in crystals may be generated by molecules. which prevent close packing by their constitution, the molecular bulkiness or rigidity in suitable positions. Hexahosts, *molecules of the* ''wheel *and axle" type and coordinatoclathrates are representative*

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012806

examples of nanoporous structures exhibiting guest inclusion.[8–11]

More often, geometrical approaches prove useful. Molecules or metal ions in crystals may be considered as nodes and the intermolecular interactions as connectors.[12,13] This widely accepted concept facilitates a design of one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) networks by the "building block" principle (Fig. 1a).[14,15] However, there is a significant problem associated with this concept. Because of a gain in lattice energy by n-fold interpenetration, many attempts result in densely packed structures.

Some of the basic principles leading to a large number of zeolite-type materials are summarized below. In view of what is known today, the series of examples is by no means complete.

Avoiding Close Packing: A Delicate Issue

Giving a concise definition for an organic zeolite remains an ambiguous task. In inorganic zeolites, the crystal structure is determined by ionic and covalent bonding. Directional and nondirectional forces play the important role for design of organic crystal structures.

Porous organic lattices may thus be designed, using the idea of nodes and connectors similar to inorganic networks. This principle is used above all in coordination polymers. Compared to these, in organic compounds; much weaker interactions are responsible for the assembly of a porous network. Therefore, structures tend to be flexible, being unstable in many cases and not able to maintain empty cavities after removal of a template. However, cavity-type channel systems exist that can be obtained free of guests, featuring reversible exchange.

In some cases, a polymorphic modification referred to as apohost (host without guest) is left after desorption of guests. Apparently, network topologies are interesting, which after desolvation and collapse of their cavity structure can restore porosity. Other networks allow a partial desorption of guests or guest exchange, without passing through a solvent-free stage. A delicate issue is, thus, the avoidance of interpenetration.

POTENTIAL ORGANIC ZEOLITES: STRUCTURAL AND KINETIC ASPECTS OF THEIR FORMATION

The fundamental questions in view of structural and kinetic aspects of organic zeolites are reduced to the following: How can structures with stable voids be generated, and by which mechanism can guest exchange occur?

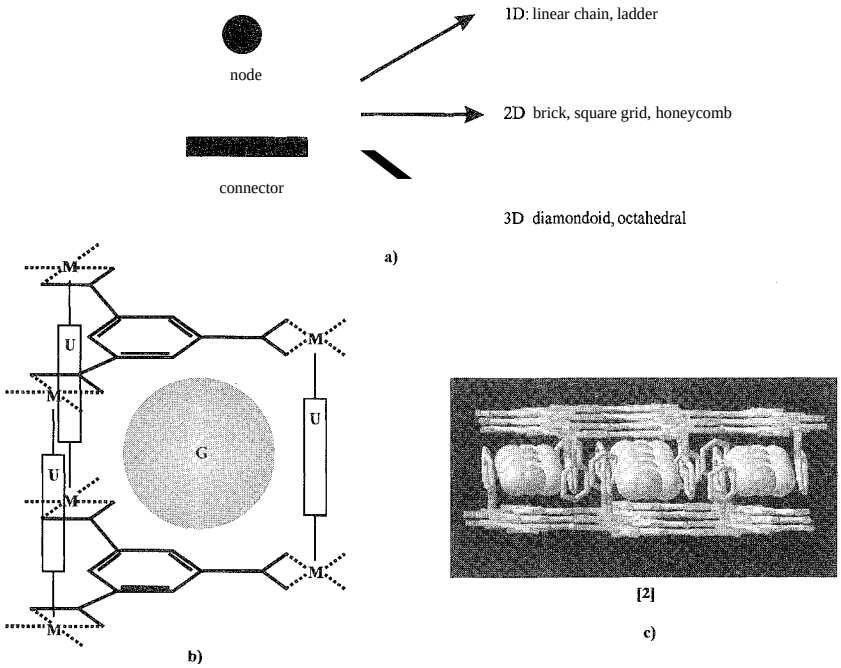

Fig. 1 Node and connector principle for metal–organic networks design. (a) Basic approach to form 1D, 2D, and 3D architectures using the principle of nodes and connectors. (From Refs. [14, 15].) (b) BTC-ligand occupying the vacant metal sites perpendicular to layers. This can produce a porous metal–organic framework with large channels. A variation of the metal ion (M) and the molecular unit (U) provided many options for the design of networks (G: guest). (From Ref. [16].) (c) Structure of $CoC_6H_3(COOH_{1/3})(NC_5H_5)_2(NC_5H_5)_{2/3}$ [2] with a rigid disk-like conformation, where pyridine is incorporated in the free space of the metal–organic framework (Co: green, O: red, N: blue. C: gray). (From Ref. [16].) (View this *art* in *color at www.dekker.com.*)

Structural Aspects of Stability

Metal–organic frameworks (MOF) and coordination polymers

A known strategy to prevent interpenetration is based on symmetry and functionality. Coordination polymers are built from ligand-to-metal bonding between transition metals and suitable organic ligand types. It is noteworthy that the geometry of the metal environment reproduces itself over the bridging ligands, i.e., by its network topology. Benzenetricarboxylate (BTC) offers three equally spaced carboxylate groups linked to an aromatic ring to form a rigid disk-like conformation. Metal–carboxylate (MC) layers result with first-row-transition metal–ions, being altered by molecular units (U) to produce alternating MC and *U* layers (Fig. Ib). Depending on the nature of *U*, a suitable environment for selective inclusion of guests between layers was achieved.''' Upon exchange, the crystal lattice is preserved, and the distance between the MC layers remains constant. The dimension of the metal-BTC-porous framework depends on the solvent used for synthesis and on the strength of the base applied for the deprotonation of trimeric acid (TMA).[17] In $Zn_2(BTC)(NO_3)(H_2O)(C_2H_5OH)_5$ [**1**], the triple-bidentate functionality of BTC promotes rigidity for the Zn-BTC-network, in which the metal centers can undergo unsaturated coordination. In $CoC_6H_3(COOH_{1/3})_3(NC_5H_5)_2(NC_5H_5)_{2/3}$ [**2**], rectangular channels (7 x 10 Å^2) are developed (Fig. 1c).[16]

By means of copolymerization of Zn(II) with the bidentate ligand 1,4-benzenedicarboxyl (BDC) a 3D porous framework of the composition $Zn_3(BDC)_3(CH_3OH)_6$ [**3**] was formed. The unsaturated zinc centers are able to coordinate guests selectively.[18]

After desorption of water in $Zn(BDC)(DMF)(H_2O)$ [**4**], only O···Zn interactions are responsible for stabilization of the remaining guest-free rnicroporous network (Fig. 2a).[19]

A further prominent strategy is based on the metal carboxylate chemistry, where an organic dicarboxylate linker is used to yield octahedral clusters being capped with monocarboxylate. $Zn_4O(BDC)_3(DMF)_8(C_6H_5Cl)$ [**5**] consists of $Zn_4(O)(CO_2)_6$ clusters, which spawn a pore sphere as large as 8 Å in diameter (Fig. 2b).[20] The bidentate linkers can be varied and functionalized, whereby crystalline materials are obtained with an open space up to 91.1% of the crystal volume. The diameter of the pores can be varied from 3.8–28.8 A. Some compounds reveal densities of 0.21 g/cm^3 and thus represent the lowest densities for crystalline materials.'''

In the polymer of $CuSiF_6(bipy)_2$ [**6**], Cu^{II}-ions are coordinated by four 4,4-bipyridyl (bipy) ligands forming a

Fig. 2 Stabilized Zn(BDC) networks due to cluster formation. (a) Formation of strong O···Zn interactions was obtained in the absence of water in the Zn(BDC) framework. The crystal structure of $Zn(BDC)(DMF)(H_2O)$ [**4**] showed 1D channels, which are occupied by DMF molecules (Zn: blue. C and H: gray, 0 : green, and N: red). (From Ref. [19].) (b) Eight clusters of $Zn_4(O)(CO_2)_6$ in the metal–organic framework of compound $Zn_4O(BDC)_3(DMF)_8(C_6H_5Cl)$ [**5**] surrounding a large cavity (yellow sphere). Approximately 55–61% of the space is accessible to guest species. The color scheme is the same as that in Fig. 2a. (From Ref. [20].) (*View* ***this*** *art in color at www.dekker.com.*)

3D network. Here, SiF_6 anions connect layers, preventing interpenetration. Channels with pore sizes of 8 x 8 Å^2 along the c-axis. and 6 x 2 Å^2 along the h-axis are formed (Fig. 3a).[21]

The elongation of the spacer enables variation of the void structures as well as the pore sizes. A noninterpenetrated square-grid arrangement with 4,4-*bis*(4-pyridyl)biphenyl [**7**] and Ni(II) was obtained. In this network, channels are stretched and offer a pore dimension of about 20 x 20 Å^2.

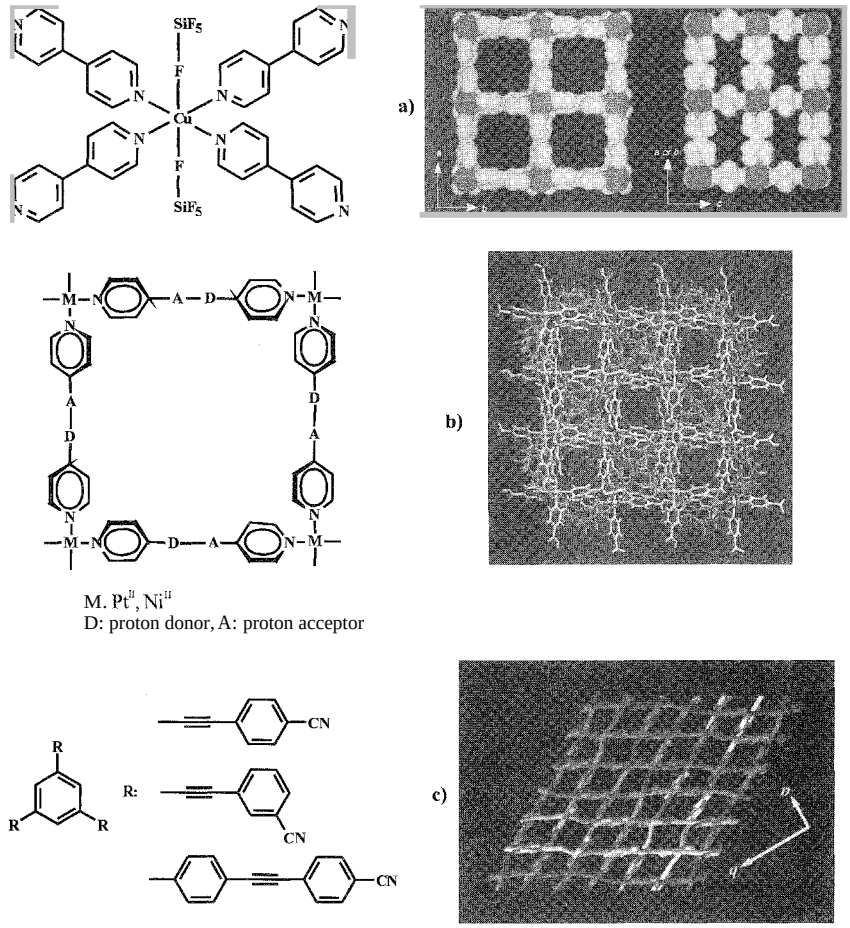

Fig. 3 Coordination polymers—a successful approach to permanent voids. (a) The porous coordination polymer $[CuSiF_6(4,4'\text{-bipyridine})_2]_n$ [**6**] produced a 3D network with channels in all directions in the crystal (Cu: blue, N: red, Si: green; F and C: gray). (From Ref. [21].) (b) Pt^{II}- and Ni^{II}- metal ions coordinating pyridine and forming a square arrangement stabilized by donor–acceptor interactions. (From Ref. [23].) (c) Trigonal rigid arrangements of the phenylacetylene nitrile molecules producing a honeycomb channel structure. Despite six interpenetrating networks (different colors) in the (*a,b*)-plane of benzene-1,3,5,-TEB-silvertriflate [**8**], a channel with a diameter of 15 Å was obtaincd along the c-axis. (From Refs. [24–26, 45].) (*View this* art in color at *www.dekker.*corn.)

Therein, guest molecules occupy more than 50% of the crystal volume, thus providing high porosity.[22]

Because of donor–acceptor interactions through hydrogen bonding between pyridinc derivatives and coordination to Pt or Ni, a square-planar cavity structure was obtained that showed decomposition above 300°C (Fig. 3b).[23] Mutual penetration of individual networks can give rise to an increase in thermal stability, even though empty cavities still exist.

Guest removal and exchange were investigated for benzene-1,3,5,-TEB-silvertriflate [TEB=*tris*(4-cthynyl-benzonitrile)] [**8**] (Fig. 3c).[24] The nitrile functionality of the trigonal phenyl-acetylene-derived ligand coordinates to silver cations forming a (3,3)-connected 3D network. A honeycomb-like structure with a channel dimension of 15 x 22 $Å^2$ was obtaincd. Further examples appeared in the literature involving coordination of Ag by CN ions. Here, the length and shape of the rigid axle appear to diversify, and thus, the channel diameter of the networks becomes variable (Fig. 3c).[25,26]

In the zeolite-like material, 4,6-di(1-imidazolyl)-1,3,5-triazin-2-one (dimto) [**9**], large pores were found in which a dimto anion can act as a threefold ligand forming a continuous box-like unit with Zn(II) featuring a pore size of 9.6 x 5.5 $Å^2$ (Fig. 4a).[27]

The 1,2-dipyridylglycol (dpgy) acts as a functional pillar in the case of $Cu_2(pzdc)_2(dpyg)(H_2O)_8$ (pzdc: pyrazine-2,3-dicarboxylate) [**10**]. A 3D pillared-layer structure was obtained, whereby the resulting microchannels show a cross section of 4 x 6 $Å^2$ (Fig. 4b).[28]

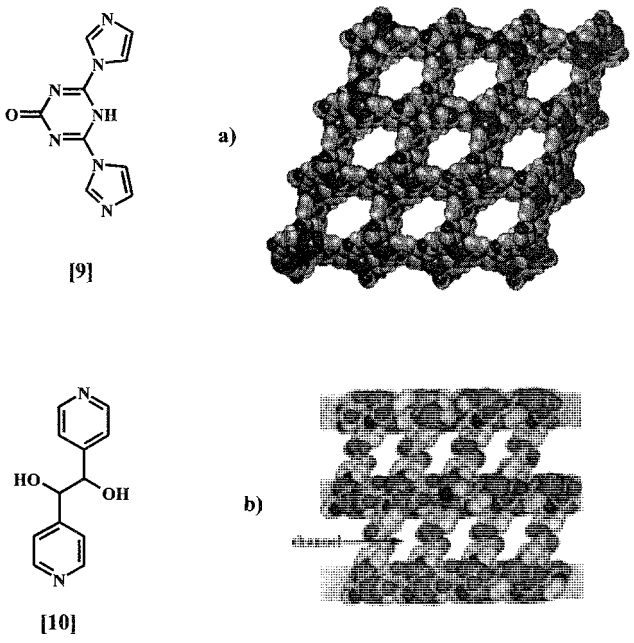

Fig. *4* Slight deformation of the lattice in coordination polymers after removal of the guests. (a) The 4,6-di(1-imidazolyl)-1,3,5-triazin-2-one [**9**] can form a counterion-free framework with channels of a cross section of 9.5 x 5.5 Å^2.[27] (b) In compound $Cu_2(pzdc)_2(dpyg)(H_2O)_8$ [**10**], the 1,2-dipyridylglycol acts as a flexible and functional pillar to form a 3D pillared-layer structure. Channels with a dimension of 4×6 Å^2 undergo a slight change after removing guests. (From Ref. [28].)

Porphyrins

Disk-like molecules such as porphyrins can be modified to form porous network architectures. Porphyrins and their derivatives yield large pores and show excellent thermal and oxidative stabilities. In addition to these properties, porphyrins represent an extremely versatile platform for tailoring porous solids. On the one hand, they can easily be "programmed" by adding various substituents and, on the other hand. by introducing recognition sites.[29] Starting from meso-tetraphenylporphyrins (in which π–π interactions occur between aromatic metalloporphyrins), many compounds were synthesized. In the lattice of Zn(TCPP) [**11**] (TGPP = tetra (4-carboxyphenyl) porphyrin) (Fig. 5a), self-penetration due to large interporphyrin voids is present (16 x 21 A'). To prevent interpenetration. different auxiliary species. such as nitrobenzene and potassium or sodium 18-crown-6, were introduced to sustain the lattice by a concerted ion-paired coordination. Further structural stability can be achieved by coordination through bidentate ligands, e.g., bipy. whereby bridge formation of adjacent layers stabilizes the networks. The cross sections of resulting pillars are 8 x 10 and 8 x 12.5 Å^2. The framework lattice occupies just 42% of the total crystal volume. Porphyrins gives access to coordination polymers. which are shaped by metal–ligand interactions and by a variation of substituents.[30]

Coordination polymers with a composition [{M(tpyp)}$_6$]guest (M: Co^{II}, Mn^{II}; tpyp: tetrapyridylporphyrin) were obtained by hydrothermal reactions. Their structures

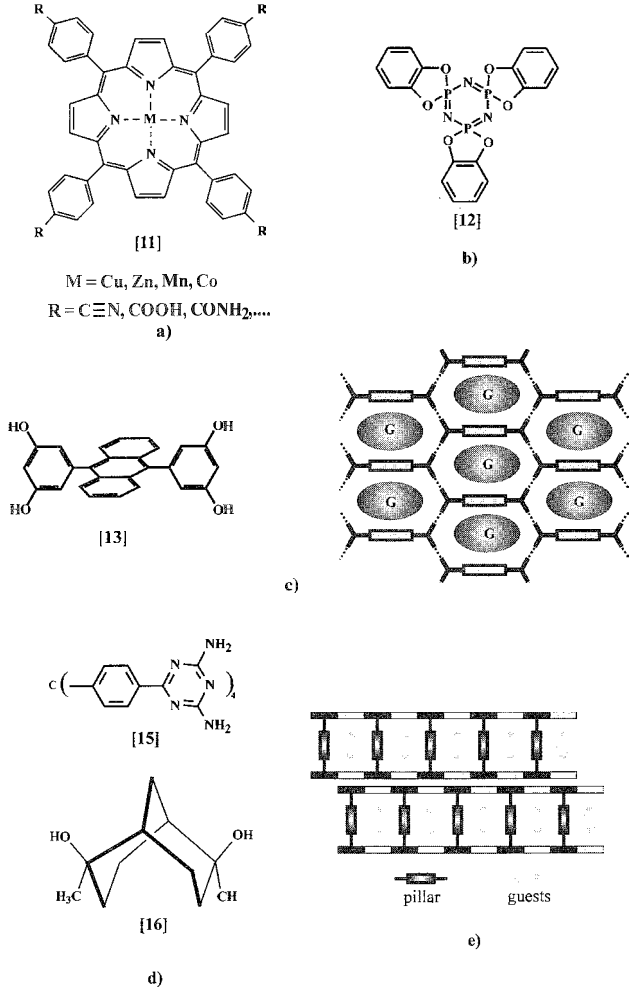

Fig. 5 Porphyrin and formation of hydrogen bonds for stabilizing empty channels. (a) The variation of metal ions and substituents in metalloporphyrin is a basic approach to tailoring networks.[30] (b) The trigonal spirocyclophane *tris*(*o*-phenylenedioxy)cyclotriphosphazene [**12**] yields a hexagonal channel topology.[33,34] (c) *Bis*(resorcinol)anthracene [**13**] forms a 2D network, in which hydrogen bonding occurs between the guest (G) and host molecules.[35-37] (d) A tecton of 2.4-diarninotriazine [**15**] and the helical diol 2,6-dimethylbicyclo[3.3.1]nonane-exo-2-exo-6-diol [**16**] give access to organic zeolites. in which the porous network is merely stabilized on the basis of hydrogen bonding.[39,40] (e) Bilayer structure in which two opposing hydrogen-bonded sheets are linked by organodisulfonate pillars. (From Refs. [42, 43].)

indicate a hexagonal cage showing an effective pore size of 13 x 16 Å^2.[29]

Hydrogen bonds and other weak interactions

Is it possible to produce stable porous channel structures. held together only by hydrogen bonds?

A trigonal symmetry of host molecules provides a typical template for obtaining cavities or channels. In the crystal structure of α-TMA (TMA=trimeric acid, the parent acid of the BTC anion), mutual triple catenation of hydrogen-bonded TMA was found.[''] However, self-penetration is preventable, if the TMA was crystallized with template molecules or is functionalized with bulky substituents to obtain a rigid arrangement.[32]

Another well-known trigonal rigid-structure motif is given by *tris*(*o*-phenylenedioxy)cyclotriphosphazene (TPP) [**12**] (Fig. 5b). The crystallization from different solvents results in a hexagonal channel structure of an average diameter of 5 Å. An empty channel-like structure was obtained by removing volatile guests. Formation of a pseudohexagonal crystal structure was observed.[33,34]

Compared to rigid derivatives of compounds featuring trigonal symmetry in which a planar arrangement can produce a channel system, a flexible *bis*(resorcinol)anthracene [**13**] motif (Fig. 5c) is known as well to generate a stable pore system, essentially being structured by hydrogen bonds.[35,36] A widespread 2D hydrogen-bonding network results from an orthogonal aromatic-triad strategy, with sheets layered in a staggered manner. thus preventing close packing. Anthracene and resorcinol rings are oriented nearly perpendicular to each other and form an extensive hydrogen-bonded network showing zigzag polyresorcinol chains and face-to-face stacked anthracene columns. This channel system undergoes no interpenetration and offers a pore diameter of 10 Å (Fig. 5c).

The intermolecular hydrogen bonding between derivates of 2-pyridone [**14**] rings forms a diamond-like network structure featuring rectangular channels able to accommodate guest molecules. However: this diamond architecture collapses after complete removal of guests, whereas the network is porous enough for an exchange of guest, retaining the lattice.[37,38]

A tecton of 2,4-diaminotriazine [**15**] (Fig. 5d) consists of 16 intertectonic hydrogen bonds supplying a 3D network that is stable enough, even if most guest molecules were desorbed. The resulting network defines channels of 11.8 Å diameter.[39]

A chiral bicyclic diol and its derivatives crystallize in a series of hydrogen-bonded species surrounding parallel channels in which guest molecules can be trapped by a cross section as large as 35 Å^2.[40] An example for a helical tubuland is 2,6-dimethylbicyclo[3.3.1]nonane-exo-2-exo-6-diol [**16**] (Fig. 5d), which contains parallel channels with a triangular pore size of roughly 20 Å^2. The guest-free diol was obtained in different ways: sublimed twice under reduced pressure, inclusion compounds heated (100°C) under reduced pressure, and recrystallized from mesitylene.

A channel-type organic material providing a stable empty nanoporous architecture was found by extracting gossypol (Gp), 2,2′-[1,1′,6,6′,7,7′-hexahydroxy-3,3′-dimethyl-5,5′-diisopropyl-8,8′-diformyl]-naphthalene [**17**], from cotton plants.[41]

A similarly remarkable arrangement of molecular sheets is formed by alkane- or arensulfonate anions (RSO_3^-) (S) and the guanidinium cation (G) [**18**].[42,43] This quasihexagonal 2D GS network sustains strong (G) N–H···O (S) hydrogen bonds and forms nanoporous galleries with 1D channels (Fig. 5e). A method was devised of manipulating the gallery in terms of their height, shape, and chemical environment through a choice of the disulfonate pillars. As a result of the size of the pillars, two basic structural motifs were obtained: a single-layer motif of large pillars: which favors large guests; and sterically undemanding pillars preferring small guests by a bilayer motif. The gallery heights are given by the size of the organodisulfonate, ranging from 5.5–11.5 Å. If guest molecules are removed from the host lattice, a new crystalline phase forms.

Kinetic **Aspects and** Properties

Guest-free cavities are obtained by removing volatile guests for materials when heated or put into vacuum. In many cases, the crystal structure collapses and forms more densely packed arrangements. However, due to strong

Table 1

Coordination polymer	Type of adsorption isotherm	Guest sorption
Zn(BDC)(DMF)(H_2O) [**4**]	I	N_2, CO_2
$Zn_4O(BDC)_3(DMF)_8(C_6H_5Cl)$ [**5**]	I	N_2
{[$CuSiF_6$(4,4′-bipy)$_2$]$_n$} [**6**]	I	CH_4
Tb(bdc)NO_3 [**20**]	I	CO_2, CH_2Cl_2, different alcohols
$Cu_2(pzdc)_2(dpyg)(H_20)_8$ [**10**]	II, hysteresis	CH_3OH, H_2O
[(**13**)$^{4-}$ 2Zr(O^{t}Bu)$_4$] [**19**]	II, hysteresis	N_2, AcOEt. hexane, benzene

intermolecular interactions, remarkably stabile guest-free crystals may arise in some networks, up to 300°C.

X-ray powder diffraction (XRPD), thermo gravimetric (TGA) analysis, solid-state nuclear magnetic resonance (NMR), and measurements of adsorption isotherms are key methods for characterizing zeolite-like behavior. However. a simple proof for observing structural changes during the sorption processes is XRPD.

Evidence for solvent-free pores can also be gained by ^{129}Xe-NMR spectroscopy. This was first applied for Dianin's clathrate. It is particularly suited for the study of void spaces. including amorphous materials.[44]

Stable voids in crystal networks

Stuctural stability of a supramolecular network after complete removal of guest molecules representing a significant part of the volume is an astonishing phenomenon.

In Zn(BDC)(DMF)(H_2O) [4] for example, one water molecule is released at 65°C followed by the evaporation of DMF at 160°C.[19] Empty pores (5 Å) remain because of an increase of the O···Zn bonding in the absence of guests.

A promising designs strategy of the architecture and functionalization of the pores stems from metal carboxylate cluster chemistry. Noninterpenetrated empty

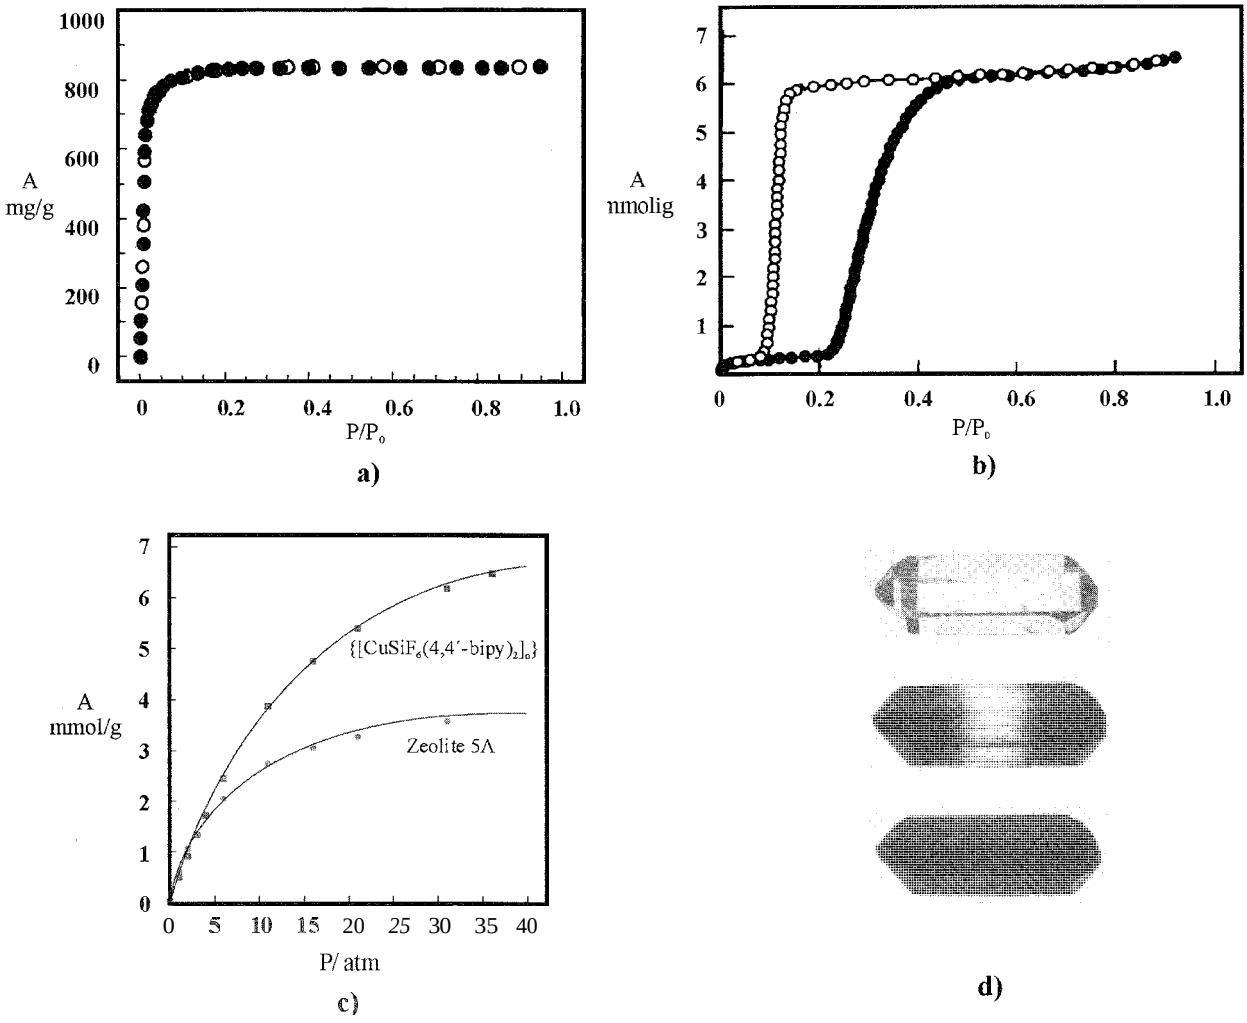

Fig. 6 Demonstration of zeolite-like properties by means of selected examples. (a) Nitrogen gas sorption at 78 K for $Zn_4O(BDC)_3(DMF)_8(C_6H_5Cl)$ [**5**] showed a Type I adsorption isotherm. (From Ref. [20].) [P/P_0 (P: gas pressure; P_0: saturation pressure).] (b) Adsorption and desorption investigations for methanol in the crystal structure of $Cu_2(pzdc)_2(dpyg)(H_20)_8$ [**10**] (298 K). Isotherm with hysteresis loop (A: absolute absorption, P/P_0 is the same as in Fig. 6a). (From Ref. [28].) (c) Comparison of the adsorption isotherm for methane by the inorganic zeolite 5A as compared to $[CuSiF_6(4,4'\text{-bipyridine})_2]_n$ [**6**], demonstrating a larger affinity of the organic compound (A: absolute absorption). (From Ref. [21].) (d) TPP shows a remarkable affinity to include iodine by *in*-diffusion. The staining started from capping faces, extending continuously into the volume (from top to bottom). (From Ref. [48].) (*View this art in* color *at www.dekker.com.*)

networks with a modifiable pore sire up to 28.8 Å were obtained. Despite the large empty voids and the low density of this crystalline material, the crystal structure is maintained after evaporation of the inclusion solvents.[3]

Structures 5–7 show similar behavior. The solvents can be fully removed or exchanged by other guests without destruction of the pores and are stable up to 300°C.

Guest molecules were exchanged for $[Ag(TEB)CF_3SO_3](C_6H_6)$ [**8**] in the liquid state while the framework remained intact. Complete substitution with C_6D_6 was confirmed by NMR spectroscopy.[45] Here. guest exchange does not seem to be limited to benzene because of a preference for selective sorption of aromatic alcohols and, to lesser extent, for unfunctionalized aromatics or aliphatic molecules.[24]

Flexible network structures

After heating the inclusion adducts of Structure [**13**] in vacuum. a polycrystalline guest-free apohost was obtained. This apohost is capable of reversibly binding ketones and esters. The uptake of guests in various liquids is fast (completed within seconds).

Solid–solid complexation of an apohost with compounds in the solid state. such as benzophenone or 1,2-cyclohexandiol, is feasible as well. Host–guest formation in the solid state may be considered a heterogeneous equilibrium, where guest molecules are bonded at the surface of the apohost and by translocation enter the host pores. However, the mechanism is not yet understood.

A bidentate ligand is similarly a candidate for the coordination to metal ions. Polycondensation with $Zr(O^tBu)_4$ provided an insoluble, amorphous. and microporous powder [$\mathbf{13}^{4-} \cdot 2Zr(O\text{-}^tBu)_4$] [**19**] that forms a stable 0-Zr-Q network with a pore size of 7 Å. The completely insoluble Zr-host system allows for Diels–Alder reactions. In this case, a batch flow system was set up for continuous processing.[46]

An empty channel-like structure and formation of a pseudohexagonal crystal structure is shown by TPP [**12**], which can be obtained by removing volatile guests. In these crystals, a reversible gas transport of xenon in 1D channels was reported and analyzed by laser-polarized ^{129}Xe-NMR spectroscopy.[33,34]

After slow removal of dichloromethane from the inclusion co pounds of gossypol, a polymorph was formed with an ink-bottle-like empty space of an average diameter of 5 Å.[41]

CONCLUSION

Organic zeolites are interesting material, for an application in catalysis. gas storage, separation, or implementation of some physical properties.

The effectiveness of organic pore systems is generally explored by measuring adsorption isotherms. Most examples for reversible sorption properties are reported for coordination polymers. Two types of adsorption-isotherms were found: reversible Type I adsorption isotherms (Table 1) were observed for guest-free metal–organic networks (Fig. 6a). Isotherms showing a hysteresis loop (Type II) provide evidence for the crystal structure undergoing a slight deformation during the sorption process (Fig. 6b).

In comparison to inorganic zeolites, organic porous networks show a considerably higher uptake of different guests. $CuSiF_6(bipy)_2$ features a higher affinity to methane than that found for the inorganic zeolite 5A (Fig. 6c).

In addition to the reversible uptake of CO_2, the solvent-free derivative $Tb(bdc)NO_3$ [**20**] revealed a further application potential in view of a sensor technology, where lanthanides play an important role.[47]

An efficient guest exchange was observed for TPP and iodine (Fig. 6d). Here, a dark conductivity along the channels in the order of pure $I_2(s)$ was reported.[48]

The completely insoluble Zr host system [**19**] allows for Diels–Alder reactions. In this case. a batch flow system was set up for continuous processing.[46]

To summarize. present examples reflect a great variety of different materials opening space for a tailoring of the pore size, the sorption, and other properties.

Organometallic Anion Receptors

Paul D. **Beer**
Elizabeth **J.** *Hayes*
University of Oxford, Oxiord, United Kingdom

INTRODUCTION

Anions are ubiquitous species, and therefore. their sensing is of considerable interest. Anion receptors containing redox-active organometallic groups such as ferrocene or cobaltocenium allow the binding of anions to be detected by an electrochemical response of the metallocene redox couple. These systems were incorporated into various acyclic, macrocyclic, and calix[4]arene frameworks. many of which include an arnide hydrogen-bonding group. Receptors can operate in a range of environmental conditions, including aqueous solution.

COBALTOCENIUM-BASED ANION RECEPTORS

The cobaltocenium moiety was studied extensively in the context of redox-responsive anion receptors.[1,2] The first class of anion receptor based on this system was reported by Beer and Keefe in 1989.[3] The ester functionalized *bis*-cobaltocenium macrocyclic Receptor 1 bound and electrochemically sensed bromide in acetonitrile via favorable electrostatic interactions.

Amide functionalities were appended to the cobaltocenium moiety to provide hydrogen bond donors capable of coordinating anions, such as in Receptors 2 and 3 in Fig. 1.[4] Proton NMR anion titration studies in d_6-DMSO reveal considerable downfield shifts. particularly for the arnide protons. indicative of a strong hydrogen-bonding interaction. Receptors 2 and 3 selectively bind dihydrogenphosphate over chloride in CD_3CN, with differences in stability constant of approximately an order of magnitude [$K(H_2PO_4^-)$ 1200 M^{-1} and $K(Cl^-)$ 100 M^{-1} for 2, $K(H_2PO_4^-)$ 320 M^{-1} and $K(Cl^-)$ 35 M^{-1} for **3**].[5] This selectivity may be attributed to the greater basicity of the $H_2PO_4^-$ anion. The importance of the amide hydrogen-bonding interaction was highlighted by studies with cobaltocenium receptors containing tertiary amides.[6] These receptors exhibit negligible anion binding. Crystal structure analysis of the bromide complex of Receptor 2 clearly shows hydrogen bonds to the arnide proton. as well as to Cp and aryl protons.

These receptors are also capable of electrochemically recognizing anions. Complexation of an anionic guest stabilizes the positively charged cobalt center, making it more difficult to reduce. and results in substantial cathodic shifts of the reversible Cp_2Co^+/Cp_2Co redox couple. Dihydrogenphosphate induces cathodic shifts of 200 and 240 mV, respectively, for Receptors 2 and 3, whereas chloride produces shifts of lower magnitude, 30 and 85 mV, respectively. This complements the higher binding constants obtained via NMR for the $H_2PO_4^-$ anion. Macrocyclic compounds also provided evidence for an anion chelate effect.[7]

A variety of novel calix[4]arene receptors 4–6 were prepared,[8–10] and it was shown that the anion-coordination properties are dependent upon the degree of upper-rim preorganization. For instance, 4 binds acetate much better than dihydrogenphosphate in DMSO, whereas the trend is reversed with the isomeric **5.** The bridged cobaltocenium calix[4]arene **6** forms thermodynamically more stable complexes with carboxylate and $H_2PO_4^-$ than either 4 or 5, with notable selectivity for acetate. The upper-rim bidentate amide group of **6** provides a hydrogen-bond cavity suitable for complexing bidentate anions such as carboxylates.

Ditopic *bis*-cobaltocenium receptors such as molecule 7 were synthesized in an attempt to enhance selectivity and complex stability.[7] Various spacer groups separate the two metallocenes. ^{1}H-NMR titrations revealed that the receptors with ethyl, propyl, and butyl spacers bound halide anions in CD_3CN in a 1:1 complex, with a preference for chloride. However, increasing the length of the alkyl chain leads to an overall decrease in the stability constant and in the degree of selectivity. Longer aromatic spacers gave 2:1 complexes with anions, presumably due to the increased size of the cleft cavity. Electrochemical measurements for all receptors showed considerable cathodic shifts in the cobaltocenium redox wave with a variety of anions.

A novel cobaltocenium porphyrin receptor 8 was synthesized,[11] in which four metallocenes were appended to the porphyrin. The selectivity is atropisomer dependent. and the *cis*-$\alpha,\alpha,\alpha,\alpha$-atropisomer shown exhibits the selectivity trend $Cl^- > Br^- \gg NO_3^-$. Proton NMR titrations in acetonitrile showed shifts of up to 0.7 ppm

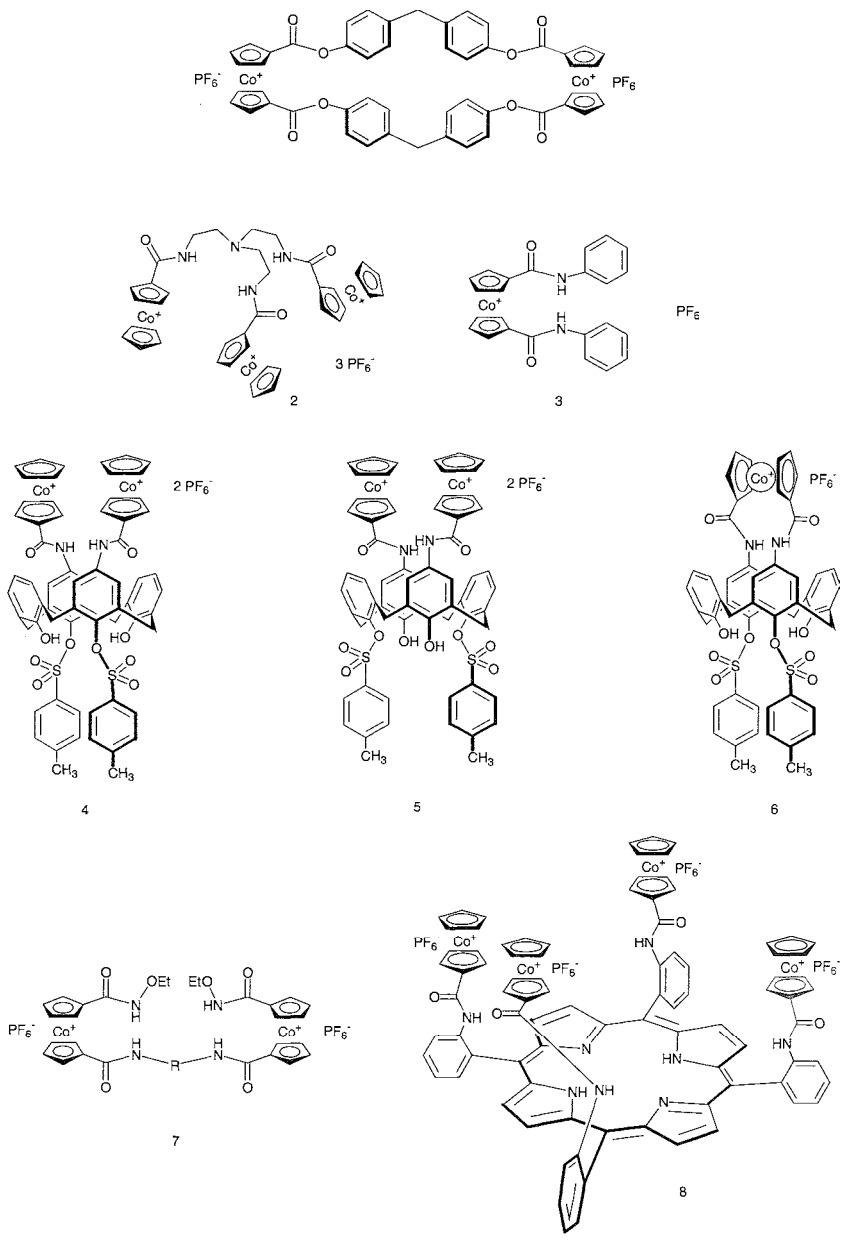

Fig. 1 Cobaltocenium-based receptors.

for the amide. Cp, and pyrrole protons upon addition of halide anions. Chloride and bromide bound in 1:1 stoichiometry and gave stability constants of 860 M^{-1} and 820 M^{-1}, respectively, whereas nitrate exhibited weaker binding with $K=190\ M^{-1}$. The molecule exhibits complicated electrochemistry, with multiple redox waves due to the cobaltocenium and the porphyrin. The addition of anions to acetonitrile solutions of 8 resulted in cathodic shifts of the cobaltocenium redox couple of 35–75 mV for chloride, bromide, and hydrogensulfate, and 225 mV for dihydrogenphosphate. Smaller shifts were observed for the porphyrin oxidation redox couple.

FERROCENE-BASED ANION RECEPTORS

The ferrocene moiety was also used in the sensing of anions, with many of the receptors similar in design to the cobaltocenium molecules.[7,8] One of the significant differences is that the ferrocene analogues are neutral and. therefore, have no inherent electrostatic interaction.

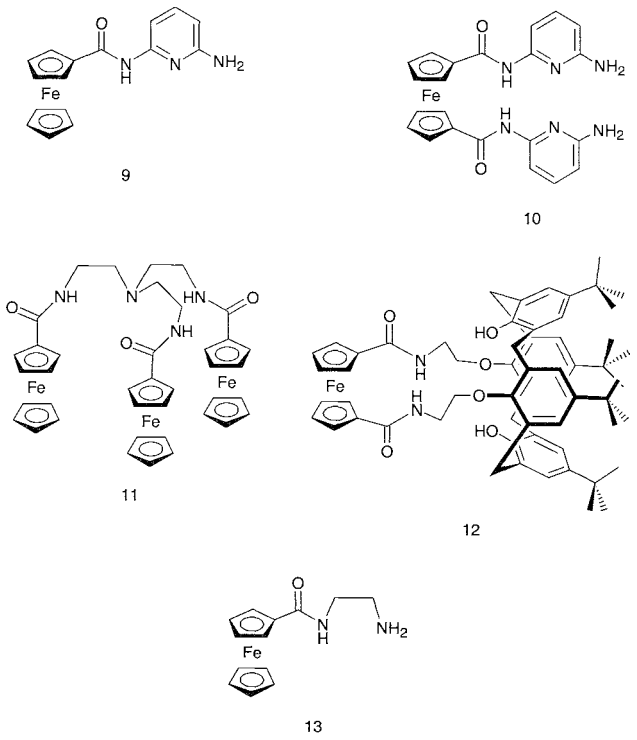

Fig. 2 Ferrocene-amide-based receptors.

NMR-determined stability constants are therefore lower in magnitude. The ferrocene does not directly interact with the anion until it is oxidized to ferrocenium, when electrostatic interactions are '.switched on."[12]

A range of receptors incorporating ferrocene units with secondary amides is shown in Fig. 2.[12,13] Molecules **9**–**12** exhibited $H_2PO_4^-$ induced cathodic shifts of up to 240 mV in acetonitrile in the presence of a 10-fold excess of HSO_4^- and Cl^-. Receptor **13**, on the other hand, exhibits selectivity for HSO_4^- in the presence of $H_2PO_4^-$, with a shift of 220 mV. The HSO_4^- anion protonates the basic amine functionality, which then binds the SO_4^{2-} anion.

A ferrocene-zinc metalloporphyrin analogous to 8 was prepared, in which anions are bound via the Lewis acidic zinc center and amide hydrogen bonding.[14] As with the cobaltocenium analogue, the atropisomer dictates the selectivity, and anion complexation in 3:2 CH_2Cl_2/CH_3CN results in cathodic electrochemical perturbations of the porphyrin and ferrocene redox processes. Lower-rim polyferrocene-substituted calixarenes were aiso synthesized and shown to electrochemically sense Cl^-. HSO_4^-, and $H_2PO_4^-$ anions in CH_2Cl_2, with shifts of up to 160 mV being observed with $H_2PO_4^-$.[15]

The relative ease of synthesis and substitution of ferrocene led to its widespread use. In particular. it has been attached to various well-known anion-binding structures in an attempt to introduce a responsive element. For example, Astruc and coworkers produced dendriiners containing up to 18 ferrocene units and found evidence for a dendritic effect in the anion recognition process.[16] $H_2PO_4^-$ induces the largest cathodic shifts, from 110–315 mV. Recently. this group synthesized functionalized gold nanoparticles containing (amidoferrocenyl) alkanethiol (AFAT) ligands for the purpose of redox recognition of oxoanions. These compare favorably to the

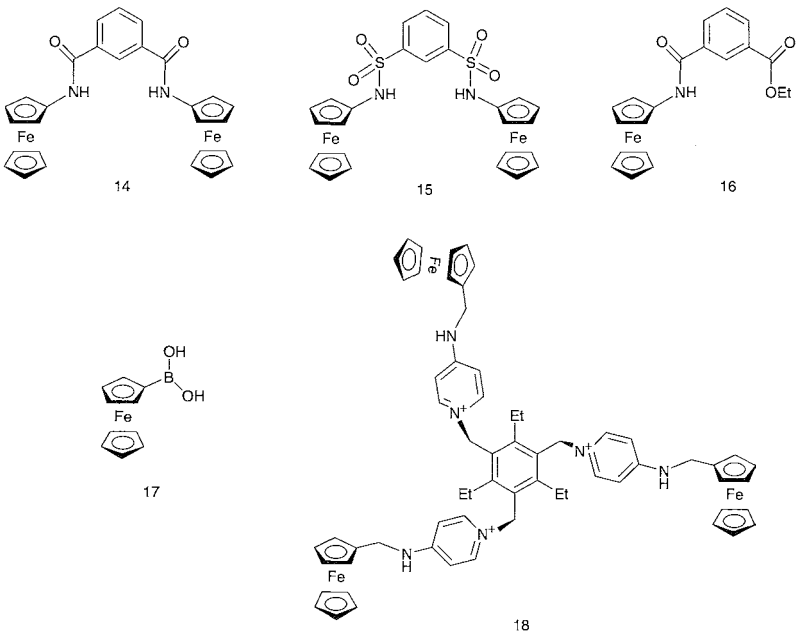

Fig. **3** Other ferrocene-based receptors.

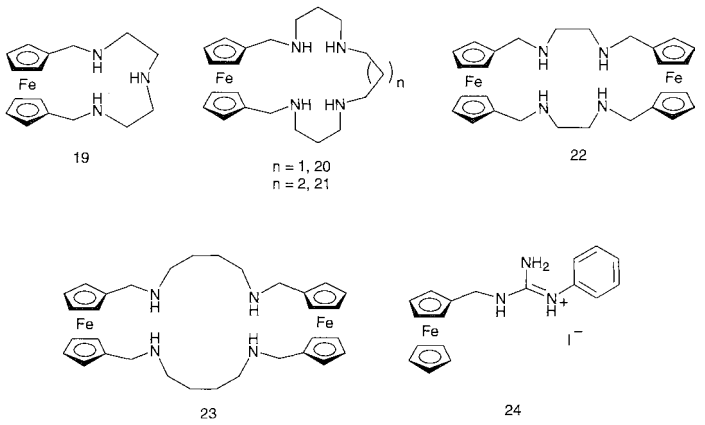

Fig. 4 Water-soluble ferrocene-amine receptors.

dendrimers in terms of selectivity for $H_2PO_4^-$ over HSO_4^-, with $H_2PO_4^-$ induced shifts of around 200 mV in CH_2Cl_2, and 100–175 mV in the presence of HSO_4^- and Cl^-.[17]

Crabtree and coworkers incorporated ferrocene subunits into isophthaliinide and disulfonamide frameworks.[18] The addition of Cl^- anions to CD_2Cl_2 solutions of **14** and **15** (Fig. 3) resulted in large chemical shift changes, up to 3.13 ppm for the amide N–H proton of 15. The stability constant for 15 was found to be 9500 M^{-1}, whereas that for the monamide 16 was only 30 M^{-1}, demonstrating the importance of the two convergent hydrogen-bonding groups. Disappointingly. relatively low cathodic electrochemical shifts of 20 and <5 mV were observed for 15 and 16, respectively. after addition of one equivalent of Cl^-. Ferrocene was also attached to imidazolium salts[19] and calix[4]pyrroles.[20]

Shinkai and coworkers reported that ferroceneboronic acid 17 (Fig. 3) acts as an electrochemical anion sensor.[21] It exhibits excellent selectivity for fluoride ions in the presence of other halides and anions such as SCN^-, SO_4^{2-}, and $H_2PO_4^-$. A K_{ox} value of 1000 M^{-1} in $MeOH/H_2O$ was found for fluoride, compared to values of less than 2 M^{-1} for chloride and bromide. The fluoride ion is a hard base and. therefore. interacts considerably with the hard boron atom. Oxidation results in the ferrocene group becoming more electron withdrawing. The electron density of the boron atom decreases; therefore, the strength of the fluoride complex increases. A bidentate *bis*(boronate) Lewis acid was also shown to act as a fluoride sensor.[22]

Steed and coworkers synthesized a series of "Venus flytrap'' anion sensors; such as 18 (Fig. 3), based on podands with a hexasubstituted core and arms with hydrogen-bonding and cationic pyridinium groups, with ferrocene attached to the pyridinium.[23,24] The host is preorganized into a cone conformation and shows considerable affinity for halides. and chloride in particular. with complexation-induced chemical shifts of up to 1.54 ppm for the NH protons in CD_3CN. The selectivity trend is $Cl^- > Br^- > I^-$, and some selectivity is also shown for acetate. Preliminary electrochemical studies suggest relatively poor coupling between binding and signaling moieties, but the observed selectivity sequence is in agreement with that obtained by NMR.

Receptors capable of operating under aqueous conditions are obviously important, given the prevalence of anions in biological and environmental systems. However, the large hydration energies of anions make their sensing in water a challenging task.[25] Beer et al. synthesized a series of acyclic and cyclic ferrocene-amine ligands, as shown in Fig. 4. These were shown to selectively bind and electrochemically sense phosphate and sulfate as well as nucleotide ions in aqueous solution.[26–28]

In general: the selectivity of these receptors is dependent upon pH. Results from ^{31}P-NMR imaging showed that Receptors 19, 20, and 21 (Fig. 4) bind adenosine triphosphate and hydrogenphosphate in water. At pH 6.5. where at least two of the nitrogen atoms are protonated. 1:1 complexes were formed. Electrochemical experiments at the same pH showed cathodic shifts with the phosphate anions of 60–80 mV. Receptor 22 discriminates for sulfate over phosphate at pH 4 in 70:30 THF/H_2O, with cathodic shifts of 54 and <10 mV, respectively. Compound 23 shows shifts of 23 mV with sulfate at pH 4 and 30 mV with phosphate at pH 8.

Molecule 20 shows a perturbation of the Fc^+/Fc redox couple by 50 mV upon addition of phosphate at pH 7 in water. Sulfate, on the other hand, results in a negligible shift. Calibration curves of the change in the half-wave potential $\Delta E_{1/2}$ versus the $[A^-]/[L]$ ratio at a certain pH value showed that the concentrations of phosphate and sulfate in the presence of competing anions can be quantitatively determined using Receptors 20 and 22.

This demonstrates their potential for use as prototype anion sensors.

The ferrocene-appended guanidinium receptor 24 senses pyrophosphate in methanol/water mixtures. exhibiting cathodic shifts of up to 70 mV.[29] Azamacrocycles functionalized with ferrocene arms were also shown to possess anion-binding properties and are capable of electrochemically detecting sulfates, phosphates, and ATP in 70:30 THF/H_2O solutions.[28,30]

OPTICAL SENSORS CONTAINING METALLOCENES

An acyclic $[Ru(bpy)_3]^{2+}$-ferrocene receptor 25 was prepared (Fig. 5).[31] The ferrocene units quench the emission of the ruthenium center in the free receptor. but addition of $H_2PO_4^-$ ions increases the emission by 20-fold in acetonitrile. This increase is not observed with Cl^- or HSO_4^- ions. Competition experiments in the presence of these anions gives rise to an emission increase identical to that obtained upon addition of $H_2PO_4^-$. Receptor 25 can therefore be considered a $H_2PO_4^-$ selective luminescent anion receptor. Particularly noteworthy are Receptors **26**–**27**, synthesized by Beer and coworkers. that exhibit a marked selectivity for chloride ions.[32] Stable 1:1 complexes are formed in DMSO, with stability constants of up to $4 \times 10^4\ M^{-1}$. No evidence of $H_2PO_4^-$ binding was shown with ^1H- and ^{31}P-NMR. Luminescence studies show a blue-shift of the MECT emission band with significant intensity enhancement in response to the addition of chloride anions but no response to $H_2PO_4^-$. Anion-induced cathodic shifts of the metallocene redox-couple of up to 110 mV were observed upon addition of chloride anion. The rigidity of the inacrocycle is thought to contribute to its selectivity. because acyclic analogues tend to prefer $H_2PO_4^-$. The larger size and tetrahedral shape of this anion make it incompatible with the macrocycle's cavity. However, increasing the size of the cavity by two or four methylene units dramatically reverses the trend in anion selectivity.

ARENE AND OTHER ORGANOMETALLIC RECEPTORS

Atwood and coworkers made considerable progress in the synthesis of new anion hosts by directly attaching cationic organometallic arene moieties to the calixarene aromatic rings.[33,34] Of note is Receptor 28 (see Fig. 6), which is capable of binding anions in aqueous solution. Nitrate and halide anions give binding constants in the range 100–550 M^{-1}, as determined by ^1H-NMR. Binding constants decrease in the order $Cl^- > Br^- > I^-$ and are significantly increased in nonaqueous media. This approach was also used to synthesize $[CpFe(arene)]^+$-derivatized cyclotriveratrylenes. such as 29. that bind halides and PF_6^-. The upper-rim charge preorganization allows anion binding within the host cavity.'''' Astruc also used different metallocenes. having synthesized a cationic metallodendrimer with 24 $[CpFe(\eta^6\text{-}N\text{-alkylaniline})]^+$ termini. This molecule is capable of recognizing chloride and bromide.[36]

Beer and coworkers made several simple receptors by substituting one cyclopentadienyl ring of a ferrocene with a benzene ring. to give the amide arene CpFe 30 in Fig. 6. The same article also described the synthesis of the arnide arene tricarbonyl chromium compound 31.[37] Downfield shifts of the arnide N–H protons are observed for both receptors upon addition of chloride or bromide in CD_3CN. For instance, with chloride, Receptor 30 exhibits a shift of 2.5 ppm and 31 a shift of 0.9 ppm. Negligible shifts are observed with unsubstituted metallocene and nonmetallated aromatic molecule.

Gale and coworkers synthesized Receptor 32 in Fig. 6.[38] Electron-withdrawing $Cr(CO)_3$ groups were attached in order to increase the acidity of the NH protons.'''' ^1H-NMR titrations of 32 in CD_3CN showed a

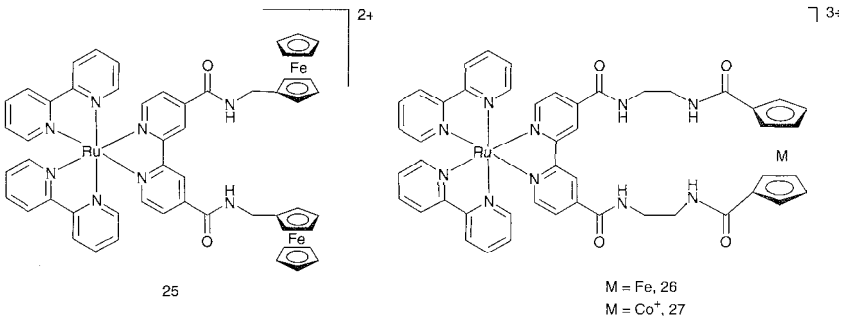

Fig. 5 Fluorescent organornetallic anion receptors.

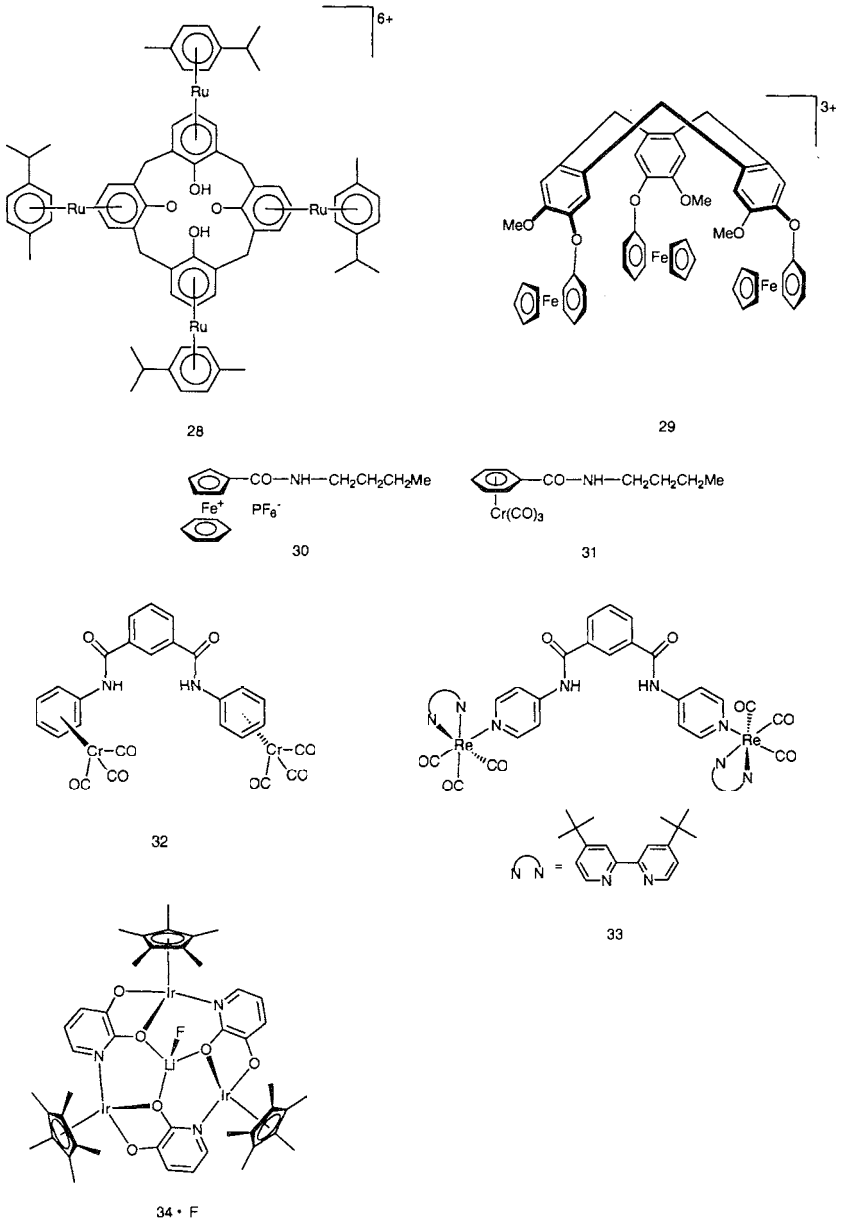

Fig. 6 Other organometallic receptors

selectivity for chloride over other anionic guests. with a log K value of greater than four. Selectivity for chloride over dihydrogen phosphate is high. perhaps reflecting the steric bulk of the $Cr(CO)_3$ moieties, which may hinder the approach of the bulky $H_2PO_4^-$ to the amide cleft. Receptor 33 was shown to have high affinities for halides, cyanide, and acetate anions.[39] The addition of anions results in a significant downfield shift of the N–H protons in $CDCl_3$ and quenching of the luminescent intensities in CH_2Cl_2. Binding constants as high as 10^4–10^5 M^{-1} and a detection limit as low as 10^{-8} M were observed.

Severin and coworkers synthesized an organometallic metallacrown complex **34**.[40] The receptor was found to be highly selective for fluoride, even in the presence of an excess of other anions. Electrochemical ineasurements in 2:1 $CHCl_3/CH_3CN$ showed a cathodic shift in oxidation potential of 203 mV upon addition of fluoride. whereas other anions induced rhifts of less than 24 mV.

CONCLUSION

Organometallic groups such as ferrocene and cobaltocenium lend themselves extremely well to the synthesis of anion receptors Their relative ease of substitution led

to the inclusion of them in acyclic. macrocyclic, calix[4]arene, and many other receptor systems. Anion-induced cathodic shifts in the redox potential of the metallocene provide a physical means of monitoring the anion-binding process. These two metallocenes. as well as other organometallic moieties. are continually being used in new classes of redox-responsive anion receptor, and it is apparent that this strategy is highly effective.

Organometallic Oligomers and Polymers

Alaa S. Abd-El-Aziz
The University of Winnipeg, Winnipeg, Manitoba, Canada

INTRODUCTION

Historically, metal-containing oligomers and polymers have been utilized for hundreds of years; however, it was not until the development of ferrocene in the early 1950s that organometallic polymers emerged as a focused area of research. Despite the fact that these materials were only developed within the past 50 years, there have been significant advances in this field, most importantly, within the past two decades. Organometallic oligomers and polymers are currently the focus of considerable attention in light of their electrical, magnetic, optical, catalytic, and biological properties.[1–3]

Brganometallic polymers are often classified according to the types of o- or π- (metal–carbon) bonds within their structures. Within this classification, these macromolecules can be further divided based on the placement of the metallic moieties in the polymer backbone or side chain. This review will highlight some of the main families of organotransition metal-containing oligomers and polymers, focusing on the most widely studied organornetallic systems; namely, metallocene-based polymers and their closely related transition-metal-coordinated arene- and cyclobutadiene-containing oligomers and polymers. In addition to these n-coordinated systems, there are also a number of examples of materials with metals o-bonded to carbon in the polymer backbone and polymers incorporating metal–metal bonds.

METALLOCENE-BASED POLYMERS

The first example of a metallocene-based polymer, polyvinylferrocene, was described in 1955.[4] This macromolecule was synthesized via the radical and cationic chain growth polymerization of vinylferrocene and incorporated the ferrocenyl unit pendent to the polymer backbone. Over the next 20 years. a multitude of reports detailed the mechanistic features of the addition polymerization of vinyl-substituted fessocene derivatives. In the 1960s, heteroannularly substituted ferrocenes were subjected to polycondensation reactions, which resulted in polymers with the ferrocenyl units in the backbone. Early investigations also described the direct polymerization of ferrocene and its derivatives; these reactions produced homo- and heteroannularly substituted polyferrocenylenes, in which the cyclopentadienyl rings were directly bonded to one another.[1,2]

The polymerization of vinyl metallocene-containing monomers is still an active area of research. In particular. current research is focused on new types of catalysts, copolymer synthesis, and the development of polymers with interesting biological, nonlinear optical: liquidcrystalline, electrical, and optical properties. Polyiner 1 is an example of a liquid-crystalline polymethacrylate containing ferrocenyl moieties in its side chains.[5] This polymethacrylate exhibited enantiotropic smectic C and smectic A phases with a weight average molecular weight of 100,000. Other classes of polymers containing metallocenes in their side chains were prepared by ring-opening polymerization reactions. For example, Allcock and coworkers reported the synthesis of fessocene- and ruthenocene-functionalized polyphosphazenes such as Polymer 2. which is a polyphosphazene with transannular and pendent ferrocene moieties.[6] It was possible to prepare this class of polymer either by ring-opening the metallocene-substituted cyclic phosphazene monomers or by reacting metallocene complexes with preformed polyphosphazenes. Ring-opening metathesis polymerization of norbornene monomers substituted with fessocenyl moieties also allowed for the

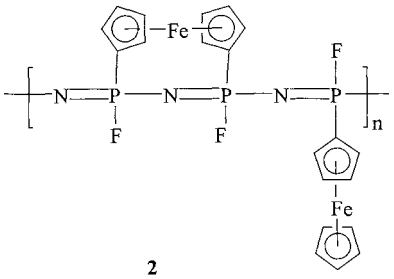
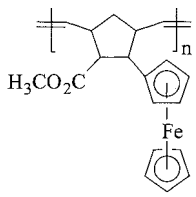
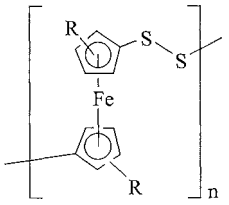
production of metallocene-based polynorbornenes such as **3** using well-defined transition metal catalysts.[7]



2

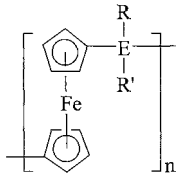


3



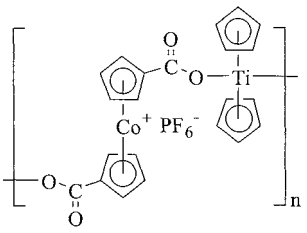
4

There continue to be developments in the synthesis of functional polymers, most importantly from the ring-opening polymerization (ROP) of ferrocenophanes. In the early 1990s, Rauchfuss reported the desulfurization- and deselenization-induced ring-opening polymerization of [trithiaferrocenes and [3]selenaferrocenes using PBu_3.[8] Reduction of the resulting high-molecular poly(ferrocenylene persulfide) 4 with $LiBHEt_3$ resulted in cleavage of the disulfide linkages in the polymer and the production of a monometallic complex; however, the polymer could be regenerated upon oxidation with iodine. Manners and coworkers pioneered one of the most important developments in metallocene-based polymers.[9,10] It was reported that high-molecular-weight polyferrocenylsilanes could be prepared by the thermal ring-opening polymerization of [1]silaferrocenophanes. Since that time, a number of research groups have been active in this area, and a number of reports detailed the syntheses, properties. and applications of polymers prepared via ROP of [1]ferrocenophanes.[11,12] These polymers. **5**. have since been prepared where the bridging element is silicon. germanium, tin, phosphorus. and boron.[9–13] [2]Ferrocenophanes containing carbon. sulfur. and phosphorus bridges were also polymerized. Initiation of ring-opening reactions was achieved thermally, using anionic and cationic initiators and using */-irradiation. A number of copolymers and cross-linked polymers were also synthesized.[13]



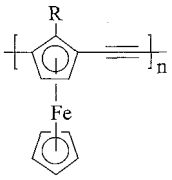
5

The synthesis of cobaltoceniurn-based polymers has also been described since the 1970s; however, there are only a limited number of reports on these cationic polymers in light of the difficulties involved in the derivatization of cobaltocene. As well, there are a number of reports detailing the synthesis of metallocenes, where the polymer chain propagates through the metal atoms rather than the cyclopentadienyl rings. These polymers include polyethers, thioethers, amines. and esters of metallocenes (M = Ti, Zr, Hf). Polymer 6 is an example of a mixed-metal polymetallocene in which the cobaltocenium complex is substituted via the cyclopentadienyl rings. and the titanocene complex is bonded through the titanium atoms.[14]



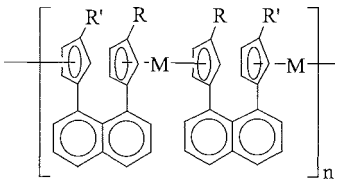
6

There has also been considerable interest directed toward the synthesis of conjugated polymetallocenes due to the electronic communication that these materials may possess. Many polymetallocenes were produced via polycondensation reactions of I,1'-disubstituted metallocenes. More rare are examples that describe the polycondensation of 1.3-disubstituted metallocenes. The synthesis of an optically active homoannularly substituted conjugatedpolyferrocene **7** was recently reported by Plenio and coworkers.[15]

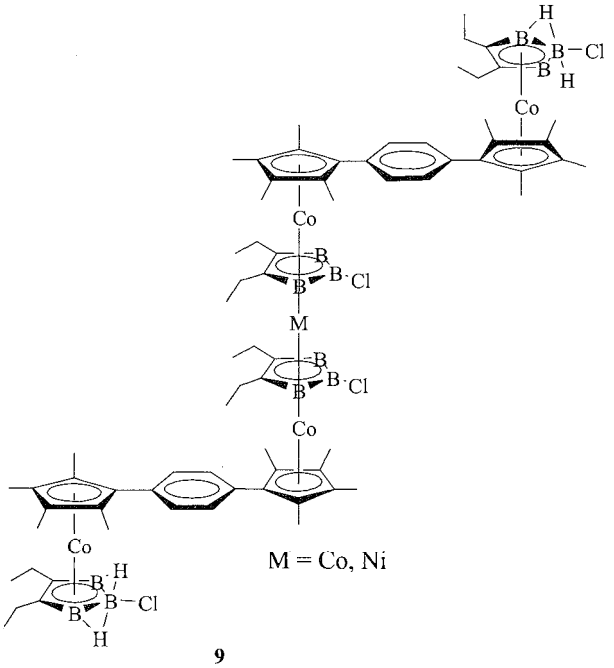


An interesting class of metallocene-based macromolecules is the face-to-face and stacked polymetallocenes.

Rosenblum and coworkers described the synthesis of oligomeric and polymeric materials, 8, using iron, ruthenium, cobalt. and nickel complexes.[16] Closely related are the metailocarborane oligomers that were produced by Grimes and coworkers.[17] *Bis*(cobaltocarborane) complexes were deprotonated and, subsequently, underwent coordination reactions with cobalt or nickel complexes to produce the pentainetallic complex 9. This oligomer could be further reacted using the same strategy to produce higher molecular weight materials.



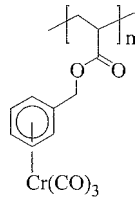
8



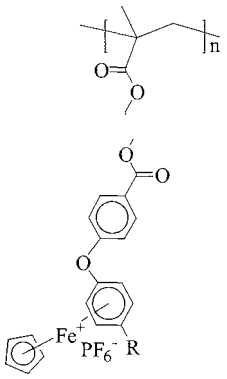
9

POLYMERS CONTAINING ARENES COORDINATED TO TRANSITION METAL COMPLEXES

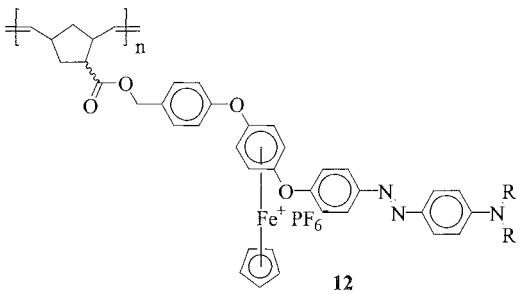
The coordination of transition metal moieties to arenes alters the reactivity of the aromatic ring. making it more susceptible to nucleophilic addition and substitution reactions and also making substituents on the arene more readily deprotonated. Some of the first examples of polyiners containing arenes n-coordinated to transition metal moieties were described by Pittman and coworkers.[17] Acrylate and methacrylate monomers containing arenes coordinated to chromium tricarbonyl moieties were hoino- and copolymerized using a radical initiator to yield polymers such as 10. More recently. cationic cyclopentadienyliron-functionalized methacrylate monomers were synthesized using a metal-mediated strategy.[18] These monomers were subsequently polymerized to yield the cationic organoiron poly(methyl methacrylate); 11. Abd-El-Aziz et al. also prepared polynorbornenes such as 12 with arene complexes of cyclopentadienyliron pendent to the side chains.[20] The incorporation of azobenzene chromophores into the side chains of these polynorbornenes, polyarornatic ethers. and ether-thioethers allowed for the formation of orange and red materials. Photobleaching of azobenzene-substituted polyethers was achieved in the presence of hydrogen peroxide.[19]



10

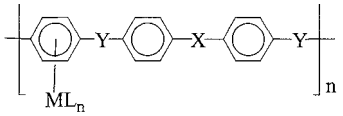


11



12

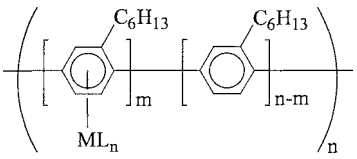
A number of polymers containing transition-metal moieties coordinated to arenes in the polymer backbone were synthesized by polycondensation reactions. Polymer 13 shows the general structure of this class of polymer. in which the linkages between the complexed arenes include esters. amides, imines, amines, ethers, thioethers. and acetylene groups. It was found, in most cases, that the incorporation of the chromium, iron, and ruthenium complexes pendent to the backbones of these aromatic polymers increased their solubilities significantly.[''' The coordination of electron-withdrawing $CpFe^+$, $CpRu^+$, and Cp^*Ru^+ moieties to dichloroarenes also allowed for the preparation of polyaromatic ethers and thioethers via nucleophilic aromatic substitution reactions using mild reaction conditions. The cationic polymers were found to exhibit polyelectrolyte effects in polar organic solvents.[19] The synthesis of oligomers and polymers with structures such as 14, with pendent cyclopentadienyliron cations and skeletal ferrocenyl moieties were also recently reported.[22] Another strategy utilized to produce transition-metal-coordinated aromatic polyiners is to use complexation reactions of organic polymers with transition-metal complexes. Nishihara reported the isolation of poly(hexyl phenylenes), 15, coordinated to cyclopentadienyliron. molybdenum tricarbonyl, and chromium tricarbonyl moieties using this methodology.[23]



ML_n = $Cr(CO)_3$, $CpFe^+$, $CpRu^+$, Cp^*Ru^+

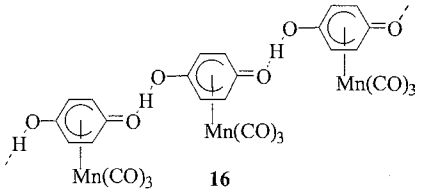
13

The production of supramolecular polymers containing chromium tricarbonyl and manganese tricarbonyl moieties was described.'''' Sweigart recently reported the self-assembly of η^4-quinone and η^5-semiquinone complexes derived from hydroquinone coordinated to cationic manganese tricarbonyl moieties.''''' The metal-mediated deprotonation of these complexes allowed for the production of polymers such as 16.



ML_n = $CpFe^+$, $Mo(CO)_3$, $Cr(CO)_3$

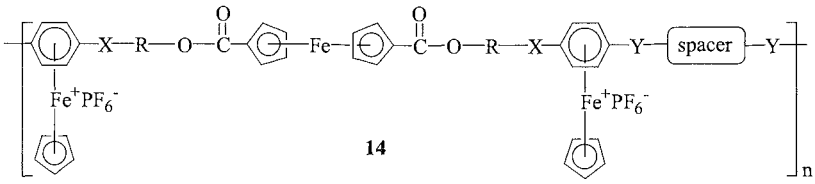
15



16

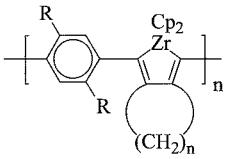
POLYMERS CONTAINING METALLACYCLOPENTADIENE RINGS AND CYCLOBUTADIENE RINGS COORDINATED TO CYCLOPENTADIENYL METAL COMPLEXES

Tilley and coworkers synthesized a number of linear polymers and macrocycles containing zirconacyclopentadiene units in the backbone.[25] Polymers such as 17 were synthesized by the intramolecular coupling of zirconocene with poly(*p*-phenylenediyne)s. Metallacycling polymerization was also utilized to prepare polymers with cobaltacyclopentadiene moieties in the main chain. For example. Polymer 18 was synthesized by reacting (η^5-cyclopentadienyl)bis(triphenylphosphine)cobalt with bifunctional diynes.[26] Thermal rearrangement of this class of polymer results in the formation of polymers containing main-chain cyclobutadiene rings coordinated to cyclopentadienylcobalt moieties. An alternative approach to the synthesis of polymers with complexed cyclobutadiene units in the main chain is to react monomers already containing these complexes in their structures. Liquid-crystalline polymers such as 19 were prepared by nickel-catalyzed debromination polycondensation of a complex containing terminal bromophenyl groups.[27] Oligomers containing cyclobutadiene rings coordinated

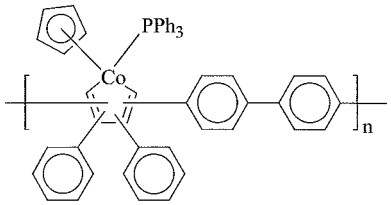


14

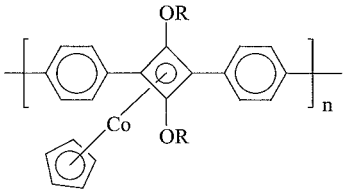
to cyclopentadienylcobalt and iron tricarbonyl moieties **20** were synthesized by Bunz and coworkers.[28]



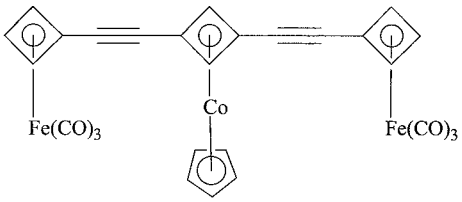
17



18



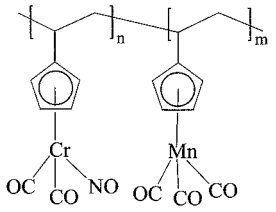
19



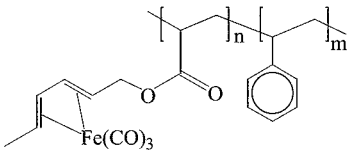
20

METAL CARBONYLS PENDENT TO POLYMER BACKBONES AND SIDE CHAINS

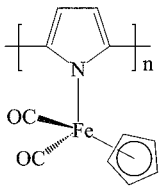
There are a number of different types of polymers that contain metal carbonyl complexes attached to polymer backbones and side chains. In the 1970s, Pittman and coworkers reported the synthesis and polymerization of a wide range of vinyl monomers containing transition-metal-coordinated cyclopentadienyl rings. Polymer **21** is an example of a copolymer containing chromium and manganese complexes in the side chain.[29] Another class of polymer incorporates iron tricarbonyl moieties π-coordinated to dienes in the side chains of polyacrylate homo- and copolymers.[30] The copolymer with styrene **22** could be converted to π-allyliron tri- and tetracarbonyl derivatives. Oxidative polymerization of dicarbonyl(η^5-cyclopentadienyl)(η^1-pyrrolyl)iron using dodecylbenzenesulfonic acid and tetrabutylammonium persulfate gave a polymer, **23**, with a conductivity of 7×10^{-3} S/cm.[31] This polymer lost its carbonyl ligands in solution upon heating to yield an azaferrocene derivative.



21



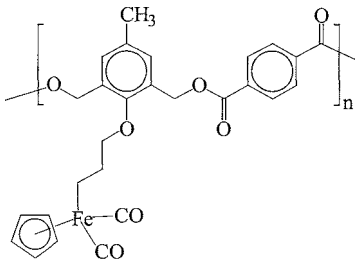
22



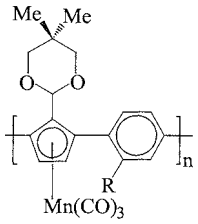
23

Mapolie and coworkers prepared metal-containing polyesters via polycondensation of iron- or rhenium-containing diols.[32] The organometallic monomer [(η^5-C_5H_5)$(CO)_2Fe(CH_2)_3O$–{2,6–$(CH_2OH)_2$–4–CH_3–C_6H_2}] was synthesized via the reaction of 2,6-*bis*(hydroxymethyl)-*p*-cresol with an iodopropyl complex. Polycondensation of this monomer with terephthaloyl chloride in toluene in the presence of triethylamine gave Polymer **24**. Molecular weight analysis of the toluene-soluble fraction of the iron-containing polyester showed that it consisted of low-molecular-weight oligomers. The tricarbonylmanganese-coordinated Polymer **25** was synthesized via Suzuki coupling of substituted diiodocyclopentadienylmanganesetricarbonyl with *p*-phenylenediboronic acid.[33]

This manganese-based polymer had a number-average molecular weight of 11 x 10^3, with a polydispersity of 6.4.

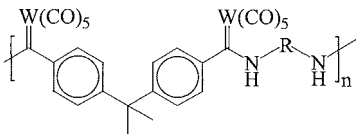


24



25

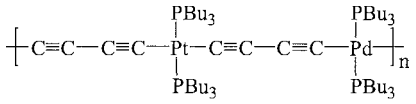
One of the few articles on metal-carbene-containing poiymers was authored by Masuda and coworkers.[34] Polycondensation reactions of a bifunctional alkoxycarbene with diamines allowed for the preparation of polymers such as 26. with metal-carbene units attached directly to the polymer backbone. The polymers were air stable but were unstable in solution. These polymers had number-average molecular weights in the range of 3900–8800 and polydispersity indices between 2.15–2.90.



26

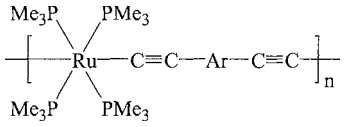
POLY(METAL ACETYLIDES)

In the 1970s, Hagihara and coworkers reported the synthesis of oligomeric and polymeric poly(metal acetylides), also called poly-ynes. containing transition metals in the main chain.''] Conjugated poly-ynes containing platinum or palladiuin complexes in their backbones were prepared by polycondensation of a metal chloride and an acetylene monomer in the presence of CuI. Platinum and palladium complexes were introduced into the backbones of these rigid polymers via reaction of *trans*-$(PBu_3)_2$-$Pt(C{\equiv}C{-}C{\equiv}CH)_2$ with *trans*-$(PBu_3)_2PdCl_2$ or via reaction of *trans*-$(PBu_3)_2Pd(C{\equiv}C{-}C{\equiv}CH)_2$ with *trans*-$(PBu_3)_2PtCl_2$ to give the alternating metal Polymer **27**.

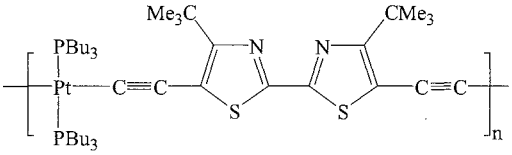


27

The rigid-rod linear ruthenium poly-yne 28 was prepared via the reaction of *trans*-$[Ru(PMe_3)_4Cl_2]$ with $Me_3Sn{-}C{\equiv}C{-}R{-}C{\equiv}C{-}SnMe_3$ in a 1:1 stoichiometric ratio.''' Using similar strategies, polymers containing a vast array of transition-metal complexes in their backbones were synthesized. This class of rigid-rod polymer exhibits interesting electrical and optical properties, and research is currently focused on optimizing these features. For example. platinum polyacetylides. such as 29, containing bithiazole units functionalized with electron-donating and electron-withdrawing substituents, were recently reported.[37] These soluble platinurn polyacetylides showed photoconducting behavior.



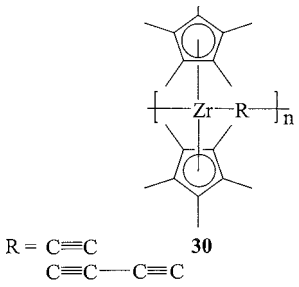
28



29

Interesting zirconocene polyacetylides such as 30 were synthesized by reaction of *bis*(pentamethylcyclopentadienyl) zirconium(IV) dichloride with dilithiated acetylene monomers.[38] These polymers had weight average molecular weights between 55.000 and 68,000, as measured by gel permeation chromotography (GPC). Acetylide complexes of platinum and palladium functionalized with cyano groups were polymerized by hydroboration to produce Polymer 31 with cyclodiborazane units in the backbone.[39] The platinum and palladiuin polymers showed enhanced solubility and had number average molecular weights around 6000. This class of polymer

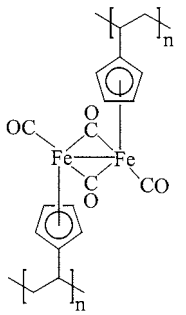
exhibited π-conjugation via the transition-metal atoms and the boron atoms.



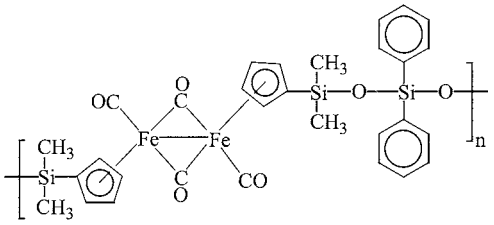
30

POLYMERS WITH METAL–METAL BONDS

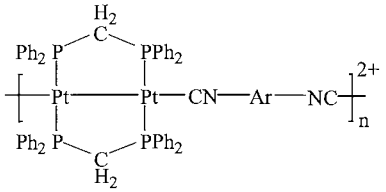
There are relatively few reports on organometallic polymers with metal–metal bonds in their structures. Tyler and coworkers synthesized a number of polyurethanes, 32, amides, and ureas containing photodegradable metal–metal bonds in their backbones by polycondensation reactions.[40] Cross-linked polymers. 33, were also produced by the radical polymerization of vinyl monomers containing Fe—Fe bonds.[40] Cuadrado described the synthesis of silicon-based polymers with iron–iron bonds either within the polymer backbone, as shown in 34, or pendent to the polymer backbone by reaction of polysiloxanes with $Fe(CO)_5$.[41] These polymers had lower solubility compared to the dimer precursors. The thermal gravimetric analysis of Polymer 34 showed initial weight loss at 300°C, however, analogous polymers with Fe—Fe moieties pendent to the polymer backbone showed higher thermal stability due to cross-linking. Puddephatt reported the synthesis of a number of organometallic oligomers and polymers containing Pt–Pt bonds in their backbones.[42] These polymers, containing acetylide, phosphine, or isocyanide. 35, bridges in their backbones exhibited poor solubilities in organic solvents.



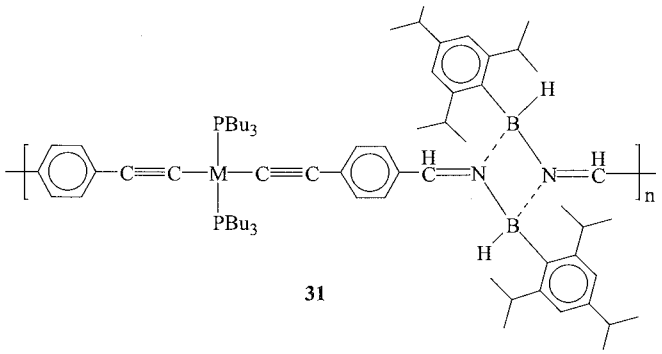
33



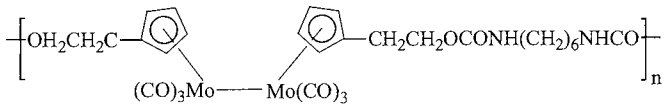
34



35



31



CONCLUSION

The field of organometallic oligomers and polymers received considerable attention over the past two decades. The transition-metal-containing oligomers and polymers described in this article were produced using well-established methodologies. which include olefin, condensation, coordination. and ring-opening polymerizations. While the discovery of new classes of organometallic macromolecules continues to be an important area of research. the focus of many investigations is currently on tailoring the properties of these materials for specific applications. Some of the most widely studied of these properties include electrical, magnetic. and optical properties. There is also considerable interest devoted to exploring the biological properties of organometallic oligomers and polymers.

Stanford University, Stanford, California, U.S.A.

INTRODUCTION

The three classes of blood-oxygen carriers that reversibly bind and store oxygen are hemoglobin(Hb)/myoglobin(Mb), hemocyanin(Hc), and hemerythrin(Hr). Heme, copper. and nonheme iron models, respectively, of these proteins were utilized to target structure and function relationships of the respective active sites for a better understanding of properties and biological functions. Although biomimetic studies need not duplicate the structural or the physical characteristics of the native enzyme, past research shows that careful design of tunable systems helped identify important factors (coordination geometry, nature of ligands, potentials, cooperativity), which in turn have contributed to an understanding of the protein structure. spectroscopy. and mechanism of oxygen binding.[1,2]

In this article. a brief background to oxygen-binding proteins will be presented and recent development of their models highlighted. Reasons underlying differences in dioxygen binding affinities will be emphasized. Particular attention will be given to the hemoglobin family. which has been studied in more detail than any other group of proteins. Although CO binding acts in conjunction with oxygen binding, this matter is not in the scope of this review. and the reader is encouraged to read one of the reviews portraying that subject (e.g., Refs. [3–5]).

BIOLOGY: STRUCTURE, FUNCTION, AND O_2 BINDING OF OXYGEN CARRIERS

Myoglobin and Hemoglobin

The most common reversible oxygen-binding proteins in biological systems are Mb and Hb. This family of globins is found in all vertebrates (except in the Antarctic fish *Cyclostomata*), many invertebrates (including molluscs, annelid worms, and insect larvae). and some plants (leghemoglobin in *Leguminosae*).[3] In 1960, the first high-resolution x-ray crystallographic structures of sperm whale myoglobin[6] and horse hemoglobin A were determined.[7,8] The active site heme in Mb (16 kDa), an iron(II) protoporphyrinIX, is encapsulated in a pocket, where hydrophobic interactions from protein residues hold the heme in place. Iron(II) (high-spin, S=2), coordinated to four pyrrole nitrogens, is bound to the protein via a fifth ligand, a proximal histidine (HisF8), and is located about 0.5 Å from the heme plane in the direction of the histidine. Although invertebrate Hb may have as many as 192 subunits, Mb contains only one heme prosthetic group, while mammalian HbA holds four structurally analogous subunits ($2\alpha + 2\beta$), each with one heme prosthetic group; these four hemes are involved in cooperative dioxygen binding.[3,4]

The most significant property of Hb is its allosteric (cooperative) O_2 binding[3,8] where the Hill constant n is a measure of the degree of cooperative binding. The value for Hb is 2.8. Due to these allosteric interactions of tetrameric hemoglobin, dioxygen binds cooperatively under high O_2 concentrations (--20 mM), allowing the globin to become nearly saturated in the lungs. Oxy-Hb is transported via the bloodstream to areas of low oxygen concentration in muscle tissue, where a thermodynamically favorable O_2 transfer occurs from hemoglobin to myoglobin. The monomeric, predominantly α-helical globular protein Mb stores oxygen during rest until short bursts are required for oxidative phosphorylation, at rates higher than would be provided by the venous oxygen flow. Relative to a noncooperative system. at low O_2 availability, dioxygen release is facilitated; at high O_2 availability, dioxygen binding is facilitated. Binding of O_2 to the vacant sixth coordination site modifies the structure and electronic configuration of the heme. Careful studies indicate that the so-called T or tense state is a low O_2 affinity structure, and the R or relaxed state is a high O_2 affinity structure. The out-of-plane iron atom in the deoxy form is restrained in a T state until the successive O_2 binding relieves the tension as the oxygenated protein adopts the relaxed R state. This cooperativity between heme centers is propagated via structural changes associated with the $T \rightarrow R$ states. The geometry of the bent (120°), end-on O_2 binding mode to the six-coordinate nearly centered (low-spin) iron atom in oxy-Hb was proposed as early as 1936 by Pauling.[9] Crystallographic and spectroscopic studies of native HbO_2 *(2)* and MbO_2 provided evidence for H-bonding between the imidazole N–H of the distal histidine (HisE7) and the bound O_2 of

the polarized $Fe\delta^+-O_2\delta^-$ unit (Fig. 1). The proximity of the terminal O_2 atom to N^{ε} of HisE7 was found to be 2.6 Å in MbO_2, 2.8 Å in HbO_2-α, and 3.5 Å in HbO_2-β subunits. Whereas binding of dioxygen to Mb or to isolated a or β subunits of Hb shows 1:1 association ($Mb + O_2 \rightarrow MbO_2$), the equilibrium uptake of O_2 by tetrameric hemoglobin is more complex due to the cooperative effect of oxygen binding. In addition, the extent of O_2 binding to Mb/Hb depends on several factors: pH (Bohr effect), temperature, partial pressure of oxygen, the proximal ligand, and the phosphate effect (O_2 binding is altered by the binding of an organic phosphate to Hb).

Hemocyanin

Hemocyanins. found in arthropods (e.g., lobsters and scorpions) and molluscs (e.g., octopi and snails), are large multisubunit proteins capable of transporting oxygen. Although the spectral features of the two types of Hc are similar, arthropod Hc is composed of −75 kDa subunits (assembled into hexamers or multiple hexamers), whereas the molluscan Hc consists of −350−450 kDa subunits (assembled into cylinders of five- or 10-fold symmetry). In the arthropod Hc, each subunit contains a single oxygen binding site, while in mollusc Hc. multiple oxygen binding sites are found. In both Hc types, oxygen is reversibly bound at a dinuclear dicopper active site (Cu_A and Cu_B), ligated to N-atoms of three histidines in the protein side chains (**4**).[3,10]

Similar to Hb. hernocyanins demonstrate a high degree of cooperativity in oxygen binding. Chemical and spectroscopic similarities of the mollusc and arthropod forms indicate a closely related active site structure and binding mode. Oxygenation of the dinuclear center alters

the oxidation states from Cu(I) (dl^0, colorless) to Cu(II) (blue) with a consequent geometry modification from trigonal to square planar arrangement. In oxy-Hc, the two closest histidines and two oxygen atoms ($\mu-\eta^2:\eta^2O_2^{2-}$) are coordinated to the copper centers (Fig. 1) (d_{Cu-Cu} = 3.6 Å; $\nu(O-O) \sim 750\ cm^{-1}$; EPR-silent).[10]

Hemerythrin

Hemerythrin is a relatively rare oxygen-carrier protein in marine invertebrates, including sipunculids (nonsegmented worms), annelids (segmented worms), priapulids, and brachiopods (shrimps). It parallels the functions of mammalian Hb and Mb as an O_2 transport and storage protein for invertebrates. Hr exists mostly as an octamer of ~14 kDa subunits. although monomers (myohemerythrin) and oligomers are known with active sites of four-helix bundles. In its asymmetric deoxy-Hr form (Fig. 1), the two Fe atoms, roughly 3.3 A apart. are held in the protein by seven amino acid side-chain residues (five histidines and two carboxylic acid residues). Three histidines are bound to one Fe(II) center and two to the remaining Fe(II). Glutamic acid. aspartic acid. and hydroxide bridge the two metals, yielding an antiferromagnetic coupling between the metals ($J \sim -15\ cm^{-1}$).[3,11]

Upon oxygenation, the colorless protein becomes purple-red. and an asymmetric tribridged diiron(III) is formed with novel features; an oxobridged (Fe–0–Fe) unit ($J \sim -120\ cm^{-1}$), and a terminal end-on Fe(III)–O–O–H unit (6) (hydrogen-bonded to the bridging oxygen atom; $\nu(Fe-OO) = 503\ cm^{-1}$, $\nu(O-O) = 844\ cm^{-1}$). A Bohr effect (release or uptake of protons) is absent in oxygen binding to Hr, ruling out hydroxo-bridged oxy-Hr.[12]

SYNTHETIC ANALOGUES OF O_2 TRANSPORT PROTEINS

Models for Myoglobin and Hemoglobin

Synthetic requirements

Necessary conditions for synthetic models to mimic oxyhemoglobins are formation of a five-coordinate heme precursor with a proximal base (e.g., imidazole, pyridine), prevention of μ-peroxo/μ-oxo (M–O_2–M/M–O–M) dimer formation upon oxygenation (i.e., reversible oxygenation). and exclusion of protons and nucleophiles. Model systems should be easily modified and allow probing of distal and proximal influences. Tetraphenylporphyrins (TPP) serve as the basis of numerous model complexes, because they are less susceptible to oxidation and relatively easy to synthesize. derivatize, and crystallize. Other *meso*- and pyrrole-substituted models have also proven valuable.

The six-coordinate low-spin (d^6) iron(II) gains electronic stabilization relative to the high-spin five-coordinate species due to ligand field stabilization energy. As a consequence, there is a larger equilibrium constant for the addition of the second ligand than for the first, causing the heme to be predominantly six-coordinated. Many approaches were presented to limit six-coordinate formation in models: 1) steric hindrance of the axial base; 2) covalent attachment of the proximal base to the heme backbone; 3) steric hindrance of one (or both) of the heme faces: and 4) preparation of "integrated hemes''—a combination of two or more of these features. Whichever method is utilized, the axial base needs to be a strong σ donor to increase dioxygen affinity at the metal center.

Heme models

The high-spin complexes Fe(TPP)(2-MeIm) (7) and Fe(TpivPP)(1,2-diMeIm) (10) are examples of five-coordinate Fe(II) with sterically hindered axial bases (Fig. 2). Both porphyrins show similarity to the globins (10–11° off-axis tilt of the proximal ligand; 0.5–0.6 Å out-of-plane iron displacement), suggesting that 2-MeIm gives a good model for axial ligation in T-state deoxy-Hb.[8,13] Formation of *bis*(2-MeIm) adducts is never observed at room temperature, even at high ligand concentrations. Another successful approach to five-coordination was achieved by covalent attachment of the axial base to the periphery of the heme (Fig. 2). In these models. an imidazole or a pyridine ligand is often covalently attached through ester or amide linkages to either the propionic acid side chains of the porphyrin sing to the β-pyrrole position of a TPP ring or to the *ortho* position of a *meso* phenyl ring of TPP. Although five-coordination is enhanced via covalent attachment of base to porphyrin, a disadvantage is the possible dimerization into mixed 416-coordinate dimers favored at low temperatures and high concentrations. Chain length and position of attachment have dramatic effects on the ligand-binding properties. A more recent tactic to obtain five-coordinated hemes is the preparation of sterically encumbered porphyrins, wherein the obtained cavity leaves one face of the porphyrin protected and the other open for coordination. A plethora of architecturally distinct model porphyrins following this approach have been studied. e.g., picket fence (10), pocket (BP), *bis*-pocket (17), cyclophane (16), cofacial (two covalently bridged porphyrins). strapped (aliphatic chains). cross-strapped (13), capped (14), crowned (crownether cap). hybrid (combination of picket fence and strap with one

face open), jellyfish (combination of picket fence and strap on opposite faces). picnic basket (**12**), reverse picket fence (both faces picket fence substitution), and dendritic (18) porphyrins.[8,14,15] The binding of the external base highly depends on the size of the host cavity. A large and constrained steric group near the axial position lowers affinity of ligand binding. resulting in a five-coordinate iron. However, formation of a six-coordinate species prior to oxygenation cannot be excluded. because dioxygen is able to replace an axial base in hemochromes. Whereas Fe(II) complexes with 2-MeIm may be considered good analogs of the T state. the Fe(Piv$_2$C8PP) is a reasonable model for the R state of hemoglobin.

Today. the most effective mimics of deoxy-Hb(Mb) are the integrated complexes, which use the both-faces-hindered concept. Within this design, an endogenous nitrogenous base (pyridine or imidazole) is inserted into a proximal strap ensuring a high degree of five-coordinated iron(II). The other sterically hindered distal face inhibits *inter*molecular association. Although synthetic procedures were known, efficient preparation and isolation of the required $\alpha_3\beta$ atropisomer was first reported in 1998. As depicted in Fig. 2, high-spin. five-coordinate ferrous porphyrins were synthesized following this both-faces-hindered concept, including the picket-fence (**19**), capped (**15**), pocket (**21**), and bridged (also called hanging-base, where the base is integrated into the strap; in some instances chiral bridges are used) (**20**). In some cases, distal pickets were designed to accommodate a second metal, thereby modeling bimetallic enzymes such as C*c*O. In other examples, distal *N*-donor caps such as TACN. cyclam, cyclen,[16] or tren were utilized. Studies of these complexes show that the iron(II) coordination environment can be satisfactorily modeled, but that the corresponding O_2 binding strongly depends on the distal and proximal features of the porphyrin.

Oxygen binding

It is essential to understand that oxygen binding to a metal center involves a redox process whereby one electron is transferred to O_2, yielding a superoxide complex. Correspondingly, when two metal centers bind O_2, a bridging peroxide complex is formed. Only appropriate redox centers such as Fe(II), Co(II), and Cu(I) form dioxygen complexes; dioxygen is not a simple Lewis base.

In hemoproteins, dioxygen is bound and released at a rapid rate, and the polypeptide chain surrounding the heme prevents irreversible autoxidation of iron(II). Simple ferrous porphyrins tend to undergo rapid and irreversible autoxidation upon oxygenation (usually yielding an inactive metal in a higher oxidation state), which limits their use as models for hemoprotein active sites. This review portrays reversible models of O_2 binding, thus, only models that undergo repeated oxygenation1 deoxygenation cycles without appreciable loss of activity will be discussed.

The first thoroughly studied iron porphyrin model was picket fence porphyrin (10), which binds O_2 reversibly and yields dioxygen equilibrium affinities values similar to those exhibited by Hb/Mb. Other systems that reversibly bind dioxygen at room temperature with limited oxidation over several cycles are the capped (14) and *bis-pocket*[17] porphyrins. Although O_2 affinities in biological carriers span five orders of magnitude, the same wide range of O_2 affinities has not yet been paralleled in synthetic systems, which is demonstrated in Tables 1 and 2. However, the numerous iron and cobalt porphyrin mimics prepared during the past 30 years have played an important role in developing the understanding of dioxygen binding in the two native enzymes.

dioxygen affinity, principally by slowing the dioxygen dissociation rates. The dipolar nature of $Fe\delta^+-O_2\delta^-$ is stabilized by polar solvents (nearby the reaction center) and by covalently bound polar groups near the iron center, indicating that O_2 affinities are enhanced by polar environments and by hydrogen bonding to neighboring X–H groups (Fig. 3). For instance, the two sterically similar models Fe(TpivPP)(1,2-diMeIm) (10) and Fe(*bis*-Poc)(1,2-diMeIm) (17), show $P_{1/2}(O_2)$ values of 38 torr and 508 torr (toluene). respectively. The higher O_2 affinity of Fe(TpivPP) is attributed to local polar effects (and B-bonding) arising from the picket amide groups. In recent studies of dendritic ferrous porphyrin models,[15] derivatives with and without H-bond donor functionality were prepared. Dendrons with amide groups show strong O_2 binding affinity [$P_{1/2}(O_2) = 0.035$ torr/toluene], whereas dendrons with ester groups lead to rapid irreversible decomposition. In structurally characterized oxyhemoglobins, the coordinated dioxygen ligand is hydrogen bonded to the distal histidine or a water molecule. This O_2–HN interaction was supported by EPR spectroscopy measurements of cobalt oxyhemoglobin.[17] An estimate of 1.5 kcal/mol for the free energy associated with hydrogen bonding was reported when O_2 binding constants were compared between native and mutant myoglobins.[18]

Proximal and Distal Steric Effects. Similar to Hb, R and T states can be induced in heme models by intentional choice of proximal bases. If 1-MeIm is replaced with 2-MeIm or 1,2-diMeIm, the planar heme

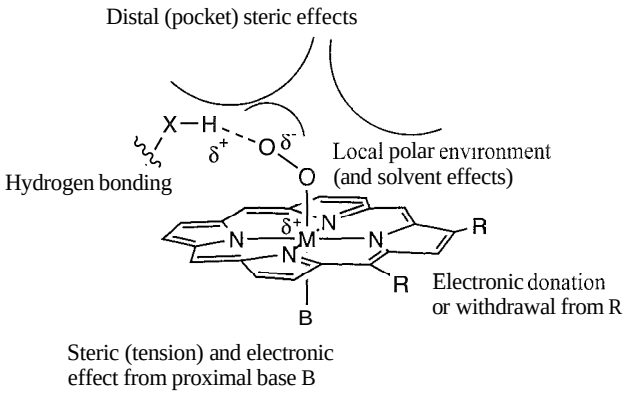

Fig. 3 Environmental effects on dioxygen binding to a heme model.

geometry is deformed due to steric interaction between the 2-methyl groups and the porphyrin ring. A steric deformation also occurs with a short chain in a chelated heme, which causes tilting of the proximal base and thus strain in the iron–imidazole bond. Such strain decreases association rates. increases dissociation rates, and, consequently, decreases dioxygen affinity. For example, Fe(C2Cap)(1-MeIm) (14) has 10^2 higher affinity for dioxygen than does Fe(C2Cap)(1,2-diMeIm) [$P_{1/2}(O_2)$ = 23 and 4000 toss, respectively].[3] In hemoglobins, low-affinity O_2 binding appears to be associated with the inability of the Fe-histidine(proximal) unit to move toward the plane of the porphyrin.

In addition, when dioxygen is absent, x-ray structural studies of heme proteins reveal that nearby lying side-chains occupy some of the space that would otherwise be required by O_2. Hence, O_2 binding rate constants decrease according to the distal sizes of the heme pockets: hemoglobin (R state) > myoglobin (domed T state) > horseradish peroxidase.[4] Comparable results were found for heme models, where O_2 binding rates are influenced by distal sterics. Typically, pocket, strapped, and capped porphyrins exhibit lower rates of O_2 binding than open-faced and picketed ones. In comparison. Fe(TpivPP)(1,2-diMeIm) (10) binds dioxygen 50 times faster than Fe(PocPiv)(1,2-diMeIm) (11).[3]

Other hemoglobin models

Paralleling the Fe(II) systems, studies of Co(II)Mb and Co(II)Hb reveal reversible dioxygen binding [CoMb (sperm whale): $P_{1/2}(O_2)$ = 33 torr/20°C], a similar degree of cooperativity (n ~ 2.5), and retaining of Bohr and phosphate effects. Cobalt porphyrin complexes prove useful in understanding factors that determine oxygen binding in Hb and Mb. The advantages of choosing cobalt over iron include a small equilibrium constant for addition of a second axial base, no **O–O** bond cleavage and dimerization to form a μ-oxo species, and stable paramagnetic $Co–O_2$ adducts characterized by EPR. These differences simplify the interpretation of spectral changes upon oxygenation. The O_2 affinity is generally lower for cobalt than for iron but increases with greater axial ligand basicity or electron-donating groups on the porphyrin ring. The same effects that influence dioxygen affinity in cobalt systems are often found for iron. These effects and many examples thereof are discussed in comprehensive reviews.[19,20] Other synthetic $Co–O_2$ models were used to obtain thermodynamic and kinetic parameters that may be extrapolated to iron systems. Among these. the "lacunas" complexes, i.e., compounds with a cavity or void to accommodate O_2 or another small ligand, were studied.[21] Macrocyclic Schiff-base (bridged or non-bridged) Co and Fe complexes of salen, cyclidene, malen, and oxime were investigated. and their dioxygen affinities were shown to be influenced by cavity size (bridging length/group/location; causing doming), macrocycle substituents (steric and electronic effects), and nature of base (the stronger the base, the higher the O_2 affinity) in a similar manner to porphyrin systems.

Models for Hemocyanin

During the past 20 years, the dicopper active site of Hc attracted the attention of inorganic and bioinorganic chemists. In order to understand the complex behavior of copperldioxygen chemistry, synthetic dicopper models were prepared, and their spectroscopic and magnetic properties were elucidated upon oxygenation (e.g., Refs. [22,23]). Whereas μ-oxo and *bis*-μ-oxo dicopper centers are frequently observed in $Cu(I)/O_2$ chemistry. the μ-peroxo dicopper adducts are more difficult to obtain. In 1992, the unusual $Cu_2[HB(3,5\text{-}i\text{Pr}_2\text{pz})_3]_2(O_2)$ (22) complex was synthesized and characterized.[24] The peroxo-dicopper(II) adduct is generated at reduced temperatures by reacting O_2 with $Cu(I)[HB(3,5\text{-}i\text{Pr}_2\text{pz})_3]\text{-}CH_3CN$, or via an acid-base reaction of hydrogen peroxide with $Cu(II)[HB(3,5\text{-}i\text{Pr}_2\text{pz})_3]\text{-}bis\text{-}\mu\text{-}(OH)_2\text{-}Cu(II)[HB(3,5\text{-}i\text{Pr}_2\text{pz})_3]$. An unprecedented side-on-bound $\mu\text{–}\eta^2\text{:}\eta^2$ bridged O_2 binding mode was observed. The physical and spectroscopic properties of 22 [d_{Cu-Cu} = 3.56 A: $\nu(O–O) = 741\ cm^{-1}$ ($^{16}O_2$), 698 cm^{-1} ($^{18}O_2$)] were found to be almost identical to those in oxy-Hc. In a series of functionalized TACN-capped Cu(I) complexes, the binuclear complex (1,4,7-*i*Pr$_3$-TACN)-Cu(II)-($\mu\text{–}\eta^2\text{:}\eta^2$–$O_2$)-Cu(II)-(1,4,7-*i*Pr$_3$-TACN)$^{2+}$ was formed when treated with O_2 at −80°C in dichloromethane [$\nu(O–O) = 722$ cm ' ($^{16}O_2$), 680 cm^{-1} ($^{18}O_2$)].[25] Dioxygen binding could be reversed by warming under vacuum or by purging with N_2 or Ar. A reversible scission and formation of the **O–O** bond was observed between the two cores $[Cu\text{-}(\mu\text{-}O)_2\text{-}Cu]^{2+}$ and $[Cu\text{-}(\mu\text{–}\eta^2\text{:}\eta^2\text{–}O_2)\text{-}Cu]^{2+}$. It is unclear how different solvents, counterions, and TACN ligand substituents induce preferential stabilization of these forms. Reversible dioxygen binding was reported for the Cu(I)TMPA system.[26] A structurally characterized trans-1.2-peroxo dicopper(II) complex (23) was isolated [d_{Cu-Cu} = 4.359 Å; $\nu(O–O) = 832\ cm^{-1}$. $\nu(Cu–OO) = 561\ cm^{-1}$]. An initial transient adduct, $[(TMPA)Cu–O_2]^+$, is formed at 183 K ($k_1 = 2 \times 10'\ M^{-1}\ s^{-1}$; $K_1 = 1.9 \times 10^3\ M^{-1}$), which yields the final stable product 23 upon reaction with another $[(TMPA)Cu–CH_3CN]^+$ complex ($K_{formation} = 4.3 \times 10^{11}\ M^{-2}$). Compound 23 is not stable at room temperature due to an unfavorable entropy term. The $[LCu(II)\text{-}(\mu\text{–}\eta^2\text{:}\eta^2\text{–}O_2)\text{-}Cu(II)L]^{2+}$ complex (24) (E = 1,2-*bis*{2-[*bis*(6-methyl-2-

pyridyl)methyl]-6-pyridyl}ethane) (25°C, dichloromethane), which shows reversible dioxygen binding, is presently the most stable peroxo-bridged dicopper species at room temperature ($t_{1/2} = 25.5$ h).[27] Other dinucleating ligands show reversible dioxygen binding, but usually at low temperatures (e.g., Ref. [10]). To conclude, temperature. solvent, counterion, and steric effects strongly influence the oxygenation of copper complexes. Tridentate ligands tend to facilitate side-on O_2 binding, while tetradentate donor ligands promote *trans*-μ-1,2-peroxo coordination. Changes in reactivity upon modification of donor atoms, chelate ring sizes, and bulky substituents indicate the importance of ligand effects in copper(I)/O_2 chemistry.

Models for Hemerythrin

The protein backbone in Hr has an important role of bringing together the asymmetric diiron(III) nucleus. Although many μ-oxodiiron(III) complexes exist, only a few are asymmetric (e.g., Ref. [28]) due to synthetic challenges. Few nonporphyrinic ferrous complexes were found to react with dioxygen to form stable adducts, and only a handful of these exhibit reversible dioxygen binding. One of the more robust nonheme iron dioxygen complexes is the peroxo-bridged {Fe(III)[HB(3,5-*i*Pr_2pz)$_3$]}$_2$(O_2) biscarboxylate adduct (25), which exhibits O_2 binding reversibility between −50 and −20°C in noncoordinating solvents (Fig. 4).[29] The resonance Raman spectrum of 25 shows an O–O stretch at 876 cm^{-1} ($d_{Fe-Fe} = 4.3–4.4$ Å; $J = -33$ cm^{-1}) and is supported by $^{18}O_2$ isotope shifts. The steric bulk of the tridentate ligand is believed to be responsible for the added stability. Another complex, the diiron HPTMP (26). exhibits reversible dioxygen binding [$P_{1/2}(O_2) = 42$ torr and 6 torr for the CF_3COO^- and $PhCOO^-$ complexes. respectively] at −35°C in dichloromethane.[30] From stopped-flow measurements. internal ligand rearrangement is postulated to open a coordination site for dioxygen coordination prior to peroxide bridge formation. Moreover, small amounts of DMSO or other polar aprotic solvents have a stabilizing influence on 26, although the reason for this effect is uncertain. The diiron complex of the dinucleating ligand MTPPDO (27) creates hydrophobic pockets via *tert*-butyl groups, mimicking the hydrophobic peripheral structure of the active site of Hr.[31] Fe(II)$_2$HTPPDO and benzoate in acetone manifest reversible O_2 binding at −50°C, where the peroxo anion binds to the Fe_2 core in a μ-1,2 bridging mode [ν(O–O) = 873, 887 cm^{-1}; Δν($^{16}O_2$/$^{18}O_2$) = 48, 48 cm^{-1}]. The thermodynamic stability and reversible O_2 binding of this rare asymmetric Hr model are proposed to depend on the hydrophobic environment over the diiron center rather than the iron redox potentials.

CONCLUSION

In order to enhance dioxygen delivery and storage in respiratory and metabolic processes. biological systems developed O_2 carriers that reversibly coordinate O_2 to a transition metal (Fe or Cu) bound to a protein. Many of the attributes of the oxygen-binding proteins have been reproduced with well-designed functional models. Hemoglobin and myoglobin are fairly well understood due to significant development in model studies. Additional work can be anticipated in nonheme iron and copper synthetic analogues.

Peptide Nanotubes

Carl Henrik Görbitz
University of Oslo, Oslo, Norway

INTRODUCTION

The first peptide that formed a tubular arrangement in the crystal structure was the cyclic tetrapeptide L-Ser(*O*-*t*-But)-β-Ala-Gly-L-β-Asp(OMe), presented as far back as in 1975,[1] but it was the breathtaking image on the front page of the November 25 issue of *Nature* in 1993, showing self-assembly of cyclic octapeptides by β-sheet-like hydrogen bonds[2] that made the scientific community aware of the new class of nanotube-forming compounds. In the years that passed. further research on these systems revealed a series of intriguing properties, including membrane incorporation that leads to antibacterial activity.[3] Construction of channels as models for membrane pores is one of the key issues in studying peptide nanotubes, but they may also find use as transport vehicles, in catalysis, and as artificial receptors. Such a diversity is possible due to the subsequent discovery of yet other classes of nanotube-forming peptides. with internal van der Waals' diameters ranging from 3–10 Å for hydrophobic dipeptides up to 10,000 Å (1 μm) for surfactant-like peptides and peptide derivatives.

CLASSIFICATION OF PEPTIDE NANOTUBES

Peptide-based nanotubes can be constructed in several different manners depending on the sizes and types of molecular building blocks:

- Nanotubes from the rtacking of cyclic peptides
- Nanotubes from dipepiides
- Naturally occurring peptide membrane channels
- Amphiphilic surfactant-like nanotubes
- Bolamphiphilic peptide nanotubes

NANOTUBES FROM THE STACKING OF CYCLIC PEPTIDES

Cyclic peptides with an even number of α-amino acids can adopt a flat. low-energy conformation in which all backbone amide functionalities are oriented approximately perpendicular to the plane of the molecule. If. furthermore, an alternating sequence of D- and L-amino acids is used. all peptide side chains lie on the outside of the ensemble, allowing formation of a hollow tubular structure through formation of intermolecular β-sheet-like hydrogen bonds as shown in Fig. 1. The first evidence of nanotube formation by stacking of cyclic α-peptides was provided by Ghadhiri and coworkers for cyclo[(D-Ala-L-Glu-D-Ala-L-Gln)$_2$-], a structure that was going to coin the expression ''peptide nanotube.''[2] Early work on these systems was reviewed in Ref. [4].

A wide range of applications was predicted for cyclic D,L-α-peptide nanotubes. Theoretical calculations have, for instance, indicated a wide HOMO–LUMO gap (−5 eV), which suggests that this material can be engineered to yield useful microelectronic devices.[5] Still. the most important property is undoubtedly their ability to be integrated into lipid membranes and thus act as models for biological transmembrane channels. With recent results from experiments on bacteria, this research has taken a dramatic step forward by demonstrating that appropriately designed peptides may be able to selectively target and self-assemble in bacterial membranes and create extensive damage by increasing the membrane permeability.[3] Each peptide was designed to bear at least one basic residue to enhance its target specificity toward negatively charged bacterial membranes. Systematic exchange of amino acids showed that it was possible to fine-tune the biological activity. For example, cyclo(D-Lys-L-Lys-D-Leu-L-Trp-D-Leu-L-Trp) displayed broad-spectrum antibacterial activity in vitro, while cyclo(D-Lys-L-His-D-Leu-L-Trp-D-Leu-L-Trp) (L-Lys substituted by L-His) showed a high degree of specificity against methicillin-resistant *Staphylococcus aureus* (MRSA). Cyclo(D-Arg-L-Arg-D-Leu-L-Trp-D-Leu-L-Trp), on the other hand, was particularly active against *Escherichia coli*. In these experiments, essentially no disruptive effect on red blood cells was observed. Moreover, the bacteria were killed in minutes, in contrast to the timescale of hours for most antibacterial agents. Experimental in vivo results showed that mice infected with a lethal dose of MRSA were protected by a 10 mg k g ^{1} dose of cyclic peptide. Toxicity studies in mice indicated that high doses were tolerated with no or limited, temporary signs of toxicity.[3]

The remarkable pores of the cyclic octapeptides have a van der Waals' internal diameter between 7 and 8 A,

Encyclopedia of Supramolecular Chemistry

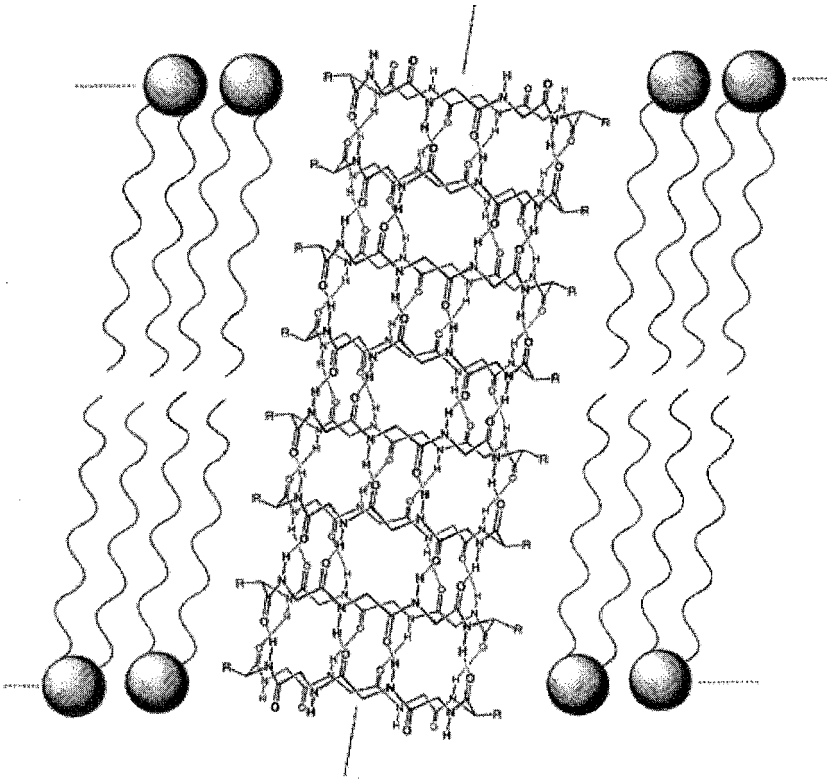

Fig. 1 The assembly of cyclic D,L-α-octapeptides in a lipid bilayer. Antiparallel β-sheet-like hydrogen bonds are shown as dotted lines. Reprinted with permission from Ref. [9]. Copyright 1998 American Chemical Society.

enough to allow efficient, size-selective transport of small ions[6] and water molecules. The organization and diffusion of water molecules through the channels were studied by molecular dynamics simulation of a stack of 10 peptide molecules.[7] During the simulation, an average of 33 water molecules were found inside the tube. while the diffusion constant was $0.44 \times 10^{-5}\ cm^2\ s^{-1}$: one sixth of the self-diffusion constant of bulk water and much faster than diffusion through the structurally related gramicidin A transmembrane channel (see below). Transmembrane transport of larger molecules. like glutamate and glucose, is not possible with a 7–8 Å pore size, but they are transported through channels formed by decapeptides with a 10 Å van der Waals' diameter.[8]

In the first models of incorporation of cyclic peptide stacks in membranes, a perpendicular orientation of the central axis of the nanotubes relative to the bilayer plane was assumed. Subsequent investigations of cyclo[(L-Trp-D-Leu)$_3$-L-Gln-D-Leu-] in functionally relevant lipid membranes by polarized attenuated total reflectance (ATR), grazing angle reflection–absorption and transmission Fourier transform infrared (FT-IR) techniques showed that this is not quite so.[9] In fact, their central axes are aligned parallel to the hydrocarbon chains of the lipid and are. thus. tilted approximately 7° from the axis normal to the bilayer plane, as shown in Fig. 1.

The two subunits at the ends of the channel assembly. termed "caps," differ from other subunits by their mode of interaction and the microenvironment in which they reside, which should make it possible to incorporate structurally distinct peptides as cap units.[10] Various experimental observations derived from single-channel conductance measurements support formation of such heteromeric noncovalent assemblies. It was suggested that such an approach may find utility in the design of ligand-gated channels and stochastic sensing.[10]

Cyclic tetramers of α-unsubstituted-β-chiral-β-amino acids (β^3-amino acids) can also adopt flat-ring conformations and stack in solid state through backbone–backbone hydrogen bonding.[11] The resulting hollow tubular ensembles are structurally analogous to those formed by the cyclic D,L-α-peptides, but because all C=O groups are aligned in the same direction (and vice versa for the N–H groups), the tubes have a dipole moment. Cyclic β^3-peptides with appropriately chosen hydrophobic side chains can self-assemble in lipid bilayers to form highly efficient transmembrane ion channels.[12]

A recent development of hybrid systems utilizes cyclic peptides in which (1*R*,3*S*)-3-aminocyclohexanecarboxylic acid alternates with D-x-amino acids. In such structures. the β-methylene moiety of each cyclohexane constitutes a part of the inner surface of the cylinder. creating a partially hydrophobic cavity with an approximate van der Waals' internal diameter of 5.4 Å.[13] By adding functional groups to C2, it should be possible to prepare nanotubes with greater selectivity as ion channels, catalysts, or receptors, a possibility that is precluded for a- and β-nanotubes, because all side chains lie on the exterior of the ensemble.

The very low solubility of the cyclic peptides has frustrated all attempts to grow crystals of a useful size for single-crystal x-ray diffraction investigations; structures have, in general, been characterized by electron microscopy. electron diffraction, calculations, FT-IR spectroscopy, and x-ray powder diffraction. The need for a high-resolution structural model was addressed by designing cyclic peptides with a selectively *N*-alkylated (usually *N*-methylated) backbone that blocks peptide aggregation. Several of these compounds were shown to self-assemble into discrete soluble cylindrical dimers in nonpolar organic solvents (Fig. 2a).[14,15]

The inherent solubility problem of the cyclic peptides was overcome by construction of special cyclic tripeptides made from unsaturated δ-amino acids. The resulting lipophilic lactams could easily be crystallized by diffusion (ethanol and diethyl ether). X-ray data[16] confirmed the expected tubular structure (Fig. 2b). with all the carbonyl groups pointing in the same direction. giving, as for the cyclic β^3-peptides,[11,12] a dipole arrangement. Furthermore. the highly polarized tubes orient in the same direction in the whole crystal, yielding an extremely strong dipole.

Incorporation of small aromatic units into the backbone of a cyclopeptide constitutes an alternative approach in creating flat-ring peptides. Thus, 18-membered macrocycles containing an alternating sequence of L-serine and aromatic (Phe or Pyr) units were demonstrated to self-assemble into tubular structures using aromatic Phe-Pyr and Pyr-Pyr π–π interactions as the main organizing force.[17] New classes of cystine-based nanotubes were constructed by closing polymethylene chains by -X-Cys-S-S-Cys-X- bridges, where the link X may be urea functionalities (cyclic bisureas.[18]) or simple amide bonds (cyclobisamides[19]).

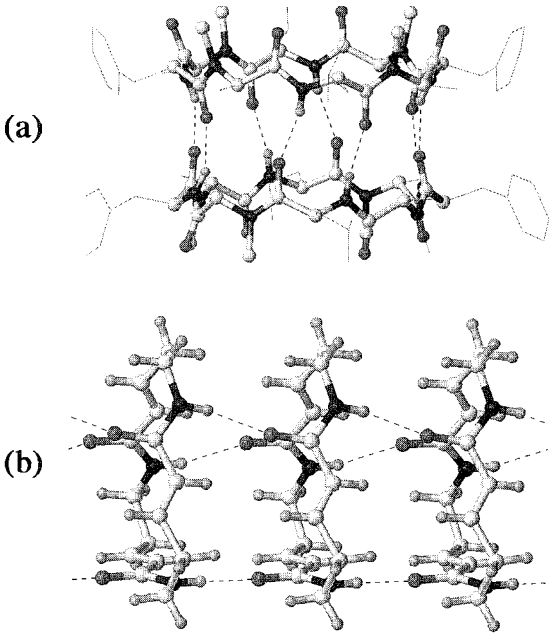

Fig. *2* (a) Dimeric β-sheet assembly formed by cyclo[(L-Phe-D-^{Me}*N*-Ala-L-Leu-D-^{Me}*N*-Ala)$_2$-].[15] For clarity. stick drawings were used for heavy atoms in the side chains. (b) Alignment of dipoles by stacking cyclic tripeptides built from 6-amino acids. (From Ref. [16].)

NANOTUBES FROM DIPEPTIDES

Crystal structures of dipeptides are often divided into distinct hydrophilic and hydrophobic layers. the former containing two $-NH_3^+\cdots{}^-OOC$ head-to-tail hydrogen-bonded chains. The essential third amino H atom is accepted by a functional group in one of the side chains or in a cocrystallized solvent molecule. In solvent-free crystals of dipeptides with two hydrophobic residues. neither alternative is available. which raises an inherent packing problem: How can three acceptors still be positioned around each amino group? A series of crystal structures revealed a number of ways to solve this problem. one of them being the surprising formation of nanotubes.

The first dipeptide nanotube system was L-Val-L-Ala (VA), which forms crystals with narrow hydrophobic channels (diameter about 5 Å) lined by peptide side chains.[20] This structure is conceptually different from those of the cyclic peptides in that the pores are generated from self-assembly of small molecules. which are hydrogen bonded. head-to-tail, into helices (Fig. 3a). The extremely robust three-dimensional hydrogen-bonding scaffold was since observed for a series of other hydrophobic dipeptides.[21] Pore size can be regulated from 3.3 Å (L-Ile-L-Val) to 5.2 Å (L-Ala-L-Val) by adjusting the bulk of the hydrophobic side chains. Furthermore, L-Ala-L-Val has pores that can adapt their shapes and sizes to absorb large solvent molecules like 2-butanol.[22]

Dipeptides with L-Leu and L-Phe residues also form nanotubes, but these structures are completely different from those in the VA class. In a sense. the basic construction of the VA class was wrapped inside-out. giving a

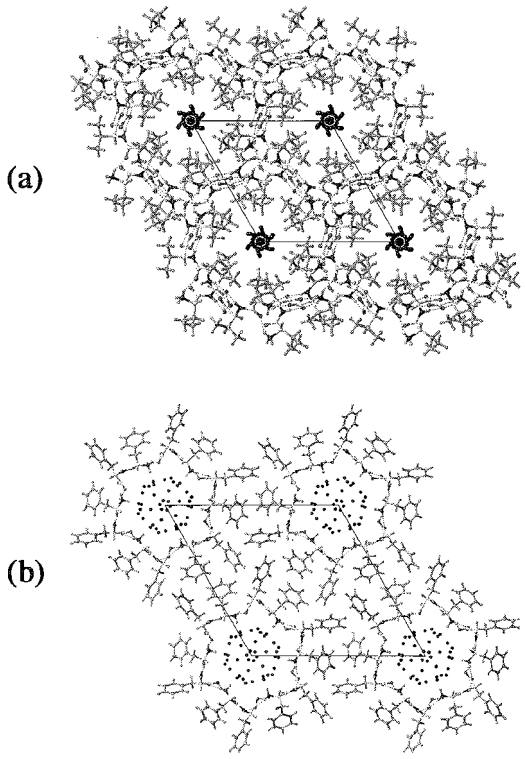

Fig. 3 Views along the hexagonal axes (space group $P6_1$) of (a) L-Val-L-Val[21] and (b) L-Phe-L-Phe.[23] Atoms in the side chains are shown in a grey tone; refined positions for oxygen atoms of disordered water molecules are shown in black.

one-dimensional hydrogen-bonding pattern in the shape of cylinders. as shown for L-Phe-L-Phe (FF) in Fig. 3b.[23] It follows that the tubes have hydrophilic inner surfaces, and one of the amino H atoms points straight into the channel interior, where it is accepted by a disordered solvent water molecule. Because the interior is chiral, it was suggested that these structures may act as chiral receptors or selectors.[23] For L-Trp-Gly·H_2O (WG), which forms crystals with tecragonal symmetry also belonging to the FF class, an unusual negative thermal expansion (NTE) for the axis parallel to the channels was observed.[24]

NATURALLY OCCURRING PEPTIDE MEMBRANE CHANNELS

Biological membrane channels are formed not only by integral membrane proteins like porine but also by certain peptides antibiotics called ionophores that vastly increase the permeability of membranes to particular ions.[25] The antibiotic properties of ionophores arise from their tendency to discharge vital concentration gradients. The principal channel-forming peptides are gramicidin A and the peptaibol peptides.

Gramicidin A

Gramicidin A is a linear 15-residue hydrophobic peptide produced by the bacterium *Bacillus brevis* that permits passage of protons and alkali cations but is blocked by Ca^{2+}. The amino acid sequence is HCO-L-Val-Gly-L-Ala-D-Leu-L-Ala-D-Val-L-Val-D-Val-L-Trp-D-Leu-L-Trp-D-Leu-L-Trp-$NHCH_2CH_2OH$. The unique alternating L- and D-configurations make gramicidin A an obvious reference and benchmark for the properties of the cyclic D,L-α-peptides discussed previously. There was some discussion about the structure of the peptide in its conducting, membrane-bound state. Previously, most models involved a head-to-head dimer of two single-stranded helices, but the most recent crystallographic investigations report gramicidin A to occur as right-handed double-stranded double-helical dimers, as shown in Fig. 4.[26] The ion-conducting channel has a van der Waals' diameter of no more than 4.6 Å.

Peptaibol Peptides

Alamethicin is a 20-residue peptide from the fungus *Trichoderma viride* that contains a high proportion of the unusual amino acid x-aminoisobutyric acid (Aib). As for gramicidin A. both termini are blocked, and the amino acid sequence is Ac-Aib-L-Pro-Aib-L-Ala-Aib-L-A~~-L-Gln-Aib-L-Val-Aib-Gly-L-Leu-Aib-L-Pro-L-Val-Aib-Aib-L-Glu-L-Glu-L-Phl (Phl=phenylalaninol). Peptides with high Aib (and Pro) content have a marked propensity to form helices. Indeed, crystal structure determinations of alamethicin and the related peptaibol peptides Leu-zervamincin and antiamoebin[27] show that these molecules are predominately x-helical. It follows from the secondary structure of the peptide chains that the mechanism of channel formation must be completely different from that of gramicidin A. In the crystal structure of antiamoebin,[27] three symmetry-related peptide molecules in bent conformations apparently form hourglass-shaped channels. One cocrystallized octanol molecule mimics a membrane segment along the exterior of the channel assembly, while a second octanol molecule resides inside the channel.

AMPHIPHILIC SURFACTANT-TYPE NANOTUBES

While all peptide nanotubes considered thus far have fairly small pores (up to 13 Å van der Waals diameter for cyclic D,L-α-dodecapeptides[4]), nanotubes in a completely

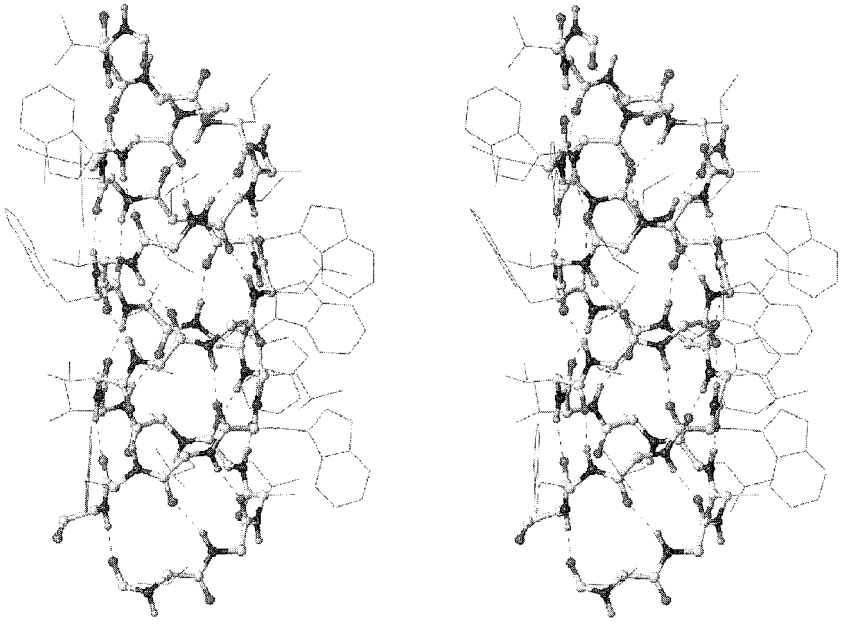

Fig. 4 Stereo illustration of the right-handed double-stranded helical dimer of the pentadecapeptide antibiotic gramicidin A.[27] The inner channel has a diameter of approximately 4.6 A. For clarity, heavy atoms in the side chains are shown in a stick representation.

different size range with typical diameters of *300–500* Å can be formed by several surfactant-like peptides. thus broadening the diversity of building blocks of self-assembling peptides for scaffolds and biological materials.[28,29] The peptide monomers contain seven or eight residues. with a hydrophilic head composed of aspartic acid and a tail of hydrophobic amino acids. such as alanine. valine, and leucine. The length of each peptide is the same as that of biological phospholipids, about 20 A. A model for nanotube formation by the heptapeptide Ac-(L-Val)$_6$-L-Asp is shown in Fig. 5. Studies of peptide surfactant molecules may have significant implications for the development of scaffolds and biologically inspired materials.

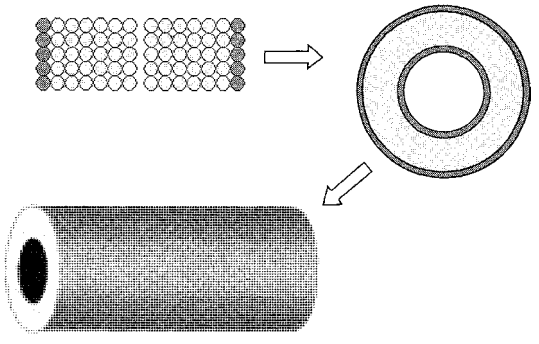

Fig. 5 Suggested pathway of Ac-(L-Val)$_6$-L-Asp peptide nanotube formation Peptide molecules interact with one another to form closed rings. which ultimately yield nanotubes upon stacking

BOLAAMPHIPHILIC PEPTIDE NANOTUBES

Molecules like *bis*(*N*-α-amido-Gly-Gly)-1,7-heptane dicarboxylic acid (Fig. 6) belong to a class of compounds called bolaamphiphiles that form tubular aggregates at low pH.[30,31] These peptide nanotubes have diameters in the range of 200–10,000 Å (1 μm) and are thus comparable in size to those of the surfactant molecules, but hydrogen bonds rather than hydrophobic interactions are responsible for self-assembly (Fig 6). Each bolaamphiphile peptide contains at least one free ainide site in the tubule assembly. which may interact with protein molecules. At high pH. the carboxpl groups gradually lose their acidic H atoms, and the acid–acid dimer is replaced by anion–acid hydrogen bonds (COO –H– OOC). This hydrogen-bonding modification triggers a molecular rearrangement that eventually leads to transformation of tubes into helical ribbons. These observations suggest that the bolaamphiphiles could be useful in controlled release applications. with the pH-dependent structural transformations serving as simple release mechanisms.[31] In the presence of Ni^{2+} ions. macroscopic bundles of well-ordered peptide nanotubes are assembled,[32] probably driven by the ability of adjacent nanotubes to form metal coordination bridges.

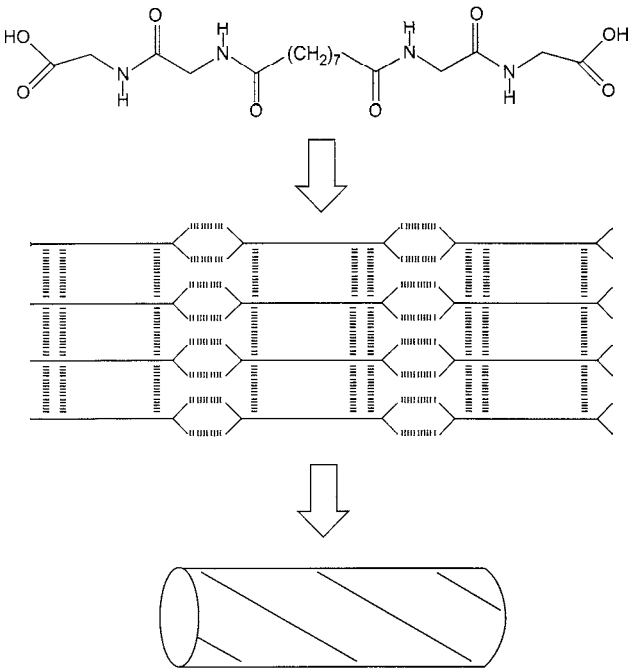

Fig. 6 Self-assembly of *bis*(*N*-α-amido-Gly-Gly-1,7-heptane dicarboxylic acid) into sheets and then into nanotubes by formation of acid diiners and amide–amide hydrogen bonds. (From Refs. [31,32].)

CONCLUSION

Nanotubes constructed by peptides comprise a promising group for development of membrane-mimics, antibiotics, carriers, electronic devices, sensors, scaffolds, and biological materials. Future areas of interest may include catalysis and use as chiral selectors. Except for the surfactant-like peptides, the driving force in the self-assembly process is formation of hydrogen bonds. As the knowledge of and experience with hydrogen bonds as design tools are developed further, new avenues will open to the development of classes of materials different than those discussed here. in the solid phase (crystal engineering) as well as in solution.

Phase-Transfer Catalysis in Environmentally Benign Reaction Media

Silvio Quici
Amedea Manfredi
Gianluca Pozzi
CNR-Istituto di Scienze e Tecnologie Molecolari, Milano, Italy

INTRODUCTION

Phase-transfer catalysis (PTC) was discovered more than 30 years ago,[1-3] but this powerful means of conducting reactions between two or more reactants present in two or more immiscible phases still attracts considerable scientific and practical interest. Nowadays, the term PTC encompasses several effective techniques of which typical advantages are simplicity, mild conditions, high reaction rates, high selectivities, and the use of inexpensive reagents. The interested reader is encouraged to refer to some books[4-7] and reviews[8-14] for a thorough survey. which is far beyond the scope of this brief article, where the basic principles of PTC and a few recent advances toward the use of safe and environmentally acceptable reaction media in combination with PTC will be outlined.

GENERAL PRINCIPLES

Liquid–Liquid PTC

Anionic reactivity can be promoted by dipolar aprotic solvents such as hexamethylphosphoramide (HMPA), dimethylsulfoxide (DMSO), and dimethylformamide (DMF), which dissolve inorganic salts by selectively solvating the cation. while the unsolvated anion becomes highly reactive.[15] This traditional approach is no longer appealing due to the considerable pressure to replace toxic and environment-detrimental reaction media. Dipolar aprotic solvents can be highly toxic and generally exhibit high boiling points and water solubility. making their recovery and product separation difficult. From its emergence, PTC aimed to perform anion-promoted reactions under mild multiphase conditions. usually in liquid/liquid "aqueouslorganic" or solid/liquid "solid salt/organic'' two-phase systems, thus avoiding the use of hazardous solvents. The basic idea is that solubilization of the anion in a low-polarity organic solvent and activation by decreasing the coulombic interaction with the cation are two primary requisites for high anionic reactivity. The PT catalyst fulfills both functions, forming lipophilic ion pairs A^+B^-, in which A^+ is a large organic or organometallic cation (e.g., tetraalkylammonium, tetraalkylphosphonium, or alkali metal complexes of cryptands and crown ethers), and B is the anion. The large size accounts for the low charge density on the surface of the cations: accordingly, interactions with the anion are strongly reduced, and this leads to increased anionic reactivity.

The first PTC mechanism proposed by Starks assumed that the catalyst, an ammonium or phosphonium salt (Q^+X^-), is partitioned between two immiscible liquid phases. In this way, the reacting anion X^- is transferred from the aqueous to the organic phase. where the reaction occurs, and the product anion Y^- is released in the aqueous phase (Fig. 1).[3]

Subsequently. it was found that the catalytic efficiency of a quaternary salt is directly related to its solubility in the organic phase, other conditions being the same. This and other observations support the mechanism reported in Fig. 2, in which anion transfer does not necessarily require the partitioning of the quaternary cation, the charge parity in both phases being ensured by the quaternary and the metal cation. respectively.[16,17]

This mechanism also applies when lipophilic crown ethers or cryptands are used as catalysts. The extent of anion extraction into the organic phase and its reactivity depend on the combination of many parameters, including the nature of the anion (its charge. size. polarizability, etc.). the concentration of the inorganic salt in the aqueous phase. the dielectric constant of the organic solvent: the separation between cation and anion in the ion pair. and the number of water molecules associated with the anion in the organic phase. The influence of these parameters on the reaction rate was exhaustively discussed.[18]

Solid–Liquid and Gas–Liquid Phase-Transfer Catalysis

Under classical aqueouslorganic PTC. a small amount of water is also extracted into the apolar organic phase. mainly as a specific solvation sphere of the anion. The

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012709

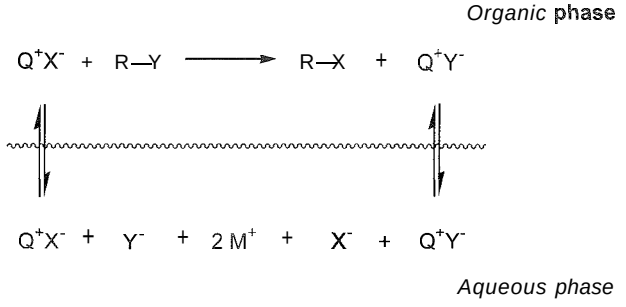

Fig. 1 Basic PTC mechanism. Adapted from Ref. [3].

presence of water. besides reducing reaction rates. may produce undesired side reactions that can be avoided by using a solid salt suspended in an anhydrous organic solution of the substrate as a source of the nucleophile. Under these conditions. the PTC catalysts transfer the anion as a reactive ion pair from the surface of the solid into the organic phase. Solid–liquid conditions are particularly suitable for reactions involving strong basic reagents such as carbenes and carbanions generated in situ. Eipophilic crown ethers and cryptands are the catalysts of choice in this case, because they show higher chemical stability in comparison to onium salts, and. more importantly. they interact more efficiently with the solid surface, thus promoting the collapse of the crystal lattice.[19] Diffusion can play a critical role in solid–liquid PTC, and in many cases. mass transfer is the limiting step of the overall process. This drawback can be partly overcome by using organic solvents such as acetonitrile or acetone. in which most solid salts used as sources of nucleophiles are slightly soluble.

Gas–liquid phase-transfer catalysis (GL-PTC) relies on the use of thermally stable PT catalysts adsorbed onto a solid support, which can also act as a source of the desired nucleophile. Reactions are carried out at a temperature that ensures that the catalyst is in a molten state and that reagents are in the vapor phase. and that the chemical transformation occurs in the organic microphase of molten catalyst. The products are recovered after condensation outside the reaction vessel. Only catalysts having melting points lower then the process temperature <180°C are active. but despite this limitation, GL-PTC is a versatile technique that has been applied to a number of chemical transformations.[20]

Inverse PTC

Liquid–liquid PTC typically involves the extraction of an anionic reactive species from the aqueous phase to the organic solution where the reaction occurs. However. a different approach based on the transport of a lipophilic reactant into the aqueous phase. named inverse phase-transfer catalysis (IPTC), was expressly introduced in 1986.[''''] In the presence of 4-(dimethylamino)pyridine, the reaction of aqueous alanine with acyl chlorides was greatly accelerated. Analogously. 4-pyrrolidinopyridine and a polymeric analogue were found to catalyze the hydrolysis of p-nitrophenyl caproate, although 4-pyrrolidinopyridine had to be used in excess with respect to the substrate. Further studies proved that IPTC includes an interphase component. as evidenced by competitive transacylation experiments carried out in the presence of 4-(dimethylamino)pyridine, pyridine N-oxide, or Et_3N in CH_2Cl_2-water.[22] Moreover, in the pyridine-catalyzed reaction of benzoyl chloride with aniline in $CHCl_3$-water, the rate of Cl^- appearance exceeded the sum of the rates of aniline transport (from water) and benzoylpyridinium chloride transport (into water), indicating that reaction occured in both phases.[23] Several factors, including the concentration of reactants and catalyst, the ionic strength of the aqueous phase. stirring rate, and, above all, the nature of the organic solvent, greatly influence the mechanism of IPTC reactions catalyzed by pyridine derivatives.[24–26] Also, when simple onium salts are used, as in the case of the epoxidation of chalcone with H_2O_2 catalyzed by dodecyltrimethyl ammonium bromide (DTAB) in water/heptane, interfacial processes are involved in IPTC. in addition to the transport of the lipophilic reactant into the aqueous phase.[27]

TOWARD PTC WITHOUT VOLATILE ORGANIC SOLVENTS

The advent of PTC had a positive impact on the need to eliminate some hazardous solvents and reagents from the laboratory and industrial practice. However, many PTC reactions still involve the use of volatile organic solvents, which are partly discharged into the atmosphere with a host of negative environmental effects. Replacement of these solvents with reaction media such as water,

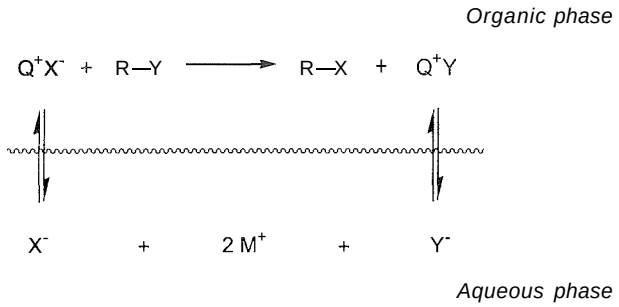

Fig. 2 PTC inechanisrn without partitioning of the onium salt. Adapted from Ref. [17].

supercritical fluids,[28] and ionic liquids,[29,30] brings about potential advantages, such as the opportunity for environmentally benign processing, lower costs, and easy separation of the catalysts from the reaction medium.

PTC in Water as Bulk Solvent

Although the understanding of IPTC is still limited in comparison to that of normal PTC, it is clear that this method is apt to effect organic reactions in water. As discussed in the introduction: simple pyridine derivatives were introduced mainly in connection to kinetic and mechanism studies. but more recently. it was shown that the use of host compounds; such as cyclodextrins[7,8] and water-soluble calix[*n*]arenes,[32] offers the opportunity to combine IPTC, molecular recognition, and transition metal catalysis, with additional economic and environmetal advantages deriving from the use of water as a bulk solvent.

Cyclodextrins are cyclic glucose oligomers. and the 6-. 7-, and 8-units terms are commercially available under the names of α-, β-, and γ-cyclodextrin, respectively. These compounds are characterized by a typical shape that can be described as barrel-like (Fig. 3). The inner cavity is essentially hydrophobic and can host organic guests, whereas hydrophilic-OH groups span from the upper and the lower rim, ensuring water solubility to the molecule. The free hydroxyl groups can be selectively functionalized. thus making possible the fine-tuning of the inclusion and solubility properties of these compounds.

It is interesting to note that unmodified α-and β-cyclodextrins were investigated as carriers of organic molecules into water before the concept of IPTC was rationalized. For instance, Trifonov and Nikiforov reported that in the presence of β-cyclodextrin, the rate of the nucleophilic displacement of neat octyl bromide with aqueous cyanide, iodide, and thiocyanate anions was considerably increased.[7,8] After the IPTC concept was established, commercially available cyclodextrins found applications as inverse PT agents in several important organic reactions catalyzed by transition metals. including the aerobic oxidation of olefins to ketones in water, in the presence of $PdCl_2$ and $CuCl_2$ (Wacker process),[34] the $IrCl_3$ catalyzed isomerization of 4-allylanisole,[35] the hydrogenation of conjugated dienes to monoolefins catalyzed by $HCo(CN)^{5-}$, generated in situ from $CoCl_2$, KOH, and KCN. and promoted by lanthanide halides.[36] In 1994 Mortreux and coworkers reexamined the application of IPTC to the Wacker process and found that 1-decene could be oxidized to 2-decanone with excellent yield (98%) in water; using $O_2/PdSO_4/CuSO_4/H_9PV_6Mo_6O_{40}$ as the redox system. The organic substrate was transferred into the aqueous phase containing the catalytic system by an amphiphilic β-cyclodextrin, in which about 60% of the free-OH groups were methylated.[37] Other cyclodextrins (native α-, β-, y-, fully acetylated β-cyclodextrin or 2-hydroxypropyl-β-cyclodextrins with different degrees of substitution) were tested with limited success. The correct balance between lipophilic and hydrophilic character had an overwhelming importance. but the results obtained pointed also to the possible role of molecular recognition based on reversible interactions between the cyclodextrins' host cavity and 1-decene. The same modified β-cyclodextrin was successfully used as inverse PT catalysts for the rhodium-catalyzed hydroformylation of water-insoluble olefins in an aqueous two-phase system free of organic solvent (Fig. 4).[38] In the case of 1-decene, conversion reached 100%, with 95% selectivity and a ratio nliso-aldehyde = 1.9. Other terminal olefins gave similar

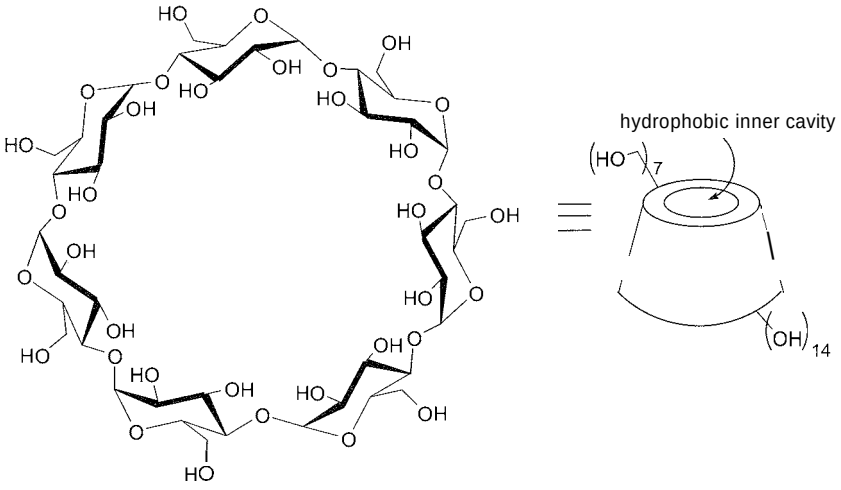

Fig. *3* β-cyclodextrin

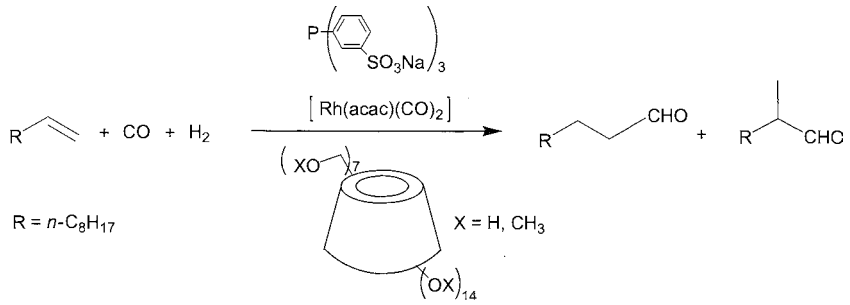

Fig. 4 Hydroformylation of 1-decene in the presence of methylated β-cyclodextrins. Adapted from Ref. [38]

results, but less-reactive internal olefins were found to be almost inert.[39]

A common picture emerged from these studies: the amphiphilic cyclodextrin acts as a host, wrapping the hydrophobic substrate and transferring it into the water phase, where the reaction occurs. The stability constant of the new host–guest complex is lower. and the product is then released into the organic phase (Fig. 5).

The validity of these working hypotheses was tested in other catalytic organometallic reactions. Interesting results were obtained in the biphasic hydrogenation of water-insoluble aldehydes to alcohols catalyzed by $RuCl_3$/$P(C_6H_4SO_3Na)_3$,[40] the cleavage of allylic substrates in the presence of $Pd(OAc)_2$/$P(C_6H_4SO_3Na)_3$,[41,42] and the hydrocarboxylation of olefins catalyzed by $PdCl_2$/$P(C_6H_4SO_3Na)_3$ to give carboxylic acids.[43] Deeper insight into the effective role of cyclodextrins in the catalytic system was thus achieved. In two recent independent studies, the influence of partly methylated β-cyclodextrins on the other component of the catalytic system was been evidenced in the case of the hydroformylation of alkenes. Kalck and coworkers proposed that a gradual supramolecular organization in the interphase occurs for the catalytically active rhodium complex. which should involve at least two cyclodextrin molecules.[44] Monflier and coworkers refined their previous model, taking into account the formation of inclusion complexes between the cyclodextrin and some components of the catalytic system. in particular, $P(C_6H_4SO_3Na)_3$. It was concluded that chemically modified cyclodextrins influence the biphasic reaction not only by acting as inverse phase-transfer agents but also by modifying the equilibria between the components of the catalytic system.[45]

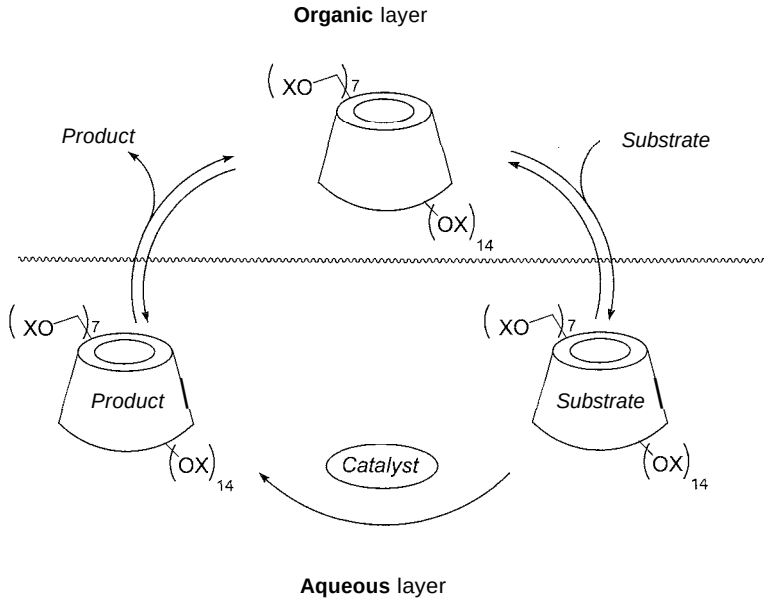

Fig. 5 Proposed role of chemically modified cyclodextrins as carriers in aqueous-phase organometallic catalysis. Adapted from Ref. [43].

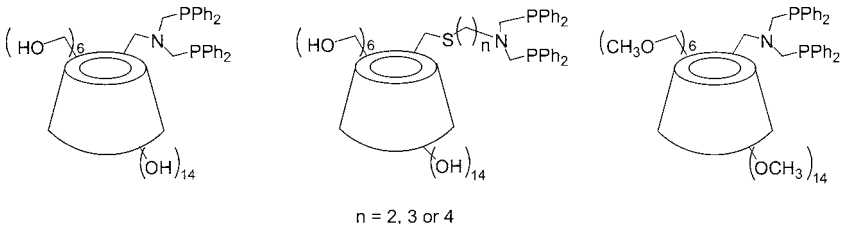

Fig. 6 Multicomponent ligands for organometallic catalysis Adapted from Ref [46]

A more sophisticated β-cyclodextrin-based catalytic system combining different functions in the same molecule was also conceived. Rhodium complexes of multicomponent ligands featuring a chelating diphosphine covalently linked to the upper riin of β-cyclodextrin (Fig. 6) were used as catalysts for the hydrogenation and the hydroformylation of alkenes in water–organic two-phase systems.[46]

These supramolecular catalysts showed high substrate selectivity in competition hydrogenation experiments and exceptional activity in the hydroformylation reactions. In contrast to the simple methylated β-cyclodextrin previously mentioned, even internal and cyclic olefins were converted into aldehydes. Such improvements were explained with the formation of an inclusion complex at the phase boundary. with the cylodextrin host fixing the substrate in the proximity of the catalytically active metal center (Fig. 7).[47]

In contrast to cyclodextrins, water-soluble calix[*n*]arrenes (*n* = 4, 6, 8) were proposed as inverse PT catalysts only a few years ago.[48] Shimizu and coworkers reported the use of previously known calix[n]arenes bearing trimethylarninonioinethyl groups **1–3** (Fig. 8) in the nucleophilic displacement of alkyl and arylalkyl halides with NaCN, KI, KSCN in water. The catalytic activity of these compounds exceeded that of β-cyclodextrin, whereas (4-methoxybenzyl)trimethylammonium chloride **4** (the monomeric unit of the calix[*n*]arene catalysts) did not show any activity. It was also found that the efficiency of the calix[*n*]arenes varied depending on the sizes and shapes of the substrates. and it was proposed that they behave similarly to cyclodextrins. forming inclusion compounds with the substrate that is thus transferred into the aqueous phase.

Calix[*n*]arenes **1–3** were used as inverse PT catalysts in the alkylation of active methylene compounds with alkyl halides in aqueous NaOH solutions,[49] and in aldol-type condensation and Michael addition reactions.[50] In the aikylation of phenylacetone with octyl bromide. the IPTC procedure enhanced the alkylation versus hydrolysis and *C* versus *O* alkylation selectivities with respect to those observed under classical PTC reactions in the presence of tetrabutylammonium bromide (TBAB) or hexadecyltributylammonium bromide (HTPB). Moreover, the aqueous catalyst solution was easily separated from the organic phase containing the products, and no organic solvent was required. In the case of the aldol-type condensation of benzaldehyde with indene or acetophenone in aqueous NaOH (Fig. 9), IPTC reactions catalyzed by **1** were compared with those conducted in aqueous micelles in the presence of cetyltrimethylammonium bromide (CTAB) as the sufactant. Although selectivities and yields were similar. the IPTC procedure avoided the formation of emulsions, thus facilitating product separation and catalyst recovery. In the light of the results obtained. water-soluble calix[*n*]arenes **1–3** were proposed

to form host–guest complexes in the aqueous phase with the carbanions that arise from the deprotonation of the active methylene compounds. The nucleophilic attack of the hosted anion on the acceptor would then take place at the interface.

Analogously to cyclodextrins, water-soluble calixarenes were integrated into catalytic systems, where the ability to perform IPTC and organometallic catalysis are combined in a single molecule. Phosphacalix[4]arenes **5** and **6** (Fig. 10) were synthesized and used as dual functional ligands in the rhodium-catalyzed hydroformylation of I-octene and I-decene.[51] Both ligands afforded better conversions and yields than $P(C_6H_4SO_3Na)_3$ or $P(C_6H_4SO_3Na)_3$/2,6-di-*O*-methyl-β-cyclodextrin, and **8** proved to be particularly effective [nonanals (73%) and undecanals (52%) were obtained with linear/branched aldehyde ratio = 1.7 and 2.3. respectively]. Moreover, the aqueous layer was recycled twice with no apparent decrease of activity and selectivity. The beneficial effect of **5** and 6 was reasonably explained with the improvement in the mass transfer of the substrate and products between the phases. but neither formation of inclusion

complexes nor transport ability of the ligands were specifically investigated.

The inclusion of aromatic guests in the hydrophobic pocket of the water-soluble calixarenes 7–9 (Fig. 11) was recently studied by ^{1}H-NMR titration experiments in aqueous buffered solutions and molecular modeling studies combined with ab initio NMR shift calculations.[52]

Association constants of various aromatic compounds with **7** and 8 were found to be close to those observed with β-cyclodextrin, with the exception of iodobenzene, which showed a remarkable higher affinity to β-cyclodextrin than to the calixarenes (K_{ass} > 1000 M^{-1} versus about 60 M^{-1}). Under acidic conditions, the association

constants with the amino methyl-substituted calixarene 9 were also higher than those measured with 7 and 8 at pH 7.4. Calix[4,6]arenes 7–11 were then evaluated as IPT catalysts in the Suzuki coupling of phenylboronic acid and iodobenzene in water, yielding diphenyl as a product. The influence of 7–11 was studied at low levels of conversions (10–15%) in order to compare initial reaction rates (t = 30 min) and to exclude product inhibition effects. Amino-substituted calix[4]arenes 9–18 gave better results. with increases of initial yields up to a factor of 12.7 in the case of 10.

PTC in Supercritical Fluids

Besides environinental and separation advantages, the use of supercritical fluids associated with PTC provides the extra benefit of an increased mass transfer. Viscosities and solute diffusivities of supercritical fluids are gas-like, and this can avoid the mass transfer limitations often encountered in liquid PTG systems.

The first reported example of a PTC reaction carried out in a supercritical fluid was the nucleophilic displacement of benzyl chloride with solid potassium bromide, in the presence of tetraheptylammoniurn bromide (THAB) or 18-crown-6 as catalysts.[53] Supercritical CO_2 ($scCO_2$) was used as a bulk solvent, with variable amounts of acetone added in order to increase the solubility of the catalyst. The kinetics of the nucleophilic displacement was studied, and the reaction was found to follow first-order, reversible kinetics in the case of THAB and zero-order kinetics for reactions catalyzed by 18-crown-6.

A detailed mechanistic study of the nucleophilic displacement of benzyl chloride with potassium cyanide catalyzed by THAB in $scCO_2$ was reported.[54] This simple, irreversible S_N2 model reaction is also of practical interest, and it was thoroughly investigated in a liquid

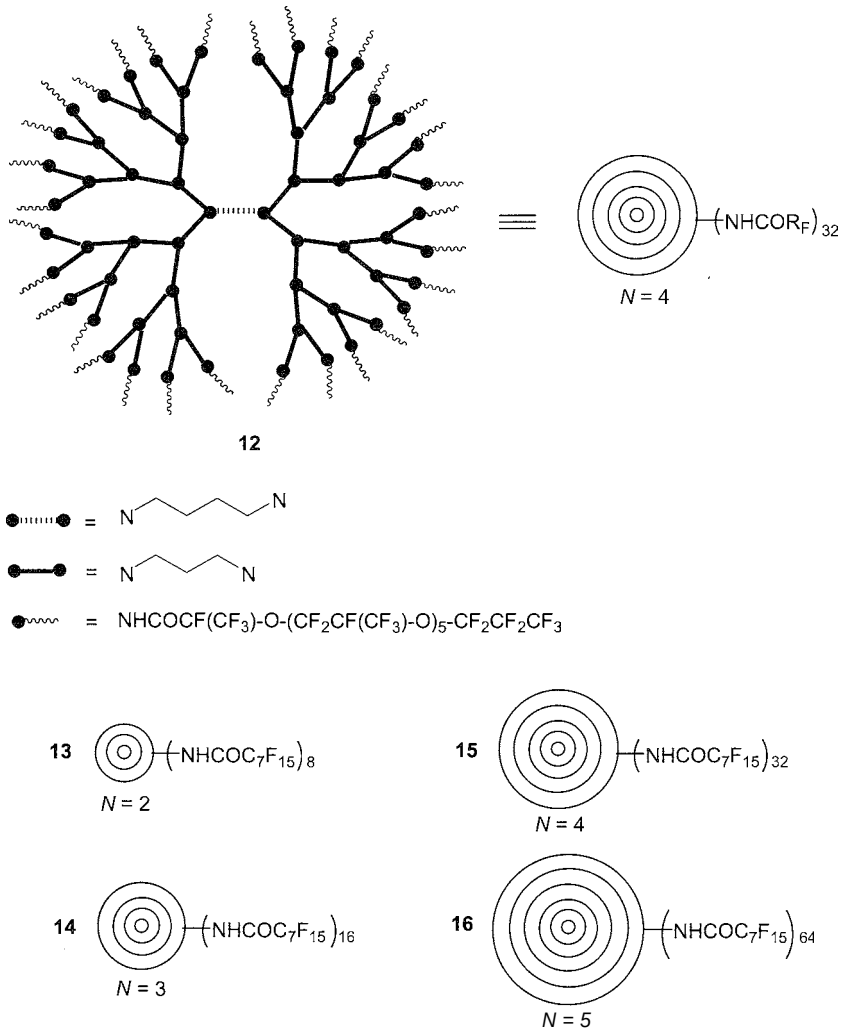

Fig. 12 Fluorinated poly(propylene imine) dendrimers. Adapted from Refs. [55,56].

system. thus making the comparison particularly interesting. The kinetic data together with catalyst solubility measurements clearly showed that three phases (a $scCO_2$ phase, a catalyst-rich phase. and a solid potassium salt phase) exist in the reaction system, and that the nucleophilic displacement proceeds in the catalyst-rich phase. The observed decrease of reaction rate upon addition of acetone is consistent with this particular phase behavior, which also partly justifies the lower efficiency of two nonionic catalysts [18-crown-6 and poly(ethylene glycol)] with respect to THAB.

Although the low solubility of TMAB in $scCO_2$ does not seem to be a major issue in the case of the above-mentioned reactions. better control of the solubility of PT catalysts could considerably extend the scope of PTC in supercritical fluids. Dendritic surfactants featuring perfluorinated ponytails attached to a polar interior are able to extract hydrophilic compounds from water into liquid CO_2. It was found that the apolar fluorous layer surrounding the unimolecular micellar-like structure of 12 (Fig. 12) shows a great affinity for CO_2, whereas the aqueous-soluble dye methyl orange is confined to the inner cavities of the dendritic host.[55] On the basis of this observation, perfluoroalkyl-functionalized poly(propylene imine) dendrimers 13–16 (second-. third-, fourth-, and fifth-generation, respectively) were synthesized and used as phase-transfer catalysts for the halogen exchange reaction of benzyl chloride into benzyl bromide and for the esterification of oxalic acid with pentafluorobenzyl-bromide in a biphasic system $H_2O/scCO_2$.[56]

The dendrimer extracts the bromide ions or oxalic acid from the aqueous phase to the $scCO_2$ phase, and the tertiary amine groups in the dendrimer core are responsible for the extraction. Dendrimers of different generations were compared, keeping the concentration of the tertiary amine groups constant. It was found that the rate of reaction strongly depends on the generation number N of the dendrimer. In the case of the halogen exchange. second-and third-generation dendrimers 13 and 14 afforded similar reaction rates. while in the presence of the fourth-generation dendrimer 15 (bearing 32 fluorinated ponytails). conversion of benzyl chloride proceeded essentially at the same rate as without a PT catalyst. This indicates that mass-transfer limitations occur within the unimolecular micellar-like structure of the higher-generation dendrirners, with cores that are almost completely shielded from the bulk $scCO_2$ phase. Similar behavior was observed in the case of the esterification of oxalic acid.

Beside modification of the PT catalyst by incorporation of ''CO_2-philic'' groups, other approaches to the problem of the poor solubility of polar compounds in $scCO_2$ were envisaged. Fluorinated surfactants (perfluoropolyether ammonium carboxylates) were used as stabilizers of $H_2O/scCO_2$ microemulsions.[57] The nucleophilic displacement of benzyl chloride with aqueous potassium bromide in $H_2O/scCO_2$ microemulsions[58] or emulsions[59] was reported. Reaction yields in the case of $H_2O/scCO_2$ emulsions were slightly better than those obtained with dendritic PT catalysts. A third approach was recently described that takes advantage of immobilized onium salts.[60] The S_N2 displacement of n-octyl methanesulfonate by bromide and iodide anions was performed using silica-supported ammonium or phosphonium phase-transfer catalysts in $scCO_2$, both under solid–liquid (stoichiometric amounts of functionalized silica) and liquid–liquid PTC (added aqueous KBr or KI) conditions. Although the anionic reactivity was found to be comparable to that observed in conventional organic solvents: the use of $scCO_2$ has no environmental impact and simplifies recovery of the catalyst.

Due to the low critical temperature and pressure (T_c = 31°C, P_c = 74 bar), $scCO_2$ is certainly the most investigated supercritical medium, as also witnessed by the examples reported here . However, alternative supercritical fluids must be explored in cases where the intrinsic reactivity of CO_2 cannot be neglected. As recently reported, the PT-catalyzed alkylation of phenylacetonitrile with ethyl bromide can be conveniently carried out in supercritical ethane in the presence of tetrabutylammonium bromide (TBAB) and solid potassium carbonate as a base (Fig. 13).[61] Under classical liquid–liquid PTC conditions, this reaction typically requires the use of strong aqueous bases (sodium amide, 50% NaOH), leading to the formation of significant amounts of diethylated product. Under solid-supercritical fluid PTC, only traces of this by-product were detected. Moreover, the use of a weak solid base presents evident advantages in view of an industrial application of the method. It should be noted that the use of $scCO_2$ as a bulk solvent led to the formation of an undesired cyanoester as the main product (Fig. 13), because the carbanion formed by deprotonation of phenylacetonitrile quickly reacts with CO_2, forming a carboxylate anion that is then alkylated by ethyl bromide.

Nucleophilic Substitution in Ionic Liquids

The use of ionic liquids comprised of bulky organic cations as novel reaction media is gaining a great deal of attention due to the remarkable properties of these compounds. which include low-temperature melting point, negligible vapor pressure. high thermal stability, and inertness to air and water. Examples of their applications are appearing at an increasing rate in the literature, ranging from catalytic reactions[62] to enhanced product recovery.[63]

Room-temperature ionic liquids are generally salts of tetraalkylammonium, tetraalkylphosphonium. *N*-alkylpyridinium. and 1,3-dialkylimidazolium containing a wide variety of anions (Cl^-, NO_3 . BF_4 , PF_6 , $CH_3CO_2^-$, $CF_3CO_2^-$, etc.). the nucleophilicity of which can be enhanced by the lack of solvation. Therefore, it was recently proposed that ionic liquids could act as reaction media and anion activators in some organic transformations. The use of 1-*n*-butyl-3-methylimidazolium hexafluorophosphate, one of the most widely used room-temperature ionic liquids. as a solvent for reactions between organic compounds and inorganic salts, was demonstrated.[64] The displacement of benzyl chloride with solid potassiuin cyanide and the KOH-promoted cycloalkylation of phenylacetonitrile (Fig. 14) were carried out in the absence of any classical PT catalyst, relying on the ability of the ionic liquid to act as a catalyst for the activation of the anion.

Kinetic data for the benzyl chloride displacement indicated that at 40°C. the mass transfer of KCN into the solvent is the rate-limiting step. However, at 60°C and 80°C. reaction rates were high, and pseudo-first-order kinetic behavior was observed in agreement with an efficient transfer of the salt into the liquid, which is faster than the reaction step.

n-Butanol, *sec*-butanol, *tert*-butanol, and n-octanol were converted to their corresponding alkyl halides at room temperature using 1-*n*-butyl-3-methylimidazolium halides in the presence of a Brønsted acid (typically H_2SO_4).[65] Reaction conditions are significantly milder than those required by classical methods. and the products are easily removed from the reaction mixture. The proposed mechanism involves protonation of the alcohol followed by nucleophilic displacement by the halide anion. This step is accelerated by the effective charge separation in the transition state, which is ensured by the lack of extensive solvation in ionic liquids. The assessment of the role of these peculiar reaction media on the reaction mechanism is still underway.

CONCLUSION

PTC is now an established branch of catalysis, and applications for it are found in the laboratory as well as in large-scale processes. The design of PTC systems able to work in the absence of common volatile organic solvents is a promising field of research that deserves investigation in order to better understand manifold factors (solubility of the catalyst. formation of new phases, influence of the reactants on the physical state of the bulk fluid. etc.) that could influence the outcome of the reaction. However, as shown by the examples discussed here, the combined utilization of PTC and nontraditional reaction media affords new opportunities for improving numerous chemical processes while reducing emissions to the environment.

Photochemical Sensors

Luigi Fabbrizzi
Università di Pavia, Pavia, Italy

INTRODUCTION

A sensor is a device that responds to an external input by generating a measurable signal. The most common sensor in chemistry is probably the glass electrode, which responds to a change of H^+ concentration with a variation of the eiectrical potential, and, following appropriate calibration, directly communicates pH units. Other devices respond to physical inputs; for instance. a thermocouple is a temperature sensor, and the generated signal is still a variation of potential. Noticeably, the definition of a sensor can be brought to the molecular level. In this case, the sensor is a discrete molecule (or, better, a multitude of single molecules) that responds to a chemical or physical stimulus by generating a signal detectable and measurable by an external operator. In particular, the molecule constituting the sensor has to be equipped with two basic subunits: 1) a fragment capable of selectively interacting and recognizing the desired analyte (e.g., H^+, Ca^{2+}, Cl^-, CO_2); and 2) a functionality that signals the occurrence of the recognition. The signal can have a different instrumental nature. For instance, it can be the shift of an NMR line. the displacement of a voltammetric wave, a color change with the associate modification of the absorption spectrum, or a change of luminescent activity. Luminescence, in particular, is a convenient property for sensing purposes. for a variety of reasons: it is visual, it can be measured with not-too-expensive instrumentation (a spectrofluorimeter). and it can be detected with remarkable sensitivity. As an essential requirement, the interaction of the recognizing moiety (the receptor) with the analyte must activate a mechanism that substantially modifies the light-emitting properties of the luminophore.

FLUORESCENT MOLECULAR **SENSOR**

An efficient fluorescent molecular sensor is available for the determination of intracellular calcium(II) concentration, $[Ca^{2+}]$.[1] The molecular system, **1**, has as a receptor moiety, a fragment reminiscent of ECTA, a ligand displaying a special affinity toward alkaline-earth metal ions. In particular; ECTA gives with Ca^{2+} a 1:1 complex, with a stability constant K that is about 10^{11}, i.e., five orders of magnitude higher than that of the corresponding complex with the competing ion Mg^{2+}. This feature is important, because intracellular $[Mg^{2+}]$ can be up to 10^4 times higher than $[Ca^{2+}]$. In system **1.** an indole fragment is covalently Iinked to the EGTA framework as a light-emitting subunit. In particular, this subunit, when excited with ultraviolet light (λ = 338 nm), emits light in the full visible region (λ_{max} of the emission band is 500 nm). Ca^{2+} complexation induces a drastic structural rearrangement of **1**, which causes a modification of the energy of the π orbitals of the indole fragment, and as a consequence, the emission band is displaced to λ_{max} = 400 nm. This spectral shift is especially useful, as the ratio of the emission intensities at the two wavelengths provides a measure of $[Ca^{2+}]$ independently upon the concentration of the fluorescent probe and the length of the optical path. After the fluorescent sensor **1** (commercially known as indo-1), other fluorescent molecules were developed by following the same approach. They are currently employed in the laboratories of cell physiology for the determination of $[Ca^{2+}]$, in real time and real space, by using a fluorescence microscope.[2]

LUMINOPHORE–SPACER–RECEPTOR PARADIGM

The previously outlined approach—covalently link a luminescent fragment to the receptor of the envisaged

DOI: 10.1081/E-ESMC 120012791

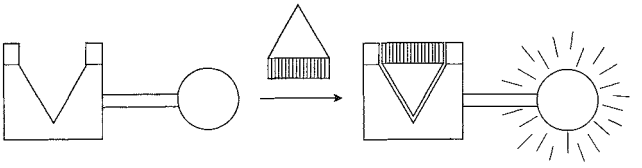

Fig. 1 The fluorophore–spacer–receptor paradigm. It is expected that the interaction of the desired analyte with the receptor portion drastically modifies the emission of the nearby fluorophore. In the case illustrated, the recognition process restores the quenched fluorescence. Alternatively, the fluorescence before recognition may be on and after recognition be off.

analyte––is known as the luminophore–spacer–receptor paradigm and is pictorially illustrated in Fig. 1. Such an approach was utilized for the design of sensors for a variety of substrates, both electrically charged and neutral.''

As an example, the two-component system 2 in Fig. 2 was developed for the fluoriinetric determination of the K^+ ion.[4] In system 2, the receptor moiety belongs to the family of crown ethers: in particular, the macrocycle can be considered as deriving from the 18-crown-O_h macrocycle, in which an ethereal oxygen atom was replaced by a secondary amine group; –NH–. The 18-crown-NO_5 ring of 2 possesses the right size to selectively include (''recognize'') the K^+ cation, in the presence of the other alkali metal ions. The problem is now to communicate to the outside that recognition has taken place. To this purpose, the classical fluorescent fragment anthracene was linked. through a $-CH_2-$ spacer, to the nitrogen atom of the macrocycle. It has to be noted that in spite of the presence of a powerful fluorophore, molecular system 2 is not fluorescent. In fact, one of the two electrons of the lone pair on the nitrogen atom of the macrocycle is transferred on the half-filled HOMO π orbital of the photoexcited anthracene fragment, a process that fully quenches fluorescence. However: when K^+ is included within the macrocycle. the lone pair on the nitrogen atom is fully engaged in the metal–ligand interaction with K^+, and no electron can be transferred to the excited fluorophore. Then. in the absence of electron transfer, the photoexcited anthracene fragment deactivates in its typical radiative way. As a consequence. K^+ recognition is clearly signaled by the revival of the blue fluorescence of anthracene. System 2 is an ingenious device, because a typically redox-inactive substrate, K^+. is able to promote an electron-transfer process. This was made possible by the presence of the amine nitrogen atom, that behaves as an electron relay.

The design of a luminescent sensor for transition metal ions based on photoinduced electron transfer is, at least in principle, easier, because d-block metals exhibit a natural tendency to uptake/release electrons. Thus, a transition metal ion should be able to promote the transfer of one electron from/to an excited luminophore in the absence of any relay. An example is provided by system **3.** shown in Fig. 3, in which (following again the luminophore–spacer–receptor approach) an anthracene fragment was linked, through a $-CH_2-$ group. to the carbon framework of a quadridentate chelating agent containing two secondary amide groups and two primary amine groups.[5] In its neutral form. ligand **3**, in view of the poor coordinating tendencies of the amide groups. does not coordinate any metal ion. However. in the presence of divalent metal ions late in the 3d series. i.e., Cu^{II} and Ni^{II}, at pH values close to the neutrality, the two amide groups deprotonate, and the ligand coordinates the metal according to a square-planar stereochemistry. In each deprotonated amide fragment. the negative charge is distributed on both nitrogen atoms via a π-delocalization mechanism. Opportunely for sensing purposes. metal complexation modifies the light-emitting properties of the anthracene subunit and can be followed through spectrofluorimetric titration experiments.

Titration of **3** in the absence of metals does not modify the emission intensity of the anthracene fragment, I_F,

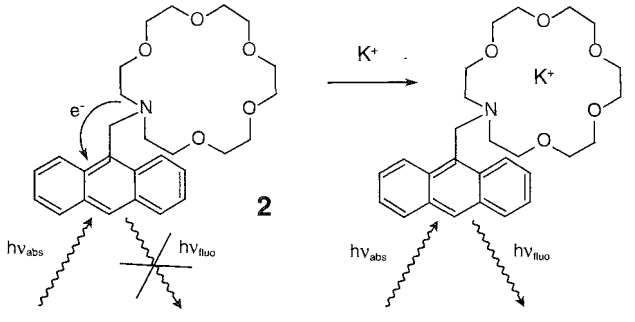

Fig. 2 Fluorescent sensing of the K^+ ion. Metal inclusion within the macrocycle interrupts a preexisting quenching mechanism (due to a nitrogen-to-tluorophore electron-transfer process) and revives anthracene fluorescence.

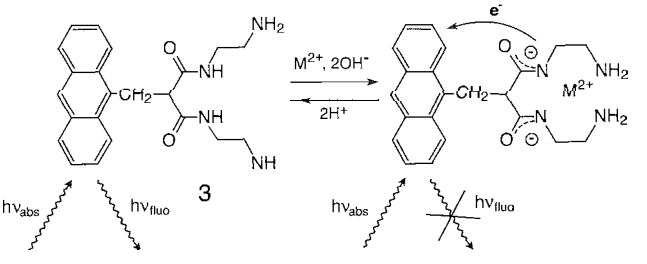

Fig. **3** Fluorescent sensing of transition metal ions (M = Ni, Cu). Following complexation. an intramolecular metal-to-fluorophore electron-transfer process takes place that quenches anthracene fluorescence.

which remains constant on moving from pH = 2 to pH = 12 (diamonds in Fig. 4). However, if an equimolar amount of Cu^{II} is added to the solution, a sharp decrease of I_F is observed beyond pH = 5, and complete fluorescence quenching takes place at pH = 7 (full triangles in Fig. 4). Sigmoidal I_F decrease is to be associated with the complexation of Cu^{II} by **3.** In particular. the fluorescent emission is quenched due to the occurrence of an electron-transfer process from the Cu^{II} center to the excited fluorophore, An^*. The occurrence of such a process can be accounted for on a thermodynamic basis.

In particular, the free-energy change value associated with the Cu^{II}-to-An^* electron transfer, ΔG_{eT}°, can be calculated taking profit from the thermodynamic cycle illustrated in Fig. 5. by combining pertinent photophysical and electrochemical quantities. The obtained value is distinctly negative (– 0.50 eV) and accounts for the observed quenching efficiency. Thus, in contrast to that previously observed for K^+, Cu^{II} recognition is signaled through quenching. rather than from revival, of anthracene fluorescence. A careful examination of the varying contribution to ΔG_{eT}° indicates that the signal controlling mechanism; i.e., the metal-to-fluorophore electron transfer, results from easy access to the Cu^{III} state. Such an access is favored by the strongly donating donor set consisting of two amine groups and, in particular, from two deprotonated amide groups. The intense in-plane interactions exerted by the four nitrogen atoms raise the energy of the antibonding level. essentially centered on the metal, from which the electron is abstracted on Cu^{II}-to-Cu^{III} oxidation. The presence of a double negative charge on the coordinating system further facilitates the oxidation process that involves a moderate increase of the

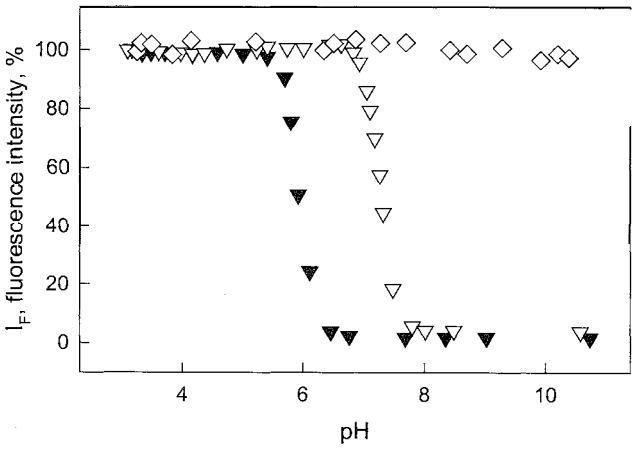

Fig. 4 The pH dependence of the fluorescence intensity of system 3 in the absence (open diamonds) and in the presence of an equimolar amount of transition metal ions (full triangles: Cu^{II}; open triangles: Ni^{II}). Other metal ions (Mn^{II}, Fe^{II}, Co^{II}, Zn^{II}) do not affect the emission of the anthracene fragment.

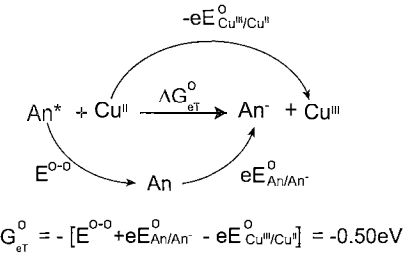

Fig. 5 Thermodynamic cycle suitable for calculating the free-energy change value, ΔG_{eT}°, associated with the copper(II)-to-anthracene electron transfer within system Cu^{II}-**3**. ΔG_{eT}° is obtained from the appropriate combination of photophysical and electrochemical quantities.

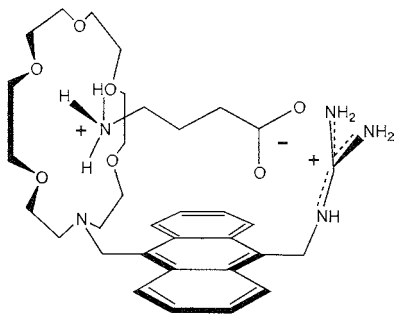
overall electrical charge from *0* to *+1*. It derives that a judicious choice of the coordinating tendencies of the ligating subunit allows for the transduction mechanism of the sensing system to be determined.

An analogous behavior is observed with Ni^{II}. In particular, it is observed that the sigmoidal decrease of I_F (in Fig. 4) is centered at pH = 7.5, i.e., two units higher than that observed for Cu^{II}. This reflects the lower stability of the Ni^{II} complex with the deprotonated amide–amine ligand, compared to Cu^{II}. In this case too, fluorescence quenching has to be ascribed to the formation of the complex with the doubly negatively charged ligand and to the thermodynamically favored Ni^{II}-to-An^* electron-transfer process (ΔG_{eT}° = – *0.35* eV). Noticeably, if analogous pH-titration experiments are carried out in the presence of other divalent cations of the *3d* series (Mn^{II}, Fe^{II}, Co^{II}, Zn^{II}), the anthracene emission is not modified over the 2–12 pH interval. This behavior is to be ascribed to failure in the formation of the corresponding metal complexes, even in a distinctly basic solution. In particular. the deprotonation of the two amide groups of **3** is an endoergonic process that can be compensated for only by the formation of strong metal–ligand interactions. This is the case of Cu^{II} and Ni^{II} but not of the other metal ions. which do not profit too much (or do not profit at all) from ligand field stabilization effects. Thus, system **3,** among *3d* cations, recognizes Cu^{II} and Ni^{II} and signals the occurrence of the recognition process through fluorescence quenching.

Let us now consider the case of polyatomic analytes. The analyte can be multifunctional, i.e., it can contain distinct groups of different natures and electrical charges—in this case. the receptor must provide distinct binding sites of appropriate characteristics. A representative case is that of amino acid in their zwitterionic forms: NH_3^+–CH(R)–COO^-. The first example of a molecular fluorescent sensor amino acid was presented by de Silva.[6]



4

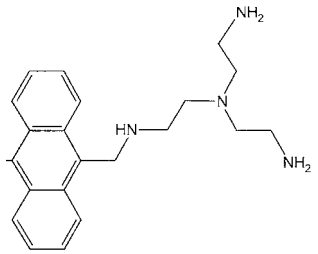
In the ditopic system 4, the light-emitting anthracene fragment also displays the function of a spacer, as it links the two binding sites for the bifunctional substrate—a guanidinium subunit, suitable for electrostatic interaction with the carboxylate group of the amino acid: and the 18-crown-NO_5 moiety, which can establish hydrogen-bonding interactions with the ammonium residue. As outlined with the K' sensor 2, also in this case; the presence of a tertiary amine nitrogen atom in the crown, close to the anthracene subunit, is essential for the sensing behavior. Prior to substrate binding, the amine group undergoes the thermodynamically feasible transfer of an electron to the nearby excited fluorophore, thus quenching its emission. Therefore, one would expect that, following the amino acid recognition, and, in particular, after the nonbonding electron pair of the nitrogen in the crown becomes engaged in a hydrogen-bonding interaction with the ammonium group of the amino acid; the eT process is interrupted. and the fluorescence is revived. Actually, the interaction of 4 with a series of amino acids of general formula NH_3^+-$(CH_2)_n$-COO^- in an aqueous methanol solution is signaled through a significant enhancement of the anthracene emission. Interestingly, system 4 displays linear recognition features, the highest binding constant, and the more significant increase of the emission intensity being observed with $n = 4$. It appears that in the case of the latter amino acid (-/-amino butyric acid, GABA), the distance between the carboxylate and the ammonium residues fits well the separation of the binding sites provided by the heteroditopic receptor 4. Interestingly, the natural amino acid glycine. as well as glutamic acid [NH_3^+–CH(COO^-)– $(CH_2)_2$–COO^-, the physiological precursor of GABA], induces a negligible fluorescence response. even if added in large excess with respect to the sensor.

However, if one is interested in sensing natural amino acids, with the general formula NH_3^+–CH–(**R**)–COO^-, and in which the distance between the charged groups to be recognized, $-NH_3^+$ and $-COO^-$, is the same. sensing systems of the type of 4 cannot be used. But. in order to obtain the most selective recognition of the desired α-amino acid, one should try to ignore the common $-NH_3^+$ and $-COO^-$ fragments and center attention on the **R** residue. In particular, a receptor subunit should be designed exclusively for the **R** moiety of the substrate. This case is illustrated by the design of a fluorescent sensor for histidine, with an **R** group that is an imidazolyl fragment. An effective receptor for imidazole can be designed by taking advantage of its tendency to deprotonate and to act as an ambidentate ligand. Imidazole, ImH. $pK_a = 14.5$, is a weaker acid than H_2O and does not deprotonate in aqueous solution. However, in the presence of two prepositioned metal ions M^{II} (M = Cu, Zn), the ImH molecule deprotonates, and the I m anion that forms bridges the two metal centers, according to the equilibrium:

$$[M^{II}_2]^{4+} + ImH = [M^{II}(Im^-)M^{II}]^{3+} + H^+ \quad (1)$$

A basic requirement for reaction (1) to proceed is that the two M^{II} centers occupy predetermined positions, in a rather rigid coordinative framework, at the correct distance. This is the case of system ***5*** in which two tripodal tetramine subunits of the *tren* type are linked to an anthracene fragment that acts both as a spacer and as a fluorophore.[7]

Each *tren* subunit binds a metal ion, e.g., Zn^{II}, according to a trigonal bipyramidal stereochemical arrangement, in which the fifth coordination site is left available for a further ligand, either a solvent molecule or an anion (see structural sketches in Fig. 6). At pH = 9–10, the dizinc(II) complex 6 forms that behaves as a specific receptor for imidazole, to give the bridged imidazolate complex 7. In particular, titration with imidazole of an aqueous solution of the dimetallic complex 6 induces quenching of the anthracene fluorescence, thus providing a visual mechanism for recognition. Noticeably, titration with 1-methyl-imidazole, which cannot undergo deprotonation, does not induce any modification of the anthracene fluorescent emission. confirming that signaling is promoted by Zn^{II}–Zn^{II} bridging of the imidazolate fragment. Quenching in the dimetallic complex 7 has to be ascribed to the occurrence of an intracomplex electron-transfer



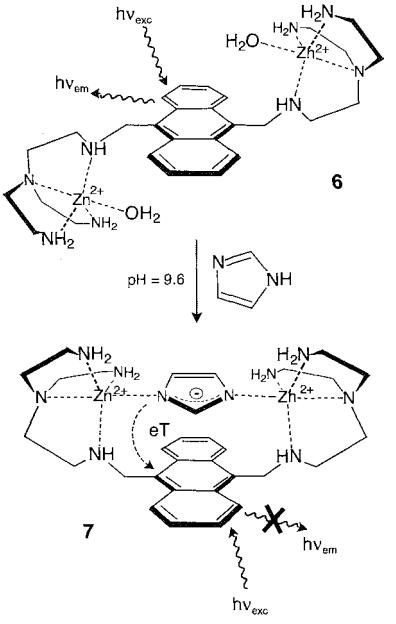


Fig. **6** Recognition of the imidazole fragment (e.g., from L-histidine) by a dizinc(II) polyamine receptor. Recognition is signaled by quenching of the emission of the anthracene subunit, which results from an electron-transfer process from the bridged imidazolate anion to the excited fluorophore.

process from a π orbital of the electron-rich im^- moiety to a π^* orbital of the photoexcited anthracene fragment.

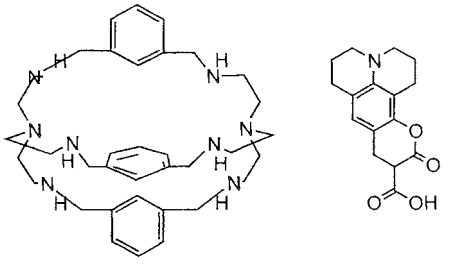
Spectrofluorimetric titration of complex **6** with the natural amino acid L-histidine induces a similar, even if slightly less pronounced, fluorescence quenching. Interestingly, the titration profile is not modified when the solution contains even a large excess of any other amino acid. As an example, the addition of L-histidine to a solution buffered at pH = 9.6 and containing the receptor 6 plus 10 equivalents of any other natural amino acid gave the same titration profile. The lack of interference is due to the fact that the only anionic group any amino acid other than histidine can offer, i.e., the carboxylate fragment, does not display bridging tendencies toward the dimetallic core of receptor 6. Thus, 6 recognizes and senses L-histidine in the presence of any other natural amino acid.

CHEMOSENSING ENSEMBLE APPROACH

Other approaches than the luminophore–spacer–receptor paradigm exist, illustrated in the preceding examples, for designing a molecular system for sensing analytes in solution. An efficient one—the chemosensing ensemble approach—is reminiscent of the antibody-based competition test in immunoassays.[8] According to this approach, the plain receptor interacts in solution with a fluorescent indicator, i.e., a light-emitting substrate. Two main requirements have to be fulfilled: 1) the receptor/indicator interaction must not be too strong; and 2) the indicator must show significantly different emissive properties when bound to the receptor and when dispersed in solution. Thus, on titration with the desired analyte, the indicator is displaced from the host cavity and released back to the solution, where it displays drastically different emission features. An example of a chemosensing ensemble suitable for determining of inorganic anions is described below.[9]

The receptor, 8, consists of a bistren octamine cage that includes two Cu^{II} ions. Each metal ion is coordinated by the four nitrogen atom of each *tren* subunit and. as it likes five-coordination, offers a binding site available for the interaction with a further donor atom. Thus, in the intermetallic cavity, there is room for an ambidentate anion, i.e., an anion presenting two distinct donor atoms. The chosen fluorescent indicator is coumarine 343, 9, which, in its anionic form, should be capable of bridging the two Cu^{II} ions of 8, with the carboxylate group. In fact, titration of a solution of coumarine 343, buffered at pH = 7, with a solution of the dicopper(II) cage complex 8, induces quenching of the intense coumarine emission at λ_{max} = 487 nm. Quenching is associated with the bridging of the two metal ions by the carboxylate group of coumarine 343 and with the occurrence of an electronic energy transfer involving the metal center(s) and the excited fluorophore. Thus, the desired chemosensing ensemble can be generated by making a degassed aqueous solution 2 x 10^{-4} M in **8** and 10^{-7} M in the fluorescent indicator, i.e., two thousands times less concentrated.

Titration of the resulting cheinosensing ensemble solution with a standard solution of carbonate (Fig. 7, full triangles) results in an almost complete recovery of the coumarine emission. This result indicates that there is successful competitive binding of the HCO_3^- ions and displacement of the indicator from the intermetallic cavity of complex 8. Full restoration of the coumarine emission is also observed when the solution of the chemosensing ensemble is titrated with N_3^- and with



8

9

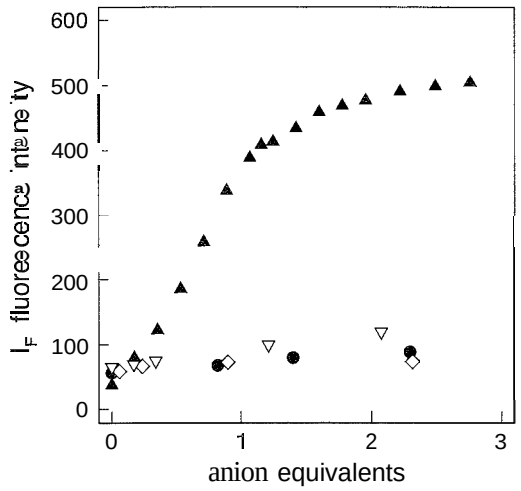


Fig. 7 Titration of the chemosensing ensemble [**8** + 9] with some inorganic anions. HCO_3^- is able to displace the indicator from cape **8.** an event signaled by fluorescence revival of the released indicator 9 (full triangles). Other anions do not displace the indicator and do not make fluorescence revive: phosphate (open triangles); acetate (full circles): and sulfate (open diamonds).

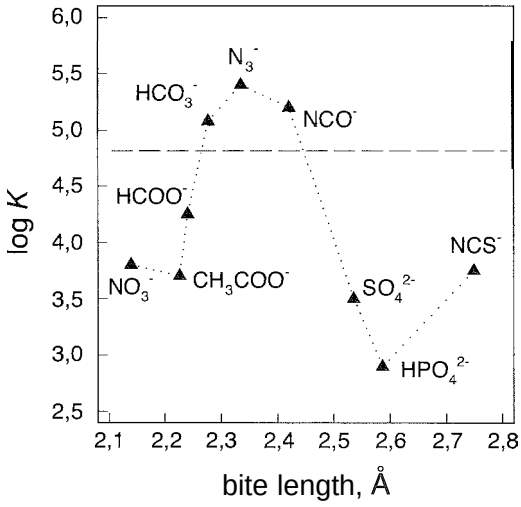

Fig. 8 Selective inclusion of ambidentate anions into the dimetallic cage 8. Log*K* values refer to the anion inclusion equilibrium at pH = 7. The bite is the distance of two consecutive donor atoms of the anion (see Fig. 9 for examples). Only anions with an inclusion constant K that is higher than $10^{4.8}$ (which corresponds to the inclusion of indicator 9, value indicated by the dashed horizontal line) are able to displace the indicator from the cage. with consequent fluorescence revival. Anions with a lower K are neither recognized nor sensed.

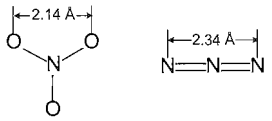

Fig, 9 The definition of anion bite: the distance of two consecutive donor atoms of an ambidentate anion. For linear anions like N_3^- . bite coincides with anion length.

NCO . However. titration with a variety of ambidentate anions induces only a slight enhancement of the fluorescence. As an example. fluorescence intensity data for phosphate (open triangles). acetate (full circles), and sulfate (diamonds) are shown in Fig. 7.

The behavior described above can be interpreted on the basis of the diagram shown in Fig. 8. In this diagram. the log*K* values for the equilibrium for the anion inclusion into the dimetallic cage **8**. at pH = 7 (full triangles). are plotted versus the anion bite length, i.e., the distance between two consecutive donor atoms of the arnbidentate anion. As an example, bite length for N_3^- and NO_3^- anions is shown in Fig. 9.

The diagram in Fig. 8 displays a well-defined selectivity peak pattern, the highest inclusion affinity being observed with the N_3^- anion. In particular. N_3^- has the correct bite length with which to place its donor atoms in the positions required by the two Cu^{II} centers. without inducing any endoergonic rearrangement of the cage. Almost ideal bite length values are exhibited by HCO_3^- and NCO^- . with inclusion affinities slightly slower than those for N_3^-. On the other hand. anions like NO_3^- and N C S exhibit bite lengths that are too short or too long, respectively. and their incorporation within the cage induces an endoergonic rearrangement of the host cavity. either contraction or expansion. which makes inclusion affinity drastically decrease. The horizontal dashed line at log*K* = 4.8 corresponds to the inclusion affinity of the coumarine 343 indicator.

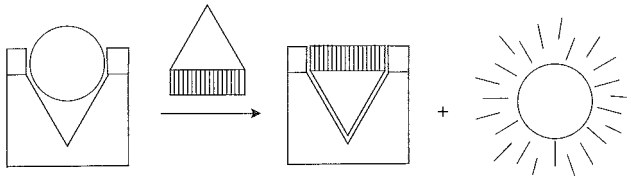

Fig. P0 The chemosensing ensemble paradigm. A fluorescent indicator occupies the cavity of a receptor. and its emission is quenched. When displaced by an analyte showing a higher affinity for the receptor, it displays its full fluorescence, so signaling the occurrence of analyte recognition.

Such a line defines the anions that can be revealed through the chemosensing ensemble procedure. by using coumarine 343 as an indicator. In particular, those anions with log$K$ values that stay above the dashed line are able to displace the indicator from the cage and can be fluorimetrically detected. On the other hand, anions with log$K$ values that stay below the dashed line are not able to displace the indicator from the host cavity and cannot be fluorimetrically detected.

CONCLUSION

The principle of the chemosensing ensemble approach is pictorially illustrated in Fig. 10. It has to be noticed that, compared to the luminophore–spacer–receptor paradigm, the chemosensing ensemble approach presents a significant benefit: it does not involve any tedious synthetic step for covalently linking together the luminophore and the receptor, which can be used as such. Moreover, a further element of selectivity is introduced, in addition to that related to the analyte–receptor interaction. This selectivity term is associated with the choice of the indicator. The indicator's higher or lower affinity toward the receptor (i.e., the height of the dashed line in a diagram like that shown in Fig. 8) determines which analytes can be detected and which cannot.

INTRODUCTION—TYPICAL ADVANTAGES OF PHOTOPHYSICAL METHODS

During the last two decades, there has been an enormous increase in the use of photophysical methods in supramolecular chemistry. Until recently, photophysical methods, such as transient spectrometry and time-resolved fluorescence spectrometry, were primarily research tools in the arenas of photokinetics of small molecules. materials physics, and biophysics. This situation changed dramatically with the introduction of commercial. user-friendly electro-optical components such as charge-coupled detector (ED)-based spectrometers, solid-state pulsed lasers, and other instrumentation necessary for time-resolved measurements. As a result. time-resolved spectrometry became more available to the community of supramolecular chemists, who now reached the level of sophistication that can benefit from the new horizons offered.

Photophysical methods generally offer numerous advantages of crucial importance for suprainolecular chemists. particularly high sensitivity. i.e., reliable output at low concentration. Also important is the possibility of selectively probing individual chromophoric parts of molecules and supramolecules. The accessibility of the information from dilute samples (typically 10^{-5}–10^{-7} mol/l) is important to a supramolecular chemist. as the typical features studied in supramolecular chemistry, such as receptor–substrate association and formation and dissociation of supramolecular associates and complexes, typically suffer from side effects such as receptor–receptor self-association and component homoassociation at higher concentrations ($>10^{-4}$ mol/l). Additional advantages of photophysical methods are the usually nondestructive nature of the measurements and the small sample volume required for the experiments.

Most importantly. however, photoexcitation methods allow the detection of transient species. While an entity with a lifetime of 50 ns or less can be comfortably analyzed by transient absorption or fluorescence spectrometry, other physical inethods of steady-state character are likely to fail. For example, the timescale of most NMR experiments is longer than ca. 100 ms. which renders this method unsuitable for studies of short-lived species. Moreover. the typical tools of supramolecular chemistry. such as NMR spectrometry. require concentrations usually in excess of 10^{-4} mol/l. and other favorite methods such as mass spectroscopy [fast-atom bombardment (FAB), electrospray ionization (ESI), matrix-assisted laser desorption ionization (MALDI)], and vapor-pressure osmoinetry do not directly provide information about supramolecular behavior in solution. The most favorite method, x-ray analysis. suffers from the limitation posed by the ultimate requirement of being able to grow single crystals. While this is. in numerous instances, possible in the case of pure molecular entities. supramolecules, being mixed molecular objects by nature, are usually difficult to grow in the form of a single crystal.

These statements are not meant to be demeaning of the classical tools of supramolecular chemistry. rather to point out that photo-techniques offer researchers in this field another level of information. The previous paragraphs are meant to define the areas where photophysical techniques may be particularly useful. and a major purpose of this article is to alert the supramolecular chemistry coinmunity to the potential of photo-methodology and to provide encouragement for its utilization.

SUPRAMOLECULAR BEHAVIOR OF CHROMOPHORES

The focus of supramolecular chemistry is on the development and application of molecules with highly selective structure-specific interaction. i.e., molecules that can "recognize" each other and form complexes or supramolecular associates together. A typical object of study investigated using photophysical methods is the association of chromophoric species. The requirements for this are that at least one of the entities forming the associate has to be a chromophore, or contain a chromophoric residue, and that the process of association must be accompanied by an observable perturbation of the photophysical properties of the chromophore. If this is the case, photophysical methods are able to provide invaluable information about the behavior and environment of the chromophore. simply by observing the absorption and emission patterns and their changes with time.

Luminescence Methods

The most common methods of measuring excited state lifetimes involve monitoring the time dependence of the sample emission after exciting it with pulsed excitation. From the sample response relative to the excitation pulse, information about the decay kinetics and about the amount of species generated (quantum yield) can be obtained. One such instrument used by these authors is depicted in Fig. 1. This apparatus is based on a nitrogen-pumped broadband dye laser [2–3 nm full width at half maximum (FWHM)] (PTI GL-3300 N_2 laser; GL-301 dye laser). The N_2-laser fundamental output at 337.1 nm can be employed directly, or it can be used to pump the dye laser to obtain the excitation pulses. For example, the authors used Coumarin 460 (440–480 nm) for excitation of Ru(II) diimine complexes, see below. Pulse energies were typically attenuated to ~100 μJ/pulse. The luminescence was recorded at 90° to the incident beam via a long-pass optical filter to cut out scattered laser light, focused through a lens system onto the entrance slit of an *f*/3.4 monochromator (± 4 nm). The emission was detected with a Hamamatsu R928 photomultiplier tube (PMT), wired for fast response, and was negatively biased with a Stanford Research PS325 power supply. The PMT signal was terminated through a 50 ohm resistor to a Tektronix TDS 380 digital oscilloscope (400 MHz). The CRO data, representing an average of 128 laser shots collected at 2–3 Hz, were transferred to a computer and processed using Microcal™ Origin™ software. This system, depicted in Fig. 1, allows measurement of luminescence lifetimes from a few ns upwards, with excellent signal-to-noise and data reproducibility. Such an instrument is an excellent choice for studies involving various luminescent metallocomplexes that display relatively long-lived excited states.[1,2] One can find countless examples of supramolecular structures utilizing the photophysical properties of diimine and other complexes of Ru(II), Os(II), and Re(I). An important advantage of such an instrument is that it can be straightforwardly assembled from parts by nonexperts at relatively low cost. The dye laser allows excitation tuning over a wide variety of visible wavelengths (*v.i.*).

The instrument described above may be conveniently used to investigate supramolecular association of species with long-lived excited states. A typical example of such a situation is the binding of a substrate to an optical sensor. In principle, one can consider two possible situations: quenching of the fluorescence intensity or an increase in fluorescence intensity. In the first, the fluorescence intensity is quenched as a result of decreases in the fluorescence lifetime or quantum yield on binding. The fluorescence quantum yield may decrease because of dynamic or static quenching, depending on whether the quenching of the excited state is due to diffusion of the luminescent entity and the quenches, or whether the

qucnchcr forms a weakly (or non-) luminescent complex with the luminophore in the ground state. The concentration quenching process is utilized in so-called lifetime-based sensing. The lifetime here is used to observe the degree of saturation of the sensor by the substrate. Such lifctime measurements are most effectively performed using compounds with long-lived excited states, making for a higher degree of sensitivity to added substrate concentration, for example, sensors incorporating *tris*(phenanthroline)Ru(II) or *tris*(bipyridine)Ru(II) complexes that exhibit long-lived metal-to-ligand charge-transfer (MLCT) excited states with lifetimes up to 150 ns,[3] e.g., complex **1.** Complex **1** is an efficient sensor for fluoride and cyanide anions, which are bound to the sensor presumably via hydrogen bonding to the pyrrole NH groups (Fig. 2).[4]

Shown in Fig. 2 is the luminescence lifetime quenching of sensor **1** as a function of the cyanide concentration. Prior to cyanide addition, **1** exhibits a single exponential lifetime (τ=380 ns). At low [CN], the decay profiles could be adequately fit by a single exponential function, with a slightly reduced lifetime (340 ns). At higher [CN], the time profiles exhibit biexponential kinetics. Both exponential components remain effectively constant, ranging from 320–370 ns (long ?) and 13 to 17 ns (short ?). The average lifetimes shorten as a function of the CN concentration, because the fractional intensity shifts from an initial dominant long lifetime component to the short lifetime component as the C N concentration increases (Fig. 1, right panel, inset). These data suggest that there are at least two distinct luminescent species, consisting of anion-bound **1** (short τ) and free **1**, the sum of which results in the observed lifetime qucnching. In this case, the shift in fractional intensity makes **1** a suitable lifetime-based sensor for anions.

While the above-described instrumentation is an excellent choice for long-lived excited states such as the Ru^{2+} and Os^{2+} polypyridyl complexes, organic-based chromophores and fluorescence labels frequently used by supramolecular chemists require higher time resolution. Commercially available time-correlated single photon counting (TCSPC) instruments can readily access

Fig. **4** *Sensor* **2**. *Excited state decays of pyrene and Sensor 2 when excited in DPQ moiety and in the pyrene antennae. (Right-bottom) The excitation (trace a, left axis,* emission *at 490 nm) and absorbance (trace b, right axis) spectra of* **2.**

lifetimes as short as 500 ps, and longer than 1 μs. Such instruments are relatively expensive, but their great advantage is modularity. Commercial instruments may be purchased as turnkey lifetime/continuous wave (CW) instruments, and their modularity allows for continuous upgrading and adding of different excitation sources, thus providing avenues for development of the instrument to suit the increasing needs of the users. The price of such instruments (see. for example, Fig. 3) is in the U.S. $70.000–100.000 range, depending on the accessories required.

An example of a commercially available TCSPC instrument used by the authors is shown in Fig. 3. The excitation source in the steady-state configuration is a 450 W Xe lamp optically coupled to a monochromator (2 nm). The emission is gathered at 90" and passed through a second monochromator (2 nm). The emitted light is detected with a Peltier-cooled (−30°C), R955 red-sensitive photomultiplier tube (PMT). This same instrument can also be configured for TCSPC measurements, when the excitation source is a nanosecond flash lamp operating under an atmosphere of H_2 gas (0.50–0.55 bar, 0.7 nm FWHM, 40 kHz repetition rate), the output of which is dispersed with a monochromator prior to sample excitation. This particular setup allows access to lifetimes as short as 300 ps. It should be noted, however, that with an alternative light source and detector, TCSPC can measure lifetimes as short as a few ps. The data from time-correlated experiments are analyzed by iterative convolution of the luminescence decay profile with the instrument response function using software packages that are usually provided by the manufacturer.

One example of the use of this instrument is in the investigation of the resonance-energy-transfer-amplified sensing of inorganic anions by Compound *2*. The dipyrrolylquinoxaline (DPQ) moiety of Compound 2 is an efficient energy acceptor for the two pyrene antennae inolecules present in the structure. The excitation of pyrene does not result in emission from pyrene moiety ($\lambda_F = 395$ nm, τ = ca 30 ns). Instead, the energy of the pyrene excited state is rapidly transferred into the DPQ residue of the sensor, which emits ($\lambda_F = 495$ nm. $\tau = 1.8$ ns). This behavior is schematically shown in Fig. 4. The kinetic experiments together with the steady-state excitation spectrum of *2* (which shows remarkable resemblance to the absorption spectrum of 2, including the well-resolved bands of pyrene) were recorded using the above-described TCSPC instrument.

Transient Absorption Spectrometry

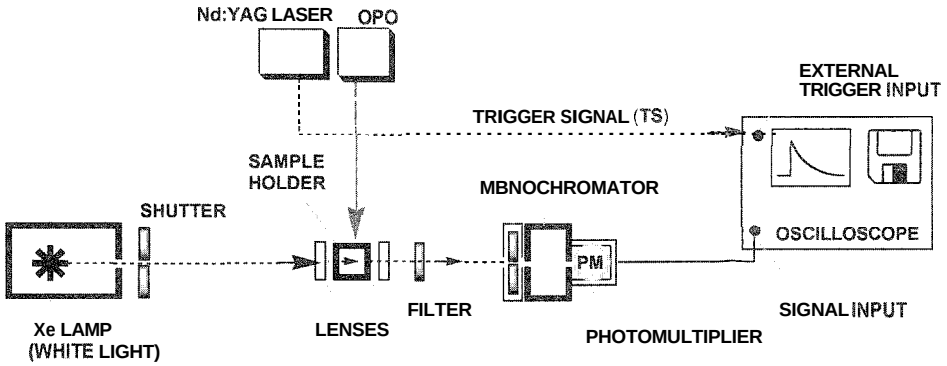
The observation of luminescence. in general. and fluorescence, in particular, requires that the excited state being monitored undergo a radiative decay process that is significant with respect to all the other deactivation processes. If this is not the case, then techniques based on light emission become useless. However. most excited states, radicals, and other transient species of potential

interest to the supramolecular chemist absorb light to some degree. It is this property that is harnessed in transient optical absorption spectrornetry. In the so-called flash photolysis instrument, the absorption spectra and the kinetic behaviors of transient entities are recorded by monitoring their electronic absorption spectra before, during, and after photoexcitation of the sample with a short laser pulse. While this technique is not routinely used in the supramolecular chemistry community, we anticipate that it has the potential to become one of the favorite spectrometric methods for study of the behavior of multichromophoric supramolecular systems.

Instrumentation

Experiments that do not require resolution below a few ns have a distinct advantage in terms of the relative simplicity of instrumentation, because they can be carried out using "real-time" detection. In those cases, a suitable continuous or pseudocontinuous probe source is generated, and the intensity of the probe beam transmitted by the sample can be monitored as a function of time using a photomultiplier tube or suitable photodiode. A typical response time of a PMT+amplifier combination is of the order of 3 ns, and its output can be digitized in real time by a digital storage oscilloscope; currently, oscilloscopes capable of digitizing at 1 Gsamples/s are found. The oscilloscope records the time profile of transmitted light intensity (measured as voltage). The construction details of laser flash photolysis instruments vary between research groups. In recent years, commercial units became available.[5] The schematic layout of a typical nanosecond laser flash spectrometer used by the authors is shown in Fig. 5.

The instrument uses an excitation source of one of the harmonics (266 nm/355 nm/532 nm, 7 ns FWHM) of a Nd:YAG laser (Continuum Surelite I) or tunable visible light from an optical parametric oscillator (OPO) (Opotek). Other pulsed lasers can be employed, the criteria being that a short pulse of light (<20 ns) be produced, with sufficient per pulse energy to generate enough absorbance to rise above the noise inherent in the spectrometer. During the experiment, the laser beam excites the sam-



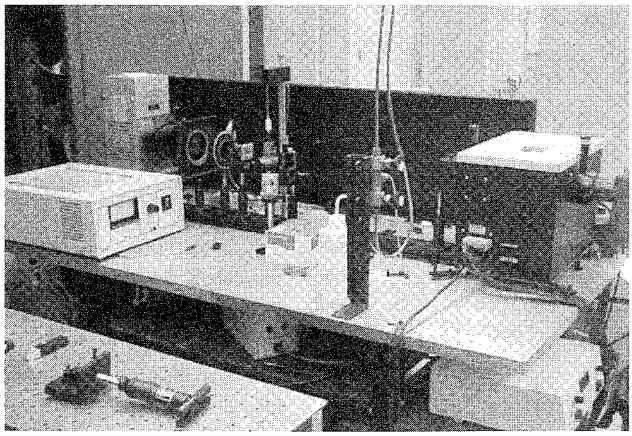


Fig. 5 Nanosecond time-resolved absorption spectrometer located in the author's laboratory. The excitation source is one of the harmonics (355 nm/532 nm, 7 ns FWHM) of a Nd:YAG laser (Continuum Surelite I) or tunable visible light from an OPO (Opotek). Data are acquired at 5 Hz and analyzed with programs assembled using LabView (National Instruments) software. (View *this art in* color at w+vw.dekker.com.)

ple generating the transient species. In many instruments, the pump and the probe beams are perpendicular to each other, but collinear and counterpropagating configurations are also employed. Continuum light sources such as the xenon arc or quartz-halogen lamp are most often used for a probe beam source. These lamps in CW mode provide useful output across the ranges 200–800 nm and 300–1000 nm, respectively. In some cases, it is advantageous to briefly pulse the monitoring lamp to high intensity.

The CW white light transmitted by the sample contains embedded information on the time-dependent absorption spectrum of the generated transients. One method of extracting the information is to select a wavelength of interest with a monochromator, placing a photo-detector at the exit slit. The most widely used detectors are photomultiplier tubes (PMT), chosen for their high sensitivity and fast time response. Solid-state devices, based on Si (200–1100 nm), InGaAs (700–1800 nm) and Ge (800–1800 nm), were also employed. but their lack of dynode amplification necessitates coupling them to high-bandwidth, high-gain amplifiers.

The electrical charge collected by the anode of the detector is caused to run to ground through a load resistance (most often the input impedance of a waveform processing device). This generates a voltage across the resistance. which is processed by a digital storage oscilloscope, or other analog-to-digital converter. These devices can also be used to filter and average signals. The digitized voltage-time profile (at one wavelength) is transfened to a PC for processing and data analysis. Then, the wavelength can be changed by a chosen interval and the data acquisition process repeated sufficient times until sufficient data are accumulated to assemble an absorbance wavelength time, or $A(\lambda,t)$, surface (see Fig. 8). In practice, some signal treatment is required, because often the difference between the amplitudes of the incident and transmitted monitoring beams is very small. of the order of <1% of the total signal, and severely distorted by the intrinsic noise in the spectrometer. In such cases. data acquisition is repeated many times at each wavelength step, and signal averaging techniques are employed. Described above is a method termed "continuous photoelectric recording."

Instead of using the monochromator–detector combination and collecting time profiles at single wavelengths, a spectrographic technique can be employed. In this method, the exit slit of the monochromator is removed, and an anay detector (e.g., a CCD) is placed at the focal plane of the grating/mirror. In this way. the dispersed white light spectrum illuminates the array and each pixel views a given narrow wavelength region, depending on the dispersion of the grating. Thus, the whole transmitted light spectrum is recorded simultaneously. This is termed the multiplex, or Felgett, advantage. Array detectors are limited in time resolution, so to use this method for microsecond and shorter-lived species, a gating method must be used to restrict the time for which the detector views the probe beam to short durations. For example, if dealing with a transient state having a 500 ns lifetime, in order to obtain a time profile with sufficient resolution, it would be necessary to sweep the profile with gate widths of no more than 50 ns.

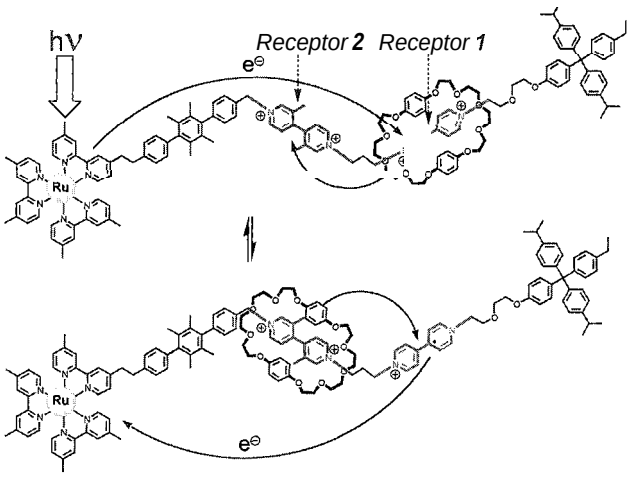

Fig. **6** A photochemically driven translation isomerism in a [2]rotaxane supramolecular machine according to Ashton et al. The flash photolysis data, together with electrochemistry observations, allowed the authors to obtain a complete electronic picture of the processes governing the switching mechanism in this [2]rotaxane, from both energy and kinetic perspectives.

For a supramolecular chemist who wants to investigate the association processes between several chromophores capable of interaction, such as donor–acceptor pairs in resonance energy transfer (RET) or photoinduced electron transfer (PET), laser flash photolysis is an indispensable technique. A particular example is given in a report of a light-driven molecular machine by Ashton et al.[6] The authors studied a [2]rotaxane system consisting of a π-electron-donating macrocyclic polyether bis-*p*-phenylene-34-crown-10 and a dumbbell-shaped component that contains a Ru^{II} trisbipyridine complex as one of its stoppers in the form of a photoactive unit; a *p*-terphenyl-type ring system as a rigid spacer; a 4,4′-bipyridinium unit and a 3,3′-dimethyl-4,4′-bipyridinium unit as π-electron-accepting receptors; and a tetraarylmethane group as the second stopper. The stable translation isomer is the one in which the crown-ether macrocycle is docked in the 4,4′-bipyridinium unit. Upon excitation of the Ru^{II} trisbipyridine moiety of the rotaxane, the photochemical reduction of the 4.4'-bipyridinium takes place. As a result, the polyether macrocycle is shifted to the second receptor site, the 3,3′-dimethyl-4,4′-bipyridinium unit. The reverse electron transfer from Receptor 1 to the Ru^{II} trisbipyridine complex results in a polyether macrocycle shift back from receptor

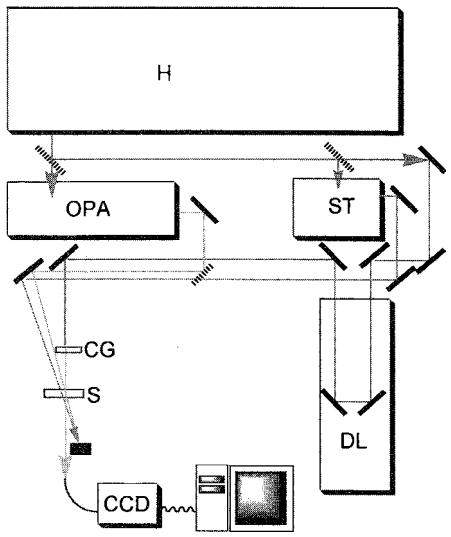

Fig. 7 An ultrafast transient spectrograph used by authors. *(View this art in color at www.dekker.com.)*

1 to Receptor 2. This mechanism of photochemical switching is shown in Fig. 6. The photochemical behavior of the rotaxane. as well as model compounds, was thoroughly investigated by laser flash photolysis, which allowed the authors to observe growth and decay of the individual excited states of the [2]rotaxane components, thus allowing for study of the sequential character of the processes involved.

Ultrafast Techniques

The major limitation of the photoelectric recording widely used for flash photolysis studies on the suprananosecond timescale is what can be thought of as the nanosecond bawier. This limitation arises because of the intrinsic time response of the electronic devices that must be used to acquire and process the photon-generated cathode current of the PMT or photodiode. All such devices have impedance, and even the best-designed circuitry has stray capacitance of typically 20 pF, which, when combined with the 50 Ω industry standard of electronic amplifiers, yields a RC time constant of 1 ns. Hence. instruments built from conventional electronic units will have minimum rise times in the ns region. and therefore. chemical changes that have lifetimes less than 5 ns. say, will be severely deformed. Of course other reasons may intervene (e.g., 10 ns wide laser pulses) that make the instrument response even poorer than implied by the nanosecond barrier.

It is important to find a way around the nanosecond barrier problem if reactions occurring in the subnanosecond regime are to be investigated, and the pump-probe method provides the path. In this, two light pulses are generated: one to excite the sample and one to probe the system at a given time postexcitation. Early pump-probe experiments used high-energy flash lamps for generating the transients and lower energy flash sources as interrogating beams. The two flashes were electronically delayed, one with respect to the other. This procedure stems from the methodology employed by Norrish and Porter in 1949 as part of their invention of flash photolysis leading to the Nobel prize in Chemistry in 1967 and which revolutionized the study of short-lived transient species.[7,8]

Flash lamps were superceded by pulsed laser sources, which are monochromatic, highly collimated, and have a much higher repetition rate. Using a single laser source. the probe pulse can be a small amount split from the main pump beam and sent to the sample via a variable length delay line. Because the pump and probe pulses are of the same wavelength. this experiment is restricted to measuring the kinetics of repopulation of ground state absorption removed (bleached) by the pump pulse. In spite of this restriction, this method was fruitfully employed in several laboratories.[9–12] Significantly more information is available when the probe pulse is a white light continuum coupled to spectrographic dispersion. Coherent continua are generated by taking a few μJ of the laser output, sending it around an optical delay line with a step resolution of 6.6 fs, and focusing it into a suitable liquid or crystal to generate self-phase modulation (a nonlinear optical process involving stimulated Raman and multiwave mixing within the waist of a high-peak-power laser beam). The resulting white light is directed through the irradiated sample, where it picks up the absorption information, and from there it is dispersed in the spectrograph and finally incident on a CCD detector at the focal plane of the spectrograph. Under these conditions. one obtains an absorption spectrum of transient species formed or ground-state species removed by the initiating pulse. This spectrum will be registered at a time that is given by the difference in arrival times of the pump and probe pulses at the sample, and it will be an average over the temporal width of the probe pulse. An alternative method of obtaining spectral information is to employ a probe beam of a selected, but changeable wavelength. Such a beam can be isolated from a continuum by one of a set of interference filters, or it can be generated by an optical parametric amplifier that can be scanned to provide spectral coverage.[13,14] In both instances. the detector is a commonplace photodiode.

Repetition of the spectrum acquisition sequence at different probe pulse arrival times provides a series of spectra delayed with respect to each other. Thus. time resolution of the reaction is achieved in a point-by-point manner, whereby the $A(\lambda,t)$ surface can be produced. In this experiment type, the detector of the transmitted probe

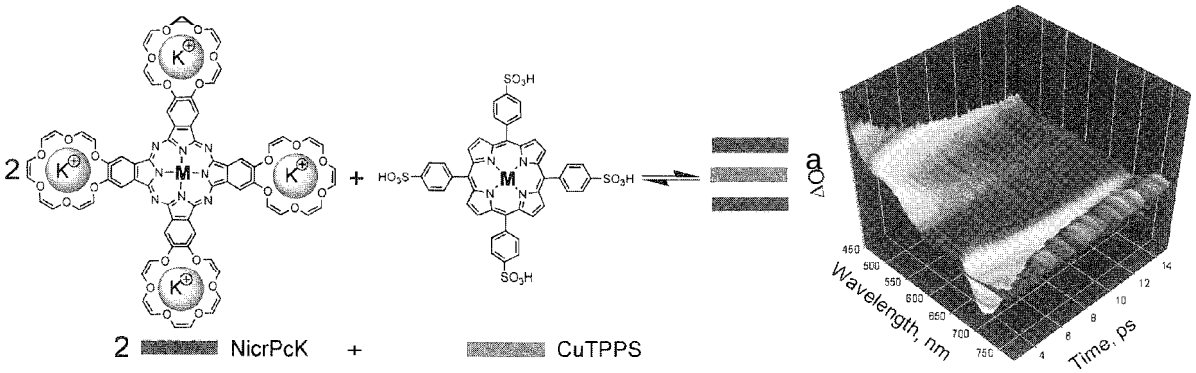

Fig. 8 The dynamic surface shows the first 15 ps postexcitation of the complex formed between NicrPcK and CuTPPS (*View this art in color at www dekker com*)

light (CCD) behaves as a photon integrator only, and the time resolution derives from the instrument's capability for measuring the difference in the time of arrival of the pump and probe pulses. This capability provides an intrinsic limitation to the pump-probe method, which depends critically on the width of the pulses being employed. These days, light pulses as short as 20 fs or less are available.

A schematic layout of the ultrafast system extant at the Ohio Laboratory for Kinetic Spectrometry at Bowling Green State University is shown in Fig. 7. The excitation source (H) is a mode-locked, amplified Ti-S laser (SpectraPhysics, Hurricane). The output (red line) is typically 1 mJ per pulse at a repetition rate of 1 kHz (1 W average power). To obtain useful excitation wavelengths (400 nm, 266 nm) the output of the amplifier is coupled to a harmonic generator (CSX, SuperTripler, ST). To achieve tunable excitation wavelengths in the visible and near 111, the 800 nm beam is employed as a pump for an optical parametric amplifier (OPA-400, SpectraPhysics). The white light probe is generated (CG) by focusing a few μJ of the 800 nm beam into a thin sapphire plate. It is delayed with respect to the pump beam with the variable delay line (DL). It is overlapped with the appropriate pump beam in the sample cuvettc (S) steered into a fiber optic cable, then to the spectrograph (CCD). The PC controls all aspects of data acquisition and processing.

This instrument was employed to examine the excited state dynamics of supramolecular systems generated from self-asseinblies between metal-substituted 18-crown-6 tetra-substituted phthalocyanines (McrPc) with K^+ ions contained in the crown sites (McrPcK) and metal-substituted *meso*-tctrakis(4-sulfonatophenyl)porphyrin (MTPPS) or *meso*-(4-carboxylphenyl)porphyrin (MTPPC). In the absence of added potassium ions, no hetero-complexes were formed. In the presence of K^+, absorption spectral changes indicated the formation of a ligand-to-ligand charge transfer (LLCT) state between the constituent π-systems. Excitation could be carried out at 400 nm, which populated the porphyrin-localized S_2 state or directly into the CT band (690 nm).[15]

Each complex studied showed transient features and kinetics that were independent of the excitation wavelength. The dynamic surface depicted in Fig. 8 shows the first 15 ps postexcitation of the complex formed between NicrPcK and CuTPPS. Subsequent to 400 nm excitation, all coinplexes displayed rapid (sub-ps) conversion to the low-lying LLCT state, deactivation of which involved metal-centered states. In many complexes, the metal-centered states were formed within 2 ps, with lifetimes that varied somewhat with the metal center. In the case of the complex in Fig. 8, repopulation of the ground state occurred with a lifetime of 8 ps. In the figure, the immediate bleaching of the 690 nm LLCT absorption can be seen as a rapidly recovering negative absorption. This is accompanied by a growing spectral band to the red side of the bleach and at shorter wavelengths by the positive absorption assigned to the LLCT state.

Ultrafast fluorescence techniques such as up-conversion and streak camera methods were not described in this article, as these were recently reviewed elsewhere.[''''']

CONCLUSION

After three decades of rapid development, time-resolved absorption and luminescence spectrometry emerged as powerful tools for studying the supramolecular behavior of molecules and materials Such techniques provide complementdry information to steady state UV/Vis nuclear infrared spectroscopy, which may be used to study the supramolecular behavior in the ground state The general sensitivity ot time-correlated techniques combined with insight into the process dynamics and low

amounts of samples required for experiments make these the methods of choice for investigation of supramolecular behavior of chromophores or chromophore-containing materials. With the exception of ultrafast methods, the experimental setups are, in most instances, relatively straightforward and commercially available to supramolecular chemists. At this point, the studies reviewed in this article illustrate how transient and time-resolved luminescence spectrometry can be used to observe and understand the processes of association between molecules and ions in solution. The authors believe that future trends in applications of photochemical techniques would involve. among others, the development of instrumentation and experiments for application to multicomponent (multichromophore) systems and supramolecular behavior on interfaces between solid and liquid. liquid and liquid, etc. Most notably, with the growing accessibility of instrumentation and widening scope of applications, we envision that photochemical methods in conjunction with microscopy will constitute the cutting edge in the transition from bulk-material to supramolecular chemistry on a single-chromophore level.

Phthalocyanines

Marco Evangelisti
Leiden University, Leiden, The Netherlands

INTRODUCTION

Porphyrin-like structures received considerable attention because of their interesting chemical and physical behaviors, and because of nature's ubiquitous use of porphyrins in electron-transfer processes. The phthalocyanine (hereafter referred to as Pc) is a porphyrin-like dye that has been known for many years. The word phthalocyanine, from the Creek for naphtha (rock oil) and cyanine (blue), was first used by Linstead in 1933 to describe a new class of organic compounds.[1] Phthalocyanine was probably discovered by accident in 1907. as a by-product during the synthesis of o-cyanobenzamide, but it was not until almost 20 years later that a patent was filed describing a manufacturing process. Linstead and coworkers showed that a vast range of phthalocyanines, the metal (M)-substituted forms of the molecules (hereafter referred to as MPcs), were all based on the structure depicted in Fig. 1. In a classic series of papers, starting in 1935, Robertson and coworkers showed that the environment of the metal atom in MPcs was square planar and coordinated with four pyrrolic *N* atoms, and moreover, that the entire Pc-molecule was flat within the limits of uncertainty.[2,3]

To date, a large number of different MPcs were synthesized and studied. with a concomitant huge literature of thousands of publications. The impact of the phthalocyanines is so high that. since 1997. John Wiley & Sons Ltd. publishes in regular issues *The Journal of Porphyrins and Phthalocyanines.* Also. monographs on phthalocyanines and their derivatives can be found in the literature.[4] Ill academic laboratories, MPcs received extensive attention for the reasons that follow. They provide a versatile chemical system, and they can be easily crystallized and sublimed, resulting in materials of very high purity. Crystals of phthalocyanines are exceptionally stable in a huge range of temperature and pressure variations. Also. strong acids or bases do not affect conventional MPcs. The conjugated π-system, containing 18 electrons in the macrocyclic ring, leads to reinarkable electronic and optical properties.[5] Especially intriguing is the ability to adjust the phthalocyanine's structural and electrical properties by synthetic means. thus making them ideal model compounds. They are. moreover. of great interest for their magnetic properties, because manganese phthalocyanine (MnPc) was one of the first molecular magnets,[6] and iron phthalocyanine (FePc) has one of the largest internal hyperfine fields ever reported for iron coordination compounds. regardless of the spin value.[7]

USES OF METALLOPHTHALOCYANINES

As a consequence of their chemical and physical properties, phthalocyanines are widely exploited in industry in a variety of applications.[8,9] For example. the English Royal Mint uses the popular copper-substituted variety (CuPc) as a blue dye in £5 notes. Besides as conventional dyestuffs. MPcs are commercially used as coatings for read/write CD-ROMs, with obvious implications for the coinputer and communications industries. Moreover, many types of chemical sensors based on phthalocyanines were proposed, including thin-film resistive devices, FET sensors; and Langmuir–Blodgett films. They are also used for electrochromic display devices, photovoltaic and electrophotographic devices, shields against electromagnetic interference, germicides. and deodorants. In addition, cobalt phthalocyanine is used as a homogeneous catalyst in the industrial desulfurization of crude petroleum (the Merox process), while iron phthalocyanine (FePc) is a useful laboratory catalyst for several oxidation reactions: including hydrocarbon oxidations.[10] Particularly important, in this respect. is that FePc is currently used to prepare arrays in large-scale production of carbon nanotubes[11] that have electronic properties currently of great interest for promising technological applications. Also, in medicine, the fluoroaluminum phthalocyanine was extensively studied for potential use as a target molecule in anticancer treatments. For these purposes, more than 50,000 tons of Pcs are used per year.

A VERSATILE CHEMICAL SYSTEM

The methods of synthesis. originally described by Linstead, are still the most widely used for preparing phthalocyanines. Effective solvents to obtain metal-free Pc (M = 2H) from 1,2-dicyanobenzene are found to be dialkylalkanolamines. Many MPcs are obtained by reacting a derivative of 1,2-dicyanobenzene with a finely

DOI: 10.1081/E-ESMC 120019177

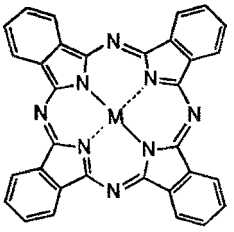

Fig. 1 Chemical structure of metallophthalocyanines.

dispersed metal or a metal salt. The reactants are usually heated in high-boiling-point solvents like *o*-dichlorobenzene and chloronaphtalene. The nature of the sequestered metal ions has an influence on the physicochemical properties of the MPc. For example, the oxido-reduction behavior of the molecular unit or the nature of the photochemical excited state may be altered by changing the metal ion in the complex. By varying substituents on the ring, the range of properties of MPcs may be expanded even further. In recent years, many reports appeared on the synthesis of new phthalocyanine derivatives. These experiments are aimed at the development of materials with specific properties. Of the numerous compounds based on Pcs. some selected examples are reported in what follows.

SELECTED EXAMPLES OF PHTHALOCYANINES AND THEIR DERIVATIVES WITH SPECIFIC PROPERTIES AND POSSIBLE APPLICATIONS

Indium Phthalocyanines as Optical Limiters

Phthalocyanines have interesting optical properties that may be useful for nonlinear optical applications of these complexes. In this respect, optical limiting of indium phthalocyanines (InPcs) is particularly promising, as evidenced by the research activity of Hannack and coworkers in the last few years.[12] They succeeded in optimizing InPc for optical limiting using different axial and peripheral substituents and expanding the ring to naphthalocyanines. Among the phthalocyanines, the materials with tetra-tert-butyl peripheral substitution and (*para*-trifluoromethyl)phenyl-, and perfluorophenyl- axial substituents

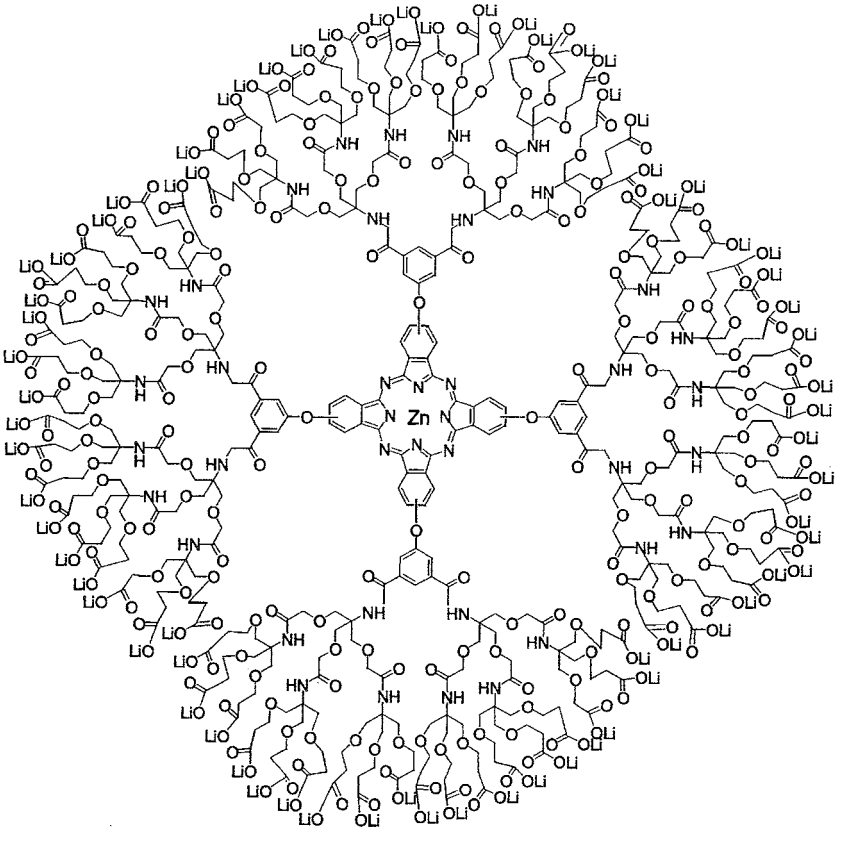

Fig. 2 The first reported and water-soluble dendritic phthalocyanine. (After Ref. [13]. Reproduced by permission of The Royal Society of Chemistry.)

were found to be useful materials for optical limiters in the 480–580 nm range.

A Phthalocyanine-Based Dendrimer for Harvesting Low-Energy Photons or for Photoinduced Electron Transfer Reactions

Metallophthalocyanines are poorly soluble in water. A way to increase their solubility is by introducing substituents onto the aromatic rings. This is the case, for example. of the first dendritic phthalocyanine that was reported in 1998 by Kobayashi's group.[13] The octakis[3,5-(dicarboxy)-phenoxy] ZnPc was first synthesized and eight triply-branched carboxyethylesters containing amino groups were reacted in the presence of dicyclohexylcarbodiimide. The 23 terminal ester groups were hydrolyzed with LiOH in MeOH–H_2O. A repeat of this reaction gave the second-generation dendrimer. After hydrolysis, the compound became the first water-soluble dendritic phthalocyanine (Fig. 2) with an approximate diameter of 5 nm. Dendrimers are of great interest for their possible uses, because they function for harvesting low-energy photons[14] or giving a hydrophobic environment in aqueous solutions.[15] Because Pcs are robust. dendrimers of MPcs are promising candidates for future research.

Electronic Conductors Based on Phthalocyanine Complexes

Similarly, the solubility of Pcs in organic solvents is increased by introducing bulky substituents on the ring. For example, Pc derivatives substituted with crown ether macrocycles[16] are soluble enough in organic solvents to be deposited from solutions and arranged in thin films. which may, thus, be used for electrical devices and sensors. Even if these materials are insulators when undoped (as are conventional MPcs), they possess, however, accessible π and π^* orbitals that make at least partial oxidation or reduction of the macrocycle possible with gases such as NO_2. This yields more or less conductive molecular materials. The presence of the metal ion is not a prerequisite for high electrical conductivity. For example, room temperature measurements on the 15-crown-5 metal-free Pc derivative showed that the conductivity increases notably (with satisfactory reversibility) when the layers are exposed to NO_2 in the range of 1–5 ppm.[16] Of importance here there is that there are, also, Pc complexes of rare-earth ions,[17] which are far more easily oxidized and reduced than the Pc derivatives substituted with crown ether macrocycles. These rare-earth-containing derivatives are most often

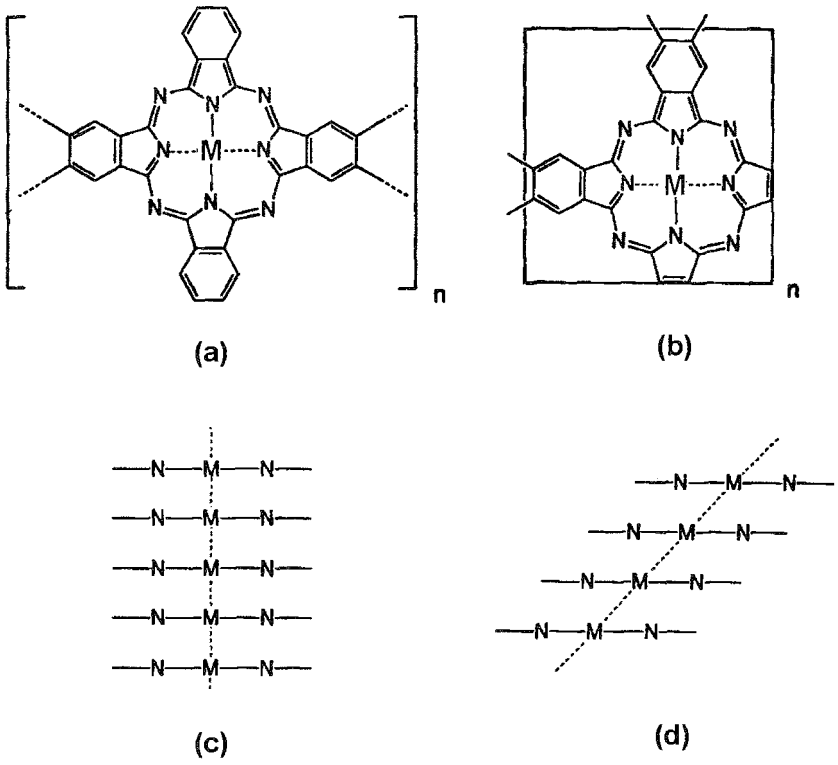

Fig. *3* Different ways of assembling phthalocyanines: (a) a ladder polymer: (b) a plane polymer; (c) and (d) stacked arrangements

dimeric, with the metal "sandwiched" between the two Pc rings. Rare-earth ions are normally in the 3+ state, and the dimer is a neutral molecular radical. This radical was reported to be the first intrinsic molecular semiconductor.[18] For a recent review on dimers of phthalocyanines and related compounds, we refer the reader to Ref. [19]. Organic conductors based on Pcs were investigated extensively (see. i.e., Ref. [20]). Large systems of these metal complexes can be assembled in three different ways (Fig. 3). A first a rangement is that of the ladder polymers and a second one that of the plane polymers.[21] The latter type, e.g., polyCuPc, has conductivity 10"" times higher than that of monomeric CuPc. A third possible way of assembling MPcs is via the stacked arrangement. This arrangement leads to low-dimensional materials and permits electron delocalization by π–π overlap of the macrocycles. This stacking is thought to be a prerequisite for facile electrical conduction.

Network Planar Polymers of Phthalocyanines as Catalysts or Adsorbents

Network planar polymers of phthalocyanines (Fig. 3) are a subject of ongoing research: because they have potential technological applications, such as catalysts and adsorbents. Because phthalocyanines are highly stable toward low pressure, a range of solvents. and elevated temperatures; they are desirable in applications. The drawback is that, in comparison with catalysts and adsorbents made by inorganic nanoporous materials, with surface areas as high as 1200 m^2/g, phthalocyanine-based network polymers usually have low porosity, with low values of surface areas ($\approx$1 m^2/g). However, promising preliminary studies of novel phthalocyanine-based network polymers showed that the surface area may be notably increased (450–950 m^2/g) by using *bis*(phthalonitrile), which provides a rigid spirocyclic linker for the phthalocyanine molecules.[22]

MAGNET16 PROPERTIES OF METALLOPHTHALOCYANINES

Polymorphism and Magnetic Interactions

From the discussion above, it is, thus, clear that the packing of the Pc molecules has a strong influence on the physical properties of the materials. Pcs seldom crystallize in the stacked arrangement shown in Fig. 3. Generally. the packing is as illustrated in Fig. 4, for the so-called α- and β-forms. These two forms were first reported in the early days for the CuPc and. subsequently. for other MPcs. A detailed description of the early research on the polymorphism of MPcs can be found in Ref. [23]. In more recent

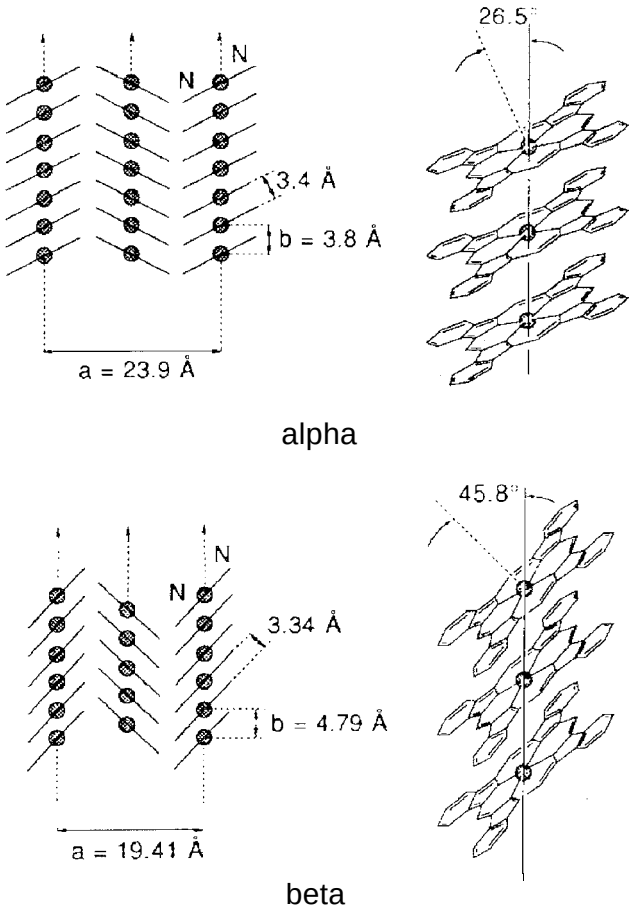

Fig. 4 Structural arrangements of macrocycles in the α- and 8-forms.

years, several new forms were reported." The main differences between the polymorphic structures are, for example, different angles of the Pc molecules with respect to the stacking axis, linear or slipped arrangement of the molecules along the stacking axis, and, consequently. different overlapping of the neighboring molecules. In what follows. we will consider only the a- and β-forms, which are the most well known. We will see how they determine the magnetic properties of some selected examples of MPcs. nominally manganese and iron phthalocyanines.

Manganese Phthalocyanines

In the a- and β-forms, the molecules are tilted by a substantial angle with respect to the chain axis (Fig. 4): in the a-form. the angle between the stacking axis and the molecular plane of MPc is about 65°. while in the β-form,

"For a detailed description of crystal structures of Pc complexes. see Refs. [4,24].

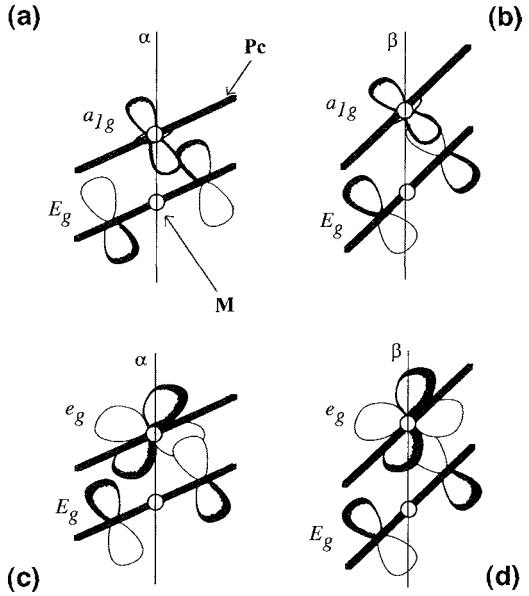

Fig. 5 The a_g–E_g interaction for α-form (a) and β-form (b), and the e_g–E_g interaction for α-form (c) and β-form (d).

it is about 45°. The angle at the parallel adjacent chain is opposite. thus constructing a so-called "herringbone" structure. The particular structure in the β-form of manganese phthalocyanine (β-MnPc) is thought to cause the Mn–Mn ferromagnetic interactions that make this compound one of the first molecule-based magnets.[6] Upon cooling below 8.6 K, β-MnPc undergoes a phase transition to a canted ferromagnetic state. The magnetic moment associated with each molecule is essentially perpendicular to the macrocyclic plane, and, hence, is canted with respect to the stacking axis. On the contrary, the a-form of MnPc is antiferromagnetic.[25] To understand these different behaviors, we will examine the spin correlation between Mn ions in adjacent molecules, because the orbital overlaps determine the magnitude of the magnetic interaction (Fig. 5). Here we must notice that the orthogonal metal $3d^5$ and Pc π orbitals in the same molecule make the ferromagnetic interaction. Under the assumption that the electronic configuration of the $3d^5$ electrons is $(d_{xy})^2(d_{xz})^1(d_{yz})^1(d_{z2})^1$, the ferromagnetic interaction is caused by the overlap between the d_{z2} unpaired electron (a_g symmetry) with the π orbital of E_g symmetry of the adjacent aromatic ring, which is orthogonal to the d_{z2} orbital of its metal ion. The antiferromagnetic interaction is due to the overlap of the $d_{xz}d_{yz}$ orbitals (e, symmetry) with the same π orbital of E_g symmetry. If the angle between the stacking axis and the Pc-ring increases from 45" to 65°, the overlap of the d_{z2} and the adjacent π orbital moves from the electron-rich N atom towards the node. Consequently, the ferromagnetic interaction will become weak. Thus. in the β-MnPc, the ferromagnetic mechanism dominates, while in the α-MnPc. the antiferromagnetic path prevails over the much weaker ferromagnetic path.

A Ferromagnetically Ordered Metalloporphyrin

The search for molecular magnets is. at present. a subject of intense investigation.[26] It follows that the observation of ferromagnetic correlations in the β-form of manganese phthalocyanine stimulated the research on the magnetic properties of this kind of material. Nevertheless, the most interesting results were obtained only recently. Structurally similar to the phthalocyanines, the metalloporphyrins may also stack in different forms, giving rise to different magnetic properties. In 1998, it was reported that iron(II) octaeihyitetraazaporphyrin crystallizes in two structures: the α-form, which is a canted molecular ferromagnet. with a critical transition temperature $T_c = 5.6$ K, and the β-form, which remains paramagnetic down to I K.[27] Thus, iron(II) square coordinated complexes also seem prone to show different magnetic behavior depending on the stacking structure.

Iron Phthalocyanines

In view of these experimental findings. a detailed characterization of the magnetic properties of iron phthalocyanines (FePc) was recently carried out.[7] There are two forms of FePc described in the literature. The a-form is metastable and obtained either as a polycrystalline powder or as a thin film formed by vacuum deposition onto a cold substrate. The β-form is the most stable and may be obtained from the sublimation technique in the form of a single crystal. Since 1935, the β-form of this compound has been repeatedly reported to behave as a paramagnet down to the lowest measured temperatures. Instead, detailed magnetic studies of the a-form of iron phthalocyanine (α-FePc) showed the onset of strong ferromagnetic correlations within the Fe ions along the stacking axis.[7] For comparison. the magnetic susceptibilities of the a- and the β-forms are shown together in Fig. 6. It can be seen that the two susceptibilities are coincident at high temperatures, but that they strongly differ once the temperature is lowered below 100 K. The fact that the susceptibility of β-FePc goes to zero at very low temperatures was explained in terms of zero-field splitting of the $S = 1$ triplet state of the Fe ion. leaving a nonmagnetic singlet as the lowest energy level occupied. Differently, the susceptibility of α-FePc increases strongly by lowering the temperature, indicating the presence of ferromagnetic correlations among the Fe ions. Only at

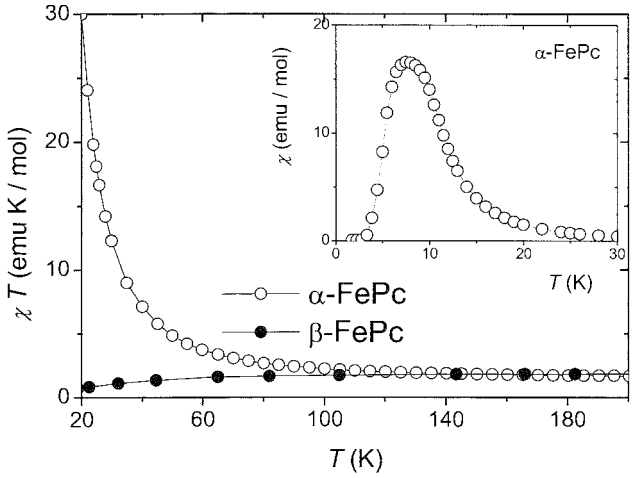

Fig. 6 Experimental $\chi_m T$ versus T curves for α-FePc (O) and β-FePc (●). In the inset: the low-temperature variation of the molar magnetic susceptibility of α-FePc.

about 10 IS does the susceptibility show a change of slope, and a rounded maximum is found at still lower temperatures (inset of Fig. 6). The decrease below the maximum was explained in terms of increasing domain-wall stiffness of the ferromagnetically coupled Fe ions along the stacking axes with decreasing temperature. which is common in molecularly based ferromagnets exhibiting anisotropy and low magnetic density. By means of alternate-current magnetic susceptibility measurements, it was also reported that the maximum in the susceptibility depends strongly on the frequency of the alternate current."' Such a behavior was already observed in metalloporphyrins,[27,28] which have similar structures to the FePc, and implies that a fully ferromagnetic ordered state is not achieved in these systems. The reason is again intrinsic to the magnetic structure. The low-temperature properties of anisotropic ferromagnetically coupled Fe (or Mn) ions along the stacking axes are dictated by the thermal excitation of domain walls. It follows that if the metal ions belonging to neighboring axes are weakly magnetically correlated. the establishment of a fully ordered magnetic state can become a delicate process that is readily disturbed by the presence of lattice defects. i.e.. stacking faults of the molecular arrangement along the axes. The presence of structural disorder was already directly observed by means of high-resolution transmission electron microscopy in several metalloporphyrins and metallophthalocyanines.[29] The magnetic behavior of α-FePc strongly resembles that of a glassy system, in which a freezing of the magnetic components is formed below a certain temperature into a state of random magnetic disorder.

Curiously, the magnetic phenomenology of the FePc forms is opposite that reported above for the MnPc forms: i.e., FePc is ferromagnetic when it is in its α-form, while MnPc is ferromagnetic when it is in its 6-form. To explain such a difference, we should again consider Fig. 5 and Fig. 4. Using the same arguments that we used for the MnPc forms. it is easy to show that the only possible electronic configuration of the Fe ions giving rise to ferromagnetic correlations is given by $E_gB\ (d_{z2})^2(d_{xz})^2(d_{yz})^1(d_{xy})^1$. However, the intensity of the ferromagnetic exchange should probably be weak: because it is in the *xy* plane, and the overlap is small. Thus. most likely, the ferromagnetic coupling present in the a-form does not originate from exchange interactions. On the other hand. the condition for enhancement with respect to the β-form of the direct Fe–Fe interaction is fulfilled. because the Fe–Fe distance is reduced from 4.8 Å (6-form) to 3.8 Å (a-form). In this respect, the overlap between a half-filled and a full orbital gives rise to ferromagnetic coupling. It follows that if the orbital configuration is $E_gA\ (d_{xy})^2(d_{xz})^2(d_{yz})^1(d_{z2})^1$, as proposed by Coppens and coworkers for the β-form from accurate x-ray diffraction,[30] the overlap may take place between two $(d_{xz})^2(d_{yz})^1$ orbitals. Of course, this overlap will decay strongly when the atoms are separated further by 1 Å, and so the fe romagnetic interaction weakens to the extent of being negligible in the β-form.

CONCLUSION

The β-MnPc and the α-FePc are the only known examples of phthalocyanine-based magnets. A strategy to achieve molecular magnetic ordering was to couple in three dimensions ferromagnetically coupled chains. The β-MnPc compound. having the Mn ions ferromagnetically correlated along the stacking axes of the molecules, belongs to this class, with $T_c = 8.6$ K.[6] Other attempts to obtain ferromagnets with this strategy, such as α-FePc and the metalloporphyrine electron transfer salts. have in common the incomplete achievement of magnetic long-range order at low temperatures.[7,26,27] This is inconvenient in the search for molecular magnets. The reason for this shortcoming is that the building elements are ferromagnetic linear chains. and they are sensitive to defects, because a single defect breaks long-range magnetic order in a chain. So, the shortcorning is inherent to the approach. However, and for the same reason, they provide new phenomenology to clarify the interesting field of coexistence of ferromagnetism and glassy behavior.

π–π interactions: Theory and Scope

Ban *Dance*
University of New South Wales, Sydney, New South Wales, Australia

INTRODUCTION

Intermolecular interactions involving aromatic sections of molecules are common in chemistry, biology, and materials science. The prototypical properties and conceptual framework for these interactions are introduced first, then the scope of the interaction will be surveyed, followed by more detailed description of key current fields of investigation and application.

FUNDAMENTALS

An aromatic hydrocarbon molecule, usually flat, contains a cyclic or polycyclic carbon framework that supports π-delocalized electron density. The n-electron density is polarizable, and this enhances the stabilizing dispersion interactions between the aromatic molecule and its neighbors. In addition, if there are more polarizable (larger Z) atoms or groups involved in the n-delocalized bonding, these dispersion stabilizations are further enhanced. In these ways, the underlying van der Waals contributions to intermolecular stabilization energy are more favorable for π-delocalized aromatic molecules than for analogues without this bonding.

There is also an electrostatic component of the intermolecular stabilization, and this provides directionality. In an aromatic hydrocarbon, there is small polarization of C–H bonds, yielding a slightly negative charge over the n-bonded core, relative to the slightly positive rim of hydrogen atoms on the edge of the molecule. This may or may not introduce a molecular dipole, depending on the structure of the molecule, but it will introduce higher multipoles: benzene, for example, possesses a quadrupole moment.

Maximization of the electrostatic stabilization energy between multipoles is the source of directionality in aromatic–aromatic interactions. The concepts of multipoles can be substituted with the more chemically intuitive concepts of favorable orientation of the relatively positive and negative sections of the molecule. Consistent with these fundamental properties, there are two commonly observed geometrical relationships between adjacent aromatic molecules. These are illustrated for benzene in Fig. 1, and they are known as the offset-face-to-face (OFF) motif, and the edge-to-face (EF) motif. In the OFF geometry, the molecules are exactly or closely parallel but are offset so that the oppositely charged regions of the molecules are closest. In the EF motif (sometimes vertex-to-face, sometimes called T-shaped) the relatively positive hydrogenic rim is directed toward the central negative π-electron density.

There is a third geometrical type, in which parallel aromatic molecules are parallel but not offset, i.e., face-to-face (FF) or eclipsed. For the electrostatic reasons just outlined, this is not an energy minimum for a pair of identical molecules in a symmetrical motif and is rarely observed. However, if the two aromatic molecules in a motif are different, with complementary electron distributions, the FF motif can be the energy minimum. One of the better-known instances of this is the intermolecular interaction between a hydrous arene and a perfluorous arene. Due to the opposite polarization of the C–H and C–F bonds, the molecular quadrupoles of C_6H_6 and C_6F_6 are oppositely signed, and so the electrostatic intermolecular stabilization between them is maximized with FF geometry.

In this article. the adjective "aromatic" is generally used to encompass many chemical types characterized by delocalized n-bonding and relatively flat local geometry.

The term "n-stacking" is commonly used for aromatic–aromatic interactions. This is sometimes appropriate. but often is not because only two molecules are involved, or because there is EF geometry. Throughout this article, the generic description "aromatic–aromatic interactions" is used, and the term "stack" is used only for legitimate sequences of parallel molecules.

The content of this article is restricted to systems with at least two aromatic molecules: there are other sets of intermolecular interactions involving cations, or hydrogen-bonding molecules,[1] interacting with the π-delocalized aromatic molecules.

At the outset, it is important to appreciate the energies of aromatic–aromatic intermolecular interactions. The stabilizing energy for a pair of benzene molecules in either the OFF or EF arrangement is about 2.2 kcal mol^{-1} (9 kJ mol^{-1}), which is about 40% of the energy of a hydrogen bond between two water molecules. Further energy information is provided later in this article in the section entitled "Geometries and Energies of Intermolecular Aromatic Interactions."

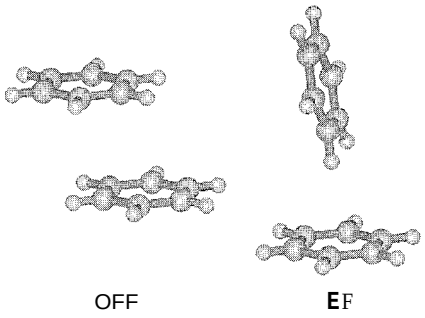

Fig. 1 The offset-face-to-face *(OFF)* and edge-to-face *(EF)* motifs for benzene. *(View this art in color at www.dekker.com.)*

The primary concept for aromatic–aromatic interactions is nondirectional van der Waals stabilization, enhanced by π-polarizability, plus electrostatic stabilization that is directional. This concept needs to be expanded, because there are additional sources of stabilization. Where two aromatic molecules have different electron affinities, such that there is a complementary relationship of electron-donor–electron-acceptor, then there is a stabilizing charge-transfer component to the interaction (see section below entitled "Polarizable π-Donors and n-Acceptors and Significant Charge-Transfer Solids"). As an extension of this, if one of the aromatic entities is charged, there is additional electrostatic stabilization of the interaction. and if two adjacent aromatic entities have opposite charges, there is strong electrostatic stabilization that dominates the other intermolecular energies. Partial charging of aromatic entities in opposite directions occurs when there is substantial difference in electron affinities or redox potentials, and electron transfer occurs from donor to acceptor.

In addition, the general hydrophobic character of aromatics (at least of aromatic hydrocarbons) leads to a solvophobic stabilization in polar and hydrogen-bonding solvent systems: the concept is that segregation of hydrophobic and hydrophilic components in the condensed phases is thermodynamically advantageous.

Another basic determinant of aromatic–aromatic interactions is molecular shape. The aromatic sections of molecules are generally flat and disc shaped. Purely geo-

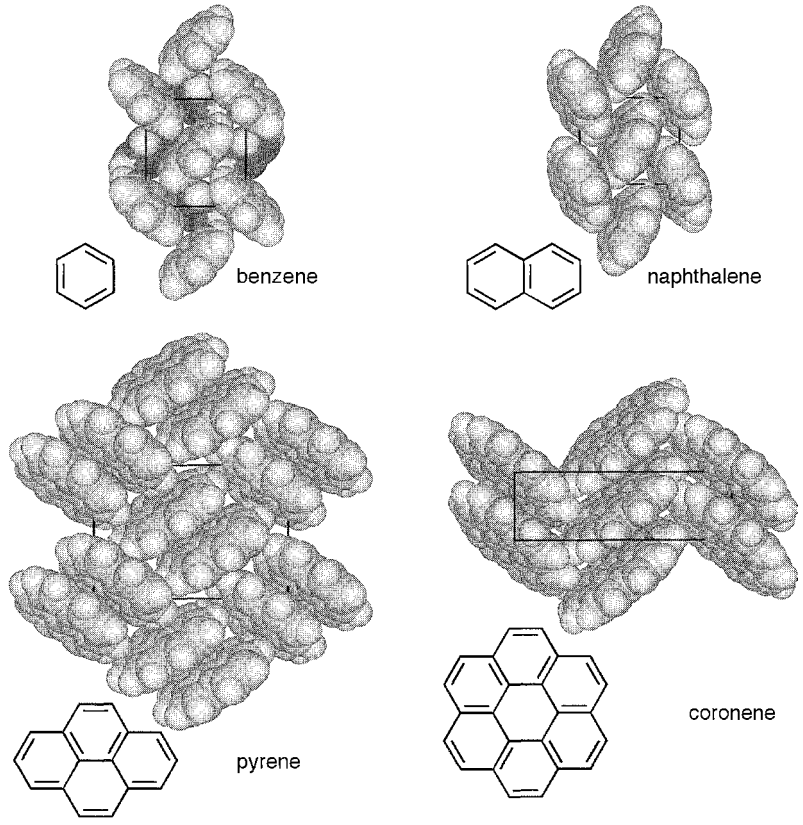

Fig. 2 Comparable representations of the crystal structures of benzene, naphthalene. pyrene, and coronene. Each projection is along the appropriate crystallographic axis. and in all structures except benzene, the molecular arrangement is simply translated along the projection axis. The different packing of benzene is illustrated by inclusion of part of the layer behind. with carbon colored blue. (*View this art in color ut www.dekker.com.*)

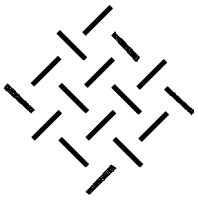
metric factors are involved in considerations of the modes of association. A stacking of discs is clearly efficient but also generates substantial intermolecular space around the edges of the discs. The area of the disc relative to its thickness influences the modes of association of aromatics. For relatively small areas, the EF motif can be developed more effectively than the OFF motif, and the herringbone pattern that contains only EF motifs is commonly observed. As the area of the aromatic face increases, the OFF motif becomes more prevalent. This trend in geometrical structure for aromatic–aromatic interactions is manifest in the crystal structures of polycyclic arenes, as exemplified in Fig. 2 for benzene. naphthalene. pyrene. and cossolene. In benzene and naphthalene, the crystal packing is herringbone, with no OFF motifs. In crystalline pyrene, pairs of molecules in the OFF motif are repeated in herringbone fashion, while in the larger corrolene molecular crystal, there are infinite offset stacks of aromatics, with the maximum number of OFF motifs. This analysis was applied to a larger number of polycyclic arenes.[2]



herringbone pattern

In Fig. 2. it is noticeable that there is variation in the angle between arene planes in the EF motifs. This is characteristic of aromatic–aromatic intermolecular motifs: there is little variation in energy with angle, and the concept of a continuous range of stability between the parallel OFF motif and the angled EF motif is valid. Aromatic–aromatic intermolecular potentials are soft.

At the upper size limit of aromatic systems, nonmolecular graphite, the structure is completely π-stacked. and offset. The shearing softness of graphite manifests the soft energy variation with the degree of offset in parallel motifs. (Further information on this is provided in the section below entitled "Geometries and Energies of Intermolecular Aromatic Interactions.") Offset stacks are also named "slipped π-stacks'' or "skew stacks."

THE SCQPE OF AROMATIC–ARBMATE INTERACTIONS

In this section. some of the diversity and scope of aromatic–aromatic interactions is illustrated. For example, the curved surfaces of C_{60} and other fullerenes are known to engage in parallel and oblique interactions with other arenes, mimicking the OFF and EF motifs.[3]

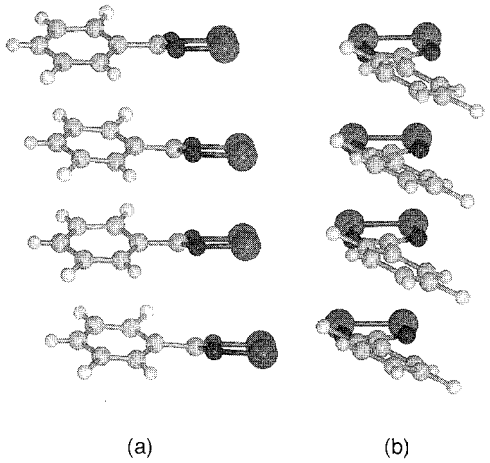


Fig. *3* The stacking of the difluorophenyl diselenadiazolyl radicals (2. E = Se) showing (a) the almost eclipsed stacking of diselenadiazolyl rings and (b) the offset stacking of the difluorophenyl rings: Se. red: N, blue; F, yellow. (Adapted from Ref. [5].) (View *this art* in color *at www.dekker.com.*)

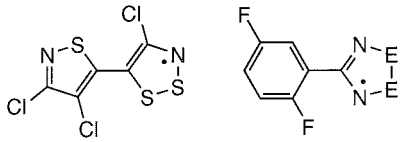
Heteroarornatic molecules. and particularly polycyclic arenes with N, O, or S substitution for carbon. are prone to aromatic–aromatic interactions. As the size of the x-delocalized system increases, the OFF motif prevails over EF, but because the charge distribution and occurrence of dipoles and higher electrostatic multipoles can be variable in heteroaromatics, the nature of any offset between parallel planar molecules can similarly be variable. Net charges that can occur on heteroaromatic molecules also influence intermolecular energy and geometry.

Odd-electron aromatic systems, such as the thiazolyl radicals **1**[4] and **2**[5] form x-stacks. Shown in Fig. 3 are details of the stack formed by 2 (Se). revealing that the diselenadiazolyl rings are stacked in almost eclipsed FF geometry. while the difluorophenyl ring is twisted from the plane of the diselenadiazolyl ring so that the stack of difluorophenyl rings has the normal offset geometry. Some radical species undergo a weak dimerization and pairing of the electrons. which results in irregular stacking: these effects are significant for the magnetic properties and applications of these paramagnetic aromatic materials.



1 **2** E = S, Se

Metalloporphyrins **3** and metal phthalocyanine complexes 4, as well as the metal-free ligands, commonly engage in aromatic–aromatic interactions.

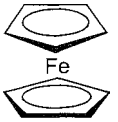
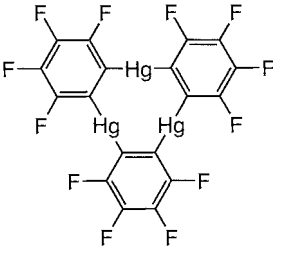
Metallocene molecules, such as the prototype ferrocene 5. pack in crystals mainly with EF motifs, similar to the crystal packing of benzene.



5

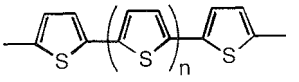
Organometal compounds like 6 form π-stacks[6] as illustrated in Fig. 4.



6

A significant property of Structure 6 is the intercalation of polycyclic arenes to form binary stacks of alternating 6 and arene.[6,7] The structure of the mixed stack of **6** and pyrene is shown in Fig. 5. The photophysical properties of these compounds are significant. and the binary stacked compounds with pyrene. naphthalene. and biphenyl exhibit strong phosphorescent emissions in the red. green, and blue regions. respectively.[7]

Aromatic interactions occur between conducting partially oxidized polyheteroarene polymers. such as polythiophene.[8]



polythiophene

sion stabilization of intermolecular interactions. Further, substitution of electron-donating or electron-withdrawing atoms or groups at appropriate locations in a molecule can change its overall electronegativity. This leads to π-delocalized heteroaroniatic molecules with distinct donor and acceptor properties, which then leads to partial charge transfer when donors and acceptors are combined. This charge transfer influences the electrostatics of the heteroaromatic–heteroaromatic interactions. Donor properties correspond to relatively low ionization potential (or favorable electrochemical oxidation potential), and are enhanced by electron-releasing substituents or negative charge, while acceptor properties are the opposite. Many combinations of polarizable π-donors and polarizable n-acceptors are now known in condensed phase materials, mainly crystals. Extensive investigation of these compounds has been stimulated by discoveries so that a number of them have enhanced electron conductivity and are regarded as "organic metals."

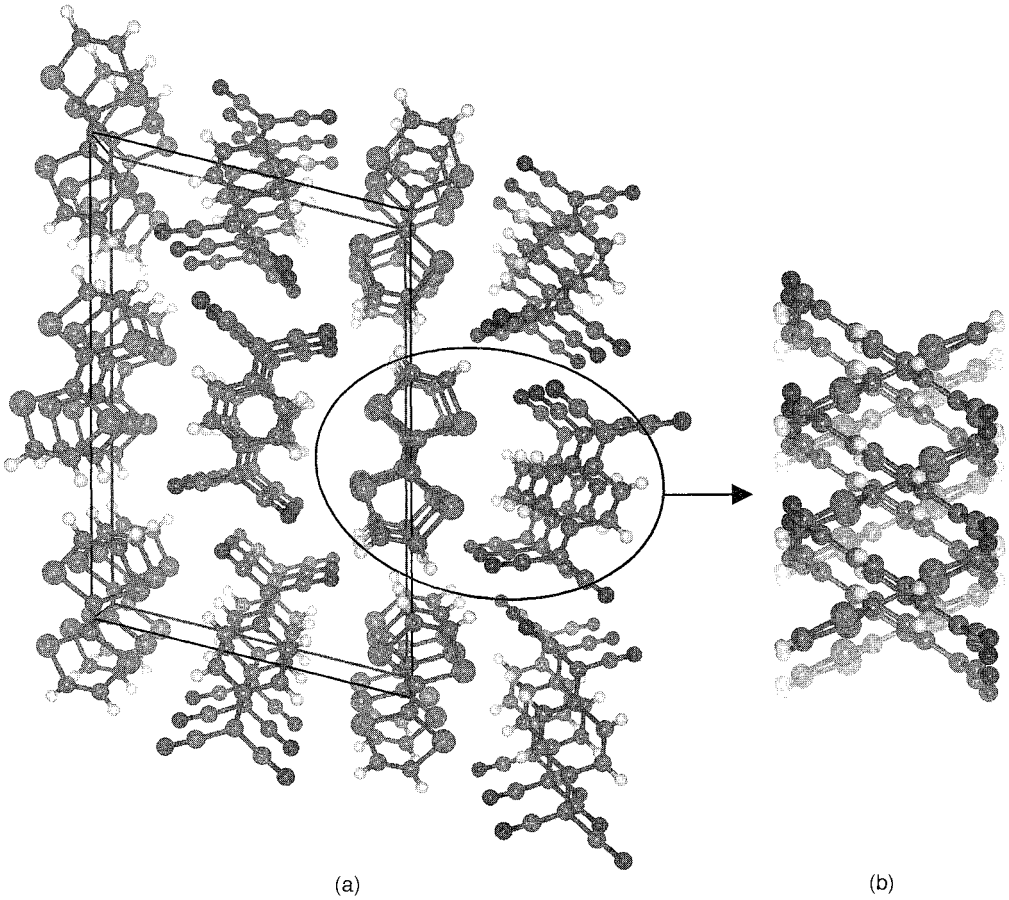

Fig. 6 Aspects of the crystal structure of TSeF–TCNQ [14] (a) The tuo components. TSeF (Se. led) and TCNQ, occur in segregated stacks. drawn with perspectıve (b) The stacks of TSeF and TCNQ are oppositely inclined to the stacking axıs (25° TSeF, 34° TCNQ). and within each stack, the molecules are OFF (*Vieu this aıt ın colo1 at www dekker coin*)

A few typical examples of the hundreds of such donor and acceptor heteroaromatic molecules[11,12] are shown in Charts 1 and 2.

Metal dithiolene complexes[13] such as $[M(mnt)_2]^z$ and $[M(dmit)_2]^z$ (see Chart 3) are electron-transfer active and can be readily generated in oxidized or reduced forms with variable charge z and can be used as either donors or acceptors.

One of the most studied donor–acceptor complexes is TTF–TCNQ, and its selenium homoiogue TSeF–TCNQ. Shown in Fig. 6 are aspects of the crystal structure of TSeF–TCNQ.[14] It is estimated that the degree of charge transfer in this solid is 0.63,[15] i.e., the species are $TSeF^{+0.63}$ or $TCNQ^{-0.63}$. The n-interactions occur within the stacks of homo-charged species, and the interplanar spacings are relatively small. 3.52 Å for TSeF and 3.21 Å for TCNQ. TTF–TCNQ and TSeF–TCNQ are one-dimensional conductors along the stack direction.

In Fig. 7, part of the structural chemistry of a different example is shown, with the composition $(BEDT\text{-}TTF)_2[Br_{1.3}I_{1.1}Cl_{0.6}]$.[16] The anion component is a mixture of the mixed trihalides I_2Br^-, IBr_2^-, $BrICl^-$, and ICl_2^-, which is specifically required to form this material that has three crystal phases. One phase. β″, is metallic and occurs in two separate temperature ranges; <185 K and >395 K, and is shown in Fig. 7. It contains stacks of $BEDT\text{–}TTF^{+1.5}$ cations, separated by layers of trihalide monoanions. The other phases have different geometrical relationships between the $BEDT\text{–}TTF^{+1.5}$ stacks.[16]

There are numerous examples of donor–acceptor complexes involving components like those in Charts 1 and 2 and dithiolene complexes. While there is considerable structural diversity, n-stacking is a common feature. Another common property is partial charge transfer from donor to acceptor, and anions such as $(TCNQ)_3^{2-}$ occur. As intimated in the previous example: small variations in structure can have large effects on physical properties.

Metallic conductivity, superconductivity, and cooperative magnetic properties are the most significant attributes of these donor–acceptor (and partial charge transfer) solids.[15] These properties derive from the partially occupied delocalized n-orbitals of the donor and acceptor species. which overlap to form energy bands along the stacks. Interactions between the stacks are less important, as the conductivities are usually anisotropic. Enlargement of the donor and acceptor species diminishes the coulombic destabilization of stacks of homo-(partially)-charged molecules.

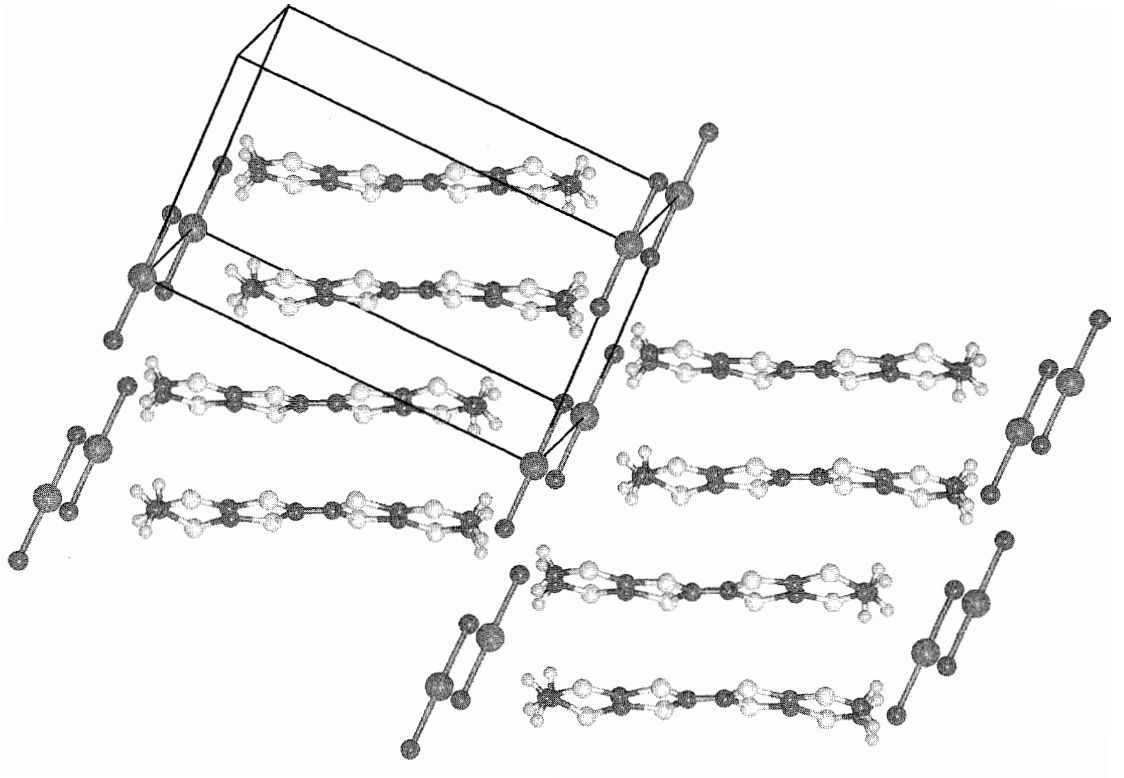

Fig. 7 The crystal structure of the metallic β″ phase of $(BEDT\text{-}TTF)_2[Br_{1.3}I_{1.1}Cl_{0.6}]$,[16] illustrating the stacking of $BEDT\text{-}TTF^{+1.5}$ cations. The trihalide ion represented in magenta and brown is a disordered mixture of I_2Br^-, IBr_2^-, $BrICl^-$ and ICl_2^-. (*View this art in color at www.dekker.com.*)

SINGLE-MOLECULE π-STACKED METALLIC CONDUCTION

Most of the molecular compounds with significant electrical conductivity or magnetic properties contain donor–acceptor pairs or are comprised of partially charged n-delocalized molecules. The two solids described in the previous section exemplify these two types. The generation of these properties in a single molecule, desirable from the practical perspective of sure fabrication. is more difficult. The strategy is to choose a molecule with small separation between the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO), such that they form partially occupied bands. A molecule that achieves this is uncharged Wi-$(tmdt)_2$,[17] (Chart 3) which is metallic down to 0.6 K. The important aspects of the crystal structure are shown in Fig. 8.

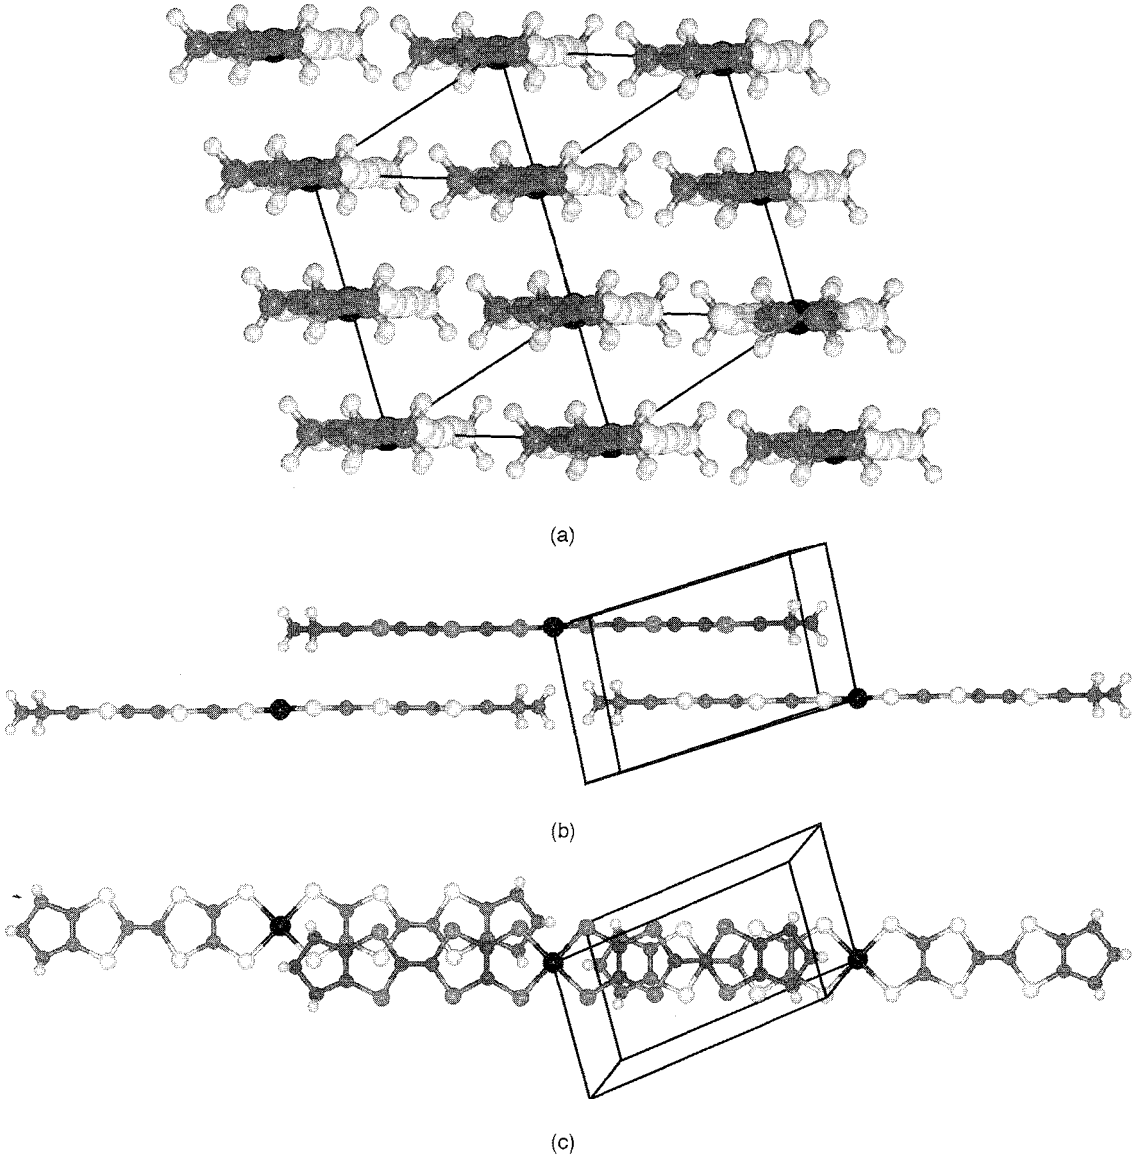

Fig. 8 The crystal structure of $Ni(tmdt)_2$,[17] space-group $P\bar{1}$. (a) End view of the chains of molecules. and their occurrence as slightly offset stacks of chains. Near chains are almost coplanar. (b) The stepped relationship between molecules adjacent in one stack. (c) Detail of the offsets between molecules [colored as in (b)] in a stack: the view direction is perpendicular to the molecules. The C (blue)/S (red) molecule is offset laterally relative to one greenlyellow underlying molecule, and offset longitudinally relative to the next green/yellow underlying molecule. Note also that molecules (greenlyellow) in a chain are slightly twisted relative to the chain axis in order to reduce interference between the propylene ends of each molecule and increase packing density. DONOR–ACCEPTOR π-INTERACTION IN CATENANES

An extensively studied and deployed donor–acceptor π-interaction occurs between a 1,5-dioxynaphthalene system (as donor) and a 4,4′-bipyridinium (also known as paraquat) acceptor. The association of these two species can be used as a template for the cyclization reactions involved in the synthesis of mechanically linked chemical structures,[18] such as the [2]catenane shown in Fig. 9.

The augmented electrostatic contributions to a donor–acceptor interaction such as this can override the electrostatic influences that cause a parallel n-aromatic interaction to be offset. and so the geometry of the motif can be FF, as illustrated in Fig. 9c. to maximize the electrostatic component of the stabilization.

The TTF molecule (Chart 1) is a π-delocalized system with readily accessible redox states. TTF. TTF^{+}, and TTF^{2+}. The reduced form functions as a n-donor in FF interactions, but the oxidized forms have n-acceptor character. Incorporation of one TTF moiety into a donor cycle also containing 1.5-dioxynaphthalene, and catenation with a *bis*-4,4′-bipyridinium n-acceptor cycle. leads to a switchable [2]catenane (Fig. 10). In the reduced TTF form (Fig. 10b), the TTF molecule, as donor, is sandwiched between the two 4,4′-bipyridinium acceptors. When oxidized (chemically or electrochemically). so that the TTF has a positive or 2+ charge (Fig. 10a), electrostatics cause rotational translation of one cycle relative to the other to displace the positive TTF to the outer section of the catenane. This switching is reversible.[19]

In crystals. [2]catenane molecules, such as those in Fig. 9 and Fig. 10b, stack in order to further use n-donor and n-acceptor motifs between catenane molecules, as illustrated in Fig. 11.

MULTIPLE AROMATIC EMBRACES

The examples so far involve independent aromatic moieties, freely able to arrange into OFF and EF motifs. There are also chemical systems in which the aromatic component is a substituent or is part of a more elaborate molecule. In these; the mutually dependent configurations and conformations of the aromatic groups influence the intermolecular interactions they can form. A considerable number of classes of compounds allow synergy of individual aromatic–aromatic interactions. and the generation of concerted sets of OFF or EF motifs. These are termed embraces, because they are multi-armed, mutual, concerted. and attractive. Some of the principal types of embrace are outlined here for representative molecules.

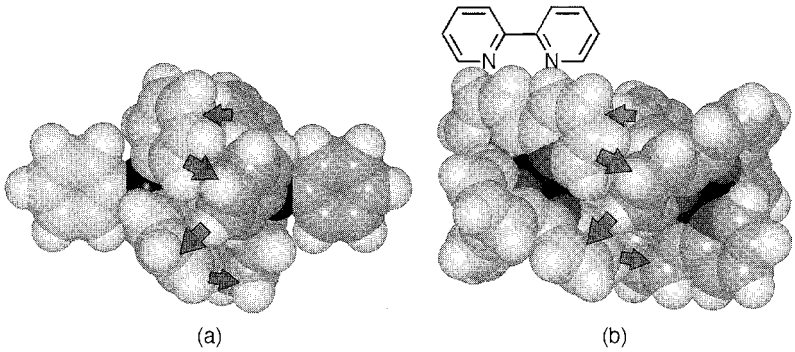

Fig. 12 The concerted $(EF)_6$ embrace (a) between a pair of Ph_4E molecules, involving six phenyl groups. and (b) between a pair of $[M(bipy)_3]$ octahedral inetal complexes. involving six pyridyl groups. The arrows point to the EF primary motifs. two of which are obscured in each example. Different colors are used for the carbon atoms of the inversion-related molecules in each embrace. (*View this art in* color. *at www.dekker.com.*)

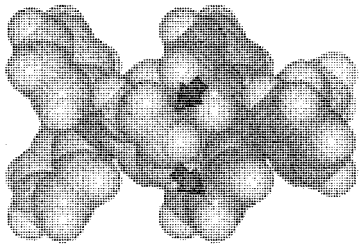

Fig. 13 The $(EF)_4$ embrace between a pair of Ph_4E molecules (*View this art in color at www.dekker.com*)

Concerted $(EF)_6$, Sixfold Aryl Embrace

Molecules with a threefold rotor conformation of three phenyl groups can engage across a center of inversion (exact or approximate) to form a concerted cycle of six intermolecular EF motifs (Fig. 12a). This multi-armed mutually favorable concert is called a sixfold phenyl embrace motif: there are six phenyl rings and a cycle of six EF motifs between heterochiral rotors. This embrace occurs frequently for molecules of type Ph_4E and type Ph_3EX. A similar embrace motif forms between end pyridyl groups of $[M(bipy)_3]^z$ octahedral metal complexes (Fig. 12b) Again a concerted cycle of six pyridyl-edge to pyridyl-face motifs occurs, between heterochiral complexes

A tetrahedral molecule Ph_4E can have more than one threefold rotor set of phenyl groups and can form more than one $(EF)_6$ embrace. There are many instances in crystals of zigzag chains based on two such embraces per Ph_4E molecule, especially between Ph_4P^+ ions: $–Ph_4E–(EF)_6–Ph_4E–(EF)_6–Ph_4E–$[20] A $[M(bipy)_3]$ complex has

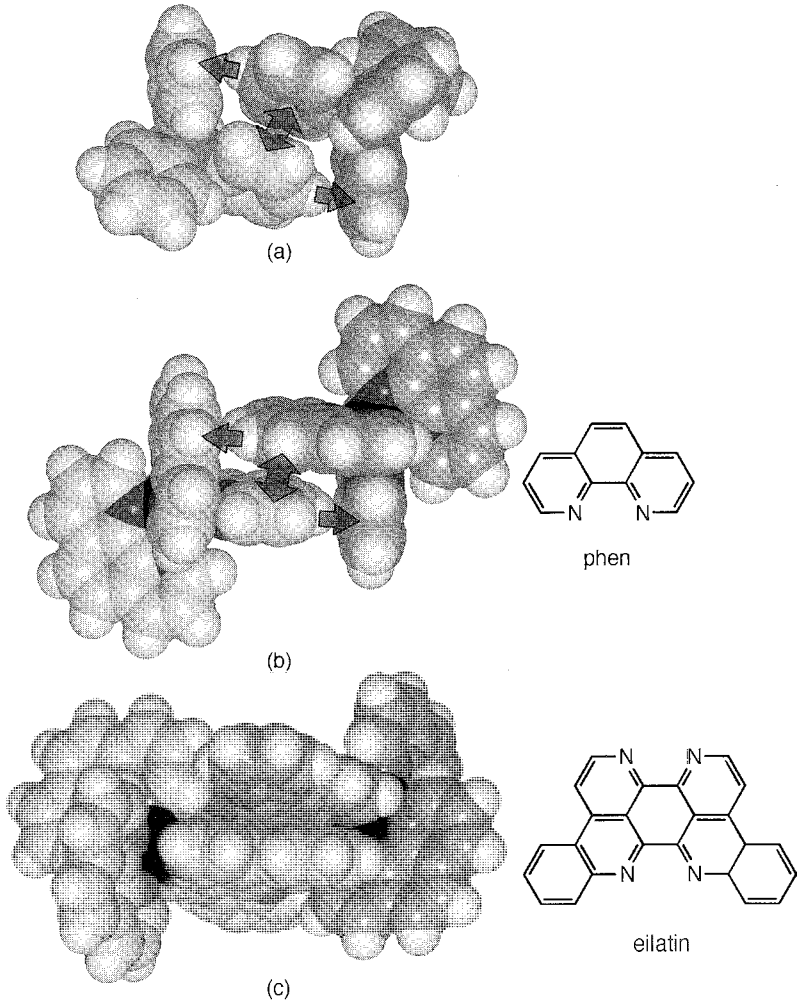

Fig. 14 The concerted $(OFF)(EF)_2$ embrace as it occurs for (a) a pair of Ph_4E molecules and (b) a pair of $[M(phen)_3]^z$ complexes. (c) This shows the embrace between two complexes $[Ru(phen)_2(eilatin)]^{2+}$,[23] emphasizing the OFF motif. Each example is centrosymmetric. (*View this art* in *color at www.dekker.com.*)

equivalent ends along its (pseudo) threefold axis and. thereby. forms linear chains of $(EF)_6$ embraces: –[M(bipy)$_3$]–$(EF)_6$–[M(bipy)$_3$]–$(EF)_6$–.[21]

Concerted $(EF)_4$, Fourfold Phenyl Embrace

The fourfold analog of the sixfold embrace just described is shown in Fig. 13: four phenyl rings are engaged in a concerted cycle of four EF motifs. This occurs mainly with Ph_4E systems, for which the relationship between the two molecules involved is simple translation, and infinite chains with a repeat of just one molecule occur in crystals.

Concerted $(OFF)(EF)_2$ Embrace

This involves two aryl groups on each molecule, and usually it is centrosyminetric. As shown in Fig. 14a,b, there is an OFF motif between two groups, each of which is also donor in an EF motif. The $(OFF)(EF)_2$ embrace is also named the parallel fourfold phenyl(aryl) einbrace, to differentiate it from the orthogonal fourfold phenyl embrace. $(EF)_4$.[22] As the size of a heteroaromatic ligand increases, as in eilatin. the OFF motif in the embrace becomes dominant (Fig. 14c), and the association of the complexes $[Ru(phen)_2(eilatin)]^{2+}$ in acetonitrile is measurable.[23]

This $(OFF)(EF)_2$ embrace and variants commonly occur for $M(phen)_2$ and $M(phen)_3$ complexes,[24] as shown diagrammatically in Chart 4.

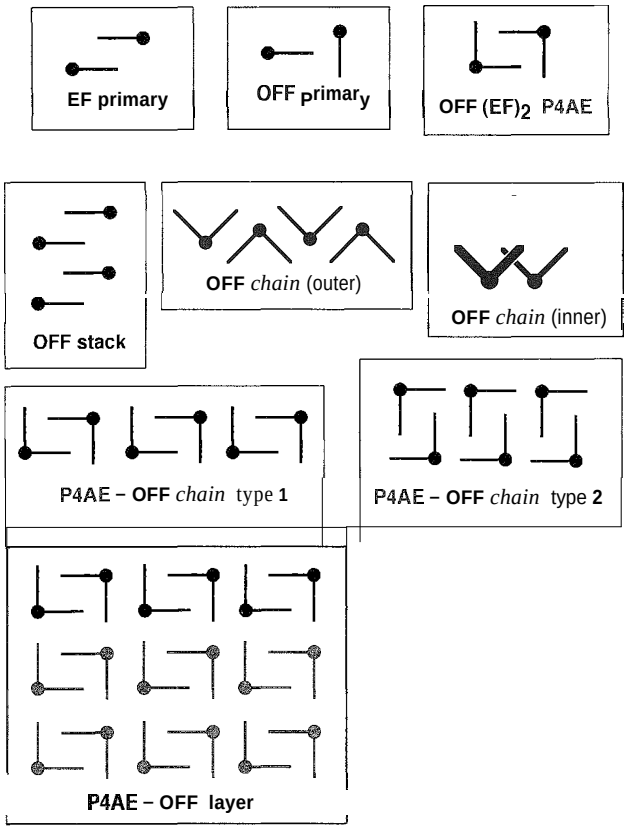

Chart 4 Diagrams of OFF, EF. and $OFF(EF)_2$ motifs that occur for $M(phen)_2$ and $M(phen)_3$ complexes (Adapted from Ref [25].)

The Terpy Embrace Motifs

Octahedral metal coinplexes with two planar heterocyclic tridentate ligands, such as [M(terpy)$_2$] (Fig. 15a), can form an $OFF(EF)_2$ embrace like that already described, involving the outer ligand heterocycles. Because the two ligand planes arc orthogonal. this embrace is propagated to generate a two-dimensional net, shown in Fig. 15b. with actual or approxiinate fourfold symmetry.[26] This close-packed terpy embrace layer contains deep and shallow grooves on each surface, as illustrated in Fig. 15c.

GEOMETRIES AND ENERGIES OF INTERMOLECULAR AROMATIC INTERACTIONS

The benzene pair has been the subject of a number of experimental investigations in the gas phase, and the subject of numerous theoretical studies. There is experimental evidence (summarized in Ref. [27].) for the less symmetric EF geometry and more symmetric OFF structures. and for structural variability. The estimates of the dissociation energy (D_0) are 1.6 ± 0.2[28] 1.6 a 0.5.[29] and 2.4 ± 0.4[30] kcal mol^{-1}. The more accurate theoretical calculations are converging toward values of 2–3 kcal mol^{-1} for the binding energy (D,) at the energy minimum, for both the OFF and EF geometries. The zero-point vibrational energy ($ZPE = D_e - D_o$) for the benzene pair is estimated to be 0.3–0.5 kcal mol^{-1}. The general consensus of experimental and theoretical work is that the dissociation energy of a pair of benzene molecules in the OFF and EF geometries is in the range of 2–2.5 kcal mol^{-1}.

The rich crystallographic databases for organic and organometallic compounds and for biological macromolecules enable statistical analyses of the metrical relationships between aromatic functionalities. The metrical properties of main interest are the separation and offset of the aromatic planes in the OFF motif. and the separation of the ring centroids and the angle of inclination of the rings in the EF motif. The most commonly observed properties of the OFF motif are a plane separation of 3.4–3.6 Å, with an in-plane offset of ca. 1.8 Å, while the EF motif for a pair of phenyl groups has a centroid–centroid separation of ca. 5 A. A useful reference point for the OFF motif is the graphite layer separation of 3.6 A.

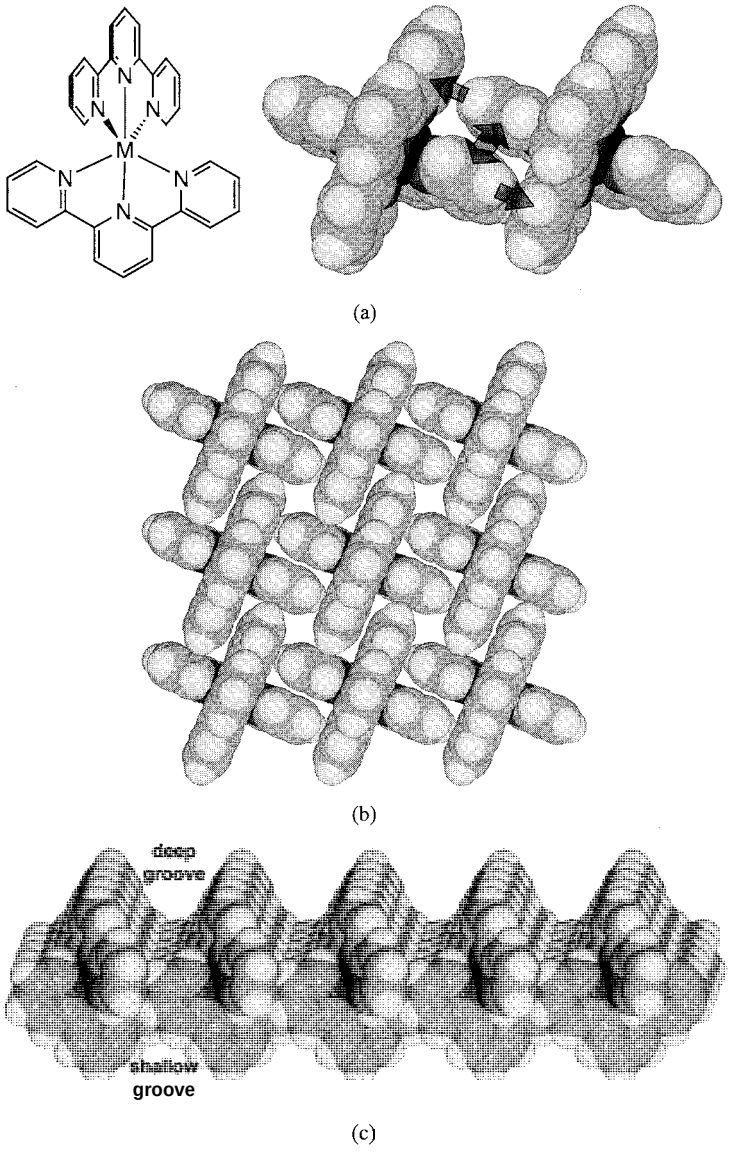

Fig. 15 (a) The OFF(EF)$_2$ embrace, or terpy embrace, formed by a pair of [M(terpy)$_2$] complexes. (b) The two-dimensional net generated by the propagation of terpy embraces. (c) The deep and shallow grooves that occur on both sides of an infinite terpy embrace layer. (View *this art* in *color at www.dekker.com.*)

In this context, it is important to recognize that the intermolecular potentials for aromatic–aromatic interactions are very soft, meaning that relatively large variations in geometry are associated with relatively small changes in energy. This is illustrated in Fig. 16 for the OFF motif of a pair of naphthalene molecules. showing the effect of offset or sliding of one naphthalene molecule over the other, in the direction pictured.[31] For electrostatic reasons, the stabilization decreases strongly when the molecules are eclipsed, and energy minima occur in the potential when there is overlap of H and C atoms. Note that significant intermolecular energy remains when the molecules slide away from each other. The interactions between aromatic molecules operate over long ranges. Analyses of the principal contributions to the intermolecular energy indicate that the dispersion energy is the principal component, and that longer-range electrostatic interactions are also significant and provide the directionality.[32] Since the potentials are soft, interpretations of aromatic–aromatic interactions should not necessarily attach significance to deviations from standard geometries.

In solution; the aromatic–aromatic interactions are ameliorated by solvation and subject to entropic influences. Modeling calculations give the free energy of association of the benzene pair as -0.4 kcal mol^{-1} in benzene solvent, -1.0 kcal mol^{-1} in chloroform: and

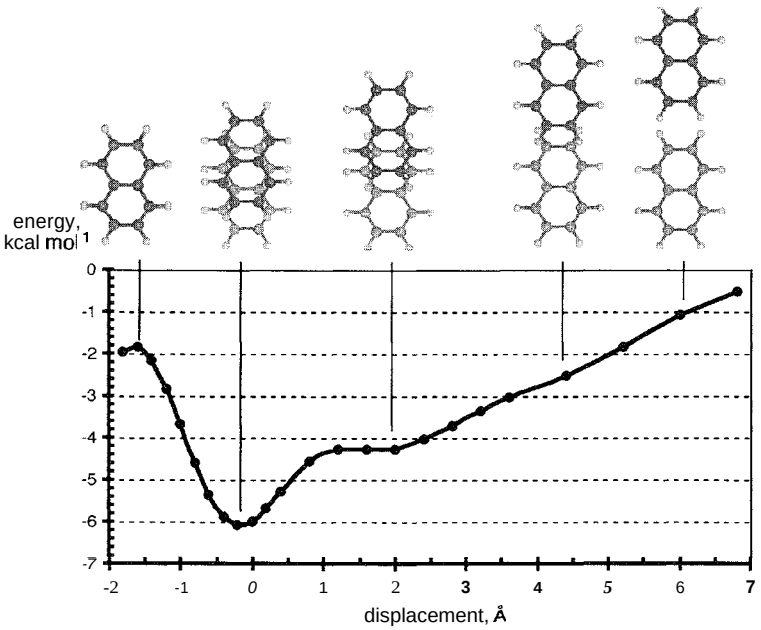

Fig. 16 An intermolecular potential for the OFF motif between a pair of parallel naphthalene molecules and interplanar separation 3.35 Å, illustrated as the energy variation according to the degree of in-plane displacement pictured. (*View* this art *in* color *at www.dekker.com.*)

-1.5 kcal mol^{-1} in water.[''''] This sequence illustrates the hydrophobic stabilization of aromatic–aromatic aggregates in hydrogen-bonding solvents.

A considerable number of chemical systems designed to probe aromatic–aromatic interactions were reported.[10,34] Many of these are host–guest combinations. in which designed host molecules with one or more exposed aromatic surfaces are used to measure the thermodynamics of inclusion of aromatic guests. This approach was also used to assess the influence of substituents on aromatics. In general, the association energies are determined to be ca. 1–2 kcal mol^{-1}.

The involvement of charged species in aromatic–aromatic interactions increases the stabilization energy. For the benzene pair radical cation. $(C_6H_6)_2^+$, experimental values of the dissociation energy are 17, 15, 8. >10 and 14.8 kcal mol^{-1}.[35] Similarly. for the C_6F_6 pair, experimental dissociation energies[36] of 7.2 ± 1 kcal mol^{-1} for $(C_6F_6)_2^+$ and 10.4 ± 1 kcal mol^{-1} for $(C_6F_6)_2^-$ are larger than the estimated 4 kcal mol^{-1} for the uncharged pair $(C_6F_6)_2$.[37]

An unusual interaction occurs for $TCNE^-$ radical anions, which associate as an eclipsed pair $(TCNE)_2^{2-}$ in a number of crystals, with a distance of about 2.9 Å between the central C atoms of the two molecules. This is interpreted in terms of competition between the electrostatic destabilization of the two anions and weak stabilization of nascent C–C bonds.[38]

Chart 5

DNA BASE STACKING

An essential characteristic of DNA is x-stacking. The base pairs are separated by 3.4 Å, which is the rise of the double helix per base pair. The stacking is not offset: and the different base pairs are essentially coaxial with the local stacking axis. The stacking stabilizations per single base in DNA were measured via the effects of additional nucleoside bases at the end of a DNA sequence. These experiments, on realistic condensed phases (1 M aqueous NaCl, 10 mM sodium phosphate buffer, pH 7, 37°C), yield stacking free energies of 1–2 kcal mol^{-1}.[39] There is considerable compensation of favorable enthalpies and unfavorable entropies in the stacking of nucleotide base pairs.

Many polycyclic heteroaromatic molecules with essentially planar geometry and extensive n-delocalization are able to intercalate the base pair stack, separating the base pairs, and then functioning like an extraneous base pair in the stack. This is an expanded modification of the n-stacking of DNA. An example of such intercalation is shown in Fig. 17, where two DACA molecules are inserted into a six-base duplex.[40] Other examples of well-studied DNA intercalating molecules are 9-aminoacridine and ethidium (Chart 5). This intercalation interferes with the normal functions of the DNA and attracts pharmaceutical interest. There is a substantial electrostatic component of the stabilizing energies of the base stacking and the intercalation.[41,42]

CONCLUSION

Identifiable interinolecular interactions and motifs between molecules with n-delocalized bonding are ubiquitous. The essence of the interaction is dispersion stabilization, enhanced by the polarizability of the π-electronic structure. In addition. there is electrostatic stabilization, the magnitude of which can vary widely, from relatively small in the prototypical aromatic hydrocarbons, to dominant when partially or fully charged molecules are involved. The electrostatic component of the intermolecular energy provides directionality to the interaction.

The geometries of these interactions are also influenced by the molecular planarity associated with x-delocalization. Planar molecules (or parts of molecules) usually arrange with parallel or steeply inclined geometry. and for pairs of equivalent molecules, the OFF and EF primary motifs are prevalent. These geometries are favored by the electrostatic components of intermolecular energy. Dissimilar n-delocalized molecules. particularly pairs with complementary electron-donor and electron-acceptor properties, are commonly arranged face-to-face: in order to maximize the electrostatic energy between them. The parallel primary motifs, OFF, and FF. favor continuous stacking (n-stacking).

The π–π interactions occur in all areas of chemistry and for chemically diverse molecules. The stacking of π-delocalized molecules favors cooperative phenomena. such as electron conduction. The n-stacking motifs are key components of the design of molecular materials with ensemble properties. Nucleotide base-pair stacking is fundamental to molecular biology. and aromatic interactions between amino-acid side chains influence protein structure.

The x–n interactions are valuable fundamental components of contemporary research in the frontier fields of molecular engineering. molecular machines, and crystal engineering.

π–π Stacking as a Crystal Engineering Tool

Stuart L. James
Queen's University Belfast, Belfast, Northern Ireland

INTRODUCTION

Although it is widely realized that significant attractive interactions can occur between aromatic molecules, and they are often described as such in the discussions of new *crystal structures. their deliberate exploitation as tools for controlling crystal structure has lagged behind that of hydrogen bonding. However, positive developments are now occurring, with crystal packing "synthons"* (i.e., *reliable. recurring crystal packing arrangements) being identified and beginning to be exploited. This article is divided into two sections. First, examples of potentially useful structural trends and actual crystal packing* synthons, *which were identified through crystal structure database searches or through new synthetic studies, are reviewed. Second, some examples of deliberate crystal engineering that rely on the exploitation of n – π synthons to control crystal structure, and so control solid-state reactivity, are described. For discussion of the fundamental nature of aromatic interactions. readers should consult the article entitled ''π – π Stacking:Theory and Scope" in this Encyclopedia.*

STRUCTURAL TRENDS IN MOLECULAR **CRYSTALS**

Aromatic Hydrocarbons

Crystalline benzene adopts a packing arrangement that is widely referred to as the "herringbone" pattern'" and that is characterized by intermolecular edge-to-face contacts (Fig. 1). That benzene molecules adopt this geometry in the crystal is consistent with the theoretical prediction that the most stable arrangement for the benzene dimer *is edge-to-face.'" Molecular beam dipole moment measurements also suggest that the benzene* dimer *adopts this T-shaped geometry in the gas* phase.[3] *For crystals of larger aromatic hydrocarbons (a group of 32, including napthalene,* pyrene, *etc.). three additional packing modes were identified (called stacked* herringbone, γ *and* β), *each exhibiting edge-to-face or offset face-to-face stacking between* neighboring molecules.[4] *The different packing modes were correlated by the authors with the C:H ratios of the compounds involved: those with high values favoring face-to-face stacking* (i.e., *C...C contacts) and those with low* C:H *ratios favoring* herringbone (i.e., *C–C and C–H contacts).*

Multiple Aromatic "Embraces"

Dance and coworkers extensively searched the Cambridge Crystallographic Database to identify recurring packing motifs in compounds that contain multiple aromatic groups in the form of pyramidal EAr_3 *units* (E = P, *As, B,* etc.).[5,6] *Such species include transition metal complexes of triarylphosphines as well as salts containing such ions as* EPh_4^+ (E = P, *As) and* BPh_4^-. *A number of motifs were classified, the most symmetrical being the so-called sixfold phenyl embrace, or* 6PE. *illustrated in Fig. 2. In this multiple aromatic interaction, two* X-PPh_3 *groups make contact through six edge-to-face contacts. so that the interaction has local approximate* C_3 *symmetry and the two* P–X *bonds are approximately colinear. The frequencies with which* 6PEs *occur was been found to vary greatly according to the precise chemical species involved: however, it was found to be highest for* PPh_4^+ *cations. occurring at a probability level of ca.* 60%.[5,7] *It should be borne in mind, however. that* PPh_4^+ *can engage simultaneously in more than one 6PE. and the 60% probability value does not refer precisely to* a *60% likelihood per cation. However, this fairly high probability suggests that the 6PE may be a usable crystal engineering synthon for this cation. whereas for other species (such as metal complexes* M-PPh_3), which *statistically engage* in 6PEs *significantly less often, it seems less likely to be useful. Despite this, the 6PE provides an interesting pointer for further research: for example, it is quite likely that synthetic derivatization can increase the predictability of packing in* PAr_3 *complexes. Attractive energies as large as* -60 kJmol^{-1} *were calculated for certain* 6PEs. *corresponding to 9–12* kJ mol^{-1} *per* phenyl–phenyl *contact.*

Porphyrins

Hunter and Sanders correlated the experimentally determined packings of porphyrins *with an essentially electrostatic* model *of the* n – x *interaction between two molecules.'"* The *optimum geometry predicted by the model*

DOI: 10.1081/E-SMC 120012766

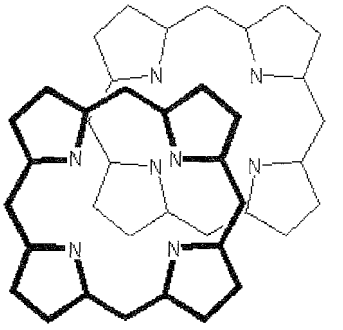

Fig. 3 The predicted preferred mutual orientation of two porphyrins.[8]

is with one pyrrole ring over the π-cavity of its neighboring porphyrin, and with the porphyrins not rotated with respect to each other (Fig. 3). The database study was intended to ascertain the accuracy of the electrostatic model, and so porphyrins with packings that were constrained, for example. with bulky side groups or axial ligands, were not included.

Packing Involving Hydrocarbyl and Fluorinated Aromatics—$Ar^H...Ar^F$ Interactions

In 1960, Patrick and Prosser reported that when benzene and hexafluorobenzene were mixed under ambient conditions, 1.1 cocrystalr formed, which had a melting point significantly higher (23.7°C) than that of either of the pure components (5.4 and 5.0°C for benzene and hexafluorobenzene, respectively).[9] The 1:1 cocrystal exhibits temperature-dependent behavior. The lowest temperature phase consists of columns in which equispaced face-to-face benzene and hexafluorobenzene molecules alternate (Fig. 4).[10] The face-to-face interactions are slightly offset. or in other words. the planes of the molecules are not perfectly orthogonal to the propagation direction of the column, tilting away from this "ideal" by 23° for benzene and 27" for hexafluorobenzene. The distance between the molecular centroids is *3.77* A. The formation of this type of $Ar^H...Ar^F$ stacked motif was since found to be fairly general.[11–22,24,25] A crystallographic study was made of hexafluorobenzene and its complexes with a range of methyl-substituted aromatics.[10] A structural trend within this series was identified. in that the inter-planar separations were generally lower for the greater number of methyl subsiituents on the electron-rich aromatic. This was noted to be in contrast to the general lack of structural trends identified for π–π* charge-transfer complexes. Vangala et al.[12] studied the crystal structures of diaryl azines that

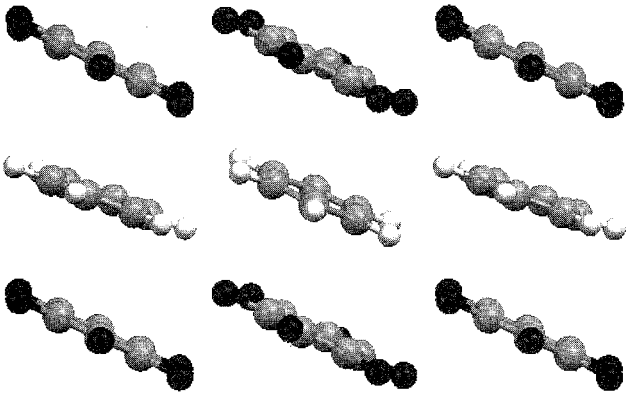

Fig. 4 Crystal packing in the cocrystal $C_6H_6C_6F_6$, showing the alternating stack5 (H = white, F = black). *(View this art in color at www.dekker.com.*)

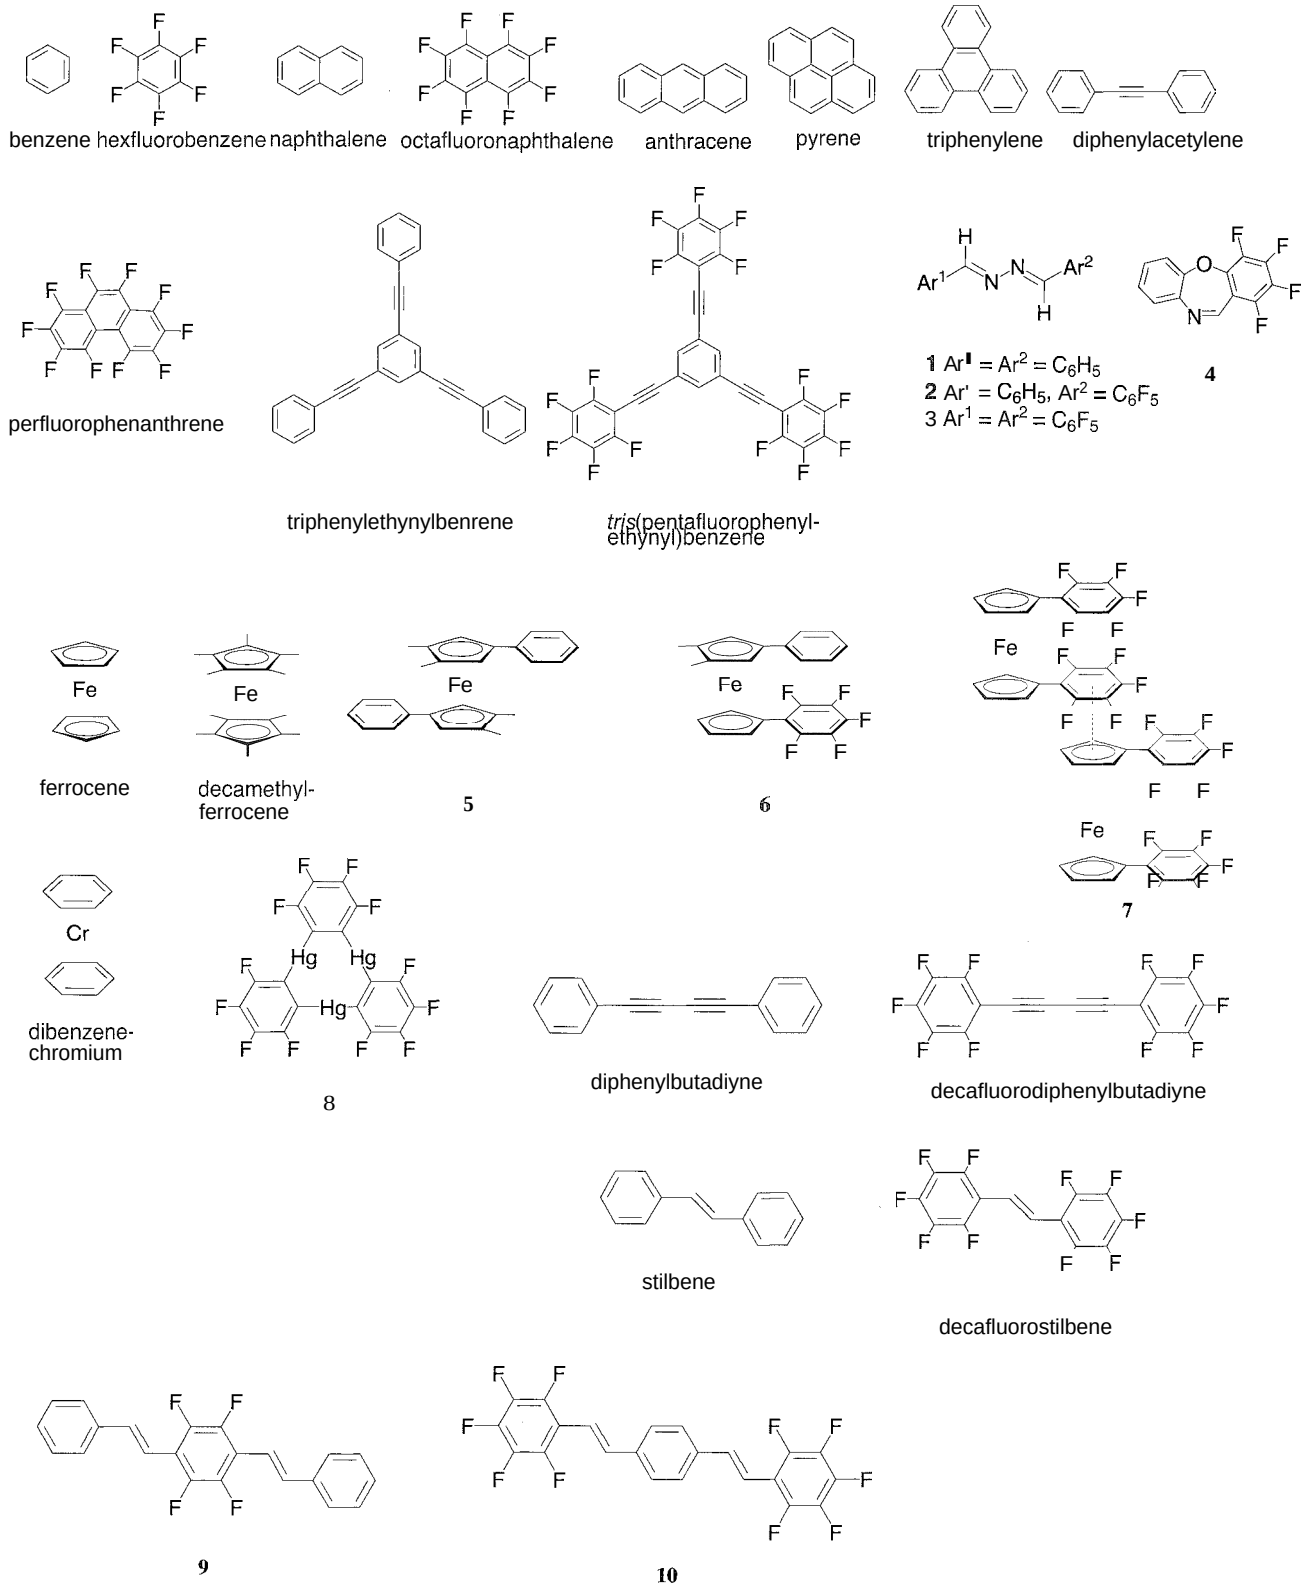

Fig. 5 Hydrocarbon and fluorinated molecules used to investigate $Ar^H...Ar^F$ interactions

contained C_6H_5 or C_6F_5 groups (**1**, **2**, and **3**—Fig. 5). It was concluded that the cofacial stacking of C_6H_5 and C_6F_5 groups dominated in determining the crystal packing over other potentially competing stabilizing interactions such as C–H...F, herringbone, and F...F contacts. Vangala's molecules were effectively planar. and the crystal packing ''synthon'' involves fivefold fluorine substitution on the aromatic group. The 1,2,3,4-tetrafluorodibenzoxazepine (**4**—Fig. 5), characterized by Saunders and Nieuwenhuyzen,[13] has a curved shape (due to buckling of the central seven-membered ring) and involves only fourfold fluorine substitution on one of the rings. Nevertheless, this compound also stacked in columns with head-to-tail packing so that again, alternating $Ar^H...Ar^F$ stacks occurred.

A series of investigations by Batsanov. Marder, and coworkers. into 1:1 cocrystals of perfluorinated aromatics and hydrocarbon aromatics, where each component was varied over a range of molecular sizes and shapes. showed that the basic alternating stack motif occurred in all the cocrystals obtained.'''' Thus. octafluoronaphthalene formed alternating stacks with anthracene, phenathrene, pyrene, and triphenylene. Even the smaller hexafluorobenzene reliably formed alternating stacks with hydrocarbons as large as pyrene and triphenylene. as well as with naphthalene and anthracene.[15] The planes of neighboring aromatics within the stacks were all almost parallel, however, the ''slip angles'' (the angles made by the normals to the molecular planes to the direction of propagation of the stack) within stacks and the three-dimensional packings varied, and no simple relationship between these aspects of the packing and the molecular sizes and shapes was identified. Clearly, though. the basic alternating stack motif can be expected to occur widely and may, therefore, be exploited in controlling the solid-state structures of molecules containing diverse hydrocarbyl and fluorocarbyl aromatic groups. A 1:1 cocrystal structure of octafluoronaphthalene and diphenylacetylene was also described.[16] Although this formed the expected alternating stack. with an interplanar separation of 3.6 Å, the octafluoronaphthalene interacted with the alkyne fragment as well as the phenyl rings, so that the fluorinated and nonfluorinated rings were not actually eclipsed.

The examples above relied on either one or two intermolecular ArH...ArF contacts per molecule. Seigel et al. showed that 1,3,5-*tris*(pentafluorophenylethynyl)-benzene and its nonfluorous analogue 1,3,5-triphenylethynylbenzene (Fig. 5) also formed a 1:1 cocrystal via three ArH...ArF stacks, forming slipped stacks of alternating molecules.[17]

The effect of phenyl and pentafluorophenyl substituents on the inter-and intramolecular structures of crystalline ferrocene derivatives (**5–7**, Fig. 5) was investigated by Hughes and coworkers.[18] In the crystal structure of the homoleptic purely hydrocarbyl ferrocene $Fe(Me_2PhCp)_2$ **5**, the phenyl groups were found to be in *anti* positions about the central Fe. However, the mixed-ligand compound $Fe(Me_2PhCp)(C_6F_5Cp)$ **6** adopted an eclipsed conformation with inter-and intramolecular stacking between the C_6H_5 and C_6F_5 groups. The $Fe(C_6F_5Cp)_2$ **7** crystallized again with eclipsed stacked rings. Intermolecular stacking in this case occurred between the C_6F_5 groups and Cp rings. It was concluded that $Ar^H...Ar^F$ stacking was the dominant crystal packing interaction in these compounds. and that it could be of further use as a crystal packing synthon.

Ferrocene was found to form a 1:1 cocrystal with octafluoronaphthalene.[15] Interestingly, in this case. only half of the octafluoronaphthalene molecules in the crystal actually formed face-to-face contacts with the cyclopentadienyl groups of ferrocene, and the structure was not a straightforward alternating stack. These workers found that hexafluorobenzene did not cocrystallize with ferrocene. The bulky decamethylferrocene was found by other workers to form 1:1 cocrystals with fluoroaromatics, for example, perfluorophenanthrene.[19] Despite the presence of the bulky methyl groups on the ferrocene, the interplanar separation between molecules was still only 3.7 A. Short F...C(methyl) distances of ca. 3.36 A suggested that there may also have been significant F...H contacts. The bond lengths within the molecules suggested that the structure was not of the charge transfer $[Fe(Cp^*)_2]^+[C_{10}F_{14}]^-$ type. However, Perutz et al. found a different situation when yellow-green dibenzenechromium $[Cr(\eta^6\text{-}C_6H_6)_2]$ reacted with C_6F_6 to give the cocrystal $[Cr(\eta^6\text{-}C_6H_6)_2].C_6F_6$ as claret-or yellow-colored crystals.[20] The claret crystals consisted of stacks of alternating $[Cr(\eta^6\text{-}C_6H_6)_2]$ and C_6F_6 units with an interplanar distance between stacked rings of ca. 3.5 Å. The rings were almost eclipsed with the angle between ring normals being 5.9''. Bands in the UV were assigned. in this case, to charge-transfer transitions, and EPR spectra were consistent with the formation of $[Cr(\eta^6\text{-}C_6H_6)_2]^+$ to some extent (3.3% in the presence of a fivefold excess of C_6F_6 in toluene solution).

Gabbai and coworkers[21] found that the perfluorinated planar metallotrimer $[Hg(o\text{-}C_6F_4)]_3$ **8** (Fig. 5) could cocrystallize with hydrocarbon aromatics to form alternating stack structures. For the naphthalene and biphenyl cocrystals. it was actually Hg(II)...arene interactions that were established in the crystal, rather than arene–fluoroarene contacts, but for the triphenylene complex, arene–fluoroarene contacts were also present. All three compounds exhibited luminescence associated with the nonfluorinated arene component. but the emission from the triphenylene complexes was shifted to longer wavelengths than normal for this chromophore. This was tentatively correlated with the presence of $Ar^H...Ar^F$ interactions.

DELIBERATE EXPLOITATION OF AROMATIC INTERACTIONS AS TOOLS FOR DESIGNING CRYSTAL STRUCTURE AND REACTIVITY

Desiraju and coworkers cocrystallized cinnamic acids bearing electron-withdrawing NO_2 or electron-donating OCH_3 groups, relying on the formation of charge-transfer face-to-face interactions between the electron-poor and electron-rich aromatic rings (Fig. 6a).[22,23] Although in all cases the expected packing occurred: and the alkene groups were separated by less than 4.2 Å, a distance criterion for allowing photochemical 2+2 additions, the substitution pattern on the rings of the electron-poor aromatics was crucial to the solid-state reactivity. Only when NO_2 groups were in the 3,5 positions, i.e., unable to conjugate with the alkene, did photochemical cyclization occur.

Some successful synthetic crystal engineering was also based on the ArH...ArF synthon.[24,25] Daugherty and Grubbs et al.[23] exploited phenyl–pentafluorophenyl stacking interactions to control the arrangement of diaryldiynes in the solid state. and by this method, also controlled their solid-state polymerization behavior (Fig. 6b). Solid-state polymerization of diynes to give *trans*-polybutadiynes was well documented, but it is sensitive to the solid-state packing geometry of the diyne. By inducing strictly cofacial orientation of the aromatic diyne substituents, through $Ar^H...Ar^F$ stacking at an intermolecular separation of 3.4–3.6 Å, these workers anticipated that solid-state polymerization should be able to occur, and further that polybutadiynes with novel ***cis*** geometry might result (Fig. 6b). Diphenylbutadiyne and decafluorodiphenylbutadiyne were successfully cocrystallized from ethanol solution to give a 1:1 adduct with packing of the two molecules in the expected alternating stack. While neither of the pure diynes were susceptible to UV-induced polymerization, UV irradiation of the alternating 1:1 cocrystal gave up to 50% yield of oligomers, making them markedly more active. The *cis*/*trans* geometry of the polymeric product was not established.

In related work,[25] alkenes and dienes bearing phenyl or pentafluorophenyl groups were similarly investigated

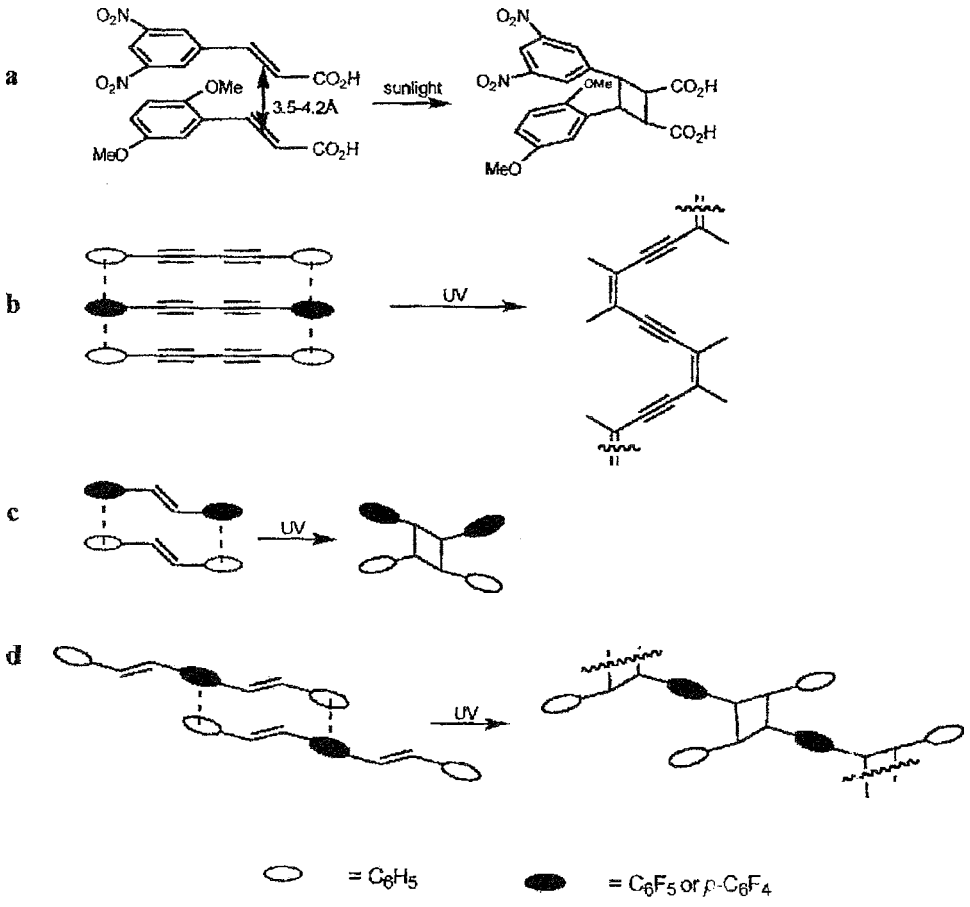

Fig. 6 *Solid-state organization* of *alkenes,* alkynes, *and dienes through* $Ar^H...Ar^F$ *interactions for photoinduced dimerization and polymerization reactions.*

by Coates and Grubbs et al. for their crystal packing arrangements and associated photoactivity toward [2+2] reactions in the solid state. When phenyl and perfluorophenyl groups were present, they directed the crystal packing to give geometries and distances generally conducive to the photoinduced reaction. In particular, the 1:1 cocrystal of trans-stilbene and *trans*-decafluorostilbene exhibited the expected stacked structure with C...C separations of the alkene groups of 3.784 and 3.749 Å. Whereas the pure components were not susceptible to solid-state dimerization, under UV irradiation, this cocrystal gave the photodimerization product quantitatively after 5 h (Fig. 6c). The studies were extended to the photopolymerization of diolefins such as 1,4-*bis*(2-phenylethenyl)-2,3,5,6-tetrafluorobenzene, **9** (Fig. 5 and Fig. 6d). This diolefin packs in strongly slanted stacks because of the expected cofacial arrangement of the central fluorinated group with the outer nonfluorinated groups of its two nearest neighbors. The intermolecular separation of the double bonds was 3.823 Å. Irradiation produced in 15% a mixture of soluble dimer and tetramer, and the insoluble remainder was taken to be higher oligomers. However, the "inverse" analogue of this diene, trans,trans-1,4-*bis*(2-pentafluorophenylethenyl)benzene, **10**, was completely photostable. Correspondingly. x-ray analysis showed that the packing was not as anticipated, with the pentatluorophenyl groups face-to-face with the *trans*-alkenes, rather than with the 1,4-phenylene group, resulting in an alkene–alkene separation of 4.86 Å—too great for the photoreaction. However, when this compound was cocrystallized with o-xylene, the structure exhibited face-to-face packing of Ar^H and Ar^F units, both between the diene units and between the diene and included solvent. Irradiation gave dimerization, to which the crystal structure was predisposed. The cocrystal **9**·**10** was also susceptible to photoreaction, but its crystal structure was not determined.

CONCLUSION

The field of crystal engineering based on π–π interactions is now changing from the initially necessary surveying of crystal structures (in order to determine packing trends and recurring packing arrangements), to include the application of synthons to control crystal structure and properties. The fundamental natures of these interactions are also becoming clearer (see *n-n* Stacking: Theory and Scope, p. 000), which will aid their further application in control and prediction of crystal structure. The identification and design of further synthons and the more detailed testing and application of existing ones. in order to demonstrate control over material properties, are likely to be important aspects for future research. Synthetic studies aimed at deliberately increasing the reliability of some identified synthons will also provide stimulating research challenges.

INTRODUCTION

A molecular host that completely surrounds its guest provides a means to stabilize reactive and transient chemical intermediates, to transfer biologically active molecules to target cells, and to construct molecular-scale devices.[1–2] To design such a host, such a shell requires positioning of organic and/or *inorganic chemical subunits in space such that the topological relationship of its subunits approximates a hollow spherical shell S capable of packaging single or multiple guests (Fig. 1).*[1] *A simple design strategy for the construction of such a host involves utilizing principles of solid geometry, wherein the chemical subunits positioned along the surface of S conform to either a Platonic or an Archimedean* solid.[1–3]

SPHERICAL HOSTS

A spherical virus (e.g., *rhinovirus) is a* familiar *example of a spontaneous process of self-assembly that gives rise to a spherical shell with a closed cavity able to host atoms and molecules as* guests.[1] *Such a spherical structure is desirable. because it employs an economy of information. providing access to a shell with chemical subunits in identical chemical environments where surface area is at a minimum and strain energy is distributed evenly along the surface. Whereas nature utilizes identical chemical subunits in the form of proteins. which assemble by way of* noncovalent *forces* (e.g., *hydrogen bonds), to construct a spherical virus. chemists have a wide variety of organic and inorganic building blocks at their disposal that may be used to design atomic- and nanometer-scale shells held together by* noncovalent *or covalent bonds.* In *a similar way to a spherical virus. such a shell may be designed to exhibit a targeted property* (e.g., *catalysis). The targeted property* may *be less available, or completely inaccessible. by nature.*

SPHEROID DESIGN

To construct a molecular host with a spherical structure. the framework must *be derigned so that the guest is centralized within a hollow spherical shell S.*[1] *From a chemical standpoint, such a framework, however. is impossible to design, because atoms and molecules are discrete entities. whereas the surface of S is uniform. Thus, to construct a spherical molecular host, one must consider the number of identical chemical subunits n for spheroid design and their placement along the surface of the shell.*

SUBUNITS FOR SPHEROID DESIGN

The simplest host chat may be constructed using chemical *subunits that approximate a sphere is a shell based on* $n=4$ *subunits with a structure that conforms to a tetrahedron.[1,3] Such* a *shell consists of four identical subunits in the form of equilateral triangles. where edge-sharing by the triangular faces provides the curvature along the surface of the shell. The polygonal subunits of the tetrahedron are related by combinations of twofold and threefold rotation axes such that the* framework *is of cubic symmetry* (i.e., *32 symmetry).*

PLATONIC SOLIDS

The tetrahedron belongs to a closed family of five convex uniform polyhedra known *as the Platonic solids (Fig. 2).* named *after the ancient Greek philosopher* Plato *(circa 427–347* BC),[5] *who speculated that the five solids were the shapes of the* fundamental *components of the universe. Each member of this family possesses cubic symmetry* (i.e., *32, 432. or 532 symmetry) and is* made *of the same regular polygons* (e.g., *equilateral triangle. square) arranged* in *space so that* its *vertices and edges, and* three *coordinate directions. are equivalent. That there is a* finite *number of such polyhedra* is *a consequence of the fact that a limited number of* ways *exist in which identical regular polygons may be* adjoined *to construct a convex corner. Equilateral triangles* may *be adjoined in three ways. while squares and pentagons* may be *adjoined* in *only a single manner. These principles give rise to* five *isometric polyhedra that are achiral.* with *polygons that are related by* combinations *of* n-fold *rotation axes. The Platonic solids include the tetrahedron, which belongs to the point group* T_d *and possesses 32 symmetry; the* cube *and octahedron,*

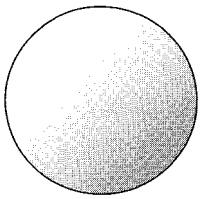

Fig. 1 Hollow spherical shell *S*.

which belong to the point group O_h and possess 432 symmetry; and the dodecahedron and icosahedron, which belong to the point group I_h and possess 532 symmetry.

ARCHIMEDEAN SOLIDS

In addition to the Platonic solids, a family of 13 convex uniform polyhedra known as the Archimedean solids (Fig. 3) exist, first described by the Greek philosopher Archimedes (287–211 or 212 BC).[6] The original work was lost and was reported second-handedly by Pappus of Alexandria (290–350), a Greek geometer. Each member of this family of solids is made up of at least two different regular polygons and may be derived from at least one Platonic solid through either truncation or twisting of faces. In the case of the latter, two chiral members, the snub cube and the snub dodecahedron, are realized. Like the Platonic solids. the Archimedean solids possess identical vertices and exhibit 32, 432, or 532 symmetry. The Archimedean solids exhibit a larger variety of polygons than the Platonic solids. These include the equilateral triangle, square. pentagon, hexagon, octagon. and decagon.

MODELS FOR THE DESIGN OF SPHERICAL MOLECULAR HOSTS

With a synthetic scheme for designing spherical shells based on principles of solid geometry realized, chemists exploited such geometric principles for the synthesis of spherical hosts that encapsulate atoms and molecules as guests.[1–3] In serving as models for the construction of spherical hosts, the Platonic and Archimedean solids provide a means with which to determine where chemical subunits should be placed along the surface of S and the bonding arrangements they should adopt. To demonstrate these principles. examples of spherical inolecular hosts derived from the laboratory and nature will be described.

Platonic Solids

As stated, the Platonic solids constitute a family of five convex uniform polyheda made up of the same regular polygons and possessing 32. 432. or 532 symmetry.

Tetrahedral hosts

The macrotricyclic spherand designed by Lehn was the first tetrahedral host (Fig. 4a).[7] The bridgehead nitrogen atoms and ethyleneoxy units supply the threefold and twofold rotation axes, respectively. This molecule, and its tetraprotonated form, was shown to bind an ammonium and chloride ion, respectively.

Saalfrank was the first to introduce metal-based tetrahedral cages by using metal ions as corner units and bridging malonate ligands as edges (Fig. 4b).[8] Owing to a bend in each ligand, these cages are adamantane-like. In terms of host–guest behavior, an iron-based system was shown to complex a single ammonium ion.

Octahedral hosts

A cyclophane-based system reported by Murakami was shown to conform to a structure of a cube (Fig. 4c).[9] The sides of the host consist of tetraaza-[3.3.3.3]paracyclophane units, and its octaprotonated cation was shown to bind anionic guests. A polyoxovanadate. $(VO_6)(RPO_3)_8]^+$ (R=*t*Bu,$OSiMe_3$), reported by Zubieta[10] and Thorn,[11] was also shown to adopt an octahedral framework (Fig. 4d). The vanadium atoms of the shell are located at the vertices of an octahedron, while the phosphorus atoms are located at the corners of a cube. A cube with a structure based on deoxyribonucleic acid (DNA) was described by Seeman (Fig. 4e).[12] The directionality and ability of the double helix to form branched junctions were exploited for the edges and vertices, respectively.

Icosahedral hosts

Spherical viruses, found in nature, are examples of molecular hosts related to an icosahedron (Fig. 4f).[11] Possessing identical copies of proteins that assemble by

(*View this art* in color *at www.dekker.com.*)

way of noncovalent forces (e.g., hydrogen bonds), these hosts range from 15–90 nm in diameter and encapsulate strands of ribonucleic acid.

Archimedean Solids

As stated. the Archimedean solids constitute a family of 13 convex uniform polyhedra made up of two or more regular polygons and, like the Platonic solids. possess 32, 432, or 532 symmetry.

Truncated tetrahedron

Fujita,[13] Stang,[14] and Steel[15] described metal-organic cages that are topologically analogous to a truncated tetrahedron (Fig. 5a). These systems consist of metal ions and aromatic-based bridging ligands that constitute the twofold and threefold rotation axes. respectively. In terms of host–guest behavior, x-ray crystallographic studies revealed the assembly reported by Fujita to form a complex with four adamantyl carboxylate ions, while that reported by Steel to encapsulate a molecule of dimethylsulfoxide. According to mass spectrometric data, the cage described by Stang associates with four triflate ions.

Cuboctahedron

Gonzalez-Duarte described the ability of eight cadium ions and 16 thiolate ligands to assemble to form a highly charged cage. $[ClCd_8\{SCH(CH_2CH_2)_2N(H)Me\}_{16}]^{15+}$, the sulfur atoms of which sit at the vertices of a cuboctahedron.[16] The host contains a central chloride ion and an inner tetrahedral array of cadmium ions. A large metal-organic shell that conforms to a cuboctahedron and is based upon Cu(II) ions that assemble with a triazo ligand was described by Robson.[17] The shell possesses a cavity with a volume of approximately 816 $Å^3$ and is speculated to accommodate five to six molecules of dimethylformamide.

Truncated octahedron

Seeman constructed a DNA-based shell analogous to a truncated octahedron.[18] The edges of this molecule, each of which contains two turns of the double helix, contain 1440 nucleotides. The molecular weight of the structure, which is an overall 14-catenane, is 790,000 Daltons. The design strategy relied on a solid support approach, where a net of squares is ligated to give the polyhedron.

Rhombicuboctahedron

Müller showed that 24 oxygen atoms of the polyoxometalate $[As_4Mo_6V_7O_{39}]^{2-}$ may be attributed to the structure of a rhombicuboctahedron.[19] A strong "tetrahedral distortion" of each ion is required to correspond each host to the polyhedron. This shell was shown to complex a sulfate ion in the solid state.

Snub cube

MacGillivray and Atwood demonstrated the ability of six resorcin[4]arenes and eight water molecules to assemble in apolar media to form a spherical molecular assembly that conforms to a snub cube (Fig. 5b).[20] Each resorcin[4]arene lies on a fourfold rotation axis and each H_2O molecule on a threefold axis. The vertices of the square faces of the polyhedron correspond to the corners of the resorcin[4]arenes and the centroids of the eight triangles that adjoin three squares correspond to the water molecules. The assembly, which exhibits an external diameter of 2.4 nm, possesses an internal volume of about 1400 $Å^3$ and is held together by 60 O–H···O hydrogen bonds.

Truncated icosahedron

Buckminsterfullerene. an allotrope of carbon, is topologically equivalent to a truncated icosahedron, an Archimedean solid based on 12 pentagons and 20 hexagons (Fig. 5c).[21] Each carbon atom of the framework corresponds to a vertex of the polyhedron. As a result, C_{60} is held together by 90 covalent bonds. the number of edges of the solid.

CONCLUSION

Although chemists demonstrated an ability to utilize principles of solid geometry to design spherical hosts that encapsulate atoms and molecules, it is clear that much work remains to be accomplished. Indeed, although there exists a limited number of ways (i.e., Platonic and Archimedean solids) in which polygons may be arranged to enclose space. that chemists are able to mimic such structures chemically means that, in principle, an unlimited number of shells. with sizes that range from the angstrom — to the nanometer-scale level. and beyond (i.e., >10 Å), may be constructed. Moreover, a recent report by Swiegers illustrated that a classification system that accounts for different assembly processes available for a given polyhedron is feasible, meaning that a variety of routes to Platonic and Archimedean structures remain unexplored.[22] Notably. whereas nature utilizes template-directed synthesis to form the polypeptide chains that assemble to form a spherical virus, chemists utilized a fundamentally different approach to synthesis that relies on diffusion-controlled synthesis to construct the subunits of spherical hosts.[23] Moreover, an ability of chemists to mimic such template-controlled processes could provide access to spherical hosts with properties not accessible using a more classical approach synthesis. The imagination of the chemist, concomitant with an understanding of principles of biology and geometry, will lead to further advances in this area.

Podands

Edwin Weber
Technische Universität Bergakadernie Freiberg, Freiberg, Germany

INTRODUCTION

The discovery of crown ethers and their unique complexation properties in the 1960s[1–3] initiated an explosive development of the field that is now called "host–guest chemistry''[4] or, within a broader scope of understanding, "supramolecular chemistry.''[5] This gave rise to an enormous number and structural variety of compounds all tracing back to the original crown ethers. Apart from the parent-type crown compounds, they range over the monocyclic coronands, the bi- and oligocyclic cryptands, the spherands, cavitands, carcerands, and even more sophisticated structures showing the course of evolution to very complex systems.[6] Weighing the advantages and disadvantages of such complicated structures. e.g., high selectivity and high stability of complexation on the one hand, but high expenditure of preparation and low kinetics of complexation on the other hand. contributed to the opposite course of development. that is to say, design of less-complicated acyclic structures. This process resulted in the synthesis of the so-called "podands." which are by definition open-chained analogues of crown compounds and cryptands. Podands now exist in a great many structural variations ranging from single-chained basic compounds to multiarmed dendrimers like inolecules and from highly flexible to rather rigidly preorganized molecular architectures.[7–9] However, it should also be noted at the beginning that compounds of the podand type were well known, long before the discovery of crown ethers, because many of the traditional ligands. e.g., oligoamines, salens, etc., used to form chelate complexes of metal ions are podands in their structural features.[10] Other long-known compounds of podand type are the commercial oligo- and polyethylene glycols (PEGs) and their dimethyl ethers (glymes).[11,12] Moreover, certain natural cation-binding ionophores (antibiotics. siderophores) are also close to the structure of podands,[13,14] giving a foretaste of the diversity of compound types classified among the podands with a broad range of occurrence and applications being discussed in the following sections.

DEFINITION, BASIC STRUCTURE, AND TERMINOLOGY

Coming from supramolecular. coordination, or host–guest chemistry, the podands are classified as multidendate organic ligands or multidonor-site host compounds.[15] Within the general class specification of supramolecular ligands and host compounds. the structural feature characteristic of a podand are the alignment of donor atoms (D) in an open-chain framework[16] (Fig. 1a). Thus, within the most generalized system of nomenclature for organic ligands, the podands represent noncyclic structures, coinpared to the monocyclic coronands (Fig. 1b) and bi- or oligocyclic cryptands (Fig. 1c). Referring to the noncyclic backbone of a podand that can be a simple line of atoms or a branched or multibranched structural arrangement. a subdivision is made into mono-, di-, tetra-. oligo-. or multipodands.[16] Exemplary cases of general construction representative of these structural types are shown in Fig. 1. e.g., mono- (Fig. 1a). di- (Fig. 1d), tri- (Fig. 1e). tetra- (Fig. If). podandobridged tetra- (Fig. 1g), or multibranched (Fig. Ih) podands. While the single-strand monopodands do not involve a so-called anchor group (A in Fig. I). the branched oiigo- and inultipodands. beginning with the dipodands, have at least one such anchor group or branching point incorporated in their structure. The anchor groups or branching points refer to any construction element or branching unit to which the podand segments are attached, mostly being an aromatic unit or an oligovalent atom (often N, P. or C).[7–9] Because the donor atoms, as well as the bridging units (ethylene, 1,2-phenylene) of ordinary podands are mostly the same as used for the construction of the crown ethers, coronands. and cryptands, it is understandable that the podands are sometimes compared with the cyclic or bicylic counterpart structures of crown ethers[7,8] and cryptands and are called open-chain crown ethers (cf. Fig. 1d with Fig. 1b) or open-chain cryptands[17,18] (cf. Fig. 1e with Fig. 1c). Although the name podand comes from the Greek meaning "foot,.' it is also spoken of "arms" in this structural context.'"']So. mono-. oligo-, and multipodands

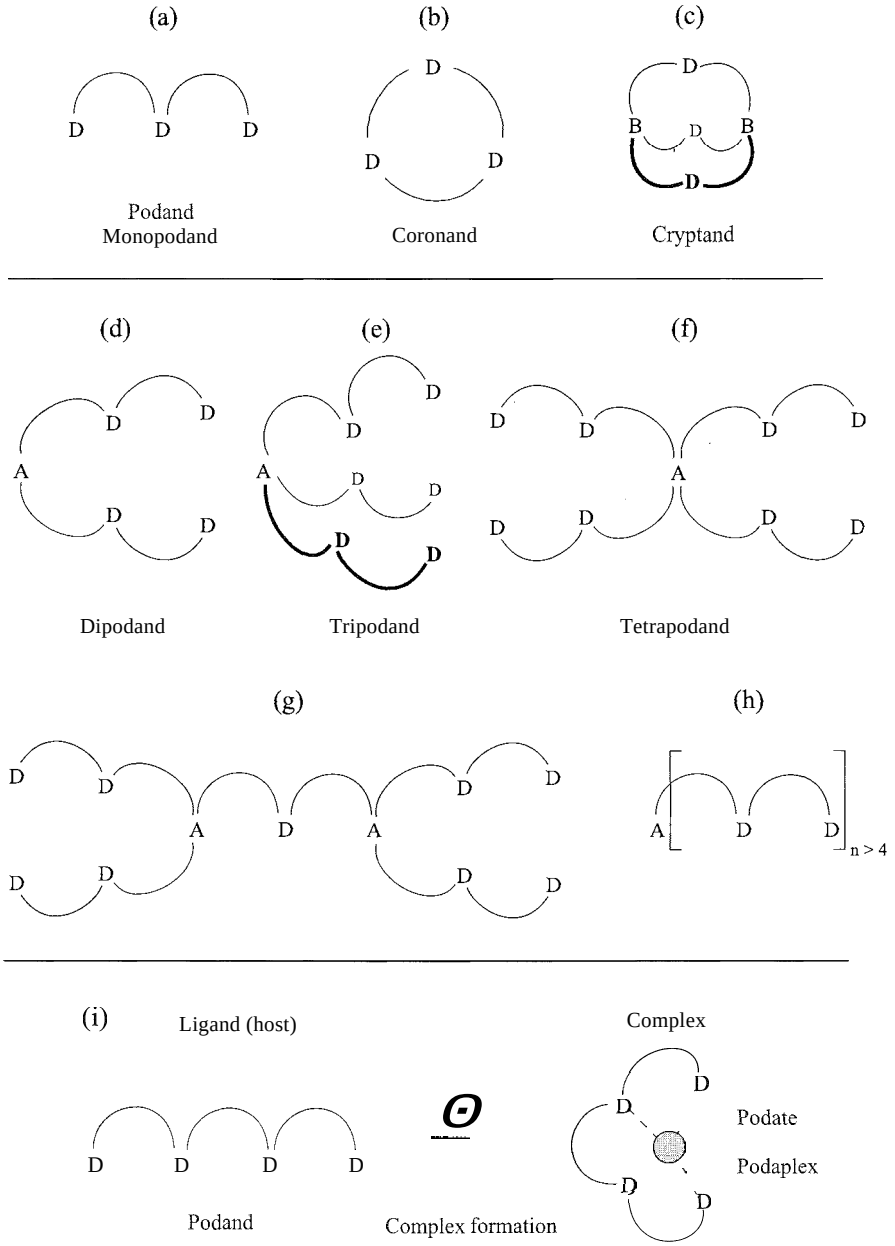

Fig. 1 (a)–(h) Definition, specification, and nomenclature of podands. including (i) podand complexes.

are synonymous with mono-, oligo-, and multiarmed open-chain ligands or host compounds, rerpectively.

Finally, most of the podands were synthesized with the formation of complexes (mostly with metal cations, see below) in mind. These complexes are termed "podates,''[15,16] or sometimes ''podaplexes''[19,20] (Fig. 1i).

REPRESENTATIVE COMPOUNDS AND SPECIFIC NOMENCLATURE

Because the acyclic podands were developed by imitating the crown ethers to a large extent, the podands featuring an open-chain framework with alignment of oxygen atoms bridged via ethylene units and having hydroxyl (Fig. 2a, R=OH) or alkoxy (especially methoxy) terminal groups (Fig. 2a, R=OCH_3, OAlkyl) are perhaps the most commonly known conventional podands.[7–9] According to their structures, they are oligoethylene (di-, tri-, tetraethylene, etc.), polyethylene glycols (polymers of ethylene oxide) or their dialkylether derivatives. Although many names were applied to the higher polymers of ethylene oxide (Carbowax, Jeffox, Nycolene, rnacrogol). they are conveniently designated as PEG followed by a number (e.g., PEG-200), where PEG is the abbreviation for polyethylene glycol. and the number designates the

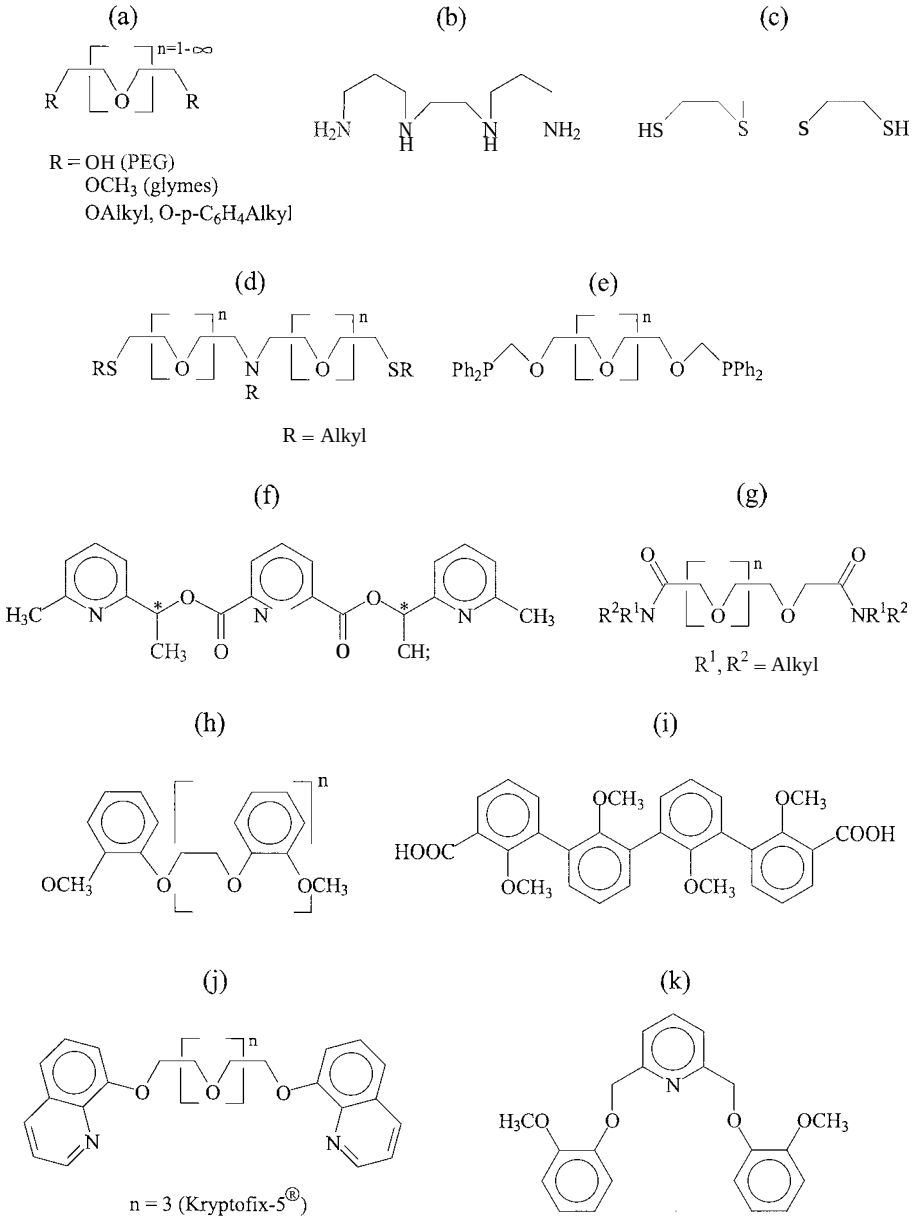

Fig. *2* Exemplary cases of linear podand types (monopodands. open-chain crown compounds): (a) conventional: (b,c) modified donor atoms: (d)–(g) mixed donor groups: (h,i) rigid building blocks; and (j,k) specific donor end groups.

molecular weight. which is an average molecular weight for commercial compound mixtures (e.g., 190–210 Da for PEG-200).[11] The dimethylether derivatives of the oligoethylene glycols are called ''glymes'',[12] which is short for glycol methyl ethers. or more specifically, diglyme (Fig. 2a, R=OCH_3, n=1), triglyme (n=2), tetraglyme (n=3), or oligoglyme (n being a higher number). In another naming of these compounds, the number following the class name glyme denotes the total number of ether oxygens connected with the ethylene glycol linkages, e.g., glyme-4 is tantamount to triglyme.[7,8] Moreover, numerous polyethylene glycol relatives exist in which only one of the terminal hydroxyl groups of polyethylene glycol is replaced by an alkoxy residue[1''] (cf. Fig. 2a). Important industrial representatives of this compound type[11,12] contain a long alkoxy chain as the terminal group. e.g., ''Laureth 9,'' which is short for nonaethylene glycol monododecyl (lauryl) ether. In addition. the family of industrial compounds known as ''nonoxynols'' are also mcnosubstituted derivatives of PEGs, but they possess a p-nonylphenyloxy residue at one end of the PEG chain (e.g., an undecaethylene glycol in the case of ''nonoxynol 11'') (cf. Fig. 2a). Similar compounds derived from polypropylene glycols are also in existence but play a less

important part compared to the PEGs and their derivatives.'" A block copolymer of ethylene oxide and propylene oxide having a molecular weight of $\sim 3 \cdot 10^3$ Da is termed ''poloxalene.''

On the other hand, open-chain analogues of the coronands featuring donor atoms different from oxygen are known in an immense variety,[7–10] including among all nitrogen and sulfur podands any mixed arrangement of potential donor atoms (O, N, S, P, As). Examplary cases are given in Fig. 2b–e. As for the crown compounds and cryptands, the donor atoms of podands may also be an integral part of a heterocyclic ring, a composite functional group, or a substituent (Fig. 2f,g). Although the most common bridging element connecting the donor atoms of podands is the aliphatic ethylene unit, the 1,2-phenylene (Fig. 2h) and analogous groups as aromatic counterparts are also in use. providing conformational rigidity of the podand framework and thus enhancing the overall organization or preorganization of the podand. For the same reason, the rigid all aromatic1 heteroaromatic group containing podands (Fig. 2i) may be referred to as open-chain spherands.[19,20] A further alternative to achieve organized podands is based on the so-called "end group concept''.[21,22] Here, use is made of a well-considered combination of strong donor sites and rigid building blocks to yield the end groups that are attached to the termini of a podand chain. The 8-oxyquinoline (Fig. 2j), 2-methoxyphenoxy (Fig. 2k) and analogous units (cf. Fig. 3e) were often used in this respect.

In most published cases of the tripodands (tripodes),[7–9] the three podand subunits are attached to nitrogen as the branching point and are usually the same in structure, but may be different. making the compounds symmetrical triamines (Fig. 3a.b). Also, in many representative cases of this compound class. rigidifying terminal groups according to the end-group concept are a particular feature of the structure (Fig. 3b). Nevertheless, many tripodands differing significantly from this structural principle were reported,[7–9] such as the derivatives of glycerol with carbon as the branching point (Fig. 3c). Others contain a central benzene or a 1,3,5-triazine nucleus (Fig. 3d) as the branching unit. Tetrapodands and higher polypodal ligands are similarly constructed,[7–9] using ethylenediamine (Fig. 3e), pentaerythritol, benzene units. or a calixarene framework (Fig. 3f) as the multibranching elements. Compounds of the latter type are called .'calixpodands.''[23,24] A striking example of a hexapodand is shown in Fig. 2g. Because of the pictorial parallelism to an octopus (in the strict sense a hexapus), benzene and other derivatives of this general structure are termed "octopus molecules."[25,26] However, as it may have appeared. podands are not exclusively manmade but also originate from nature. A variety of nonmacrocyclic ionophore antibiotics, such as grisorixin and nigericin[13] or the acyclic siderophlores[14] are podands in their overall structures. It is a common feature of the antibiotic structures that many of the donor atoms are located in tetrahydrofuran or tetrahydropyran rings (Fig. 3h). Another typical feature of the podal antibiotics is their chirality effected by a multitude of chiral centers. This structural property was also imitated by artificial podands, of which an example is shown in Fig. 2f.[27]

Finally, it is worth mentioning that in the same way as for the crown compounds and cryptands. a specific notation system was developed for podands.[16] However, because of the broad structural range of the podands: it is complex in layout and rules and is, therefore, only scarcely in use. For instance, applying this notation system to the simple compounds of Fig. 2a (R=OCH_3, n=2) and Fig. 2j (n=3) would result in the designations ''1,10-dimethyl<O_4 podand-4>'' and ''<(8)quinolino, O_5 (8)quinolinopodand-7>.'' respectively. The latter compound is sold under the tradename Kryptofix-5®; the names more common in use for the former compound (see above) are triglyme or glyme-4.

SYNTHESIS OF PODANDS

Most of the conventional podands, including the oligo-/polyethylene glycols and their rich variety of simple derivatives (glymes. PEG monoalkyl ethers, nonoxynols, etc.) are industrial products: usually obtained by polymerization of ethylene oxide (oxirane) or from oxirane and alcohols or oxirane and phenols, respectively.[11,12] Unfortunately, the polymerization process results in a mixture of compounds (oligomers of oxirane). causing difficulties when pure compounds are required, but the reactions per se are without problems. Indeed, even the bench synthesis of more specific acyclic podands is, by far, less problematic as for the macrocyclic crown compounds and macrobicyclic/oligocyclic cryptands.[28] This is mainly a consequence of their noncyclic structure, making superfluous laborious and other specific preparative methods (high dilution techniques, template support), usually required for the synthesis of macrocyclic ligands.[29] Hence, the podands are generally obtained by using conventional synthetic methods including common ether. sulfide, ester, or amide bond formation.[7–9]

However, certain difficulties may arise from the substrates that are often bi- or even oligofunctional in their structures: thus causing problems with respect to the control of the reactive sites. In order to eliminate these problems. protective group techniques are used. in particular, when hydroxyl or amino functions are involved. For that purpose, the interfering functions are temporarily

paralyzed through transformation into the corresponding labile ether, acetal, ester, or urethane derivatives. In this context, it is interesting to note that the purely accidental discovery of the first crown ether, dibenzo-18-crown-6, by Pedersen is the result of an incompletely protected substrate (catechol), while he aimed at preparing a bisphenolic podand.[1–3] Mention should also be made that many of the podands are simply intermediates of a crown ether, coronand, or cryptand synthetic sequence.[28,29] Here. they are mostly found at the level before final ring closure and may contribute to the accomplishment of a template effect.[30]

COMPLEXATION PROPERTIES AND HOST BEHAVIOR OF PODANDS

Because the podands were developed from the crown compounds and are seen as their open-chain analogues, properties similar to the crown compounds are to be expected for the podands. This is most evidently shown by the ability to form complexes.[4,5] In case of the podands, they are called "podates''[15,16] or sometimes ''podaplexes.''[19,20] This behavior of the podands to act as open-chained multidonor ligands was assessed with a variety of metallic and organic cations.[7–9] However, due to the acyclic structure of the podands. as contrasted with the macrocyclic crown compounds, there are also differences in the behaviors of the two compound types. including pros and cons.

Complexation of Cations (Metal Ions)

To begin with the simple polyethylene glycols and glymes. they both were found to form complexes with alkali metal cations (Na^+, K^+) of increasing stability with increasing chain length of the podand.[7–9] Incorporation of an organizing 1,2-benzo unit into the glyme structure does not fundamentally alter the facts. These observations accord nicely with the general understanding of the complexation phenomenon accepted for crown ethers.[29,31] However, when making a comparison between crown ethers and the open-chained relatives, the macrocyclic crown ethers generally exhibit much higher cation affinity than their acyclic podand analogues.[32] To set an example, the stabilities of the potassium cation complexes of pentaglyme (glyme-6) (Fig. 4a) and 18-crown-6 (Fig. 4b) differ by about four orders of magnitude in favor of 18-crown-6, depending on the solvent (e.g., methanol). The enormous binding difference is said to result from a so-called "macrocyclic effect" and may be explained by enthalpic and entropic effects, unfavorable in case of the podand.[33] The potassium complex of cryptand [2.2.2] is still more stable (again by about four orders of magnitude; Fig. 4c), as a consequence of the macrobicyclic effect or cryptate effect.[33] Thus, with reference to the three basic types of oligodentate organic ligands (Fig. la–c). one may reach the conclusion that the podands give the weakest complexes of the series. Nevertheless, the podands profit from the well-known chelate effect,"' which relates to the observation that metal complexes of bidentate or oligodentate ligands are significantly more stable than closely related materials that contain unidentate ligands (such as diethyl ether or ammonia). When drawing a comparison between the cation complexes of simple monopodands or dipodands and the topologically higher tripodands (open-chain cryptands). the tripod complexes are somewhat more stable than the analogous complexes of the mono- or dipodands.[7,8] On the other hand, the complex stabilities for the tetrapodands were generally found to be somewhat lower than for the tripodands. which is attributed to potential steric hindrance of the terminal groups in the complex arrangement (an effect also believed to affect the complexation of higher oligopodands).

However. the affinity for metal cations is also regulated by the character of the donor atoms contained in the podand framework.[7–9] While the all-oxygen podands, in keeping with the hard nature of the oxygen donor atoms, favor the formation of complexes with alkali and alkaline earth metal cations: incorporation of nitrogen and sulfur donor atoms into the podand framework is attractive, as it alters the binding tendency of all-oxygen podands so that they may more readily complex cations of the transition metals, such as Ag, Cd, Hg, Co, or Ni.[33] Several other donor atoms (P, As) and types of donor groups, including functional units (ester, amide, etc.) may stabilize specific podand cation complexes. including complexes with NH_4^+ and organic (chiral) ammonium ions."' But probably the most general effect of complex stabilization in this context is produced by the end-group concept mentioned above, which is effective when sufficiently rigidifying donor end groups are present.[21,22] A complex stability constant typical of an end-group-assisted podand is exhibited by the 1:1 K^+ complex of Kryptofix-5® (cf. Fig. 2j, $n=3$) with log $K_s=3.5$ (in methanol).[34]

Another typical feature of the podands is that the stability constants of their complexes are largely independent of the metal cation radius, resulting in relatively small discriinination factors $K(M_1^+)/K(M_2^+)$, i.e., relatively low cation selectivity, as compared to the more preorganized crown compounds and cryptands [cf. $K(K^+)/K(Na^+)$ in Fig. 4a–c].[32] This is a consequence of the flexible podand chain that can more readily adapt to the various ions. Nevertheless. when circumstances meet the structural requirements, podands may definitely achieve useful metal cation selectivities, most distinctly manifested by the natural ionophores (e.g., nigericin significantly prefers K^+ over Na^+, while monensin is in the reverse order)[13] or the so-called ''stereognostic ligands''[35] detigned for specific target cations such as $[UO_2]^{2+}$ or $[VO]^{2+}$.

However, in one important respect, the podands are undoubtedly superior to the cyclic analogues, which is the kinetics of complexation and decomplexation of cations.[32] In fact, it is a general phenomenon that the more rigidly preorganized a host is for cation binding, the slower the kinetics of the process are. The same is true for decomposition of the complex. Thus, both the forward (k_1) and reverse complexation rates (k_{-1}) of the podands are high, while the rates for the forward and back reactions of the macrocycles are slower, in practice, 10^2–10^3 times slower than with open-chain ligands. The complex

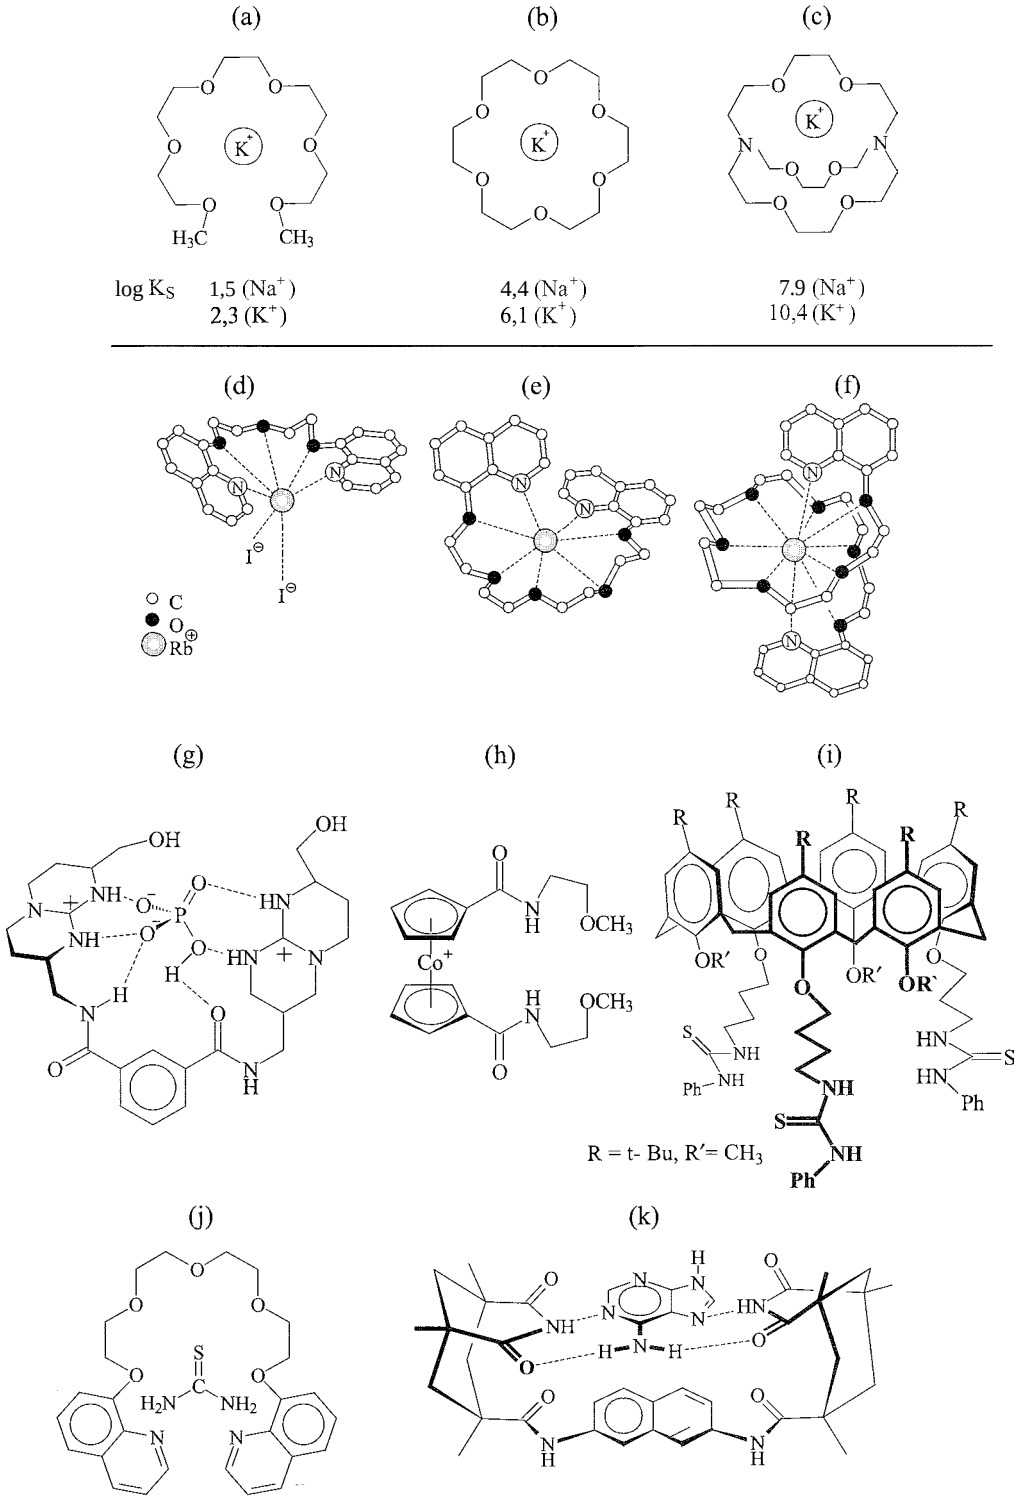

Fig. 4 Complex formation of podands: (a)–(c) log K_s of the Na^+ and K^+ complexes of (a) pentaglyme, (b) 18-crown-6, and (c) [2.2.2] cryptand demonstrating the macrocyclic and cryptate effects: (d)–(f) Rb^+ coordination spheres in the solid-state structures of the RbI complexes of bisquinolino podands of different chain length (cf. Fig. 2j); (g)–(i) podand anion complexation: (g) podand HPO_4^{2-} complex, and podands for (h) halide (Cl^-, Br^-) and (i) carboxylate (benzene-1.3.5-tricarboxylate) complexation: and (j,k) complexes of podands with uncharged molecules involving (j) thiourea and (k) adenine.

stability per se then results from the rates for complexation and decomplexation ($K_s = k_1/k_{-1}$), giving rise to a static or dynamic complex stability. The podand complexes are mostly affected from kinetics. This is an important point in the use of podands (see below).

Solid-state structures of complexes between podands and metal cations were solved in great number, including the complexes of simple glymes[36] and of the natural acyclic ionophore antibiotics,[13] but perhaps most of the structures that have become known relate to the complexes of podands involving rigid donor end groups of which three representative examples are illustrated in Fig. 4d–f.[7,8] In all three cases, the podand chain is wrapped around the cation (Rb^+), and all donor atoms coordinate. Nevertheless, the conformation of the ligands reveals significant differences dependent on the chain length, being approximately planar and folded like a butterfly (Fig. 4d), helically arranged (Fig. 4e), or spherically wrapped (Fig. 4f) for the penta-, hepta-, and decadentate podands, respectively, giving an impression of the flexible structure and adaptability of the podand chains. Moreover, as shown with the pentadentate ligand, if the solvation sphere of the cation is not satisfied by the donor atoms of the podand, anions are alternatively used to fill the coordination sphere. While most of the complexes are of mononuclear 1:1 stoichiometric type, the long-chain multidentate podands were also found to form dinuclear 1:2 stoichiometric or polymeric complexes.[7,8,32]

Complexation of Anions

In comparison to the complexes of cations, complexation between podands and anions is a rather recent development.[5] Nonetheless, different types of anion-complexing podands were designed.[37] Due to the special features of the anions that must be addressed, they include positively charged, organometallic, coordination interaction, or hydrogen-bonding structures of which representative examples are illustrated in Fig. 4(g–i). Anions often complexed by these hosts range from simple inorganic halide ions to the biologically relevant phosphate or carboxylate ions. Among the cationic podand structures, the guanidinium-based receptors are certainly the most important. One of these compounds that incorporates two guanidinium pendant arms attached to a 1,3-phenylene unit, e.g., allows effective complex formation of hydrogenphosphate, even in water (Fig. 4g). The organometallic cobaltocenium receptor of Fig. 4h endowed with additional amide hydrogen-bonding functionality in the podand subunits, developed for halide (Cl^-, Br^-) complexation, makes possible the electrochemical detection of anion binding [e.g., $K_s(Cl^-) = 20\ M^{-1}$ in DMSO]. The high affinity of actinide metals such as uranium for oxoanions is used in a ditopic coordination-type receptor to bind two $H_2PO_4^-$ anions, while the podand hosts not bearing any positive charge but based mainly on hydrogen-bonding interactions are mostly ureas of rigid-cleft structure or tripods derived from the *tren*, 2, 2′, 2″-*tris*(aminoethyl)amine, motif. A particular example of complementary anion complexation is shown by a tripodal thiourea receptor featuring a trifold symmetric calix[6]-arene scaffold that binds the trianion of trimesic acid markedly well in chloroform ($K_s = 2 \cdot 10^5\ M^{-1}$), while halides are only moderately bound (Fig. 4i). Other uncharged hydrogen-bonding podands, comprising a chiral framework, show chiral discrimination in the complexation of carboxylates (tartrate, amino acid anions). Thus, the podands are capable of selective anion complexation, although the complexes are only of moderate stability.

Complexation of Uncharged Molecules

The complexation between podands and uncharged molecules appears to be even less strongly explored than between podands and anions.[5] To this day, complexes of simple glymes with neutral molecules have not successfully been isolated. Only when the podands have a somewhat more specific or rigid structure are complexes with uncharged molecules formed or isolated in crystalline state. In most cases, these podands are of rigid-cleft type or contain rigidifying donor end groups.[38] Conventional guest molecules are water, urea, and thiourea, but relatively complex neutral guest molecules, such as nucleic acid bases or sugars, are also efficient in complex formation.[5] The main interactions that hold these complexes together are hydrogen bonds and π-stacking. Remarkable cases of complexes are illustrated in Fig. 4j,k. On the other hand, the so-called solid-state complexes of multiarmed podands (e.g., hexahosts) with neutral molecules are more likely to be classed with clathrates (crystal void inclusion compounds).[39]

APPLICATION OF PODANDS

Considering the properties of podands, as demonstrated in the previous section, several important applications can be deduced. They relate to utilization of podands or to molecular classes that evolved in part from podand chemistry.[7–9]

Chemical Synthesis

Due to cation complexation and aftereffects relating to the increased solubility of inorganic salts in low-polarity organic media and enhanced activity of the counterion reactant (quasi-naked anion), the podands, just as the crown compounds and cryptands, are promising catalysts in the synthetic methodology of phase-transfer catalysis,

both in liquid–liquid or solid–liquid systems.[40] Although the crown compounds and cryptands are more active in complexation and surpass the podands in anion activation; these agents also show deficiencies: as compared to the podands. In the first place, they are relatively expensive, being an obstacle to industrial use, and second, they are much slower in the kinetics of the complexation/decomplexation process (see above), which is of general disadvantage for the catalysis. Hence, making use of the podands as a PT-catalyst saves costs and time. thus affording a reasonable alternative to the crown compounds and cryptands. and in some respect, also to the conventional quaternary ammonium salts. This is, in particular, true for the siinple oligo-/polyethylene glycols (PEGs) and their methyl ethers (glymes) (Fig. 2a). They proved to be effective catalysts in a variety of anion-proinoted reactions, involving nucleophilic substitutions with anions such as fluoride, cyanide, acetate. azide, thiocyanate, and sulfide or eliminations using hydroxide as a base, both under liquid–liquid and solid–liquid PT-conditions.[7–9] Mostly. the reactivity increases by increasing the molecular weight of the ligands, however, the catalytic activity does not appear to be generalizable for any kind of anion-promoted reaction. For instance, when considering the dehydrobromination of 2-bromoethylbenzene with 60% aqueous KOH, pentaethylene glycol (Fig. 2a. R=OH, n=3) was found to be the optimum PT-catalyst, while higher and lower glycols, and even 18-crown-6 (cf. Fig. 4b). proved to be less effective. This specific behavior is presumably attributed to the self-solvating behavior of PEG, unlike the crown ether. Because the PEGs are so inexpensive, they may even be used as solvents in processes of this type. Moreover, particular end-group-assisted linear podands (Fig. 2j) and tripods (Fig. 3b), as well as oligopodands, derived from trisubstituted triazine (Fig. 5a), respectively, hexasubstituted benzene (Fig. 3g). cyclotriphosphazene, or cyclotriveratrylene, are. in part, very good catalysts, mainly in solid–liquid PTC. showing superiority to similar commercial ligands like the ''Trident'' (Fig. 3a).[7–9] Finally; the possibility of solving the catalyst recovery problem by attaching active catalyst centers to insoluble polymeric matrices (''three-phase-catalysis''), which is of high interest from the industrial point of view. was also used with podands.''''' And last but not least, glymes are excellent solvents in the laboratory use of organometallic reactions. while the PEGs and other simple podands of this type are useful starting materials in the preparation of crown compounds and cryptands[28–30] as well as in the synthesis of many other commercial products of the chemical industry.''''' A few out of this wide range of compounds were mentioned in earlier passages.

Another field of application where the flexible podand structure offers advantages to chemical reactions is enzyme modeling.[41] Without going into detail, this has given rise to a variety of catalysts being inspired of enzyme activity, such as the Zn^{2+} complex of the tripodand shown in Fig. 5b. which is an esterase mimic.

Chemical Analytics

Compound separation and concentration determination are important processes in analytical chemistry. In both respects, the podands are useful tools.[42] Considering the so-called ''solvent extraction'' of metal ions, which uses a water/organic solvent two-phase system for separation and enrichment of metal ions, suitable ligands operate as carriers.[43] Their effectiveness not only depends on their complexation ability but also on the partitioning between the two phases. This factor is taken into account by modification of the podand with lipophilic substituents to a balanced degree, such as butyl or higher alkyl groups at the termini of an oligoethylene glycol chain (Fig. 2a, R=OAlkyl). Nevertheless. due to their flexible structures, these lipophilic derivatives of glymes were found to be much less efficient in the extraction and separation of alkali metal ions as compared to lipophilic crown compounds. However. amido analogues of this compound type (Fig. 2g) show clear preferences in the extraction of rare earth [Yb(III), La(III)] and alkaline earth [Ca(II), Sr(II)] metal ions, while certain aza and thia derivatives of the lipophilic glymes (Fig. 2d) show good carrier properties for the extraction of Hg(II), Cu(II), Ag(I), Au(III), and other ions of polluting or precious transition metals. On the other hand, as compared to the macrocyclic hosts, the podands have only scarcely been used as carriers in membrane transport, which is another technique used to accumulate and separate chemical species such as metal cations''''] (e.g., the podand of Fig. 2f being selective for Ag^{+}), though most of the natural podands (nonmacrocyclic ionophore antibiotics)[13] are typical of this behavior.

Owing to the fast complexatioddecomplexation kinetics. podands have found wide applications in chemical sensing, such as in ion-selective liquid-membrane electrodes: which in some relevant cases contain a lipophilic podand as the sensor component.[44] These podands mostly possess an amide structure and have long alkyl chains that are needed to retain the compounds in the lipophilic medium of the membrane. Based on this strategy, ion-selective membrane carriers are available for nearly all cations of interest in concentration analytics (metal ions, ammonium ions), including clinical. biological, and environmental fields. Remarkable cases with indication of the ions to be determined are illustrated in Fig. 5c–e. Also, among the immense variety of fluoroionophores designed for cation-sensitive fluorescent sensors. the fiuorogenic podands rank high.[45] These podand structures contain a fluorogenic subunit that tranduces the chemical information of the ion–podand interaction, ion

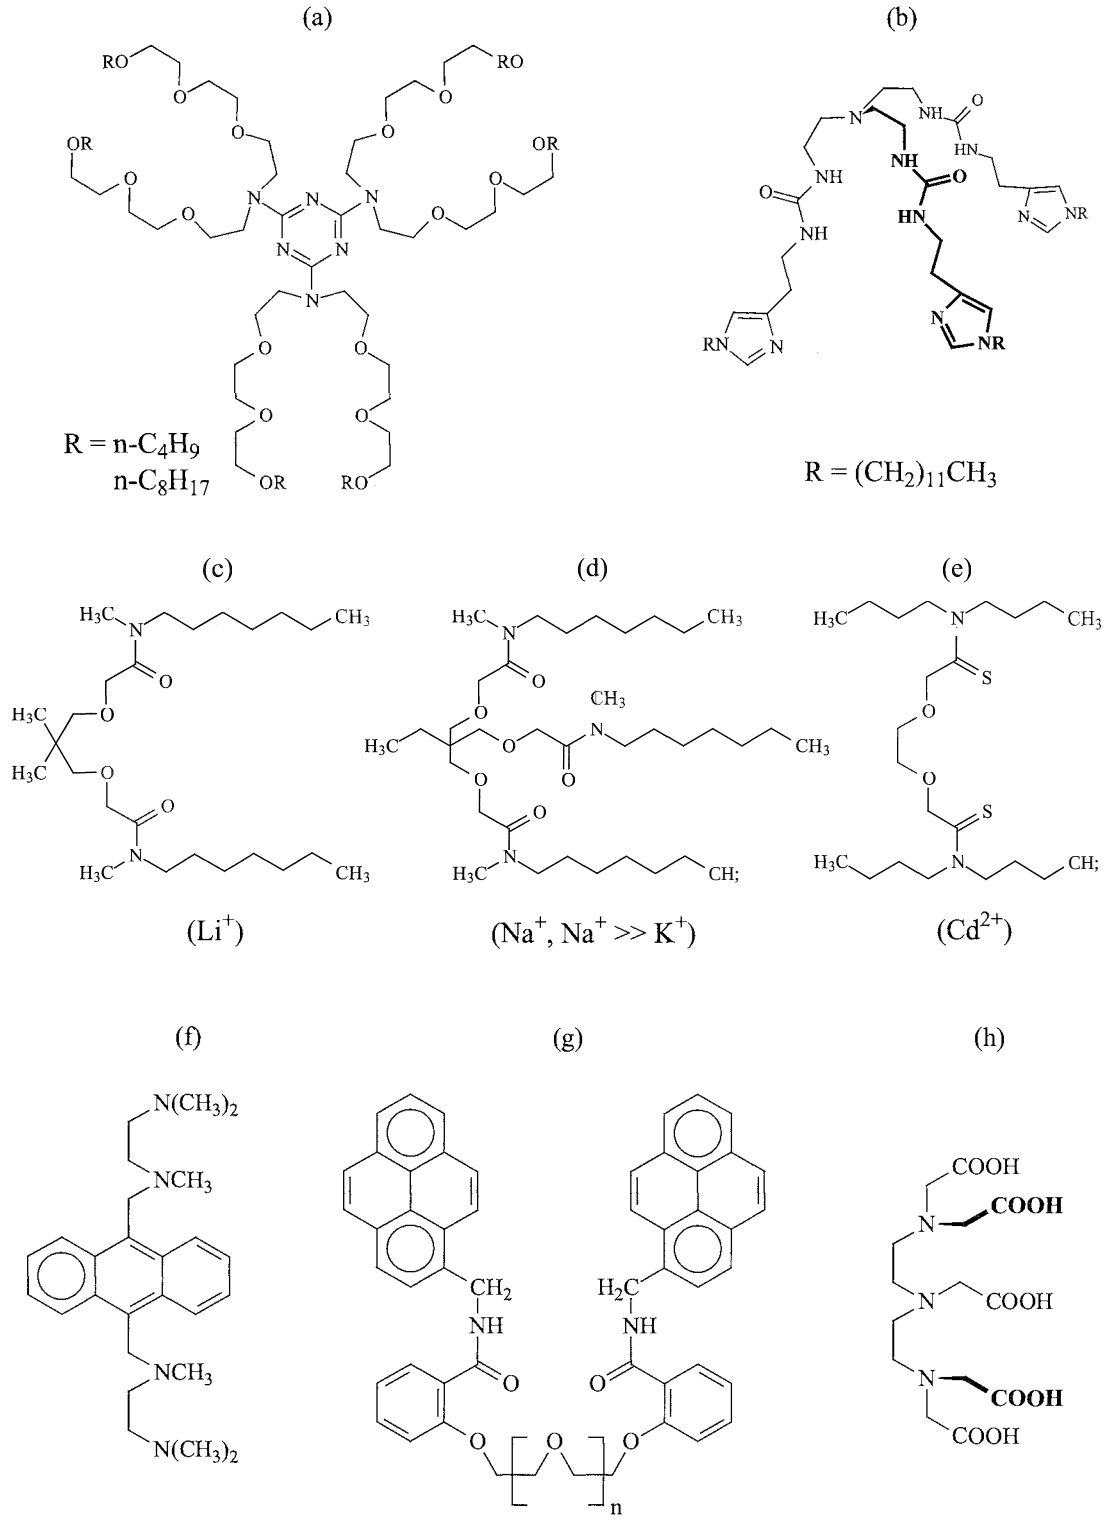

Fig. 5 Podands with reference to practical uses: (a) PT-catalyst: (b) enzyme model: (c)–(e) selective membrane carriers (ions to be determined in parentheses); (f,g) fluoroionophores: and (h) imaging agent.

selective and in dependence of concentration, in an optical signal. Often. the fluorophore unit is an anthracene or pyrene derivative. while the podand donor sires are oxygen or nitrogen atoms with affinity for hard alkali and alkaline earth or soft transition metal ions, respectively. Relevant examples are shown in Fig. 5f,g. Moreover, certain paramagnetic lanthanide complexes of oligopodands (Fig. 5h) are in clinical use as contrasting agents for magnetic resonance imaging.[46]

Other Uses and Potential Applications

Although the podands classify a particular compound type, including numerous structural variations,[7–9] certain other molecular types that have grown into separate compound classes trace, in part. back to the chemistry of podands. This holds, in particular. for the so-called "lariat ethers" or more general ''lariat compounds'. (from the Spanish "la reata" meaning "the rope," due to their graphic resemblance to a lasso) featuring a coronand (crown ether) ring with one or more podand side chains attached to it[47] (Fig. 6a–c). Because the "rope and tie" analogy is less satisfactory for the two- and higher-armed macrocyles (Fig. 6b,c), the term ''bracchial'' (from the Latin ''bracchium'' meaning ''arm'') was adopted. Thus, leading to names bibracchial lariat ether (BiBLE) or tribracchial lariat ether (TriBLE) for a two- or three-armed system. and so on.[47] Referring to the general class specification of supramolecular ligands elaborated with the terminoiogy of podands. the lariat compounds go by "podandocoronands," e.g., monopodando- or dipodandocoronand. and so on."'' Moreover, following the previous designation open-chain cryptand for the tripodands, the podandocoronands are occasionally called "half-open" or "semi-closed" cryptands. The overall goal in developing the lariat ether (podandocoronand) structures was to prepare a class of flexible but selective alkali and alkaline earth metal cation complexing agents. Another inspiration came from the naturally occurring TriBLE enterobactin, which is an iron-sequestering compound.[14] Heterodederivatives of the side-armed structures were also pursued with interest in the complexation of different transition metal ions.'" These compounds are of particular use for imaging and targeting purposes[46] as well as for supramolecular catalysis.[41]

In recent years, the tree-like molecular constitutions. being a logical extension of the oligopodands. developed explosively, thus now being classed under new general terms. Those multibranched structures consisting entirely of branched repeat units are usually called "dendrimers" or "hyperbranched polymers." The hyperbranched polymers are usually the product of a noniterative polymerization procedure and exhibit an irregular structure with incompletely reacted branch points throughout the structure. Dendrimers, on the other hand, are highly ordered, regularly branched. globular macromolecules prepared by a stepwise iterative approach with ''dendrons'' (cascade branching subunits) being part of it.[48] Numerous examples of this class of compounds are relevant to polypodands. of which typical illustrations are given in Fig. 6d.e. Because of their well-defined, unique macromolecular structures, dendritic architectures are attractive scaffolds for a variety of high-end applications, including nanoscale electronics. energy harvesting and conversion, nanoreactors, or highly targeted drugs.'"'

Another unique type of podands constituting a separate class of compounds are the helicands. They feature molecular threads containing a number of discrete metal-binding domains separated by spacer groups that give rise to the formation of helical complexes termed ''helicates.''[50] The majority of helicands contain nitrogen donor atoms, often incorporated in heterocyclic rings such as pyridine or 1,10-phenanthroline. In pasticular cases. double and triple helicates are created via self-assembly (Fig. 6f). Similar preorganized compounds, closely related to the podands. showed remarkable ability in the construction of molecular cages, grids, and rods through metal coordination, having advanced the new field of metallosupramolecular chemistry.[51] In addition, podands of PEG-type, bearing voluminous stoppers at the ends, brought new efficient approaches to rotaxanes to fruition.[52] Here. podands are used as the rod-like component for threading of the macrocyclic components. which are held together by mechanical bonds (Fig. 6g). All of these fascinating compounds and appealing structures suggest the possibility of generating electrochemically responsive and photochemically active molecular and supramolecular devices and materials at the nanoscopic level with precise functions and shapes. thus being promising to future high-tech applications.[53]

Finally, mention should be made that podands were in use long before the term was coined and one began to take notice of their complex formation property.[9] Strictly speaking, the conventional PEGs and glyme-type compounds (Fig. 2a, R=OH, OCH_3) are broadly used as solvents, solubilizers. emulsifiers. lubricants; finishings, sizings, softeners, wetting agents. and binders in technical products including varnishes. colors and oils, or cosmetics and pharmaceutics (such as face lotions. lipsticks, crèmes, ointments. and pills).[11,12] Others involving the PEG monoethers with one long alkyl chain or alkylphenyi residue as the terminal group (Fig. 2a, R=OAlkyl, O-p-C_6H_4Alkyl)) generally exhibit amphiphilic, detergent. or surfactant properties, and, accordingly, many are used industrially, including pharmaceutical preparations and emulsifying agents used in foods.[54] This may indicate that the ordinary podands are probably harmless for health. unlike the crown compounds and cryptands.

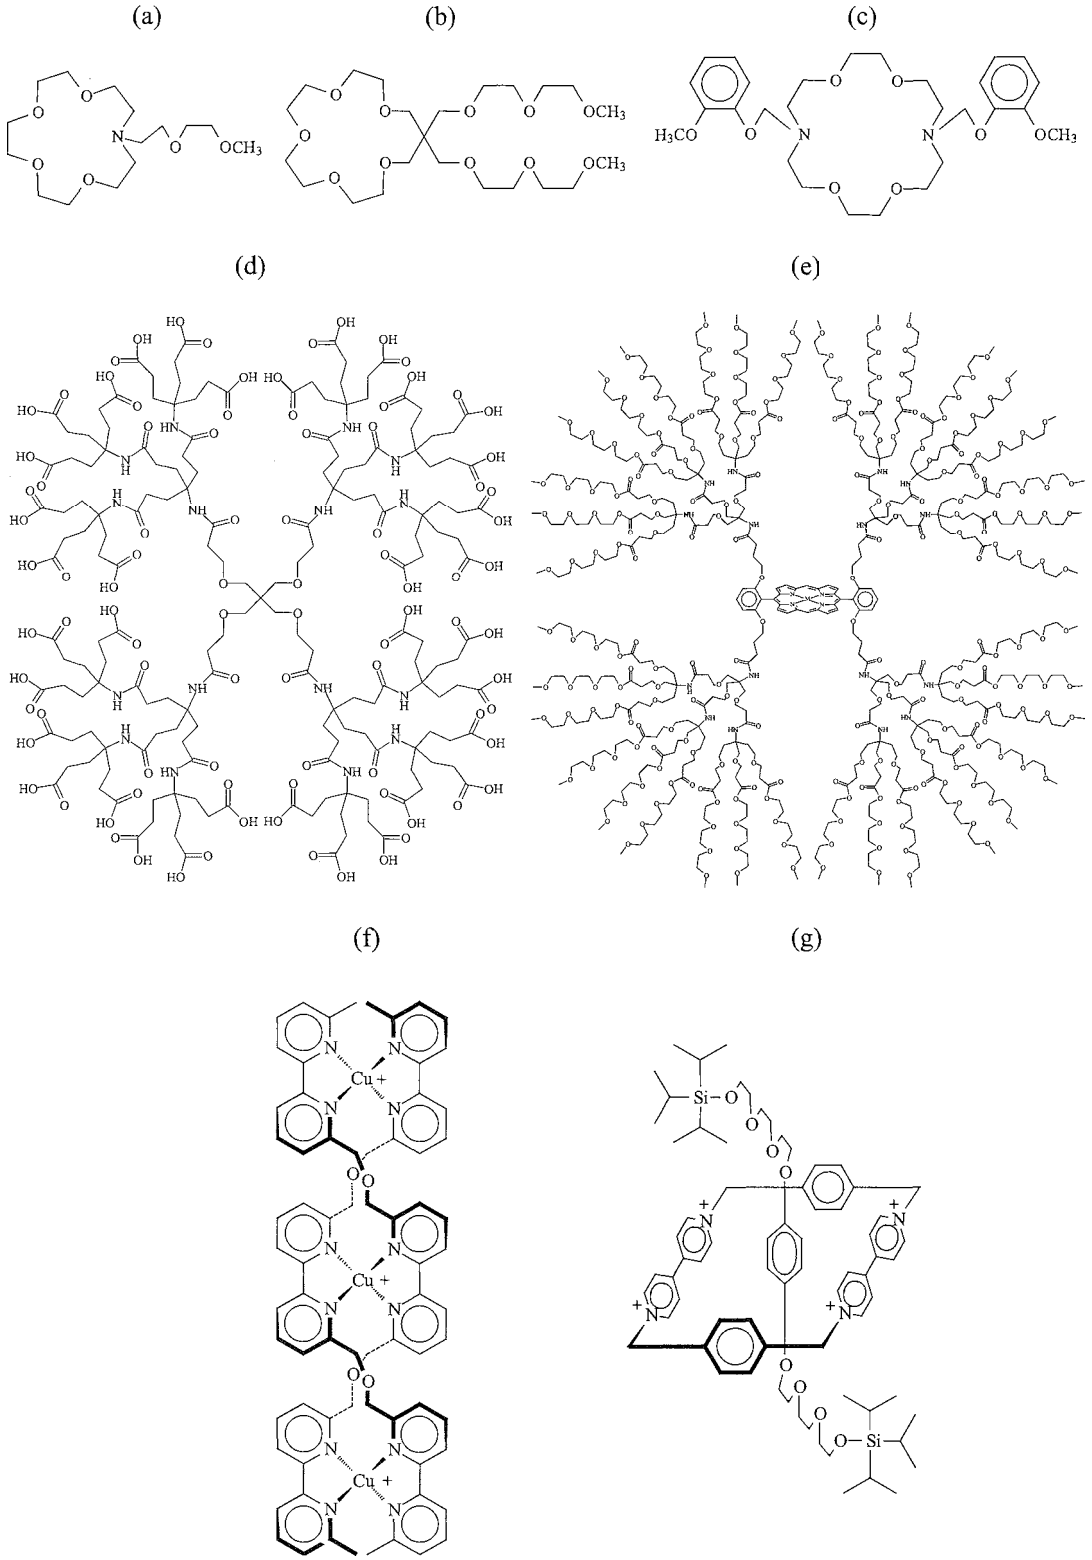

Fig. 6 Typical examples of (a)–(c) podandocoronands (lariat and bibracchial ethers); (d,e) dendrimers; (f) a helicate (double helicate); and (g) a rotaxane.

CONCLUSION

Despite the fact that the podands were well known before crown compounds and cryptands were recognized. it was only when the particular cation-binding ability of the latter was discovered that the study of podands took on a new impetus. This development has given rise to a vast array and enormous variety of novel structures of podands. which still continues. Beyond that, the podands inspired new structural variations such as those given by the lariat ethers. dendrimers, helicands, or rotaxanes that have grown into separate compound classes. Although the fundamental property of podands is to complex metal ions, other species, including organic cations, anions, or neutral molecules, are also bound. However, in comparison with the crown compounds and cryptands, the complexes of the podands are less stable and, as a rule, also less selective but kinetically much faster in formation and decomposition, which is advantageous in phase transfer, ion transport, sensing, and other promising fields of application. The most important advantage podands have. however, is their inherent inexpensiveness. The synthesis of podands is a comparatively simple one, not requiring high dilution or template processes, and is thus economic and enhances their commercial utility. Hence, there is little doubt that podand frameworks are versatile building blocks that will be used increasingly in a variety of real and innovative applications, indicated in the text, in addition to the ordinary use of podands, e.g., as solubilizers and detergents. But these latter properties, in the true sense, are not explained by the term ''podand'' and are, thus. beyond the scope of this article.

Polarity Formation: Markov Chain Model

Jürg Hulliger
University of Berne, Berne, Switzerland

INTRODUCTION

In nature. polarity (defined as a nonvanishing vector sum of dipolar moments) is widely present in living systems. It has been known for more than 35 years that bones. teeth, tendons, and other connective tissues show effects of macroscopic polarity. i.e., a pyroelectric effect. Later, it was shown that host–guest compounds[3] can feature a high occurrence of the effect of polarity, and that crystals grown from dipolar molecules[4–6] can show polarity, although the packing is found to be centrosymmetric by x-ray diffraction. The unifying principle behind these phenomena was recently recognized[7,8] as a Markov-chain mechanism of polarity formation by polar building blocks subjected to unidirectional growth.

The review is arranged as such to first provide an introduction to polarity. followed by drawing attention to aspects of crystal design and to supramolecular systems explicitly found to match the conditions for a Markov process of polarity formation. Theoretical aspects are reviewed in a separate section. Techniques for mapping grown-in polarity are briefly introduced as well. A generalization to polarity formation in single-component molecular crystals, mechanical objects; and collagen fibril fusion in tendon is given at the end.

POLARITY: DEFINITION AND MACROSCOPIC EFFECTS

Molecules or crystals can show spatial distribution of electrical charge giving rise to a dipolar moment. In physics, electrical polarity is described by a vector pointing from the negatively to the positively charged part of a system. Because of charge separation. polarity can only exist in point groups classifying molecules and crystals that preserve a vector property. For crystals,[9,10] there are 10 polar point groups called the pyroelectric groups (1. m, 2. mm2. 3, 3m. 4, 4mm. 6. 6mm). In cases where the orientation of the macroscopic polarization vector can be changed (inverted or tilted) by action of an external electrical field. we have ferroelectricity. or in case of stress, we speak of ferroelasticity. These properties are known for many inorganic compounds, however, so far. they have not been frequently observed for crystals grown from neutral molecules.[1,12]

Because species carry positive or negative charges, crystals classified by polar group do not show a permanent macroscopic polarization at constant temperature (T), electrical field (E), or stress (σ), respectively. As a matter of existing charges in the environment of a crystal, the negative and the positive ends of the polar axis are likewise covered by compensating charges. Here we notice a fundamental difference of magnetic systems, for which no compensation of the spontaneous magnetization by monopoles exists. A rapid change of temperature (AT) or stress ($\Delta\sigma$) thus induces a spontaneous polarization $\boldsymbol{P}$, which can be detected by an electrometer for crystals placed into a capacitor. In case of AT. we observe a pyroelectric effect. In the case of $\Delta\sigma$, a piezoelectric effect is observed:

$$P_i = p_i \Delta T \quad i = 1, 2, 3 \tag{1}$$

$$P_i = \sum_{j=1}^{3} \sum_{k=1}^{3} d_{ijk}\, \Delta\sigma_{jk} \quad i, j, k = 1, 2, 3 \tag{2}$$

where p_i are the pyroelectric vector components, d_{ijk} are the elements of the piezoelectric tensor (third rank), σ_{jk} are the elements of the stress tensor (second rank). and A indicates that a change is necessary in order to induce a macroscopic polarization $\boldsymbol{P}$.

At this point. we will make an amendment concerning the piezoelectric effect. Piezoelectricity[9,10] is found for 20 of the 32 point groups describing crystals, 10 of them also belonging to the pyroelectric class. Piezoelectricity is not a vector property, it is defined by a third-rank tensor. Given by symmetry. there are piezoelectric groups that are not polar. although effects of polarity can occur (e.g., charged faces). Other effects of polarity are represented by a third-rank tensor—the second-order nonlinear optical and the linear electrooptical effect.[11,13] A summary of noncentrosymmetric point groups is provided in Table 1. allowing for some solid-state properties of crystals.[9,10]

Are there further manifestations of a polar axis in crystals? Obviously, the morphology,[15] the crystal growth speed,[16,17] the form of etch figures,[18] and the chemical reactivity[11] of faces are properties that can express a polar symmetry.

Along the present review, we will focus on polarity in the strict sense, thus being a vector property.

ASPECTS OF CRYSTAL DESIGN: HOW TO OBTAIN A POLAR CRYSTAL?

> We consider this approach [supramolecular approach by inclusion formation] to be an important achievement that points to new methodology. a paradigm of guest–host induced dipolar alignment that can be used by chemists to engineer solid-state materials with specific properties.[11]

Present crystallographic data on the crystal structures of molecular compounds show that polar structures represent a minority, even among noncentrosymmetric (~24%, n.c.) ones. The main reason for this may be found in the electrostatic contribution to the packing energy of molecules, tending to align polar subunits (molecules, chains. planes) in antiparallel fashion. There are a few structures featuring perfectly aligned dipoles,[20–22] however, in most packings of polar structures, dipole moments are inclined by an angle θ to the polar axis. The field of nonlinear optics[13,14] generated a large number of compounds crystallizing in noncentrosymmetric structures. From the point of view of crystal design,[11] it is clear how to align dipolar, functionalized molecules into polar chains or planes (driven by synthon interactions[11]). however, the striking difficulty enters in preserving polarity in the bulk.

Classically. there is only one way to obtain a noncentrosymmetric crystal packing. The use of enantiomerically pure dipolar cornpounds ensures crystallization in one of the 11 enantiomorphic groups, whereof 10 show a piezoelectric effect. Only five (namely, those featuring an unique rotational axis: 1, 2, 3, 4. 6) of the enantioinorphic groups that are piezoelectric also allow for pyroelectricity (see Table 1). At present. there is no design concept with which to obtain a polar point group by spontaneous nucleation.

In the following, we review a supramolecular concept[3,25] that demonstrates that the idea of supramolecular interactions, may provide an answer. Essentially, this is achieved by aligning dipolar molecules into a parallel array provided by an inclusion lattice, in which guest molecules are subjected to orientational selectivity of the dipoles

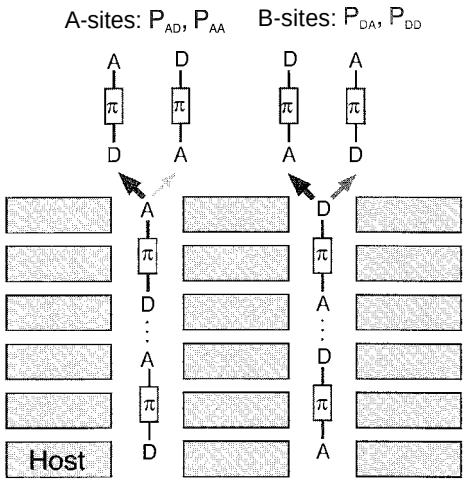

Fig. 1 Polarity formation for channel-type inclusion compounds. where A–D molecules enter channels, while the crystal grows in the direction of the channels. Orientational selectivity for A–D molecules is assumed to occur independently for each channel (A-and D-sites). *(View this art in color at www.dekker.com.)*

when included (Fig. 1). A further important effect of a channel-type architecture is to weaken lateral interactions between dipolar molecules, which frequently tend to an antiparallel packing. Examples from the literature are inclusion compounds of thiourea,[26] perhydrotriphenylene,[26,27] *tris*(*o*-phenylenedioxy)cyclotriphosphazene,[28] and others,[29] including polar molecules, into their channels.

THE MARKOV GROWTH MODEL OF POLARITY FORMATION

In case dipolar molecules A–D (A: acceptor-type, D: donor-type molecular fragment) and a symmetrical host molecule H are self-assembling into a channel-type inclusion compound $(A–D)_xH$, where A–D entities are aligned into chains in channels made up by H molecules, we may model the system as shown in Fig. 1. Spontaneous nucleation has only to create the inclusion-type lattice, where existing chains of A–D molecules in channels may at this early state show no bulk polarity. If such a seed is growing lo macroscopic size. molecular recognition (synthon interactions[24]) taking place during individual channel formation can provide conditions for orientational selectivity, irrespective of the type of interactions of guest molecules to the channel wall made up by H entities. Generally speaking, interactions of guest to guest and guest to surface (wall at entry of a channel) can contribute to polarity formation.

During further attachment (growth), the orientation of the incoining guest molecule is subjected to probabilities P. For the channel to the left, continuation of the preexisting polarity is given by P_{AD}, whereas inversion is induced by P_{AA}. Similar arguments hold for the channel to the right (P_{DA}, P_{DD}). Because we can assume here that the process of orientational selectivity is taking place independently at all channels exposed to growth. there is polarity formation. if $P_{AA} \neq P_{DD}$. The queuing system we have here can be modeled by a Markov-chain:[25,30,31]

$$\begin{bmatrix} X_A\ (q) \\ X_D\ (q) \end{bmatrix} = \begin{bmatrix} P_{AD} & P_{DD} \\ P_{AA} & P_{DA} \end{bmatrix}^q \begin{bmatrix} X_A\ (0) \\ X_D\ (0) \end{bmatrix}$$

where X_A, X_D are the molar fractions of the functional groups A or D appearing at the growing surface: q is the index for the actual layer of growth. starting at $q=0$ (seed) and rising to $q=\infty$, the macroscopic crystal. Note that $P_{AD}+P_{AA}=1$, $P_{DA}+P_{DD}=1$, and $X_A+X_D=1$.

Because of the ergodic property of a Markov chain. the result at $q=x$ is independent of the initial state of seeding. i.e., the initial values $X_A(q=0)$, $X_D(q=0)$. This means that the supramolecular approach generating polarity through a process of growth is circumventing the basic difficulty of creating polarity by spontaneous nucleation.

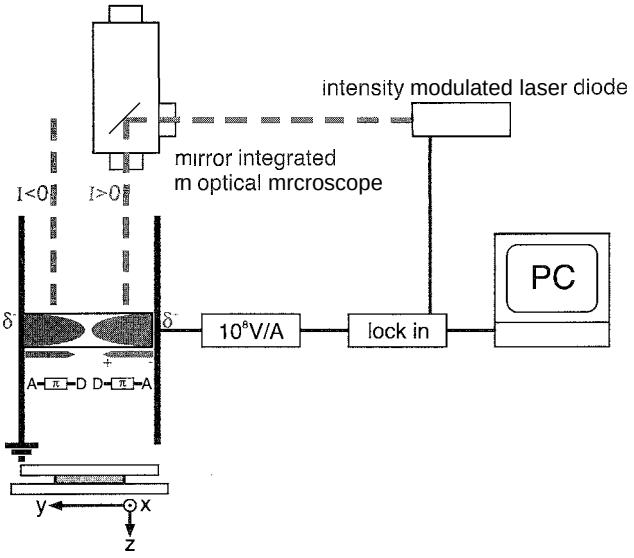

Fig. 2 Experimental setup for scanning pyroelectric microscopy (SPEM). As indicated, the sample may consist of two domains of opposite polarization. Local heating in either domain of polarization produces excess charges at both ends of the polar axis. This induces a current flow in the outer circuit. Opposite polarity is seen because of a change in the current direction.[33,36] *(View this art in color at www.dekker.com.)*

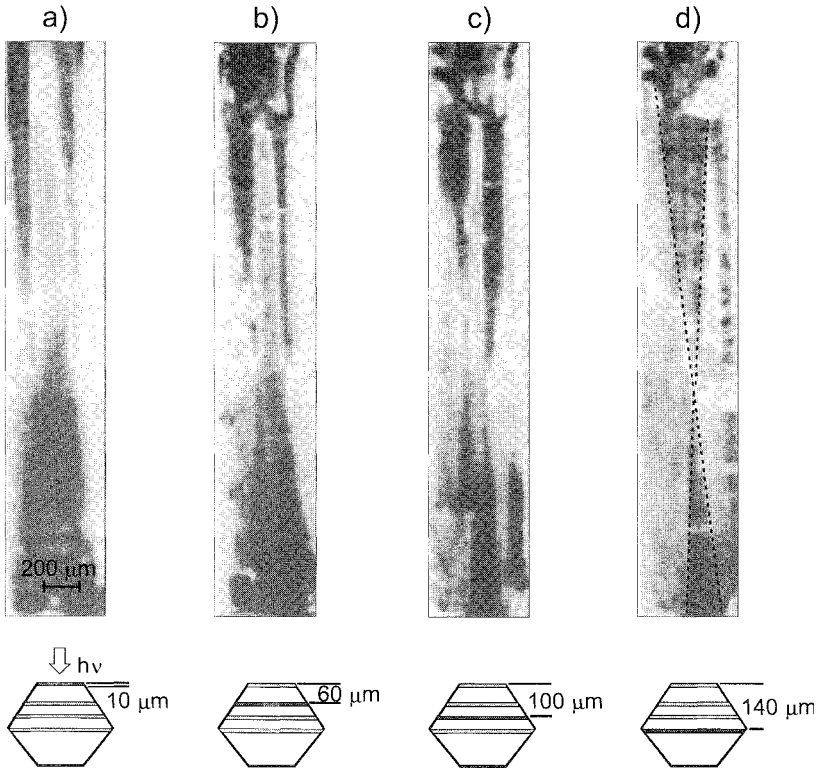

Fig. 3 SPEM images of perhydrotripenylene inclusion crystals[26] with a dipolar guest molecule [1-(4-nitrophenyl)piperazine], thinned in three steps. A two-dimensional mapping of the pyroelectric response in the channel direction is shown for a constant modulation frequency of the heating laser source of 415 Hz. Color code: red=positive current; blue=negative current. Low color intensity: no current.[3336] Moving from the outer to the inner part of the needle-shaped crystal shows that at all depths, there are two main domains of opposite polarization: although somehow interpenetrating. In the middle of the needle, a cone-shaped structure of polarity distribution is seen, which is typical for a Markov-type growth in two dimensions. Qualitative agreement with stochastic simulations is obtained. *(View this art in color at www.dekker.com.)*

The net fraction X_{net} (where A groups preferably cover the surface) of polarity may be defined by

$$X_{net} = X_A(q=\infty) - X_D(q=\infty) = \frac{1-e^{-\Delta E_f/RT}}{1+e^{-\Delta E_f/RT}+2e^{-\Delta E_A/RT}} \quad (4)$$

where $\Delta E_A = E_{AA} - E_{AD}$, $\Delta E_f = E_{AA} - E_{DD}$; with E_{AA}, E_{DD}, E_{AD} being the three basic interaction energies for a collinear geometry of A, D functional fragments of guest molecules A–D (additionally, we define $\Delta E_D = E_{DD} - E_{AD}$, see Fig. *6)*. Possible interactions to the surface other than to groups A, D are not explicitly introduced here, although they may exist.

From the point of view of optimizing the extent of polarity formation,[32] we may ask for the best type of A–D molecules in order to obtain X_{net} close to 1 at lowest possible q. The Markov model gives the answer. Guest molecules providing an A–R structure (R: fragment undergoing no typical synthon interactions) featuring $E_{AR} \approx E_{RR} \approx 0$, $E_{AA} > 0$, can develop an X_{net} of more than about 0.95 just after about six steps of attachments, if a strongly repulsive-A···A-interaction between A-fragments is the dominant contribution at a typical van der Waals distance when supposed to enter a growing channel.

We should emphasize here that Markov-grown polarity is not the result of a kinetically controlled growth process (i.e., fast grow), although we assume kinetic stability for the grown-in state of polarity. This means that guest molecules do not reverse their dipolar direction if definitively included in a channel.

As growth may be allowed along both directions of the channels, bipolar crystals are obtained, showing an inhomogeneous polarity distribution essentially because of the lateral growth by newly formed channels (see scetion on Physical *Methods)*. The interplay of growth along channels and in the lateral direction can result in a cone-like distribution of polarity (see Fig. 3).

PHYSICAL METHODS FOR A SPACE-RESOLVED MAPPING OF THE MACROSCOPIC POLARIZATION IN POLAR MATERIALS

Scanning Pyroelectric Microscopy (SPEM)

The compensation of the macroscopic polarization by outer charges in polar materials can be disturbed by a rapid change in. e.g., the temperature producing excess surface charge because of the pyroelectric effect. A two-dimensional mapping of the polarization distribution is possible when an intensity-modulated beam of a laser is scanning over the sample surface coated by a thin absorption layer (black). The lateral resolution in surface SPEM is limited by the spot size of the laser. An experimental setup is shown in Fig. 2. Tomographic information is obtained by layered thinning of a sample (Fig. 3). In the case of channel-type inclusion crystals, SPEM was the first technique to reveal the bipolar structure, the cone-shaped distribution of polarity (Fig. 3d) because of effects of lateral growth,[33] and the sign of polarization.

Phase-Sensitive Second Harmonic Microscopy (PS-SHM)

Norinal second-harmonic microscopy (SHM) may show that polarity is present in certain growth sectors, however. 180° domains cannot be resolved. Sectors featuring an opposite average polarity can be made visible by a phase sensitive technique,[34] introduced in Fig. 4. Provided the crystal thickness is in the range or below the coherence length of the second harmonic generation (SHG) effect, a reference beam of a polarized second-harmonic (SH) wave will undergo a constructive or destructive interference with an SH wave generated by the sample. By adjusting the phase difference between the fundamental and the SH reference wave. all parts of a bipolar crystal with the proper sign of the nonlinear optical tensor element allowing constructive interference will appear bright, whereas the adjacent domain will release an SH signal of much lower intensity (ideally zero). Keeping all optical settings constant but rotating the crystal around an angle of 180° (perpendicular to the incident beam), will interchange the brightness of the macrodomains, where enhanced or attenuated SH waves are released. Essentially. the contrast is due to inversion symmetry, changing the sign of the nonlinear optic (NLO) coefficient when transforming the tensor from one coordinate system into the other (Side I into Side II; Fig. 4).

In Fig. 5 we show the SHG response of a micrometer thin plate of a single component organic crystal, releasing green light only from the + and – b-sector (Fig. 5a). Phase-sensitive inforination is retrieved from Figs. 5b, c demonstrating that this crystal grew into a bipolar state. This is the first experimental demonstration that centrosymmetric molecular crystals can feature a grown-in bipolar state.[35]

For further details on the SPEM and the PS-SHM techniques, see a review in Ref. [36].

GENERALIZATION TO MECHANICAL OBJECTS, CRYSTALS, AND NATURAL TISSUES

The Markov growth model is generalized in the following way.[7] When polar building blocks attach to a surface, there is, by symmetry, a difference in the probabilities of attaching "tip-first" or "back-first." This difference drives polarity formation, irsespective of lateral interactions that may suppress a parallel alignment of vectors. However, if a packing energetically tends to arrange

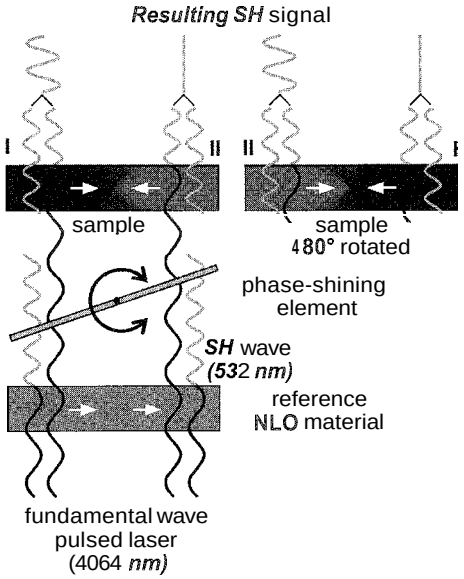

Fig. 4 Far-field phase-sensitive second-harmonic microscopy (PS-SHM).[34] Oppositely oriented domains (colored in blue. red) in a sample with uniform thickness below the coherence length emit SH light with a phase shift of π. Domain contrast is achieved by using the interference effect between the sample and a homogeneous SHG reference crystal. Angle-tuned phase shifting is used to adjust the phase between the fundamental wave and the SH wave from the reference in order to achieve a maximum interference of the green light of the reference and green light produced by the sample in, e.g., Domain I (blue). Keeping optical settings constant but rotating the sample by 180° leads to an interchange of the interference contrast. For clarity. it should be noticed that the laser beam direction is perpendicular to what is shown about the sample. (View *this* art in color *at www.dekker.com.*)

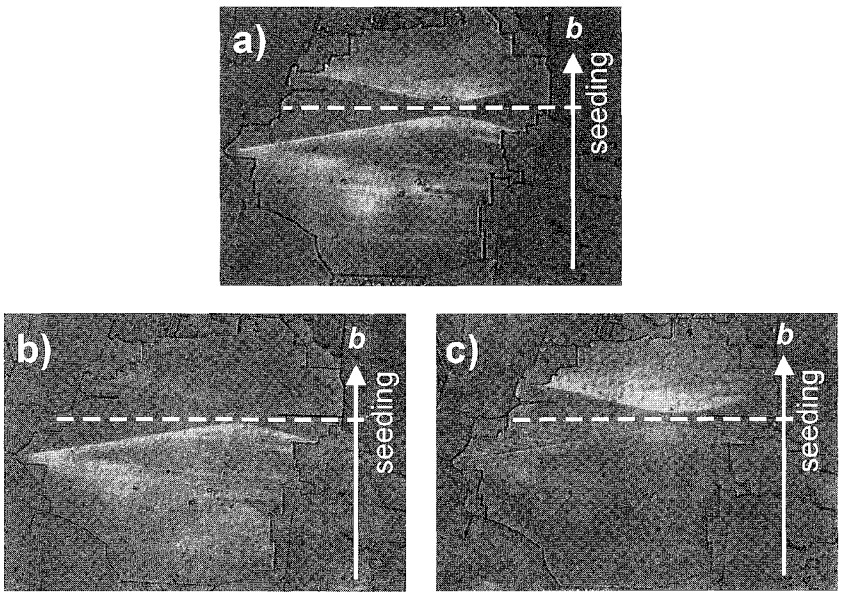

Fig. 5 Second-harmonic generation analysis[7,35] to show polarity formation in the centrosymmetric crystal structure of 4-chloro-4′-nitrostilbene. Micromctcr thin crystal plate with (001) orientation, grown from the melt. (a): Polarization of the fundamental wave (1064 nm) parallel to the *b*-axis. Both the upper and lower h-sectors emit green light. (b): Effect of phase contrast for the lower b-sector. (c): Correspondingly, upper *b*-sector. The change in contrast within sectors allows us to conclude that the average polarization in the lower (b) sector is opposite that in the upper (c) one. (*View this art in* color *at www.dekker.com.*)

building blocks in a centrosymmetric fashion, the Markov mechanism of polarity formation represents just a perturbation to a crystal. Examples include crystals of dipolar compounds refined to, e.g., $P2_1/c$, for which SHG techniques (see previous section), nevertheless, may reveal some polarity.[5,6,37] In 4-chloro-4'-nitro-stilbene (CNS), crystallizing in $P2_1/c$, with phase-sensitive second-harmonic microscopy (Fig. 5) a bipolar structure was found. Polarity in agreement with theoretical predictions develops in the + and – h-sectors.

In centrosymmetric structures, there are at least two different growth sites (similar to those shown in Fig. 1) for which we may assume independent Markov chains,[5,6,37] such as to describe polarity formation by taking into account longitudinal ($\Delta E_A, \Delta E_D$) and transversal (E„: parallel packing, E_{ap}: antiparallel packing; $\Delta E_\perp = E_p - E_{ap}$) interaction parameters. The general case for crystals calculated by a Markov model is summarized in Fig. 6: Assuming typical values for ΔE_A, ΔE_D, net polarity X_{net} is shown as a function of the transversal parameter $\Delta E_\perp$ at 300 K.

For a structure strongly preferring antiparallel packing (AP, to the right). only little polarity may appear. On the other hand, if A E is negative (P, to the left), the stochastic process may to some extent reduce X_{net} from being 1. In between (P', middle), we find a window, where polarity strongly depends on $\Delta E_\perp$. At $\Delta E_\perp{}^c$, a phase transition separates structures being centrosymmetric but perturbed (*AP*) from those being highly disordered but polar (P'). Note that polarity can well exist at $\Delta E_\perp = 0$ (case of inclusion compounds.[326–29] To the left, there is a second border given by $\Delta E_\perp(T_c)$. Below a certain value for $\Delta E_\perp$, a polar crystal may become metastable with respect to growth along one direction of the polar axis (for details, see Refs. [5,6,36,37], for which most of the dipoles should invert their orientations.

The Markov-type analysis lets us conclude that polarity in molecular crystals built up by dipolar coinpounds is a general property, however, X_{net} depends strongly on specific parameters given by intermolecular interactions. A further example is given by solid-solution formation[38–40] of A–D (crystallizing in a centrosymmetric lattice) with A–A or D–D (centrosymmetric as well). The $(A–D)_1$,(A–A), and $(A–D)_{1\ x}(D–D)_x$ crystals can develop polarity for the same reasons discussed above.

Finally, we can extend our view further in demonstrating that the stochastic growth of heaps (1D, 2D, 3D) using polar mechanical objects is yielding polarity as well.[7] Surprisingly; the existing pyroelectricity[1] in connective tissues was recently explained[7,8] by the following theory. Driven by chemical recognition, collagen fibrils during the process of self-assembly into tendon (Fig. 7) show the property of fusing[41,42] in a way that can produce macroscopic polarity. This occurs because the fusion probabilities P_{CC} for C-termini differ from that for N-termini (P_{NN}). Polarity evolution at the level of the early state of a piece of tendon may start with an

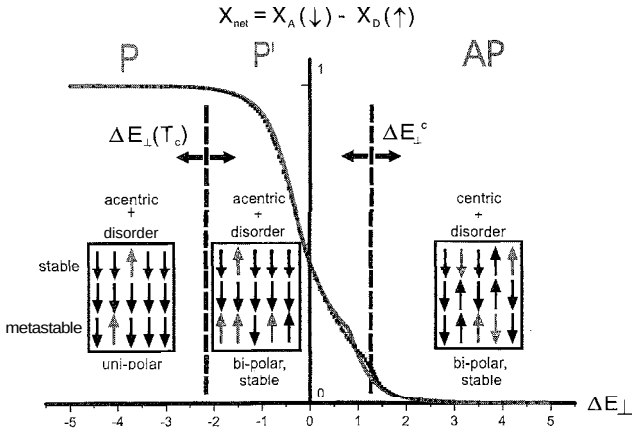

Fig. 6 Summary[37] of the behavior of stochastic polarity formation in crystals. showing the influence of $\Delta E_\perp$ (lateral interactions) on net polarity X_{net} for given values $\Delta E_A = 5$ kJ/mol and $\Delta E_D = 2$ kJ/mol at 300 K and a square lattice. Points: Monte Carlo simulation (periodic boundary conditions): red curve: Markov-chain model taking into account lateral interactions. P: structure with polar order showing some defects reducing polarity: P': polar order with many orientational defects; AP: centrosyrnmetric structure showing some orientational defects. For an explanation of boundaries separating AP. P'. and P, see Ref. [37]. (*View this* art *in color at www.dekker.com.*)

equal number of "up" and "down" fibrils exceeding elongation (see Fig. 7) in extracytoplasmic channels. Following ideas developed for inclusion compounds (see Fig. 1), we model polarity formation in growing tendon by two independent Markov chains (I, II; see Fig. 7). Driving forces for the lateral aggregation may support or work against macroscopic polarity formation. As a result of the interplay of all interactions, in principle. polarity can evolve if a difference in P_{CC} and P_{NN} is effected by a stochastic mechanism of self-assembly. A stochastic delivery of small aggregates of procollagen to extracytoplasmic channels (secretion: see Fig. 7) is provided because of a translocation time along the cell that is larger than the rotational diffusion of small aggregates. In agreement with experimental findings, only a small percentage of collagen fibrils in the bulk of tendon show polar order for a reasonably small ratio[7,8] of P_{NN} and P_{CC}. As found experimentally[1] in tendon, N-termini are preferably oriented in the direction of growth.

Summarizing. we can say that polarity is a property that can arise in systems showing unidirectional stochastic growth by use of polar building blocks. In other words, an average $<P>$ of the pertinent polar property P of building blocks is preserved by a stochastic process of growth,

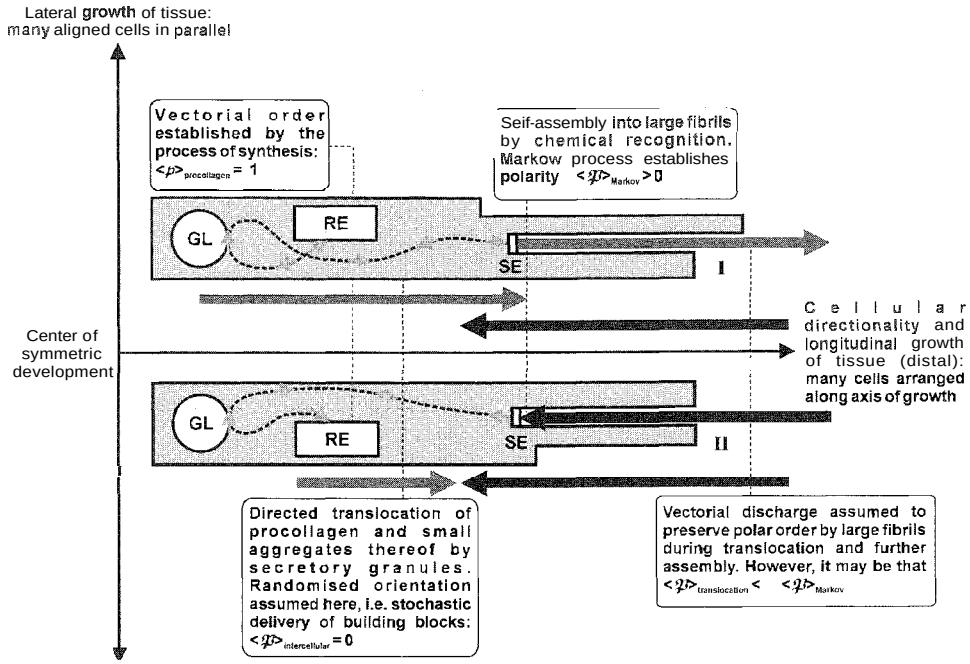

Fig. 7 How cells (green part) aligned in the direction of longitudinal growth of tendon produce fibrils (red and blue arrows) from small segments secreted (SE) into extracytoplasmic channels. Self-assembly is assumed to occur in the channels. Cells and produced fibrils are interwoven. RE: endoplasmatic recticulum: GL: Golgi apparatus; and SE: secretion. I and II refer to the basic orientations of the polarity of fibrils starting growth (compare with channels in Fig. 1). $P_{procollagen}$: polarization of the molecule: $<P>$: macroscopic polarization. As a result of the Markov process,[8] the sum of red vectors is larger than that of blue vectors, because here $P_{CC} > P_{NN}$.[41,42] Small pink arrows: intercellular translocation of procollagen and aggregates thereof. (*View this art in color at www.dekker.com.*)

because the growing system represents polar symmetry as well. In essence: there is always some bulk polarity $<P>$, although in most real cases; it may not reach the maximum extent. The extent of stochastic polarity depends on the ratio of P_{AA} and P_{DD}, both of which may be functions of longitudinal and transversal intermolecular interactions. Interesting to see that. particularly, a supramolecular system (e.g., channel-type inclusion compounds) can reach X_{net} values close to unity. This is because the negative influence of transversal interactions can be strongly reduced by any approach that succeeds in shielding guest molecules, as they do not prefer to align in an antiparallel fashion.

ACKNOWLEDGMENTS

Polymorphism

Mino R. Caira
University of Cape Town, Rondebosch, Western Cape Province, South Africa

INTRODUCTION

Purification of a solid organic compound is achieved principally by crystallization, a process involving the successive formation of prenuclear aggregates of the molecules in question. crystal nuclei: and eventually, mature crystals. Altering the experimental conditions of crystallization of a given substance can lead to its isolation in different crystalline forms, or polymorphs, each of which is unique in terms of its thermodynamic stability and physical properties. Two polymorphs of a given compound may exhibit properties as different as those displayed by two distinct compounds. This versatile aspect of solids. particularly insofar as it presents opportunities for selecting an appropriate crystalline form for a specific application, continues to be exploited in all areas of chemical and materials research. In a systematic experimental study of the polymorphism of a given compound, investigators are likely to encounter not only polymorphs but also solvated crystal forms (sometimes called pseudopolymorphs) and amorphous forms, ail of which are unique and of practical relevance because of their possible interconversion and potential utility.

OCCURRENCE AND GENERAL IMPACT

Polymorphism and polymorphic transformations are phenomena encountered during the manufacture, handling, processing. and storage of solid materials, both in small-scale operations in academic laboratories and in bulk processing in commercial establishments. The challenges they present are considerable. the foremost being those of establishing the conditions for reproducible preparation of a specific solid form with desired properties (for application in areas such as suprarnolecular chemistry, crystal engineering. explosives manufacture, food chemistry. agrochemicals, and pigment and pharmaceutical manufacture) and retention of that form during the lifetime of its application. Patent litigation hinging on the polymorphism and pseudopolymorphism of commercially or strategically important materials is becoming more frequent as companies strive to protect their intellectual property.

CRYSTALLIZATION DYNAMICS AND POLYMORPHIC STABILITY RELATIONSHIPS

Understanding the origin of polymorphism and ultimately controlling the outcome of crystallization processes require consideration of the thermodynamic and kinetic factors involved.'" At specified temperature and pressure, only one polymorph of a given compound is thermodynamically stable (i.e., has the minimum Gibbs free energy): and all other polymorphs are metastable to varying degrees. If this factor alone determined the outcome of crystallization. then only one polymorph (the most stable) should appear. However. because the nuclei of different polymorphs have unique structural and interfacial properties, their free energies of activation differ, and hence, the nucleation rates of different polymorphs of the same compound generally differ. Consequently, if conditions are such that the nucleation rate of a metastable polymorph exceeds that of a more stable polymorph, crystallization of the former will be favored. The successive crystallization and dissolution of increasingly more stable (less-soluble) forms from a solution of a compound, described by Ostwald's Rule of Stages, is a manifestation of the interplay between the thermodynamic and kinetic factors operating in such a system. Each polymorph has an associated "occurrence domain," i.e., solvent medium, temperature range, and other conditions under which it will crystallize.[2] Simultaneous crystallization of two or more polymorphs ("concomitant polymorphism") is not uncommon[3] and may occur if the occurrence domains of these species intersect. Establishing the limits of this intersection provides a rational basis for polymorphic control in crystallization.

Thermodynamic stability relationships between polymorphs are conveniently represented in schematic energy–temperature diagrams.[4] Shown in Fig. 1 is such a diagram for the system comprising three polymorphs of the hypocholesterolemic drug lifibrol (4-{4-[4-(1,1-dimethyl)phenyl]-2-hydroxybutoxy} benzoic acid) **1,** established on the basis of measured thermal, solubility, and spectroscopic data.'" Focusing first on the curves G_{I}, G_{II}, and G_{liq}, which represent the temperature variations of the Gibbs free energies of polymorphs I, II, and their common liquid phase. respectively, it is evident that

Fig. 1 Semischematic energy–temperature diagram for three polymorphic modifications of lifibrol 1. (Reprinted from the European Journal of Pharmaceutics & Biopharmaceutics, Vol. 49. A. Burger and A. Lettenbichler. Polymorphism and preformulation studies of lifibrol, pp. 65–72. 2000 (Ref. [5]), with permission from Elsevier Science.)

polymorphs I and 11 melt at the temperatures $T_{f,I}$ and $T_{f,II}$, where each solid phase is in equilibrium with the liquid. The curves G_I and G_{II} intersect at the temperature $T_{p,II-I}$, which represents their transition point. At temperatures less than $T_{p,II-I}$, the curve G_{II} lies below curve G_I, indicating that polymorph II is more stable in this temperature region. In the temperature range between $T_{p,II-I}$ and $T_{f,I}$, however, polymorph I is the more stable form. Thus. heating polymorph II above $T_{p,II-I}$ will result in its conversion to the more stable polymorph I, and conversely, cooling polymorph I below $T_{p,II-I}$ will yield polymorph II. These features are the hallmarks of enantiotropy, and polymorphs I and II are said to be enantiotropically related. Because the curve G_{III} (for the third polymorph of lifibrol) lies above those of G_I and G_{II}, polymorph III is evidently metastable with respect to both polyrnorphs I and II. Owing to its metastable nature, polymorph III has a natural tendency to convert (irreversibly) to I or II and will do so under favorable conditions (e.g., via solution-mediated transformation or by mechanical treatment). The polymorphs I and III are accordingly said to be related monotropically, as are 11 and III. Establishing whether polymorphs are enantiotropically or monotropically related is of practical significance, because it guides crystallization strategy.[6] For example. in order to isolate one of the polymorphs in an enantiotropic system. it is necessary to maintain the temperature and pressure conditions at which the Cibbs free-energy curve of the desired polymorph is below that of the undesired one. Included in Fig. 1 are the enthalpy (H)–temperature variations for the various phases present, from which the relative magnitudes of the enthalpy changes for possible solid–solid and solid–liquid transformations can be deduced. Ideally, the construction of an energy–temperature diagram for each new polymorphic system encountered is desirable, as such a diagram summarizes a considerable amount of thermodynamic data for the system and enables prediction of phase stability and possible phase transformations. The conclusion of the study on lifibrol[5] was that polymorph 11 (stable at both room temperature and body temperature) is suitable for pharmaceutical formulation.

Consideration of the general features of energy–temperature diagrams has enabled us to formulate several practical guidelines (Burger's rules) for distinguishing monotropic and enantiotropic systems.[4] The heat-of-transition rule and the heat-of-fusion rule are especially useful. The second, for example, states that if the enthalpy of fusion of the lower melting form is greater than that of the higher melting form, the polymorphs are enantiotropically related. (This is evident in Fig. 1 for polymorphs I and II, for which $\Delta H_{f,II} > \Delta H_{f,I}$). Extension of the theory underlying energy–temperature diagrams has led to formulae for calculating $\Delta G(T)$, the difference in the Gibbs free energy for two polymorphs as a function of temperature.[7] Extrapolation of this quantity to zero enables estimation of their transition temperature.

GENERATION AND CHARACTERIZATION OF POLYMORPHS

Preparative Methods

A thorough practical investigation of the propensity for the existence of different solid forms of a new compound

should follow the type of systematic program that has become mandatory for drug substances.[8] This involves isolation of all possible forms of the compound (including polymorphs. solvates, and amorphous phases), followed by application of physicochemical methods of analysis to establish the identity of each form as well as the stability and structural relationships among the various forms. Both steps in this procedure are outlined here.

Methods for generating polymorphs. hydrates, solvates, and amorphous phases have been reviewed.[9] Starting with the raw material (in whatever form available), polymorphs may be obtained by sublimation. crystallization from solvents (single or mixed), precipitation from solution by pH adjustment (for acidic or basic compounds). vapor diffusion, thermal treatment, crystallization from the melt. seeding. thermal desolvation of crystalline solvates, and grinding. As regards pseudopolymorphs, hydrates may be obtained by crystallization of the anhydrous compound from water or by exposure of water vapor. Analogous procedures using organic solvents may yield the corresponding solvates.

Because crystallization from a given solvent may yield either a polyrnorph or a solvate, some guideline is desirable for predicting the likely outcome. A useful recent study assessed the tendency for different solvent molecules to be incorporated in the crystallized product.[10] Mere, account was taken of the frequency of occurrence of solvates as well as the frequency of usage of specific solvents in crystallization experiments. This enabled a ranking of common solvents according to their probabilities of leading to solvate formation. Thus. despite the fact that diethyl ether is used much more frequently as a recrystallization medium than 1.4-dioxane. it has a inuch lower tendency to form solvates. These observations can be rationalized on the basis of solvent–solute interactions. Retention of organic solvents in the product crystal is facilitated for solvents such as 1,4-dioxane that can interact with appropriate polar functions of the solute molecule through multiple-point recognition, e.g., via strong O(solvent)···H–O, O(solvent)···H–N as well as weak O(solvent or solute)···H–C hydrogen bonds. The practical significance of pseudopolymorphs should not be underestimated. If the parent compound has a tendency to solvate. it may crystallize in only one or two polymorphs but generate a large number of pseudopolymorphs. On desolvation. the latter produce polymorphs, among which hitherto unobserved forms might be present. The versatile drug sulfathiazole 2 is remarkable in forming over 100 solvates.[11] Structurally, these crystal modifications fall into the classes of clathrates, cocrystals, and salts.

Finally, to generate amorphous phases from the parent compound, the various methods include rapid cooling of the melt, particle size reduction (by milling. with or without additives), spray-drying. freeze-drying, eliminating solvents from solvated phases, and adjusting solution pH. Amorphous phases are thermodynamically metastable and, therefore, more soluble than polymorphs of the same compound. As such, they may be useful pharmaceutically to enhance bioavailability provided their tendency to revert to more stable forms can be prevented.

Physicochemical Characterization

A wide range of physicochemical techniques is available for the characterization of polymorphs and pseudopolymorphs. A brief description of the most widely used methods follows, but it should be noted that numerous other techniques have been employed in special cases. and the ingenuity of future investigators will no doubt lead to the application of novel methods. X-ray diffraction remains unique in its ability to distinguish different polyrnorphs of the same compound, because each species yields its own characteristic x-ray powder pattern.[12] Shown in Fig. 2 are the distinctly different experimental patterns for the polymorphs I–III of lifibrol **1**[5] that permit their unequivocal identification. The technique is also used dynamically and variable-temperature powder x-ray diffraction is being increasingly employed to identify polymorphic phase transforinations and to determine transition temperatures. When single crystals of a polymosph are available, x-ray analysis permits complete elucidation of the molecular and crystal structures. enabling the investigator to correlate bulk properties of the polymorph with details of the molecular conformation. crystal packing. and hydrogen-bond interactions. The refined crystal data (atomic positions, displacement parameters. unit cell dimensions) and space group data for any structure are also required for the computation of the idealized x-ray powder pattern of that crystalline phase. Such a pattern is invaluable as a fingerprint for future phase identification.

Standard thermal methods of analyzing polymosphs include differential scanning calorimetry (DSC). thermogravimetric analysis (TGA), and hot-stage inicroscopy (HSM). These methods are applied routinely in the pharmaceutical industry to monitor the integrity of specific polymorphs intended for formulation and to detect and characterize solvated forms.[10] Whereas polymorphs yield zero mass loss upon heating up to the melting point, solvates usually lose their included solvent. as indicated by an accurately measurable mass loss on TGA (enabling calculation of the solvate stoichiometry). an endothermic peak in the DSC trace. and the formation of bubbles of released solvent when the crystals are heated under an inert medium in HSM. DSC traces for various forms of lifibrol **1**[5] are also shown in Fig. 2. Primary data from DSC include characteristic onset and peak temperatures of thermal events (polymorphic transitions:

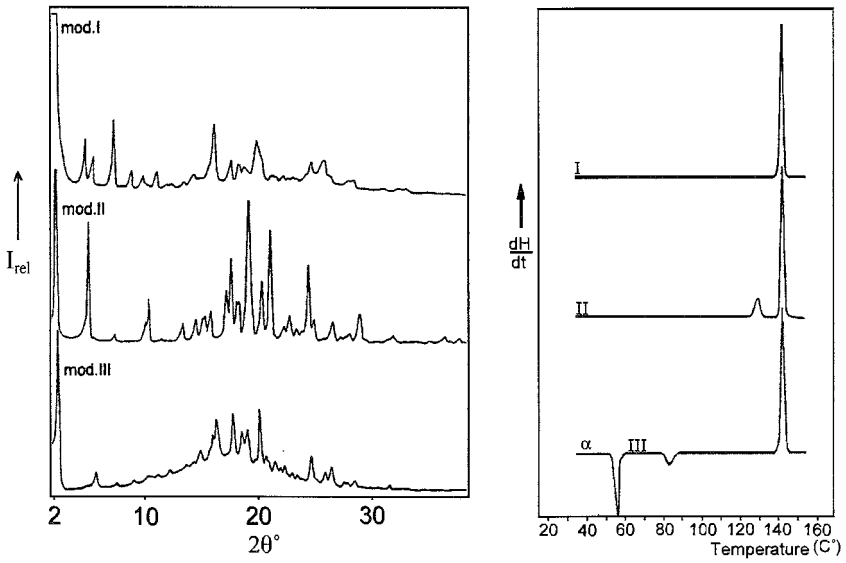

Fig. *2* Powder x-ray diffraction patterns (left) for three polymorphs of lifibrol I and DSC traces (right) for modifications I and II as well as the amorphous α-modification that transforms into modification III. (Reprinted from the European Journal of Pharmaceutics & Biopharmaceutics, Vol. 49. A. Burger and A. Lettenbichler, Polymorphism and preformulation studies of lifibrol. pp. 65–72, 2000 (Ref. [5]), with permission from Elsevier Science.)

fusion). as well as their associated enthalpy changes. Accurate enthalpies of fusion for different polymorphs are used in conjunction with Burger's rules to distinguish enantiotropic and monotropic behaviors.[4]

FTIR and Raman spectroscopy are frequently used to characterize polymorphs.[12] Both the molecular conformation and the crystal packing may lead to differences in the FTIR spectra of polymorphs; the differences are more pronounced for compounds capable of hydrogen bonding. Characteristic shifts in C=O, N–H, and O–H stretching frequencies often lead to unequivocal polymorphic identification. Differences in fine structure and in the positions and intensities of IR bands enabled seven crystalline forms of the steroid prasterone 3 to be distinguished.[9,11] The presence of characteristic absorption bands due to included solvent molecules allows ready distinction between polymorphs and pseudopolymorphs.

Solid-state WMR (mainly ^{13}C) is rapidly gaining popularity as a method for distinguishing polymorphs.[12] The existence of different crystal-packing schemes inherent in a series of polymorphs implies that specific nuclei of the parent molecule will generally experience different local magnetic environments in the various crystals, yielding characteristic shifts in resonance positions. The method allows for detection of subtle structural features. including differences in molecular conformation, crystallographically independent molecules, and molecular disorder. It is. however, desirable to confirm the presence of such features using x-ray analysis.[12] It should be emphasized that thorough and unambiguous characterization of polymorphic systems usually requires application of several techniques in combination, and that all of these should be conridered as supporting the definitive technique of x-ray diffraction.

STRUCTURAL ASPECTS OF POLYMORPHIC SYSTEMS

Rigid or Semirigid Molecules

For a system comprising two or more polymorphs, x-ray crystal structure analyses of the various forms are highly desirable, because they reveal, at an extraordinary level of accuracy and precision; how chemically identical molecules can be accoinmodated in different crystalline architectures. This knowledge is indispensable for establishing and interpreting structure–property relationships. The vast majority of polymorphic crystal structures were determined using single-crystal x-ray techniques. but there is an increasing incidence of successful structural elucidation from high-resolution powder x-ray diffraction data, especially for metastable phases and in cases where the crystallite size is very small.

Molecules possessing few conformational degrees of freedom frequently crystallize in different polymorphic forms with retention of a common. low-energy conformation but with different intermolecular relationships, reflected in their space group symmetries. Examples

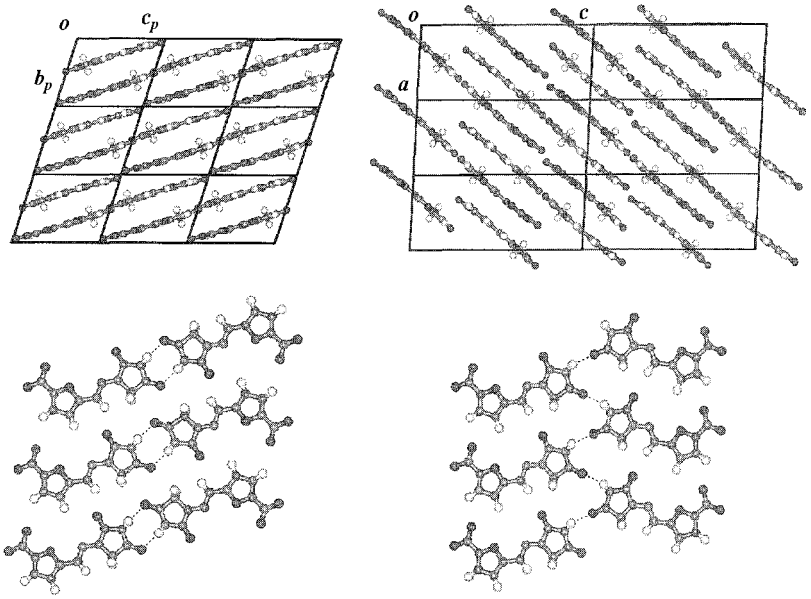

Fig. 3 Crystal structures of nitrofurantoin polymorphs: layer stacking (top left) and hydrogen bonding within a layer (lower left) for the a-polymorph; and layer stacking (top right) and hydrogen bonding within a layer (lower right) for the β-polymorph. Only the N–H···O hydrogen bonds are indicated. (Adapted from E.W. Pienaar, M.R. Caira and A.P. Lotter, Journal of Crystallographic and Spectroscopic Research. 23(10), 1993, 785–790. with permission from Kluwer Academic/Plenum Publishers.) (*View* this *art in color at www.dekker.com.*)

include the compounds maltol 4, sulfamerazine **5,** nitrofurantoin 6.[14] and acetaminophen (paracetamol) **7**.[15] Shown in Fig. 3 are the crystal packings in the α-polymorph (triclinic, space group $P\bar{1}$) and the β-polymorph (monoclinic, $P2_1/c$) of nitrofurantoin 6, both of which are based on the stacking of molecular layers.''''' The same types of hydrogen bonds (N–H.·O, C–H···O) occur in both phases, but their arrangements within the layers of the two polymorphs differ substantially. One consequence of the structural difference is that the dissolution rates of the two polyrnorphs differ significantly. Two polymorphs of acetaminophen **7** provide a striking example of such a structure–property relation.''''' The crystal structure of the stable monoclinic polymorph ($P2_1/c$) is based on a complex molecular array stabilized by intermolecular hydrogen bonds that assume a variety of spatial directions, whereas the less-stable orthorhombic crystal (Pbca) contains hydrogen-bonded molecules assembled in layers that lack strong cohesion. As a consequence, the crystals respond differently to the application of pressure. The monoclinic polymorph resists compaction in the absence of excipients, while the orthorhombic polpmorph may be tabletted without additives, owing to the presence of graphite-like slip planes in the crystal. Numerous polymorphic structure–property relationships are documented.''''' Other bulk properties that were correlated with crystal structures of polymorphic systems include electrical conductivity. magnetism, photovoltaic and photoconductive effects. nonlinear optical (NLO) activity, photochromism, thermochromism, and mechanochromism. Such properties are intimately associated with special structural features of the polymorphs displaying them (e.g., NLO activity, occurring exclusively with noncentrosymmetric polymorphs).

Conformational Polymorphs

Conforrnationally flexible molecules frequently possess several low-energy conformations, two or more of which may appear in different crystal structures. giving rise to ''conformational polymorphism.''[14] Examples of compounds crystallizing as conforrnational polymorphs and the variety of space groups represented include dichloro-N-benzylideneaniline 8 ($P\bar{1}$, Pccn), iminodiacetic acid **9** (trimorphic, with two polymorphs in $P2_1/c$, one in $Pbc2_1$), spironolactone **10** (two polymorphs in $P2_12_12_1$), and probucol **11** (two polymorphs in $P2_1/c$). Two enantiotropically related polymorphs of piroxicam pivalate **12** fall into this category.[17] Form 1 is orthorhombic (Pbca), with one molecule in the asymmetric unit. Form 2 is inonoclinic ($P2_1/c$), with two molecules (A. B) in the asymmetric unit. As shown in Fig. 4. the molecular conformations differ significantly for all observed conformers. Examination of the crystal structures revealed that the arrays of A and B molecules in Form 2 are located in separate domains, each with a distinct hydrogen-

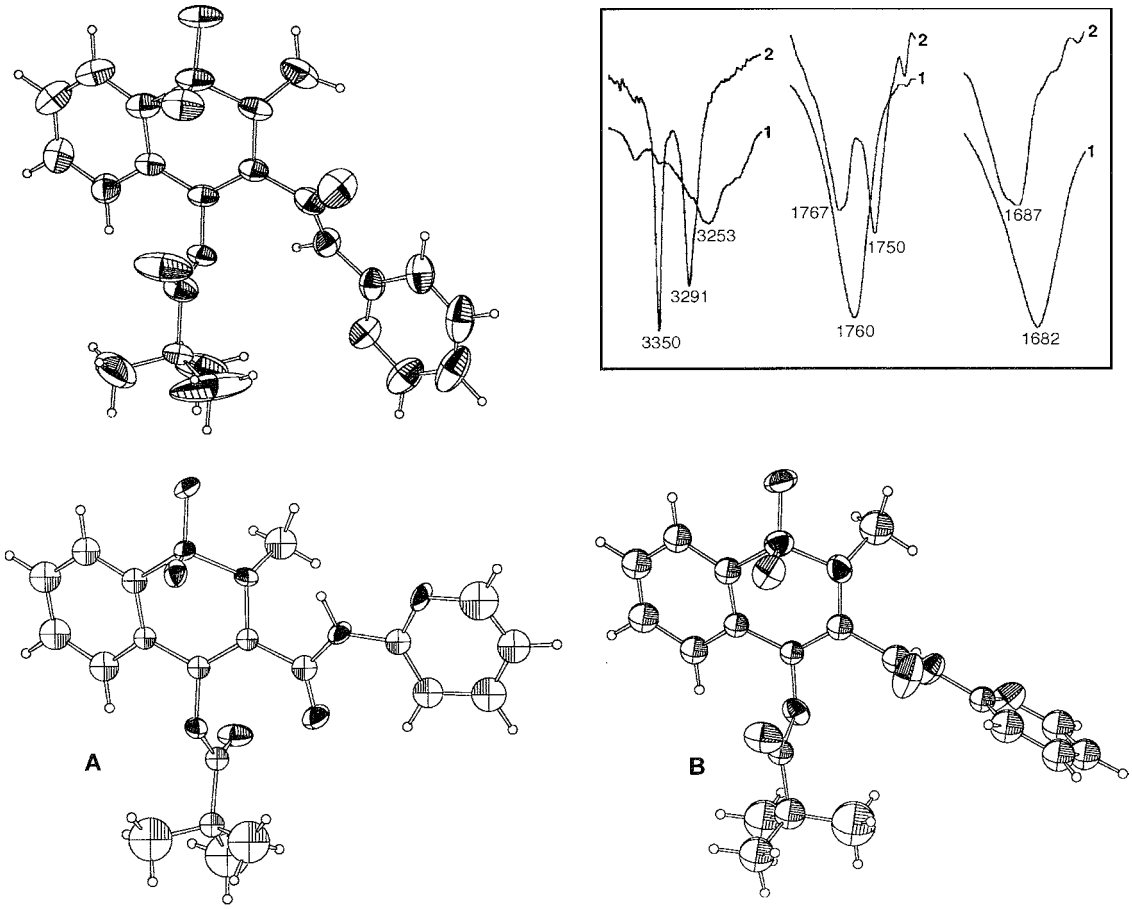

Fig. 4 Conformational polymorphism in piroxicam pivalate **12**: the single conformer occurring in Form 1 (top left). two independent conformers (A. B) found in Form 2 (lower left, lower right). and the IR absorption bands (c m $^{-1}$) in Forms 1 and 2 in the amide N–H. ester C=O. and amide C=O stretching regions (upper right). (Adapted from the Journal of Pharmaceutical Sciences. Vol. 87. M.R. Caira, M. Zanol. T. Peveri, A. Gazzaniga. and F. Giordano. Structural characterization of two polymorphic forms of piroxicam pivalate, pp. 1608–1614. 1998 (Ref. [17]), with permission from Wiley-Liss, Inc., A Wiley Company.)

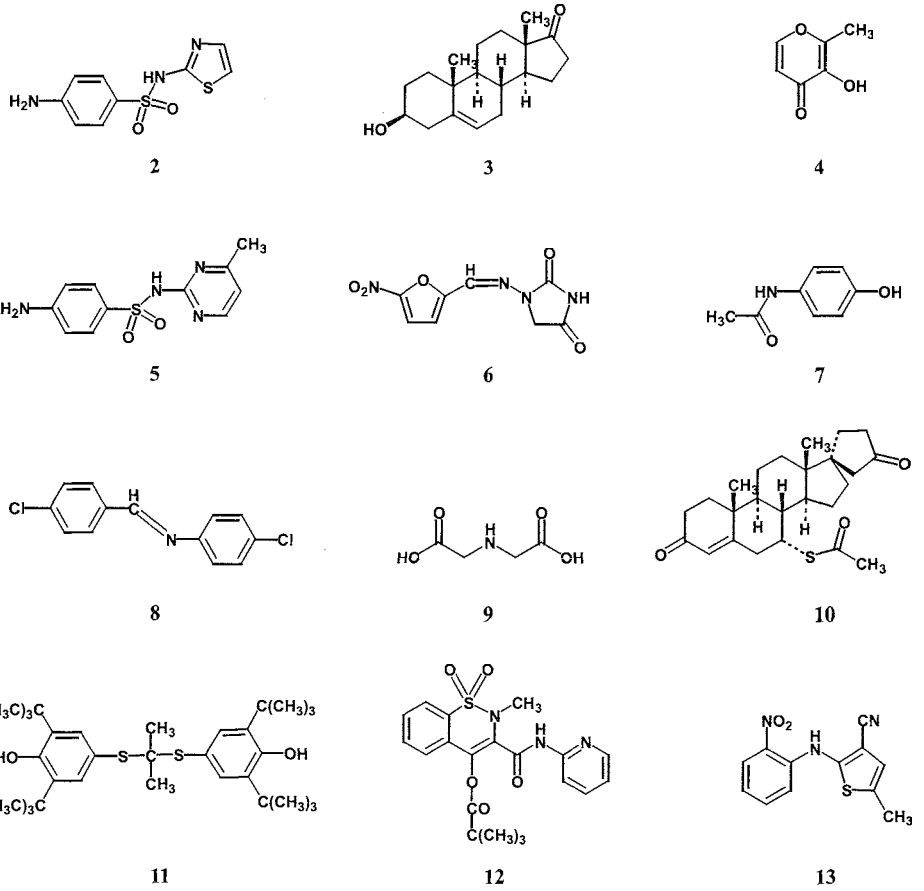
bonding arrangement. These structural features could be reconciled with the appearance and positions of the IR absorption bands for the amide N–H, ester C=O, and amide C=O stretching vibrations (Fig. 4), the Form 2 spectra accordingly showing higher peak multiplicities.

Conformational polymorphs have been exploited for structure–property relationships. A recent study of the color polymorphism (red. orange. yellow) displayed by six conformational polymorphs of 5-methyl-2-[(2-nitrophenyl)amino]-3-thiophenecarbonitrile 13 showed that this phenomenon could be explained by conformational differences that change the extent of π-conjugation between the *o*-nitroaniline chromophore and the thiophene ring.[18] This thorough investigation employed optical crystallography, polarized single-crystal absorption spectroscopy, and computational methods. In the context of polymorphic control (see below). in comparison with rigid molecules, the crystallization of conformationally flexible molecules is especially challenging[19] because of the reduced tendency for such molecules to crystallize and the possibility of their crystallizing in a variety of structural arrangements.

CHALLENGES AND REGENT DEVELOPMENTS

Polymorphic Control

Several challenges in the area of polymorphism continue to be the focus of intensive research. These include polymorphic control in crystallization, structural elucidation of polymorphs available only as powders, and the central problem of crystal structure prediction by theoretical methods from a knowledge of the molecular structure only. Here, the essential features of these challenges are described, and some recent developments that attempt to address them are outlined.



2 3 4

5 6 7

8 9 10

11 12 13

The crucial need to control the outcome of crystallization of a polymorphic compound was alluded to above. Failure to manufacture the desired polymorph reproducibly can lead to massive financial loss and, in the case of pharmaceutical compounds, to the more serious risk of compromising human health. A recent dramatic case involved the anti-AIDS drug ritonavir **14** that failed dissolution requirements in mid-1998.[20] The cause was traced to the sudden appearance of a new, thermodynamically more stable polymorph with a solubility only ~ 25% that of the known polymorph (measured in hydroalcoholic solvents. at the required formulation storage temperature of 5°C). The original polymorph temporarily "disappeared," having been "displaced" by the more stable form. Only after extensive investigation were manufacturing processes developed for selective crystallization of the two polymorphs. Some of the strategies for polymorphic control include recrystallizing from specified solvent systems, altering the crystallization conditions from "thermodynamic" to "kinetic" or vice versa, using of seeding, and employing designed additives to induce crystallization of a desired polymorph. The use of specific solvents or mixtures of solvents does not guarantee isolation of a particular polymorph unless other experimental conditions are carefully controlled. Critical factors include the degree of solvent purity, solute concentration, temperature program, and the time of harvesting the crystals. Increasing emphasis is being placed on the need to accurately record these conditions to ensure reproducibility of the outcome.[21] Metastable polymorphs may generally be obtained under kinetic (i.e., far from equilibrium) conditions of crystallization (e.g., rapid cooling of the solution, conditions of high supersaturation), whereas more stable forms tend to crystallize under thermodynamic conditions (e.g., slow cooling. slow evaporation). The latter may also be obtained by solvent-mediated transformation, as a result of spontaneous dissolution of metastable forms and subsequent recrystallization. The seeding technique is commonly employed in industrial batch crystallizations and enables control of the polymorphic outcome.[22] Its rational application does, however, rely on a thorough knowledge of the stabilities and relative solubilities of the polymorphs involved. Exclusive crystallization of a metastable polymorph is a desirable goal in industry. A novel batch crystallizer was recently employed to exclusively isolate the metastable form of L-glutamic acid **15** from aqueous solution.[23] This was achieved

through separate control of the crystallization temperature and the nucleation temperature. Another strategy for stabilizing and isolating a metastable polymorph from solution involves preventing its transformation to a more stable polymosph by deliberately adding a trace amount of another compound. The latter may be found serendipitously or by design, and its role is one of inhibiting the nucleation and crystal growth of the more stable form. Polymorph I of sulfamerazine **5** normally undergoes a solvent-mediated transformation to the more stable polymorph II in acetonitrile medium. If, however, any of the structurally related species N^4-acetylsulfamerazine **16**, sulfadiazine **17**, or sulfamethazine 18 is present as an impurity. it retards this transformation significantly.[24] For this system. it was found that the rank order of the inhibitory effect of the three additives corsesponded with the rank order of the calculated binding energy of the additive to the crystal surface of polymorph II. These results, incidentally. also serve to highlight the possibility that discovery of a polymorph might actually be delayed due to the presence of unknown impurities in a crystallizing system. Rational design of inhibitors is possible. provided that detailed knowledge of the relationships between crystal structure and crystal morphology for both the desired and undesired polymorphs are known.[25] This again underscores the constant need for x-ray structural elucidation of polymorphs.

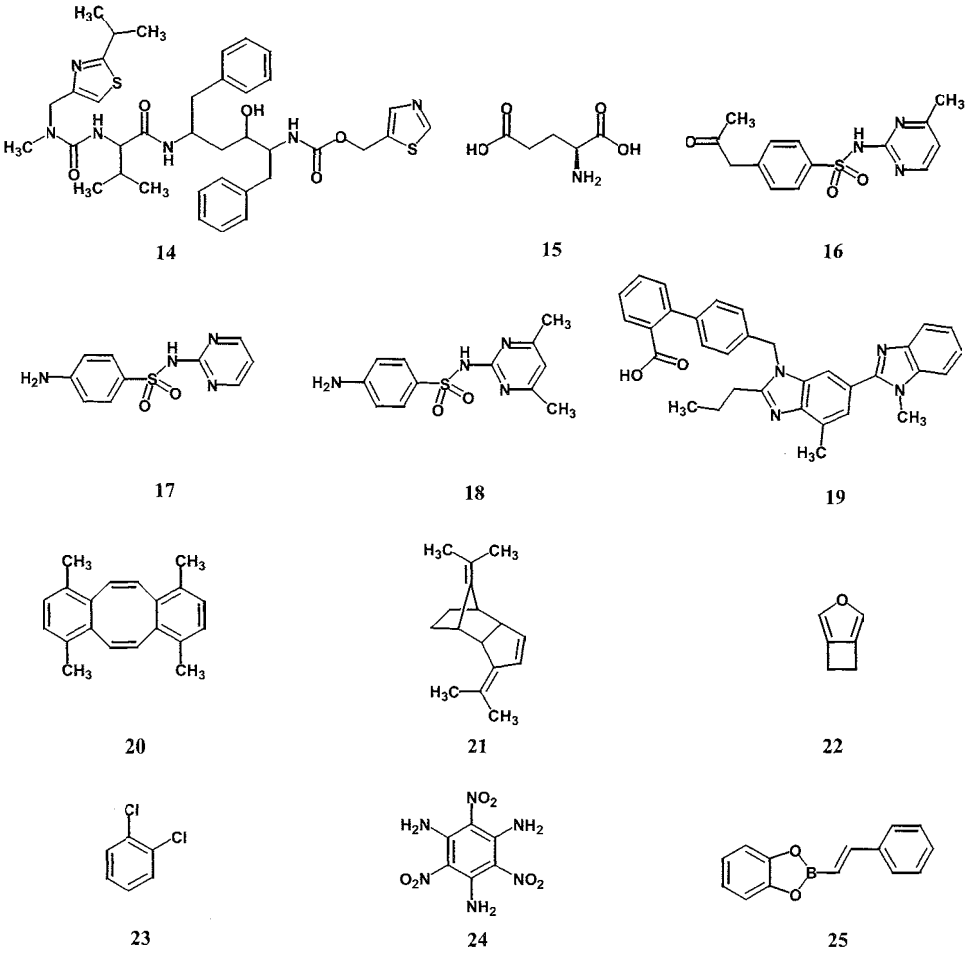
Polymorphic Structures from X-ray Powder Data

Many industrially important polymorphs can be prepared in microcrystalline form only, preventing their crystal structure solution by conventional single-crystal x-ray techniques. However, considerable progress in elucidating crystal structures from high-resolution powder x-ray diffraction data was achieved in recent years. The essential steps in the procedure include indexing of the powder diffraction pattern; optimization of the molecular unit by modeling methods, generation of trial structures. and Rietveld refinement. Developments that improved the success rate in this area include the use of synchrotron radiation for rapid data capture, superior treatment of overlapping reflections. more reliable indexing routines, and more flexible methods of obtaining trial structures. As an illustration of the power of the method, the crystal structures of two polymorphs of telrnisartan **19** (an angiotensin II receptor antagonist with considerable conformational flexibility) were solved from high-resolution x-ray powder diffraction data.[26] Structure solution required the determination of 13 degrees of freedom in each case (three translational, three orientational, and seven torsion angles) and was achieved on a personal computer (Pentium II 350 MHz) in about 2 hours using the method of simulated annealing. One limitation of the method, however. is that while molecular conformations in different polymorphs may be determined with high precision, the same is not true for bond lengths and angles.

Polymorphs and Crystal Structure Prediction

Finally, what may be considered as a central goal in this research area is the complex problem of prediction of the crystal structure of a compound, given only its molecular connectivity. The problem is better formulated as computer generation of a set of potential polymorphs of the compound: detection of the most stable one at a given temperature, and modeling of the nucleation kinetics to determine which phase will actually appear under given conditions.[27] This is a vast and rapidly developing subject in its own right, and only a brief outline of the challenges that this problem presents can be given here. Two general approaches to crystal structure prediction are discussed in a recent review.[28] The first step in one established approach[27] is the generation of trial crystal structures by utilizing the known, limited number of symmetry operations that relate molecules spatially in crystals. Frequently, the more populous space groups of the 230 theoretically possible are selected for structure generation. Structures with the highest possible packing efficiencies are accepted as the most plausible, and these are further optimized by minimization of the lattice energy. Crystal structures predicted in this way have similar energies, so that several candidates ensue, and ranking their likelihood of representing realizable structures is thus difficult. (On the other hand, if the x-ray powder pattern of a polymorph is available. its coincidence with a pattern generated from one of the predicted structures immediately characterizes it structurally). Conformationally flexible molecules are especially challenging for crystal structure prediction. as no general algorithms enabling simultaneous optimization of molecular conformation and crystal structure are available. In such cases, the most stable conformations are usually determined. each then being treated as a rigid model in the approach described above. Pseudopolymorphs clearly present a severe challenge for crystal structure prediction, as the correct relative positions and orientations of host and guest molecules must be established before trial structure generation can proceed.

The factors leading to correct structure prediction are not easily defined. Examples of molecules with predicted (i.e., computed) crystal structures that coincide with their observed x-ray structures are shown as **20**, 21, and 22. On the other hand: for the molecules 23. 24. and 25, which superficially do not appear to be any more challenging, the observed x-ray crystal structures are very different from the most stable computed models. These anomalies



14 15 16 17 18 19 20 21 22 23 24 25

and other concerns (e.g., the inaccuracy or inadequacy of current empirical force fields, neglect of dynamic effects) were recently brought into perspective by a pioneer in the field.[29] and the successes and failures of current approaches were highlighted. Incorporation of molecular dynamics is suggested as a promising adjunct to current strategies.

CONCLUSION

Crystal polymorphism is assuming ever-increasing importance in the solid-state chemistry of materials. Every newly synthesized compound has the potential for existing in multiple crystalline forms as polymorphs or pseudopolymorphs. If advantage is to be gained from exploiting the physical properties of a specific crystalline form of a compound. it will be necessary to manufacture it reproducibly and ensure that it maintains its integrity. Major research challenges in the area of crystal polymorphism include control of the crystallization process, routine determination of crystal structures of polymorphs available as powders. and accurate prediction of crystal structures by computational methods. Different levels of success were attained in each area. Perhaps the most important outcome of the increasing volume of scientific literature relating to polymorphism is the creation of an awareness of its ubiquity and its enormous practical significance in the science of solids.

Porphyrin Derivatives, Functional

Mladen Žinić
Rudjer Bošković Institute, Zagreb, Croatia

INTRODUCTION

Porphyrins, named "molecules of life," constitute active sites of bacterial photosynthetic systems and important groups of enzymes such as cytochrome P450, cytochrome C. oxygen carriers (hemoglobin), etc. In supramolecular chemistry. posphyrins and metalloposphyrins are frequently used building blocks for construction of systems with energy- and electron-transfer properties aimed at preparation of artificial antenna systems, photosynthetic center mimics, photonic wires, gates. and redox switches with potential applications in supramolecular devices and machines. Due to the well-established synthetic methodologies and favorable photophysical properties, posphyrins are frequently used for construction of receptor molecules with a high degree of constitutional and chiral recognition properties. Metalloporphyrin (MP) derivatives with peripheral binding and recognition functionalities and catalytically active metal ions bound in the macrocycle endow new organic oxidation catalysts or cytochrome P450 mimics working in bilayer membranes. The advantage of coordinative binding of nitrogen and other ligands by metalloposphyrins combined with additional peripheral binding or coordination functionalities enables construction of a wealth of impressive supramolecular architectures and organized multiporphyrin arrays by self-assembly processes of predesigned supramolecular synthons. This article gives a brief outline of the supramolecular chemistry of functional porphyrins and presents some selected examples illustrating the impressive achievements associated with this topic.

PHOTOINDUCED ELECTRON AND ENERGY TRANSFER

The covalently linked or self-assembled systems constructed from free-base porphyrins or metalloposphyrins and various quenchers and related studies of excited-state energy-transfer and electron-transfer processes in such systems are a widely studied topic of contemporary supramolecular chemistry.[1,2] There are two major reasons for the exceptional interest in the topic: a challenge to synthesize artificial systems for harvesting solar energy of efficacy comparable to natural photosynthetic membranes of bacteria,"." and the more recent one, directed toward preparation of photo- or electroactive organized systems suitable for application in the fast-emerging field of nanotechnology.[5,6] The building block approach to the synthesis of covalently linked posphyrin architectures allowed "in depth" studies of the mechanisms of electronic communications such as excited-state energy transfer and ground-state hole/electron hopping.[7,8] Both processes occur predominantly via a through-bond mechanism, and their rates can be tuned over a wide range by varying structural and conformational characteristics of the linkers joining the posphyrin–acceptor dyads or by changing metal ions present in the metalloposphyrin units. The numerous studies resulted in successful design of a light-harvesting antenna (Fig. 1a), photonic wires, optoelectronic gates, and gates with redox-switching sites. Different examples of covalently linked dyads, triads, and polyads constructed, in most cases, from a free-base porphyrin as an electron donor and various electron acceptors, were prepared and studied to date. aiming to mimic the natural photosynthetic reaction center (see selected reviews: Refs. [9–12]). Major problems in the artificial systems with porphyrins involve the short-lived donor–acceptor charge-separated states disabling efficient conversion of photonic to chemical energy. Besides quinone as the biomimetic electron acceptor, which is present in natural photosynthetic systems, fullerenes were also used in combination with porphyrins. The lifetime of initial charge-separated states in fullerene-based dyads is, in general. considerably longer than in similar systems with quinones, and the photoinduced electron-transfer processes can take place in nonpolar solvents at low temperatures. Remarkably, the charge recombination reaction occurs in a fullerene-based dyad with a rate constant of ≈ 25 times lower than in a quinone-based dyad.[13] The latter is of the highest importance for designing new, more efficient, artificial systems for conversion of photonic energy. The following example describes another successful strategy based on competing donor systems. The carotenoid (C)–FbP–C_{60} molecule (Fig. 1b) presents the triad, with prolonged lifetime of the final charge-separated state and a quantum yield of 0.88. In the system, the carotenoid acts as the second electron donor unit by giving an electron to the initially formed C–FbP^{+}–C_{60}^{-}

charge-separated state; this process successfully competes with C–FbP^{+}–C_{60}^{-} charge recombination and gives the final long-lived C^{+}–FbP–C_{60}^{-} charge-separated state.[14] Besides the covalently linked porphyrin–electron–acceptor molecules, there are numerous recent examples of supramolecular systems in which weak intermolecular forces hold the components in the complex. The linking forces (supramolecular bonds) in the majority of such complexes are hydrogen bonds. coordinate bonds with MP, hydrophobic, and aromatic π–π-stacking interactions or their combinations (see selected recent reviews from Refs. [3,10–12] for examples). The hydrogen-bonded and the covalently bonded dyads shown in Fig. 2a are constructed by having the ZnP as electron donor and the FeP as an electron acceptor; for the supramolecular and the covalently linked dyad. the electron-transfer rate constants, k_{ET} of 8.1×10^{9} s^{-1} and 4.4×10^{9} s^{-1} were measured. respectively. The results reveal that the double-hydrogen-bond interface between the components is more effective in mediating electron transfer than

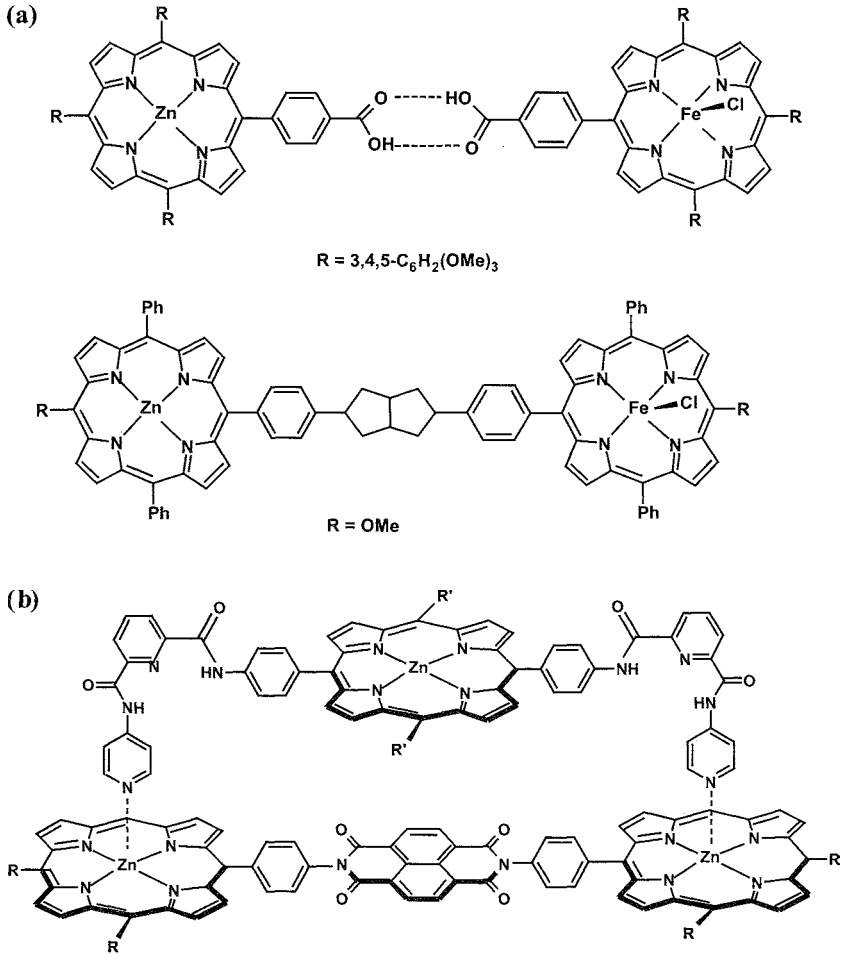

Fig. *2* (a) Hydrogen-bonded and covalently linked ZnP donor and FeP electron-acceptor dyads (Ref. [15]). (b) The self-assembled donor–acceptor system exhibiting through-space electron transfer (Ref. [16]).

is the interface of comparable length consisting of C–C σ-bonds.[15] Examples of protort-coupled electron-transfer processes were also found in the hydrogen-bonded dyads. Besides covalent and hydrogen-bond interfaces for electron transfer. it was shown that in the properly designed supramolecular coinplexes that ensure close spatial proximity of electron donor and acceptor units (Fig. 2b), the electron transfer occurs through space, or more accurately. through the solvent molecules occupying the cavity between the donor and acceptor units.[16] Electron-transfer processes were also observed to occur in the supramolecular systems of a high level of complexity, which include protein complexes or artificial bilayers. Zinc porphyrin bearing ta·o side arms with altogether eight carboxylate groups can be inserted into the horse heart apomyoglobin as an artificial prosthetic group. Such reconstituted Zn inyoglobin was shown to bind positively charged viologen. and the singlet electron-transfer process from zinc myoglobin to viologen acceptor was encountered via intermolecular interaction.[17] In another remarkable achievement. the cholenyl Mn(II)P–imidazolyl trianionic ZnP complex of linear shape was shown to span the artificial bilayer membrane locating trianionic porphyrin at the membrane surface. Cytochrome C binds the trianionic site. The electron-transfer process occurs by electron movement from cholenyl Mn(II)P via trianionic ZnP to Cytochrome C bound at the membrane surface.[18] Recently. the artificial photosynthetic reaction center became a reality; the carotenoid (C)–porphyrin–(P)–quinone (Q) triad and free quinone (Q_f) constitute a proton pump inserted in the lipid bilayer membrane of a liposome vesicle. Upon absorption of light. the charge-separated C^+–P–Q^- state is generated, which upon subsequent redox loop on Q_f produces the proton motive force across the bilayer. Remarkably. the addition of ATP synthase and ADP into this system results in production of ATP and presents a biomimetic nanoscale machine capable of converting sunlight into chemical energy.[19]

MOLECULAR RECEPTORS

A porphyrin system provides an excellent platform for construction of molecular receptors with well-defined geometry. because diverse binding functionalities can be introduced at porphyrin *meso*-positions by using well-established synthetic procedures.[20,21] The favorable spectroscopic features of porphyrins, such as the typical molar extinction coefficients in the range of 250,000 M^{-1} cm^{-1} for the Soret band (B band, $S^{o} \rightarrow S_2$) and 5000 to 35.000 M^{-1} cm^{-1} for the Q bands ($S^{o} \rightarrow S_1$) are due to the conjugation of 18π electrons and provide the advantage of easy and precise monitoring of guest-binding processes by spectroscopic methods (UV, CD. fluorescence, and NMR). The binding and photophysical properties of porphyrins can be varied by selecting metals bound in the macrocyclic ring or by increasing the number of pyrrole units, the latter giving the important family of expanded porphyrins (sapphyrins, rubyrins. and texaphyrins).[22,23] An exhaustive review of porphyrin and metalloporphyrin receptors and their binding and recognition properties toward different guest molecules (carbohydrates; amino acid derivatives, and nucleotides) was written by Ogoshi et al., and four recently published reviews are focused on zinc(II)-porphyrin receptors. allosteric and cooperative effects.[24–27] and analytical applications of porphyrin receptors.[28] Several basic structural types of porphyrin receptors were prepared to date: the monoporphyrinic receptors of the picket-fenced. strapped, and basket-handled types and acyclic and macrocyclic types incorporating two or more porphyrin units. In the vast majority of cases. the Zn(II)-5,10,15,20-tetraphenyl- or -5,10-diphenylporphyrin systems are used for the construction of receptors by introducing various binding functionalities at the ortho-positions of the phenyl rings. The tetracoordinated square planar Zn(II) serves for strong axial ligation of nitrogen base guests and also for much weaker ligation of the oxygenated ligands. Some remarkable examples of the picket-fence, strapped, and basket-handle receptors[29–31] are shown in Fig. 3a, b. and

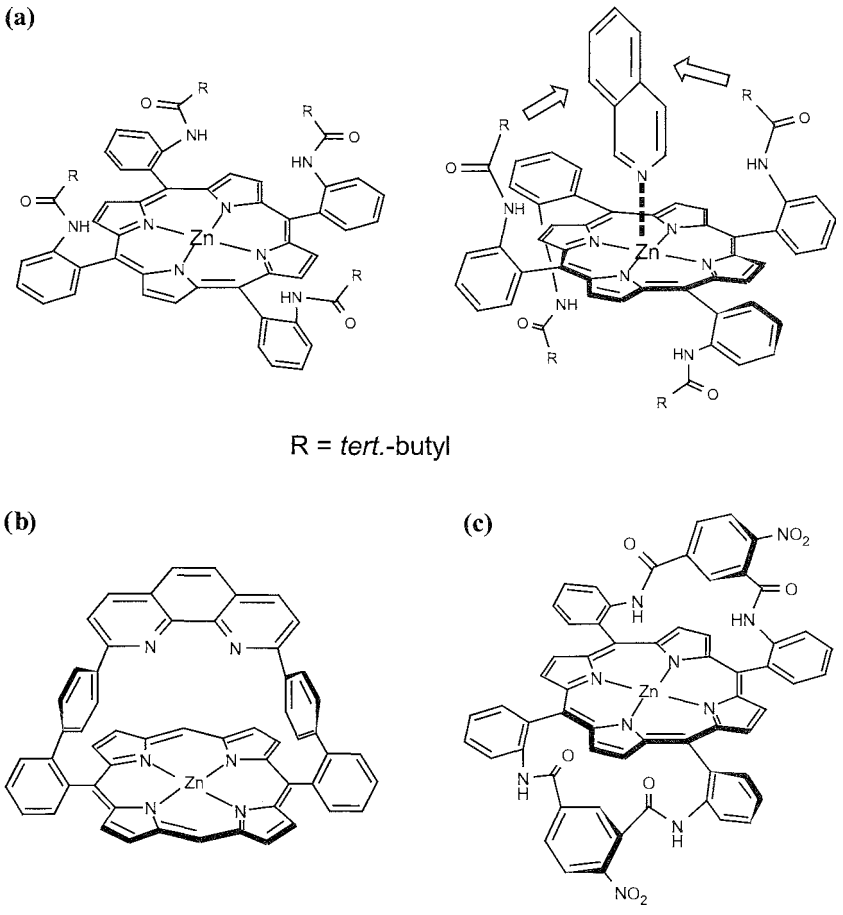

Fig. *3* (a) The α^4- (left) atropisomer and *trans*-α^2-atropisomer (right) with bound isoquinoline in the picket-fence porphyrin receptor (Ref. [29]). (b) The strapped porphyrin receptor with a rigid phenanthroline strap (Ref. [30]). (c) Chiral basket-handle receptor exhibiting a high degree of chiral recognition of amino acid derivatives (Ref. [31]).

c, respectively. The picket-fence receptor synthesized by Imai and Kyuno illustrates the importance of atropisomerism [32] the α^4-atropisomer binds isoquinoline from the open porphyrin face only by axial ligation to Zn(II) ($\Delta G^0 - 25.5$ kJ mol^{-1}), while the *trans*-α^2 isomer exhibits stronger binding ($\Delta G^0 = -34.1$ kJmol^{-1}) due to additional CH–π interactions between *tert*-butyl groups and isoquinoline.[29] A highly rigid posphyrin receptor containing phenanthroline strap strongly binds 2-methylimidazole in dichloromethane with the association constant (K_{ass}) close to 2 x 10^7 M^{-1} as a consequence of axial ligation to Zn(II) and two equivalent hydrogen bonds formed with phenanthroline nitrogens.[30] Chiral recognition of amino acid guests is achieved. by successfully designed chiral porphyrin receptors. The selected example of the chiral basket-handle receptor shows that a high degree of chiral recognition can be achieved giving the ratio of K_{ass}L/K_{ass}D of 7.5 for (–)-isomer of the receptor and L- and D-Val methyl esters.[31] An important class of receptors constructed by capping Zn(II)-porphyrins with the chiral cavity of cyclocholate was synthesized by Sanders.[33–35] The bowl-shaped receptor with four steroid units (Fig. 4a) exhibits high affinity for morphine and codeine derivatives in dichloromethane due to hydrogen bonding with four converging hydroxyl groups. The receptors capped with cyclocholate units on one (Fig. 4b) or both sides of the porphyrin were also prepared and shown to exhibit recognition of axial nitrogen bases. Remarkably. the anhydride of 3-carboxypyridine in the presence of 2,6-dichlorobenzoic acid binds and reacts inside the receptor cavity, giving selectively the monoacylated derivative of doubly capped steroid Zn(II)-porphyrin.[34,35] Exclusively aromatic κ–n interactions could be operative in some receptor–substrate complexes; the flexible macrocyclic receptor with two Zn(II)-porphyrin units (Fig. 4c) is capable of binding fullerene due to strong π–π interactions between surfaces of Zn(II)–posphyrin and fullerene. The complex is so stable that

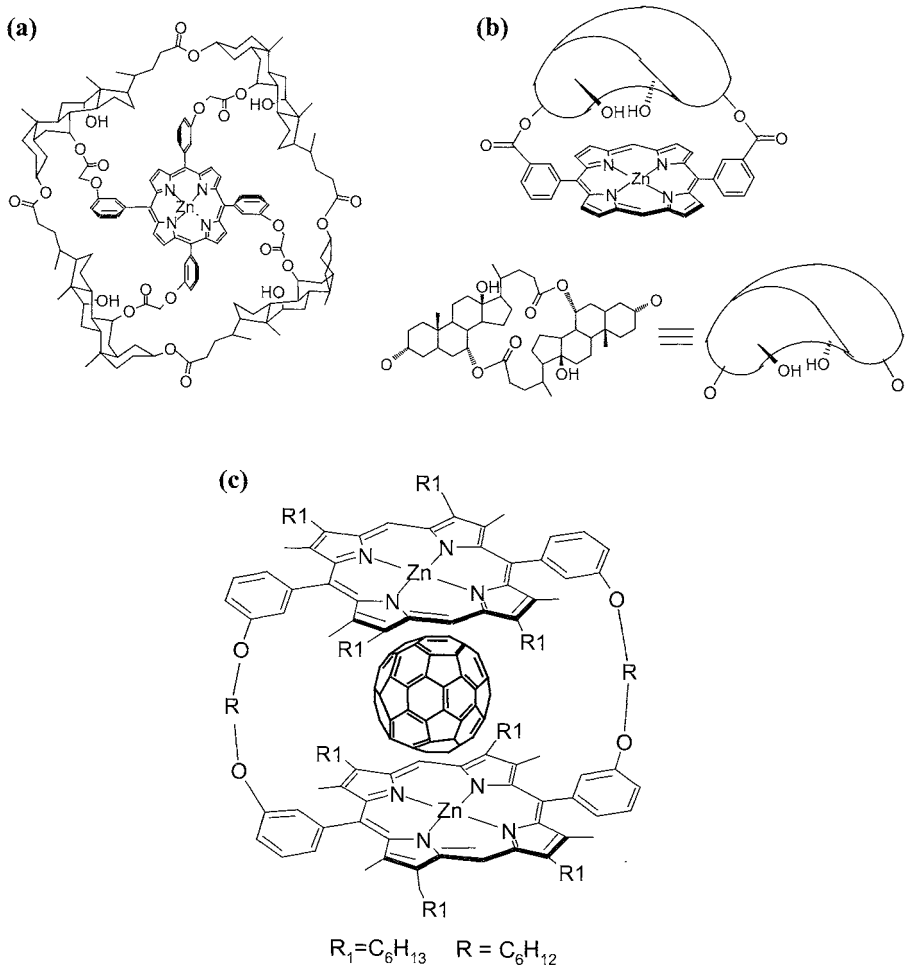

Fig. 4 (a) The bowl-shaped receptor with four steroid units (Ref. [33]). (b) Singly capped cyclocholate-porphyrin receptor (Ref. [34]) (c) Macrocyclic *bis*-ZnP receptor capable of strongly binding C_{60} (Ref. [36]).

chromatographic separation is possible.[36] Chiral as well as achiral porphyrin receptors were used as chromophoric chirality probes for amine guests. Binding of chiral amino acid in an achiral porphyrin receptor or chiral diamine with the acyclic bisposphyrin derivative results in induced circular dichroism (ICD), with the sign directly related to absolute configuration on the chiral center.[37–39]

CATALYSTS AND **ENZYME** MODELS

Cytochrome P450-dependent monooxygenases are membrane-bound enzymes that incorporate Fe(III) protoporphyrin IX as the active site and catalyze many oxidative transformations including epoxidation of alkenes and hydroxylation of alkanes and aromates. Successful preparation of porphyrin receptors with guest recognition properties inspired supramolecular chemists to consider the construction of new organic oxidative catalysts based on metalloporphyrin receptor structures with catalytically active metal ions, most frequently Fe(III) and Mn(III), bound in the posphyrin ring. Several recent reviews are available presenting in-depth coverage of this topic.[27,40–42] Some remarkably successful supramolecular oxidation catalysts are shown in Fig. 5. Chiral Fe(III)-tetraphenylporphyrin bearing two binaphtyl bridges in the α–α–β–β arrangement (Fig. 5a) gives high e.e.s (80–90%) and yields (80–95%) in catalytic epoxidation of styrene derivatives with iodosylbenzene at the rate of 40 turnovers/min [43] Taking advantage of the chiral cyclodextrin cavity for binding of lipophilic substrates. the cyclodextrin–porphyrin models were prepared;[27] the porphyrin with four cyclodextrin units prepared by Breslow[44] (Fig. 5b) is capable of binding cholesterol and alkene derivatives in a specific orientation and can perform site-specific and stereoselective hydroxylations and epoxydations of alkene derivatives in the presence of iodosylbenzene as the single oxygen donor. The Diederich group[45] prepared a water-soluble Fe(III)-porphyrin–azacyclophane catalyst (Fig. 5c) capable of oxidizing acenaphtylene to acenaphtylen-I-on in the presence of iodosylbenzene. A number of impressive self-assembled model systems of cytochrome P450 functioning in bilayer vesicle membranes were reported.[40] For example, the lipophilic Mn(III)-tetraphenylporphyrin bearing four cholesteryl units in α–α–β–β arrangement can be incorporated into DMPC bilayers, and in the presence of flavoprotein pyruvate oxydase and aniphiphilic flavine. the reductive activation of molecular oxygen is

achieved. The self-assembled system is capable of producing 20 mol of acetophenone per I mol of porphyrin derivative from ethylbenzene within 15 h at 30°C.[46] Also, the amphiphilic rhodiuin bipyridine complex Mn(III)-porphyrin–DHP vesicle system described by Nolte[47] is capable of oxidizing α-pinene with turnover numbers comparable to those of Cytochrome P450 at room temperatnre.

SELF-ASSEMBLED MULTIPORPHYRIN ARRAYS

Porphyrins and metalloporphyrins represent a highly advantageous class of building blocks for the construction of large functional supramolecular architectures. These architectures have potential applications as new photonic materials, molecular wires. switches, photon funnels,

elements for information storage, new magnetic materials, catalysts. etc., due to their favorable and tunable photophysical and redox properties and established synthetic methodologies enabling the introduction of a diversity of binding functions at the periphery of the porphyrin ring.[48] Selected recent reviews present a wealth of impressive self-assembled architectures based on porphyrin building blocks and methods of their construction.[49–51] Starting with the simplest self-assembly based on one free-base porphyrin with an attached single donor group at the periphery interacting with a metalloporphyrin having a five-coordinate metal (e.g., Zn) or a six-coordinate metal with one position occupied by a kinetically inert ligand [e.g., Ru(II) or Os(II) coordinated to CO] stable dimeric[52] to pentameric[53] porphyrin complexes could be prepared (Fig. 6a,b). In such systems, the porphyrins are mutually perpendicular, and there is no interaction between their π-systems. The UV spectra are the sum of monomer absorptions. Cyclic voltammetry confirms that there is no electrochemical communication between monomers so that they are oxidized and reduced independently. Combining the described coordination approach with covalently linked Ru(II)CO-porphyrine oligomers, Sanders succeeded in preparing large

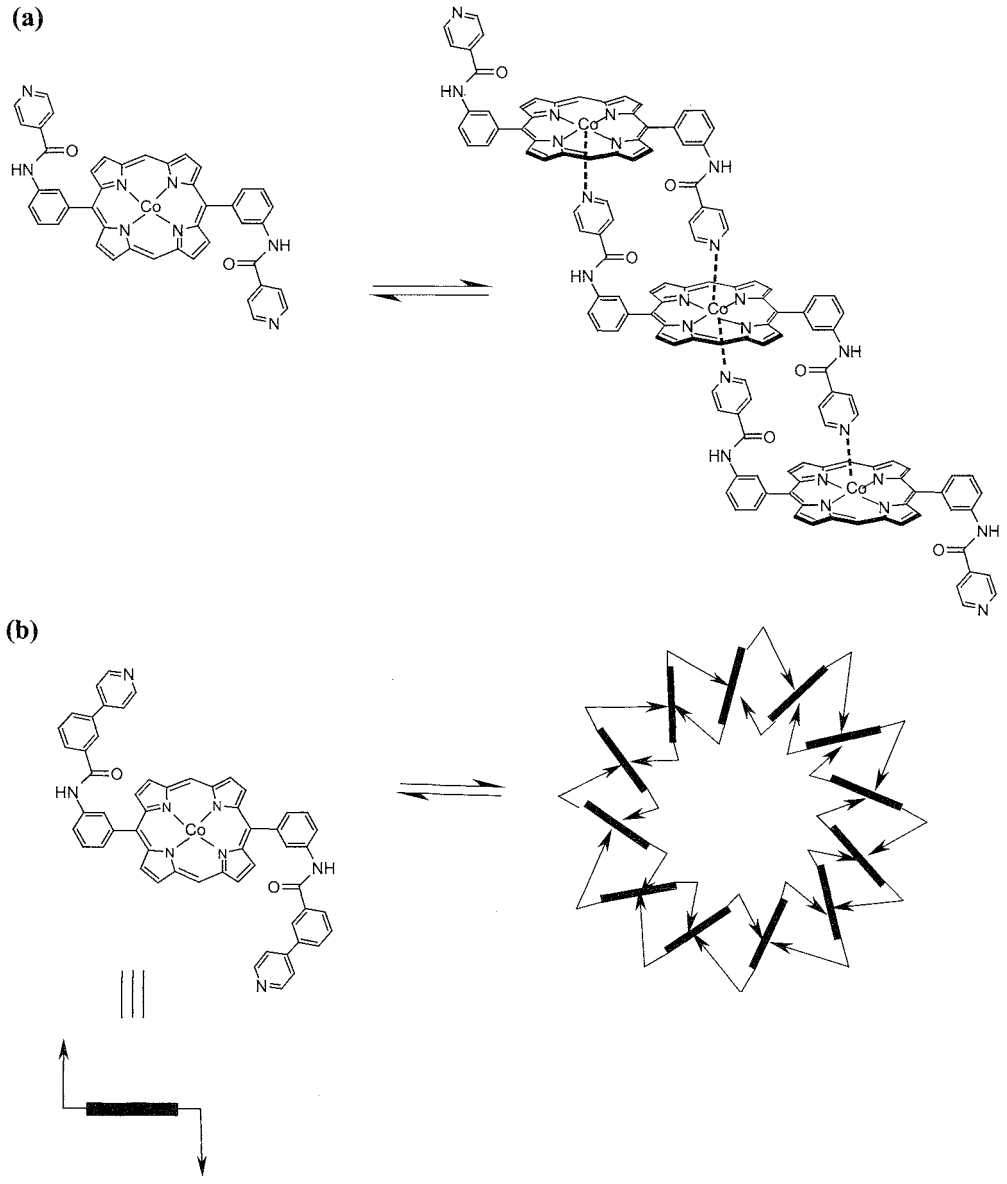

Fig. 7 Controlled coordinative self-assembly giving a linear supramolecular polymer (a) or a macrocyclic dodecamer (b) achieved by altering geometry and length of ligating arms of self-complementary porphyrin monomers (Ref. [60]).

assembled assays containing up to 21 porphyrins.[54,55] In another approach, the use of bidentate ligands with metalloporphyrins led to formation of the complexes with parallel arrangement of porphyrins: for example, the triple-decker complex with 4,4′-bipyridine (Fig. 6c) was prepared, and electrochemical studies proved that terminal porphyrins could interact with each other.[56] Diaza compounds such as 1,4-diazabicyclo[2,2,2]-octane (DABCO). pyrazine, 4.4'-bipyridine. 1,2-*bis*(4-pyridyl)-ethane, and *trans*-1,2-*bis*(4-pyridyl)ethylene were most frequently used as bidentate ligands with Ru- or Fe-porphyrins. Zn-porphyrins also interact with diaza ligands, however, giving kinetically and thermodynamically less stable complexes. The strategy based on the combination of the coordination approach with the self-complementary metalloporphyrin components possessing various binding functionalities at the periphery (hydrogen bonding, salt bridges, other metal coordination sites) endows the self-assembled receptors with a higher level of complexity, capable of binding and recognizing various guests. Impressively, the self-assembled dimer shown in Fig. 6d forms with a high association constant (K_{ass} of 2×10^8 M^{-1}) and strongly binds terephthalic acid derivatives in chloroform.[57] Organized porphyrin arrays of diverse geometries could be prepared by heterocoordination-driven self-assembly of appropriately designed porphyrin units bearing additional metal coordination sites at the periphery.[49–51] Linear supramoleclar polymers named ''shish kebab'' are formed when a bidentate ligand bridges two inetalloporphyrins with hexacoordinated metals. Supramolecular structures of this type were studied mostly with regard to their conductivity properties.[58] The Co(II)-porphyrins bearing two arms with pyridyl groups at meso-positions form supramolecular polymers by pyridine–cobalt coordination. Importantly, the Co(II)-porphyrin with a single pyridine arm can be used as a chain capping agent to control the average chain length.[59] Supramolecular self-assembly can also be controlled by tuning structural and conformational properties of the ligating arms of self-complementary porphyrin monomers. By altering the lengths and geometries of pyridine-containing arms. the process can be directed toward unidirectional self-assembly, giving linear polymers, or toward formation of a closed macrocyclic dodecarner (Fig. 7a,b).[60]

CONCLUSION

The most vivid research activity in supramolecular chemistry of functional porphyrin derivatives in the last two decades resulted in the preparation of many impressive supramolecular systems of high complexity. These include artificial light conversion systems. photonic wires. switches and gates, efficient receptor molecules exhibiting a high degree of constitutional and chiral recognition. new organic oxidation catalysts, the artificial ATP-producing nanomachine. and a diversity of remarkable supramolecular architectures possessing well-organized multiporphyrin assays. The success achieved is becoming of the utmost importance for the present and future scientific and technological activities aiming to prepare supramolecular systems of an even higher level of structural and functional complexity, necessary for the development of nanotechnology. The utmost advantage of functional porphyrin derivatives as building blocks relies on their favorable photophysical properties, the advantage of using coordinative self-assembly, the acceptable complexity of synthetic methods that enable introduction of a variety of additional binding functionalities, and the possibility of modifying and fine-tuning their propertiesby an almost unlimited variation of metals bound inthe macrocyclic ring and binding functionalities at their periphery.

Porphyrin-Based Clathrates

Israel Goldberg
Tel Aviv University, Tel Aviv, Israel

INTRODUCTION

The term "clathrate," in its modern version, is defined in the Oxford and Webster's English Dictionaries as a compound formed by the inclusion of chemical species of one kind (guests) within the crystal lattice (host) constructed by molecules or ions of another kind. An effective building block of such host lattice is often characterized by noncomplementary molecular shape or by specific coordination or molecular recognition features that prevent a compact intermolecular organization of these entities in the condensed crystalline phase. The favored aggregation of the host components in the form of an open lattice, along with the requirement to minimize void space in solids, provide the driving force for their cocrystallization with additional species that are present in the crystallization environment. Inclusion of a guest or solvent in an ordered crystalline lattice (i.e., formation of clathrates or solvates) is a commonly observed, though less-frequently predictable; phenomenon in the formation of organic and inorganic crystals. It was generally considered a by-product of the crystallization process and deserved little attention. However, a systematic study of clathrate chemistry, which started with the pioneering publication by H. M. Powell in 1948,[1] revealed a number of host compounds with consistently high propensity to yield clathrate materials with interesting properties. These include, for example, the β-quinol, tri-o-thymotide, urea and thiourea. choleic acids, Dianin's compound. cyclodextrins. and a number of other species, some of which are discussed in other entries of this Encyclopedia *of Supramolecular Chemis-tn*. More recent investigations revealed and characterized the fascinating clathrate features of the *meso*-tetraaryl derivatives of porphyrins and metalloporphyrins. The porphyrin platform provides excellent building blocks for the design of porous solids with tunable nanosized pores (typically between 0.5–2.0 nm in diameter) and a wide variety of new solid receptors for the effective inclusion or clathration of other species. With the rapid development of the chemistry of the intermolecular bond in the last two decades, the search after, and deliberate design of, new clathrate solids with attractive properties lies in the focus of materials science.

THE UNIQUE FEATURES OF THE TETRAPHENYLPORPHYRIN SYSTEM

The porphyrin macrocycle is one of the most widely studied chemical systems in solution and in the solid state due to its high relevance to catalysis, as well as to electron- and energy-transfer processes and related biological functions. It is characterized by an extensive conjugation, a nearly square-planar symmetry, and a considerable thermal as well as oxidative stability. The synthetic compound is most readily available in the forms of alkyl or aryl derivatives, with the corresponding aliphatic or aromatic substituents attached to the *beta-* or *meso*-positions of the macrocycle, respectively. In this context, the 2,3,7,8,12,13,17,18-octaethylporphyrin and the 5,10,15,20-tetraphenylporphyrin (TPP) provide leading examples. The latter is characterized by a more rigid. flat conformation and remarkable structural robustness, particularly when given in its metallated MTPP form (Fig. 1). Insertion of a bivalent metal ion within the porphyrin core is associated with elimination of the two inner *N*-pyrrole protons, yielding a neutral species; when metals at other oxidation states are applied, the presence of suitable counterions in the crystal lattice is required to balance the charge. The peripheral aryl groups substituted at the *meso* positions of the porphyrin macrocycle are oriented in a roughly perpendicular manner with respect to the central aromatic core and introduce roughness and the desired noncomplementary packing features to the molecular shape of this unit. Then, the coordination properties of the metal entity in the center of the porphyrin ring, provide an element of "programming." by allowing association through coordinative metal–ligand interactions with additional species along the axial directions. Fmther activation of the lipophilic TPP framework can be achieved readily by substituting polar functional groups on it during the porphyrin synthesis. In a typical system, functionalities with coordination or hydrogen-bonding capacity are symmetrically placed at the peripheral positions of the aryl rings and may control, to a considerable extent: the intermolecular organization of the TPP units along the lateral directions. Representative examples include replacement of the phenyl substituents by 4-pyridyl groups [to yield tetra(4-pyridyl)porphyrin—TPyP], and

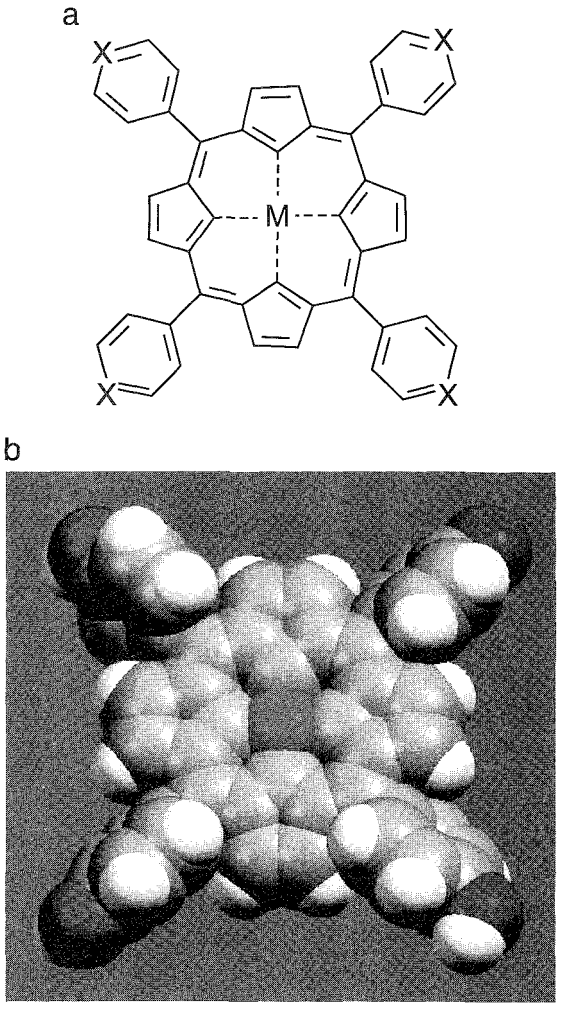

Fig. 1 (a) The tetraarylmetalloporphyrin building block. For MTPP, MTPyP, and MTCPP, X=C—H, N: and C—COOH, respectively. M represents a metal ion inserted into the porphyrin core (M=H_2 for the free-base porphyrin). (b) Space-filling model of the MTPP moiety substituted with OH polar groups at the 4-position of the peripheral phenyl ring. The M and OH sites symbolize here the molecular recognition features active in directional interactions with the surrounding species. Note that the aryl groups are oriented nearly perpendicular to the central porphyrin macrocycle. Fig 1b and all the following illustrations of molecular and crystal structures were produced with the aid of the relevant crystallographic information freely available from the Cambridge Crystallographic Database.[2] (View this art in color *at www.dekker.com.*)

substitution of the phenyl rings at their 4-positions by carboxylic [to yield tetra(4-carboxyphenyl)porphyrin—TCPP] or hydroxylic (Fig. 1b) functions. The above features make the TPPs versatile and attractive building blocks (termed "tectons") for the assembly of open multi-porphyrin lattice arrays through diverse interaction motifs/molecular recognition algorithms (termed "synthons").

THE "PORPHYRIN SPONGES" AS TYPICAL CLATHRATE SYSTEMS

Numerous publications in the scientific literature confirm that the TPP and MTPP molecules provide remarkably attractive building blocks for the formulation of lattice clathrates. Due to a poor packing efficiency in three dimensions, the vast majority of their crystal structures was found to contain solvate/guest molecules incorporated within the porphyrin lattice. These clathrate structures, which are stabilized primarily by weak dispersion forces, form readily. The large base of available structural information with major contributions from the groups of Scheidt and Strouse now amounts to several hundreds of TPP-based crystal structures.[2] The TPP clathrates were structurally systematized by Strouse and coworkers.[3–5] It was observed that in many of the materials studied, the porphyrin host structure is strongly conserved in two dimensions. These materials could be characterized in terms of an intercalation-type pattern in which corrugated sheets of stacked porphyrin molecules are interspaced by sheets of the included guest species (Fig. 2). Two main features characterize the intermolecular architecture in the

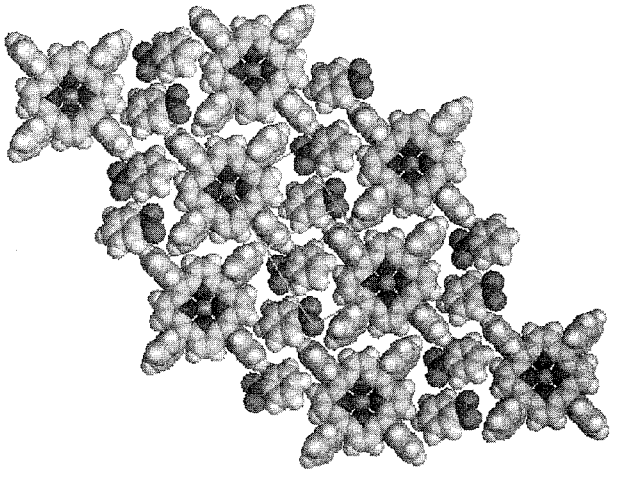

Fig. 2 A typical "porphyrin sponge" clathrate formed by MTPP, with nitrobenzene as the included guest, viewed perpendicular to the porphyrin plane.[3–5] Note the alternating arrangement of the MTPP and the nitrobenzene species. In the third dimension, the clathrate structure is characterized by an offset-stacked arrangement of such mixed porphyrin-guest layers. The interporphyrin organization in the "porphyrin sponges" expands upon the inclusion of larger guest species. (View this art in color at www.dekker.com.)

layered TPP-based crystalline solids: 1) An offset stacking of the square-planar aromatic molecules along a direction normal to the porphyrin plane at regular intervals (ca. 4.0–5.0 Å). This pattern appears to be a fundamental property of the porphyrin–porphyrin interaction required to optimize van der Waals stabilization in these solids. 2) Face-to-face as well as edge-to-face interaction modes between the peripheral phenyl rings within the layered arrangement of the TPP frameworks in a direction parallel to the porphyrin plane (Fig. 2). The intralayer interaction mode between the phenyl rings is similar to that observed in solid benzene and other structures containing aryl derivatives.

The lack of specific interactions between the porphyrin building blocks (other than by dispersion) allows for little constrained expansion of the porphyrin arrays by inclusion of guest components of versatile nature, size, and shape in different molar ratios, giving rise to the classification of these clathrate materials as "porphyrin sponges."[3–5] The guests included in such TPP clathrates vary from small species such as methanol and water, through medium-size aromatic moieties or metallic complexes such as anthracene and ferrocene, to the very large C_{60} and C_{70} fullerene entities.[6,7] In the latter case, the interaction of the curved π surface of a fullerene with the planar π surface of a porphyrin macrocycle were found to stabilize unique supramolecular porphyrin/fullerene aggregation modes (Fig. 3). Smaller guests (e.g., nitrobenzene or pyrene) can also associate strongly or weakly with the porphyrin building blocks through coordination to the metal center or by π overlapping the delocalized porphyrin core. The structures of these clathrates tend to be centrosymmetric due to the high symmetry of the individual tecton unit, with symmetric disposition of the guest components with respect to the porphyrin core. Potential applications of the porphyrin sponges include molecular separations by occasionally preferential inclusion of a given component from solvent mixtures. and controlled guest release of volatile organics from the porphyrin lattice voids.[3–5] A practical example of the latter in the area of pest control involves incorporation and slow release of fly sex pheromones.[5]

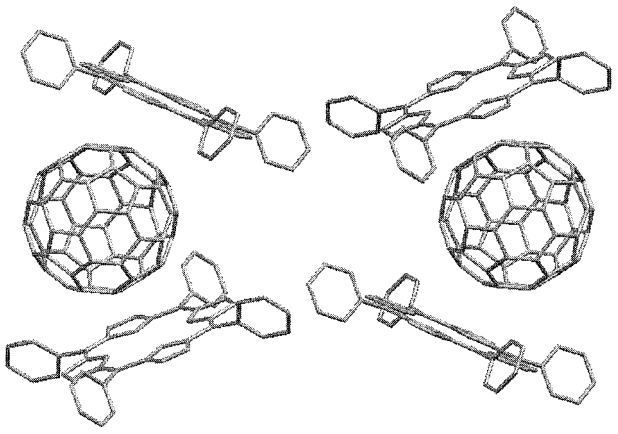

Fig. 3 Characteristic inclusion mode of Buckminsterfullerenes (C_{60} is shown) within the crystal lattice of TPP.[6,7] (*View this art in color at www.dekker.com.*)

FROM "PORPHYRIN SPONGES" TO THE "PORPHYRIN SIEVES" CONCEPT

It is well known that the intermolecular organization in organic solids usually reflects molecular recognition features (i.e., a scheme of specific and directional interactions) between the component species.[8,9] In the last decade, this paradigm was also applied effectively to the porphyrin-based solids, by activating the porphyrin framework, on its periphery, with polarized aryl groups. It involved the use of diverse molecular recognition algorithms to modify and direct the spontaneous buildup of the porphyrin lattice,[10–12] leading to more rigidly assembled molecular arrays and to porphyrin-lattice architectures with better-defined dimensionality than that in the common porphyrin clathrates (see above). For example, the addition of functional substituents at the four peripheral phenyl groups, capable of forming specific directional noncovalent links with the neighboring building blocks, allows directed aggregation of the porphyrin species in the form of porous layered networks. On the other hand. the introduction of polar groups capable of axial ligation to metal ions placed in the porphyrin center enhances formation of multiporphyrin oligomers and polymers by axial coordination of one porphyrin species to the metal centers of the neighboring moieties. Formation of other kinds of enforced supramolecular porphyrin arrays was achieved by the use of external auxiliaries that may readily associate with the functional groups of several neighboring units at the same time. This includes external metal ions and organic ligands that can mediate extended connectivity by coordinating to, and linking between, the metal centers of the peripheral functional groups of adjacent metalloporphyrins. A combined expression of the various molecular recognition algorithms along the lateral as well as axial directions in the same structure represents the most desirable approach to the design and construction of multiporphyrin architectures with high structural integrity. As opposed to the sponge character of the simple porphyrin-based clathrates, which are little sensitive to the nature and size of the guest component (see above), the intermolecularly linked lattices based on the functionalized porphyrin building

blocks are characterized by a better-defined pore structure and guest selectivity features.

REALIZATION OF CLATHRATES WITH ENFORCED PORPHYRIN LATTICE MOTIFS

Different types of lattice clathrates based on two-dimensionally or three-dimensionally interconnected posphyrin units were developed. As mentioned earlier, the use of peripherally substituted TPPs dictates, in many cases, the formation of open-layered porphyrin assemblies (β-molecular networks) sustained by lateral interactions between adjacent tecton units. In the crystal, these layers are arranged in an offset-stacked manner. The presence of intra- as well as interlayer voids drives incorporation of suitably sized guest components into the lattice during crystallization. Formulations of such flat-layered porphyrin anays can be effected by direct dipolar attractions[10] and by multiple hydrogen bonds'"' between adjacent posphyrin units. Depending on the type of the functional groups involved in these interaction synthons, the observed widths of the guest-accessible open space within the porphyrin layers may vary from 0.4 nm (with halogen and hydroxyl substituents) to 1.O–1.5 nm (with nitrile and carboxylic substituents). An example of a molecular-sieve-type structure coinposed of hydrogen-bonded two-dimensional porphyrin layers in which the flat networks stack in an almost overlapping manner along the normal direction at an average interlayer distance of 4.7 Å is illustrated in Fig. 4. The posphyrin lattice in this material occupies less than 40% of the crystal volume and contains 1.5 nm-wide guest-accessible channels propagating through the crystal. It is perfectly suited for guest transport applications.

Structures based on stacked porphyrin networks with larger interporphyrin voids are difficult to obtain. When the size of the individual building block is smaller than that of the interporphyrin cavity, interpenetration of the Rat networks occurs to partly fill the void space.[14] The crystallization template also plays an important role in directing the preferred intermolecular organization, when the functional porphyrin units can self-assemble in more than one mode.[11,12] Formation of clathrate structures, which consist of open-layered porphyrin assemblies aided by external metal ion auxiliaries. is also feasible.[15–17] The metal ions can coordinate to. and bridge between, theperipheral functional groups (e.g., pyridyl. hydroxyphenyl, or carboxyphenyl) of neighboring porphyrins, thus yielding robust two-dimensional structural motifs with open voids conveniently accommodated by suitable guest species. Conespondingly. it is possible to control to a considerable extent the porosity of the porphyrin layers. and thus the nature of guest components preferably

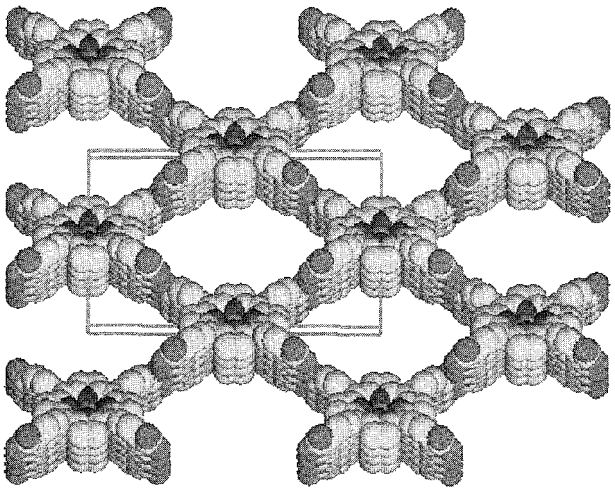

Fig. 4 Porphyrin-sieve-type clathrate consisting of stacked networks of hydrogen-bonded MTCPP moieties, showing four to 5 overlapping layers. The van der Waals width of the interporphyrin channels propagating through the crystal and accessible to other species is about 1.5 nm.[13] (*View* ***this*** *art in color at www.dekker.com.*)

incorporated within the interporphyrin cavities. This tuning can be accomplished by changing the type of the sensor group bound to the porphyrin framework as well as by introducing an external bridging template.

Association of the porphyrin moieties aiong the axial direction (i.e., roughly perpendicular to the porphyrin plane) provides another useful tool for constructing enforced supramolecular porphyrin aggregates. Columnar motifs of the porphyrins are readily achieved, for example, by means of axial coordination interaction of a bidentate bridging moiety (e.g., of the binitrile or bipyridyl type) to transition metal ions (with either five or six-coordination preference) inserted into the posphyrin core.[16,18,19] Theу can also be constructed by using multiple hydrogen bonds between peripheral polar groups oriented in a direction perpendicular to the porphyrin plane.[20,21] The void space created between and within such one-dimensional porphyrin columns leads to the incorporation of guest species into the crystal lattice and creation of clathrates. Some materials of this type were found potentially useful as molecular magnets'"' or solid-state catalysts.[20]

The columnar one-dimensional, or network two-dimensional, polymeric motifs can be further varied in different ways to construct three-dimensional lattices of interlinked porphyrin species with better-defined pore sizes. One way to achieve this goal is to apply external transition metal-bridging auxiliaries with three-dimensional coordination features. These include, for example, zinc,'"' copper,[22] and molybdenum,[23] metal ion bridges that can associate

simultaneously with several neighboring porphyrin units. Another way to effect extended supramolecular architectures is to bring to expression a concerted mechanism of the lateral (i.e., parallel to the porphyrin planej as well as axial (i.e., approximately perpendicular to the porphyrin plane) interaction schemes between the porphyrin building blocks. Different combinations are possible: 1) direct interporphyrin hydrogen bonding in the equatorial directions combined with axial coordination through a bridging organic ligand: 2) equatorial intercoordination through metal ion auxiliaries combined with axial coordination through a bridging organic ligand; 3) equatorial as well as axial interporphyrin coordination through an organic ligand; and 4) self-assembly of multiporphyrin coordination polymers without resorting to external auxiliaries, in which the peripheral functional groups (e.g., pyridyl) of one porphyrin associate with the transition metal center (e.g., zinc or molybdenum) of neighboring metalloporphyrin units.[11,12,24] The geometric restrictions imposed by directionality and specificity of the intermolecular interactions lead, in most of the known cases, to the formation of architectures with intralattice voidr of restricted dimensions and are. thus. characterized by selective guest-entrapment features.

DESIGN OF PORPHYRIN-BASED ZEOLITE ANALOGUES

Formulation of porphyrin clathrates, which resemble to a significant extent the structure and function of the naturally occurring zeolites, represents one of the highlights of the porphyrin clathrate chemistry. Pioneering publications came out simultaneously from the research groups of Robson[22] and Goldberg[25] in 1994. The two groups reported the first porphyrin materials of this kind that represent single-framework open architectures based on coordination polymerization, either direct or through an external auxiliary. between the porphyrin tectons. Robson et al. used the Cu^{II}TPyP units tessellated together by Cu^{I} external transition metal auxiliaries to prepare a solid network structure with wide channels (diameter >1 nm). However, these frameworks did not survive solvent removal and were found to deteriorate rapidly in open air at ambient conditions. On the other hand. and in order to eliminate the need to use an external auxiliary along with its counterion, Goldberg et al. used the Zn^{II}TPyP building blocks to induce direct interporphyrin coordination. These efforts led to successful formulation of a homogeneous multiporphyrin honeycomb architecture of trigonal symmetry. which contains an array of parallel −0.6 nm-wide channels centered around the threefold rotation axes and propagating through the structure (Fig. 5). The inner walls of these channels are hydrophilic. facilitating an easy absorption of small polar guests in a reversible manner. More recent evaluations of identical Co^{II}TPyP and

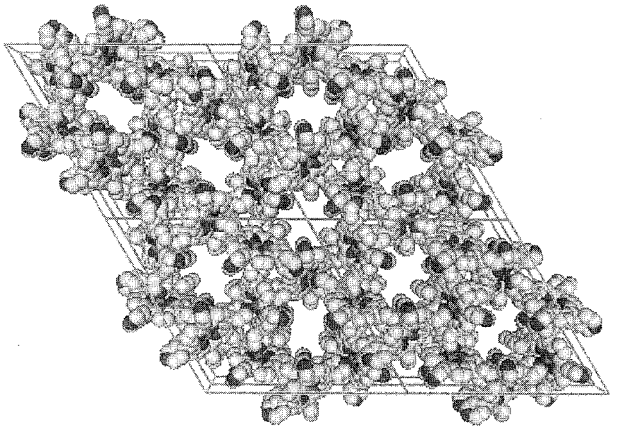

Fig. 5 Channel-type molecular-sieve structure based on the self-assembly via coordination of MTPyP building blocks. View down the channel axis. The width of the parallel one-dimensional channels is 0.6 nm. suitable for the storage and transport of small molecules.[25,26] *(View this art in color at www.dekker.com.)*

$Mn^{III}TPyP$ architectures confirmed the high structural integrity and thermal stability (up to ca. 400°C) of this material, its sorption capacity, and its potential utility in shape-selective catalysis.[26]

The two other examples of successful construction of stable metalloporphyrin zeolite involve the MTCPP building blocks and external organic and metal ion auxiliaries. The first represents a single-framework three-dimensional coordination polymer fully sustained by a specific and directional interaction scheme (Fig. 6). The structure consists of porphyrin bilayers held together via coordination, through their carboxylic functions, by bridging sodium metal ion auxiliaries. These layers are then cross-linked in the axial directions by bipyridyl ligands. which associate to the central zinc ions of successive bilayers. The crystal lattice thus formed is perforated by wide-open galleries (0.8×1.2 nm^2 and 1.0×1.2 nm^2), which extend between the bipyridyl pillars.[27] The polymeric framework occupies less than 40% of the crystal volume, the remaining space being accessible to the guest component, and maintains it stability up to ca. 150°C.

The second example relates to a functional nanoporous material based on the supramolecular assembly of the CoTCPP tectons, which was fabricated by Suslick et al. with the aid of solvothermal techniques.[28] Its structure is based on peripheral coordination of the porphyrin building blocks to each other, into a three-dimensional coordination polymer, with the aid of external cobalt ion auxiliaries (Fig. 7). The bending of the CoTCPP units allows formation of a three-dimensionally intercoordinated single-framework architecture, without the organic bridging ligand applied in the previous example. The resulting solid is thermally robust, and 74% of its total crystal volume is accessible to solvent and guest species. It contains large, refillable tridirectional channels (with cross section dimensions of 0.7×0.9 nm^2 and 0.7×1.4 nm^2), exhibiting extraordinary hydrophilic character. It also reveals selective guest absorption properties with considerable preference for water and amines, highlighted by its remarkable ability to remove water from common organic solvents. In the latter context, this porphyrin system was found to outperform common zeolites.

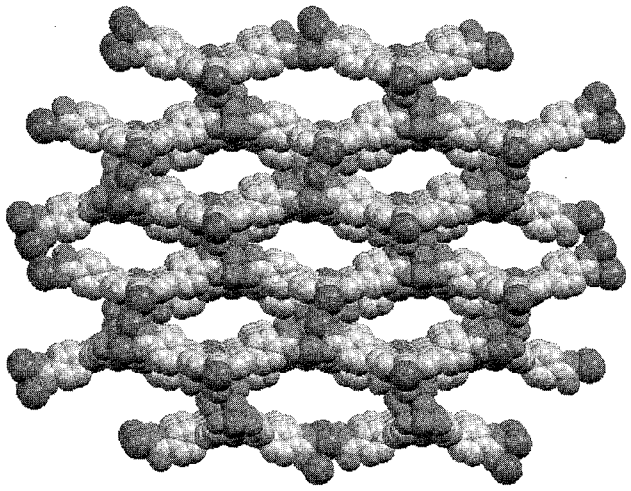

Fig. 7 Suslick's porphyrin zeolite, based on a Co-bridged CoTCPP self-assembled framework, showing its open architecture.[28] This structure is also perforated by smaller channels that propagate roughly perpendicular to the porphyrin planes. *(View this art in color at www.dekker.com.)*

CONCLUSION

The intensive research on porphyrin-based clathrates over the past decade led to interesting formulations of novel materials. The properties of the porphyrin sponges and their potential applications as slow guest release agents were extensively explored. It was further shown that suprainolecular chemistry along with crystal engineering provide useful concepts and synthetic tools for the designed construction of enforced lattices with genuine molecular-sieve properties.[13,25–28] These methods involve the generation of high-order structures with controlled geometries from robust molecular building blocks, by exploring diverse interaction motifs that can exist between the functionalized porphyrin molecules. The design of organic molecular solids with structural and functional similarity to inorganic zeolites and high structural integrity remains an exciting challenge in materials chemistry.

Nanoporous solids in general, and the porphyrin sieves materials in particular, provide an increasingly important class of materials for potential applications in the areas of enantioselective separations, molecular sorption and sensing, heterogeneous catalysis, and as possible nanoscale reaction chambers. Until the end of 2002, only a small fraction of the newly designed porphyrin-based solids were found to exhibit unprecedented nanoporosity and structural rigidity at high temperatures. Most of these materials still lose their crystallinity upon expulsion of the intercalated guest and are not suitable for practical uses. Further effort is required to optimize the porphyrin building blocks, reveal more specific and stable interaction synthons, and improve the preparative techniques in order to formulate new zeolite-type materials that can rivai the naturally occurring aluminosilicates. The remarkable achievements in nanoscale supramolecular

synthesis of molecular sieve architectures achieved thus far establish strong potential for the successful development of a new generation of useful functional materials in the near future.

Preorganization and Complementarity

John C. Sherman
University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

Chemists have long been entranced by nature's example of sophistication in recognition. Our drive as scientists has been to understand how nature manages such exquisite specificity, and how we can use such information to our own ends. Biologists are mostly concerned with elucidation of natural processes, with hope that such understanding may lead, for example, to new therapies, better control in agriculture, and perhaps even to "more useful" organisms. Chemists too have been interested in elaborating on how such recognition is manifested, usually on a more fundamental molecular level. Our approach has included mimicry, and this has led us further, to create new systems that can potentially perform tasks that nature cannot or simply does not. As chemists, we are interested in understanding the fundamentals of recognition processes and in applying this knowledge to our synthetic bent. Thus, we seek to create nonnatural supramolecular assemblies that are limited in scope only by our imagination.

Our ability to synthesize complex molecules and to characterize their structure, conformation, and dynamics continues to grow. So does our appetite for grander schemes. With enzymes and receptors as nature's examples of billions of years of honing recognition, chemists sought to capitalize. and perhaps even leap-frog nature. Key transitional compounds were available in the 1950s: cyclodextrins are naturally occurring compounds that are capable of recognizing and binding a variety of organic molecules.[1] Although naturally occurring cyclodextrins manifest some specificity, they do not compare to enzymes or receptors in this regard. In the 1960s came cyclophanes, which are synthetic compounds that are macrocyclic in structure, but they lacked the elements needed for binding of guest molecules.[2,3]

A hallmark in supramolecular chemistry came in 1967, when Pedersen created the first crown ethers.[4] These were entirely synthetic, macrocyclic, and capable of recognizing and binding small ions. Crowns opened the door to many possibilities. Most importantly, new ideas began to flood, and a new field was created. called host–guest chemistry. Donald J. Cram was among the first to recognize the potential of crowns, and he assimilated his knowledge of cyclophanes, crowns. cyclodextrins. as well as recognition in biology, including concepts such as the lock and key theory of Emil Fischer, to create the field of host–guest chemistry.[2,3,5,6] Charles Pedersen, Jean-Marie Lehn, and Donald J. Cram won the Nobel Prize in Chemistry for their work in host–guest chemistry.

COMPLEMENTARITY

The synthesis of host–guest chemistry from the above elements began with the definitions of the terms that title this chapter. Complementarity in simple terms refers to host and guest complementing each other, again akin to the lock and key model of Fischer. The shape and size of the cavity of the host must match that of the guest. The electronic interactions between host and guest must be attractive. Of all the possible interactions between host and guest, including ion–ion, ion–dipole. dipole–dipole, hydrogen bonds, π–π, and van der Waals interactions, the more complementary the host and guest, the stronger will be their binding. Or as Cram put it, "to complex, hosts must have binding sites which can simultaneously contact and attract the binding sites of guests without generating internal strain or strong nonbonded repulsions."[3]

Two striking early examples of complementarity from the lab of Jean-Marie Lehn are cryptands 1 and 2 (Fig. 1).[7] Cryptand 1 shows selective binding of Li^+ over Na^+ by a factor of 4800, and cryptand 2 shows selective binding of Na^+ over Li^+ by a factor of 440,000. Both hosts are complementary to small spherical cations. The inwardly pointing lone pairs of electrons on the oxygens and nitrogens donate into the alkali cations. and thus. they electronically complement the guests. The lone pairs form an essentially spherical cavity, which is complementary in shape to the spherical cations. This is an electronic conlplementarity as well, because such cations do not have stringent structural or electronic requirements for ligand arrangements, such as a square planar geometry. Finally, there is size complementarity, which is clearly switchable from the smaller to the larger, as demonstrated by the two examples (vide infra).

Cryptand 1 Cryptand 2

Fig. I

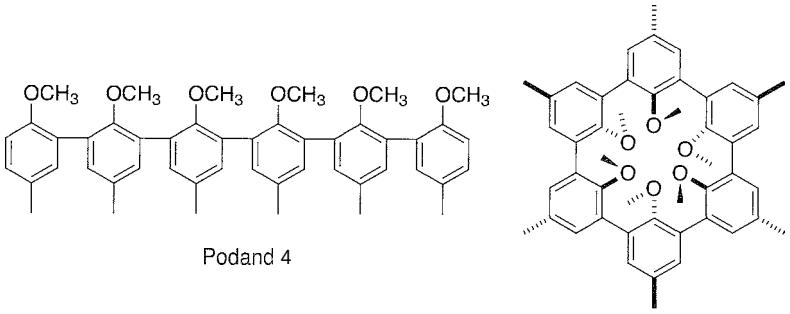
PREORGANIZATION

Preorganization essentially comes down to "you can pay me now or you can pay me later." The currency of payment in this case is energy. Energy in terms of binding affinity and energy in terms of synthetic labor. As Cram stated, "the more highly hosts and guests are organized for binding and low solvation prior to their complexation, the more stable will be their complexes."[3] A highly flexible host is not well preorganized. It will show weak binding, because there will be only one or perhaps a few similar conformations that are optimal for guest binding. Although many other conforinations are available to the free host. most of these conformations are denied access upon binding. This costs energy in terms of entropy, and will be reflected in the low energy of binding. As well, a poorly preorganized host will be highly solvated. Desolvation will be required before binding can take place. This will cost energy in terms of enthalpy and entropy and again will be reflected in the weak binding of host and guest.

The classic example of preorganization is the contrast between podand **3** and spherand 4 (Fig. 2).[3,8,9] The difference in the binding constants for these two compounds for Li^+ is $>10^{12}$. The electronics of the molecules are nearly identical. For the podand, a multitude of conformations must be denied, which costs energy in terms of entropy. The conformation that is most complementary for binding is likely a relatively high energy conformation. so there is an enthalpic price to be paid as well. And there is the problem of desolvation of each of the ether oxygens. In contrast. the spherand pays these prices up front, before coming in on binding day. The synthesis of spherand 1 is an arduous one,[8,9] and the host must possess a reasonable amount of strain. This up front payment brings to the table a host with its six oxygens fully preorganized for binding small cations. The lone pairs (one from each oxygen) point into the cavity toward the guest, and the methyl groups effectively preclude solvation. No conformations need to be frozen out, and any strain that there may be in the binding conformation is already present in the free host. so there is no additional price to pay. All advanced payment. i.e., energy, goes to binding. In boxing terms. the spherand has come to the bout well trained and at the proper weight (preorganized), so it performs with astounding strength. In contrast, the podand did not prepare well and is overweight (i.e., is not preorganized). It must work off some weight on the day of the bout (i.e., it must arrange itself into a binding geometry) and is thus left with little energy for the bout.

One might expect such highly preorganized species to slow the process of binding. What is affected considerably is the rate of decomplexation. The rates of complexation are not as affected." In principle, a fully preorganized host could shut down the rate of complexation to the point where binding is no longer reversible. This is the case for carcerands, which are discussed in another article. In cases of highly preorganized spherands such as 4. a guest can be slowed considerably. to as low as $10^{-12}s^{-1}$.[3]

One final comment on complementarity. One can intuit that it is possible to create a host with a cavity that is selective to Li^+ over Na^+ by making the cavity small, such that Na^+ will cause strain: either host and guest occupying the same space or host will have to adjust to a high-energy conformation to avoid occupying the same space as the



Podand 4 Spherand 4

guest. This is illustrated in the example of cryptand **1** showing selective binding of Li^+ over Na^+ by a factor of 4800. as stated earlier. What is even more challenging is the reverse. The complementarity and preorganization must be very high for cryptand 2 to show selective binding of Na^+ over Li^+ by a factor of 440,000. The host must be unable to shrink its cavity to accommodate the Li^+, or if the host can. it must cost a lot of energy. In this regard, this is an amazing example. But it is not unique.

CONCLUSION

There are many exainples of complementarity and preorganization. Essentially every article in this encyclopedia contain5 examples. After all, complementarity and preorganization are precepts to supramolecular chemıstry, and thus, these concepts are integral to all supramolecular assemblies.

INTRODUCTION

Proteins fulfill a variety of functions in biological systems. They serve as biocatalysts, inolecular motors, signal receptors. building material of cellular structures, and much more. Although the strategy of protein chemists was the functional characterization of high-purity isolated proteins, most proteins seem to act not in an isolated but rather in an organized manner, at least from time to time, whether they be supramolecular assembled multiprotein complexes or aggregates. In this article, we summarize the recent contributions to the field of suprarnolecular protein chemistry. including the new methods used for the structural characterization of high-molecular-weight assemblies.

METHODS FOR THE ANALYSIS OF SUPRAMOLECULAR PROTEIN COMPLEXES

Nuclear Magnetic Resonance (NMR)

New techniques for solution nuclear magnetic resonance (NMR) studies of molecular and supramolecular structures were described by Riek et al.[1,2] The authors combined TROSY (transverse relaxation-optimized spectroscopy) and CRIPT (cross-correlated relaxation-induced polarization transfer) or CRINEPT (cross-correlated relaxation-enhanced polarization transfer) for the two-dimensional (2D) NMR analysis of ^{15}N-, ^{1}H-labeled homo-oligomeric macromolecules with masses ranging from 110–800 kDa. Practical applications of these methods are, for instance; analyses of intermolecuiar interactions in supramolecular complexes or conformational changes of a single macromolecule upon interactions with other molecules.

Electron Paramagnetic Resonance (EPR)

As a new method for the investigation of the structure and conformational switching in soluble and membrane proteins, site-directed spin labeling (SDSL) was presented as a general method.[3] In the SDSE technique, a nitroxide side chain is introduced into the protein by reacting an engineered cysteine with a selective nitroxide reagent, and the shape of the electron paramagnetic resonance (EPR) signal is determined by the motion of the nitroxide ring on the nanosecond timescale. It is known that the motion is a superposition of the rotary diffusion of the protein. internal dynamic modes of the side chain, and local backbone fluctuations. Usually, however, the experimental conditions can be arranged so that contributions from the rotary diffusion are negligible. Thus, if the internal side chain motions are known at particular sites. the local backbone fluctuations can be deduced. In a similar way, collective modes in α-helices of soluble proteins and other internal motions can be detected.''

Electron Cryomicroscopy

The applicability of electron cryomicroscopy methods on biological macromolecules and their supramolecular assemblies was reviewed by Unger.[4] Examples were presented comprising the membrane protein aquaporin, the herpes-virus capsid, and the small nuclear ribonucleoprotein complex. Developments in electron cryomicroscopy and image analysis in combination with x-ray crystallography allow scientists to investigate structure, assembly. and dynamics of biological supramolecular assemblies.[5] This is particularly interesting with regard to viral proteins and receptor proteins as, for example, the coxsackievirus-adenovirus receptor (Fig. I). Thus, the authors were able to resolve the structure of human herpes simplex virus 1 capsid at 8.5 Å resolution by combining 5860 images of particles from 130 micrographs.

Light Scattering

Some supramolecular structures are sensitive to external perturbations. which can result from sample preparation and ''harsh'' conditions during fixation of the

sample (e.g., electron microscopy). Static light scattering (SLS) and dynamic light scattering (DLS) are two techniques based on the analysis of hydrodynamic properties. These methods permit the characterization of protein supramolecular structures as they exist in unperturbed solutions. Ehrlich et al.[6] showed by DLS that the HIV-1 capsid protein CA is able to form spherical and tubular structures. However, using electron microscopy, they found that some protein assemblages were inherently sensitive to perturbations.

Mass Spectrometry

Matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) can be used for primary structure verification and protein identification. Belghazi et al.[7] described the application of MALDI-MS for the analysis of yeast mitochondrial proteins in a supramolecular complex exhibiting NADH dehydrogenase activity. Protein complexes were isolated by 2D gel electrophoresis, fragmented by Lys C digest and analyzed by MALDI-MS. Protein identification was done in a multistep procedure: first, a database search was performed with the monoisotopic masses; second, peptide peaks corresponding to promising candidates were analyzed by postsource decay; and finally, a search was performed with the postsource decay fragments to confirm the first identification. Of 38 proteins identified in this approach, most were known mitochondrial proteins.[8]

Classical Assays

The most routinely used methods in pharmaceutical research for the characterization of protein aggregations are the HP-SEC (high-performance size exclusion chromatography) and native and denaturated PAGE (poly acryl amide gel electrophoresis) techniques (for more details, see any of a number of classical biophysical and biochemical textbooks).

UNDERSTANDING THE FORMATION OF SUPRAMOLECULAR PROTEIN STRUCTURES

The term ''amyloid'' was used originally to describe certain deposits found postmortem in organs and tissues, which gave a positive reaction when stained with iodine.'" Later. it was realized that the material was predominantly proteinaceous when obtained from many ex vivo sources. Amyloids are observed when proteins self-assemble into large oligomers that are visible by, e.g., electron microscopy, as fibrils. Amyloid deposits are associated with several neurodegenerative diseases, including Alzheimer's disease and the prion diseases. The amyloid fibrils isolated from these different diseases share similar structural features. In the late 1950s, Cohen and Calkins[10] demonstrated that all forms of amyloids studied exhibit a comparable fibrillar ultrastructure: bundles of straight, rigid fibrils ranging in width between 6–13 nm (average 7.5–10 nm) and in length from 100–1600 nm.[11,12] Perutz et al.[13] described amyloid fibers as water-filled nanotubes. However, the protein sequences that assemble into these fibrils differ substantially from one disease to another. To understand the relationship between the amino acid sequence and the propensity to form higher aggregates and protein misfolding[14,15] like the amyloid structure,[16] different research groups employed an approach based on the de novo design of synthetic protein structures[17–20] by using combinatorial libraries. Basically, two different secondary structures are found in most proteins: α-helical and β-sheet structures. Both are quite different. In contrast to an isolated β-strand, which is not stable: an individual a-helix can exist in isolation, and thus a-helices can be considered independent structural modules and used as ''building blocks'' for the design of new proteins. This contrast between secondary structures stems from the fundamental difference in hydrogen-bonding characteristics. In the α-helix, the backbone hydrogen bonding is intrasegmental, in which the carbonyl of an amino residue *j* interacts with the amino group of residue $j+4$. This arrangement induces the formation of a self-contained structure. by satisfying most of its backbone hydrogen-bonding interactions without the help of an ''external'' partner. In β-strands, however. the situation for fulfilling maximum hydrogen bonds is different. The carbonyl and amino groups in β-sheets form a hydrogen-bonding network to amino and carbonyl

groups of neighboring strands. Thus, an "external partner" is usually required and, as a consequence, β-sheet strands tend to form higher supramolecular structures via the formation of defined structures to amorphous aggregates. Another issue to consider is hydrophobic interactions with other molecules with nonpolar surfaces. This is especially an issue for β-strands. Both the formation of backbone hydrogen bonds and the burial of hydrophobic surfaces require a β-strand to interact with neighboring elements of the structure. As an example, for a 0-strand going into the page, the neighboring strands on its right and left sides can form hydrogen bonds with the backbone of the amino and carbonyl groups. Amino acid side chains will point up and down, enabling hydrophobic residues to interact with neighbors above and below the original strand. Thus, the 0-strand can form favorable interactions with neighbors in four directions. This neighborliness has significant practical implications: β-strands have a tendency to aggregate and to form a precipitate in solution. However: nature developed strategies to avoid protein aggregations. Richardson and Richardson[21] analyzed a number of synthetic proteins, and from their studies, they concluded that natural β-sheet proteins use a negative design[17,18] to avoid edge-to-edge aggregation. Naturally occurring 0-sheet proteins are mostly stable and aggregate only after a longer period of time, as is observed for various diseases, whereas synthetically derived peptides and proteins with β-sheet structures have the tendency to form higher molecular arrangements of often unknown structure, and insoluble aggregates are formed. Nature, therefore, knows something and uses strategies we do not know or are actually not able to understand.[21] From their investigations, Xiong et al.[22] deduced that the periodicity of polar and nonpolar amino acids is the major determinant of secondary structure in self-assembling oligomeric peprides and is thus responsible for the formation of protein supramolecular structures.

Proteins with regular 0-sheet edges have a pronounced tendency to form aggregates, because they are already in the correct conformation to interact with any other β-strand they encounter. In their study, Richardson and Richardson[L2]" surveyed edge strands in a large sample of all-0-proteins to tabulate features that could protect against further β-sheet interactions. Of course. β-barrels avoid edges by performing continuous H-bonding around the barrel cylinder. Parallel a-helix proteins protect their 0-sheet ends by covering them with loops of other structures. The β-propeller and single-sheet proteins use a combination of 6-bulges, prolines, strategically placed charges, very short edge strands, and loop coverage. The β-sandwich proteins favor placing an inward-pointing charged side chain on one of the edge strands, where it would be buried by dimerization; they also use bulges, prolines, and other mechanisms.[21] One recent β-hairpin design has a constrained twist too great for accommodation into a larger β-sheet, whereas some β-sheet edges are protected by the bend and reverse twist produced by a glycine residue. All free edge strands were protected, usually by several redundant mechanisms. In contrast, edge strands that natively form x-H-bonded dimers or rings have long, regular stretches without such protection. The results presented by Richardson and Richardson[21] are relevant to understand how proteins may assemble into β-sheet amyloid fibers.[23,24] The possible strategies as summarized"" for the protection of β-sheet edges are shown in Table 1. Many edge-protection strategies used by natural proteins are beyond our current abilities to constrain by design, but one possibility stands out as especially useful: a single charged side chain near the middle of what would ordinarily be the hydrophobic side of the edge β-strand. This minimal negative-design strategy changes only one residue, requires no backbone distortion, and is easy to design. Wang and Hecht[25] showed with great success how to apply the concept of the inward-pointing charge strategy to turn highly aggregated β-sandwich designs into soluble monoiners. Nesloney and Kelly described another method for achieving monomeric 0-sheet designs[26] by the methylation of exposed backbone amino groups in edge β-strands to prevent aggregation. However, this strategy is only applicable for the design of synthetic peptides and not for biological protein synthesis. Thirumalai et al.[27] recently reviewed the various concepts on the molecular

Table 1 Various design strategies for the protection of β-sheet edges

Used strategy	*Frequently found?*	*Suitability as designable strategy?*
Continuous H-bonding	+ + +[a]	No

basis that govern protein and peptide aggregation, identifying the two global ''blocking'' strategies that nature utilizes to prevent edge-to-edge aggregation as the most important the minimization and protection of dangling hydrogen bonds. and inward pointing charged residues that block protein aggregation.

DESIGN OF PROTEIN ASSEMBLIES

The design of new proteins that can assemble into filaments, symmetric cages, and regular assays was described by Yeates and Padilla.[28] These investigations are based on the consideration that proteins self-assemble to fulfill their biological functions and also as part of a pathogenic process. For example, natural linear protein assemblies are, in most cases, tubular structures, such as filamentous viruses and microtubules, but this is not the case for the protein actin, which is one of the well-studied examples of a linear filament. Engineered proteins comprise head-to-tail, head-to-head, and tail-to-tail designed protein filaments. For example, two unrelated dimeric proteins were fused genetically, and the 44 kDa designed protein could self-assemble into filaments that were also seen to associate in bundles and networks (Fig. 2). A particular procedure of producing nanofibers is presented by Hartgerink et al.,[29] who reported about the self-assembly of peptide-amphiphiles, in which the supramolecular aggregation is caused by lipid chains. These fibers can reversibly be polymerized to enhance their stability,

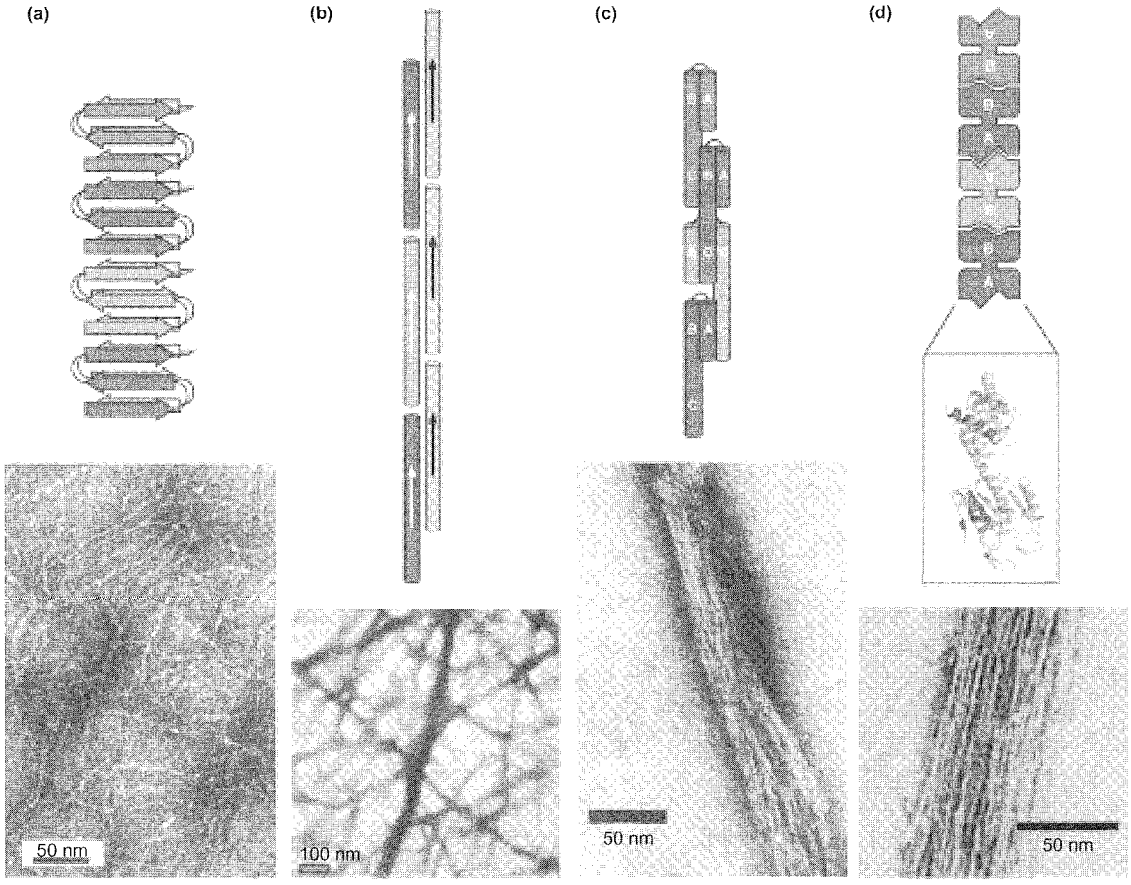

Fig. 2 Various strategies for the design of linear protein assemblies. (a) Beta-sheet polypeptides and proteins tend to associate at their edges to form fibrils that may be related to amyloid structure. (b) Protein filaments are formed by two polypeptides designed to form a parallel heterodimeric coiled coil with 'sticky ends.' (c) Protein filaments are formed by a domain-swapping mechanism from a designed protein created as a variation on a three-helix-bundle protein. (d) Filaments are formed by a fusion protein between two distinct, naturally dimeric proteins (carboxylesterase (A) and influenza virus matrix protein MI (B)). Figure is adapted from Ref. [28] and reprinted with permission from Elsevier, copyright (2002). Electron micrographs (from left to right) are reprinted with permission from Ref. [52], copyright (1999) National Academy of Science. USA; Ref. [53], copyright (2000) American Chemical Society; Refs. [54] and [55], both copyright (2001) National Academy of Science, USA. and the formation of supramolecular structure and polymerization produces a remarkably versatile material. Variants of the peptide-amphiphiles with variations in alkyl chain length, the polymerizable region, and the C-terminal peptide sequence were shown to self-assemble into a one-dimensional fibrous motif.

STRUCTURE PROTEINS

Fibrillins are found throughout the connective tissue of humans as integral components of extended fibrils, which may occur isolated or together with elastin. These polymeric structures were named microfibrils, which are particularly abundant in skin, blood vessels, tendons, and the ciliary zonules of the eye. Handford et al.[30] reviewed existing literature on fibrillins and presented information on the elucidated molecular structure and the effects of mutations on structural and functional properties. In particular, studies of functional domains in fibrillin are discussed that are important in assembling microfibrils. Immunolocalization of fibrillins can be performed within the microfibrils, residing in all tissue locations. Furthermore, immunolocalization experiments suggest an ordered arrangement of fibrillin molecules within the microfibrils. The authors conclude, however, that many questions were not answered, for example, which regions of fibrillin are rigid or flexible, which domains in fibrillins participate in the assembly of microfibrils, and whether fibrillin interacts with other molecules in the assembly process.

An important class of aggregate-forming proteins is the collagen family, a main component of connective tissues. The amino acid sequence of all collagens is now known in detail. The sequence shows a distinct domain organization, with the dominant occurrence of the amino acid glycine and of the posttranslational hydroxylation of proline and lysine residues. Although the primary, secondary, and tertiary structures of the collagens are well known, the different models of supramolecular arrangement, deduced among others from freeze-fracture or "normal" transmission electron microscopy (TEM) and atomic force microscopy (AFM), within the collagen fibers proposed in literature are far from being accepted generally (see review in Ref. [31]). The basic models are comprised of five- or eight-stranded helical microfibrils; smectic or hexagonal crystals: micelles; cylindrical or spiral lattices; compressed microfibrils; and several other arrangements (an example is given in Fig. 3).

Amelogenins are tissue-specific proteins of developing dental enamel. Regarding the biomineralization of the teeth, amelogenins seem to have an important role as a space-filling gel or an intercrystallite packing substance.[32,33] No clear definitive secondary structure is known; and unusual reversible aggregation properties

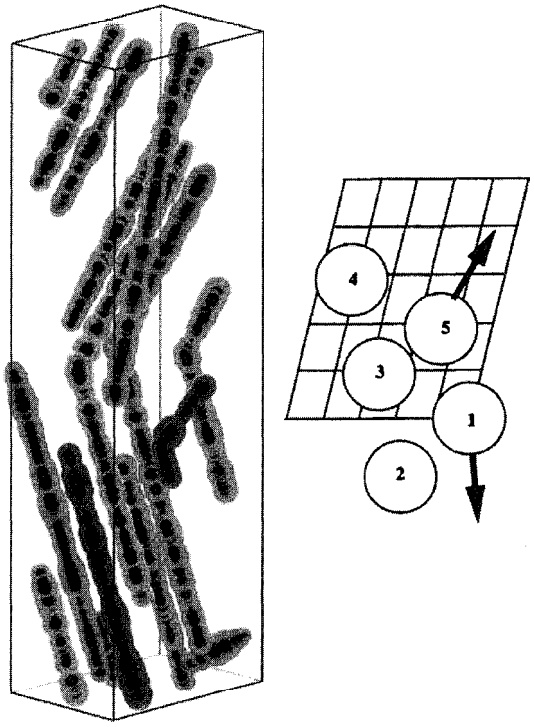

Fig. **3** 3D representation of the molecular arrangement of type I collagen according to Ref. [56] (left). The molecule is divided into five successive segments, identified with different colours. reminiscent of liquid crystal mesophases were observed. The application of dynamic light scattering and AFM exhibited an extreme dependence of the hydrodynamic radius of the major compound with a strong increase around the physiological temperature.

Another example of supramolecular protein structures is an extracellular aggregation factor (AF), a proteoglycan, from the marine sponge Microcionn *prolifera*.[34] The species-specific cell adhesion consists of the AF and a corresponding cell membrane receptor. Because the sponges were the first animals faced with multicellularity, it can be suggested that proteoglycan-like macromolecules belonged to the first extracellular matrix molecules, which originally were designed to allow precise modulation of their adhesive properties. Although early work suggested a self-association of AF due to a Ca^{2+}-dependent interaction of its carbohydrate moiety, the finding that glycan-free recombinant AF provoked specific cell aggregation of *Microciona* cells in the absence of Ca^{2+} proved a direct role of the protein moiety of AF in sponge cell adhesion.

VIRAL CAPSID PROTEINS

The viral genome and replicative enzymes of various viruses [such as the human immunodeficiency virus (HIV)] are encased in a conical shell that is assembled from a single protein subunit, the capsid protein.[35] The core shell of the virus forms a stable, effective protective barrier.[36,37] However. the shell must permit dissolution to allow transmission of the viral genome into its new host. The stability of the capsid protein depends on environmental factors like pH. The pH-dependency of some viral proteins reflects the requirement for a pH-dependent alteration in the conformation of the fusion protein (found at the outside protein core of viral systems) in order to render the protein competent for membrane fusion with the host.[38] The HIV-1 capsid protein can assemble in tubular structures and is also capable of forming spheres, depending on the pH of the protein solution. The switch from formation of one to the other occurred within a narrow physiological pH range (i.e., pH 7–6.8).[6] Below and above this range, only dimers and tubular structures were detected, respectively. Ehrlich et al.[6] found that the CA protein possesses the inherent ability to form metastable structures, the morphology of which is regulated by an environmentally sensitive molecular switch. Such metastable structures may exist as transient intermediates during the assembly and disassembly of the virus core. Icosahedral particles were found for the assembly of physalis mottle virus capsid protein in *Escherichia coli*. Amino acid carboxy termini play a role in the formation of these supermolecular protein structures.[39] Ou and collaborators[40] analyzed the minimal sequences on human JC virus, which belongs to the family polyomaviridae, VP1 required for capsid assembly. They found that the viral capsid is composed of 72 capsomers and that five VP1 molecules make up each capsomer structure. Twelve amino terminal and 16 carboxy terminal amino acids of VP1 are dispensable for the formation of virus-like particles, and further truncation at either end of VP1 leads to the loss of this property. Herpes simplex virus-1 (HSV-1) virions are large, complex, enveloped particles containing a proteinaceous tegument layer connected to an icosahedral capsid. The major capsid protein, VP5 (149 kDa), makes up both types of capsomere, pentons and hexons. Bowman et al.[37] found that alterations in the geometrical arrangements of the VP5 subunits in the capsomeres exposes different residues, resulting in the differential association of the tegument and VP26 with the pentons and hexons, respectively. The rearrangements of VP5 subunits required to form pentavalent and hexavalent capsomeres result in structures that exhibit different electrostatic properties. These differences may mediate the binding and release of other structural proteins during capsid maturation. Also; rotaviruses, a major pathogen of infantile gastroenteritis, are made of a large (100 nm) and complex icosahedral assembly, which is formed by three concentric capsid layers. However, in contrast to rotavirus, Norwalk virus, a causative agent of epidemic gastroenteritis in humans, has a simple architecture with an icosahedral capsid made of 180 copies of a single protein.[41,42] Recently, the crystal structure of the major capsid protein VP6 of rotavirus was determined. It revealed a trimer containing a central zinc ion, which is coordinated by histidine from each of the three subunit~.[~From their investigations. Erk et al.[43] were able to demonstrate that under conditions in which the histidine residues are not charged, the properties of VP6 depend on the presence of the centrally coordinated zinc atom in the trimer.

ENZYME COMPLEXES

The photosystem I (PSI) is one of the two pigment-containing reaction centers of oxygenic photosynthesis found in cyanobacteria and plants. The main function is to catalyze the light-dependent transfer of electrons from reduced plastocyanin or cytochrome c_6 to soluble ferredoxin or flavodoxin across the thylalkoid membrane. The functional reaction center, for thermophilic cyanobacteria, consists of 11 protein subunits and 90 chlorophyll molecules within a 340 kDa complex. Fotiadis et al.[44] performed surface relief reconstructions from electron micrographs and AFMs, and defined the lumenal and stromal PSI surfaces. They obtained precise information on the integration of the PSI reaction center in the lipid bilayer and determined the heights for the stromal and lumenal protrusion, which allowed for definition of the boundaries of the membrane-embedded complex.

An impressive approach to identify supramolecular protein complexes was done by Gavin et al.[45] and Ho et al.[46] They used labeled proteins as bait to capture and identify protein complexes in the budding yeast. Tags were added to the protein cDNA of interest, and these constructs were expressed in the yeast, and physiological complexes were formed. These complexes were thus easily isolated by exploiting the bait and were analyzed further by mass spectrometry. In summary, the authors reported more than 1000 proteins within several hundred supramolecular complexes in yeast, meaning the identification of several thousands of protein interactions. However, this approach: although powerful, has to deal with false positive and false negative results, and the authors failed to identify known interactions.

Grandier-Vazeille et al.[8] reported the analysis of the supramolecular organization of mitochondria1 dehydrogenases by isolation of the complex by non-denaturating electrophoresis (first dimension). Further identifications

of the complex proteins were made by SDS-PAGE analysis (second dimension). Endoproteinase Lys C digest in the gel resulted in fragments suitable for MALDI-MS and database searching. In a first screening, top-ranked protein candidates were identified by mono-isotopic mass searching. These candidates were further analyzed by postsource decay. The authors identified a supramolecular protein complex of five intermembrane space-facing dehydrogenases (Nde1p, Nde2p, Gut2p, Cyb2p, Dld1p), and the matrix-facing NADH-ubiquinone oxidoreductase Ndi1p, as well as the malate dehydrogenase Mdh1p. Three other enzymes of the tricarboxylic acid cycle were associated with this complex: fumarate dehydrogenase (Fum1p), citrate synthase (Cit1p), and succinate dehydrogenase (Sdh1p). Acetaldehyde dehydrogenase (Ald4p), a major component of the complex, implies the function as a channeling complex for matricidal NADH. The sensitivity of the method allows for the identification of physiological protein–protein interactions,[47] here NADH-producing enzymes, although some contaminants may be identified as well.

SUPRAMOLECULAR STRUCTURES ASSOCIATED WITH DISEASES

Atherosclerosis is a progressive disease of the large arteries, where lipids and proteins derived from circulating low-density lipoprotein (LDL) accumulate within cells and in the extracellular space. Ursini et al.[48] hypothesized that atherosclerosis might result from protein misfolding. Normally, protein folding into the correct secondary structure and conformation is indispensable for the biological function of proteins and is achieved during or immediately following protein synthesis. The secondary structure of apo-B 100, the protein moiety within LDL, is determined by lipid–protein interaction and dynamics, and may be affected by the addition or removal of lipids during lipoprotein metabolism. As a consequence of a change of the lipid–water interface, for example due to the oxidation of lipids, a misfolding of apo-B 100 may take place, which leads to a modified lipoprotein with several atherogenic properties. The authors conclude that atherogenesis can be considered as a disease produced by the accumulation of cytotoxic and proinflammatory misfolded lipoproteins.

Amyloid fibrils, formed by the β-amyloid peptide, are the hallmarks of Alzheimer's disease. Lakdawala et al.[49] and Antzutkin et al.[50] used molecular dynamics simulation and electron microscopy as well as NMR spectroscopy, respectively, to investigate fibril formation. Electron microscopy and solid-state NMR investigations were done with peptides Aβ(1–42) and Aβ(10–35). Fibril morphology was strongly dependent on pH. Aβ(10–35) forms single protofilaments at pH 3.7, but pairs or higher-ordered bundles of protofilaments were formed at pH 7.4. Aβ(1–42)-formed protofilaments were single or pairs at pH 7.4. Solid-state NMR revealed an in-register parallel β-sheet organization for both types of fibrils [Aβ(10–35) and Aβ(1–42)], suggesting that the supramolecular structures of both peptides are similar. However, the energetic constraints that contribute to fibril dynamics and stability are still not well understood and were investigated by molecular dynamic simulation based on the peptide Aβ(10–35). These calculations revealed high flexibility and dynamics of the fibrils, particularly in the formation of H-bonds within the in-register parallel β-strands. Therefore, the fibril interior should adopt an indefinite ensemble with ''molten globule-like'' properties.

CONCLUSION

Protein supramolecular arrangements varied widely in their molecular masses, ranging from two or more peptide chains in proteins with quarternary structures, over temporary or permanent interactions of a handful of proteins in multienzyme complexes, up to hundreds or thousands of protein subunits in structure proteins like viral capsid proteins or collagen. It is, therefore, impossible to give a comprehensive overview about this topic, so we picked out some interesting examples of the recent literature. Because most proteins are arranged in complexes and aggregate structures, supramolecular structures are an important issue to consider when discussing protein function.

Protonated Aza-Macrocycles for Anion Complexation

José M. Llinares
Kristin *Bowman-James*
University of Kansas, Lawrence, Kansas, U.S.A.

INTRODUCTION

Anions are notoriously intractable targets for selective binding. Nonetheless, the field of anion coordination chemistry continues to grow after its early beginnings in the late 1960s, with the discovery by Park and Simmons that simple bicyclic diazakatapinands could encapsulate halide ions.'" Binding in the liatapinands and in polyammonium receptors. in general, is governed by electrostatic and hydrogen-bonding interactions between protonated amines and the anion guest. In the decades ensuing the initial discovery. many elegantly designed azamacrocycles were examined for various types of anion-binding properties. These cyclic receptors can be divided into three main categories: monocyclic, bicyclic, and polycyclic. Structures for various receptors cited are depicted in Chart 1 and are labeled numerically in the sequence in which they appear in the text.

MONOCYCLIC POLYAZAMACROCYCLES

Substrates for monocyclic receptors mainly include the following: I) simple inorganic anions—oxoanions, halides, pseudohalides, and other halo anions; 2) organic anions—dicarboxylates and nucleotides: and 3) anionic metal complexes.

Simple Inorganic Anions

Monocyclic polyamines are not especially selective in the binding of simple oxoanions and halides. Binding constants for singly charged anions with monocycles are usually small. if even measurable, as seen for a simple monocycle derived from a Schiff base condensation followed by reduction, **1**, Ar=*m*-xylyl (Fig. 1). However, affinity increases with increasing charge on the anion.[2] A layered structural motif consisting of alternating anions and cations is typical of many of the observed crystal structures.[2,3] In keeping with these findings, molecular dynamics studies indicate that monocycles tend to be somewhat flexible and subject to hydration effects,[4–6] thereby decreasing their effectiveness in selective anion binding. On the other hand. structural results for certain flexible. linear oxoanions. such as pyrophosphate and triphosphate, with monocycles such as **1** (Ar=*m*-furan and *m*-xylyl) indicate a tendency for these ions to thread the macrocycle.[7–9] High affinity is also observed, e.g., log $K_{[H_6L\,PP]/[H_6L][PP]}$=13.07 for **1** (Ar=*m*-xylyl, PP=$P_2O_7^{4-}$).[8]

Organic Anions

Monocyclic polyamines are considerably better receptors for more complex organic ions.[10–13] Even simple penta- and hexa-amine macrocycles were found to bind polycarboxylates and to show selectivity for certain dicarboxylates as opposed to monocarboxylates.[11] This binding preference for dicarboxylates was improved by linking two such macrocycles together to achieve a tethered ditopic receptor (**2**).[12] An effective strategy for selective binding of dicarboxylates of varying chain lengths was also found by placing spacer chains between two diethylenetriamine units, **3,** and by matching the length of the spacers to the $-(CH_2)_m-$ chain in the dicarboxylate. In this manner. the complementarity of the receptor can be fine-tuned to a targeted dicarboxylate, as demonstrated for α-dicarboxylates with chain length, m (Fig. 2). For m=3. the most stable complex was formed with a $-(CH_2)_7-$ chain; for m=5. a chain length of $-(CH_2)_{10}-$ was best. The binding constant, log K_s, was 4.4 in both cases.[13]

Nucleotide binding was also studied extensively after the 1981 report that polyammonium macrocycles bind nucleotides with high affinity.[10] Subsequent studies indicated that, in addition to binding nucleotides, monocyciic macrocycles such as 4 cataiyze the dephosphorylation of nucleotides. Certain metal ions such as Mg(II), Ca(II), and La(III) were found to provide regulation by stabilizing or increasing an observed phosphorylated macrocyclic (phosphoramidate) intermediate.[14] These findings, coupled with the observation that the attack of 4 on formyl phosphate led to *N*-formylation instead of *N*-phosphorylation of the macrocycle led to the use of this simple ligand in a multistep reaction involving formate activation, mimicking N^{10}-formyltetrahydrofolate synthetase.[14] Further studies of the chemistry between ATP and polyammonium macrocycles of varying ring

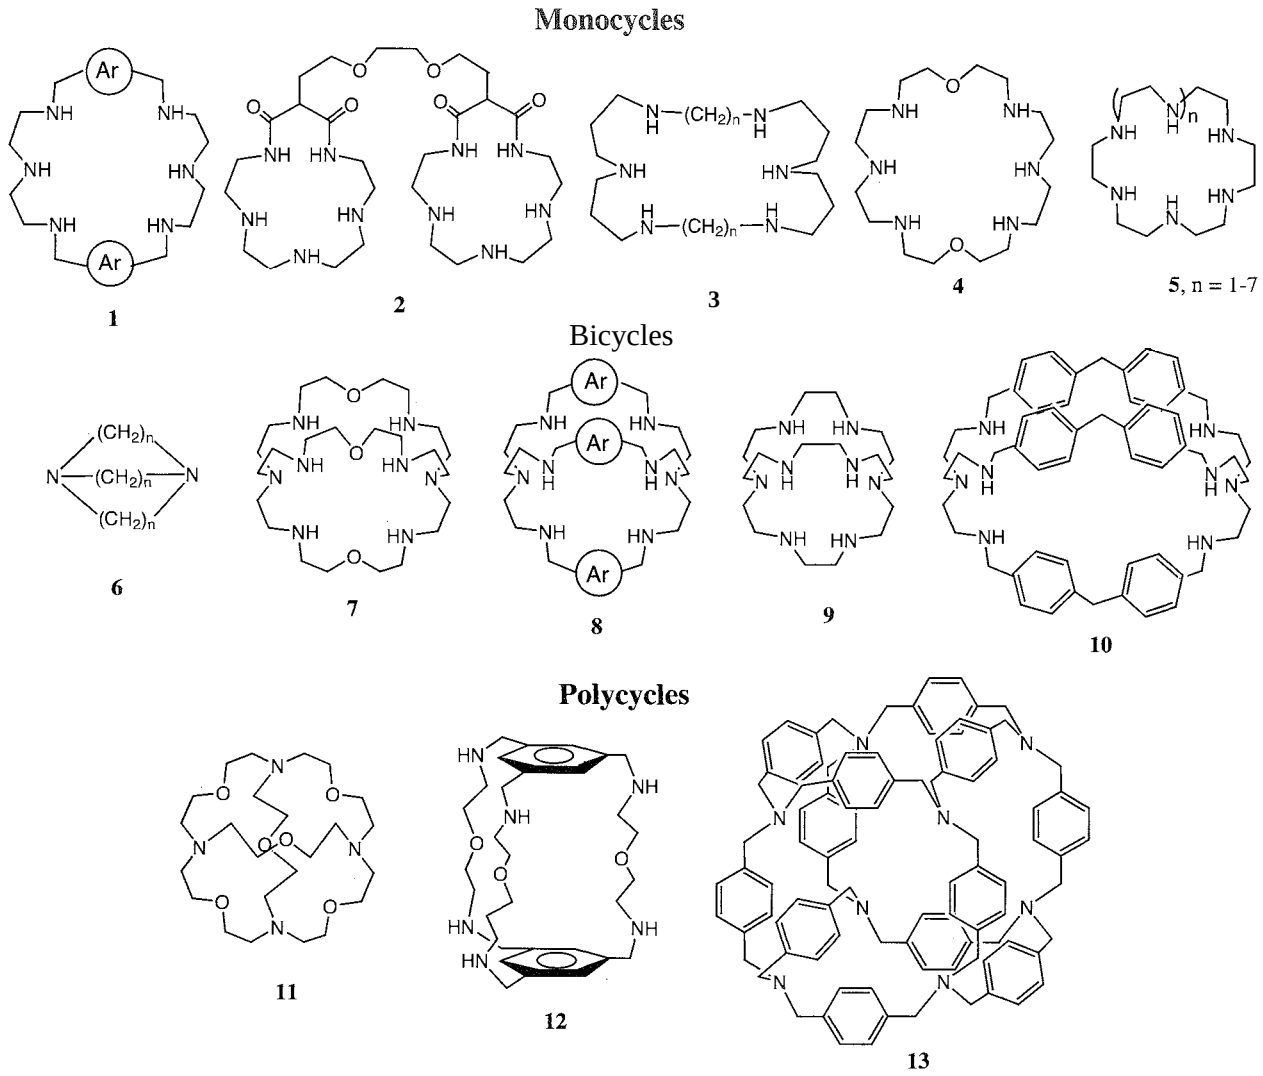

Scheme 1

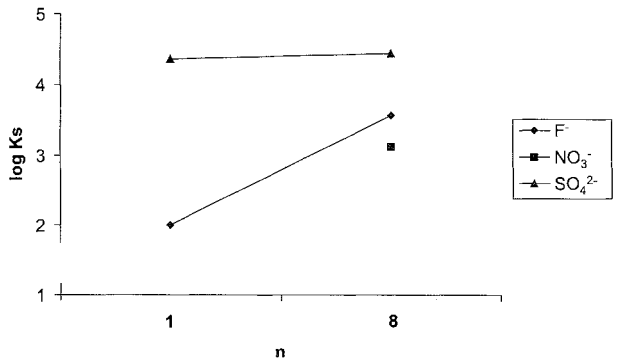

Fig. 1 Stability constants, log K_s, for binding of F^- (spherical), NO_3^- (trigonal planar), and SO_4^{2-} (tetrahedral) with monocycle **1** and bicycle **8**, $^-$(Ar = m-xylyl) in H_2O. No observable binding was observed for NO_3^- with **1**. Data were taken from Refs. [2] (NO_3^- and SO_4^{2-}) and [24] (F^-).

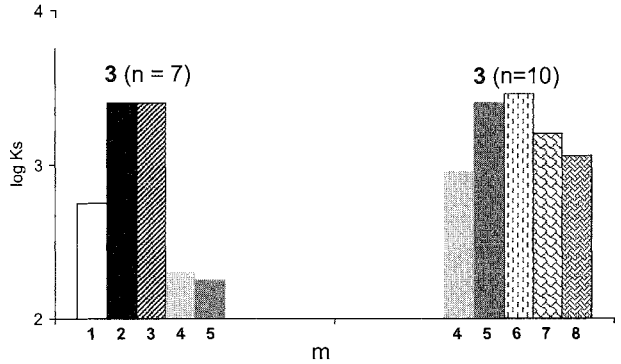

Fig. **2** Stability constants, log K_s, for dicarboxylate, $-O_2C-(CH_2)_m-CO_2-$, binding by **3**. The number in the legend *(m)* is the number of atoms separating the two terminal carboxylate groups, following this formula, $-O_2C-(CH_2)_m-CO_2$. Data were taken from Ref. [13].

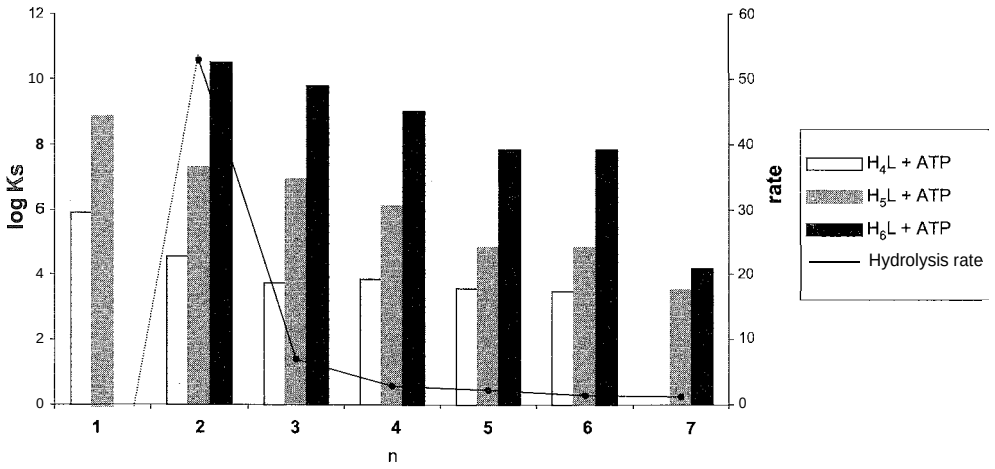

Fig. 3 Stability constants, log K_s, for ATP in H_2O with ***5*** (n=1–7). The solid line represents the first-order rate constant (min^{-1} x 10') for the hydrolysis of ATP catalyzed by ***5*** (n=2–7) at pH 7.0 and 70°C. The dotted line indicates the slow rate observed for 5, rz= 1, which was so slow as to not appear on the scale under those conditions. Data were taken from Ref. [15].

sizes (5) indicated an important correlation between size of the macrocycle and hydrolysis rate"'' (Fig. 3). By covalently attaching an additional recognition site consisting of a pendant acridine unit to enhance binding via a π-stacking effect, higher recognition for nucleotides was achieved. but catalysis was diminished.[16] Recognition of more complex anions such as dinucleotides, NAD, and NADP, was reported for 5 (n=2) and is proposed to occur by virtue of interaction of the receptor with the negatively charged phosphate portion of the dinucleotide.[17]

Anionic Metal Complexes

Large ring polyammonium monocycles also form complexes with a variety of transition metal anionic complexes.[10] Both square planar [e.g., $PdCl_4^{2-}$ and $Pt(CN)_4^{2-}$], and octahedral [e.g., $M(CN)_6^{n-}$; M=Fe, Co, Cr; and Ru: n=3 and 4] complexes were studied. Structural findings often indicate layered structures with protonated polyammonium macrocycles alternating with the anions in linear arrays.[18,19] However, an inclusion complex was observed for a $PdCl_4^{2-}$ complex with ***5***, n=5.[20] As anticipated, affinity tends to increase with increasing charge on the complex and increasing degree of protonation of the macrocycle (Fig. 4). For a given degree of protonation, however, the smaller macrocycles bind more effectively. Binding also tends to influence electrochemical[21] and photochemical[22] properties of these supercomplexes.

BICYCLIC POLYAZAMACROCYCLES

Binding constants for the azacryptands with anions are often two or more orders of magnitude higher than that observed for the corresponding monocycles. Even monoanions show significant affinities (Fig. 1).[1,22–29]

Halides and Pseudohalides

The first examples of bicyclic receptors forming inclusion complexes with anions were the katapinand halide complexes, 6. An equilibrium constant of K>10 was observed for the binding of the $-(CH_2)_{10}-$ bridged receptor with chloride.[1]

The field expanded with the introduction of the linear bis-tren azacryptand **7**,[23] which was found to be exceptionally complementary for encapsulating the linear azide ion, with an aqueous stability constant of log K_s=4.3. Crystallographic studies also indicated halide inclusion within the cavity of 7. While chloride and bromide were observed to be centrally located, fluoride was found to sit off-center, closer to one of the tren units.[23] This latter finding was attributed to the small size of the fluoride as being mismatched with that of the large azacryptand.

More recently, receptors derived from simple Schiff base synthetic strategies were found to bind fluoride and water in the cavity 8 (Ar=*m*-xylyl).[24] In a slightly larger cavity derived from a p-xylyl spacer, two fluorides were bound inside the cavity, bridged by a single water molecule in a type of cascade complex (Ar=*p*-xylyl).[25] The latter motif is reminiscent of the ditopic metal ion cascade complexes observed for these ligands.[30]

A very small azacryptand, 9, binds fluoride with almost unprecedented anion affinity and selectivity, log K=8.8 and log K_F/K_{Cl}=7.6 at pH 5.9.[26] The high binding constant was attributed to a perfect match of cryptand cavity and fluoride size, and it was speculated that the cavity was too small to admit other anions. Subsequent

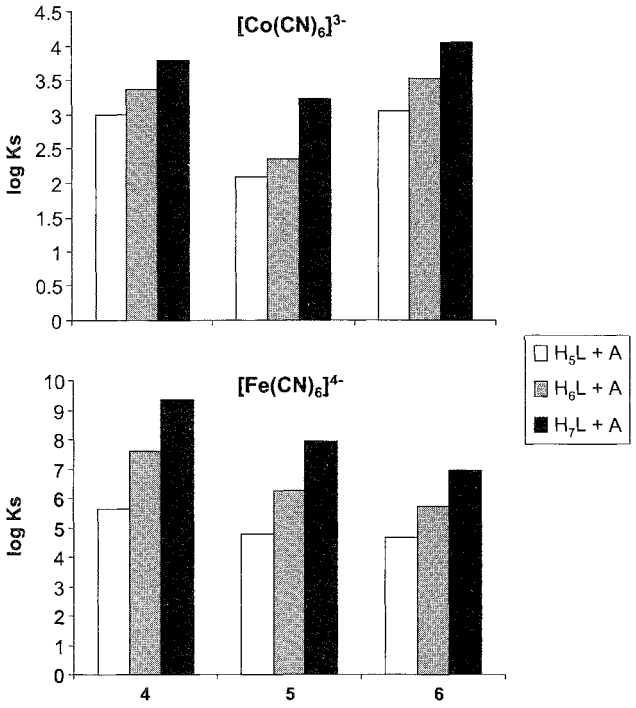

Fig. 4 Coinparison of stability constants, log K_s, for binding of $Co(CN)_6^{3-}$ (top graph) and $Fe(CN)_6^{4-}$ (bottom graph) with 5. as a function of size (n=4–6) and degree of protonation. Data were taken from Ref. [18].

studies, verified crystallographically, showed that the 9 also binds chloride internally at pHs below 2.5, presumably the point of addition of the sixth proton.[31]

Oxoanions

The first example of internal binding of an oxoanion was reported for a perchlorate encapsulated in 8 (Ar=furan).[28] Azacryptands display a variety of binding propensities with oxoanions. Even ditopic nitrate binding was observed with these versatile receptors (8, Ar=*m*-xylyl).[2,29]

Organic Anions

Azacryptands also bind nucleoiides strongly.[31] However, the bicycles are unlike the monocycles in that they are not effective hydrolysis catalysts. This inactivity was attributed to the presence of the steric constraints imposed by the cryptand cavity that might result in a lessened probability of forming a phosphorylated receptor intermediate. As noted, such an intermediate appears to be a key pathway in dephosphorylation, at least in some monocycles.

Dicarboxylates can also be encapsulated as reported for the crystal structure of terphthalate in 10.[32] In a series of linear chain dicarboxylates. $-O_2C(CH_2)_mCO_2-$, PO was found to bind adipate (m=4) better than the longer or shorter dicarboxylates of the series.

POLYCYCLIC POLYAZAMACROCYCLES

The macrotricyclic "soccer ball" ligand, 11, is perhaps the most famous of the polycyclic systems because of its versatility in binding cations such as NH_4^+, anions such as halides; and even a neutral water molecule, depending on its degree of protonation. It is especially well-suited for spherical recognition, incorporating halides inside its cavity with high affinities (log K=4.0) for Cl^-. A number of crystallographic and theoretical studies have been performed,[33] and the latter indicate a complex interplay involving anion and receptor hydration and dehydration, steric effects, and electrostatic interactions.[34]

Another structural motif effective in binding anions is that of two face-to-face 1,3,5-trisubstituted benzenes with bridges containing amines (12). These receptors were observed to bind small anions with some selectivity. In the majority of binding studies, monovalent species such as nitrate and chloride bind more weakly (log $K_s \sim 2.5$) compared to dianions such as sulfate (log $K_s \sim 6.0$).[35] This structural motif was expanded even further in the elegant azaparacyclophane (13). At pH 4, this cubane is tetraprotonated and binds anionic fluorescent molecules such as 1-anilinonaphthalene-8-sulfonate (ANS).[36]

CONCLUSION

The field of anion coordination chemistry has grown tremendously during the last three decades, from the discovery of the simple katapinand receptors to complex. cleverly designed polycyclic systems. Much of the current understanding of the chemistry of anion recognition is the result of key contributions provided by protonated aza-macrocycles, only some of which have been described in this overview. While many types of ligand frameworks now exist for anion recognition and binding, the role of the aza-macrocycles in the early development of this field will always be acknowledged.

INTRODUCTION

Pyrrole is an attractive hydrogen bond donating moiety that has a unique role to play in the design of anion receptors. Unlike amides, ureas, and similar functional groups that often self-associate via C=O···HN interactions, pyrrole does not contain a hydrogen bond acceptor. As such. it does not compete with itself for the hydrogen bonds used to bind potential anionic guests. In spite of this attractive feature, it is only in the last decade that pynoies and pyrrole-containing systems have begun to see application in the area of anion recognition. The first hint that this class of compounds could prove useful as anion receptors came in 1990. when Sessler and Ibers[1] succeeded in crystallizing the diprotonated form of sapphyrin, a pentapyrrolic expanded porphyrin, first prepared by Woodward and coworkers.[2] While expecting to obtain the *bis*-PF_6-salt, what Sessler and Hbers actually found was a mixed F^--PF_6^- complex, wherein the fluoride anion was centrally bound within the diprotonated sapphyrin core. Following this initial serendipitous finding. considerable effort was devoted to developing first sapphyrin and other expanded porphyrins as anion-binding agents and then, subsequently. a range of other pyrrole-based systems.

This work, which has flourished as the result of contributions from numerous research groups. served to establish that pyxole-containing entities far less complex than expanded porphyrins can act as effective anion receptors. In fact, Gale and coworkers recently demonstrated that pyrrole can stabilize an anion complex, at lease in the solid state. Specifically, these latter workers succeeded in elucidating the crystal structure of a pyrrole-chloride complex prepared by crystallizing tetramethylammonium chloride from pyrrole (Fig. 1a).[3] In this structure, direct hydrogen bonding interactions between the chloride anion and two pyrrole NH protons were seen (N···Cl=3.241 Å), as well as ones involving the tetramethylammonium cation. Unfortunately, these interactions were found not to persist in dichloroinethane solution for simple pynoles, at least not to an appreciable extent,[4] underscoring the need to incorporate pyrrole into a complementary host framework in order to bind anions effectively in solution. In this entry, the chemistry of pyrrole-based anion receptors is reviewed, starting from the simplest and moving to the more complex. While this presentation order deviates from that in which many of the systems in question were first introduced historically, we think it provides a better backdrop against which the current state-of-the-art in the field may be most fully appreciated.

ACYCLIC PYRROLIC AND POLYPYRROLIC RECEPTORS

In some respects, the simplest approach to generating pyrrole-based anion receptors involves modifying the pyrrole ring with groups capable of increasing the strength of the receptor-anion interaction. Not surprisingly. this approach attracted the interest of a number of research groups in the last decade. For instance. recently, Gale and coworkers prepared and studied a variety of simple 2,5-diamidopyrrole derivatives, including **1** and **2**.[5] Compounds **1** and 2 proved selective for oxoanions in polar organic solvent. However. they displayed some differences in their individual binding characteristics, with peak association constants of 2500 M^{-1} being

displayed by Compound 1 when binding benzoate anions in acetonitrile-d_3 while a corresponding K_a value of 1450 M^{-1} was observed for the binding of dihydrogenphosphate by Compound 2 in DMSO-d_6/H_2O 0.5%.

In order to confirm the participation of the two amide groups and the pyrrolic NH group in the complexation process, Gale also produced a series of monoamide pyrrole derivatives (compounds 3 and 4).[6] Solution studies revealed that these compounds, while still binding

(View *this art* in color *at www.dekker.com.*)

oxoanions selectively over halides, displayed association constants for the binding of benzoate that were at least an order of magnitude lower did their *bis*-amide analogues, 1 and 2. This finding thus provided important support for the postulate that cooperation between the three NH groups present in 1 and 2 serves to enhance the anion-binding process.

Schmuck and coworkers reported a series of pyssole-functionalired guanidinium species (e.g., Compound **5**)[7] that are excellent receptors for carboxylates. In DMSO solution, the association constant for the formation of the acetate complex of receptor **5**, proved too high to measure accurately ($K>10^6\ M^{-1}$). By moving to a more polar solvent mixture (50% water-DMSO), however, it proved possible to determine the association constant; it was found to be approximately $10^3\ M^{-1}$.[7]

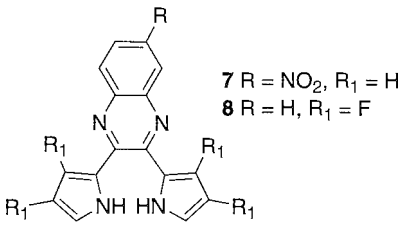
Schmuck also reported the synthesis of a pyrrole-based receptor 6 for *N*-acetyl-α-amino acid carboxylates that functions in aqueous solution.[8] Compound 6 consists of a pyrrole ring substituted in the 2-and 5-positions by an amide group and a guanidinium moiety (Fig. lb). In this case, acetate was found to be the best bound of all the carboxylate anions studied (presumably due to the absence of unfavorable steric interactions). A number of *N*-acetyl-α-amino acid carboxylate anions were also studied (Fig. lb). The identity of the side chain present in these amino acid derivatives presumably serves to modulate the strength of the anion-receptor complex with, for instance, p-stacking interactions between the acylguanidinium residue of the receptor and the aromatic ring of phenylalanine serving to enhance the stability of the 6-Ac-L-Phe complex.

Acyclic pyrrolic optical sensors were recently reported by Sessler and coworkers. Specifically, these researchers investigated the anion complexation properties of dipyrrolylquinoxaline 7 using a variety of anionic guest species including fluoride, chloride, and dihydrogenphosphate.[9] While the addition of 100 molar equivalents of the latter two anionic species to a dichloromethane solution of Compound 7 did not elicit any evident color change. the addition of fluoride anion led to a dramatic yellow to purple color change not only in dichloromethane, but also in DMSO solution. This phenomenon, which is accompanied by a quenching of the fluorescence. was rationalized in terms of the orbital overlap between the pyrroles and the quinoxaline subunits being changed upon complexation of the fluoride anion. The use of 3,4-difluoropyrrole in the synthesis leads to compound 8 that showed an increased affinity for the same anions and a higher selectivity for dihydrogenphosphate over chloride.[10] Hence, Compound **8** shows a naked-eye yellow-to-orange color change upon addition of 100 molar equivalents of fluoride or dihydrogenphosphate anions in dichloromethane solution, and does not undergo any change of color in the presence of the same concentration of chloride anion.

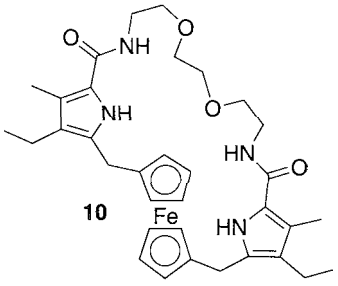
In nature, pyssole also plays a role in the chemistry of anionic species. A class of tripyrrolic linear oligomers (the prodigiosins, e.g., 9), red pigments produced by microorganisms like *Streptomyces* and *Serratia*, and some of its derivatives, are believed to symport HCl and so raise intralysosomal pH.[11] Currently, prodigiosins are being explored for their potentials in treating neoplastic disease and for their potential immunosuppressive activity.[12,13]

MACROCYCLIC PYRROLIC AND POLYPYRROLIC RECEPTORS

Pyrrole-containing macrocycles represent a class of compounds that are widely studied by an increasing number of researchers. In addition to the work with expanded porphyrins and other polypyrrolic systems discussed further in this entry, Sessler and coworkers generated a number of macrocyclic systems containing more isolated pyrrolic subunits. One of the more interesting of these is the bridged dipyrrole *ansa*-ferrocene **10**.[14] This compound contains two pyrrolic NH and two amidic NH groups that combine to make it and its analogues efficient anion receptors. In the specific case of 10, Sessler reported that the binding stoichiometry was dependent on the size of the anionic guest: Job plots highlighted a 2:1 ratio (anion-to-host) for fluoride and a 1:1 ratio for the other anions (chloride, bromide, hydrogensulfate, and dihydrogenphosphate). Quantitative



7 R = NO_2, R_1 = H
8 R = H, R_1 = F

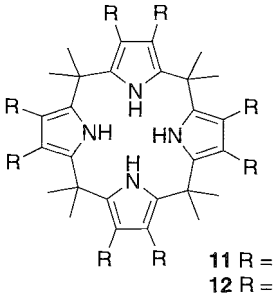


10

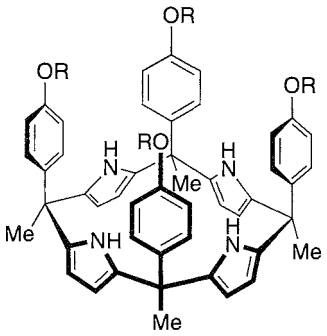
^{1}H-NMR titration experiments also revealed that this macrocyclic receptor possessed an inherent affinity for dihydrogenphosphate, fluoride and chloride over a range of other studied anions. These findings were corroborated by electrochemistry studies that allow detection of a coordinated anionic species through specific cathodic shift of the ferrocene–ferrocenium redox couple. The largest shift was observed in the presence of dihydrogenphosphate anions (136 mV) followed by fluoride and chloride (80 and 24 mV, respectively). Because these observed shifts reflect a number of chemical events. including relative binding to the oxidized ferrocenium and neutral ferrocene forms of the macrocycle, they are not a direct measure of binding per se. Nonetheless, the qualitative correspondence between the electrochemical and NMR analyses is gratifying and is inspiring a range of further work. Simple polypyrrole films were recently prepared and shown to respond electrochemically to the presence of substoichiometric quantities of anions.[15]

Porphyrinogens are a well-known class of compound that have been in the literature for more than a century. However. in the last decade. these molecules emerged as a particularly useful and important class of anion receptors, in part, because they are incredibly easy to make. Specifically. acid catalyzed condensation of pyrrole with a ketone leads to the formation of a tetrapyrrolic macrocycle that is reasonably stable to oxidation and therefore cannot be regarded as a precursor to porphyrin. Rather, they bear a strong structural similarity to calix[4]arenes, a congruence that prompted the authors to re-name these systems as calix[4]pyrroles.[4,16,17] In contrast to the calix[4]arenes, however. meso-octamethylcalix[4]pyrrole **11** and other structurally similar calix[4]pyrroles were found to bind anions such as fluoride and chloride via the formation of four convergent pyrrole-anion hydrogen bonds (Fig. 1c). Wow extensively reviewed, calix[4]pyrroles are used for a variety of applications, including sensing and anion separation technologies.[18]

Acid-cataiyzed condensation of 3,4-difluoropyrrole with acetone produces octailuorinated calix[4]pyrrole that shows enhanced affinity and selectivity for anionic species.[10] Compound **12**, for example, proved to be a better anion receptor than **11**. binding fluoride, chloride,



11 R = H, n =1
12 R = F, n =1

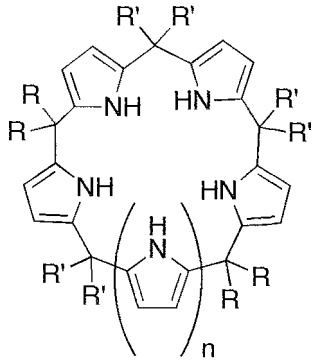


13 R = H
14 R = CH_2COOEt
15 R = CH_2CONEt_2

and dihydrogenphosphate anions with higher association constants than the corresponding unsubstituted systems; they also displayed an increased selectivity for chloride anion over hydrogenphosphate.

In 1999, Sessler and coworkers and, independently, Floriani and coworkers, reported the synthesis of deep-cavity calixpyrroles (e.g., **13**) formed from the condensation of 4-hydroxyacetophenone and pyrrole.[19,20] The $\alpha\alpha\alpha\alpha$-isomer of this species may be isolated by column chromatography or by fractional crystallization. Gale and coworkers recently reported the synthesis of ''super-extended cavity'' calix[4]pyrroles **14** and 15 in which the selectivity for fluoride is considerably increased in DMSO solution.''' No other anion is bound in this solvent, even in high concentrations (i.e., substoichiometric quantities of fluoride are bound in the presence of 100 equivalents of chloride that do not interact with the receptor).

In contrast to what is true in the case of the non-fluorinated calix[*n*]pyrroles where it has proven difficult to isolate species with $n > 4$. the synthesis of Compound 12 led to the two isolable and kinetically stable higher-order

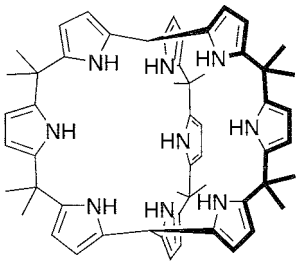


16 R = R' = F, n = 1
17 R = R' = F, n = 4
18 R = R' = H, n = 4
19 R = Ph, R' = Me n = 2

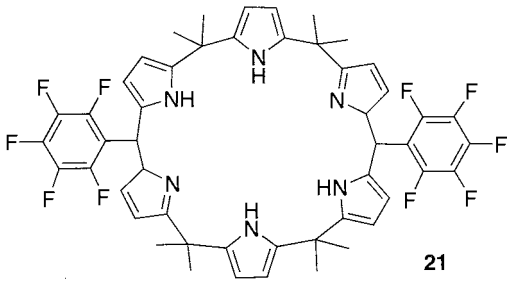
by-products, namely. the calix[5]pyrrole **16** *and the* calix[8]pyrrole **17**.[22] *Chloride was selectively* co-ordi*nated by compound* **16** *with an association constant of* 41.000 M^{-1} *in acetonitrile containing* 0.5% D_2O, *a value that proved to be a factor of four greater than recorded using the* corresponding *(but smaller)* octafluorocalix[4]-pyrrole **12**.

*Other approaches to the synthesis of higher-order calixpyrroles were pursued. For instance. the synthesis of meso-*dodecamethylcalix[6]pyrrole *18 from the previously known furan-based analogue was reported by Kohnke and coworkers."''* This *higher-order calixpyrrole was found to be a better receptor for chloride than the corresponding meso-*octamethylcalix[4]pyrrole *11, probably due to the larger core size of the macrocycle. Transport experiments from an aqueous solution to a DCM solution also revealed Compound 18 to be ca. 10 times more selective for chloride anion than Compound 11. Meanwhile, Eichen used a step-wise procedure to prepare the* calix[6]pyrrole **19** *and demonstrated that it shows a selectivity for larger anions. Specifically,* ^{1}H-NMR *titration experiments carried out in* acetonitrile-chloroform (1:9) *revealed that this system shows a preference for iodide anion over the other* halides.[24]

Recently, Sessler and coworkers reported the first example of cryptand-like calix[4]pyrrole (**20**).[25] *Compound 20 provides three identical binding cavities, leading to the consideration that it could stabilize* anion-*receptor complexes of* 1:1, 1:2, *or 1:3 stoichiometry in solution. In point of fact,* ^{1}H-NMR *experiments carried out in* dichloromethane-d_2 *and* THF-d_8 *revealed* host–*guest* stoichiometries *that* were *even more complicated and depended directly upon the anion considered. For instance. fluoride. when added as an anionic guest, was found to be bound to six of the nine pyssolic subunits.* presumably *in a* 1:1 *fashion. By contrast, it was proposed that the chloride anion interacts with two molecules of Receptor 28 in* solution (i.e., 2:1 *host-to-anionic guest binding stoichiometry)* and is *bound with a stability constant of 3.08 x 106* M^{-2} *in* dichloromethane-d_2 so*lution. Finally. a* 1:2 *(host-to-guest) stoichiometry was observed* upon *addition of nitrate with the stability constants* K_1 *and* K_2 *being* 1740 *and 420* M^{-1}, *respectively, in* dichloromethane-d_2 *solution.*



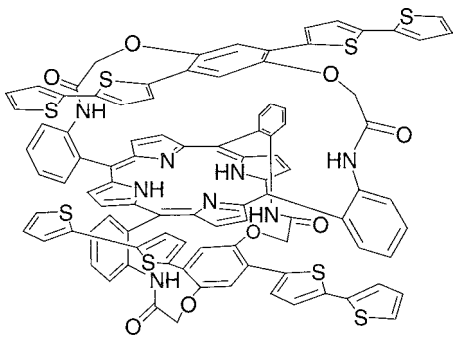
20

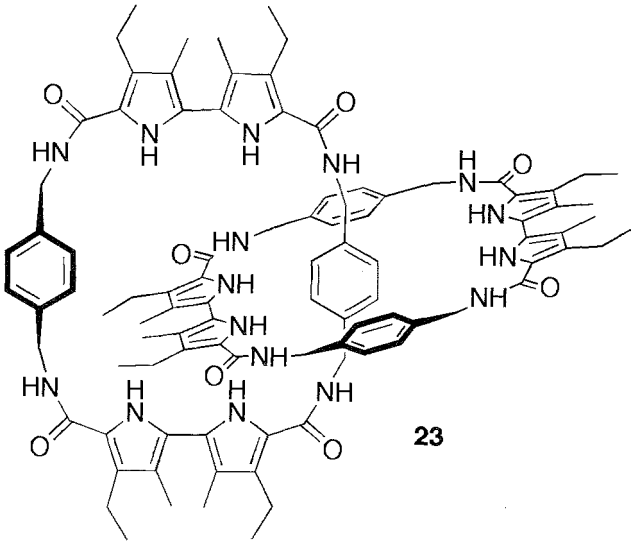


21

In the year 2000. Sessler et al. reported the synthesis of several so-called calix[*n*]phyrins, *macrocyclic compounds that may be regarded as hybrids of* calixpyrroles *and* porphyrins.[26] *Compound 21, a novel hexapysrolic system, was generated by reaction of* pentafluorobenzalde*hyde with an appropriate* tripyrrane *precursor (obtained, in turn, from the TFA acid-catalyzed condensation of pyrrole and acetone). The crystal structure of this compound reveals a molecule of water bound to the pysrolic NH protons, a finding that led to the suggestion that this system could* function *as* an *anion receptor. However. no interaction was observed between Compound* **21** *and any of a range of targeted anions (chloride. bromide, iodide, nitrate. hydrogensulfate), at least when this putative receptor was studied in its neutral form. On the other hand, both the mono- and bis-*protonated *forms were found to interact with chloride,* bromide, *and iodide anions. Unfortunately, only in the case of the latter anion and only when 21 was fully* (i.e., *di-) protonated was evidence for the formation of a clean* 1:1 *host–guest complex obtained; in this instance. an association constant of ca. 8 x* 107 M^{-1} *was estimated for a binding process involving the interaction between iodide anion and diprotonated* **21** *in acetone solution.*

Modified porphyrins have *been used to bind* anions *selectively. In* 2001, *Swager and coworkers reported the synthesis of the doubly strapped* porphyrin **22**;[27] *this compound proved to be able to coordinate two fluoride*

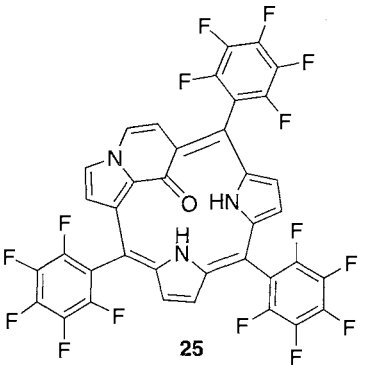




23

anions via a cooperative binding process in dichloromethane solution. Addition of larger anion such as chloride, bromide, iodide, acetate. cyanide, and dihydrogen phosphate, did not lead to perturbation of the UV spectrum. leading to the suggestion that they were not appreciably bound.

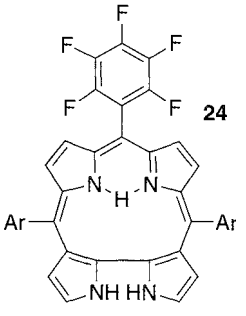
Sessler. Vogtle. and coworkers reported the first example of a dipyrrole-based[2]catenane.[28] Compound 23 was synthesized from the appropriate bipyrrole acyl chloride and p-xylenediamine building blocks. ^{1}H, ^{13}C, and ^{19}F-NMR studies carried out in 1,1,2,2-tetrachloroethane-d_2 provided evidence consistent with this compound being able to bind fluoride anions effectively as the result of changing its conformation in solution to accommodate the guest anionic species. Even more interesting results came from the coordination studies carried out in 1,1,2,2-tetrachloroethane-d_2. In this solvent. it was found that anionic species, such as chloride and dihydrogenphosphate, are bound to Compound 23 with a stability constant higher than that of fluoride. These findings led to the suggestion that these larger anions may be binding between the two rings of the catenane.



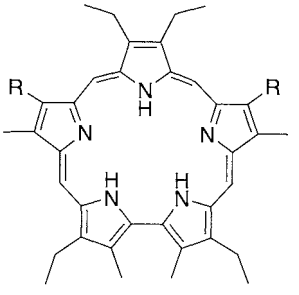
25

The tetrapyrrolic macrocycles discussed so far all contain an arrangement of inward-pointing nitrogens within the molecule core. Recently, N-confused porphyrins. tetrapyrrolic macrocycles in which some of the pyrrolic subunits are linked through at least one β position, were studied by a number of groups including Latos-Gražyński,[29] and the team of Osuka, Furuta, and coworkers.[30] One example of this class of compounds. tetrapyrrole 24, was synthesized via the acid-catalyzed condensation of an N-confused dipyrromethane with pentafluorobenzaldehyde. While this product proved to be stable in air at room temperature, treatment of 24 with $SnCl_2$ for 8 h while heating in benzene at reflux was found to give rise to the fused system 25 in 6% yield. This latter compound proved capable of coordinating anionic species with association constants comparable to those of typical: unsubstituted calix[4]pyrroles (e.g., $K_a \approx 10^4\ M^{-1}$ for fluoride anion in dichloromethane-d_2).

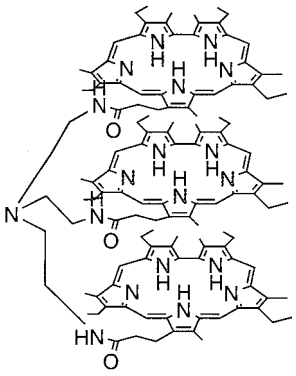
The potential advantages associated with the presence of a large central binding core containing a large number of potentially coordinating heteroatoms led to a renewed interest in expanded polypyrrolic macrocycles. Sapphyrin (Fig. Id). the first pyrrole-based anion receptor to be characterized as such (c.f., "Introduction"), belongs to this class of compound and remains one of the better studied of all anion-binding agents.[31] The synthesis of



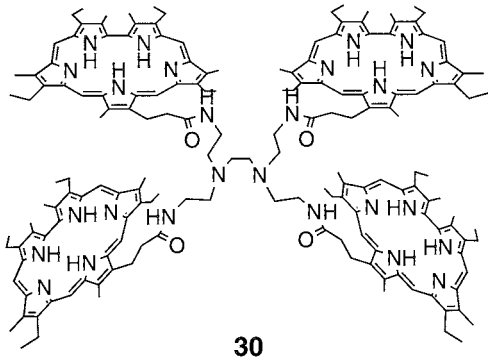
24



26 R = Et
27 R = $(CH_2)_2CH_2OH$



28



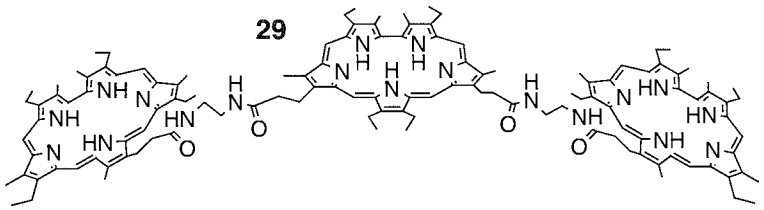
30

these compounds (e.g., 26, 27), which was recently reviewed,[31] was achieved by a variety of means, with those based on direct condensations of pyrrole and appropriately chosen linear oligopyrroles remaining the most popular. Sapphyrins are planar, rigid molecules that possess an aromatic 22 x-electron periphery. Sessler and coworkers reported a complete structural and solution study of this class of compound.[32,33] As noted in the introduction. the diprotonated forms of sapphyrins are capable of encapsulating fluoride in the solid state, holding the anion by a pentagonal array of N–H···F hydrogen bonds within a ca. 5.5 Å diameter core (Fig. 1e). Other anions are also coordinated by the diprotonated formo f sapphyrin but are not centrally bound. as is true for fluoride anion. For example, solid-state studies of the *bis*-HCl salt of sapphyrin revealed the presence of a 2:1 (chloride-to sapphyrin) complex with the two anions being held by N–H···Cl hydrogen bonds ca. 1.8 Å above and below the rnacrocycle (Fig. 1f). Presumably as a result of this structural difference and the enhanced ability of fluoride anion to act as a hydrogen bond acceptor relative to other anions, the diprotonated form of sapphyrin acts as an unique and selective fluoride anion receptor, exhibiting a selectivity at least $\geq 10^3$ relative to chloride or bromide.

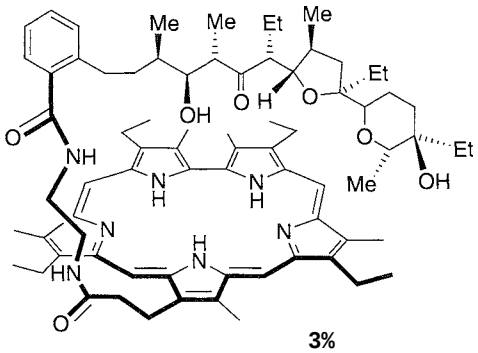
The selectivity displayed for F-relative to other halide anions encouraged Sessler and coworkers to investigate whether sapphyrin would act as a fluoride anion carrier in a model three-phase H_2O-CH_2Cl_2-H_2O bulk liquid membrane transport system.[34] When two aqueous solutions; with different fluoride anions concentrations, were separated by a dichloromethane solution, slow transfer of fluoride anions from the more concentrated to less concentrated aqueous phases was observed, due to simple diffusiono f the anionic species. The addition of an organic-soluble sapphyrin to the dichloromethane phase. however. led to a considerable increase in F-transport flux o (greater than 100-fold in the best of cases), at pH 7.0. a regime wherein sapphyrin is known to be mono-, not di-, protonated.

Diprotonated sapphyrins were also found to bind rnonobasic phosphate anions in solution and in the solid state.[32] The same proved true for monoprotonated sapphyrins, at least in polar protic solvents. This led Sessler and Iverson to consider the possibility that sapphyrins might interact with DNA.[35] Consistent with this proposition, it was found that addition of an excess of calf thymus dsDNA (ca. 200 phosphate anion equivalent) to an aqueous solution of the water-solubilized sapphyrin 26. produced an 11 nm bathochromic shift in the sapphyrin Soret band. This spectroscopic change gave an apparent stability constant of 25,000 M^{-1}. A range of follow-up experiments, including ones based on ^{19}P-NMR spectroscopy, circular dichroism studies, and DNA topoisomerase I unwinding analyses, led to the conclusion that protonated sapphyrin gives rise to a new type of small-molecule-DNA interaction that involves the specific chelation of the anionic phosphate diester group by the protonated sapphyrin. Of particular interest is the fact that this kind of interaction differs substantially from other previously reported DNA-binding motifs, including the intercalation-based ones most often invoked in the case of porphyrins.

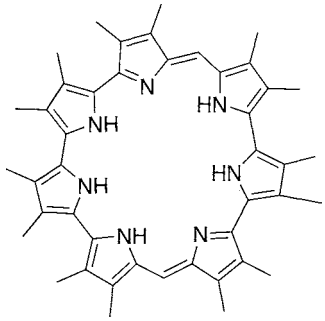
In 1995. Sessler and coworkers reported the synthesis of several novel oligosapphyrins and highlighted the efficiency of these species as potential carriers for the



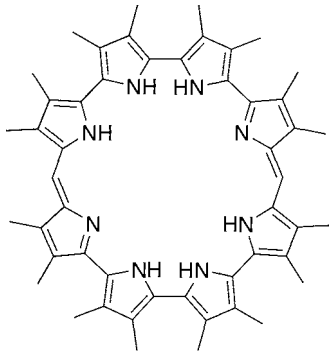
29



3%



32



33

transport of phosphorylated nucleotides.[36] The trimers 28 and 29 (linear and branched) and the tetramer **30,** showed two distinct Soret bands in the UV spectrum, a clear sign of considerable aggregation. Addition of phosphate anion was found to induce an increase in the intensity of the higher wavelength portion of the split Soret-like band at the expense of the one at the lower wavelength. This behavior may be explained by considering the encapsulation of the anionic species followed by the de-aggregation of the oligomer in solution.

The next step was the employment of Compounds 28, 29, and 38 as carriers for the transport of nucleotides across bulk liquid membranes. This was done using the same kind of U-tube setup used to study halide anion transport. Under these condiditions, Compounds 28 and 29 were found to be efficient carriers for nucleotide diphosphates. However, they failed to effect the transport of nucleotide triphosphates. By contrast, Compound **38** proved to be an effective carrier for all the phosphorylated species under consideration.

In 1996 Sessler and coworkers reported the synthesis of a new Lasalocid modified sapphyrin **31**[37] that acts as an efficient carrier for the transport of aromatic amino acids in their zwitterionic form. Again, a standard H_2O-CH_2Cl_2-H_2O U-tube transport model was used to determine the transport efficiency of Compound **31**. This receptor showed not only a high selectivity for phenylalanine and tryptophan (K_t=20 for L-Phe), but was also found to be capable in some cases of discriminating between the different chiral homologues.

More expanded pyrrole-based macrocyles were recently reported in the literature. In 1999. Sessler and coworkers presented the synthesis of[30] heptaphyrin *(1.0.0.1.0.0.0)* 32 and of[13] octaphyrin(1.0.0.0.1.0.0.0) **33**.[38] These compounds, synthesized via a directed oxidative ring closure of linear polipyrrolic species, were crystallized in their diprotonated forms in the presence of

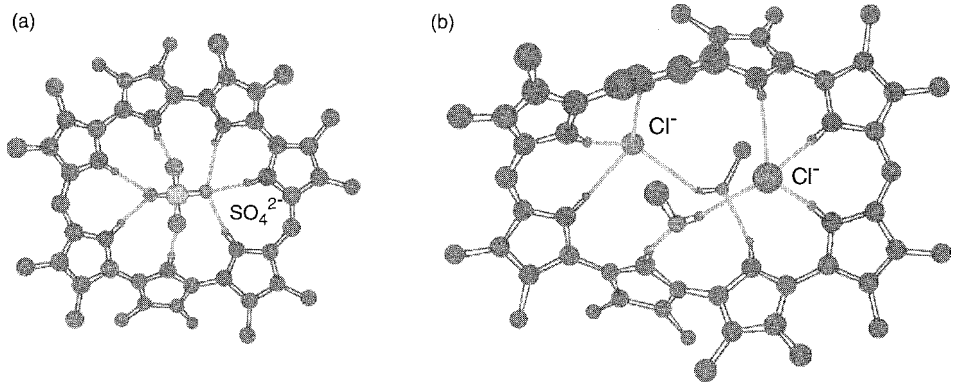


Fig. 2 (a) The crystal structure of the sulfate complex of Compound 32 (note that sulfate is bound by seven hydrogen bonds) and (b) the chloride complex of Compound **33** (including methanols involved in the hydrogen-bonding array). (View *this art* in *color at www.dekker.com.*)

sulfate and chloride anions, respectively. While compound 32 was found to encapsulate a sulfate anion within the macrocyclic core via seven hydrogen bonds in a manner reminiscent of the sulfate-binding protein,[''] and to assume a planar conformation (Fig. 2a), Compound **33,** larger and more flexible, was found to bind two chloride anions while deviating substantially from planarity (Fig. 2b). The latter binding mode is reminiscent of what is seen in the solid state for various anion complexes of a range of other protonated expanded posphyrins, including ones with rather fanciful names such as rubyrin,[40] rosarin,[41] amethyrin,[42] and turcasarin.[43] Unfortunately, as yet, there is little in the way of solution phase K_a information to support these recently reviewed solid-state analyses.[44]

CONCLUSION

Over the last decade. pyrrole has emerged as an important structural motif that may be used to construct receptor systems capable of interacting effectively and, in many instances, selectively with a range of anionic substrates. While early work concentrated on the use of so-called expanded porphyrin systems to impart a high degree of preorganization and provide systems with intrinsic, protonation-derived positive charge, increasingly it has come to be recognized that a range of simpler pyrrole-containing systems can be used to bind and recognize anions, but often at the price of selectivity or affinity. As a result. effort continues to be devoted to the synthesis and study of increasingly elaborate macrocyclic and polycyclic systems, just as attention continues to be focused on finding easier-to-make pyrrole-based anion receptors that can be readily exploited in a range of real-world applications running the gamut from sensing and transport to perhaps ultimately waste remediation and tailored drug development.

Racks, Ladders, and Grids

Marius Andruh
University of Bucharest, Bucharest, Romania

INTRODUCTION

The self-assembly processes of metal complexes into highly organized architectures (racks. ladders, grids, helicates, cages) represent one of the most important topics in supramolecular chemistry. Beyond the beauty of these supermolecules. the various topologies of the metal arrays generate interesting optical, redox, magnetic, or catalytic properties, with potential applications in nanotechnology.

Two components are necessary in every synthetic approach leading to inorganic supramolecular architectures: the suitable designed organic ligand and the metal ion. The spontaneous generation of the supramolecular entities is based on metal-ion-directed self-assembly. In the language of supramolecular chemistry, the ligand is a programmed species. that is, an organic molecule with binding sites in a correct arrangement. with encoded information that is read by the metal ion according to its coordination algorithm (stereochemical preference).[1] The main feature of the instructed polytopic ligand consists of the position and the high selectivity of its coordination sites (a polytopic ligand contains at least two coordination sites). The identity of the coordination sites (''pockets'') is given by their ability to selectively interact with metal ions having a dominant coordination geometry. For example. tetrahedral pockets (with bidentate coordination site) will recognize metal ions with a marked preference for the tetrahedral stereochemistry (Ag^{+}, Cu^{+}), while the octahedral pockets (with tridentate coordination sites) prefer transition metal ions such as Ni^{2+}, Fe^{2+}, Ru^{2+}, Os^{2+}, which currently exhibit the octahedral coordination geometry.

Racks, $[n]\boldsymbol{R}$, ladders, $[2n]\boldsymbol{L}$, and grids, $[m \times n]\boldsymbol{G}$, (Fig. 1) are examples of inorganic superstructures, which are obtained through the spontaneous and correct sequential interaction between different and highly instructed components ($[n]$, $[2n]$, and $[m \times n]$ specify the number of the metal ions in the R. $\boldsymbol{L}$, and $\boldsymbol{G}$ structures). All these architectures are the result of the thermodynamic driving force. which leads to discrete species. rather than to coordination polymers. They have in common linear polytopic ligands as building elements, which can bridge a preestablished number of metal ions. Several ligands of this type are depicted in Fig. 2.

In the realm of supramolecular synthesis. the construction of rack, ladder. and grid architectures represents a particular case of self-assembly. which relies on the three basic levels of operation of a programmed supramolecular system: recognition (selective interaction of complementary components): orientation (building up the structure through the correct spatial disposition of the components): and termination. that is, the formation of the desired discrete supramolecular entity.''

RACKS

A molecular rack. $[n]\boldsymbol{R}$, is constructed from linear n-topic ligands, which connect n metal ions in a linear arrangement. as well as from ancillary ligands attached to the metal ions, playing the role of platforms (Fig. la). If the polytopic ligand contains octahedral pockets. that is, tridentate moieties. than the ancillary ligand must be tridentate as well, in order to fulfill the octahedral stereochemistry of the metal ion. The first dinuclear and trinuclear racks (Fig. 3) were obtained by coordination of linear ligands of type **L5** (octahedral pockets) to $Ru(terpy)^{2+}$(terpy stands for 2,2′:6′,2″-terpyridyl) (Fig. 3a).[2] Complexes of this type are redox active. For the ruthenium trirnetallic complex. $[3]\boldsymbol{R}$, the cyclic voltammogram indicates the inequivalency of the Ru sites: the central ruthenium atom, located between two dipositive centers, is more difficult to oxidize (+1.88 V) than the terminal ones (+1.47 V).

The rack-type architecture can be assembled also from tetrahedral metal ions, e.g., Cu^{+}. linear polytopic ligands with tetrahedral pockets (E1). and bidentate ligands such as phenathroline or 2.2'-bipyridyl. One example is illustrated in Fig. 3b. It is a rigid rack of rotaxane-type. the ancillary ligand being a macrocyclic molecule with a 1.10-phenathroline moiety.[3]

LADDERS

The ladder topology. $[2n]\boldsymbol{L}$ (Fig. lb) can be obtained by using. as ladder sides. two linear polytopic ligands

Encyclopedia of Supramolecular Chemistry

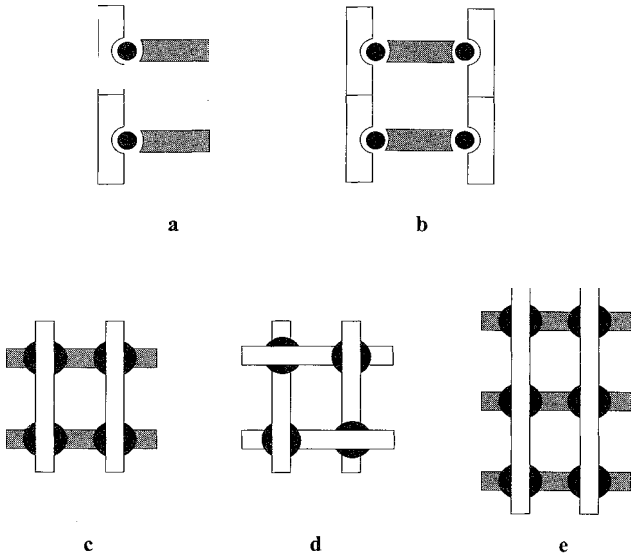

Fig. 1 Inorganic supramolecular architectures of (a) rack, [2]*R*; (b) ladder. [2·2]*L*; (c) square grid. [2 x 2]*G*; (d) chiral [2 x 2] grid; ie) rectangular [2 x 3] grid.

arranging the metal ions in parallel chains, which are further interconnected by ancillary bridging ligands (ladder steps). If the assembling cation is Cu^+, then linear polytopic ligands of type **L1** (Fig. 2a) are suited. Bipyrimidine derivatives are used as bridging ligands connecting the metal ions from two different chains (Fig. 4).[4] The orthogonality of the ligand components. which gives the orthogonality between the ladder sites and the inner "rungs," is provided here by the tetrahedral geometry of the metal ions. The formation of the [2*n*]*L* architecture, by reacting the three components (metal ions, rod-like and ancillary bis-chelating ligands) in the 2*n*:2:*n* molar ratio, illustrates a key concept in the supramolecular synthesis, namely the multicomponent self-assembly, which means that the well-defined superstructures are spontaneously generated from a larger set of components (at least two types of ligands, metal ions)."]

By mixing in the same solution two different linear ligands (**L1**, with $x=0$, and E1 with $x=1$), tetraphenylbipyrimidine, and $[Cu(MeCN)_4](PF_6)$ in the molar ratio 1:1:2.5:5, after 72 h only two products were formed, namely, the [2·2]*L* and [2·3]*L* species. This means that the 19 particles of four different types strictly follow the operations of two programs, which generate the two well-defined nanoarchitectures. each constructed from two different ligands. This is an example of an instructed mixture. with components that assemble according to two parallel programs, without crossover between the two superstructures. The instructed mixture paradigm opens wide perspectives in supramolecular synthesis.[1]

Molecular ladders with finite dimensions are still scarce. Much more numerous are the one-dimensional. infinite ladder structures. Such architectures, which are obtained serendipitously rather than intentionally, are constructed from metal ions and *exo*-bidentate ligands. From the most popular ligands. we recall here the *bis*-(4-pyridyl)-derivatives.[5,6] Both homo-and heterometallic systems with one dimensional ladder structures are characterized.

GRIDS

The molecular grid. [in x *n*]*G*, consists of a square ($m=n$) or a rectangular-matrix array of metal centers (Fig 1c,d,e) Square grids. [*n* x *n*]*G*, based on metal ions with tetrahedral coordination geometry (Cu^+, Ag^+), are constructed from n-topic, rigid, rod-like ligands with tetrahedral pockets and n^2 metal ions Alternatively, polytopic ligands with octahedral pockets may generate grids by interacting with octahedral metal centers In general, the ligands are divided into two sets, one above and one below the plane of the metal ions

Square Grids

One of the first square grids was obtained by combining a tritopic rigid ligand (**L2**, $x=2$) with tetrahedral Ag^+ ions: $[Ag_9(L2, x=2)_6](CF_3SO_3)_9$. The correct self-assembly of the 15 particles into a [3 x 3] grid was proved by means of NMR spectroscopy (^1H, ^{13}C, ^{109}Ag) and x-ray diffraction studies.[7] The ^{109}Ag-NMR spectrum recorded in D_3-nitromethane (566.06. 507.56, 406.13 ppm) is consistent with the three types of Ag^+ ions in a molar ratio 4:4:1 (four silver ions located at the corners, four silver ions at the four edge mid-positions, and the last one located at the central site).

If the cavity within a square grid is enlarged. then it can accommodate a guest molecule with appropriate size. The dimensions of the cavities can be tuned by using ligands with a larger separation between binding sites. Such a ligand. **L4** (R=C_6H_5), is represented in Fig. 2a. It contains tetrahedral pockets. The tetracopper grid is obtained almost quantitatively in nitromethane.[8] Single crystals were obtained by slow diffusion of benzene into a nitromethane solution of the tetrametallic system. The cationic grid possesses an internal box-shaped void with the dimensions: 4.2 x 3.8 Å, and 12.5 Å depth. The internal box of the grid is sufficiently large to accommodate six guests: four benzene and two nitromethane molecules.

Oligophenathrolines (**L3**, Fig. 2a) are also suited as scaffolds for the construction of grids. The reaction of ligands of type **L3** (R=anisyl, *p*-C_6H_4-OCH_3, or tolyl, p-C_6H_4-CH_3) with Cu^+ led to interesting tetranuclear square grids.'" Two additional uncoordinated ligands are hosted. one above and one below the interstitial space. generating

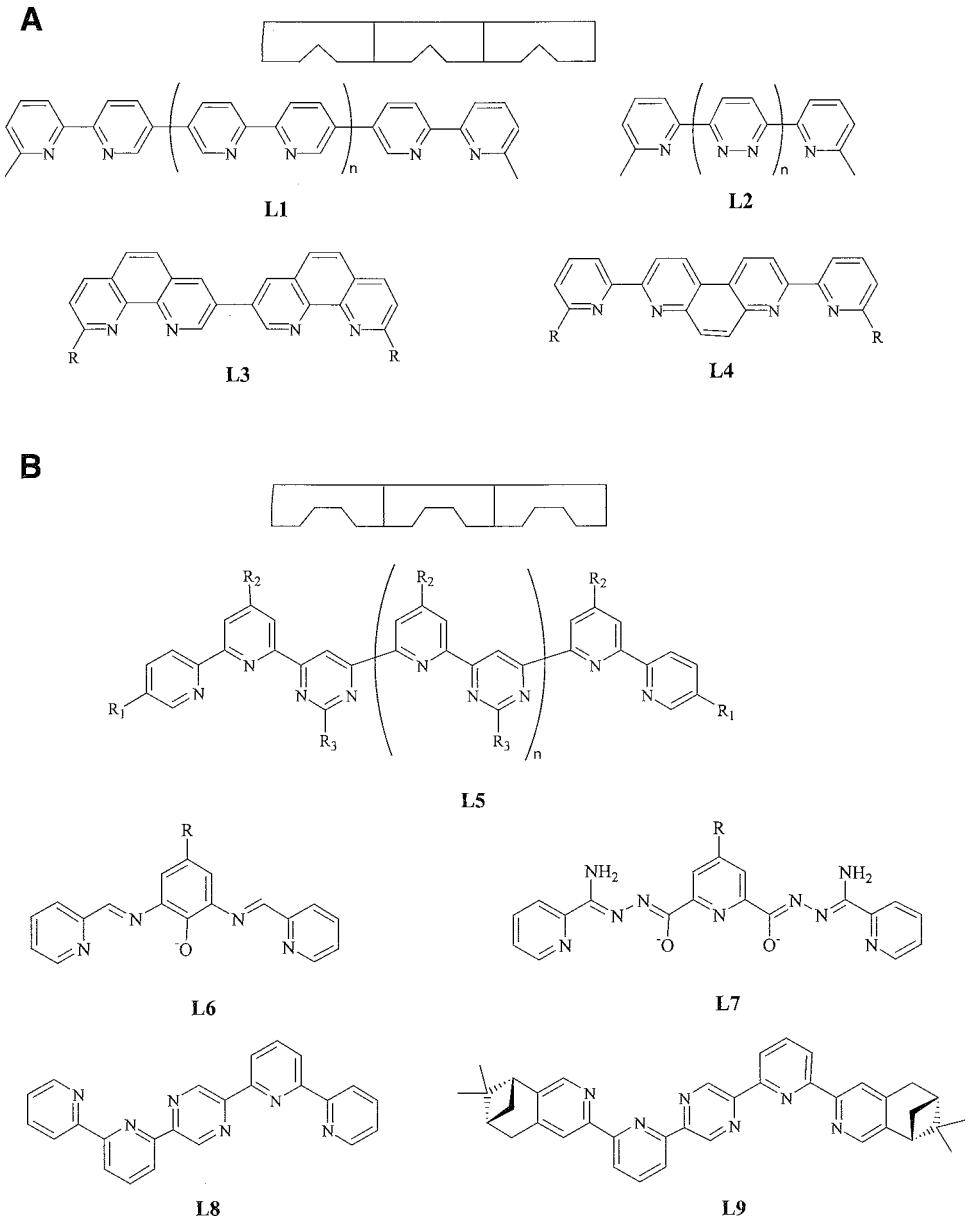

Fig. 2 Linear ligands used to generate racks. ladders, and grids: (a) polytopic ligands with tetrahedral pockets; (b) polytopic ligands with octahedral pockets.

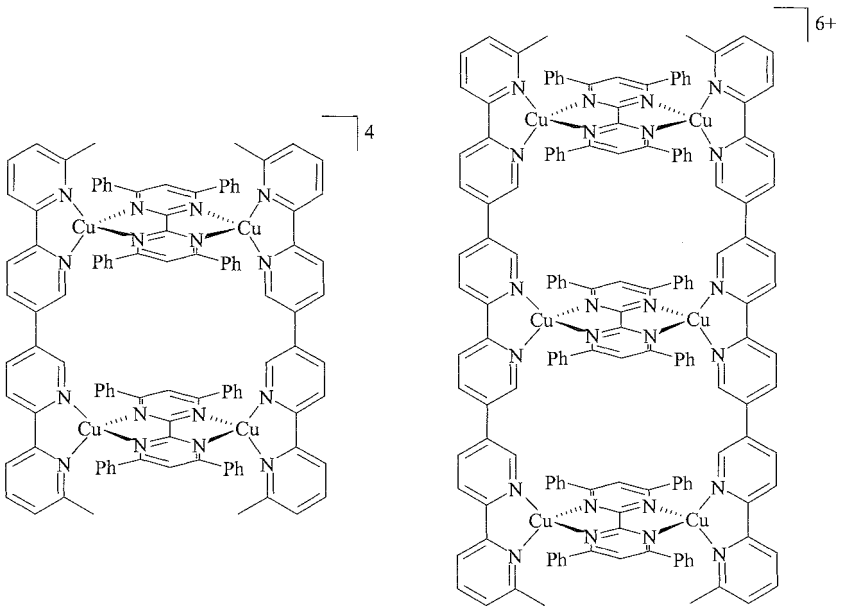
r

a 3 x 3 grid (3 here means the number of rods). The hosted biphenathroline molecules (R=anisyl) can be reversibly exchanged with two molecules of the tolyl derivative. The use of the mesityl derivative did not lead to the expected grid architectu e.

Numerous square grids were obtained by using linear ligands with octahedral pockets. **L5** (Fig. 2b) and appropriate assembling cations: Fe^{2+}[2 x 2],[10] Co^{2+}[2 x 2],[11] Zn^{2+}[2 x 2],[11] Pb^{2+}[2 x 2], [3 x 3], [4 x 4].[12] The crystal structures of all these grids were solved. The Zn^{2+} and Co^{2+} ions display a distorted octahedral stereochemistry. The Zn···Zn distances vary between 6.584 and 6.767 Å, while the Co···Co distances lie in the range 6.453–6.570 A. In both compounds. the ditopic ligand is of type **L5** with x=0, R_1=R_2=H; R_3=C_6H_5. The phenyl ring attached to the pyrimidine moiety plays an important role in the high stability of the tetranuclear complexes, being involved in interligand n – n stacking interactions. The tetrazinc grid exhibits a strong luminescence at 450 nm upon irradiation at 335 nm. at room temperature, while the uncoordinated ligand shows only a weak emission at about 410 nm, when irradiated at 272 nm. The strong



a b

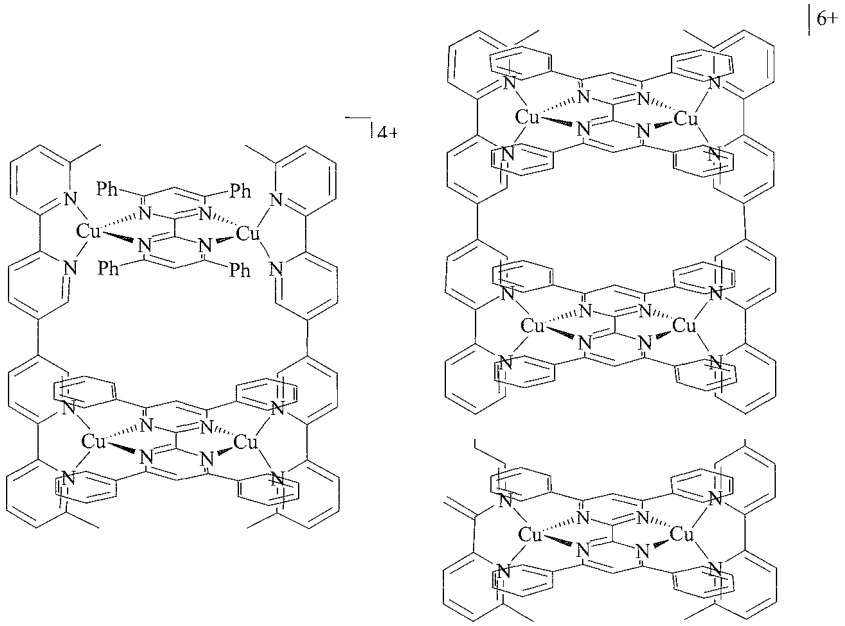
Fig. **3** Racks: (a) rack constructed from octahedral Ru(II) ions; (b) rotaxane-type rack constructed from tetrahedral Cu(I) ions.

luminescence of the tetrametallic grid is due to the rigidity of the complex, which decreases the radiationless decay. The tetracobalt grids are redox active. A unique electrochemical behavior was emphasized for the above-discussed [Co^{II}_4] grid: the cyclic voltammogram recorded at $-20°C$ shows 10 well-resolved, completely reversible reduction steps (from -0.59 to -2.73 V) involving 11 electrons.[13] These are ascribed to $Co^{2+} \rightarrow Co^{1+}$ processes. as well as to ligand localized reductions. A similar system (**L5**, $x=0$. $R_1=R_2=R_3=H$) was investigated.[14] The reduction processes of the cobalt(II) ions (-0.14, -0.24. -0.44. -0.83 V) occur at less negative potentials than, for example. $[Co(terpy)_2]^{2+}$. One of the reasons is the high charge of the tetranuclear grid, which makes it easier to reduce.[14]

The stereochemistry of Pb^{2+} in the corresponding [2 x 2] grid is interesting: it is a hemidirected structure. in which the nitrogen atoms from the ligands (**L5**, $x=0$. $R_1=R_2=R_3=H$) are coordinated to only one part of the coordination sphere of the lead ions. This is due to the presence of the stereochemically active electronic lone pair in the Pb^{2+} ions. The average distance between the lead atoms is 6.51 Å. The structure of the [4 x 4]-Pb_{16} grid was established by means of ES mass spectrometry and NMR spectroscopy. The ^{207}Pb-NMR spectrum shows three signals in a 1:2:1 ratio, corresponding to three types of lead cations: four at the corners; eight at positions 2 and 3 on the edges. and four in the interior. It is a spectacular case. where 24 components self-assemble through the formation of 96 coordination bonds, leading to the exclusive formation of the hexadecanuclear complex in the solution.

The case of the tetrairon(II) grid (**L5**, $x=0$, $R_1=R_2=H$; $R_3=C_6H_5$) is particularly interesting: at room temperature (293 K). three out of the four iron(II) ions are in high-spin (HS) state ($S=2$), with Fe–N distances ranging between 2.086(5) and 2.287(4) Å. For the fourth iron(II) ion, the Fe–N distances are shorter [1.977(5)–2.162(4) Å], values which are intermediate between those expected for HS and LS (low-spin, $S=0$) Fe(II) ions. At 100 K, three out of the four iron(II) ions display distances intermediate between LS and HS but closer to LS state [Fe–N: 1.895(6)–2.117(5) Å], while the fourth ion is in HS state [Fe–N: 2.116(6)–2.282(5) Å]. This is an indication that the iron(II) ions here are subject of a spin-transition phenomenon. Clear information on the spin state of the iron(II) ions, both at room and low temperatures. is obtained from Mössbauer spectroscopy and from the magnetic measurements. At room temperature. the value of the $\chi_M T$ product (10.0 $cm^3 mol^{-1} K$) corresponds to three HS iron(II) ions and one LS iron(II) ion (χ_M is the molar magnetic susceptibility). By lowering the temperature. $\chi_M T$ decreases. reaching a value of 5.6 $cm^3 mol^{-1} K$ at 30 K. The spin transition of the tetrairon grid was induced also by light (LIESST effect) or by pressure.

Other ligands displaying octahedral pockets and able to generate [2 x 2] and [3 × 3] grids are presented in Fig. 2b: **L6** and **L7**. They have in common the presence of the



a **b**

Fig. 4 Ladders: (a) a [2·2]***L*** architecture: (b) a [2·3]***L*** architecture.

mononegatively charged oxygen atoms, which can bridge two metal ions. The self-assembly process involving ligand **L6** (Fig. 2b) and Cu^{2+} ions leads to a tetranuclear complex of [2 x 2] grid type.[15] The copper(II) ions are connected through phenoxo bridges and adopt a distorted bipyramidal stereochemistry. The exchange interaction between the copper(II) ions located on the edge of the square described by the inetal ions was found to be weak antiferromagnetic ($J = -0.4$ cm^{-1}). The heptadentate ligand **L7** (R=H) combines with Mn^{2+}, Fe^{3+}, or Zn^{2+} ions. resulting in a nonanuclear [3 x 3] grid system with alkoxo-bridged metal ions.[16,17] The cryomagnetic investigation of the manganese(II) derivative reveals an antiferromagnetic exchange interaction between the metal ions within the nonanuclear $[Mn_9(\mu\text{-}O)_{12}]$ grid ($J = -4.6$ cm^{-1}). The crystal structure of this nonanuclear complex is represented in Fig. 5.

An alternative way to design grids (Fig. 1d) consists of the use of ligands of **L8** type (Fig. 2b). They have an important peculiarity: the orientation of the "binding vectors" of the two terpyridine moieties is antiparallel, so they coordinate to the two metal ions once above and once below the plane of the four metal ions. Moreover, the resulting grid, with a D_4 symmetry, is chiral. The self-assembly process between **L8** and Zn^{2+} ions leads to a racemic, crystallizing in the centrosymmetric *C2/c* space group."'' In order to obtain only one enantiomer, the ligand **L9** was "chiralized" by introducing pinene moieties (**L9**). The combination of **L9** with Zn^{2+} ions results in a chiral grid. The crystal contains only one diastereomer (space group *P*1).[18]

A more complex case is that of the grids containing different metal ions. For a [2 x 2] grid constructed by using two different inetal ions; two topoisomers are possible: *syn* (two identical metal ions on the same edge of the square) and *anti* (identical inetal ions disposed diagonally). The synthetic strategy must fulfill an important condition: it has to avoid the scrambling of the metal ions. The problem was solved by introducing the metal ions in a sequential way, namely. in order of the increasing lability of the coordination centers which are formed. Two $[M^{II}_2Fe^{II}_2]$ grids (*M*=Ru, Os) were obtained by using ligands of type **L5**(*x*=0; R1=R3=H, R2=S−^{n}Pr).[19] The first step was to protect one of the binding sites of the ditopic ligand. by methylating the nitrogen atom from one of the two peripheral pyridyl rings. Consequently. only one pocket is available to interact with the metal ion. The reaction of the methylated ligand with $RuCl_3$ or ammonium hexachloroosmate leads to chiral mononuclear precursors, which result as racemic mixtures. The [2 x 2] grid structure (the *anti*-topoisomer) is assembled in the presence of a second metal ion (e.g., Fe^{2+}), which combines with mononuclear precursors of the same chirality (R + *R* or S + *S*). In other words. the process is diastereoselective. the connection of an *R* and an S precursor into a *meso* diastereoisomer being precluded for geometric reasons.

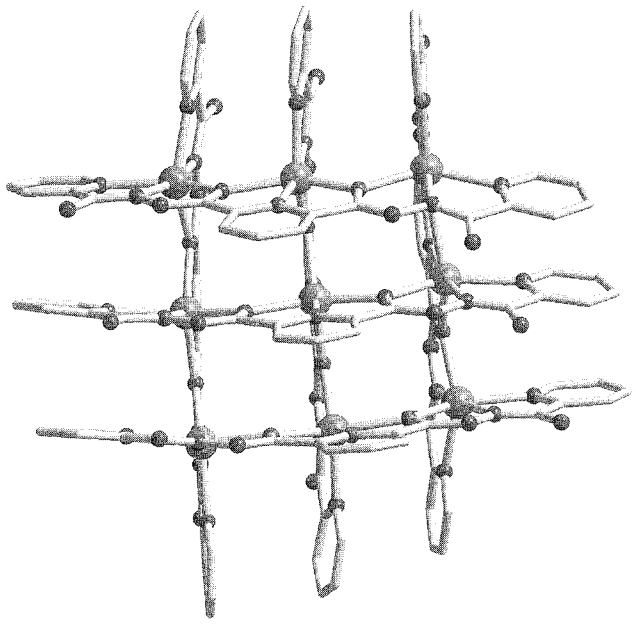


Fig. 5 Crystal structure of a $[Mn^{II}_9(\mu\text{-}O)_{12}]$ grid (adapted from Ref. [17]).

Rectangular Grids

The self-assembly of rectangular grids, $[n \times m]\boldsymbol{G}$ (Fig. 1e), needs two types of linear ligands, for example, a ditopic and a tritopic ligand. The first $[2 \times 3]$ rectangular grid was obtained by combining two ligands of the type **L2** and Ag^+as an assembling cation, in a molar ratio **L2**(x=1):**L2**(x=2):Ag^+=1.5:1:3.[20] The rectangular grid was formed in solution and in the solid state. Although the two square grids, $[2 \times 2]$ and $[3 \times 3]$, can also result, the $[2 \times 3]$ grid is formed preferentially, as indicated by ^{109}Ag-and ^{1}H-NMR spectroscopy. The $[2 \times 3]$ rectangular grid coexists in solution (nitromethane) with only 8% $[2 \times 2]$ and 2% $[3 \times 3]$ grids. (If the three grids were formed nonpreferentially, their statistical distribution, following the 1.5:1:3 molar ratio between the starting components, would have been 36% $[2 \times 2]$, 16% $[3 \times 3]$, and 48% $[2 \times 3]$.) The preferential formation of the heteroligand grid arises from the lower stability of the $[3 \times 3]$ grid in comparison with the $[2 \times 3]$ one. [In the $[3 \times 3]$ grid, the central Ag(pyridazin)$_4$ unit is less stable than the Ag(bipy) moieties.]

In the attempt to obtain a $[5 \times 5]$-Ag_{25} grid, by using a pentatopic ligand of type **L2**(x=4), two unexpected polynuclear architectures were obtained: a $[4 \times 5]$ grid, $[Ag_{20}\{\mathbf{L2}(x=4)\}_9](CF_3SO_3)_{20}$, and an Ag_{10} quadruple helicate, $[Ag_{10}\{\mathbf{L2}(x=4)\}_4](CF_3SO_3)_{10}$.[21] The two compounds crystallize simultaneously from the same reaction mixture. Actually, the $[4 \times 5]$ grid can be described as a $[2 \times (2 \times 5)]$ grid of grids. The particular topology of the metal array arises from the possibility of the ligand to adopt a *transoid* conformation (twisting around the central C—C bond). Five out of the nine ligands have this *transoid* conformation and form a parallel row, while the remaining four ligands display the all-*cis* arrangement of the nitrogen atoms (*cisoid* conformation). These four ligands are arranged into two parallel sets lying on the opposite sides of the grid, one above and one below the mean plane of the silver atoms (Fig. 6). The four outer corner silver atoms describe a rhombus with inner angles of 70 and 109°.

The grid motif is also encountered in a plethora of two-dimensional extended structures, either noninterpenetrating or interpenetrating nets, constructed from metallic ions as nodes, and various *exo*-bidentate ligands.[6,22,23]

Mechanistic aspects

The above results highlight the important role that can be played in the self-assembly process by the different conformations of the **L2**-type ligands. The reaction between **L2**(x=2) and Ag^+ was reinvestigated, with a special emphasis on the kinetic species that may or may not be direct intermediates toward the thermodynamically stable $[3 \times 3]$ grid.[24] The $[3 \times 3]$-Ag_9 grid forms immediately, as the only reaction product, when the two components are mixed in the correct stoichiometric ratio

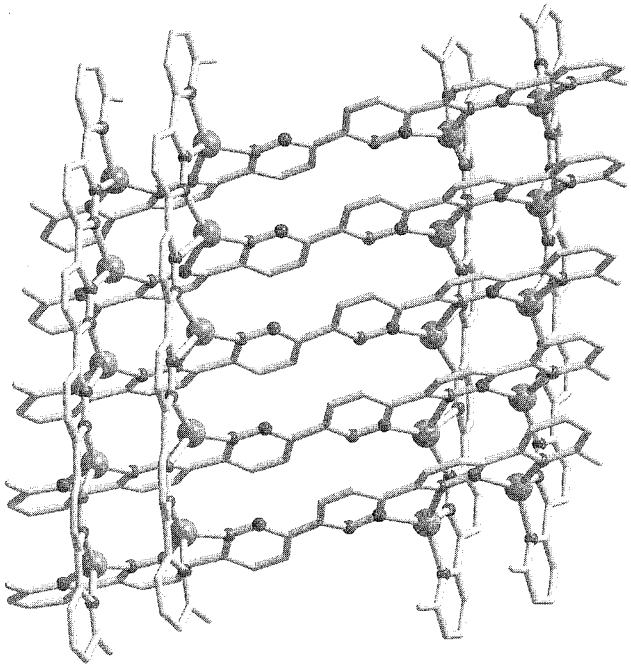

Fig. 6 Crystal structure of the $[Ag_{20}\{\mathbf{L2}(x=4)\}_9]^{20+}$ $[2 \times (2 \times 5)]$ grid (adapted from Ref. [21]).

(Ag^+:L2=9:6). The progressive addition of $AgCF_3SO_3$ to the solution of the ligand leads to a series of species that were identified by means of NMR (^1H, ^{109}Ag) spectroscopy. These are complexes of $[(L2)_nAg_n]^{n+}$ type (n=3,4-, probably triangular and square intertwined structures, with all ligands in the *transoid* conformation) and grid-like species having the composition $[(L2)_5Ag_6]^{6+}$. Two of these hexanuclear complexes are particularly important. In both of them, the L2(x=2) molecules are disposed into two sets of parallel ligands: a set of three. and another one of two ligands, their superposition making an incomplete grid, with the six metal ions disposed on the opposite edges. One of the two complexes is made up only of ligands in the *cisoid* form, *c*-$[(L2)_5Ag_6]$, while in the second one, *t*-$[(L2)_5Ag_6]$, three parallel ligands present a *transoid* conformation around the central C—C bond, and the other two are in the *cisoid* form. Ligand exchange reactions occur between the $[(L2)_nAg_n]^{n+}$ and *t*-$[(L2)_5Ag_6]^{6+}$ species, leading to *c*-$[(L2)_5Ag_6]^{6+}$, which is a prerequisite process in the way toward the [3 x 3] grid. The *c*-$[(L2)_5Ag_6]^{6+}$ entity displays three coordination sites available to bind, in a single overall step, three Ag^+ ions and one ligand molecule. completing the [3 x 3] grid architecture (termination). The process is favored by high cooperativity between the binding sites of the hexanuclear species and those of the incoming sixth ligand. The [3 x 3]-Ag_9 grid remains the only reaction product, even in a large excess of Ag^+ions, that is, above the 9:6 metal/ligand ratio.

CONCLUSION

The cases discussed here show that the self-assembly process represents a direct, efficient. and economic inethod for the construction of supramolecular inorganic architectures. Because such processes involve highly chemically informed systems, they can better be described as "informational assembly processes."[25] They are of interest for scientific and technological reasons. The emerging fields of nanoscience will benefit from the ability of chemists to create arrays of metal ions with predetermined topologies and useful physicochemical properties arising from the electronic communication between the metallic centers (redox activity. luminescence. spin-transitions, single-molecule inagnet behavior). The grid architectures are particularly attractive, because they might serve as a basis for high-density information storage devices.

A further step in programming inorganic supramolecular systems consists of the use of ligands with a double-code program, that is, ligands with two complexation subunits that code the assembly of two different structures within the same supramolecular entity. for example. a double helicate and a [2×2] grid. Each code may be viewed as a subroutrne. and the process is viewed as a "double-subroutine self-assembly "[26–28]

The implementation of information features in constructing supramolecular architectures as those described here represents a higher level in understandrng cheinistry. getting chemical synthesis closer to the complexity of the processes occurring in the living cell

Rotaxanes and Pseudorotaxanes

Petra Linnartz
Christoph A. Schalley
Kekulé-Institut für Organische Chemie und Biochemie der Universitat, Bonn, Germany

INTRODUCTION

In the early 1960s, chemists set out to investigate mechanically interlocked molecules, among them, catenanes and rotaxanes (Fig. 1a,b). Catenanes are two intertwined macrocycles, while rotaxanes are made from an axle threaded into a wheel.[1,2] The axle is restrained to remain inside the wheel by suitable stopper groups that prevent deslipping. In contrast, a pseudorotaxane (Fig. 1c) is formed when noncovalent forces bind an axle inside a macrocycle without the help of stoppers. The idea of threading one molecule through the cavity of a second macrocyclic one was not only appealing with respect to molecular geometry and topology but also promised insight into fundamental chemical questions: How would it be possible to efficiently synthesize these molecules? What would their properties be? Appropriately substituted. one envisaged a new form of chirality based only on the topology of the molecule, without the necessity of implementing chiral centers. However, the first attempts to synthesize such architectures by low-yield statistical methods[3,4] or by a tedious multistep procedure[5] involving a covalent junction between the two subunits and subsequent cleavage of the covalent bond between them quickly showed how difficult their preparation was.

Starting in the mid-1980s, the use of noncovalent templates[6] greatly facilitated the formation of rotaxanes. and the field gained fresh impetus. For years, the focus of researchers in this field was the realization of new, more complex topologies. such as oligocatenanes, rotaxanes with more than one wheel, pretzelanes, and knots (Fig. I). Because many of these architectures are chiral without bearing a chiral center. topological chirality received increasing attention.[7] However. the aesthetics of beautiful molecules lost importance as the driving force for new developments, and for modern rotaxane chemistry, functionality is of major interest. Because mechanical bonding provides ideal features with respect to the mobility of the two components relative to each other, many reports appeared on controlled motions within these complexes.[8,9] Many researchers in this area ultimately aim for the construction of molecular motors and functional molecular devices at a nanometer scale.

TEMPLATED ROTAXANE SYNTHESIS

A rotaxane can. in principle: be built by slipping the wheel over one of the stoppers at an elevated temperature. by threading the axle center piece into the wheel and capping it with stoppers, by trapping a stopper in the wheel's cavity and reacting it with the other half of the axle, or by clipping the wheel around the axle and subsequent ring closure.[10] All of these pathways only give high yields of rotaxanes if attractive forces between wheel and axle are operative. This idea led to the development of several different template effects based on noncovalent bonding between axle and wheel, which greatly reduced the synthetic demands of rotaxane synthesis. With the help of template effects, the reaction of the rotaxanes' subunits can be directed toward the formation of these interlocked molecules and avoid, more or less efficiently, undesired side reactions. In the next sections, several template effects will briefly be discussed as examples for synthetic pathways to rotaxanes. Others exist. which we cannot describe in such detail, e.g., rotaxanes with cyclodextrin wheels,[11] which are based on the use of hydrophobic effects, or Crignard-type R-Mg-R compounds[12] bearing a crown ether wheel around the central magnesium ion.

Let us start the discussion with a metal ion template,[13] which was introduced by Sauvage and his coworkers in the mid-1980s (Fig. 2, top left). A Cu(I) ion with its preferred tetrahedral coordination geometry is capable of binding two phenanthroline units. If one of the phenanthrolines is incorporated in a macrocycle, which later will become the wheel, the second ligand is drawn into the cavity by the copper ion and can be easily equipped with two stoppers. The rotaxane precursor can then be dernetallated by treatment with cyanide ions to yield the desired rotaxane. Similarly, catenanes and other mechanically bound molecules can be synthesized. Also, other transition metals were used. some of which had an octahedral coordination geometry and were reacted with terpyridine instead of phenanthroline units.

Stoddart and his group utilized π-donor, n-acceptor interactions between electron-poor paraquat (*N*-,*N*-dimethyl 4.4'-bipyridinium) and electron-rich hydroquinone or napthoquinone moieties in order to preorganize a

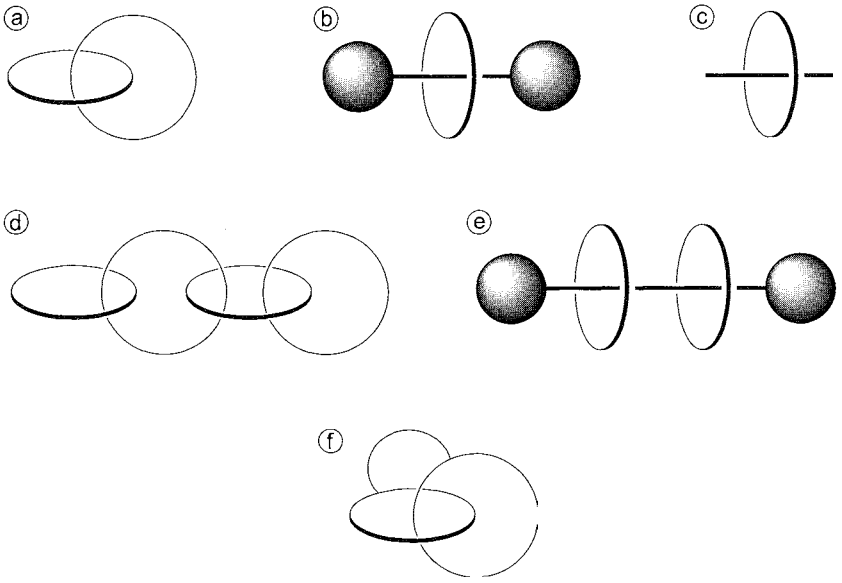

Fig. 1 Different topologies of mechanically interlocked molecules: (a) catenane, (b) rotaxane. (c) pseudorotaxane, (d) oligocatenane, (e) [3]rotaxane, and (f) pretzelane.

pseudorotaxane that can then be functionalized with appropriate stopper groups.[14] A large number of synthetic variations using this strategy are available. For example. the hydroquinone axle center piece can be threaded into a bis-paraquat wheel. and a paraquat center piece also binds inside a *bis*-hydroquinone wheel. Furthermore, a complete axle can be converted into a rotaxane by clipping the macrocycle around its centerpiece (Fig. 2, top right). Many other combinations are possible, and all of the synthetic strategies (slipping, threading, trapping. and clipping) were used.

Of course, hydrogen bonding is an excellent candidate for noncovalent templating, in particular because hydrogen bonds are directional in nature and thus may help to appropriately position two building blocks for a rotaxane relative to each other. Secondary ammonium ions can be inserted into crown ethers by hydrogen bonds and stoppered to yield a rotaxane.[14] However, hydrogen bonding also permits the use of nonionic templates. For example, amide groups incorporated in the rotaxane axle bind in the cavity of a tetralactam macrocycle with three hydrogen bonds (Fig. 2, bottom left). X-ray structures give insight into the pattern. Two hydrogen bonds form between amide NH protons of the wheel and the carbonyl group in the axle. and the third one can be considered as "backbonding" of the axle's NH proton to one of the carbonyl groups of the wheel. With this type of template effect, a large variety of different axles can be incorporated in the wheel.[15,16]

As a last example, an anion template should be mentioned that was recently discovered by Vogtle and his coworkers.[17,18] A phenolate ion is bound with its oxygen inside the cavity of the tetralactarn macrocycle by two strong hydrogen bonds ($K > 10^5\ M^{-1}$ in CH_2Cl_2). In other words, the macrocycle serves as an anion receptor strongly binding one part of the axle. This supramolecular. "wheeled" nuclophile can react with an electrophilic semiaxle through the wheel trapping it on the axle between two stoppers and thus giving access to rotaxanes with yields of up to 95% (Fig. 2. bottom right).

These examples of template effects illustrate the close relationship between host–guest and rotaxane chemistry. Appropriate concave host molecules bind convex guests in such a way that they can be equipped with two stoppers that mechanically prevent dissociation of the host–guest complex. Any macrocyclic receptor may thus be suitable for the formation of rotaxanes.

STABILITY OF ROTAXANES

For any application of rotaxanes, as. for example. the constuction of machines at a molecular scale. stability is a major issue. Stoppers too small in size permit the wheel to deslip from the axle so that the rotaxane decays into its two free components (Fig. 3).[19] A region of metastable rotaxanes exists between pseudorotaxanes without stopper groups on one side and stable rotaxanes on the other, where the barrier for the deslipping process is so high that cleavage of a covalent bond in the axle or wheel would be energetically favored.[20] In some cases, the transition from stable rotaxanes to their quickly deslipping

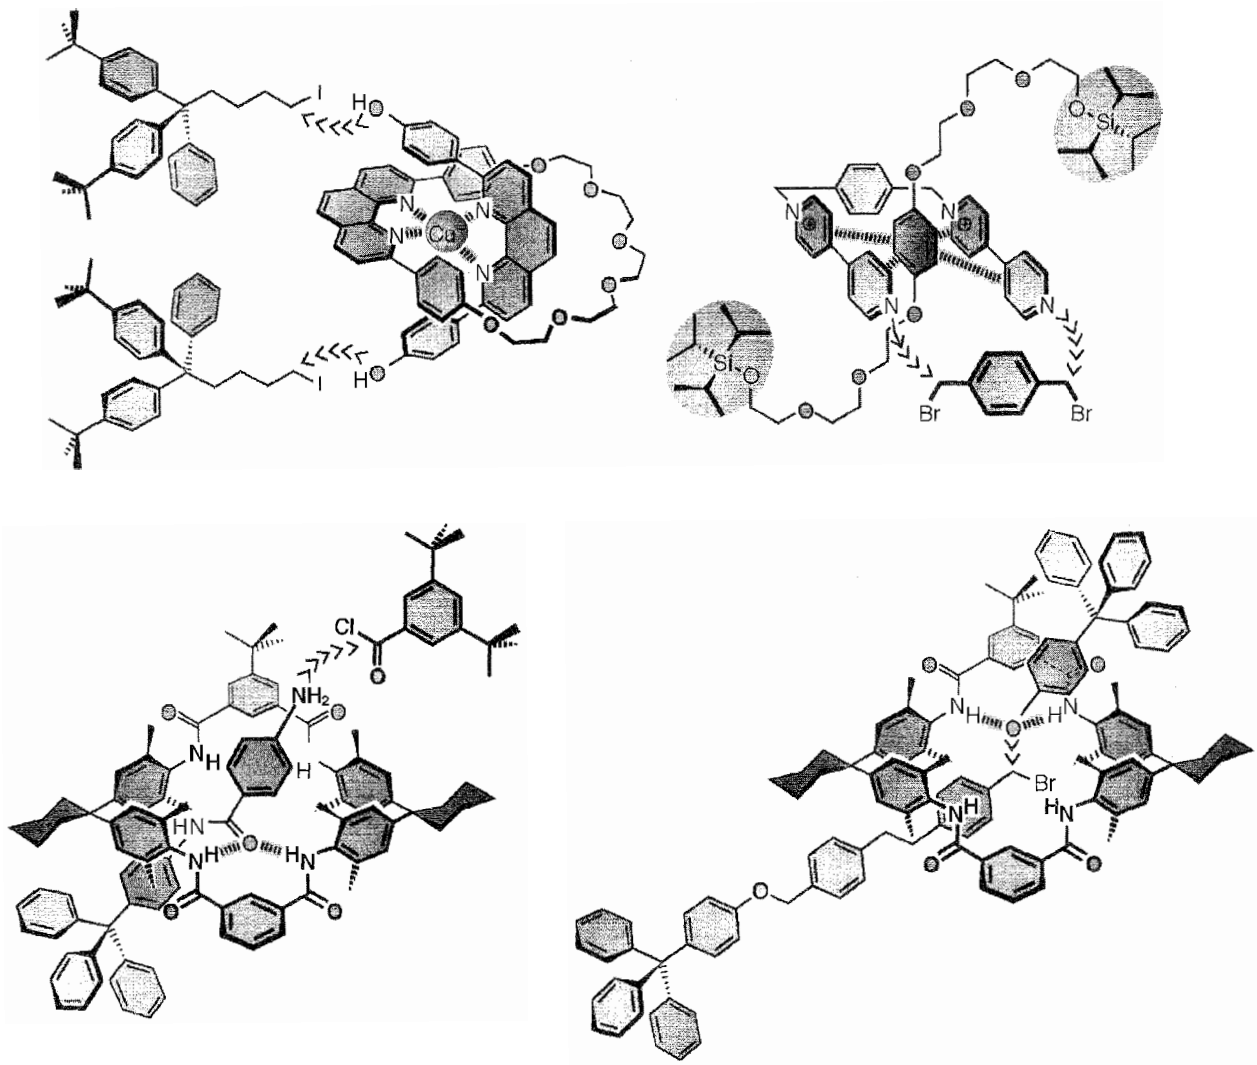

Fig. 2 Template syntheses of rotaxanes: the Cu(I) ion binds a phenanthroline ligand inside a macrocycle (top left). A *bis*-paraquat macrocycle is clipped around an axle bearing a hydroquinone center piece (top right). Hydrogen bonding permits the use of nonionic template effects for the preparation of amide-type rotaxanes (bottom left). Phenolate anions bound to the macrocycle react as a supramolecular nucleophile (bottom right).

counterparts is abrupt. and only slight changes in the rotaxane structures cause huge differences in the deslipping rates. Stoddart et al. reported an all-or-nothing effect,[21] where a simple methyl group decided the fate of the rotasane. With a *tri*-(*t*-butylphenyl) methane stopper, no deslipping occurred, while the same stopper with one i-propyl instead of a *t*-butyl group easily permitted decomposition into axle and wheel. Similarly surprising is the increase in half-life for the rotaxanes shown in Fig. 3. Replacing just a CH-group in the wheel by an isoelectronic nitrogen atom causes the'half-life at 333 K to jump from ca. 60 h to more than 10^6 h.[22] Here, the analysis of the activation enthalpies and entropies indicates that this effect is almost exclusively enthalpic. This points to a significantly more unfavorable size complementarity of stoppers and wheel. which is due to hydrogen bonding. Molecular modeling yields the geometrical parameters given in Fig. 3. A significant decrease of the space available inside the wheel's cavity is iliustrated by the N–N distances that shrink by about 10% for the pyridine wheel relative to that bearing two isophthalic acid amide units. Of course, a smaller-diameter wheel corresponds to an energetically more demanding barrier for deslipping.

Deslipping can also be used to determine the steric demand of a group of atoms. Vögtle and his group measured the effective size of dendrons by comparing the

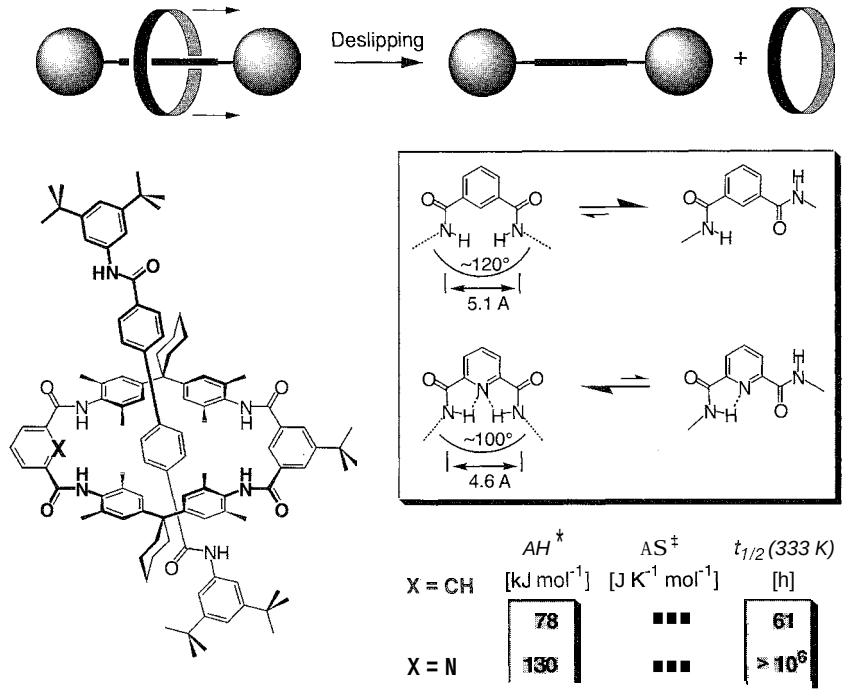

Fig. **3** Top: The deslipping process. Bottom: Intramolecular hydrogen bonding significantly decreases the ring size of the tetralactam inacrocycle bearing a pyridine dicarboxamide relative to that of a wheel with two isophthalic acid amides. This provokes a more than 10,000-fold increase in half-life. The activation parameters are given for both rotaxanes, and the effect can be almost exclusively attributed to enthalpic contributions. i.e.. the size complementarity between stoppers and wheel. Shown in the inset are the preferred conformations of the two differing building blocks and some parameters from molecular modeling, confirming the reduction of the wheel's inner diameter due to hydrogen bonding.

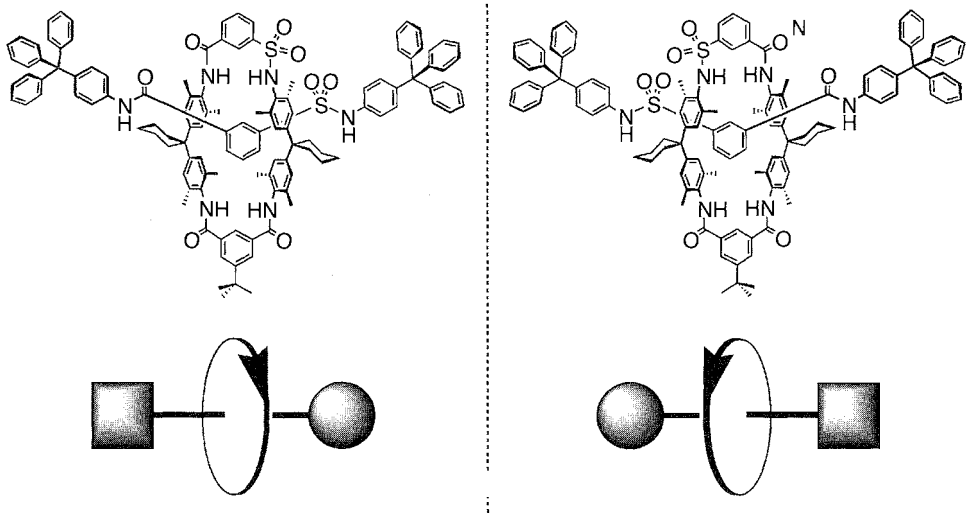

Fig. **4** Two enantiomers of an amide rotaxane. showing their overall structures. Note that the sulfonamide group in the wheel defines an atom sequence (indicated by the arrows in the bottom drawings). The sulfonamide incorporated in the axle permits the two stoppers to be distinguished. Such rotaxanes can be separated into the two enantiomers by HPLC on chiral stationary phases. and their CD spectra were measured.

half-life of several rotaxanes with dendritic stoppers to those with tritylphenol or di-t-butyl phenyl stoppers.[23,24] Dendritic stoppers appear smaller than a static, computer-generated model would imply, because their high flexibilities probably permit them to deslip in a branch-by-branch fashion. Consequently, deslipping experiments not only yield information about the stability of rotaxanes but also at the same time allow us to address fundamental questions in organic chemistry, such as that of spatial demand of functional groups. from a new point of view.

TOPOLOGICAL CHIRALITY

Let us assume that a rotaxane is formed from an axle with two different stoppers and a wheel that bears a directionality defined by the sequence of atoms in the macrocycle. Both of these subunits are achiral, both are identical to their mirror images. Nevertheless. the corresponding rotaxane exists in two enantiomeric forms, although no chiral center is present in the molecule (Fig. 4). It is the molecular topology that makes these species chiral. and consequently. this phenomenon was coined "topological chirality..' It also exists for catenanes, knots. and other mechanically bound molecules. Shown in Fig. 4 is a detailed structure of such a rotaxane. The wheel contains one sulfonamide group that provides the directionality of the atom sequence. The two enantiomers of the rotaxane can be separated and studied by CD spectroscopy.[25]

For [3]rotaxanes, i.e., an axle with two wheels, even diastereomers exist, if both wheels have a directionality with respect to their atom sequence.[26,27] Both wheels can then display the same clockwise atom sequence yielding a mirror symmetrical species that can be regarded as the supramolecular analogue of the *meso* form of tartaric acid. If the two wheels assemble on the axle with opposing directionality. diastereomers are formed.

MOLECULAR MACHINES, NANOMUSCLES, AND **OTHER** DEVICES

Nature has often been a model for scientists. and the functions of many enzymes were mimicked by chemists with the help of much less complicated model systems. A particularly fascinating enzyme is ATP synthase, a molecular motor that converts the energy stored in a proton gradient into mechanical rotation. The rotation is then coupled to the production of ATP. the major source of energy for most cellular processes. Although we can give only a sketchy description of this enzyme here. its features are interesting with respect to the construction of artificial inolecular motors.[28] First. there is geometric resemblance. The F_0 ATP synthase consists of a cyclic

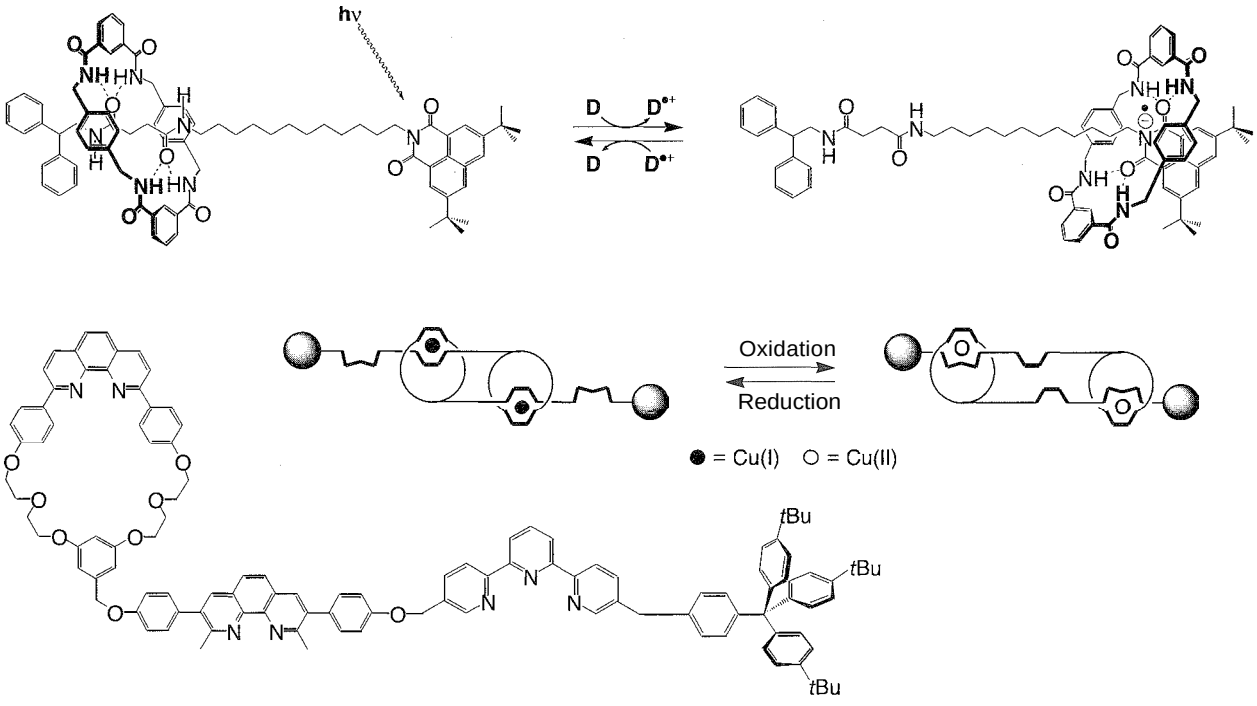

Fig. 5 Controlled molecular motion in rotaxanes: light-driven shifting of the wheel along the rotaxane axle (top); and contraction of a molecular ''muscle'' stimulated by electrochemical Cu(I)–Cu(II) interconversion (bottom).

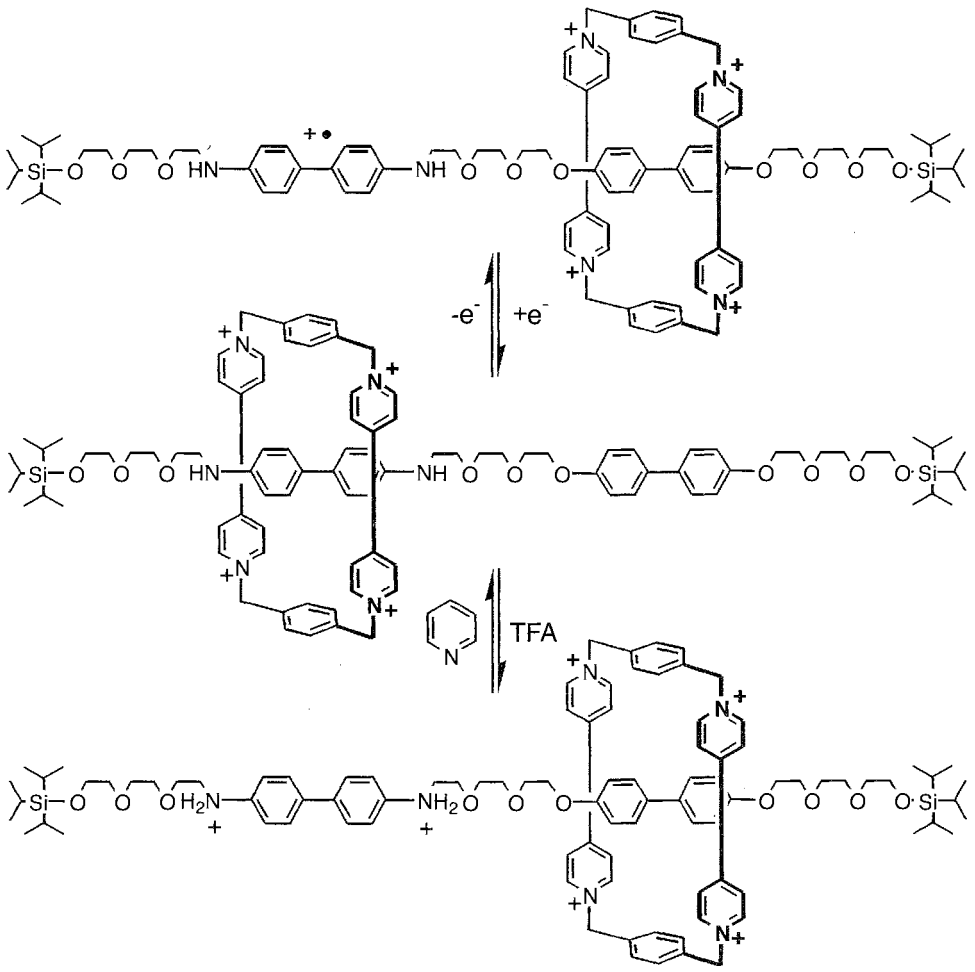

Fig. 6 A molecular shuttle controllable either chemically or electrochemically. In the resting state, the wheel is located on the left. Oxidation or protonation force the wheel to travel to the other side of the axle due to unfavorable charge–charge interactions. Considering oxidation and protonation as the two inputs and the motion of the wheel as the output. this system resembles a logic OR gate.

arrangement of membrane-inserted proteins (the stator) in which a rod-like protein (the rotor) can rotate. The source of energy for rotation comes from differences in the proton concentration inside and outside of the membrane. Thus; it is clear that the membrane separates the two compartments and prohibits immediate equilibration of the proton concentrations on both sides. Unidirectional rotation is achieved by a helical proton channel inside the membrane part of ATP synthase and by a defined orientation of the enzyme in the membrane. Axle rotation and the proton migration through the channel are coupled to each other, and immediately, it becomes clear that the chiral element of a helical proton channel is mandatory for unidirectionaiity. Finally. the rotating rod induces conformational changes in the F_1 part consisting of an $\alpha_3\beta_3$ protein hexamer. These changes in structure are the basis for the production of ATP from ADP and phosphate.

Based on these considerations. several groups attempted to construct artificial molecular motors on the basis of rotaxanes, the macrocyclic wheel being the stator. and the axle representing the rotor. The topic of controlled molecular motion was studied intensely. Several types of motion are feasible besides rotation.[29] namely, shuttling along the axle[30] and pivotal rocking of the axle. With respect to the energy sources for such movements, let us discuss two examples in which motion is induced by exposure to light of appropriate wavelengths and by redox reactions. Recently. Brower. Leigh. and coworkers published a study describing the light-controlled shuttling of a wheel along the axle (Fig. 5).[31] In its resting state. the rotaxane wheel is bound to the left side by hydrogen bonding. A light-induced electron transfer from a donor present in solution to the stopper on the right generates an anion radical with better hydrogen bond acceptor

qualities, and consequently. the wheel moves to this side surprisingly quickly. Backconversion to the resting state by reduction of the anion radical causes the wheel to shift back to the left. The second example from the group of Sauvage may be considered as a molecular analog of a muscle.[''''] Two filaments are each connected to a macrocycle. By the Cu(I) ion template, two of these molecules are threaded into each other, as depicted in Fig. 5. One of the particular features of copper is that it changes its preferred coordination geometry upon oxidation from Cu(I) (tetrahedron) to Cu(II) (trigonal bipyramid). Incorporation of one phenanthroline unit in each of the wheels and both a phenanthroline and a terpyridine in each of the filaments permits a switch between an extended form and a contracted form. Cu(I) prefers to be bound to two phenanthroline ligands. but oxidation to Cu(II) provokes preferential binding to the terpyridine unit. This change necessarily involves an increase of the distance between the two macrocycles. Reduction of the Cu(II) ion to Cu(I) reverts the process.

Other applications in nanoscale electronics can be envisaged. A molecular shuttle with two different states—despite all technical difficulties involved in writing and reading information into or from one molecule—may be considered as one bit of a miniaturized computer chip.[33] If the switching between two states can be controlled by two different stimuli, logic gates can be constructed that combine two different input signals to one output (Fig. 6).[30]a Such electronic devices at a molecular level are one of the chemists' potential answers to the visions of Feynman's bottom-up approach.[35] Because the ongoing reduction of the size of conventional electronic devices (the top–down approach) has limitations that cannot be overcome with current technology. it seems promising to start with molecules and construct electronic devices at a nanometer level.

Although the goal of perfectly functional molecular motors or electronic building blocks has not yet been reached, these examples illustrate how far the development in rotaxane chemistry and the art of controlling it has gone. For the future. we expect the field to shift more to applications, which might be the focus of the next decade.

Scanning Tunneling Microscopy

Lucidalva S. Pinheiro
Instituto de Química da Universidade de Sdo Paulo, São Paulo, Brazil

INTRODUCTION

Scanning tunneling inicroscopy (STM) was used successfully to image and propose the molecular packing of several small molecules adsorbed on surfaces. In supramolecular chemistry. a large assembly of small molecules can take place via weaker forces than covalent bonds. Supramolecular structures or their building blocks adsorbed on a surface can also be studied with STM. Physisorption or chemisorption can take place for each system. The forces acting in these two types of adsorption are important and can govern the final arrangement of the species on the surface. The range of molecular interactions observed in the solid inight be transferred to the adsorbed molecular layer. STM also offers the possibility of manipulation of the adsorbed species. This could be useful in host–guest complexation in situ. STM tip functionalization opens the possibility of recognition between species that act as hosts and guests in traditional supramolecular chemistry.

THE STM TECHNIQUE

G. Binnig and H. Rohrer[1,2] developed STM in the early 1980s. The technique is used in the study of conductive and semiconductive solid surfaces. It is based on a tunneling current between a sensor. the tip, and a sample.

The tunneling current is an exponential function of the separation between tip and sample. An approximate form of the tunneling current in the limit of low-bias voltage is given by the following:

$$I \propto Ve^{-2\kappa S} \quad (1)$$

V is the bias voltage: $\kappa=[2m(V_0-E)]^{1/2}/\hbar$; and s is the distance between tip and sample. A discussion of the tunneling cur-sent can be found elsewhere.[3,4]

STM presents a very high lateral resolution, and soon it was realized that it could be employed to study modified surfaces. The microscope can be used in ultrahigh vacuum (UHV), air, and under solutions. which makes it a very powerful technique. The STM instrument comprises a control unit and a piezoelectric device responsible for the displacements of the sample or tip. These components are interfaced to a computer.[5]

STM images are a mixture of topography and electronic information The contribution of each factor depends on the system under study Some approaches to analyze molecular layers were made, such as identifying chemical marker groups,[6] tunneling spectroscopy and fluorescence,[7,8] shape of the adsorbed species,[9] and image simulation [10 11]

STM Operation Modes

Constant current mode

In this mode, a current is chosen, and the feedback loop of the STM makes the tip track the surface to maintain this preset current. In this condition, the tip moves up and down in the z direction, while it scans in the x–y direction, rendering a tridimensional map of the surface. Scan speed in this mode is low due to the need to track the surface features.

Constant height mode

In this mode, the feedback loop of the STM is disabled. This way. the tip does not move in the z direction while scanning, keeping a constant height from the surface. The overlap between the tip states and those of the surface renders a tunneling current that is compared to that of the preset. Surfaces areas where there is effective overlap appear bright in the image. while those where the process is not so efficient appear darker in the image. Scan speed can be high in this mode, as there is no need to track the surface topography.

Tips

Tips are normally made of thin metal wires (ca. 0.25 mm), such as tungsten, platinum. or alloys (such as platinum-iridium and platinum-rhodium). Gold and silver tips can also be useful in some systems. To obtain the desired high resolution of the STM. it is necessary to have a very sharp tip with which to acquire the images. Tips can be prepared electrocheinically by etching the metal in a convenient solution, such as potassium hydroxide for W or basic aqueous cyanide solution for Pt-Ir tips. They can also be

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019172

prepared mechanically by cutting the wire. This method also produces tips capable of providing atomic and molecular resolutions. More details of tip etching and sharpening techniques were reviewed by Chen.[4]

Electrochemical STM (ECSTM)

In ECSTM, a cell with four electrodes replaces the conventional three-electrodes cell, the tip being the fourth one. In this case. a convenient design of the STM is required to allow for the inclusion of the potentiostat.[12] In ECSTM, care should be taken with the tip. The tunneling current used in STM ranges from the picoampere to the nanoampere regime. The tip can suffer electrochemical redox processes in the potential window sampled during the experiment. The current deriving from tip redox processes can overshadow the tunneling current. This problem is minimized by insulating the tip, leaving the smallest surface area exposed to solution. Tips are normally coated before the ECSTM experiment using nail varnish. wax, or polymers.

SUBSTRATES

Metals

A very flat surface without defects is normally desired when performing molecular adsorption. The condition for large terraces suitable for molecular adsorption is met by using the face-centered cubic metal surfaces of low Miller index.

The Au(111) is often employed in air and ECSTM due to its inertness. The Au(111) can be prepared as a thin film grown on mica or glass.[13] Gold beads can also be used as substrates. They are formed by melting the end of a wire on a torch following the method of Clavilier.[13] The beads present flat areas suitable for molecular adsorption. The Au surfaces are cleaned by thermal annealing in a flame before molecular adsorption. When well prepared, the Au(11I) surface presents a reconstruction known as 22 x *J3*. This structure is characterized by a pair of dislocation lines[13] and is sometimes preserved upon molecular adsorption. Other compounds promote the lifting of the reconstruction. The other low Miller index faces of Au. namely, Au(110) and Au(100), normally employed as monocrystals, were also studied.

Silver is often used in UHV STM and is also employed in air STM as a substrate to adsorb molecules. It can be used as a single crystal or as a thin film.[14,15] Single crystals of Cu. Rh, and Pt were also employed as substrates in many STM experiments for molecular adsorption.[16,17]

Layered Materials

Highly oriented pyrolitic graphite (HOPG) is one of the substrates most used for molecular adsorption. The material consists of a layered structure of carbon atoms arranged in a honeycomb lattice.[18] The atomic structure sampled with STM should be carefully analyzed. The surface atomic arrangement of HOPG imaged by STM was studied. and the conclusion is that a true hexagonal structure is not always sampled by the microscope.[18]

A characteristic of molecular adsorption on HOPG is the possibility of imaging the adsorbed layer with one set of tunneling parameters and the substrate surface by modifying these parameters. In general, the adsorbed layer is seen with high resistance in the gap, while the substrate structure can be imaged by decreasing the tunneling resistance.[19] This mechanism allows the overlay of the molecular structure on the HOPG lattice, giving information on surface site adsorption.

A layered material with semiconducting behavior, MoS_2, was used as substrate for STM. A discussion of the metals dichalcogenides structures and analyses of STM images was presented by Anselmetti and Wiesendanger.[18]

SUPRAMOLECULAR STRUCTURES

The chemistry and properties of supramolecular building blocks were presented and discussed in specialized texts.[20,21] The next topics highlight some of the STM results reported in the literature for the building blocks used in supramolecular chemistry.

Calixarenes

Adsorption of a calix[4]arene and calix[4]diquinone disulfide was carried out on Au(111) and analyzed with ECSTM.[22] The molecules form organized layers on the metal. The calix[4]arene is supposed to bind through hydroxyl groups, while the calix[4]diquinone disulfide is expected to interact with the gold through the sulfur atom. Calix[4]arenes with different functional groups were adsorbed on Au(111).[23] The molecules form large ordered adlayers. The presence of groups such as NO_2 and tert-butyl in the upper rim of the calix[4]arenes are supposed to reduce lateral interaction between the molecules.

Calix[4]resorcinarene functionalized with a thiol head was self-assembled on Au(111) from several different solvents.[24] The UHV STM was used to acquire the images of the layers. The thiol head is thought to bind to the surface, leading to molecular-ordered regions, which also depends on the preparation method.

Catenanes

Benzylic amide[2]catenanes were studied on HOPG by air STM.[25] Molecular adsorption is supposed to take place on the surface through the carbonyl groups present in the backbone. The authors comment on the possibility of molecular diffusion during imaging and also on molecular degradation upon adsorption as contributor factors to the very few features observed with submolecular resolution in the STM images.

The adsorption from solution of larger [2]catenanes consisting of two 87-membered rings was studied on HOPG.[26] The STM image shows with submolecular resolution that the [2]catenane adsorb on the HOPG forming domains. The authors discuss the thermodynamics reasons for adsorption and the dynamics of the adsorbed layer.

Crown Ethers, Cryptands, and Cyclophanes

The diaza-15-crown-5 molecule adsorbed on Cu(111) was studied by ECSTM.[27] The molecule forms a well-ordered layer on the metal under a certain range of potentials. The molecular interaction with the substrate is thought to be responsible for the adlayer formation. Dibenzo-18-crown-6-ether and its inclusion cornpound with potassium were studied on Au(111). The STM images obtained with submolecular resolution show that the species arrange in a two-dimensional (2D) supramolecular structure under potential control.[28]

A crown ether substituted phthalocyanin was adsorbed on HOPG, presenting several orientations. The molecules can be manipulated with the STM tip to adopt different orientations on the substrate.'''' The STM images of an aromatic cryptand adsorbed on HOPG show the formation of chains of molecular nanoclusters and areas with a 2D arrangement of the molecules.[29]

A cyclophane was studied on HOPG, and the authors concluded that the molecule stands upright on the surface, forming one-dimensional (1D) tubes.[30]

Cyclodextrins

The STM studies of cyclodextrins ranged from imaging to molecular manipulation. The basic units of α-cyclodextrin and β-cyclodextrin adsorbed on HOPG were imaged with submolecular resolution.[31] An inclusion compound of a-cyclodextrin and adamantane-methanol was also studied; the images showing a pattern similar to the empty α-cyclodextrin.[31] An inclusion complex between β-cyclodextrin and a triphenylphosphine sodium salt was analyzed by STM with submolecular resolution. The authors assign the STM contrast observed to the two phenyl rings of the guest molecule, while the β-cyclodextrin structure would not contribute to it.[32] An inclusion compound of a β-cyclodextrin and calix[4]arene was studied on HOPG.[33] The STM images show stripes with submolecular resolution for the inclusion compound. The adsorption of cyclodextrins functionalized with side groups such as thiol and Iipoamide was also pursued with the STM.[34,35] The final ordering of the molecules on the surface was shown to be dependent on the intermolecular interactions that are controlled by the side groups. The β-cyclodextrin, adsorbed on Au(111) and studied with the ECSTM. was found to form a nanotube-like structure on some potentials.[36] Aggregates of β-cyclodextrin threaded to polymers chains were studied on HOPG. The STM images are used to confirm the formation of pseudorotaxanes on the surface.[37] Molecular necklaces of α-cyclodextrin with poly(ethyleneglycol) adsorbed on MoS_2 were manipulated with the STM tip. The cyclodextrin units can be shuttled along the polymer thread reversibly.[38]

Polycyclic Aromatic Hydrocarbons (PAH) and barge Shape-Persistent Macrocycles

One of the methods used to grow layers on the substrate surface is molecular sublimation at low pressure.[39] However, for very large molecules this process does not work well. To adsorb the very large PAHs, such as $C_{42}H_{18}$ and $C_{132}H_{34}$, on HOPG, a wet technique with careful choice of solvent was presented.[39] The molecules are then adsorbed through self-assembly on HOPG. The air STM images were obtained with submolecular resolution, allowing the proposal of the molecular packing structure. Coronene adlayers were studied by STM on Au(111).[40] The adsorbed layer was grown by adsorption from a molecular solution. The STM imaging was then carried out under potential control. The molecules form a well-organized adlayer, and the authors suppose that there are multilayers on the surface.[40]

Large shape-persistent macrocycles containing thiophene- and pyridine-derivatived moieties were adsorbed on HOPG and imaged by STM.[41] The adsorbed layers of these large macrocycles present an interesting structure. because the large cavities of the molecules can be used to trap other molecules or ions on the surface.[41]

Porphyrins and Phthalocyanines

Several article\ dealing with the imaging of porphyrins and phthalocyanines were recently published. The key factor to image these layers by STM appears to be the adsorption step. In UHV, the layers are formed by vaporization of the molecules on the chosen substrate.[42,43] Structural defects on the layers, such as missing molecules, and the domain boundary arrangement are well

resolved in the STM images. It was possible to identify the ion core of phthalocyanines and porphyrins with high molecular resolution.[42,43] The chemical identification of the porphyrin or phthalocyanine by its central ions enables its identification in mixed layers of these molecules.[43]

STM imaging of layers of porphyrins and phthalocyanines assembled from solutions was harder to perform. Some methodologies were developed to enable this process. A porphyrin was found to adsorb on an Au surface previously modified with iodine or sulfur.[44,45] The resulting STM images showed fourfold structures assigned to the porphyrin. He et al. showed that it is possible to adsorb a porphyrin on a gold surface using only the electrochemical potential to promote the growth of the molecular layer.[46] A Co porphyrin molecule was imaged in the electrochemical environment. The molecule shows a bright central core that is assigned to the Co ion due to its dz^2 orbital, in agreement with the UHV results.[47]

HYDROGEN BONDS AS A TOOL FOR BUILDING SUPRAMOLECULAR ARCHITECTURES ON THE SURFACE

Some molecules carrying functional groups that can interact via hydrogen bonds were used to grow well-defined structures on surfaces. In this category, the molecule 2-mercaptopyriinidine (2MPy) was found to form a bidiinensional structure made of molecular dimers that align in chains separated by channels. The coadsorption of electron-rich molecules leads to the formation of mixed layers.[48,49] The structure of the 2MPy molecule opened the possibility of imaging arenes on Au(111).[48] The images of Figs. 1A,B show the coadsorption of 2MPy and azulene. The bilobed features (marked by B) seen in the images were assigned to azulene that adopts two different positions in the mixed layer. The features marked by *A* represent the 2MPy molecular dimers.

Molecules derived from benzoic acid showing optical isomerism and with application on nonlinear optics were adsorbed on Ag(111) and analyzed in UHV with STM.[14] The molecules form an ordered surface and bind through hydrogen bonds forming dimeric and trimeric rows and ribbons, depending on the surface coverage.[14] Molecules having several groups able to form hydrogen bonds can present a variety of adsorption behaviors on surfaces. Examples include molecules such as trimesic acid (1,3,5-benzenetricarboxylic acid), which was adsorbed on Cu(100) and studied by UHV STM at different temperatures. The trimesic acid is found to adopt two different structures on the surface, depending on the adsorption temperature. Adsorption at low temperatures leads to a planar arrangement of the molecules, and they bind to

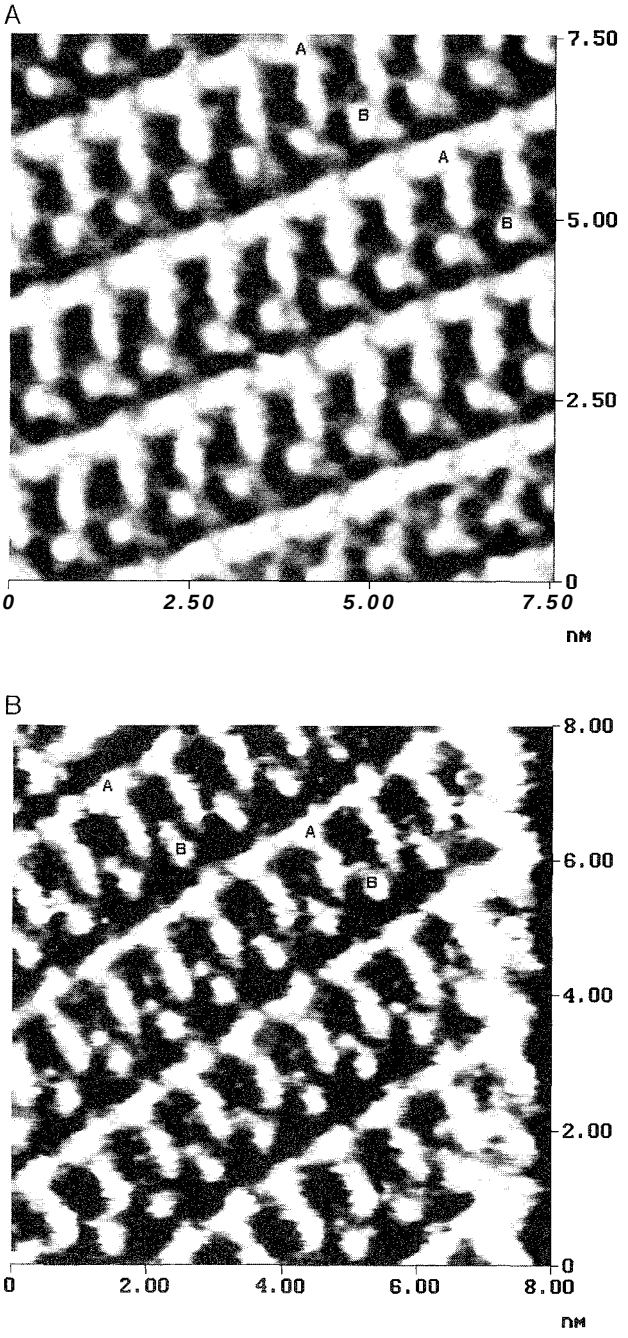

Fig. 1 (A) Air STM image of a mixed layer of 2-mercaptopyrimidine and azulene adsorbed on Au(111). Bias voltage: 400 mV; tunneling current: 3.0 nA; and area 76×76 Å^2. (B) Air STM image of a mixed layer of 2-mercaptopyrimidine and azulene adsorbed on Au(111). Bias voltage: 400 mV; tunneling current: 3.0 nA; and area 80×80 Å^2. (Parts A and B were reprinted from Curr. Appl. Phys. 2. Pinheiro, LS; Tempcrini, M.L.A. 2-mereaptopyrimidine as a suitable matrix to trap arenes on Au(111): STM probing of the modified surface. 145–153. Copyright 2002, with permission from Elsevier.)

each other through hydrogen bonding. At room temperature, the molecules are supposed to stand on the surface through their carboxylate groups. The STM data with submolecular resolution show that trimesic acid adsorbed on Au(111) forms dimers on the surface.[51]

The DNA bases, guanine, thymine, cytosine, and adenine, were studied by STM on several substrates. Some authors report hydrogen bonding or stacking of the molecules on Au(111).[52] The Cu surfaces are often used as substrates for adsorption of the DNA bases. Hydrogen-bond patterns were analyzed on this surface.[53,54]

Amino acids are molecules that can interact via hydrogen bonding in the solid state. The STM studies were performed on adsorbed layers on several substrates. The adsorption manner is governed by the substrate and also by the preparation method.[55–57] The use of electrochemical potential control enables the formation of different phases on the surface. Lysine adsorbed on Cu(001) was studied by UHV STM and found to form different phases.[55] The amino acids, with the exception of glycine, are chiral molecules, and the STM was used to examine this property along with the adsorption mode of the structure.[55,57]

MODIFIED TIPS

Some reports in the literature proposed the use of modified tips to image specific surfaces, aiming to improve the STM contrast. These reports use small molecules[58] or conductive polymers such as doped polypyrrole,[59] organic molecules that are able to hydrogen bond with the adsorbed molecule on the substrate.[60] Iodine and sulfur atoms were also tried as tips to image a thiol layer on HOPG.[61] Using this approach, it is expected that some areas of the adsorbed layer will appear brighter in the image. This is assigned to a specific interaction of a functional group on the adsorbed molecule recognizing the molecule or atom working as the tip. Carbon nanotubes were also used as tips to probe the surface and improve the adsorbed layer contrast.[62] The tip can also be modified in situ and used to form molecule–atom species, such as in the case of the interaction between Xe and Cu(II) etioporphyrin studied in UHV.[63]

CONCLUSION

The STM has proven to be useful in the study of supramolecular structures such as those formed by the traditional building blocks or hydrogen-bound layers. The results are still "new," and the best conditions for molecular deposition and imaging are being developed. The STM data for porphyrins and phthalocyanines are encouraging. because the microscope presents high-definition image5 of the internal features of individual molecules.

It was pointed out that intermolecular interactions should predominate over substrate–molecule interactions to enable the formation of supramolecular structures.[43,51] The expectation is that the STM data in two dimensions for the supramolecular structures can reach a point where the host–guest interaction can be analyzed in situ.

Second-Sphere Coordination

Derek A. Beauchamp
Stephen J. Loeb
University of Windsor, Windsor, Ontario, Canada

INTRODUCTION

The concept that a transition metal complex can interact orderly with neutral molecules to give an outer-sphere complex dates back some 90 years to Alfred Werner's original description of coordination chemistry. Werner found this idea, that we now call second-sphere coordination, essential to explain such simple phenomena as the dependence of optical rotation on the nature of the anion and solvent. the formation of adducts between amines and saturated complexes. and solvents of crystallization. The modern focus of second-sphere coordination varied from simple topics such as stability and solubility.[1] to biological concerns.[2] as diverse as transport properties.[3] and the relaxivity of MRI contrast agents.[4] Reviews by Stoddart in 1996,[5] Loeb in 1996,[6] and Steed in 2001[7] described the second-sphere coordination chemistry of transition metal complexes and alkali metals with crown ethers. This particular entry updates that published by Loeb in Volume 1 of *Comprehensive Supramolecular Chemistry* and is primarily focused on cationic transition metal complexes in which second-sphere coordination is provided by a host/receptor/ligand with an organized set of donors, such as a crown ether or macropolycyclic ligand rather than the many examples that contain second-sphere interactions with simple rnonodentate ligands or solvents. In particular, a transition metal complex that contains hydrogen-bond donor groups (i.e., NH_3 or H_2O) in its primary coordination sphere can be considered a guest capable of binding to a hydrogen-bond acceptor host via second-sphere coordination.

METAL AMMINE COMPLEXES AS GUESTS

Ando investigated the interaction of a variety ot ruthenium(II) ammine complexes[8,9] with crown ethers (Fig 1) and documented the effect ot second-sphere coordination on a variety of structural and physical properties.[10] Initially, pentammineruthenium(II) complexes **1d**, **1h**. and **1l** (Fig 2) were shown to form adducts with 18-crown-6 ether, 18C6, through NH O hydrogen bonds between the ammine ligands coordinated to the metal and crown ethei oxygen atoms.[11] Spectrophotometric, electrocheinical, and ^{1}H-NMR spectroscopic data showed that Ru(II) and Ru(III) ammine complexes form adducts with 18C6 that differ in the mode of hydrogen bonding. The crown ether binds to tmns-positioned NH_3 groups for Ru(II) but cis-oriented ammines for Ru(III). The binuclear complex **1i** was shown to form 1:2, 1:3, and 1:4 adducts in a stepwise fashion. lit was reasoned from electrochemical and ^{1}H-NMR experiments that mixed valence Ru(II)–Ru(III)-ammine complexes interact with three molecules of 18C6 in acetonitrile solution. In a mixed-valence complex, an asymmetric adduct implies the possibility of valence trapping and trapping/untrapping of the delocalized valence by adjusting the concentration of the crown ether.[11,12]

Studies involving Ru(II) complexes with fewer ammine ligands. **2a–d**, **3c–f**. and 4, demonstrated that the stoichiometry is the same as for pentammine complexes, **1c–g**, however, the electrochemical behavior is different because of the lower stability of the host–guest interaction and the steric difficulty of forming a 1:2 complex:crown adduct.[12,13]

It was found that binuclear complexes with delocalized mixed-valence states form an asymmetric 1:3 adduct to 18C6, in which there is a 1:1 stoichiometry at one ruthenium moiety and 1:2 stoichiornetry at the other. From the results of this study, it was clear that the valence of the metal center significantly affects the composition of crown ether adducts of metal complexes.[14]

In general, formation of ruthenium complexes with crown ethers was controlled by the valence of the metal center and the size of the crown ether. The change in redox potential of the ruthenium complexes was affected by the number of ammine ligands coordinating to the ruthenium, the n-electron acceptability of a ligand not interacting with the 18-crown-6. and the flexibility of the crown ether rings.[11–14] A combination of these factors makes it possible to design supramolecular adducts that possess a range of redox potentials.

In a series of papers,[15–17] Crumbliss illustrated that the siderophore ferrioxamine-B can be selectively recognized through second-sphere complexation of the protonated amine side chain by different ionophore host molecules.

The initial study focused on second-sphere coordination between Fe(III) complexes of deferriferrioxamine-B.

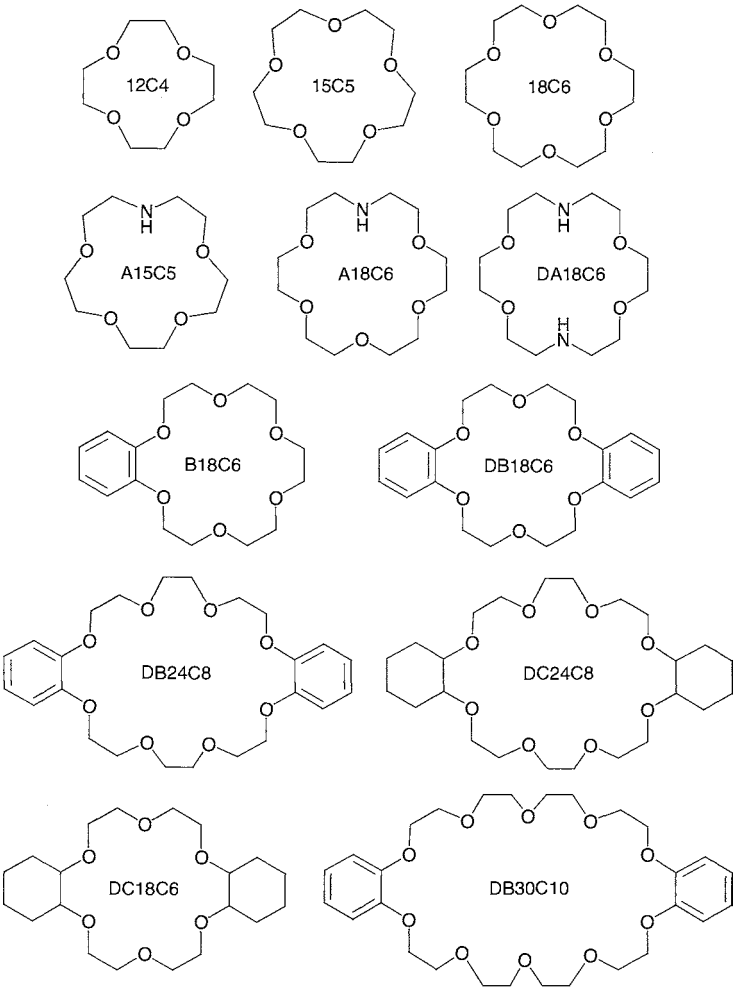

Fig. 1 Crown ether hosts used as second-sphere ligands for transition metal complex guests

$MHDFB^+$, and DC18C6.[15] The deferriferrioxamine-B complex has a distinct side chain containing an ammonium group, which is not involved in first-sphere coordination to the metal. It was shown that crown ethers could be involved in second-sphere coordination with this ammonium group by hydrogen bonding and electrostatic interactions to form a second-sphere adduct **5,** as illustrated in Fig. 3. The positive charge was demonstrated to be important, as no adduct formation was observed when the metal complex was deprotonated. Metal ion selectivity in a chloroform medium was experimentally determined to be Al(III) < Fe(III) < Ga(III) < In(III). The effect of counterion was also studied.

Although siderophore cell receptors are more complex than simple crown ethers; these studies are relevant as to how ionophores, such as antibiotics. affect the biodistribution of Fe carriers in the body. The influence of the host crown ether substituent and ring size on ferrioxamine **B** host–guest stability was studied.[16] The hosts investigated were crown ethers 18C6. B18C6, DB18C6, DB24C8. DB30C10. DC18C6. and DC24C8, as well as the natural cyclic ionophores valinomycin and nonactin. It was concluded that host–guest formation for ferrioxamine-B with synthetic crown ethers decreases in stability with increasing cavity size. These second-sphere complexes allowed for a thorough investigation of the relative efficiency of various ionophores to effect bulk ligand membrane transport of ferrioxamine.[16]

Additionally, functional groups (–RCOOH) were added to a crown ether to probe the influence of tethering the counterion to the macrocyclic host and to determine the optimum tether length for stable host–guest complex formation.[17] At an elevated pH, the substituted crown ether serves as host and counterion. It was experimentally

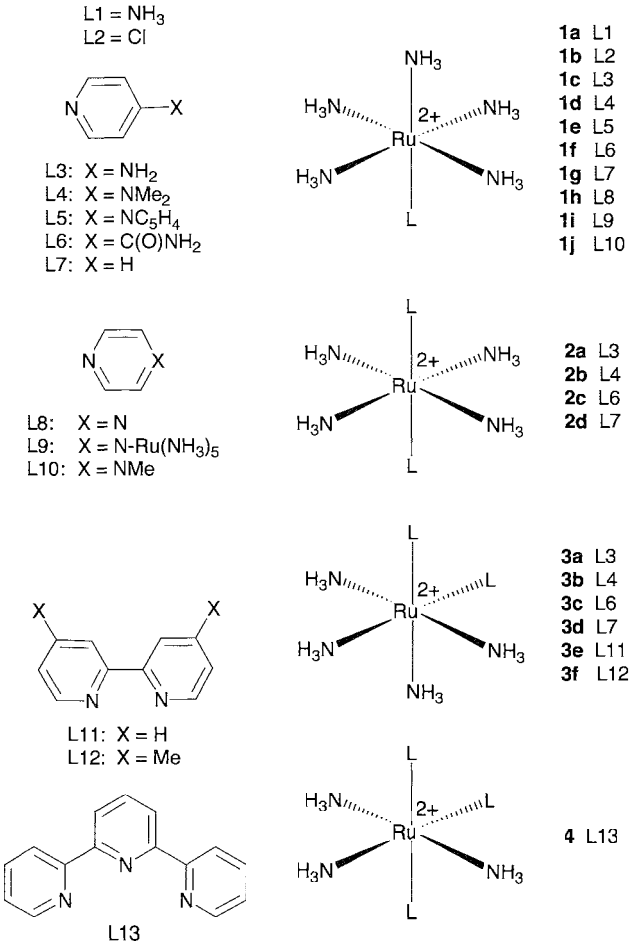

Fig. 2 Ruthenium complexes investigated as guests for crown ethers.

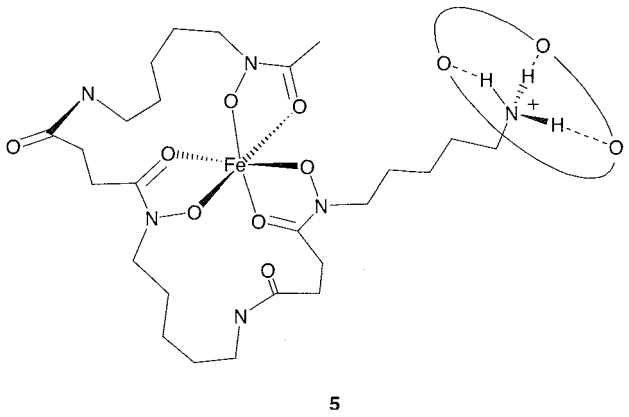
determined that a tethered, ionized carboxylate functional group significantly enhances host–guest formation. Moreover, with increased length of the side chain, the stability of the complex increased.

A new class of transition metal containing host or metalloreceptor was reported by Loeb, in which $PtCl_2(PEt_3)$ units were coordinated to the nitrogen donors of mono- and diazacrown ethers, A15C5, A18C6, and DA18C6.[18] These hosts behaved much like crown ethers, forming hydrogen-bonded adducts with alkylammonium salts. Binding could be measured by ^1H- or ^{31}P-NMR spectroscopy. One unique adduct reported in this series was 6, the second-sphere adduct formed between the monoamine complex $[PtCl_2(PEt_3)(NH_3)]$ and the azacrown ether containing complex $[PtCl_2(PEt_3)(A18C6)]$. This adduct was the first example of a host–guest complex in which both the host and the guest are transition metal complexes. As in alkylammonium adducts of crown ethers, the $[M\text{-}NH_3]$ guest perches over



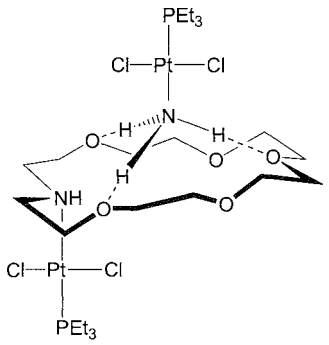
5

Fig. **3** The second-sphere adduct between a ferrioxammine B guest and an ionophore or crown ether host.

the crown ether ring and forms a three-point hydrogen-bonding scheme with alternating oxygen atoms of the crown ether host. as shown in Fig. 4.

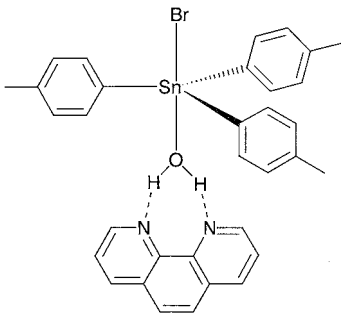
METAL **AQUA COMPLEXES** AS **GUESTS**

The unique second-sphere coordination of 1,10-phenanthroline to aquabromotri-p-tolyltin 7, was studied by Ng.[19] In this structure, the 1,10-phenanthroline ligand is coordinated in a second-sphere fashion through hydrogen bonds from the water molecule to the nitrogen atoms of the heterocycle. In contrast, the water molecules in the crystal structure of 1,10-phenanthroline hydrate are bonded to only one of the nitrogen atoms. It was suggested that electronic effects and packing forces influence

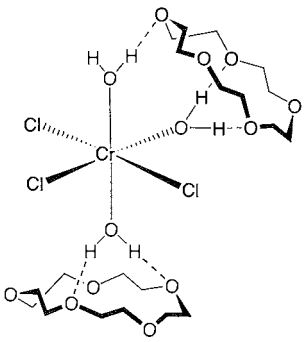


6

Fig. **4** A second-sphere. hydrogen-bonded, host–guest adduct in which both the host and the guest are transition metal complexes.



7



8

Fig. 5 Hydrogen-bonded second-sphere adducts involving aqua metal complexes.

the formation of second-sphere adducts in these compounds (Fig. 5).

Junk and Atwood recently synthesized a new structural isomer of $CrCl_3(H_2O)_3$, in which this species exhibits second-sphere coordination to a molecule of 15C5.[20] Crystals were obtained after irradiation with UV radiation and the addition of HCl(g) to a refluxing toluene solution of 15C5, H_2O, and $Cr(CO)_6$. This complex did not crystallize as discrete cations and anions but rather as a neutral Cr(III) complex, 8. The complex is coordinated in a second-sphere fashion to two molecules of 15C5 that are hydrogen bonded to the three water ligands to generate a polymeric array.[20] Interestingly, the 15C5 molecules only successively bridge the mer-isomer of $CrC_3(H_2O)_3$, and when the metal center was changed from Mo or W, one-dimensional hydrogen-bonded arrays were formed, but second-sphere coordination did not occur.

CONCLUSION

It is now well established that second-sphere adducts can be formed between transition metal guests containing hydrogen-bond donor ligands such as ammonia or water and hydrogen-bond acceptor ligands such as crown ethers. The question for the future is as follows: "How can the concept of second-sphere coordination be systematically applied to modern areas of interest in suprarnolecular chemistry." Two avenues of investigation are briefly discussed herein as examples of where second-sphere coordination might be applied in the future.

Metalloreceptors Utilizing Simultaneous First- and Second-Sphere Coordination

Loeb reported a series of macrocyclic organopalladium complexes **9a–f** that were shown to act as efficient hosts or metalloreceptors. Studies showed that these complexes can selectively distinguish between primary, secondary, and tertiary alkylamines,[21] ammonium ions,[21] isomers of aminopyridines,[22] and even DNA nucleobases.[23,24] In each case, the substrate was bound to a labile Pd(II) center by σ-donation, while noncovalent interactions such as hydrogen bonding and π-stacking to peripheral receptor sites on the ligand were used to selectively bind a particular substrate. This was extended to include the cavity of a calix[4]arene as the second-sphere binding unit that selectivity bound *para*-phenylpyridine over the *ortho* and *meta* isomers (Fig. 6).[25–27]

Solid-State Inorganic Materials

Shimizu showed the complete encapsulation of hexaqua metal ions by 12 hydrogen bonds to the second spheres of sulfonate ligands.[28] The complexes **10a–c** were prepared by mixing $M(NO_2)_3$ [M = Fe(III), Cr(III), Al(III)] and the sodium salt of 1,3,5-*tris*(sulfomethyl)-

9d: X = $(CH_2)_2O((CH_2)_2O)_4(CH_2)_2$
9e: X = *p*-$CH_2(C_6H_4)O((CH_2)_2O)_3(C_6H_4)CH_2$
9f: X = *m*-$CH_2(C_6H_4)O((CH_2)_2O)_3(C_6H_4)CH_2$
9g: X = (*p*-$CH_2(C_6H_4)OCH_2C(O)NH)_2$-calix[4]arene(O*i*Pr)$_4$

Fig. 6 Organopalladium complexes used as metalloreceptors to bind substrates via first- and second-sphere coordination.

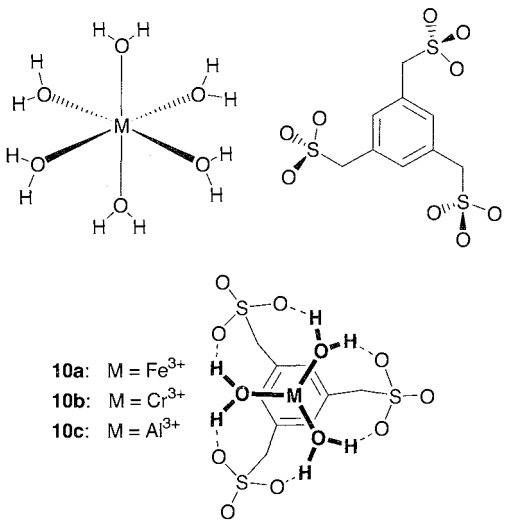

Fig. 7 A trisulfonate host forms multiple hydrogen bonds to encapsulate hexaqua transition metal coinplexes by second-sphere coordination.

benzene in aqueous media. In the crystal st ucture of **10a**, there are two types of (hexaqua)Fe(III) centers, one that is completely encapsulated by two molecules of the sulfonate ligand to give $[Fe(H_2O)_6(L)_2]^{3-}$ and one that simply acts as a second-sphere adduct held together by *12* hydrogen bonds: six to each sulfonate ligand, as shown in Fig. 7. Thermogravimetric analysis (TGA) of the solid showed that the coordinated water molecules involved in second-sphere coordination were only lost at temperatures −100°C above normal. This demonstrated that second-sphere coordination can be purposefully applied to provide thermal stability to a polymeric material.

Secondary Bonding

Ionel Haiduc
Universitatea "Babeş-Bolyai," Cluj-Napoca, Romania

S

INTRODUCTION

The "secondary bond" concept was introduced by N.W. Alcock[1] *and describes interactions characterized by interatomic distances longer than single covalent bonds but shorter than van* der Waals *distances. These interactions are weaker than covalent or dative bonds but are strong enough to play a structure-determining role in the solid state. perhaps even in solution. The secondary bonds can be* intra- *or intermolecular. In the context of* supramolecular *chemistry, intermolecular secondary bonds leading to self-assembly and self-organization are of primary* importance, *both in* inorganic[1] *and in* organometallic compounds,[2,3] *in which discrete* supermolecules *or* supramolecular *polymeric arrays can be* formed *by connecting individual molecules (tectons). Intramolecular secondary bonds will not be discussed here, although interesting structural effects are produced by this type of* interactions.[4,5]

Some formal analogy between secondary bonding and hydrogen bonding can be noted. In both cases, there is a trinuclear. basically linear (but not always) and unsymmetrical $X–A\cdots X'$ *system, in which* $A–X$ *is a normal covalent bond.* and $A\cdots X'$ *is a weaker interaction. called an hydrogen bond (when* $A=H$*) and secondary bond (when* $A\neq H$*)*(Scheme 1). *In rare cases, the hydrogen bonds are symmetrical, and this happens more often with secondary bonds.* Symmetrical $X\cdots A\cdots X$ *systems are* formed *by an electron density redistribution by which the covalent bond is elongated. and the secondary bond is shortened, until the interatomic distances are equalized. In this case, the* $A\cdots X$ *bond order is* 0.5, *sensibly more than in common secondary bonds.*

There are: however. some significant differences between hydrogen bonds and secondary bonds; in the former, *the centrai atom hydrogen is monovalent: whereas. in the secondary bonds,* the *central atom A can be* plurivalent, i.e., *can form several covalent bonds. Thus. the number and variety of synthons able to participate* in *secondary bond formation. and therefore in* supramolecular self-assembly, *is considerably greater. In Scheme 2. some secondary bond synthons are illustrated.*

In some *cases.* the *hydrogen bonds can be bifurcated, but rarely* trifurcated. *In the case of secondary bonds. this is a* frequent *occurrence. As an example, the* diorganoditellurium(IV) *halides can be* cited,[6,7]; *these compounds* display *several coordination patterns and* numerous modes *of supramolecular self-assembly.*

THEORY

The structure-determining role of the secondary bonds even in simple inorganic molecules and ions cannot be underestimated. Their formation results in increased coordination numbers and distortions of the coordination geometries. This matter was discussed in terms of valence bond and VSEPR theories, [8,9] *and* a *remarkable analysis of the coordination geometries of* Sb(III) *halides influenced by secondary bonds could serve as a* model *for similar discussion of other main group elements.*

The secondary bond is *now explained as a result of donation from the lone pair of* X' *into a* σ^* orbital *of the* $A–X$ *bond or (alternatively and equivalently) as an asymmetric four-electron three-center system, with three* σ-symmetric atomic *orbitals on A and* X, X' *combined to form three molecular orbitals: one filled bonding* MO *located between A and* X, *one filled nonbonding or weakly bonding* MO *located between A and* X' *and one* empty *antibonding orbital (Fig. 1). It seems that the secondary bonding is associated with a high electron density at the acceptor binding site (usually having one or* more *lone pairs of electrons). The bonding in such systems was studied in detail on simple* triatomic *models, and the conclusions can be extended to similar synthons incorporated in more complex* structures.[10–13]

Secondary bonds are common *in compounds of heavier* main *group elements and can be regarded as a particular case of donor–acceptor bonds. Strong acceptors, such as metals of upper rows of the Periodic Table, associated with strong donors such as fluorine. oxygen, or nitrogen (generally described as hard acids and bases) tend to form two-electron dative bonds (classical coordinative bonds). Seldom. if ever, secondary bonds of the type discussed here are observed for hard donor–hard acceptor pairs* (e.g., *Be.* Zn, Al/F, O, *N). The metals and nonmetals in the bottom rows of the Periodic Table (soft acids and bases) tend to form weaker donor–acceptor bonds and "secondary bonds." Unfortunately, there is* still some *ambiguity about these interactions, and there is not even an*

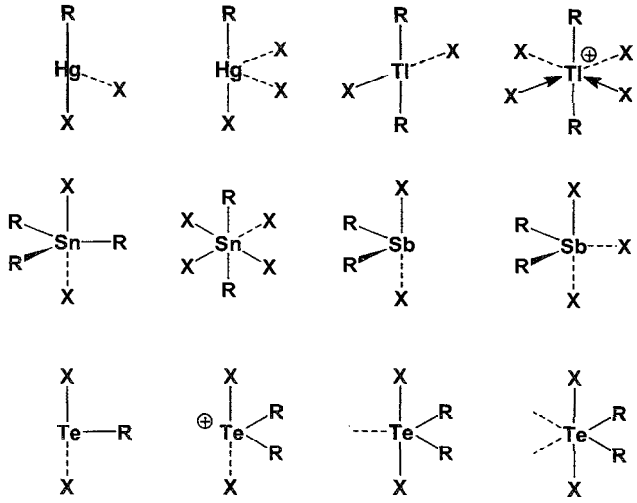
unanimously accepted mode of naming them; in addition to using the term "secondary bonds," they are referred to in the literature as soft–soft interactions. closed-shell interactions, nonbonding interactions, or semibonding interactions, with the tendency to cover a broad range of interactions under this umbrella. The complexity of the matter was analyzed in a comprehensive review.[14]

Self-assembly through secondary bonds results in the formation of discrete supermolecules (dimers, trimers, tetramers) or supramolecular polymeric arrays, both in purely inorganic systems[1] and in organometallic compounds.[2,15–18] They are frequently found in derivatives of mercury,[19,20] thallium,[20] tin,[21] lead,[22–24] antimony,[25,26] bismuth,[27–29] selenium,[30,31] tellurium,[6,7] iodine[32,33] paired with sulfur, selenium. or heavy halogens. and sometimes even with oxygen and nitrogen ligands. Some are well illustrated by the main group derivatives of phosphor-1,1-dithiolato and related ligands.[15–18]

The most common are the heteroatomic secondary bonds, but homoatomic systems containing Sb–Sb···Sb–Sb···[34,35] Bi–Bi···Bi–Bi···[36] or Te–Te···Te–Te···[37] assays are known. Also, Se···Se interactions (3.07 Å) dimerize the five-membered Se_2SN_2 rings in Se_2SN_2Cl, but $Se_2S_2N_4$ eight-membered ring molecules are associated through Se···N secondary bonds.[38] Such interactions are common between sulfur- and selenium-containing inorganic rings and lead to interesting physical properties for the design of new materials (e.g., molecular conductors).[39] Iodine...iodine interactions are important in polyiodides and produce a broad variety of supramolecular structures.[40]



Scheme 2 Some secondary bond synthons

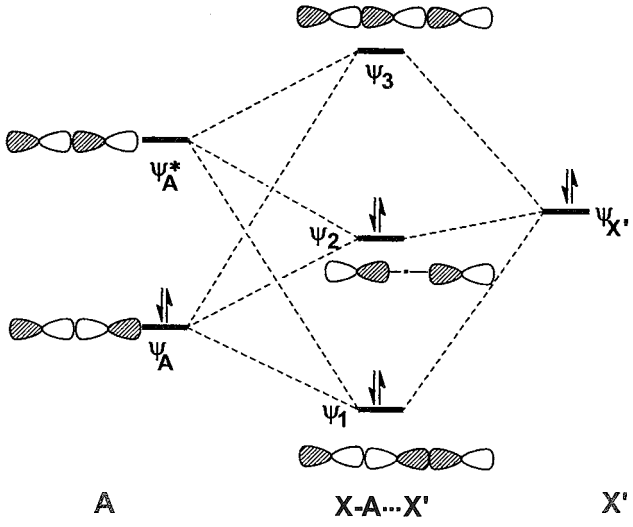


Fig. 1 Molecular orbital diagram of secondary bonding.

DINUCLEAR SUPERMOLECULES

There is a large number of dimers formed through secondary bonds. A few selected illustrative examples include organomercury halides, e.g., $[PhN{=}NC_6H_4HgCl]_2$,[41] and phosphor-1,1-dithiolates, e.g., $[MeHgS_2PPh_2]_2$,[42] and lead phosphor-1,1-dithiolates.[43] Some organoantimony phosphor-1,1-dithiolates and dithioarsinates, $[R_2SbS_2ER'_2]_2$ (E = P,As) are also dimers,[44,45] but others form polymeric arrays.[46–48] In dimeric $[Ph_2SbS_2EPh_2]_2$, the eight-membered rings are formed through Sb···S secondary interactions. The bismuth(III) analogues, $Bi(S_2ER_2)_3$ (E = P or As). are also dimers.[49–51] In $[Me_2TlSPh]_2$ supermolecules, the four-membered Tl_2S_2 rings are nearly symmetrical (TI-S 2.748 and 2.991 Å), but the difference between the two interatomic distances is significant.[52] The eight-membered cyclic adduct $[PhSeSePh.I_2]_2$[31] can be cited to illustrate a unique type of quasicyclic structure.[30] Phenyltellurium tetraphenyldithioimidodiphosphinate. $[PhTeSPh_2PNPPh_2S]_2$, is but one of many dimeric supermolecules based upon Te···S interaction~.'~Some of the cited species are shown in Scheme 3.

Scheme **3** Dinuclear superrnolecules

TRINUCLEAR SUPERMOLECULES

Trimers formed through secondary bonds are rare, probably because of inadequate bond angles, which are far from linearity. An example includes the bismuth chloro derivative, $[\{(C_5H_4Me)Fe(CO)_2\}_2BiCl]_3$, containing bent Cl–Bi···Cl units.[55] In $[(Me_3Si)_3C–PbCl]_3$, the lead–chlorine bonds are symmetrized (Pb–Cl, 2.71 and 2.74 Å), whereas in a related dimer $[(PhMe_2Si)_3C–PbCl]_2$ the difference in the bond lengths is more significant (Pb–Cl, 2.729 Å; Pb···Cl 2.962 Å).[56] Probably the nonlinearity of the Cl–Pb···Cl and the tendency of symmetriza-

tion are related to formation of the four- and six-membered rings (Scheme 4).

TETRANUCLEAR SUPERMOLECULES

Some tetrameric supermolecules based upon secondary bond self-assembly are illustrated in Scheme 5. Bulky organomercury chlorides, i.e., $[\sigma\text{-}(Me_2BuSi)C_5H_4HgCl]_4$ and (2-pyridylphenyl)mercury(II) chloride,[57] the heterocyclic antimony chloride $[C_4H_8SbMeCl_2]_4$,[58] and the organotellurium iodo derivative $[o\text{-}C_6H_4(CH_2TeMe_2I)_2]_2$ containing a Te_4I_4 cube,[59] demonstrate a great diversity of such structures. Another tetranuclear species $[Sb_4Cl_{16}]^{4-}$ [investigated as a *bis*(diphenylphosphino)ferrocenium salt][60] is a tetramer formed through secondary bond association of four $SbCl_3$ molecules (Sb–Cl in the

range 2.397–2.547 Å), with four Cl^- anions through S b . Cl^- secondary bonds ($Sb\cdots Cl^-$ in the range 2.743–3.329 Å). Each antimony atom is six-coordinate (distorted octahedral) and participates in three orthogonal Cl–$Sb\cdots Cl$ systems.

SUPRAMOLECULAR POLYMERIC ARRAYS

This is the most comprehensive family of supramolecular architectures involving self-assembly and self-organization promoted by secondary bonds. Selected examples are collected in Schemes 6 and Scheme 7. Scheme 6 comprises organometallic halides.

Among organometallic halides, organomercury(II) compounds. such as 1,2-$C_6F_4(HgCl)_2$ and 1,3,5-$C_6H_3(HgCl)_3$,[61,62] several triorganotin halides, R_3SnCl[63,64] and triorganolead(IV) halides, R_3PbX,[22–24] can be cited. Triorganotin chlorides are chain-like polymeric arrays. Thus, in Me_2Bu^tSnCl[65] and Me_3SnCl,[66] the secondary bond system is unsymmetrical and linear. Diorganotin dichlorides are also associated, e.g., Me_2SnCl_2.[67] In triorganolead halides, there is some tendency for bond equalization in the colinear bond system, as found in $Ph_2(PhCH_2)PbBr$,[22] but in the iodide Me_3PbI, the lead–iodine distances are significantly different.[23]

Organoantimony(III) and organobismuth(III) halides, R_2EX and REX_2 (E = Sb, Bi: *R* = Me, Ph, *X* = Cl,

a = 2.535; b = 3.841; c = 3.839 Å

Scheme 3 Other supramolecular chain-like arrays.

Br, I),[25–29,68,69] are almost without exception. polymeric arrays formed through secondary bond self-assembly. As an example. Me_2SbI is cited; which is a chain-like polymeric array with basically linear fragments.[25] In Ph_2BiCl, the linear secondary bond system is again symmetrized,[23] but in the dibromide $PhBiBr_2$, and diiodide $PhBiI_2$, the interatomic distances are significantly different, although the difference is small.[28] Alkylbismuth diodides, $RBiI_2$, form a family of linear-chain supramolecular arrays with symmetrized triatomic systems, resulted from electron redistribution in the I–Bi···I tricenter moieties.[27,28] Organotellurium halides also form supramolecular polymeric arrays.[6,7] The most recent examples are $MeTeCl_3$,[70] $(C_6F_5)_3TeCl$,[71] and $(C_6F_5)_3$-TeBr.[72]

Suprainolecular coinpounds other than halides are numerous. Among these; methylmercury xanthates, $MeHgS_2COR$,[73] and organothalium thiophosphinates[74] can be cited. Tin–oxygen (Sn···O 3.337 A) and lead–oxygen (Pb···O 3.180 Å) secondary bonds. much longer than usually observed between these elements. connect 2-nitrobenzenethiolato triphenylmetal molecules. Ph_3-$MSC_6H_4NO_2$-2 (M= Sn. Pb) into supramolecular chains; the oxygen atoms belong to the nitro groups. and the S–M···O systems are linear.[75] Lead and organolead phosphor-1,1-dithiolates. e.g., $Pb(S_2PR_2')_2$ and Ph_3PbS_2-PMe_2;[76,77] and organoantirnony oxides and amides. e.g., $(Me_2Sb)_2O$ and $(Ph_2Sb)_3N$[78,79] provide other examples. Diphenylantimony dimethyldithioarsinate, Ph_2SbS_2-$AsMe_2$, is the first supramolecular polymer associated through dithioarsinate bridges.[77] Mesitylselenenyl iodide. 2,4,6-$Me_3C_6H_3SeI$,[80] organotellurium azides, $ArTe(N_3)_3$,[81] and numerous others can be cited. Iodo–nitro interactions (I···O=N secondary bonds) are also important and can lead to formation of supramolecular polymeric arrays.[82] In (arylsulfonylimino)iodoarenes, $ArI–NSO_2Ar'$, supramolecular one-dimensional (ID) chains. ladders. two-dimensional (2D) layers. and three-dimensional (3D) stepladders are formed through I···O and I···N secondary bond interactions.[83] Some of the above are illustrated in Scheme 7.

SECONDARY BONDS ENHANCED BY ELECTROSTATIC INTERACTIONS

Like in the hydrogen-bond systems. when secondary bonding interactions occur between charged species, the strength of the bond is increased. Numerous examples of anion–cation secondary bond interactions can be cited, but only a few will be mentioned here for illustration. Thus. secondary bonds are responsible for the formation of the dimeric diphenyliodonium halides. $[Ph_2IX]_2$ (X = Cl, Br. I). built through secondary interactions between Ph_2I^+ cations and X-anions: the X···I···X system is symmetrical. and the I···X interatomic distances are each 0.77 Å longer than covalent I–X(g) distances.[77] A tetramer $[R_2IBr]_4$, coexisting with the dimer $[R_2IBr]_2$ in the same crystal. both built from R_2I^+ cations (R = p-MeC_6H_4) and Br^- anions kept together by secondary bonds. was also reported.[85]

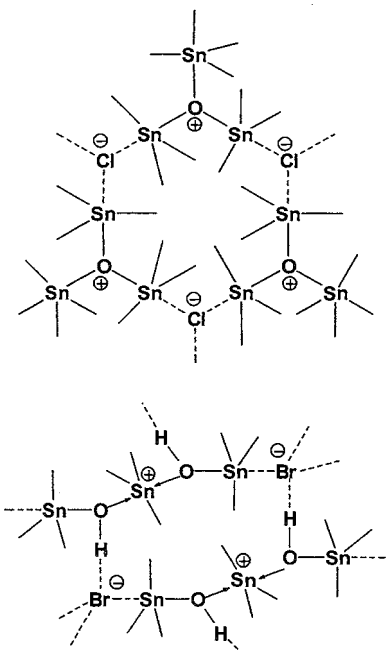
Some interesting organoiin examples can be cited (Scheme 8). In the solid-state structure of $[O(Sn$-$Me_3)_3]^+Cl^-$, trigonal planar cations interacting with Cl^- anions through both secondary bonds and electrostatic

interactions form graphite-like 2D layers.[86] In another tin–oxygen supramolecular array, trinuclear cations $[Me_3Sn(\mu\text{-}OH)SnMe_3(\mu\text{-}OH)SnMe_3]^+$, formed through dative-coordinate bonds between two Me_3SnOH molecules and a Me_3Sn^+cation, are interconnected through $Me_3Sn\cdots Br^-$ secondary bonds, and additionally through $O–H\cdots Br^-$ hydrogen bonds, into a complex 3D architecture. Cation–anion electrostatic interactions probably contribute significantly to the lattice energy.[87]

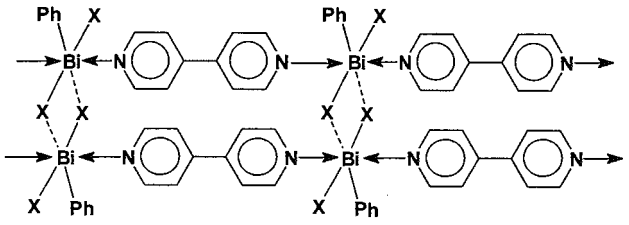
In the structure of triphenylselenonium chloride monohydrate, hydrogen bonds participate in addition to secondary bonds and electrostatic interactions between Ph_3Se^+ cations and Cl^- anions.[88]

SELF-ASSEMBLY THROUGH COOPERATION OF SECONDARY BOMBS WITH OTHER TYPES OF INTERMOLECULAR INTERACTIONS

Innumerable possibilities exist based upon the cooperative use of classical dative-coordinate and secondary bonds for supramolecular synthesis. This strategy is only in its infancy but can serve for the controlled design of materials with predictable structures. In a first alternative, discrete supermolecular species formed through dative bonds are further associated into polymeric arrays through secondary bonds. This case can be illustrated by the adduct of trimethyltin chloride with the dimeric tristannoxane $[ClMe_2SnOSnMe_2(OSnMe_3)]_2$. The dimer is formed through dative coordinate oxygen–tin bonds. In the crystal, $Sn\cdots Cl$ secondary bonds from the terminal $OSnMe_3$ moiety of the dimer to $ClSnMe_3$ molecules and from $ClSnMe_3$ molecules to the terminal Me_2SnCl moieties of the dimer. connect the two compounds in a supramolecular architecture.[89]



Scheme 8 Supramolecular structures formed through cooperativity of secondary bonds and electrostatic interactions.



Scheme 9 Supramolecular structures formed through cooperativity of secondary bonds and dative-coordinate bonds.

A second alternative is illustrated by the supramolecular architectures built from 4,4′-bipyridyl and arylbismuth(III) halides, in which infinite chains of *trans*-$[BiX_2Ph(4,4'\text{-bipy})]_x$ (formed through coordination of the ditopic ligand 4,4′-bipy) are interconnected into intricate 3D structures through $Bi\cdots X$ secondary interaction ~ [(Scheme 9).

Complex supramolecular structures involving intermolecular $Sn\cdots S$, $S\cdots S$ secondary bonds and $N–H\cdots S$ hydrogen bonds were observed in organotin derivatives of substituted 5-mercapto-1,3,4-thiadiazoline-2-thione.[91] The simultaneous presence of $S–Sb\cdots Cl^-$ secondary bond synthons and $Cl^-\cdots H–N$ hydrogen bonds in the solid-state structure of dichlorobis(trimethylenethiourea)antimony(III) chloride also leads to an interesting supramolecular self-organization.[92] The cooperation of secondary bonds and $Te\cdots\pi$ aryl interactions also produces some spectacular supramolecular architectures.[93]

CONCLUSION

Secondary bonds, alone or in cooperation with other types of intermolecular interactions, can serve as a versatile bonding motif for the supramolecular self-assembly and self-organization, and therefore, may be exploited for the design of novel materials. A great diversity of compositions and structures, based mostly on heavier main group elements, can be expected. A new chapter of supramolecular chemistry, based upon intermolecular secondary

bonding, is emerging, and significant progress along these lines can be expected in the near future.

Selectivity: Thermodynamic and Kinetic

Franz P. Schmidtchen
Munich Institute of Technology, Garching, Germany

INTRODUCTION

The introduction of selectivity into chemical systems and the understanding of its foundations are major motives for dealing with supramolecular chemistry. Examples from the living world clearly show that it is the capacity to distinguish compounds and their conversions with respect to a particular function that enables the concerted and balanced interplay of components in a complex system. Selectivity in the supramolecular context is. therefore, intimately connected to a purposefully integrated function. let it be a simple reversible adhesion phenomenon of two particles or highly sophisticated vectorial processes like catalysis. transport, or information transfer (signaling). This also includes the targetted blocking or annihilation of these functions. The basic platform defining the stage for observation of selectivity and ultimately providing a means for its deliberate alteration is the molecular complex formed reversibly from at least two, in many instances. however, many more. molecules. For the present discussion. I arbitrarily designate the species participating in this interaction as host and guest binding partners. Selectivity emerges from two stages tied to the occurrence of the noncovalently bound and truly supramolecular associate species (Scheme 1, Fig. 1).

At the level of complex formation, compounds can compete for binding at a molecular target and will thus be differentiated according to their chemical affinities. Selectivity here arises from the differential extent of binding reflected in unequal concentrations of the various host–guest complexes formed from identical guest concentrations in reversible binding equilibria. With a defined set of environmental limits given, selectivity will be time invariant and a sole function of the thermodynamic state of the system. Thus. it is termed thermodynamic selectivity. expressed as a ratio of binding constants of the competing guests.

Alternatively. selectivity may relate to a nonequilibrium process. to the differential transformation of two (or more) molecular complexes that may be formed even in similar concentrations from the various host–guest partners. In this case. the discrimination of one complex species over the others depends on differences in the respective rates of the forward reactions leading from the complex or the starting state (depending on the concentration domain) to the final function (Fig. 2). As a corollary, it is the rate of change of the system that determines the selectivity pattern under these irreversible conditions, justifying the designation as kinetic selectivity.

Both strategic versions of the origin of selectivity are widespread in nature as well as in technological applications. Typical examples for thermodynamic selectivity include molecular aggregations, like the formation of rnicelles from amphiphilic molecules (soaps), or gels from certain proteins (gelatine), or artificial gelators, respectively. Also the strand pairing of DNA. the assembly of molecular capsules from urea-appended calixarene derivatives, or the construction of virus coats from monomeric protein building blocks belong to this class. Thermodynamic selectivity principles lend themselves to the rational development of technical applications, as in the unperturbed detection of analytes with selective electrodes or the extraction and recycling of precious elements from sea water or nuclear waste.

Kinetic selectivity. on the other hand, is a constitutive part of all living systems, which necessarily operate far from chemical equilibrium. Material fluxes across membranes via dedicated carriers or molecular channels are governed by this type of selectivity, as are the generation of signals, e.g., the light emission of the firefly. Enzyme catalysis probably is the most prominent realization of kinetic selectivity. providing not only the balanced and just-in-time supply of all vital materials but also insuring high fidelity in the information transfer in DNA replication and protein synthesis. The technical exploitation of kinetic selectivity using supramolecular approaches in general is. as yet. less amenable to design than its thermodynamically based counterpart. Nevertheless. kinetic optical resolutions and asymmetric chemical inductions are shiny examples of the implementation of kinetic selectivity in high added-value industrial processes, and they demonstrate feasibility and utility.

THERMODYNAMIC SELECTIVITY

Differentiation between molecular species A. B. or C (deliberately designated heie as guests) that compete for a certain function can be established through their reversible fixation at another molecular target (named the host),

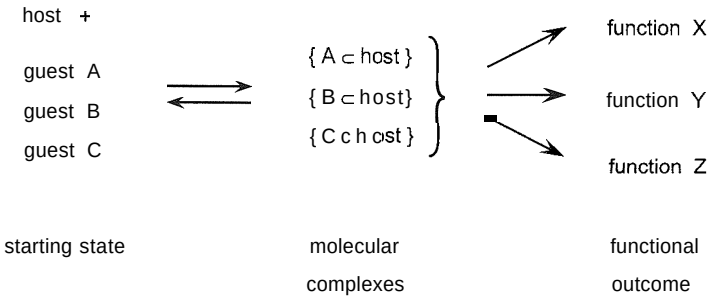
DOI: 10.1081/E-ESMC 120012656



Scheme 1 Schematic division of the molecular events producing selectivity from the pairwise interaction of supramolecular binding partners (the host and the various guests). Thermodynamic selectivity (left-hand side) relates to the differential concentrations at equilibrium of the molecular complexes formed whilst kinetic selectivity (right-hand side) refers to their differential rates of breakdown to produce some function.

resulting in a host–guest complex (Scheme I). In principle; mutual adhesion of molecules is nothing but a universal property of matter. Selectivity comes into play only if the interaction between host and guest dramatically exceeds the usual level. As a consequence, a potential well is formed that characterizes the mutual distance and orientation of the binding partners and the energetic gap separating this peculiar configuration (the host–guest complex structure) from the multitude of random collision complexes. For expression of selectivity, this state needs to be more populated in thermal equilibrium than any alternative molecular arrangement. Because the abundance of energetic states for host–guest structures of higher energy is much greater than the unique "best" structure. the preferential population of the latter can be reached only if either the thermal energy (i.e., the temperature) is very low or the energy gap is substantial. This requirement also defines the frame for the observable selectivity between competing guests, because the respective differences in their interactions with the host can only be great if the absolute size of the interaction is even greater. The central criterion here is the affinity constant K_{ass}, which describes the thermodynamic equilibrium of associated and separated binding partners, including all solvation changes. The association constant K_{ass} is related to the Gibbs energy AG" of the associative event by $\Delta G^\circ = -RT \ln K_{ass}$ (R=universal gas constant; T=absolute temperature). Thus, the optimization of thermodynamic selectivity requires maximizing $\Delta\Delta G^\circ = \Delta G^\circ\{\text{Achost}\} - \Delta G^\circ\{B \subset \text{host}\}$, which is equivalent to the ratio of the corresponding association constants $K_{ass}\{A \subset \text{host}\}/K_{ass}\{B \subset \text{host}\}$. In this scenario, selectivity is independent of the presence of the variety of other guest species. However. arguments based on statistical thermodynamics led to the conclusion that, at least in the biological context involving many potential competitors, the observable selectivity will depend on the type and concentration of every competing species in the entire ensemble.'" So far, our understanding of thermodynamic selectivity is tied to the concept of a peculiar structure that host and guest will attain. The rather frequent observation of enthalpically neutral or even endothermic host–guest binding in polar hydrogen-bonding solvents and especially in water, point to the conclusion that a unique structure as implied by a potential well (i.e., a negative enthalpy of association) is not a mandatory requirement for selectivity. The negative Gibbs energy necessary for high-affinity binding results from a compensatory interplay of enthalpy and entropy, as shown by the fundamental Gibbs–Helmholtz equation ($\Delta G = \Delta H - T$ AS) and may originate exclusively from a large and positive entropy component that outmatches any unfavorable (positive) enthalpy contribution. However, highly positive association entropies imply less-structured modes in the associated versus the starting state that most

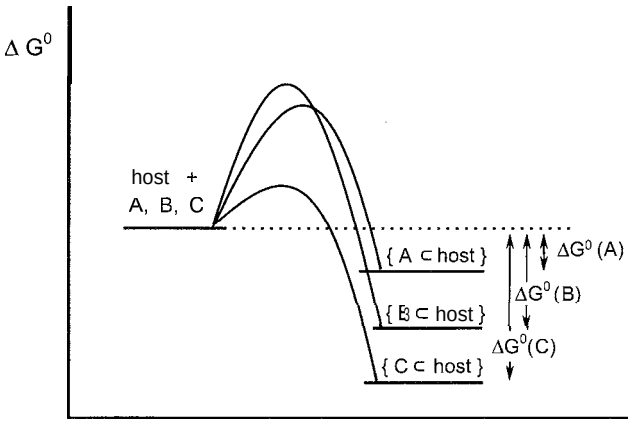


Fig. 1 Free-energy diagram relating the pertinent energy quantities to the thermodynamic selectivity of three competing guest species. The host–guest complexes are formed according to their respective host–guest affinities represented by free energies of association ΔG°. Preferential binding is expressed as AAC° [e.g., $\Delta\Delta G^\circ = \Delta G^\circ(A) - \Delta G^\circ(C)$].

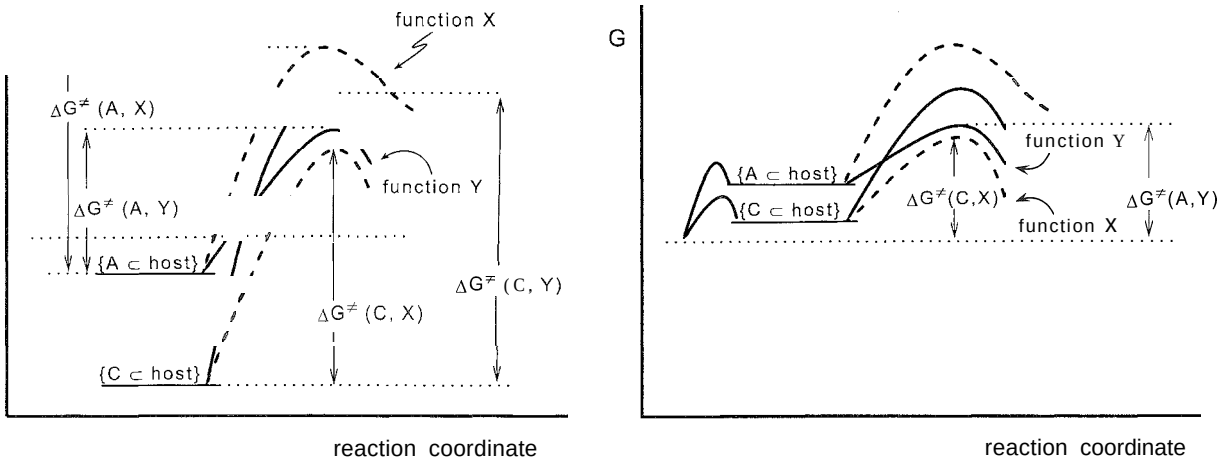

Fig. 2 Free-energy diagram relating the various barriers of activation for two competing guests (A and C) with respect to two different functions (e.g., two catalytic pathways leading to different products) to the kinetic selectivity. Two limiting situations need to be considered: The left panel shows the case when saturation of the molecular complexes occurred {[A], [C] $\gg 1/K_{ass}$ (A, C)}. In the scenario shown, Guest A would be kinetically selected to perform function *Y*, because this is the process with the lowest barrier. However, using low concentrations of the guests {[A], $[C] \ll 1/K_{ass}$ (A. C), panel on the right}, the free energies of the host–guest complexes are elevated. and the barriers relative to the starting conditions take over. This causes Guest C acting in function X to be kinetically selected.

likely do not only emerge from solvent reorganization. It is conceivable that on association of the binding partners, certain conformational restrictions present in the uncomplexed species are relieved. yielding an associated ensemble that has more degrees of freedom and thus less pairwise correspondence of atomic positions, including solvent molecules. than before the binding event. The relaxation of structural definition is compatible with the selectivity-based function but eludes ready comprehension using popular complementarity models like the lock-and-key picture of molecular recognition.[2]

Though maximizing affinity is a profitable way to boost thermodynamic selectivity, there is an upper limit to it due to practical limitations. Taking the well-studied avidin–biotin system as a prototypical example of a high-affinity supramolecular complex ($K_{ass} = 10^{15}$ M^{-1}) and assuming the fastest possible association of host and guest (diffusion controlled rate $\sim 10^9$ M^{-1} sec^{-1}), one arrives at a dissociation rate constant of $k_{off} = k_{on}/K_{ass} = 10^{-6}$ sec^{-1} corresponding to a half-life for dissociation of ca. 10 days or about 3 months for establishing equilibrium conditions. There are not many relevant processes known that rely on the exploitation of thermodynamic selectivity in this time regime.

Biological systems. which usually operate on a much shorter time span but are nevertheless in need of high affinity and seiectivity, bypass the problem of slow dissociation by polyvalent binding.[3] This binding mode refers to the simultaneous fixation of several moieties (anchor groups) of one binding partner capable of dedicated interaction with a set of corresponding substructures of the other. The participation of multiple interaction sites results in the accumulation of all free-energy contributions. compounding the total energy available for differentiating action. Contrary to single-site binding. the adhesion of host and guest can be destroyed in steps by cornpetition with monovalent guest analogues, leading to greatly improved dissociation kinetics.[3] In addition, polyvalent binding can be modulated by the mutual influence of the anchor groups on one another.[5] This influence can turn out to be opposing to binding, i.e., the following binding steps addressing the second. third. etc., anchor groups occur with smaller affinities (smaller microscopic K_{ass} values) than the preceeding ones. Though the interaction is progressively weakened in each step, the overall affinity increases with every supplementary site, contributing some free energy ΔG_i° ($\Delta G_{total}^\circ = \Sigma \Delta G_i^\circ$; ΔG_i° is more negative than ΔG_{i+1}°). Cooperativity between the various anchor groups is negative, and in general, this situation appears to be more common. However, the alternative scheme in which the affinities in subsequent binding steps are progressively strengthened, giving rise to positive cooperativity (ΔG_i° more positive than ΔG_{i+1}°), holds a peculiar virtue with respect to function: low-affinity binding of the first anchor group to a inolecular target can trigger the binding of all subsequent steps, thus providing an overall free energy of interaction that can exceed a certain threshold value defined for initiating some function. Synergistic action here approaches an all-or-nothing switch that is useful on

many occasions in supramolecular chemistry—from the clearance of antigens from the bloodstream by the immune system[3] to the formation of kinetically stable molecular capsules from calixarene building blocks.[6–8]

Tailored shaping of thermodynamic selectivity requires considerable insight into intimate molecular details. In comparison, the blocking of such delicately balanced functions by brute binding force interference should be easier to achieve. This lays the foundations for the best-established application in tailoring thermodynamic selectivity: the rational drug design. Guided by complementarity principles. artificial compounds are looked for that would interact best with a target site, for instance, in a protein that is essential for some biological function. Better binding of the artificial guest prevents binding of the natural substrate and interrupts its proper function. The need for selectivity is basically twofold, because drug binding has to override the natural host–guest process but also must avoid interfering at any other potential target site (here disregarding the equally important so-called ADME [Absorption, Distribution, Metabolism, Excretion] characteristics[9]). The approach chosen most frequently employs the computational maximization of the interaction enthalpy of drug and target. with or without taking solvent participation and the internal flexibility of the binding partners explicitly into account (docking). However. the tacit assumption that the enthalpies of interaction ΔH° derived in this way reflect or even parallel binding free energies ΔG° is not founded. Rather, it is common experience that owing to the phenomenon of enthalpy–entropy compensation,[10,11] dramatic trends in enthalpy variation do not materialize in equilibrium affinities. Nevertheless. in the absence of practicable methods to account for association entropies and with the proviso of conscience of their fundamental limitations; docking procedures can provide guidelines in thermodynamic selectivity optimization.

KINETIC SELECTIVITY

While the conversion of a supramolecular complex back into its constituent components is part of the equilibration process and, as such, is contained in thermodynamic selectivity. any alternative transformation leading to a function is characterized by a rate and a corresponding monomolecular rate constant. Principally, it can refer to just one elementary reaction yielding the function, but more likely, function generation will be composed of several successive steps. In any case, a pathway is defined that features a certain activation barrier that, in turn, determines the total flux on this route. Typical kinetically controlled vectorial processes include the transport of compounds across membranes, the photosynthetic electron translocation, or chemical transmutations of starting compounds into products using a molecular catalyst. Because a flux mandates nonequilibrium conditions, this defines a sine-qua-non restriction for establishing kinetic selectivity. In essence: the term refers to the different rates with which a single supramolecular complex decays along the various options for reaction (Scheme 1, Fig. 2). Alternatively, the differences in rates shown by the set of host–guest complexes of competing guests for eliciting the same function are addressed. The route requiring to pass the lowest activation barrier generates the highest flux and is thus preferred.

Optimizing kinetic selectivity does not necessarily require a barrier to be lowered and the speed of the corresponding process to be increased. Because it is the relative height of the barriers that counts, the uniform enhancement of the rate-determining barriers of all competing pathways excepting the desired one would be equally effective. This concept is realized in some natural catalytic systems, where it is termed "negative catalysis."[12] If the desired process cannot be accelerated sufficiently to insure preference over another fast side-reaction, inhibition of the latter may be the only means by which to foster kinetic selectivity. Another facet of the same principle is realized in the kinetic shielding (dynamic protection) of highly reactive species generated in the interior cavity of helnicarcerand hosts."'' For instance, photolytic decomposition of suitable precursor molecules trapped in the cavity of these encapsulation hosts can furnish exotic molecular species like cyclobutadiene,[14] which are too reactive to survive in free solution but can be observed and studied readily when

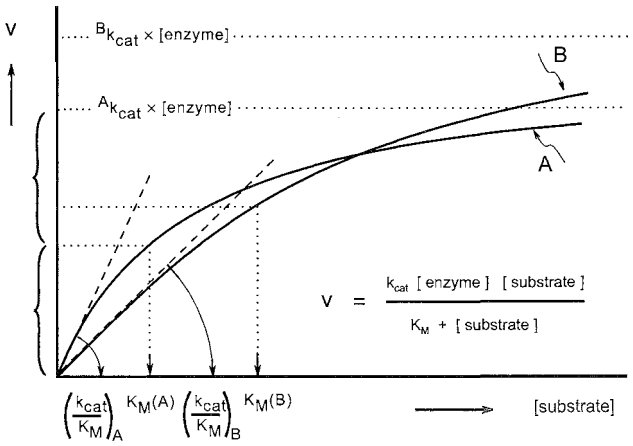

Fig. 3 Michaelis–Menten enzyme kinetics. Rate versus concentration profile for two competing substrates A and *B*. both showing simple saturation behavior. The kinetic domains are defined relative to the respective Michaelis constants K_M that represent the substrate concentrations at which just one half of the maximal rate is reached.

protected from attack from potential reaction partners behind the walls of the molecular cage. Control experiments that address the porosity of the cage can confirm that the elongated lifetime of the encapsulated species is a consequence of kinetically selective shielding rather than due to ground-state stabilization contributed by the host–guest interaction.

The most prominent example in observing kinetic selectivity is enzymatic catalysis. By definition, catalysis is a kinetic phenomenon, and though the origin of enzymic catalysis at present is not totally lucid and is still under vivid debate, it is undisputed that it mandatorily relies on the formation of a molecular complex (the so-called Michaelis complex) that determines the further fate and rate of conversion of the substrate. If it were for this fact only, it would be justified to describe enzymic catalysis as a process that provides an alternative mechanistic pathway from starting materials to products, however, with a lower activation barrier than in the uncatalyzed reaction. As a consequence of the formation of Michaelis complexes of the two competing substrates A and *B* and on the basis of fundamental Michaelis–Menten enzyme kinetics that describes the typical nonlinear rate versus concentration profile (saturation kinetics). by a hyperbolic function (Fig. 3), two kinetic regimes must be distinguished. The first can be described as follows: at high concentration of substrates A or *B*, respectively. the rates become independent of concentration. and the kinetic selectivity approaches the ratio of the unimolecular rate constants $k_{cat}(A)/k_{cat}(B)$, featuring the decomposition of the Michaelis complexes (cf. Fig. 21). Second. conversely, at low substrate concentration, the kinetic selectivity is set by the ratio of second-order rate constants $(k_{cat}/K_M)_A/(k_{cat}/K_M)_B$ representing the slopes of the tangents in the origin in the rate versus the concentration plot of the substrates. Formally, this ratio corresponds to the ratio of bimolecular productive encounter of the substrates with the enzyme molecule on the forward reaction pathway. On the basis of this scheme, it is conceivable that the kinetic selectivity will change with reaction progress (decreasing concentrations) and may even switch its preference. That is why nonlinear effects are commonplace and are regularly observed in applications that involve molecular complexes, e.g., in kinetic asymmetric inductions or dynamic racemate resolutions.[""] In spite of these complications, the kinetic selectivity can reach exorbitant values. In the enzymatic interconversion of lactate and pyruvate using lactate dehydrogenase and the coenzyme NAD, the enantiodifferentiation of the prochiral faces of the nicotinamide ring of the coenzyme is stereospecifically reliable to an error of 1 in 5×10^7 turnovers,[16] corresponding to an enantiomeric excess of L-lactate formation of about 99.999994.

Kinetic selectivity is profitably engaged in instances where high fidelity in the selective outcome must be guaranteed at reasonable speed. In the biological context. the transmission of genetic information from one generation to the next, i.e., replication of the genome,[17] or in another example, the translation of the base sequence of messenger RNA into the primary sequence of amino acids of a growing peptide strand,[18,19] provide well-studied cases. In either case, it is the kinetic distribution of a high-energy intermediate between hydrolysis and incorporation into the growing biopolymer chain that allows, e.g., in replication, the intrinsic thermodynamic selectivity of base pairing (A-T versus A-C $\sim 1{:}10^4$) to elevate to the required $1{:}10^8$ fidelity ratio mandated by prokaryotic survival. Nature set up a kinetic editing mechanism in DNA polymerase that double-checks the incorporation of the correct base that is complementary to the one in the parent strand of the duplex. Editing involves the kinetic interplay of an initial ligating step that attaches the incoming nucleotide according to the Watson–Crick rules of base complementarity and a subsequent step of its hydrolytic expulsion. If a less well-fitting nucleotide is adventitiously incorporated, an exonuclease activity inherent in DNA polymerase cleaves the misincorporated nucleotide off again, opening another chance for correct elongation of the duplex. The hydrolytic exonuclease action is not specific, and in order to avoid any erroneous incorporation. part of the correctly ligated nucleotides is also cleaved. Proofreading of the copied message as described is costly for the organism, because phosphate ester linkages are destroyed that were introduced at the expense of high-energy triphosphates and because part of the correctly formed sequence is eradicated. The formal analysis reveals that selectivity increases only if a substantial cost in erroneously excised bases is tolerated. In the concrete case of *Escherichia coli*, an enhancement of the fidelity of correct base pairing by a factor of 10^3–10^4 requires about 10% of all correctly incorporated nucleotides to be excised again in the editing step.[20]

In biological systems, kinetic schemes for selectivity augmentation are widespread but are usually built upon highly sophisticated interwoven reaction networks. Naturally, this finding obviates easy adaptation and implementation into abiotic mimicks. though the principles seem clear. and attractive applications to artificial chemical flux systems are readily envisaged.

CONCLUSION

The diversity around us, including the biological world (life), emerges from and depends on the ability to distinguish and exploit alternatives (selectivity). This discriminative process can rest on the energetic differences in thermodynamically definable and thus time-invariant states representing. however, in many cases, a

crude abstraction of the real situation in which the selectivity is expressed. Owing to the projection of reality onto the panel of concepts offered by current thermodynamic theory and to the. at times, unscrupulous introduction of framing conditions as well as to the simple omission of as yet untreatable factors (e.g., entropy), rudimentary understanding and even prediction of selective behavior is possible. The results of thermodynamic selectivity are especially helpful for the purposive destruction of selective function as demonstrated by the undisputable success of tailored drug–receptor bonding.

Even more demanding is the comprehension of kinetic selectivity, because here the appreciation of energetic differences at multiple stages along competing functional pathways is required. Additional obstacles arise from the fuzzy and experimentally hard-to-define nature of transition-state structures in chemical conversions or other functional processes that need to be correlated with the energetic profiles. Minute misassignments there can easily ruin all attempts aimed at informed design. It is not clear at present whether just one model structure chosen to picture a particular position of the profile can be taken as a reliable representation of the ensemble of actually populated states.

Beyond doubt, we are making progress in unfolding the subtleties of selectivity generation, yet we have not reached the position at which to decide whether a deeper understanding of selectivity of either type expressed in condensed phases is open to encompassing reductionistic analysis.

Self-Assembling Capsules

Dmitry M. Rudkevich
The University of Texas at Arlington, Arlington, Texas, U.S.A.

INTRODUCTION

Self-assembly is the spontaneous. noncovalent association of two or more molecules under equilibrium conditions into stable. well-defined aggregates.[1,2] In nature. self-assembly is a ubiquitous strategy responsible for the formation of cell membranes, double-stranded nucleic acids. and viruses. In chemistry, self-assembly offers a rapid way to construct receptors. catalysts, and materials.''' With appropriate curvature and careful positioning of self-complementary bonding sites. self-assembling systems generate capsules.

That noncovalent dimerization of self-complementary structures may lead to closed surfaces, capable of encapsulating smaller molecules. was initially recognized by Julius Rebek. Jr., a decade ago,[4] while describing the structure of synthetic self-replicator 1 (Fig. I). By definition, self-assembling capsules are receptors with enclosed cavities that are formed through the reversible noncovalent interactions between two or more subunits.[5] Typically. capsules assemble through hydrogen bonding and metal–ligand interactions.[6] Hydrogen bonding is directional and specific. On the other hand. metal–ligand forces are much stronger. and metal–induced assemblies are more robust. At the same time, their strength can be controlled by solvent polarity and pH. Another way to classify capsules is by their dimensions; which vary between 50–1500 A^3.

In this article. we do not intend to cover hundreds of publications on self-assembling capsules. Instead, we will overview the most recognized examples. These frequently appear in original publications. The analysis will be developed on the basis of the increasing complexity of the capsule's structures, which is determined by the capability to form stable and specific molecule-within-molecule aggregates. Subsequently. we will examine unique features of encapsulating complexes that make them so attractive and promising for chemists.

VARIETY OF CAPSULES

Early generations of self-assembling capsules include Rebek's sports balls (Fig 1) The ''tennis ball' 2 assembles via eight C═O H—N hydrogen bonds between the self-complementary glycoluril NH and C═O groups [7] The inner volume of 2 is -50 A', which allows for the encapsulation of small molecules such as CH_4, C_2H_6, and Noble gases. Larger bisglycoluril-containing balls possess extended spacers and are capable of encapsulating two benzene-sized molecules. For example, the enclosed cavity of the ''softball'' 3 is ~ 300 $Å^3$.[8]

Typical molecular complexes depend on stereoelectronic complementarity between receptor and substrate. They are held together by hydrogen bonding: metal–ligand attractions; ion–ion; ion–dipole. CH–π, and π–π interactions; and van der Waals and solvophobic forces. In contrast. self-assembling capsules rely on so-called constrictive binding: the stability of these complexes is mostly provided not through the intrinsic host–guest attraction but through mechanical inhibition of the decomplexation process. In other words, encapsulation is influenced by energetic barriers for the guest exchange. The guest's size and its shape reflect the binding ability of the hosts. In the absence of additional intermolecular forces, recognition-through-encapsulation is largely determined by host and guest volumes. An extensive analysis of occupancy factors, or packing coefficients, of molecule-within-molecule complexes in solution gave the optimal value of 55% occupancy.[9] This is believed to also be a feature of natural biological cavities such as of enzymes. Importantly. the encapsulation takes place under subtle control. because the capsule's formation-dissipation occurs under equilibrium conditions. Capsules form reversibly on time scales of 10^{-3}–10^3 s. in between diffusion complexes (-10^{-10} s) and carceplexes ($\sim 10^{10}$ s).[5,6]

Dimeric calix[4]arene tetraurea capsules **4**, which arrived shortly after the sports balls. are probably the most studied to date.[10] Noteworthy. calixarenes and their relatives had a great impact in the history of self-assembling capsules. Their rigid, concave surface, commercial availability. and rich synthetic chemistry have made them extremely popular platforms for elaboration. In this article. we will have more examples of calixarene-based capsules. In dimers 4. a seam of 16 intermolecular C═O···H—N hydrogen bonds at the upper rim is formed. Eight urea moieties. four from each hemisphere. assemble head-to-tail. as shown in Fig. 2. This results in a rigid cavity of -200 $Å^3$, which can accommodate a benzene-sized guest molecule. The encapsulated guest exchange is slow on the NMR time scale. Experimentally. capsules 4

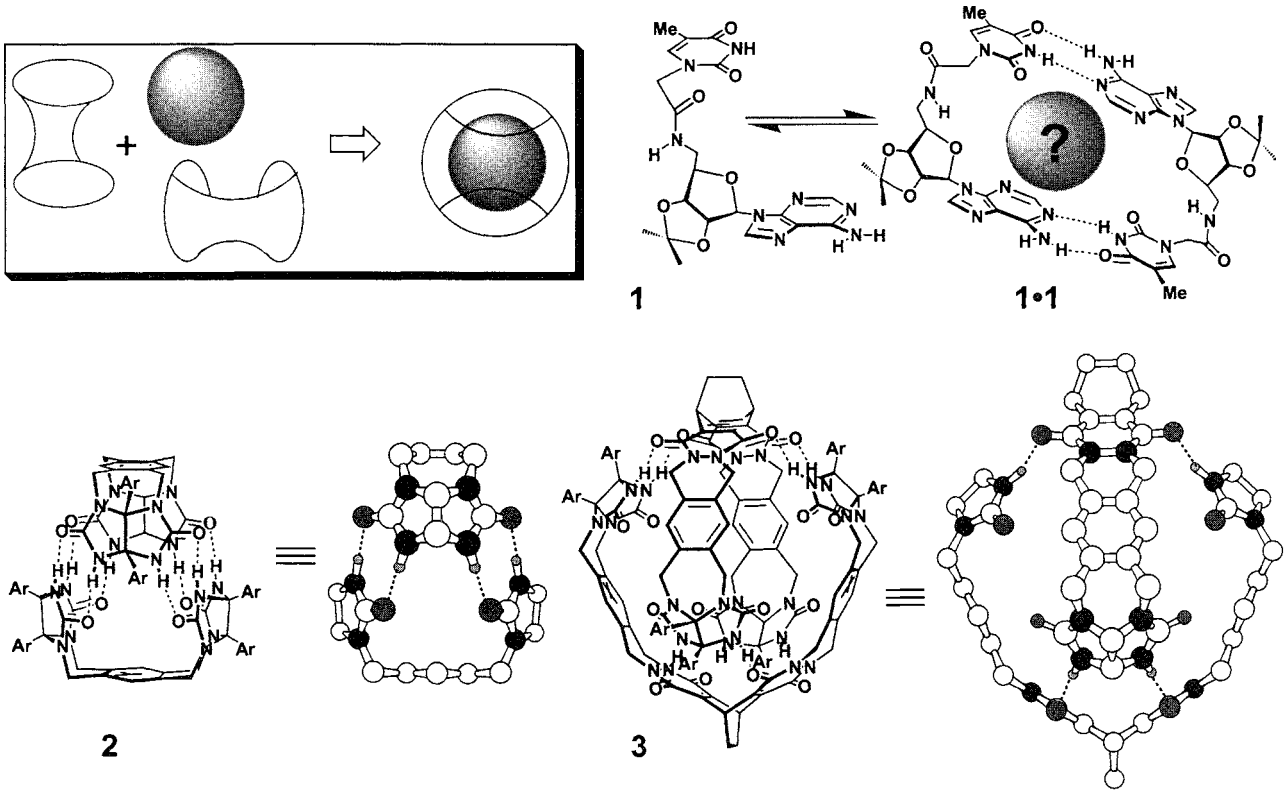

Fig. 1 Capsule formation and early examples of Rebek's self-assembling capsules: self-replicating dimer 1·1, the tennis ball 2. and the softball 3.

include benzene, toluene; halobenzenes, and polycyclic aliphatics (e.g., camphor derivatives, 3-methylcyclopentanone). The encapsulated benzene molecule. for example, is observed at -4 ppm in deuterated p-xylene. For the encapsulated fluorobenzene, the CH protons are seen between 5.5 and 3 ppm and the para- and ortho-hydrogens are separated by more than $\Delta\delta=2$ ppm. Encapsulated aliphatic guests are seen upfield of 0 ppm. From nuclear Overhauser effect spectroscopy (NOESY) experiments with the lower-symmetry capsule 4, a rate constant for the benzene exchange of $0.47\pm0.1\ s^{-1}$ was obtained.[11] The guest exchange time can, however, be significantly prolonged by introducing sterically bulky substituents (e.g., 2.6-diisopropylphenyl; 3,5-di-*t*-butylphenyl; trityl; p-tritylphenyl) to the urea moieties.[12] Some of these capsules are stable even in polar solvents.

When two different calixarene tetraureas are mixed together. heterodimers form along with the corresponding homodimers.[13] From a mixture of tetraurea and tetrasulfonyl urea. heterodimers form exclusively.[14] The increased acidity of the $-SO_2NH$ urea proton may be the reason for such selection. The preference of the aryl urea/sulfonyl urea could possibly be the basis of a binary molecular code.

Electrospray ionization mass spectrometry (ESI MS) was successfully used to characterize capsules **2**–**4** in solution and in the gas phase. Ion labeling in this case was achieved through the encapsulation of quaternary ammonium ions in $CHCl_3$.

Larger capsules entrap more than one guest. Self-complementary cyclic tetraimides built up on the resorcinarene platform and dimerize through hydrogen bonding into cylindrical capsule **5**.[15] Its estimated internal volume is 460 Å^3, and the internal dimensions are 6 x 15 Å (Fig. 2). In deuterated mesitylene, which is too bulky to fit inside, capsule 5 dissociates. but the addition of benzene or toluene immediately results in complex **5**·2Guest; two benzene or toluene molecules were quantitatively encapsulated inside 5 (^{1}H-NMR). The complexes are kinetically stable at ambient temperatures, and the encapsulation processes are slow on the NMR time scale. capsule 5 was used to entrap such useful chemical reagents as dicyclohexylcarbodiimide (DCC) and dibenzoyl peroxide (DBPO). Chemical stability of DCC and DBPO complexed inside capsule **5** was greatly improved. For example, inside the capsule, DBPO is stable for at least 3 days at 70°C in mesitylene-d_{12} solution, while in the absence of **5**, it decomposes within 3 h under those

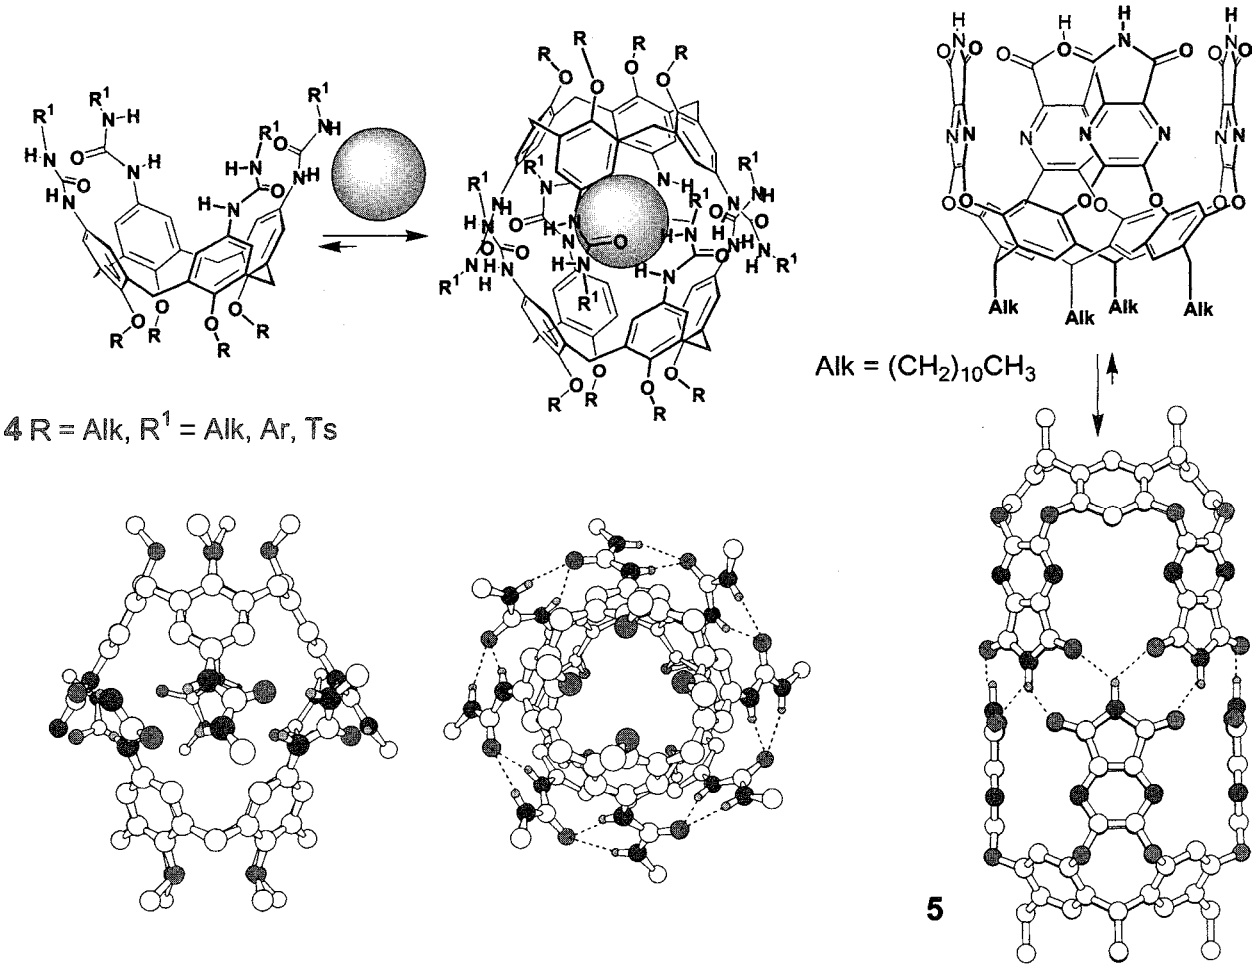

Fig. 2 Left: calix[4]arene tetraurea dimers 4. with the X-ray structure: Right: cylindrical capsule **5** and its computer-generated molecular model.

conditions. Due to the reversible nature of the hydrogen bonds stitching 5. competitive guest molecules or polar solvents can release the encapsulated DCC and DBPO.

Metal-induced capsular self-assembly **6** (Fig. 3) of two deep. resorcinarene-based cavitands was described by Dalcanale and coworkers.[16] Two tetracyanocavitands were connected through four square-planar Pd(II) or Pt(II) entities in CH_2Cl_2, $CHCl_3$, and acetone. Evidence of encapsulation of one triflate anion upon dimerization was obtained (^{19}F-NMR, x-ray analysis). For the Pt(II) case, the assembly process was shown to be reversible: Et_3N dissociated the capsule 6. while the addition of trifluoroacetic acid restored it.

Examples of Co(II) and Fe(II)[17] resorcinarene-based cages **7** came from the group of Harrison (Fig. 3). These are water-soluble and formed by combining $CoCl_2$ or $FeCl_2$ in aqueous solution at pH > 5 with the cavitand, functionalized with four iminodiacetic acid moieties. Upon synthesis, six water molecules initially occupy the inner cavity. When the appropriate guest molecule is present in the reaction mixture; it usually goes inside, replacing the water. Benzenes, halobenzenes. chlorinated hydrocarbons, (cyclo)alkanes, and alcohols were thus trapped in aqueous solution. Due to the paramagnetic nature, these complexes may act as NMR shift reagents, as they cause substantial upfield isotropic hydrogen shifts ($\Delta\delta = 25 - 40$) in the guest molecules with a signal separation of $\delta - 12$ ppm. At lower pH, the Iigand becomes protonated, the metal ion is no longer coordinated to the cavitand, and the assembly falls apart.

Fujita and coworkers elegantly combined triangular azaheterocyclic ligands with cis-protected square-planar Pd and Pt entities into highly symmetric capsules 8 and **9**.[18] The positively charged metal centers provided with water solubility on these capsules, and their hydrophobic interiors were able to accommodate a wide variety of organic guests. In capsule 8, Pd- or Pt-atoms occupy each corner of an octahedron. formed by four *tris*(4-pyridyl)

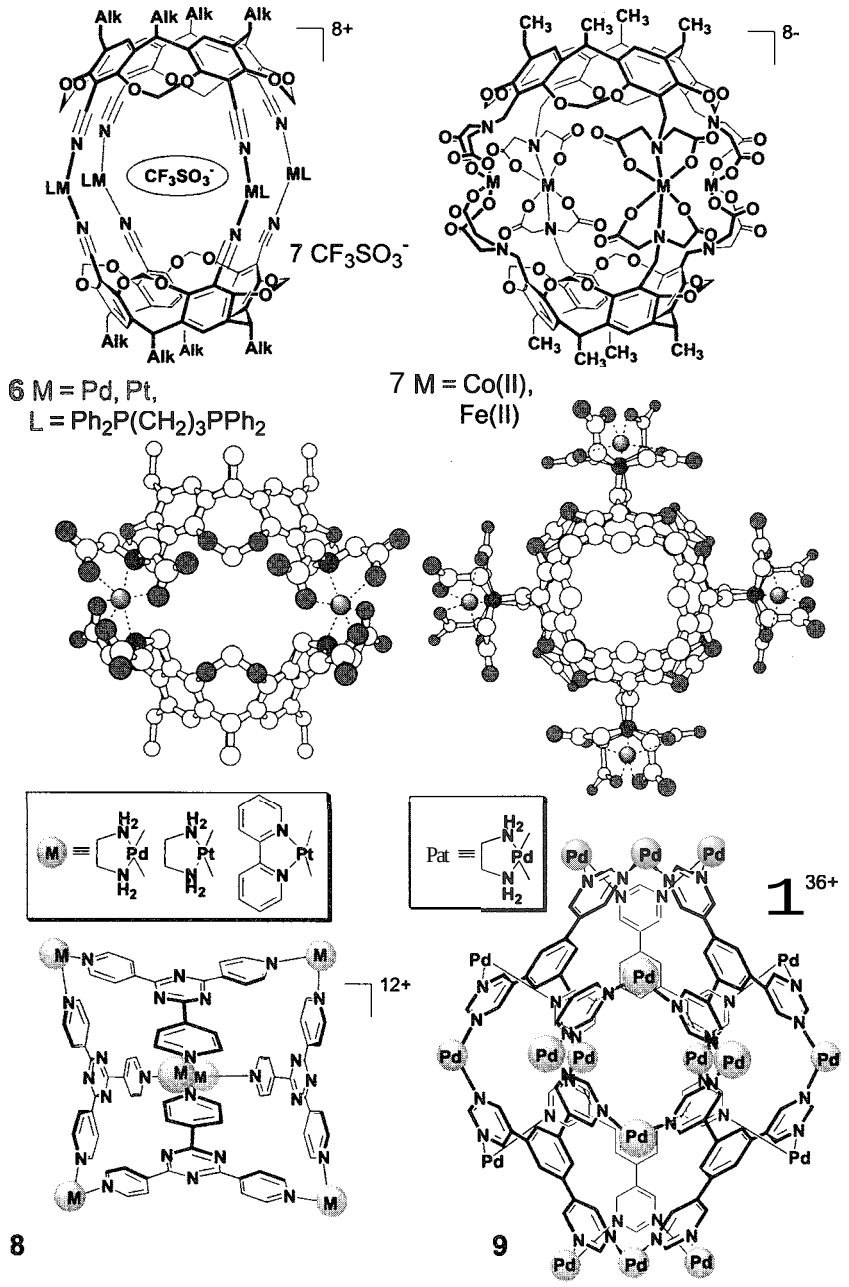

Fig. 3 Metallocapsules 6 and **7** and the x-ray structure of 7 [M=Co(II)]. Below: Fujita's self-assembling cages 8 and 9.

triazine molecules, with the longest metal–metal separation of 19 Å and the internal volume of ~500 $Å^3$ (Fig. *3*). The Pt-based assembly **8** is remarkably stable, even in HNO_3 and aqueous K_2CO_3. Cavities 8 are large enough to encapsulate four guests with the size of adamantane. two cis-azobenzenes, or two cis-stylbenes. Mixing six *tris*(pyrimidyl)benzenes with I8 Pd-complexes resulted in spectacular hexahedral capsule 9. Unlike 8. each face of the hexahedral capsule **9** is completely enclosed by the planar threefold-symmetric ligands (Fig. *3*). The volume of the inner cavity is considerably larger and ~900 Å. This means that guests like C_{60} can easily fit inside. However, only water or oxygen molecules may pass through the narrow pores (2×2 Å) in the structure.

By similar design, homooxacalix[3]arenes bearing 4-pyridyl groups at the upper rim form dimeric capsule **10** with $Pd(II)(Ph_2P(CH_2)_3PPh_2)(OTf)_2$ in a 2:3 ratio in dichloromethane[19] ((Fig. 4). A kinetically stable complex between capsule 10 and fullerene C_{60} was detected (^{1}H-

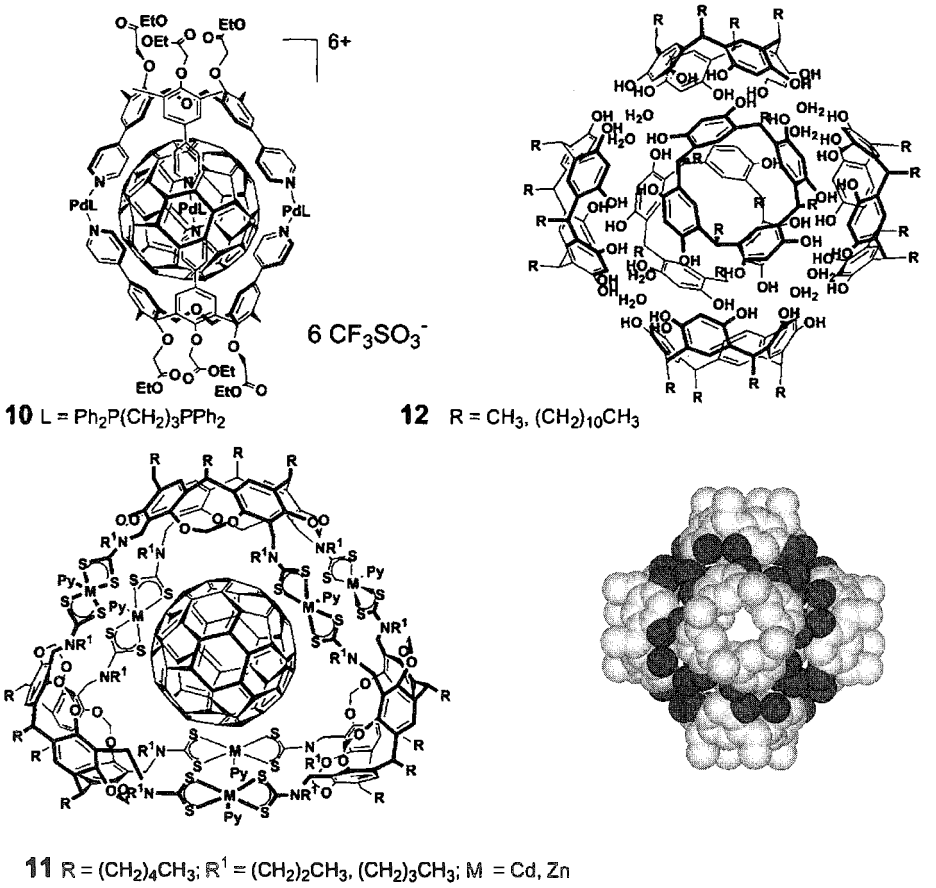

Fig. 4 Self-assembling capsules **10** and **BB** for fullerene entrapment. Atwood's hexamer 12 and its x-ray structure

and ^{13}C-NMR) in $Cl_2CDCDCl_2$; values for the association constant K_{ass} of 39 M^{-1} at 30°C and 54 M^{-1} at 60°C were obtained. Complexation of Li^+ cation at the calixarene lower rims induced their more flattened conformation, and this appeared to be even more suitable for the C_{60} inclusion: the K_{ass} value jumped to 2100 M^{-1} (30°C).

Spectacular trimeric assemblies **11** of cavitands functionalized with four dithiocarbamate units were obtained upon their mixing with Zn(II) and Cd(II) salts in EtOH/H_2O (Fig. 4).[20] In apolar solvents, the ^{1}H-NMR spectra were broad, but the complexes nicely crystallized from pyridine/H_2O; they were characterized by x-ray crystallography. Trimers **11** form stable 1:1 complexes with fullerene C_{60} in benzene and toluene solutions: the logK_{ass} values are within the range 3.5–6 (UV/Vis spectroscopy).

Six molecules of resorcinarene (R=Me or n-undecyl) and eight H_2O molecules self-assemble into a spectacular spherical nanocavity 12 with a diameter of 17.7 Å and an internal volume of ~1375 Å^3.[21] Sixty hydrogen bonds hold the nanocavity together (Fig. 4). In wet $CDCl_3$, hexamer 12 entraps bulky tetraalkylammonium and tetraalkylphosphonium cations.[22] Molecular modeling suggests that 12 is large enough to accommodate even fullerenes or porphyrins.

CAPSULES IN ACTION

The main feature of self-assembling capsules is, obviously: reversibly formed cavities, capable of encapsulating smaller molecules. Small capsules entrap single molecules, and nanosized capsules, for example **12**, may embrace up to a dozen molecules. By design, the motion of encapsulated guests may be restricted, and the guest release may be fast or slow. Chirality of capsules is also an important issue.[6] Even combinatorial libraries of capsules were invented. The level of molecular recognition, achieved within the capsule's interiors, is extremely high. Of particular importance are binary guest selection and the control of chemical reactivity.

The early case of pairwise guest selection through encapsulation was described for cylindrical capsule **5**. When benzene and *p*-xylene were added in a 1:1 ratio to a me-

sitylene-d_{12} solution of capsule 5. an unsymmetrically filled complex formed[23] (Fig. 5*)*. Such pairwise selection of the guests was also observed for benzene with *p*-trifluoromethyltoluene, p-chlorotoluene, 2.5-lutidine, and p-methylbenzyl alcohol to give new species with one of each guest inside. Moreover, capsule **5** exhibits complexation of smaller hydrogen-bonded pairs such as 2-pyridone/2-hydroxypyridine diiner. benzamide and benroic acid dimers, and *trans*-1,2-cyclohexanediol dimers.[15] When equal amounts of $\bar{\alpha}$, $\bar{\beta}$, and $\bar{\gamma}$picolines were added to a mesitylene-d_{12} solution of **5,** in addition to the corresponding homocapsules, nonsymmetrically filled heterocapsules were also formed (^{1}H-NMR).[24]

The idea of multiple guest encapsulation can also be expressed in polymeric self-assembling capsules. When two calix[4]arene tetraureas are covalently linked at their lower rims (see **13**; Fig. 5). hydrogen bonding results in a polymer chain of capsules, or polycaps.[25] The polycaps form only when a guest of proper size and shape is present; in competitive solvents such DMSO or MeOH. the polycaps dissociate. By analogy with parent capsules 4. the formation of heterodimeric systems was explored. Specifically, the polycap rapidly broke down to a dumbbell-shaped assembly when treated with an excess of the simple dimeric capsule (e.g., 4). The dumbbell featured a well-resolved NMR spectrum that showed all of the expected resonances. Combination of aryl- and sulfonylurea biscalixarenes effectively afforded heteromeric polycaps.[14] Monomers **13** were also functionalized with long alkyl groups capable of forming a liquid-like sheath

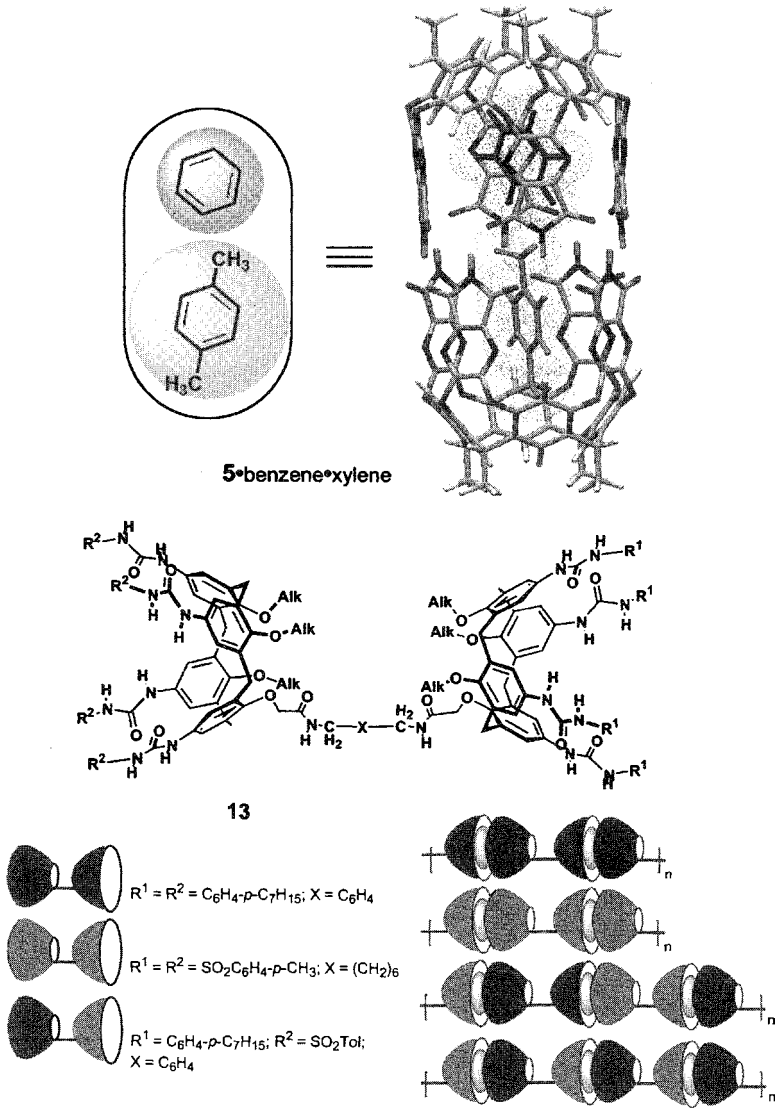

Fig. 5 Top: pairwise selection of guests aithin capsule 5: Bottom: reversibly formed polymeric capsules — Rebek's polycaps.

about them. At high concentrations. the resulting polycaps self-organize into polymeric liquid crystals.

Fujita used his capsules 8 for the stabilization of unfavored conformations. The treatment of an aqueous solution of capsule 8 with a solution of 4,4-dimethylazobenzene (*cis-trans*, 1:6) in hexane resulted in the formation of an unusual complex within the capsule walls:[26] the capsule selectively entrapped two equivalents of the cis-isomer (2D NMR). The cis-azobenzene molecules were stabilized within this encapsulation complex (Fig. 6): exposing the solution to visible light for several weeks did not result in the production of any of the thermodynamically favored *trans*-azobenzene. Most probably: the dimeric hydrophobic guest complex was formed inside the capsule: it is too large to penetrate as is. so it enters as a single species.

Another example of stabilization through encapsulation was demonstrated with capsule **5.** Upon encapsulation within 5. the tertiary anilide, *p*-[*N*-methyl-*N*-(*p*-tolyl)toluamide, is fixed in its *Z*-configuration[27] (Fig. 6). In bulk solution. these anilides exist as mixtures of E- and *Z*-isomers. with the E-configuration favored. The E-isomer, however, cannot fit inside capsule **5,** and its inherent stability is overcome by the CH–π, van der Waals, and dipolar interactions offered by the interior surface of the capsule.

Enclosed cavities in self-assembling capsules can even stabilize labile molecules formed in situ by the reaction of smaller molecular components. Thus, the condensation reaction of trimethoxysilanes in the cavity of 8 led exclusively to cyclic. trirneric silanol **14**, which was never isolated before.[28] In a typical reaction, phenyltrimethoxysilane was suspended in D_2O solution of **4** at 100°C (Fig. 6). After 1 h. the ^{1}H-NMR spectrum showed the exclusive presence of only one complex **8·14**. The formation **8·14** was also evidenced by ESI-MS and single-crystal x-ray crystallography. Not only the cyclic trimers **14** are formed in a "ship-in-a-bottle" fashion. but they were protected

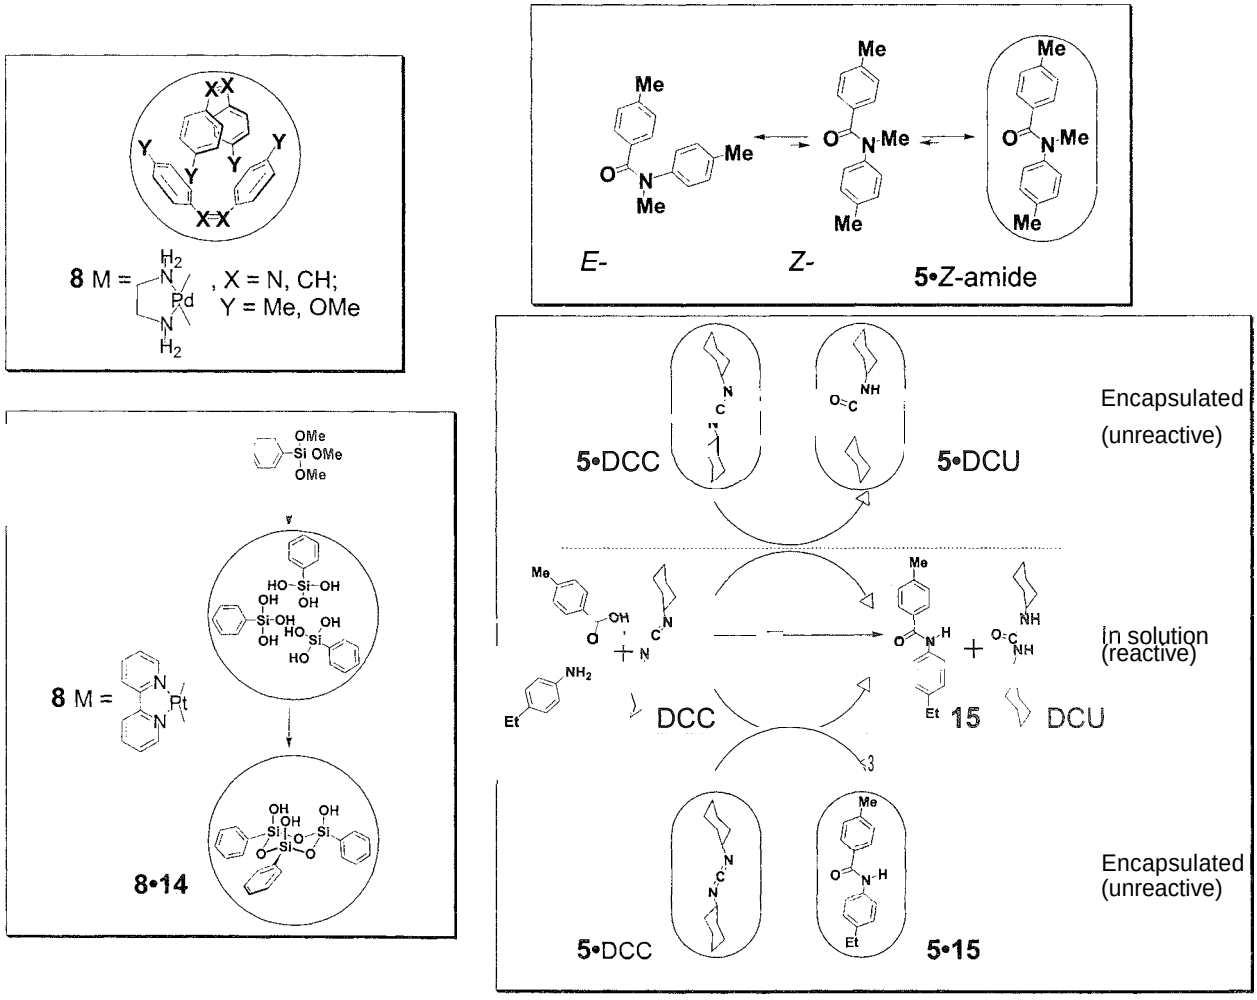

Fig. 6 Capsules in action: examples of stabilization unfavored isomers and controlling chemical reactivity through encapsulation.

by the cavity. They were stable even in acidic aqueous solutions and isolable as pure clatharate compounds.

A recent paper from the Rebek's laboratory offers a novel concept — autocatalysis with encapsulated reagent~.~''When DCC was trapped by capsule 5 (Fig. *6*), reaction between *p*-toluic acid and p-ethylaniline exhibited a complex kinetic behavior. Trace amounts of DCC free in solution proinoted the initial formation of an amide bond between the acid and the amine. The products of this reaction were anilide 15 and dicyclohexylurea *(DCU)*, and both are better guests for capsule 5 than *DCC*. Accordingly, increasing amounts of DCC are displaced from the capsule by emerging 15 and DCU, so the rate of the reaction increases as the reaction proceeds. The kinetics possesses a sigmoidal character. Such nonlinear kinetics can be viewed as an emergent property of the system as a whole. with the partnership of compartmentalization and molecular recognition giving rise to chemical amplification.

CONCLUSION

The impact of self-assembling capsules in chemistry is impressive and fully expected to grow. They already made an enormous inteliectual contribution to the field of molecular recognition, aggressively attacking the problems of intermolecular interactions and generating new supramolecular functions. The 'eversible formation of an enclosed cavity is a spectacular function. The notion of molecular cavities emerged alinost two decades ago, first with cyclodextrins and then with calixarenes and their analogs. The ambitious desire of chemists to have totally synthetic molecules permitting great structural variation; and to control the cavity's size and shape, led to the discovery of exclusive molecular containers — cavitands, carcerands and hemicarcerands, and subsequently, self-assembling capsules.[30] The functions came with cavities — sensing. separation. stabilization. and controlled release of active reagents. In some cases. significant NMR shifts of the entrapped molecules offer the possibility to deduce their structural features ''from inside,'' to determine the orientation of the guests and their interaction with each other and the receptor's interior walls. In principle. such host–guest complexes can be used for structural information/memory storage. Moreover, as two or even more guests are encapsulated. reaction/catalytic chambers can be envisioned. In biocheinistry and molecular biology. capsules are aiming at drug encapsulation, drug active transport through the cell membranes. and drug delivery. Approaches toward water-soluble assembling cavities and capsule-based polymeric materials were introduced. Construction of novel architectures will offer even wider perspectives.

Self-Assembling Catenanes

Gerhard F. Swiegers
Junhua Huang
Commonwealth Scientific and Industrial Research Organization (CSIRO), Melbourne, Victoria, Australia

INTRODUCTION

Perhaps the most challenging class of molecules to synthesize using classical organic chemistry is the intertwined species known as catenanes. Catenanes involve two or more cyclic molecular strands that are mechanically interlocked with each other.[1] The resulting attachment is not chemical in nature, although it is created by the formation of chemical linkages. The cycles are instead considered to be "topologically" bound to each other.

The preparation of a catenane involves two processes, each of which is difficult to perform using classical preparative techniques: (i) the formation of cyclic species, and (ii) the interlocking of two or more such species.[2] Because traditional synthetic organic chemistry must rely on statistical chance in high dilution processes to obtain cyclic species, only low yields can generally be obtained. Interlocking steps are similarly unfavorable, so that achieving cyclization and interlocking simultaneously is a challenging exercise.

Self-assembly techniques can, however, be used to favorably skew the probability of these processes taking place and thereby greatly simplify the preparation of catenanes.[3] In such techniques, noncovalent interactions are exploited to favorably dispose the assembly constituents for cycle formation and interlocking, thereby ensuring high-yielding procedures. A wide range of catenanes were obtained using self-assembly processes mediated by complementary n-donor–acceptor-, coordinate-, and hydrogen-bonding interactions, among others.

In this article. a brief and general review of catenanes in terms of their nomenclature, self-assembly, and a few pertinent properties; will be presented. Examples of the concepts discussed were limited to representative transition metal-mediated processes.

NOMENCLATURE

The simplest class of catenane involves two interlocked rings, as depicted in Fig. 1a. Such singly-interlocked species are termed 2-crossing catenanes and are formally given the nomenclature 2-crossing-[*n*]catenane, where *n* indicates the number of interlocked rings.[4] Multiply-interlocked catenanes, such as the doubly-interlocked species shown in Fig. 1b, have also been prepared. Such species are formally named *m*-crossing-[*n*]catenanes, where *m* refers to the number of times one strand crosses the other in traversing its full length.[4] The term "catenane" may be replaced in these terminologies with the term "catenate" or ''metallocatenate''[1,5] to indicate the involvement and presence of metal–ion coordination. Demetallation of a catenate has also been said to produce a catenand.[1]

Various multiring catenanes are known. One class involves several rings interlocked with a single. central ring as depicted in Figs. 1c,d. Such species are termed "molecular necklaces" (MN) and described using the nomenclature [*n*]MN, where *n* refers to the total number of cycles present.[6] The structure in Fig. 1c depicts a [4]MN, while that in Fig. 1d is that of a [5]MN. Two classes of linear oligocatenanes are known. Illustrated in Fig. 1e is the general structure of an [*n*]polycatenane, where *n* refers to the number of cycles present, while depicted in Fig. 1f is a poly-[2]catenane.[7] Sanders and Hamilton describe the former as catenane polymers. that is, polymers created by a series of interlocked rings. The latter are polymers containing [2]catenane structures within their backbones.[7]

SELF-ASSEMBLY OF CATENANES

Two self-assembly techniques are predominantly employed in the preparation of catenanes: "thermodynamic" self-assembly and self-assembly with covalent "modification."

Thermodynamic self-assembly involves the establishment of a dynamic equilibrium between the reagents and products in which catenane structures are energetically highly favored.[3] If such systems are kinetically labile. the products obtained in greatest proportions will be those that are also the most thermodynamically stable: that is. catenane structures. In such processes, thermodynamic influences drive the cyclization and the interlocking steps required in the formation of catenanes. Different types of

thermodynamic driving forces may: however, be employed for the different steps. For example, the formation of one type of noncovalent interaction may induce interlocking. while the formation of another creates cyclization. Entropy may also be employed to drive one of the steps.[3]

In self-assembly with covalent modification. conventional organic reactions are typically performed on self-assernbled structures in order to lock them into a kinetically stable state."'] For the preparation of catenanes, the self-assembly step is generally used to generate a precursor molecule with a disposition that allows for ready conversion to a kinetically stable catenane structure. The self-assembly step is most often employed to bring about interlocking. giving rotaxane or pseudorotaxane intermediates. These are subsequently converted to catenanes by simple cyclization reactions.

THERMODYNAMICALLY SELF-ASSEMBLED CATENANES

Illustrated in Fig. 2 is one of the most famous examples of a metal-mediated, thermodynamically self-assembled catenane. The reaction of 1 (M = Pd) with the angled bipyridyl ligand 2 was found by Fujita and coworkers to lead to the formation of cycle **3,** along with the interlocked catenane **4.**[5,8] The nature of the self-assembly process was elucidated by the fact that the relative proportions of 3 and 4 could be varied by altering the metal ion employed, the reaction solvent, the concentration of the reagents, and the substituents on the central phenyl moiety in the ligand. Thus. the use of Pt(II) led to the formation of the equivalent metallocycle 3 (M = Pt) but not the spontaneous formation of the catenane 4 (M = Pt). Concentration of an aqueous mixture of 1 and 2 (M = Pd) from 2–50 mM caused the equilibrium to shift strongly in favor of 4. Increased proportions of 4 were also obtained when using D_2O as solvent. Substitution of the central phenyl ring in 2 with fluorine atoms led to cycle 5 (M = Pd), however, no corresponding catenane structure was formed.[5]

While the lability of the Pd—N bonds clearly induced cyclization and allowed interlocking, the interlocking step itself must have been brought about by other influences. The fact that **5** would not interlock with itself, despite the lability of its Pd—N bonds, indicates that π-aromatic donor–acceptor interactions between the phenyl groups on the interlocking species played an important

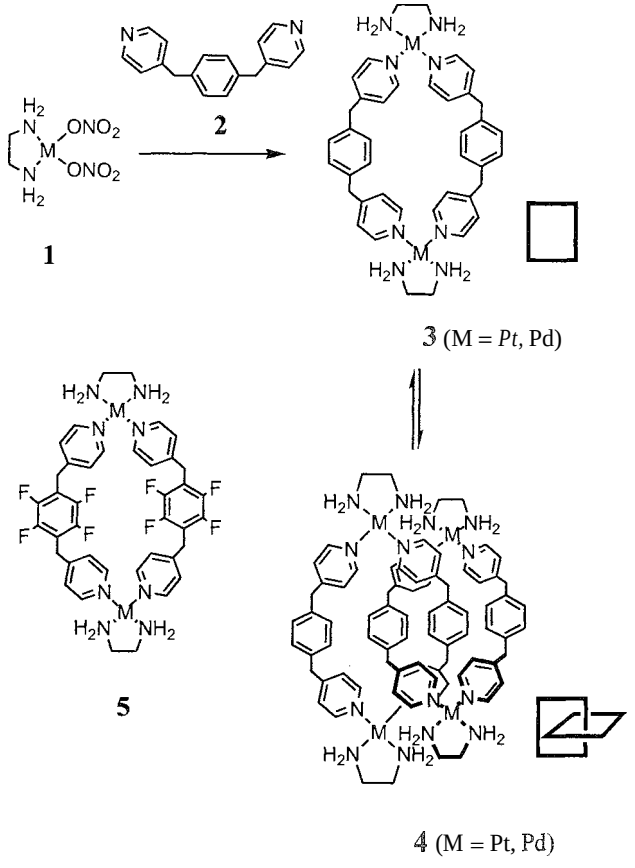

Fig. 2 Thermodynamic self-assembly: Formation of a [2]-catenane. mediated by coordinative and other noncovalent interactions.

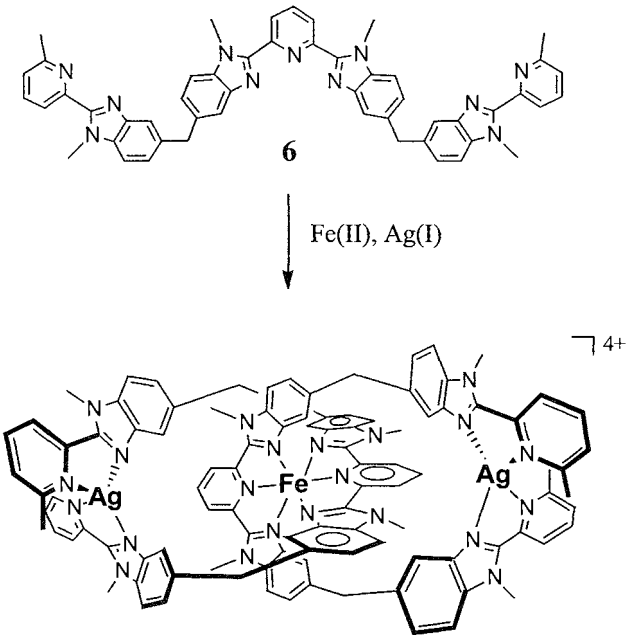
role in the formation of catenane 4. The fact that changing the solvent from water to the more polar D_2O increased the proportion of catenane produced indicates that hydrophobic interactions between the central phenyl groups in each iigand also contributed to interlocking. Finally, entropy must also have played a role in the interlocking step, because concentration of the system led to more of the catenane, consistent with the expected response of the equilibrium, as predicted by Le Chatelier's principle.[3] The role of the noncoordinate interactions was to double the free-energy change of the process, allowing quantitative self-assembly of the catenane at high reagent concentrations.[5,8]

The formation of 4, therefore, involved several different noncovalent interactions. The cyclization step was brought about by the formation of Pd—N coordinate bonds; that is, by a metal-mediated process. The interlocking step involved n- and hydrophobic/hydrophilic-mediated processes, along with an entropic effect. Catenane 4 can. therefore, be considered an example of a "'multi-mediated," multiple-interaction self-assembly.[9] Fujita referred to such processes as "double-molecular recognition" procedures, in which the two interlocking molecules bind each other in their cavities.[5,8]

The equivalent reaction with M = Pt is also interesting and informative.[5,8] As noted earlier, the reaction of 2 with 1 (M = Pt) led exclusively to the kinetically inert metallocycle ***3*** (M = Pt). Because Pt—N bonds are inert under normal conditions, the cycle is "locked" in its cyclized state. However, at high temperatures in a concentrated, highly polar medium, the coordination bonds become labilized, allowing interlocking to occur. Thus, the cycle 3 (M = Pt) was spontaneously transformed into 4 (M = Pt) by the addition of $NaNO_3$ with accompanying concentration of the mixture at 100°C. The resulting catenane could then be trapped by dilution and cooling of the mixture. Fujita referred to this procedure as a ''molecular lock," which mimics. on a molecular scale, the interlocking rings trick used by conjurers and magicians.[5,8]

While the simultaneous use of several different classes of noncovalent interactions provides an elegant means of preparing a catenane. such systems are not always easily designed. Another method of thermodynamically self-assembling catenanes involves using two or more metal-mediated interactions to carry out the cyclization and interlocking steps. Illustrated in Figs. 3 and 4 are examples of thermodynamic self-assembly of this type.

In Fig. 3 is depicted the spontaneous self-assembly of the ligand strand 6 with Fe(II) and Ag(I) to give the metallocatenate **7**.[10] Each cycle in 7 may have either *P*- or *M*-helicity, so that 7 is formed as an equal mixture of *meso* (*P*,*M*)- and racemic (*P*,*P*)/(*M*,*M*)-diastereoisomers. In this assembly, the octahedral Fe(II) ion selectively



(*P*,*M*)-**7**

(One stereoisomer depicted only)

Fig. 3 Thermodynamic self-assembly: Formation of a [2]catenane, mediated by selective coordinative interactions only.

binds the central binding sites on the ligand, inducing interlocking. Tetrahedral Ag(I) binds the outer binding sites on the ligand, inducing ring closure.[9]

In Fig. 4 is illustrated a similar class of self-assembly. The [2]metallocatenate **11** could be prepared as a mixture of (*P*)- and (*M*)-stereoisomers either by the sequential addition of Cu(I) and Ru(II) to a 1:1 mixture of 8 and **9** (left route) or by the simultaneous addition of Cu(I) and Ru(II) to the mixture of ligands (right route).[11] Because both approaches give **11,** a thermodynamic equilibrium must be present with two self-assembly processes operating. In the one process, Cu(I), which strongly favors tetrahedral four-coordination. selectively interacts with the phenylene sites on the two ligands, generating the interlocked pseudorotaxane **10**. In the other process, Ru(II), which favors octahedral six-coordination. selectively binds the *tris*(pyridyl) sites on 8, causing the arms of this ligand to cyclize. The interlocking step is therefore mediated by Cu(I), and the cyclization step by Ru(II). Because the interlocking and cyclization steps are both metal-mediated, the formation of 7 and **11** are examples of "uni-mediated," multiple-interaction self-assembly.[9]

The system depicted in Fig. 4 illustrates another noteworthy feature of catenane self-assembly; the thermodynamically most stable moiety, which would arguably

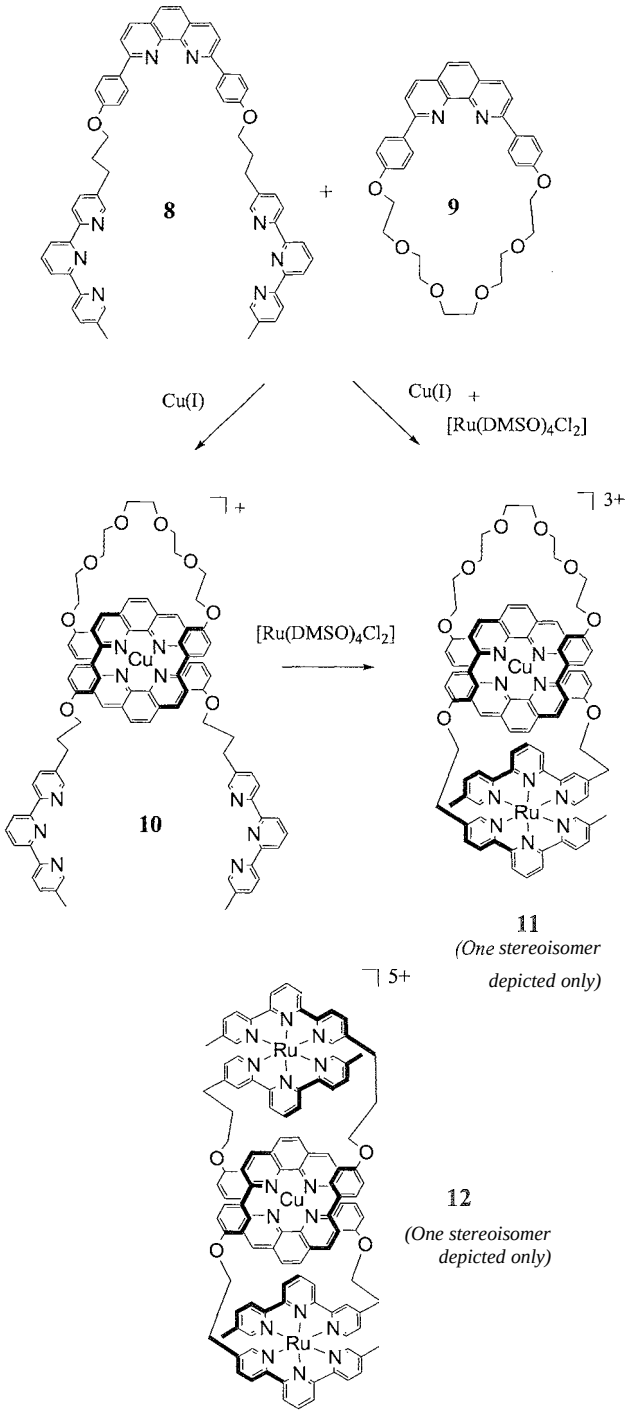


Fig. 4 Thermodynamic self-assembly: Formation of a [2]catenane, mediated by selective coordinative interactions only, in which the therniodynamically most stable moiety is not formed.

be the species 12 in Fig. 4, is not obtained.[77] This is because the stoichiometry of the reaction mixture, which involved a 1:1:1:1 ratio of 8:9:Cu(I):Ru(II), means that the formation of 12 would have to be accompanied by the formation of $[Cu(\mathbf{9})_2]^{2+}$, a species made unstable by the steric hindrance of the polyether linkages in 9 The system, therefore. transformed itself to achieve the greatest overall thermodynamic stability rather than the most stable product per se This result illustrates the usefulness of stoichiometry as a means of manipulating self-assembly processes and the dangers of attempting to predict the products of a thermodynamic self-assembly without considering the other species present

CATENANES PREPARED BY SELF-ASSEMBLY WITH POSTMODIFICATION

Catenanes have also been prepared by performing conventional organic reactions on self-assembled precursor molecules. In such cases. the interlocking step is typically carried out by a self-assembly process. with cyclization then achieved using an organic reaction.

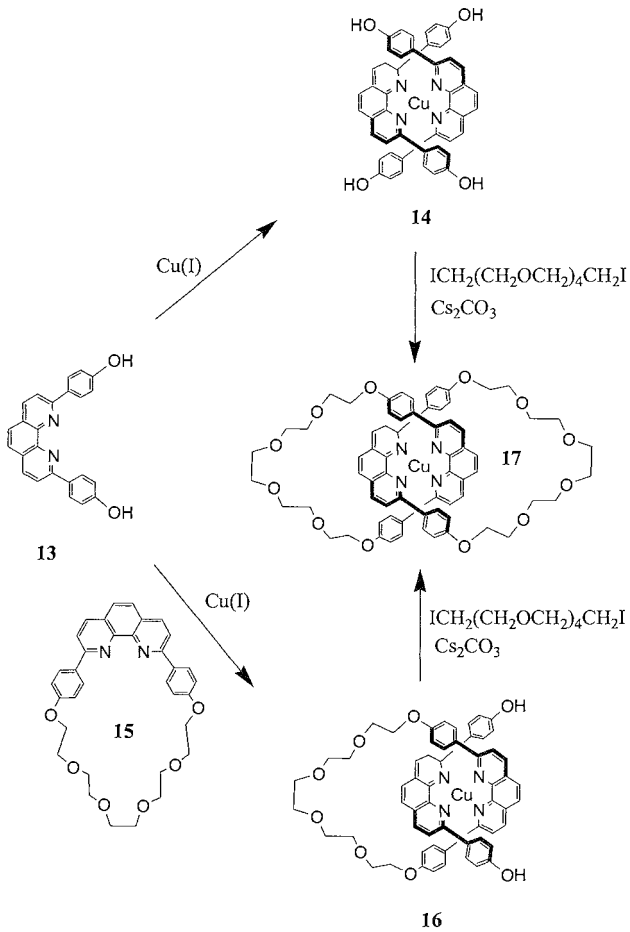

Fig. 5 Self-assembly with postmodification: Preparative routes to a [2]catenane.

Examples of such processes are depicted in Fig. 5 in which the precursor **14**. which is well-disposed for interlocking. and the pseudorotaxane **16** are self-assembled from 13 and Cu(I)/**15**.[13] When treated under high dilution conditions with a suitable polyether diiodide, **14**

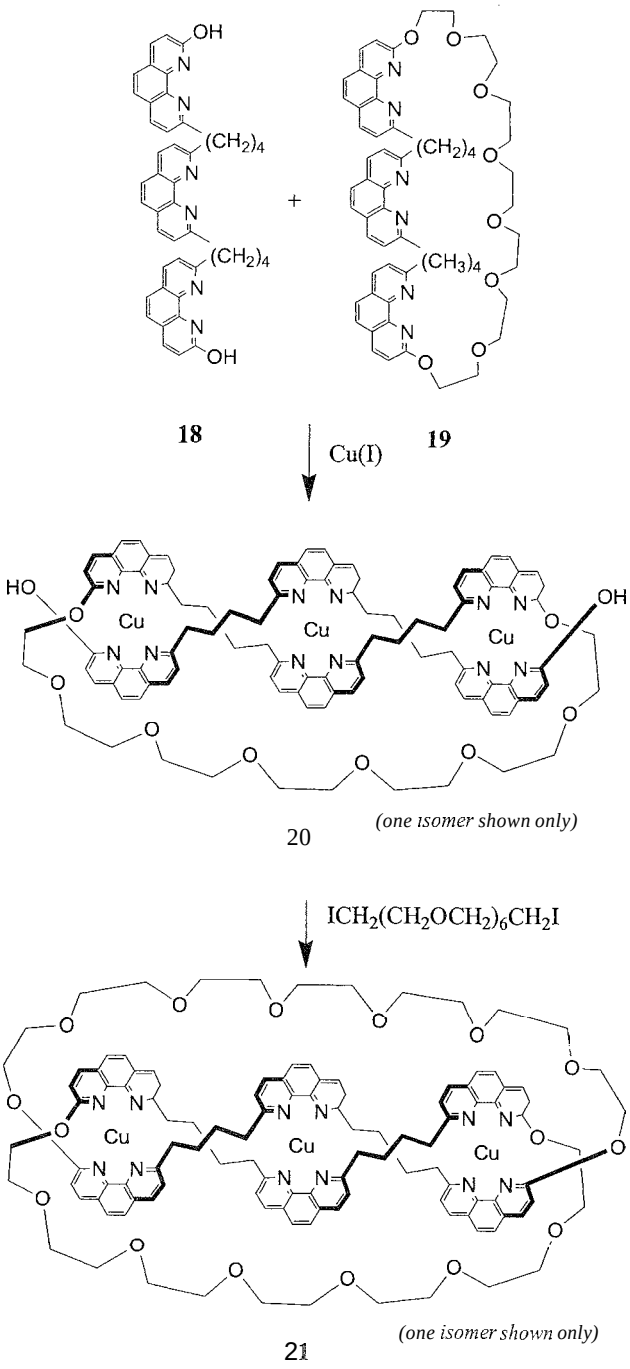

Fig. 6 Self-assembly with postmodification. Preparative routes to a 4-crossing-[2]catenane.

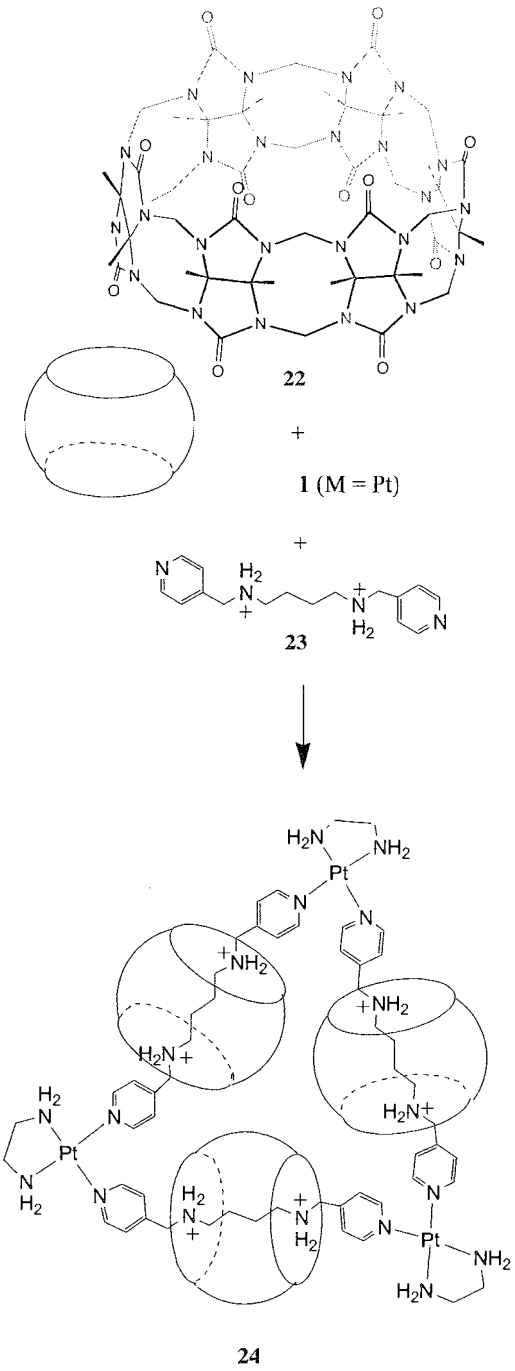

Fig. 7 Thermodynamic self-assembly of multiring catenanes—Molecular necklaces. Formation of a [4]MN, mediated by coordinative and other noncovalent interactions.

or 16 generate the interlocked catenane **17** in 27% yield (top route) or 42% yield (bottom route).[13]

This class of reaction proved particularly useful in the preparation of more complicated intertwined structures.

such as multiple crossing catenanes and molecular knots. Depicted in Fig. 6 is the formation of a 4-crossing-[2]catenane as described by Sauvage and coworkers.[14] The reaction of the tritopic ligands 18 and 19 with Cu(I) generates the double-helical complex 20, as well as its corresponding side-by-side complex (not shown in Fig. 6). When *20* is cyclized, by treatment with an equivalent polyether diiodide under high dilution conditions, it produces the 4-crossing-[2]catenane 21. Demetallization of 21 produces the equivalent, Cu-free catenand. Both 21 and its corresponding catenand are chiral thanks to the helicity of the precursor 20.

MULTIRINGED CATENANES

A range of multiringed catenanes have been prepared. One class of such molecules contain multicyclic cores.[15] Somewhat simpler species involve a single-ring core and are termed molecular necklaces (MN).[6] Depicted in

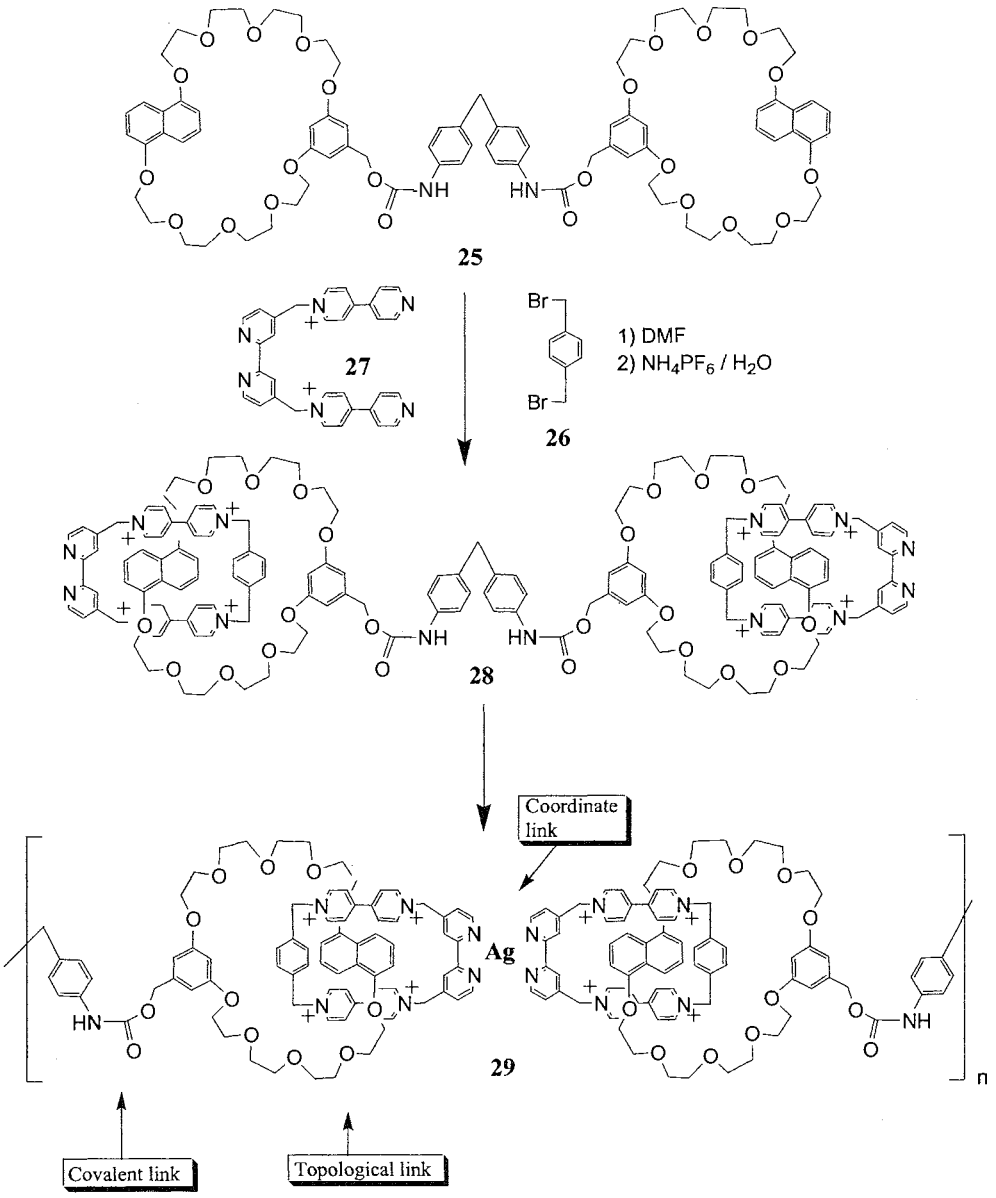

Fig. **8** Thermodynamic self-assembly of a polycatenane. Formation of a linear poly[2]catenane containing covalent, topological, and coordinative linkages.

Fig. 7 is the assembly of a [4]MN by the reaction of 1 equivalent of the cyclic molecule cucurbituril 22 with 1 equivalent of the angled metal complex 1 (M = Pt) and 1 equivalent of the dipyridyl molecule 23 after reaction for 1 day at 100°C in water.[6] Interactions between 22 and 23 result in cucurbituril spontaneously threading onto 23, completing the intertwining step. Cyclization is brought about by the formation of the Pt—*N*(pyridyl) bonds. As Pt—N bonds are labile at high temperature, either step may occur first. The structure of 24 was confirmed by an x-ray crystal structure determination. as well as by mass spectrometry and NMR. Several other [4]- and [5]MNs were prepared in a similar vein.[16]

The self-assembly of [*n*]polycatenanes having structures of the type depicted in Fig. 1e. offers perhaps a pinnacle of achievement in catenane synthesis. Unfortunately, it has thus far proved impossible to prepare such ensembles by a one-step thermodynamic self-assembly. Stoddart and Vogtle have, however. obtained [*n*]polycatenane structures by multistep, statistically based procedures.[17,18] The central problem with the thermodynamic self-assembly of oligomers of this type involves inducing an oligomerization process and then controlling it. This must be achieved in addition to the interlocking and cyclization processes required. While Sauvage suggested theoretical strategies in which the cyclization and the oligomerization steps are combined into one process. with a separate step for interlocking,[1] this approach has not yet been successfully demonstrated. Controlled oligomerization of a similar type has been achieved in only one case to the best of our knowledge — the self-assembly of a dendritic wedge."'' This technique is therefore far from being mastered in wider applications.

Poly[*n*]catenanes having the structure depicted in Fig. 1f are significantly more easily prepared than [*n*]polycatenanes: relatively few examples are nevertheless known. Illustrated in Fig. 8 is the formation of a poly-[2]catenane from a precursor 25 containing two covalently linked ringed polyethers.[20] When treated with the dibromide 26 and dication 27, the dicatenated structure 28 is obtained. Subsequently. treatment with Ag(I) produced the corresponding poly[2]catenane 29 that contained covalent-, topological-, and coordinate-linking units down its backbone.

HIGHER STRUCTURE IN CATENANES

As noted in a previous article in this *Encyclopedia*, self-assembly processes often generate compounds and materials displaying hierarchies of structure. also known as higher structures.[3] Self-assembled catenanes display similar structural hierarchies. although these are different to the hierarchies common in biology and chemistry. The interconnectivity of the individual components of a catenane must be considered the primary structure; that is. the lowest level of structural arrangement. Upon self-assembly, a secondary structure is created in the form of the closed cycles. The interlocked arrangement can also be considered a secondary structural element. However. as the term "interlocking" describes the way in which the closed cycles are organized relative to one another, it is perhaps more conveniently considered a feature of tertiary structure. Quaternary structure can be observed in oligocatenanes; Figs. 1e.f describe. for example, two different quaternary structural arrangements involving catenanes.

CONCLUSION

Several decades ago. catenanes were considered to be exotic and rare molecules. Today, thanks to self-assembly techniques. they are far more prevalent, acting even as convenient models for studies of ''molecular'' machines and motors.[21] In the future. we will see further simplifications in the preparation of catenanes, leading, perhaps, to oligomeric catenane structures with novel material and chemical properties. New types of noncovalent interactions will also be harnessed in the preparation of catenanes. Aurophilic. Au(I)–Au(I) attractions. having about the same bond strength as a hydrogen bond. have: for example, recently been plausibly employed in the synthesis of organometallic gold(I) acetylide catenanes.[22] Some practical applications of catenanes are already in the offing. Catenanes are, for example, being seriously examined as potential molecular switches, on the smallest possible scale, in information storage technologies.[23]

Self-Assembly: Definition and Kinetic and Thermodynamic Considerations

Jim *A. Thomas*
University of Sheffield, Sheffield, United Kingdom

INTRODUCTION

Self-assembly is often called upon to explain a variety of molecular processes, from the spontaneous assembly of discrete biological structures, through complex organic syntheses. to the design of new materials. This review outlines how these processes are classified, delineates the enthalpic and entropic factors that drive such phenomena, and discusses models developed to interpret the limiting factors involved in self-assembly.

WHAT IS SELF-ASSEMBLY?

Self-assembly is one of the core concepts of supramolecular chemistry. It is often defined as the spontaneous formation of higher-ordered structures from molecular building blocks. This hypothesis first arose through research into biological systems. As the complex architectures found in living cells were delineated. the concept that such constructs were built by the convergent assembly of smaller subunits was increasingly invoked.[1] In particular, its relevance to one of the core principles of molecular biology soon became apparent.

The central dogma holds that genetic information is stored. read, and duplicated by the nucleic acids DIVA and RNA, and when required, this information is translated into the specific amino acid sequence of a protein, that then folds into its functional native form. As this model was developed. it became clear that it was underpinned by another assumption: that the final three-dimensional structure of a protein. or a nucleic acid, is inherent in the linear sequence of its building blocks. In groundbreaking work on ribonuclease, the Nobel Laureate Christian Afinison labeled this supposition the "Thermodynamic Hypothesis," suggesting that, in physiological conditions, the native structure of a protein is the one in which the Gibbs free energy of the system is at its lowest.[2] This concept of self-assembly was then extended, as subsequent discoveries revealed that. in many cases; protein folding is facilitated by other factors.[3]

CLASSIFYING SELF-ASSEMBLY

In an attempt to provide a general framework for discussion and research, Lindsey introduced a wide-ranging classification scheme. built upon the work of others, that encompasses self-assembly processes in biology and chemistry.[4] This definitive scheme is broken up into seven broad, overlapping, classes.

Class 1. Strict Self-Assembly

As will be discussed later, in many ways, strict self-assembly is a restatement of Afinison's Thermodynamic Hypothesis and encompasses all processes in which components assemble reversibly. The archetype of strict self-assembly is tobacco mosaic virus (TMV).[5,6] The TMV particles consist of a single helical strand of RNA embedded in a right-handed helix composed of identical coat protein subunits. The TMV particles will dissociate into their component parts by changes in pH, temperature. or even pressure. However. once the correct conditions are again attained. protein subunits and RNA spontaneously reassemble into virus particles that are indistinguishable from the original TMV.

Glass 2. Irreversible Self-Assembly

This class is the obverse of the previous case. As steps toward the final assembly are unalterable, usually full covalent interactions, building blocks must come together into the final correct structure with no margin of error. Under the guise of tandem or domino reactions. this class of process is currently attracting much attention in synthetic organic chemistry.[7,8]

Unlike most self-assembly processes (vide infra), irreversible self-assembly is under kinetic control. Consequently. in most irreversible multistep assembly processes, the initial architectures must be precisely located and aligned.[8] However. in some cases, highly complex architectures can result from apparently nontemplated, irreversible self-assembly.[9]

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012779

Class 3. Precursor Modification Followed *by* Self-Assembly

These processes involve the synthesis of precursors that are subsequently structurally modified. A biological example is collagen synthesis. Collagens are fibrous proteins that form the major component of skin and bone. They are the most abundant mammalian protein and are found in long, extracellular polymeric structures called fibrils. In turn, these fibrils are often aggregated into larger cables, known as fibers, that are big enough to be viewed under light microscopes.[10]

The assembly of such structures within a cell would be fatal. To prevent such an occurrence, a precursor. known as procollagen, is synthesized. Procollagen consists of triple helical polypeptide strands capped at their terminal ends by amino acid chains, called propeptides, that prevent aggregation of procollagen molecules. Once synthesized, procollagen is secreted out of the cell, where proteolytic enzymes remove the propeptides. The resulting collagen molecules are several orders of magnitude less soluble than their precursors, and self-assembly of fibrils is rapidly initiated.''''

Class 4. *Self-Assembly with* Postmodification

In this case, the self-assembly process precedes the final modifications that lead to the targeted architecture. Using this powerful methodology, self-assembled structures can be irreversibly locked into position. Within supramolecular chemistry: this strategy is most commonly employed in the elegant syntheses of catananes, rotaxanes, knots. and other interlocked species.''''

Class 5. Assisted Self-Assembly

Here. external factors that are not part of the final assembly mediate the self-assembly process. This concept was developed as the function of molecular chaperones became apparent.'''' Chaperones help in folding nascent polypeptide chains by preventing aggregation of peptide sequences, and they modulate refolding of denatured proteins. Chaperones do not affect the thermodynamics of folding—the ratio of folded and unfolded polypeptides is left unchanged—but they influence the kinetics of the process. It is thought that this is accomplished by stabilizing intermediates along the folding pathway, thus decreasing activation-energy barriers.

Class 6. Directed Self-Assembly

In Lindsey's original definition, this class includes processes in which a template participates as a structural element in the self-assembly process but does not appear in the final assembled architecture. An example from biology is the scaffolding protein directed assembly of viral capsids. External and internal scaffolding protein frameworks direct the construction of the protein coat that houses the viral DNA. Packaging of DNA is then accompanied by withdrawal of the internal scaffolding, and the final virion is produced after removal of the external scaffold.[12]

An example from chemistry is the use of vesicles, liquids, and foams to direct biomimetic mineralization and polymerization. Such templates, that may only have a transitory existence: were used to template the assembly of structurally complex, three-dimensional architectures.[13]

Subsequently, within supramolecular chemistry, the term ''directed self-assembly'' has become more generally understood to include any templated process that brings together molecular components, even if the directing moiety is part of the final structure.[14]

Class *7. Self-Assembly with Intermittent* Processing

This final class incorporates elements from all the proceeding classes. It includes all processes where there are sequential phases of self-assembly and irreversible modification. Such complex processes are still the exclusive domain of biology.

WHAT DRIVES SELF-ASSEMBLY?

With the exception of the previously discussed irreversible processes. the key steps in self-assembly tend to involve the interplay of dynamic. relatively weak. interactions. In these conditions. thermodynamic products. where free energy is maximized. will be favored. Consequently. entropic and enthalpic state functions must be considered.

Solvophobic Effects

Superficially, the synthesis of discrete, ordered structures from a set of subunits would seem to be a solely enthalpically driven process—the formation of new favorable interactions is at the cost of losing translational, vibrational, and rotational degrees of freedom. However. it has long been established that the hydrophobic effect, which drives amphiphilic subunits to assemble into micelles and lipid bilayer structures such as liposomes, is largely an entropic phenomenon.[15]

Water molecules that sunound nonpolar regions of a solute form cage-like cavities. Although these arrays of

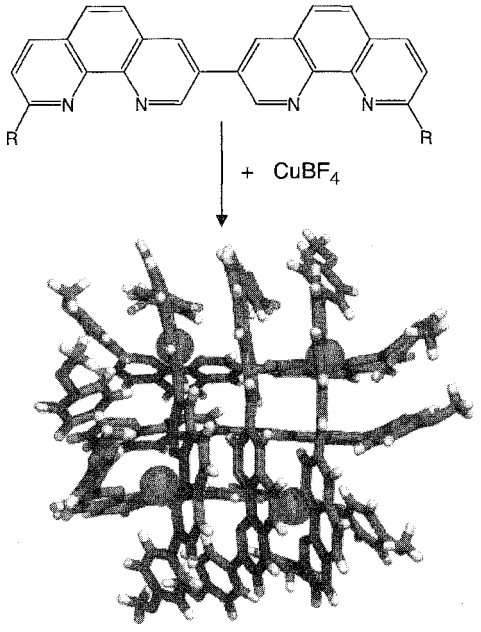

Fig. 1 Synthesis of a 3 x 3 molecular grid. Physical studies indicate that recognition processes in this assembly involve solvation effects analogous to the hydrophobic effect. (Adapted from Ref. [16].)

water molecules are fluxional, there is overall increase in local order. Creation of a bilayer means that while the polar part of the amphiphile is solvated, the nonpolar sections are not. allowing water molecules to be released into the bulk solvent. thus increasing the degrees of freedom in the system. Even in nonaqueous solvents, analogous effects drive recognition processes.

Investigating self-assembly processes involving acetonitrile solutions of ditopic 2,2′-diaryl-8,8′-*bis*-1,10-phenanthroline ligands and copper(I) metal centers, Siegal and co-workers observed the formation of a 3 x 3 molecular grid with four ligands coordinated to metal centers, forming a molecular square host, while two additional ligands filled interstitial spaces as guests (Fig. 1).[16]

Studies using the sterically demanding ligand 2,2′-dimesityl-8,8′-*bis*-1,10-phenanthroline indicated that the grid was not the product of a two-step process involving self-assembly of the square followed by a host–guest interaction, but it was, rather, a genuine cooperative process involving host and guest components. Furthermore, spin saturation transfer spectroscopy studies indicated that the host–guest interaction had a large entropic component. These observations hint that a solvation effect, analogous to the hydrophobic effect, partially drives the self-assembly process.

Further evidence of a generai solvophobic effect was revealed in an isothermal titration calorimetry study probing the recognition of carboxylates by guanidinium residues. a common motif in protein–substrate binding. When investigating this interaction in acetonitrile solution~.~Schmidtchen and colleagues obtained evidence that the entropic component to the free energy of binding—the release of solvent molecules and counterions engaged in the solvation of the free binding site—is not a marginal factor but may constitute the major part of ΔG°.

However. even if such solvent effects are disregarded, it may be argued that for strict self-assembly processes, discrete structures are still thermodynamically favored.

Enthalpy and Entropy Considerations

Consider a simple hypothetical system. where 12 components can reversibly associate. via a single, weak, enthalpically favored interaction, into a discrete four-membered cyclic structure; or alternatively, an open oligomeric structure (Fig. 2). Clearly. the formation of any oligomeric structure is enthalpically favored, as new interactions are created. but. as Lawrence et al. pointed out,[18] discrete structures are slightly favored.

The number of interactions per component created in the assembly of tetramers (one interaction per unit) is larger than that in the formation of the open oligomer (0.9167 interactions per unit). If there is more than one interaction between components, then assembly of the

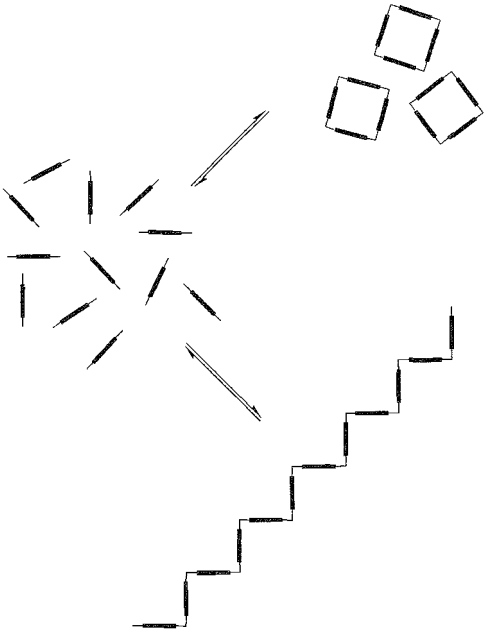

Fig. 2 Subunits that can assemble into two possible products: a discrete four-membered cyclic structure or an open oligomeric structure.

tetramer is even more advantageous. For example, if there are two interactions between individual components, then the tetramer has two interactions per unit, while the oligomer only has 1.834 interactions per unit. While it is clear from an extension of such arguments that the enthalpic advantage of assembling tetramers over open polymeric structure incorporating a large number of components will rapidly become extremely small; it is also true that a cyclic structure with N components will be enthalpically favored over an open structure with N components.

Conversely, due to losses of translational and conformational degrees of freedom, the formation of any oligomeric structure is entropically unfavorable. Nevertheless, compared to self-assembly of discrete structures, generation of open oligomers (and especially polymers) is particularly unfavorable. Again, consideration of the system shown in Fig. 2 illustrates this argument. Relative to the tetramer, it seems likely that self-assembly of the less rigid, open oligoiner results in a smaller change in conformational degrees of freedom. On the other hand, the formation of one oligomer particle, as opposed to three tetramer particles, will result in a much larger loss in translational degrees of freedom. If more components are incorporated within this polymer, the entropic disadvantage, relative to the tetramer, increases.

Seen in this light, preferential self-assembly of discrete architectures over open oligomeric structures is related to the widely studied phenomenon known as enthalpy–entropy compensation[19,20]—the enthalpic benefits of interactions are balanced by the entropic costs in losing degrees of freedom. In reports by Fujita and colleagues and Hong et al., the subtlety of this interplay is revealed.

FLUXIONAL SELF-ASSEMBLY AND DYNAMIC COMBINATORIAL LIBRARIES

In 1990, using the suitably hindered square-planer metal center [(en)Pd(NO_3)$_2$] (en=ethylene-1,2-diamine) and 4,4′-bipyridine, Fujita and coworkers reported the self-assembly of macrocyclic supramolecular squares.[21] Later work revealed that the replacement of 4,4′-bipyridine with more flexible dipyridyl ligands such as *trans*-1,2-*bis*(4-pyridyl)ethylene resulted in an equilibrating mixture of molecular squares and triangles (Fig. 3).

The ratio of products in this equilibrium was found to be concentration and temperature dependent. At low concentrations, the equilibrating reaction mixture contains significant amounts of the triangular product, while at higher concentrations, the square is the predominant product. At very high concentrations, the product mixture contains significant amounts of unidentified oligomeric structures.[22] A similar equilibrium shift toward the triangle is observed on heating the reaction mixture. These results suggest that this system is held in a fine thermodynamic balance: entropically, the triangle is favored. because it is assembled from fewer components, while enthalpically, the less-strained square assembly is favored.

In further studies on the same system, Hong and coworkers found that by exploiting host–guest interactions. it is possible to bias the equilibrium toward a specific product architecture.[23] The addition of p-dimethoxybenzene to the reaction mixture induced an equilibrium shift toward the triangle, while the addition of sodium 1.3-adamantanedicarboxylate resulted in the formation of the square as the only product (Fig. 3). The directing principal is supplied by hydrophobic interactions: in an example of the thennodynamic template effect, the free energy difference created by the appropriate guest is enough to make a specific host the favored product. These studies illustrate the protean nature of systems at the interface of self-assembly and receptor–substrate recognition. This interface was further exploited in the creation of dynamic combinatorial libraries (DCL).

A DCL consists of higher-order molecular architectures that reversibly self-assemble from a set of molecular building blocks.[24] Because the whole system is held in thermodynamic equilibrium. it is highly fluxional: a template that binds to one member of the library will drive the preferential assembly of this library member. Thus, through Le Chatlier's principle, the equilibrium shifts, evolving toward architectures that tightly bind the target template. Work by Sanders and colleagues delineates the power of this rapidly developing technique. Using hydrozone-based pseudopeptides that interconvert via transimination at the hydrozone bond, they utilized an equilibrating covalent DCL to identify and isolate a macrocyclic receptor that binds to N-methyl alkylammonium salts such as acetylcholine chloride.[25] This approach is not just limited to the design of new hosts: Lehn and coworkers showed that a DCL of folding isomers can be directed toward a specific folded form of a linear molecule.[26] While in work reported by Karan and Miller, a DCE consisting of various salicylamides ligands and Cu^{2+} ion was used to identify a compound that binds to an RNA hairpin with a high affinity, showing remarkable selectivity relative to DNA.[27]

SWITCHING FROM THERMODYNAMIC TO KINETIC REGIMES

While strict self-assembly is a particularly attractive strategy in the construction of complex molecular architectures, there are disadvantages. As the disaggregation of

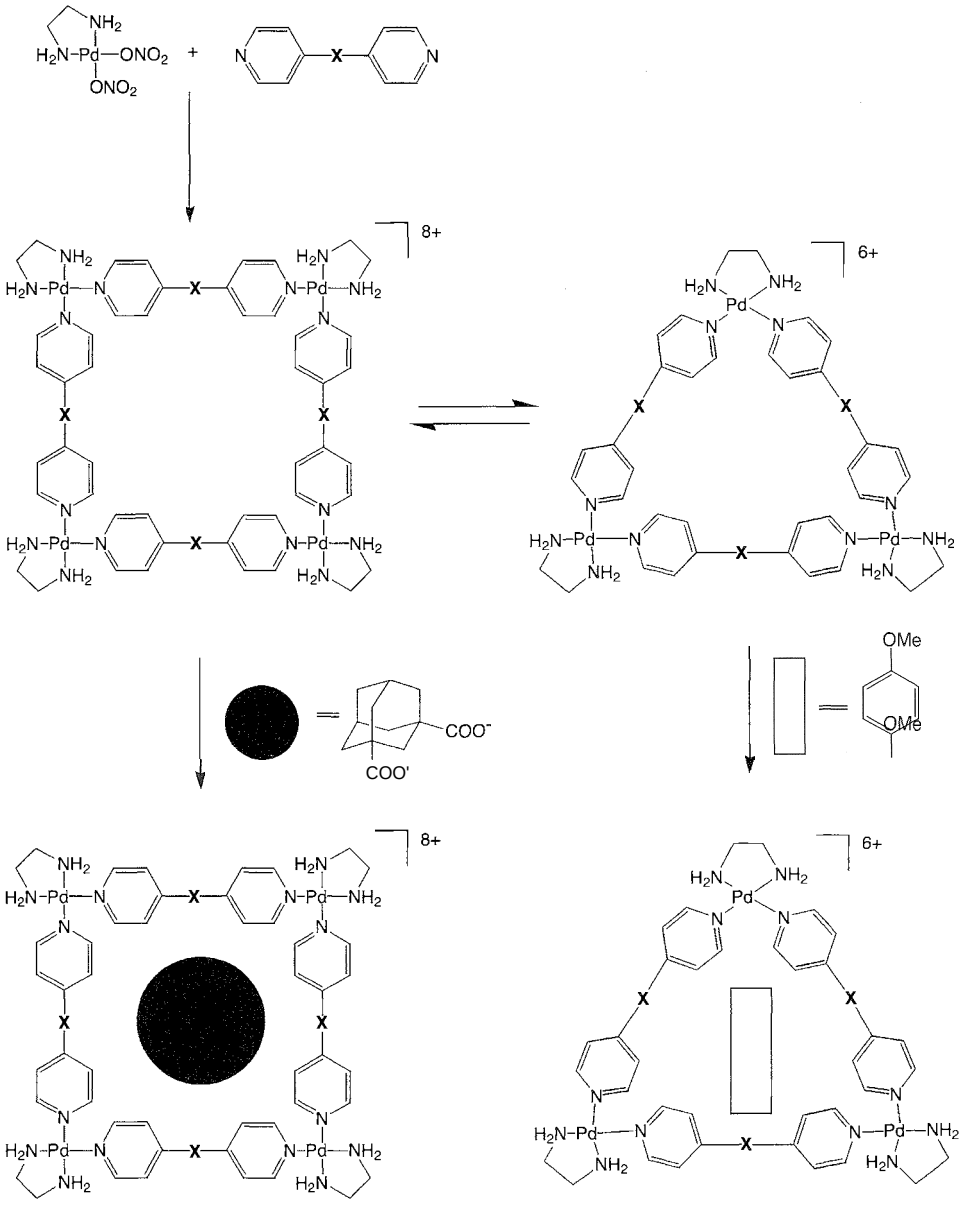

Fig. 3 Reaction of square planar inetal centers with flexible dipyridyl ligands leads to an equilibrating product mixture containing a square and triangle inacrocycle. Host–guest recognition processes bias this mixture toward specific products. (Adapted from Refs. [22,23].)

TMV particles illustrates. as the final product is thermodynamically selected, it is not necessarily kinetically robust. Consequently. synthetic chemists working to create functional architectures often adopted self-assembly with postmodification strategies.[11] However. another strategy was also pursued — one in which construction by strict self-assembly is then followed by whole-system switching into the kinetic regime. thereby locking complex architectures into structurally resilient entities.

That such an approach was possible became apparent with the work of Lehn and colleagues on Ni^{II} ternplated triple helicate complexes.[28] It was found that on crystallization. spontaneous partial resolution of A- and Δ-enantiomers rook place. Presumably due to cooperativitp inherent within such structures, these complexes racemized at much reduced rates, compared to related monomeric systems. The first true approach to kinetic locking, reported by Williams and colleagues, involved an

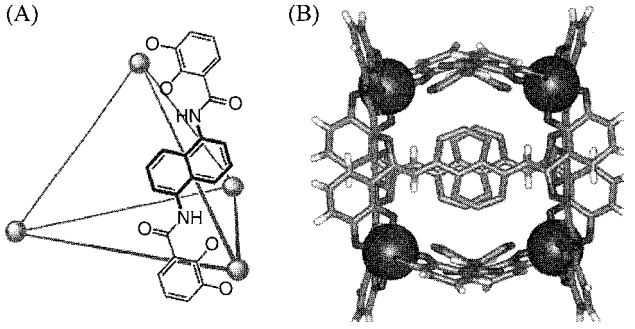

Fig. **4** Self-assembly using labile Ga^{III} results in the synthesis of kinetically stable tetrahedral cages. (A) Structure; (B) Crystal structure of AAAA-tetrahedral cage. NEt_4—guest was removed for clarity. (Adapted from Ref. [33].)

electrochemically active dinuclear triple helicate.[29] In this case, self-assembly was ternplated via Co^{II}, and then locking was achieved by oxidation of the labile Co^{II} metal centers to relatively kinetically inert Co^{III}. The racemic product mixture was then resolved into its component enantiomers via chromatography.

Fujita and coworkers developed a generalized strategy for the kinetic locking of self-assembled architecture~.['~. They exploited the dual character of platinum(II)-pyridine coordination, which in normal ambient conditions is kinetically inert. However, at elevated temperatures and in highly polar media. or in the presence of a suitable template, this interaction becomes relatively labile. Using this effect, they reacted $(en)Pt(NO_3)_2$ with appropriate ligands to isolate macrocyclic, catenated,'"] and nanosized cage'"'] architectures. Unlike their Pd(II)-based analogues, these structures are remarkably stable. For example, the isolated catananes do not dissociate at temperatures as high as 100°C. The addition of excess $(en)Pt(NO_3)_2$ to the square macrocycle constructed in this manner showed no sign of subsequent product redistribution.

Using a similar high-temperature approach to labilize Ru^{II}. Thomas and colleagues reported the self-assembly of a molecular cube incorporating eight $[Ru([9]aneS_3)]^{2+}$ ([9]aneS$_3$=1,4,7-trithiacyclononane) corners and 4,4′ bipyridine edges. The final structure enhanced the kinetic stability of the individual components. While the analogous monomeric complex, $[Ru([9]aneS_3)(bpy)3]^{2+}$, is relatively kinetically labile toward ligand substitution reactions, the final assembly was stable even at elevated temperatures.[32]

However, perhaps the most spectacular example of kinetic locking was reported by Raymond et al. Using highly labile gallium(III) metal ion (M) to template the self-assembly of inflexible C_2 symmetric bis-catecholate ligands (L), the researchers prepared chiral tetrahedral $[M_4L_6]$ assemblies[33] (Fig. 4). In the presence of a chiral anion, *N*-methylnicotinium, which is encapsulated within the cluster cavity. the homoconfigurational *ΛΛΛΛ* and *ΔΔΔA* clusters were completely resolved.

Usually. raceniization of *tris*(catecholate)gallium(III) complexes takes place quickly via a Bailar twist mechanism. Even in bimetallic helicates, where there is strong mechanical coupling between metal centers, racemization rater of 0.10 s^{-1} were determined by NMR studies. In contrast, the tetrahedral $[M_4L_6]$ assemblies are so inflexible that metal centers cannot independently racemize. Once formed. the guest *N*-methylnicotinium molecule can be replaced by Et_4N^+ with complete retention of chirality—the clusters retain enantiopurity even after remaining in aqueous solution for months. Racemization is still not observed after extended boiling of such solutions. The rigidity of the assembly results not from the individual components but the way they

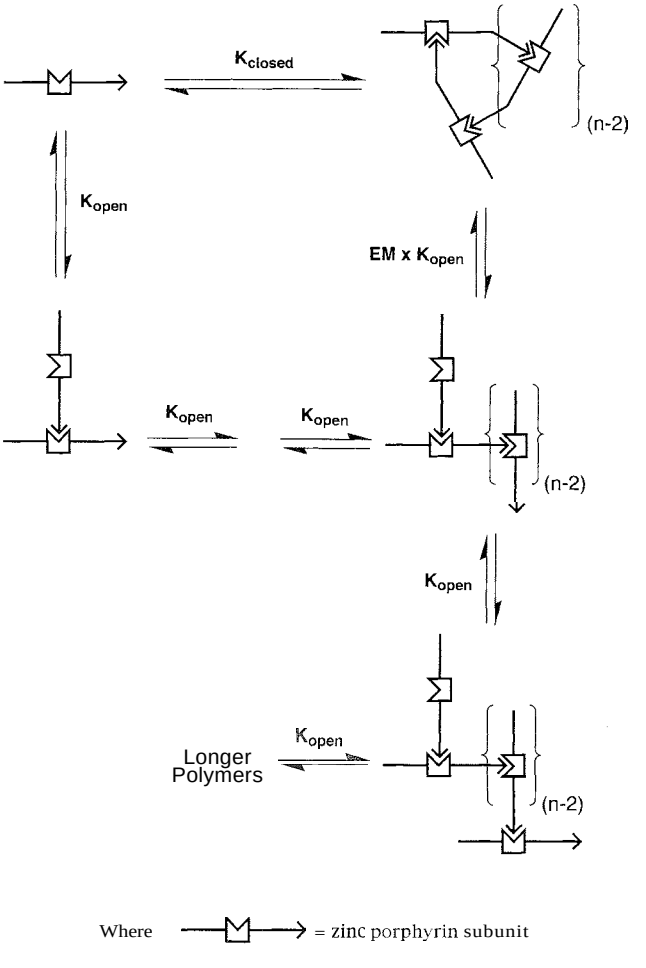

Fig. **5** Equilibria involved in the self-assembly of porphyrin macrocycles. (Adapted from Ref. [34].)

are assembled. This work demonstrates that. through judicious design. highly labile components can be made to self-assemble into architectures of extraordinary kinetic stability.

THEORETICAL MODELS OF SELF-ASSEMBLING SYSTEMS

While synthetic studies on self-assembly are rapidly developing in number and sophistication, thermodynamic models for such systems are relatively less common. One of the first studies to address this issue was presented by Hunter and colleagues.[''''] Exploiting the relatively weak coordination of pyridine to zinc porphyrins, they investigated the strict self-assembly of cyclic porphyrin oligomers. Using structural variants of porphyrin subunits, a variety of macrocycles we e targeted. Although the individual interactions used to drive these assemblies are almost identical. their behavior is quite different. A comparison of dimeric and tetrameric systems illustrates this point.

Defining critical self-assembly concentration (csac) as the concentration at which half the porphyrin inonomers are assembled into a macrocycle. the concentration dependence of the self-assembly process was investigated. It was found that csac for the dimer is 3×10^{-9} mol dm^{-3}, while the tetramer only assembles at much higher concentrations, csac $= 3 \times 10^{-5}$ mol dm '. These results were rationalized by considering the equilibria shown in Fig. 5 and the relationship between csac and the effective molarity, EM ($EM = K_{closed}/K_{open}$), leading to Eq. 1:

$$\text{csac} = \frac{1}{n^{1/(n-1)} \text{EM}^{1/(n-1)} K_{ref}^{n/(n-1)}} \quad (1)$$

Where n is the number of subunits within a structure, and K_{ref} is the equilibrium constant for the association of a zinc porphyrin subunit with a reference ligand structurally analogous to those used in the self-assembly process but incapable of assembling into a closed structure. This equation indicates that as n increases, csac rises. Furthermore, as $n \rightarrow \infty$, csac $= 1/K_{ref}$. In these conditions, significant self-assembly occurs only between $1/K_{ref}$ and EM. This analysis indicates that provided EM is kept high

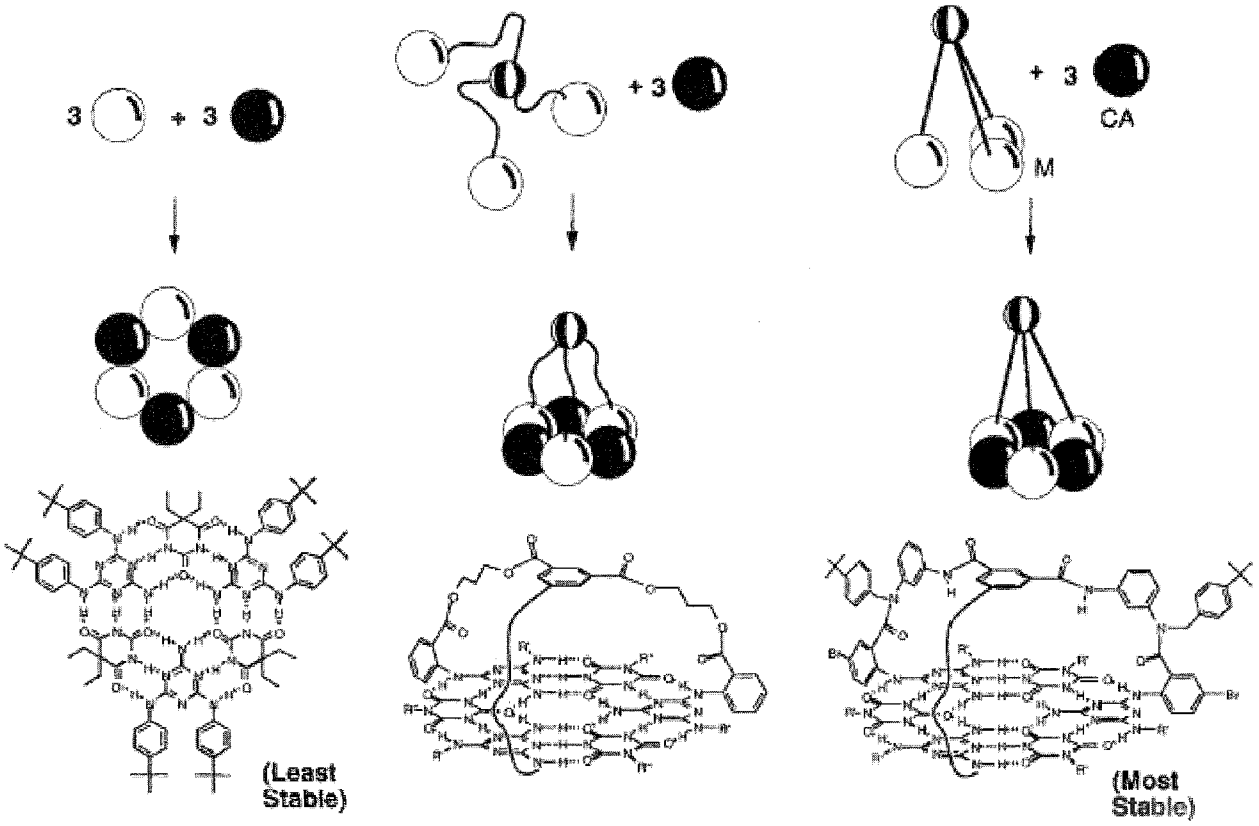

Fig. 6 Molecular structures of hydrogen-bonded cyanuric acid·melamine aggregates and corresponding schematics based on ball. rods. and string (BRS) models. (Reprinted with permission from Ref. [36].)

by using preorganized monomers, even very large multicomponent systems will self-assemble into stable. discrete structures.

In studies on derivatives of cyanuric acid and mel- amine (Fig. 6), Whiteside and coworkers developed a model to predict the relative stability of a series of hydrogen-bonded aggregates.[35] This model was developed after an analysis, analogous to that of Hunter and colleagues, revealed that the extent of aggregation is not directly reflected by the magnitude of ΔG° but depends strongly on N, the number of particles in the aggregate. Further consideration revealed that for self-assembly of a given aggregate, $\Delta S \propto (N-1)$ and the number of hydrogen bonds. HB $\propto$ AH. Using these relationships, indices that estimate the stability of cooperative and noncooperative assemblies in terms of N and HB were introduced. In particular, they showed that the index I_{TM} = HB/N 1, relates to ΔH/ΔS, and, for cooperative assemblies. correlates well with experimental stability measurements obtained from studies of deaggregation using polar solvents such as DMSO.

In a related study, Whiteside and colleagues went on to particularly focus on the entropic cost of assembling these aggregates.[36] After partitioning the entropy of self-assembly into translational. rotational, vibrational, and conformational components, they pointed out that, while there are adequate theoretical treatments for rotational and vibrational entropy, models for conformational and translational entropy changes are not accurate.

Translational entropy, S_{trans}, reflects the possible number of unique arrangements of a collection of molecules in a given space. Classically, this is described by the Sackur–Tetrode equation:

$$S_{\text{trans}} = RIn\left[\left(\frac{10^{-15/2}}{N_A^4[X]}\right)\left(\frac{2\pi MkTe^{5/3}}{h^2}\right)^{3/2}\right] \quad (2)$$

Where M and T, $[X]$ are the mass (g/mol), temperature (K), and concentration (mol/L) of the particle, respectively, and R, h, k, e, and N_A are constants with their usual meanings. This equation is a good predictor of the entropy of monoatomic gases. However, S_{trans} of molecules in liquid or solution phase is significantly lower than that predicted by the equation. By taking into account the volume occupied by the molecules in a solution. Whiteside and his colleagues used free volume theory to obtain an extended version of the Sackur–Tetrode equation that offers a significantly improved estimate of S_{trans}. This new model was used to predict the entropy of association of a six-particle aggregate compared to that of a four-particle aggregate, and agreement with experimentally obtained free energy differences was obtained.

Going on to consider conformational entropy changes on self-assembly. the researchers employed a model based on balls (hydrogen-bonding subunit) that may be free or connected by rods (rigid covalent linkers) or strings (flexible tethers) (Fig. 6). This model indicated that the conformational entropic cost of self-assembling an aggregate connected by flexible tethers would be approximately 23 kJ mol^{-1} more than that of an assembly with rigid tethers: figures that were, again, in agreement with experimental data on the free energy of aggregate assembly.

CONCLUSION

If complex and/or functional molecular assemblies are to be derived from supramolecular chemistry, a comprehensive exploration of the factors that govern self-assembly processer will be required. While theoretical models for these processes are sparse, progress in synthetic arpects of self-assembly has been relatively swift, leading to entirely new concepts such as DCLs. Concurrent to these developments, methodologies for irreversibly locking self-assembled stuctures are also beginning to emerge.

Self-Assembly in Biochemistry

Tamara D. Hamilton
Leonard R. MacGillivray
University of Iowa, Iowa City, Iowa, U.S.A.

INTRODUCTION

The term "self-assembly" has been used to describe a wide range of processes, including the capiliary force-*driven association of micrometer-sized* plates[1] *and the* arrangement *of protein monolayers* on *gold surfaces.*

For the scope of this article, we will limit *our survey to those processes that occur naturally* (i.e., *within living systems). and we will define self-assembly as the spontaneous, reversible association of large molecular components to form larger. ordered structures by way of* noncovalent *forces. The process leads the components* from *a less-ordered state to one of higher order.'" The self-assembled product then carries out a task not achievable by the* individual *components.*

Though an exhaustive description of self-assembly processes in living systems could fill many books. our goal is to provide representative examples that illustrate the diversity of the process.

THE IMPORTANCE OF SELF-ASSEMBLY TO LIFE PROCESSES

Self-assembly is important to life processes. If self-*assembly did not occur, it is certain that life could not exist.'" Natural selection has long been a central tenet in theories of the origin of life on* earth, *but it alone is not likely to* have *given rise to the emergent order of* life. *This order* can *be explained by considering that nature is operating under the influence of inherent principles of self-assembly.*[3]

The conventional method *that a chemist employs to synthesize new compounds in the laboratory relies on the sequential formation of covalent bonds. This approach is, however.* limited. *when it comes to constructing large or complex entities* (e.g., a *cell). One can imagine the sorts of difficulties that would arise if the* components *of a cell. for example. were all covalently bonded and part of one giant inolecule. Synthetic chemists have met* tremendous *challenges* in making *natural products with procedures* that *can involve upwards of 30* steps.[4] If *nature approached synthesis of these molecules or even more complicated structures* in *the same manner. not only would the kinetics of life processes be inordinately slow, but each step would need to be carried out with absolute* fidelity.[5] *Mistakes could not easily be corrected because of the comparatively high energy required to break and reform a covalent bond. Nature circumvents these limitations by creating relatively simple building blocks that spontaneously assemble into* more complex structures.[5]

Nature uses self-assembly to build highly structured systems for specific functions. Examples include the transfer and storage of genetic information in nucleic acids,[6] *the organization of lipids into protective cell membranes that serve as molecular receptors for the cell, and the hierarchical structure of spider silk, still one of the strongest known fibrous* materials.[7] *yet flexible enough to absorb the* impact *energy of an unlucky fly.*

ASYMMETRICAL SELF-ASSEMBLY: PROTEIN FOLDING

The mechanism whereby complementary parts of a long peptide *chain. often located far apart in the amino acid sequence, find each other and form a unique, biologically active, three-dimensional structure predetermined by that sequence remains* puzzling. *Because proteins need to recognize a diverse array of molecules through complex three-dimensional interactions. their secondary structure varies widely. Within this panoply of secondary structures, however, there are recognizable regularities.*

Kendrew's x-ray crystal structure of myoglobin from 1958. the first of a globular protein. revealed that the amino acid side chains found on the interior of the protein were almost exclusively hydrophobic.[8] *Further structural studies of small proteins led to the idea that the main driving force behind folding of water-soluble globular proteins is to pack hydrophobic side chains into the core. leaving a hydrophilic surface. The problem* comes *when one considers that the hydrophilic main chain (with one NH hydrogen bond donor and one CO acceptor per residue) must assemble, or fold, into the interior along with any hydrophobic side chains. The main chain is neutralized by the formation of regular hydrogen bonds to create (usually) one of two common motifs within the protein interior: the* α-helix *or the* β-sheet *(Fig.* 1), *each*

with a distinctive hydrogen-bonding pattern. These motifs are connected by short loop regions.[9]

THREE-DIMENSIONAL "SPHERICAL" STRUCTURES

Icosahedral Viruses

A virus consists of a strand of nucleic acid contained in a protective protein shell, the capsid, which serves to relay the genetic information of the core to a host cell, where it may arrest the cell machinery and replicate. Some viruses have an additional lipid bilayer membrane. an envelope, enclosing the capsid. There are two main structural types of simple virus:[10] icosahedral, discussed here, and helical, discussed later.

Crick and Watson were the first to suggest that small viruses were built up of small protein subunits packed together symmetrically to form a protective shell for the nucleic acid.[11] They reasoned that formation of small identical molecules was an efficient use of the limited information contained in the virus nucleic acid. They also realized that, of the types of symmetry possible for a three-dimensional structure enclosing space, only the cubic point groups could lead to an isometric particle, which was the known symmetry of many viruses at the time. Three types of cubic symmetry exist; namely, tetrahedral. octahedral, and icosahedral. For a virus particle, these imply, respectively, 12, 24, or 60 subunits, arranged identically on the surface of a sphere.

To account for large molecular weights of viruses, Caspar and Klug introduced the idea of ''quasi-equivalent'' structure units.[12] They showed that an icosahedron, with 20 equilateral triangular facets, has therefore 60 T structure units, where T is the triangulation number (Fig. 2), given by $T=Pf^2$ [P is any number of the series (1, 3, 7, 13. 19. 21. 31…). and f is any integer]. Subunits can therefore be arranged on the facets of an icosahedron to give icosahedral symmetry. The same types of noncovalent contacts are used between the structure units in the shell, even though they are not in equivalent environments.

The genetic material of a virus, then, contains the code for one of these structure units, which is read many times to make the number of proteins needed to assemble via

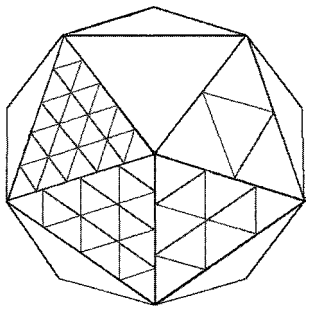

Fig. 2 An icosahedron with each face showing triangulation numbers of, clockwise from top, $T=1$, $T=4$, $T=9$, $T=16$, and $T=25$, respectively. (*View this art in color at www.dekker.com.*)

noncovalent forces into a convergent, icosahedral capsid. In addition to the capsid, enveloped viruses like Sindbis virus are enclosed on the outside by a self-assembled lipid bilayer. The *400* Å diameter capsid of Sindbis virus has $T=3$ icosahedral symmetry and is therefore composed of 180 subunits. It is surrounded by a polyhedral lipid membrane 40 Å thick. Finally, anchored in this membrane are 80 large spikes projecting from the surface, visible by electron microscopy. The spikes are arranged in a $T=4$ icosahedral lattice. The volume of each spike, as measured from electron density maps, corresponds to three copies of each of the two different spike polypeptide chains. The RNA in the core, therefore, codes for three separate protein subunits: one for the capsid and two for the spikes.[9]

Ferritin

Ferritin has two functions within the body: it protects cells from the potentially toxic effects of free iron by sequestering the metal in a mineralized form within a protein shell, and it stores iron for later use by the cell in the synthesis of heme. The shell is made of cylindrically shaped protein subunits. each composed of a bundle of four long helices, a short helix. and an extended loop. Twenty-four of these subunits self-assemble[13] to give a hollow shell with octahedral symmetry and a cavity (diameter −80 Å) capable of storing up to 4500 Fe(III) atoms (30% by weight)'''' as the mineral ferrihydrite ($5Fe_2O_3{\cdot}9H_2O$).[15] The shell is thermally stable and stable to treatment with urea or guanidinium chloride. This stability is largely due to intra- and intersubunit salt bridges and hydrogen bonds.[14]

Iron(II) atoms are oxidized at specific ferroxidase sites on the protein shell and can then enter the host through one of six hydrophobic channels about 4–5 Å wide, which lie along the fourfold symmetry axes. Once core nuclei are formed inside the structure, iron(II) oxidation can occur on the mineral surfaces.[16]

Lipid Membranes

Lipids are amphipathic inolecules composed of a polar, hydrophilic ''head'' connected to a nonpolar, hydrophobic hydrocarbon ''tail.''[17] When in an aqueous environment, lipids tend to associate noncovalently. There are two driving forces for this association: the hydrophobic effect due to the nonpolar tails. and the van der Waals interactions between the hydrocarbon portions of the molecules. This behavior in water can cause lipids to spontaneously form surface monolayers, bilayers, micelles, or vesicles, depending on the structures of the head and tail of the lipid molecule. We shall direct our attention here to the cell membrane bilayer, the most important of these biological assemblies.

The lipids of cell membranes fall into four groups: phospholipids, sphingolipids, glycolipids, and sterols (Fig. 3). The acyl chains generally have chain lengths from C_{10} to C_{28} and can be saturated or unsaturated. Notably, the dominant lipids in membrane formation have highly polar head groups and, usually, two hydrocarbon

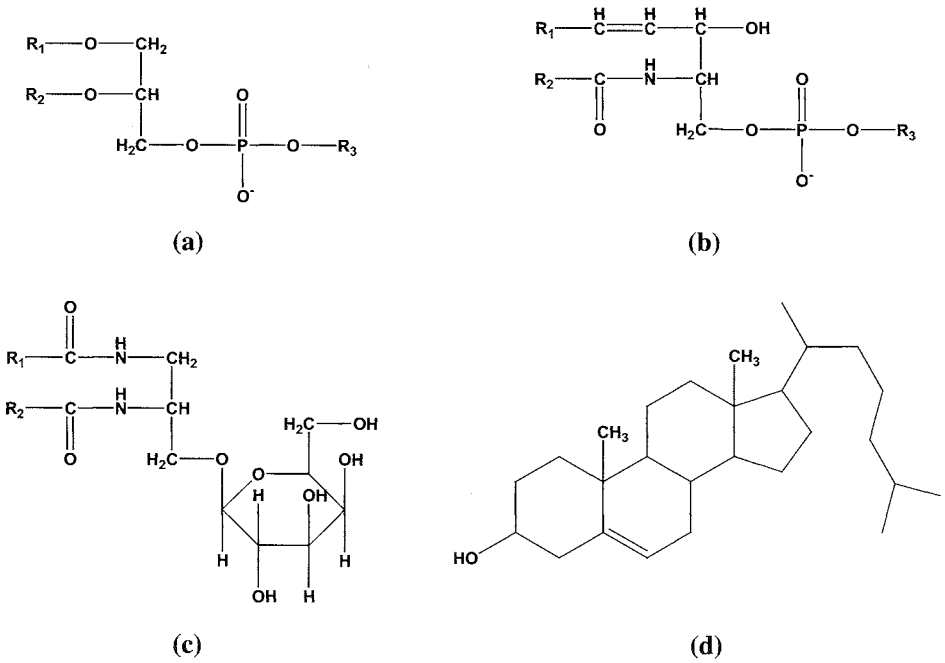

Fig. 3 The four principal groups of cell membrane lipids: (a) phospholipids, (b) sphingolipids. (c) glycolipids (cerebroside pictured), and (d) sterols (cholesterol pictured).

tails. If a large head group were attached to a single hydrocarbon chain, the resulting wedge-shaped molecules would tend to form spherical micelles upon self-association. A double tail results in molecules that can easily pack in parallel to form extended bilayer membrane sheets, with the hydrophilic head groups facing inside and outside toward the aqueous regions.

To say that a cell membrane is essentially a lipid bilayer would be an oversimplification. The basic structure of the lipid bilayer abounds with specific proteins contained within the membrane or attached to its surface. These serve as transport and recognition agents for the cell. Animal and some plant and fungal cells contain sugar residues on their surfaces. These have an important role in cell recognition processes, antigenic properties. and hormone reception.[17]

ROB-SHAPED, HELICAL, OR CYLINDRICAL STRUCTURES

Helical Viruses

Viruses with helical symmetry, or "linear" viral capsids, have their genetic material encased in a helix of identical protein subunits, the length of which is determined by the length of the encased nucleic acid. There are three main classes of simple helical viruses: the rigid rod viruses, the flexuous plant viruses, and the filamentous bacteriophage~.~The most studied of these viruses is the rigid rod Tobacco Mosaic Virus (TMV).

The TMV is composed of about 2100 identical protein subunits. each of molecular weight ~18,000. These self-assemble to form a right-handed helix with 16 $^1/_3$ subunits per turn. The final rod measures 3000 Å in length and 180 A in diameter. A single strand of RNA follows the basic turns of the helix from the inside, at a radial distance of 40 Å from the central axis, with three nucleotides binding to each protein subunit. Assembly is initiated by a preformed protein disk that serves as a sort of jig upon which the first few turns of the viral helix can assemble to reach sufficient size to be stable. It also provides a mechanism for the recognition by the protein of its RNA.[18]

Electron microscopy studies of the elongation process[19,20] showed that during elongation, the 5' and the 3' ends of the RNA extend from the same end of the growing nucleocapsid. As elongation proceeds, the 5' end of the RNA is pulled up and through the central channel of the growing rod. Assembly of the capsid around the 3' end is much slower and may not occur until the 5' end is entirely coated. It is possible that coat proteins are continually synthesized in vivo during the encapsulation of the remainder of the RNA.[10]

There are two charge clusters in the viral structure that provide stability for the capsid through electrostatic interactions. The largest is found near the inner surface of the virus, between 20 and 50 Å from the central axis. It is composed of a number of carboxyl groups in close proximity, which was described as a "carboxyl cage." Such intersubunit carboxyl clusters are a characteristic feature of many virus structures. A smaller charge cluster is found between 55 and 60 Å from the axis.[21]

Motion Machines

Biological systems have a number of ways of producing motility, where self-assembly plays a central role. The most familiar is muscle contraction that produces bodily movement, where the interaction of two proteins, actin and myosin, is critical.[6] For smaller organisms, including cells and the chromosomes and organelles of cells inside the bodies of larger organisms. motion is produced through interactions with microtubules, which are filamentous assemblies of the protein tubulin.[22]

Actin and myosin

Actin exists as a long, fibrous. helical polymer (*F*-actin) of a globular protein monomer (*G*-actin).[6] The polymerization is initiated by binding ATP to a 6-actin monomer. Myosin, on the other hand, is composed of six polypeptide chains: two identical heavy chains and two each of two different light chains. The two heavy chains have long α-helical tails. which intertwine to form a coil at the end of the myosin structure, and globular heads to which the light chains are bound. Between the head and tail domains of the heavy chain is a flexible stalk. The helical tails of myosin can join together to form a bipolar thick filament. Actin and myosin filaments interact to form long myofibers, or individual muscle cells. When a muscle moves from a relaxed to a contracted state, the headpieces of the thick (myosin) filaments pull the thin (actin) filaments together, shortening the myofibril by successively making and breaking cross-bridges in conjunction with binding and hydrolyzing ATP.[6]

Microtubule systems

Microtubules are noncovalent assemblies of the protein tubulin (Fig. 4). There are two closely related types of tubulin subunit, a and β, which alternate in the helical microtubule structure, with 13 subunits per turn. Each subunit weighs 55,000 Da. Assembly is initiated when an $\alpha\beta$ dimer binds to a molecule of GTP. The resulting microtubule is a hollow cylinder of 250 Å outside diameter and 15 Å internal diameter. The length is variable by assembly or disassembly of the subunits. a process that is sensitive to changes of cellular activity and conditions. In vivo. a continuous flow exists between assembled microtubules and the pool of free tubulin (which may represent up to 50% of the total tubulin). Because of the weak forces that hold them together, microtubules can be assembled

when and where they are requested and disassembled when they are of no more use.[22]

Microtubules are used in such diverse places as the mitotic spindle. protozoan and sperm flagella. and nerve axons.[22] They, along with actin filaments, provide the rod-like tracks upon which molecular engines (the proteins dynein and kinesin) transport packages around the cell; as well as provide scaffolding upon which a cell can alter its shape—an amoeba extending a pseudopod, for example. Cilia, used to propel microorganisms through solution and to push dirt-filtering mucus around the respiratory tract, and eukaryotic flagella, which propel the cell by an undulatory motion. both achieve movement with a highly organized bundle of microtubules called an axoneme.

BIOMINERALIZATION

The process of biomineralization involves the well-ordered construction of discrete or extended self-assembled arrangements of organic inolecules (the "organic matrix"), which subsequently associate with inorganic solids in vivo to give precisely controlled biomineral structures. The incorporation of iron into ferritin illustrates biomineralization within a discrete organic structure, the type predominant inside cells. Here we will discuss the case of biominei-alization arising from extended organic matrices, which happens mostly in the intercellular spaces of multicellular organisms to produce structures such as bones. shells. and teeth.[23]

The topology of the organic matrix involved in biomineralization (e.g., tubular, fibrous. pleated sheet) differs depending on the targeted structure. but there is a common theme underlying the process. Hydrophobic proteins first assemble into a structural framework. Then. acidic proteins like aspartic acid. often associated with sulfated polysaccharides. are built onto the insoluble framework and draw minerals, like $CaCO_3$ or SiO_2, out of the surrounding aqueous environment and into an ordered arrangement. It is thought that this molecular recognition process is controlled by electrostatic. structural. and stereochemical complementarity at the organic–inorganic interface.[23]

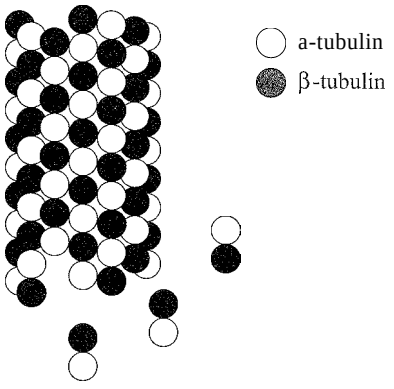

Fig. 4 Assembly of a microtubule from tubulin dimers. α-Tubulin is shown in white: β-tubulin is shown in black.

From a few simple inorganic salts, nature can construct a wide array of mineralized structures able to perform diverse functions. This shows the degree of control that can be exercised by the organic matrix, simply by controlling the crystal growth environment.[24]

For example, molluscan shells are organized composites of two different polymorphs of calcium carbonate (calcite and aragonite) arranged within a matrix of glycoproteins rich in acidic amino acid residues. The shell has a strength ~ 3000 times greater than that of its composite crystals. Different arrangements of crystals are formed, depending on the composition of the organic matrix, to give nacreous, prismatic: foliated. or crossed lamellar layers. It is thought that the chemical structure of the matrix surface complements a specific crystal face of the mineral so that nucleation is directed along a preferred crystallographic axis.[''] It is known that after a layer of calcite has grown on the nucleating protein sheet of a molluscan shell; there is an abrupt transition to production of aragonite to form nacre (mother of pearl). The production of each crystal type is accompanied by production of specific polyanionic proteins, allowing the organism to induce phase changes as needed by controlling the state of the organic–inorganic interface.[25] Though the matrix proteins typically make up less than 2 wt% of the shell. they determine its structural organization and properties.

WHY IS SELF-ASSEMBLY UBIQUITOUS IN NATURE?

Self-assembly is driven by many weak, reversible interactions to obtain a final structure that represents a thermodynamic minimum. In other words. it operates under equilibrium control. Consequently, incorrect structural units are easily rejected in the dynamic equilibrium assembly. giving the process high fidelity.[26]

Self-assembly is highly efficient. because it proceeds by organizing many small subunits that were made by sequential covalent processes to form the final, large structure. For example. if the protein coat of TMV were coded by a single, continuous gene. then the structure would require a section of RNA approximately 1×10^6 base pairs long. As 2130 identical subunits capable of self-assembling are utilized to form the protein coat. the complete structure may be coded for in a gene of around 500 base pairs in length.[26] This represents an economy of information. Additionally, only a few different molecules are normally involved in self-assembly. This means that a limited set of binding interactions is required to cause the final structure to form. allowing for further economy of information.

Finally, complementarity in molecular shape provides the foundation for association between components. This allows for molecular recognition between two specific components.

CONCLUSION

Nature has demonstrated an ability to outperform humans in efficiency of design and strength of materials. If materials scientists can learn to mimic the controlled synthetic processes employed to make durable materials such as bones, teeth, and shells, significant advances could be realized.

Thus. in a coming age of nanotechnology, it is likely that synthetic chemists will strive to make molecules of larger molecular weights, while lithography will make possible the reduction of engineered structures to roughly 1 ym. Indeed, the size gap between these two efforts is converging within a range of many self-assembled biological structures. It is therefore reasonable to assert that a better understanding of self-assembly processes in biological systems will lead to the engineering of functional molecular structures with nanometer-scale dimensions, and beyond.

Self-Assembly: Terminology

Gerhard F. Swiegers
Commonwealth Scientific and Industrial Research Organisation (CSIRO), Melbourne, Victoria, Australia

INTRODUCTION

Self-assembly processes can today be found in a variety of fields ranging from biology to materials science and electronics. While self-assembly has proven to be a valuable tool in the formation of supramolecular assemblies, it remains less a discipline in its own right than a compilation of principles that have been applied to an apparently disparate collection of research fields. One outcome of this historical development is that the concepts of self-assembly were typically defined in discipline-specific and sometimes overlapping ways. This fragmentation obscures their underlying coherence and universality. It also hinders a widespread understanding of self-assembly.

In this article. the various terminologies used to describe important concepts in thermodynamic self-assembly will be reviewed. In so doing, an attempt is made to illustrate. wherever possible, the underlying unity of the concepts and eliminate confusion arising from the different terminologies used. Most of the terminologies derive from the fields of chemistry. biology, and biochemistry.

TERMINOLOGIES TO DESCRIBE HIERARCHICAL SELF-ASSEMBLED STRUCTURES

The dramatic development of biochemistry in the twentieth century can largely be attributed to breakthroughs in the understanding of the supramolecular structure of biomolecules. Pauling and Corey's work on the structure of proteins and the discovery of the DNA double helix[1,2] demonstrated the critical importance of supramolecular structure in biology and stimulated interest in its study as well as in the processes by which it is formed.

One of the most remarkable properties of self-assembly is its ability to generate exceedingly coinplicated supramolecular structures frorn fairly simple components. Perhaps the most elegant embodiment of this phenomenon is protein structure. Proteins exhibit at least four hierarchies of structure: primary, secondary, tertiary. and quaternary structures.[1,2] Primary structure describes the covalent connections making up the sequence of amino acids in each strand. Secondary structure involves local architectural elements created when portions of a strand twist or loop into regularly repeating arrangements, like α-helices or β-sheets. The overall folding of each polypeptide chain is considered to be tertiary structure: while the spatial arrangement of several strands relative to each other is known as quaternary structure. Some of the hierarchies may be further subdivided. For example. repetitions of a secondary structural feature within one particular fold of a protein are sometimes referred to as supersecondary structures.[1,2] The tertiary structures of large proteins may also consist of domains, each of which comprises a fold or series of folds having their own interior surface and connected to other domains by an interconnecting strand of the backbone.[1,2] The individual constituents of an extended quaternary structure are typically known as protomers.[1,2]

These levels of organization are hierarchical, because each level cannot exist without the preceding level. For example. a tertiary structure requires the presence of secondary structural elements. These cannot exist without a primary structure. When viewed in a widening perspective, from an atomic level to a more macroscopic level. each of the hierarchies of organization becomes progressively obvious.

Similar levels of structural hierarchy can be discerned in nonbiological self-assembled compounds such as coordination complexes.[3] Metal helicates display secondary structure in their overall helical architectures and primary structures in the covalent connections of the organic ligands.[4] Tertiary structure can be observed in the cyclized metal helicates known as circular helicates,[5] while quaternary structure is present in certain coordination polymers.[3] The only important difference, from a self-assembly point of view. between an r-helix in biology and a metal helicate in coordination chemistry is the type of noncovalent interactions that drive the self-assembly process, i.e., the formation of coordination bonds in the latter case and the formation of hydrogen bonds. ion-pairing interactions, and hydrophobic–hydrophilic interactions in the former. While coordinate interactions are more directional and stronger (bond energies ca. 10–30 kcal mol^{-1}) than the biological interactions (bond energies ca. 0.6–7 kcal mol^{-1}), all are nevertheless noncovalent in nature.

In the study of self-assembled supramolecular assemblies directed by π donor–acceptor interactions, Stoddart

DOI: 10.1081/E-ESMC 120012878

noted the existence of structural hierarchies. In his terminology,[6] assemblies exhibiting secondary structure are termed supermolecules, with individual components that are designated as primary molecules or tectons. Assemblies displaying tertiary structures are called supramolecular arrays. while quaternary structures are found in macroscopic conglomerates.

These descriptions and terminologies are conceptually analogous, differing only in their discipline-specific framing and the nature of the interactions involved.

TERMINOLOGIES FOR DYNAMIC SELF-ASSEMBLY PROCESSES

Self-assembly in biology — the so-called dance of life — is largely driven by the enthalpy of formation of the three fundamental noncovalent interactions mentioned earlier. Other classes of interaction employed in self-assembly include coordinate bond formation and π–π acceptor–donor interactions. Steric factors, conformational preferences, and entropic driving forces also play significant roles.[3] In a kinetically rapid, dynamic, thermodynamic self-assembly; all of these possible contributions are continuously at play. They act to ensure a never-ending association and dissociation of all possible products, with the lowest-energy products being present in the greatest proportion at any one time.[7] Thus. a combinatorial library of products, each with their own structural architecture. exists in self-assembling mixtures.[8] Because of their high energies, most of the members of such a library are present in infinitesimally small proportions; the assembly can therefore be considered to be a virtual combinatorial library.[8] Each member of the library, nevertheless, represents the whole library, because it can be disassembled and reassembled into every other member. The main constituents of the library can be changed by varying an external factor. like temperature or concentration. which affects the thermodynamic stabilities of the members. Thermodynamic self-assembly is therefore truly a dynamic combinatorial process.[8]

TERMINOLOGIES DESCRIBING REPRODUCIBILITY IN SELF-ASSEMBLY

The existence of life depends, crucially, on the reproducibility of self-assembly processes in biology. Without unqualified fidelity. protein-based ion-pumps and enzymes. among other biological devices, could not operate.[2] But what are the origins of this noteworthy characteristic?

The property of reproducibility generally arises from the thermodynamic equilibrium present. In strict self-assembly,[3] the system uniformly seeks and settles upon the lowest-energy arrangement.[7] Thermodynamics dictates that this state will always be the product of the self-assembly under a determined set of physical conditions. "Strict" or "thermodynamic" self-assembly refers to processes dominated by a kinetically rapid, reversible thermodynamic equilibrium. This equilibrium exists at all times during the assembly. The products are, therefore: obtained in proportions determined by their relative thermodynamic stabilities.

It has long been known that certain types of components can drive the self-assembly of particular structures. For example, the amino acid residues alanine and leucine promote α-helix formation when they are present within a polypeptide chain, while glycine and tyrosine are considered "helix breakers."[1]

These preferences usually originate in stereochemical and structural limitations that affect the thermodynamics of the system. As such, they can be considered instructions that direct the self-assembly process.[9] In some cases, the preferences are extreme, so that they dominate the system regardless of alternative influences. In others, they are less intense and must be weighed against other factors. In a complicated multicomponent system. for example, not all of the component preferences will be aligned, i.e., the instructions may be contradictory. In such a case; self-assembly becomes a process in which the preponderance of instructions and their intensities dominate. But how does this take place?

Lehn proposed considering self-assembly in coordination chemistry to be akin to a computer program driven by an ".interactional" algorithm.[9,10] The algorithm is established by the interplay between the structure of the ligands and the stereochemistry of the metal ions. i.e., by the preferences of the components. Algorithms, however, involve a linear hierarchy of commands that execute to completion and then stop. As mentioned earlier, thermodynamic self-assembly is, by contrast; entirely pathway independent. and it never stops. Where then is the linearity and hierarchy implied in the analogy? It is energetic in nature, and it applies to the system as a whole rather than to any one constituent molecule. Thus, thermodynamic self-assembling systems transform themselves. linearly. from a high-energy to a low-energy state.[7] While many individual pathways may be followed in this process, all are characterized by a process known as positive cooperativity. This effectively involves the stepwise optimization of structural elements from those producing the greatest thermodynamic stabilization to those producing the smallest.[7] The strongest and most intense preferences or instructions must be finalized first, followed by a hierarchy of instructions from most to least energetically important. For example, self-assembly of a metal helicate involves the initial formation of an increasing number of coordination bonds. However, the instruction for the characteristic helical twisting is, for all pathways, carried out only during the last step.[7] Self-assembly processes

involving the formation of coordination bonds (strong) and π–π acceptor–donor interactions (weak) must, therefore, first optimize elements involving the former interactions and then those involving the latter. In following this linear hierarchy of thermodynamic instructions, it is, of course, conceivable that the combined instructions at the lower end of the hierarchy may overturn those at the top. but this can only happen after the former are satisfied.

This concept has important implications. It explains, for example, how proteins fold as fast as they do. For example, a protein containing 100 amino acid residues should take at least 10^{27} years to reach its lowest energy state if it does so by exploring all of its possible conformations.[12] Instead. such proteins typically fold within minutes. This can only occur because energetically highly favored local folds are formed first, and these then serve as nuclei that attract and stabilize other elements of secondary structure.[2]

Instructed, reproducible self-assembly of this type can be seen in numerous disciplines. In polymer chemistry, certain oligo(phenylene ethylenes) undergo solvophobic folding into helical conformations in polar solvents.[11] In peptide science. synthetic polypeptides containing unnatural β-amino acids spontaneously adopt helical dispositions in solution, despite being unable to form the hydrogen bonds that drive self-assembly in normal biopolymers.[12]

TERMINOLOGIES DESCRIBING THE COMPLEXITY OF SELF-ASSEMBLY PROCESSES

The thermodynamic hierarchies discussed in the previous section offer important opportunities to manipulate self-assembly processes. In particular, they raise the possibility of innovatively assembling novel structures that display unusual physical properties or that can be switched between different physical states. The latter aspect is particularly important, because it prospectively provides a means of creating a molecular computational[13] or information storage system.[14] As many self-assembled structural motifs cannot be easily obtained by other means, this concept also opens the way to a wide variety of supramolecular compounds displaying novel properties, such as self-assembling catalysts.[15]

Several researchers recognized and sought to exploit this approach. Fujita and coworkers. for example, developed so-called multiple-molecular recognition processes, in which the self-assembly of coordination bonds is accompanied in situ by the formation of weaker interactions: such as π donor–acceptor and hydrophobic/hydrophilic interactions.[16] Illustrated in Fig. 1 is an example of such an assembly. in which a molecular switch is created by the interlocking or diassociation, upon command, of two cyclic molecules.[17]

Lehn and coworkers developed a similar approach. which they term double code or double subroutine self-assembly.[18] In this technique: different metal ions in a mixture are induced to selectively interact with different binding sites on a single. hybrid ligand, giving assemblies displaying novel structures. An example of such a process is shown in Fig. 2.[19]

In general, it is possible to distinguish two classes of self-assembly in this respect:[20] single-interaction self-assembly and multiple-interaction self-assembly. Single-interaction self-assembly, also referred to as single-code self-assembly, involves the formation of one specific interaction during the self-assembly process. In Fig. 3a, an example of a single-interaction process is depicted in which a metal ion interacts with a multitopic ligand strand by forming the same type of metal–ligand coordination bond at each binding site.

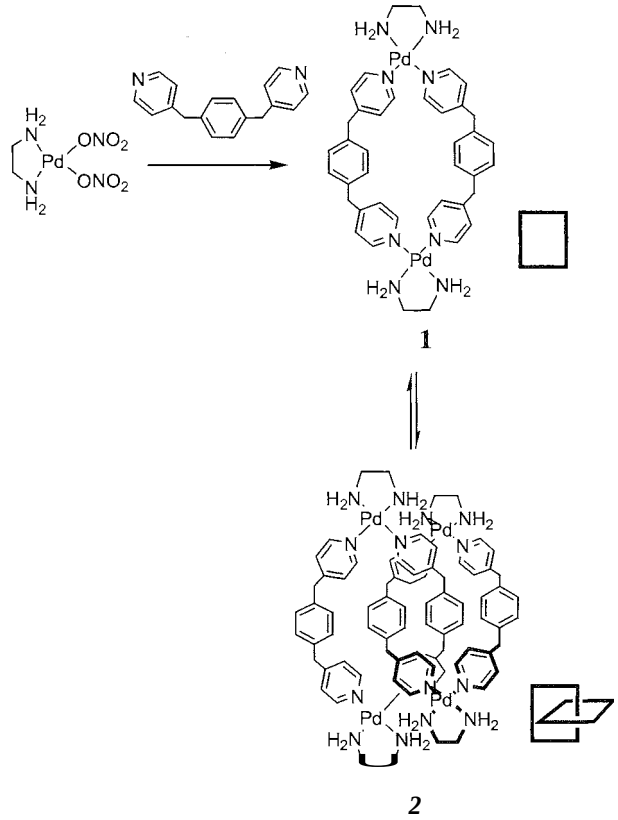

Fig. 1 Multiple molecular recognition: Free metallocycle **1** is formed in dilute solution because of the enthalpy of formation of the Pd—N coordination bonds. When the solution is concentrated from 2–50 mM, the lability of these bonds allows the in situ formation of the interlocked catenane **2**. This is driven by hydrophobic interactions to minimize the contact of the metallocycle cavities with the water solvent, the formation of π-stacking interactions between two such rings. and an entropic effect due to a decline in the number of species present in solution after interlocking.

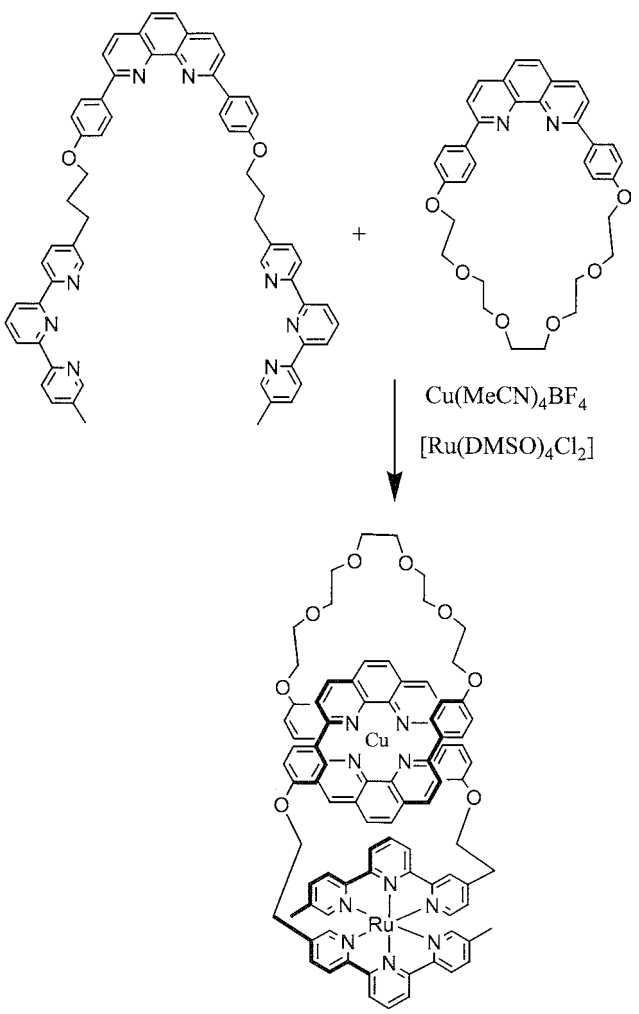

Fig. *2* Double subroutine self-assembly: The formation of a metallocatenane. (From Ref. [19].)

Multiple-interaction self-assembly involves the formation of more than one type of interaction. Illustrated in Fig. 3b is a multiple-interaction process in which two types of coordinate bonds are formed (i.e., double subroutine self-assembly). Depicted in Fig. 3c is a multiple-interaction process in which one type of coordinate bond and one type of hydrogen bond are formed (i.e., a multiple inolecular recognition process). Processes like that depicted in Fig. 3b involve mediation by one class of interaction only, and can therefore be referred to as unmediated.[20] Processes of the type depicted in Fig. 3c involve mediation by two different classes of interaction and are therefore referred to as multimediated.[20]

The three processes illustrated in Fig. 3 differ fundamentaliy in their self-assembly properties, because they exhibit different thermodynamic hierarchies.[20] Their potentials in regard to self-assembly are therefore also quite different. For example. in Fig. 3a, only one bond angle is possible: the range of architectural alternatives is therefore similarly limited. In Fig. 3b, two types of bond angles are possible, so that a greater range of possible architectures are available. The self-assembly in Fig. 3c prospectively allows for the most architectural variety. because the noncoordinate interactions are weak and poorly directed.

TERMINOLOGIES TO DESCRIBE 2-D AND 3-D CYCLIC ASSEMBLIES

Self-assembled two-dimensional (2-D) and three-dimensional (3-D) cyclic assemblies are known in fields including biology (e.g., spherical viruses) and chemistry (e.g., cryptands, polyoxometallates). While such capsules are exceedingly important entities. their architectures are highly diverse,[21] a fact which long hindered their systematic classification. MacGillivray and Atwood have. however, formalized the description of such species using an analogy based on the principles of solid geometry.[22] Their system employs the Platonic and Archimedean solids, along with prisms, antiprisms, duals. irregular polyhedra, and other pseudospherical arrangements as models of spheroidal design. The structure of a self-assembled capsule is classified according to its resemblance to these structures. The comparative nature of this approach is topologically correct, because most of the above solids

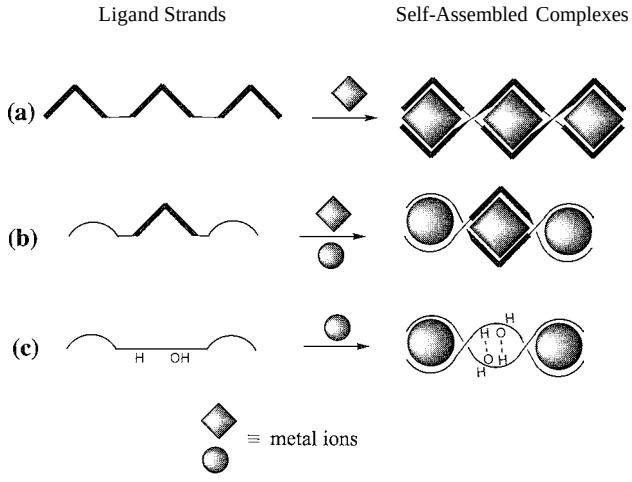

Fig. 3 Classes of self-assembly: The forination of metal helicates by: (a) single-interaction self-assembly. (b) unimediated multiple-interaction self-assembly. and (c) multimediated multiple-interaction self-assembly.[20] The circles and diamonds represent metal ions with preferences to bind the semicircular and half-diamond binding sites, respectively. on the hybrid ligand strands.

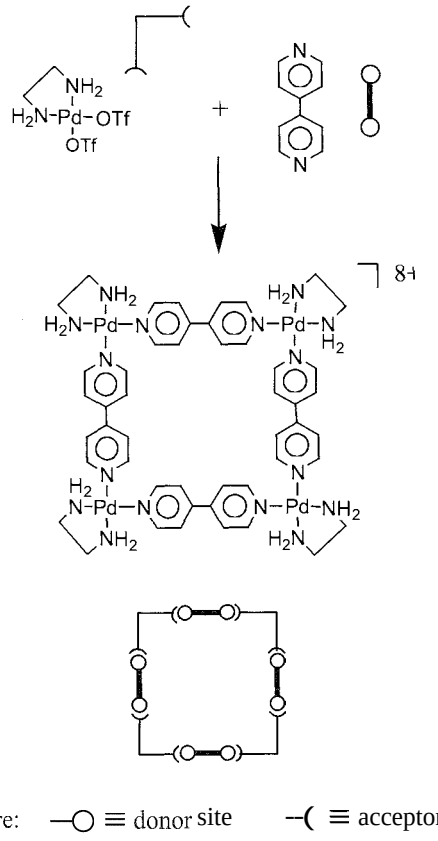

Fig. 4 Self-assembly of an edge-defined molecular square by the Molecular Library approach (From Ref. [25].)

can be continuously deformed into spheres. However. as noted elsewhere.[23] it can produce ambiguities due to the sometimes subjective nature of the comparisons; real supramolecular structures do not always clearly correspond to idealized polyhedral structures.

Various techniques were developed to aid in the rational design of self-assembling systems. The best known of these are the Molecular Library method and the Symmetry Interaction method.

The Molecular Library approach employs complementary components to generate geometrically shaped assemblies.[24] The highly directional formation of coordination bonds between suitably rigid, complementary donor (ligand-based) and acceptor (metal-based) components makes this approach most appropriate to coordination chemistry. In Fig. 4. the formation of a inolecular square by this approach is illustrated.[25] A wide variety of secondary structures displaying polygonal and polyhedral geometries have been self-assembled using this technique, including molecular triangles; hexagons, triangular prisms, octahedra, cubes. and adamantanoid and other boxes.[26] The Molecular Library approach is most suitable to the formation of edge-defined polyhedra, in which the components lie on the corners and edges of the structures.

The basis of the Symmetry Interaction approach lies in the recognition that many natural suprarnolecular assemblies are formed in symmetry-driven processes involving incoinmensurate lock-and-key interactions.[27] A polyhedral structure can therefore be designed by determining the symmetry interactions and the associated geometric relationships necessary to generate that structure from a combination of preorganized ligands and metal ions. The following terms describe these relationships in coordination chemistry.[27] The coordinate vector of a binding group bisects the chelate in the direction of the metal ion to which it is bound. The chelate plane of a metal ion is the plane that contains all of the coordinate vectors of the bound groups. The approach angle describes the arrangement of three bidentate chelators about a metal ion: it defines the angle between the plane holding the coordinating atoms of a bidentate chelating group and

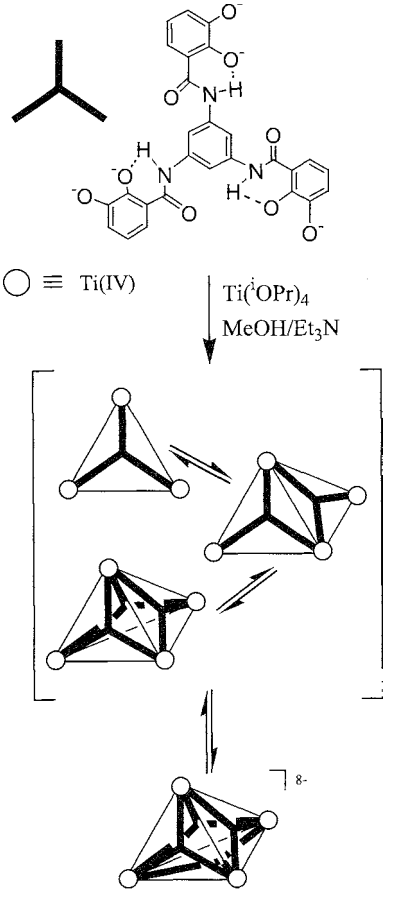

Fig. 5 Self-assembly of a face-occupied inolecular tetrahedron by the Symmetry Interaction approach (From Ref [28])

the major symmetry axis of the metal center. Each class of polyhedra involves different relationships between these variables. The Symmetry Interaction approach is particularly suited to the formation of face-defined polyhedra, in which the components lie on the corners and faces of the structure.[23] Illustrated in Fig. 5 is the formation of a face-occupied tetrahedron.[28]

Several terminologies were created to describe the composition of self-assembled structures and therefore also of the self-assembly process. Stang's assembly descriptor terminology involves treating the assembly components as linear (L), or angular (A), and then listing the numbers and types of each constituent with superscripts to describe their respective topicities.[26] An assembly, such as the square shown in Fig. 4 is therefore assigned the descriptor $A_4{}^2L_4{}^2$, because it consists of four ditopic angular units and four ditopic linear units. This approach offers a convenient abbreviation of the self-assembly process and also provides information about the number of linkages formed and the coordinative saturation of the resulting cycle.

Stang's assembly descriptor terminology was recently amended to include a designation of the nature of the linkage sites on the assembly components.[29] In this terminology, each component is further superscripted with d's or a's to indicate the types of binding sites present. The designation d signifies a donor site and a an acceptor site. A unique descriptor is thereby obtained that fully describes the self-assembly process. This approach has a number of advantages: it allows for a systematic analysis of all of the self-assembly pathways leading to a particular polygonal or polyhedral structure.[30] It also offers a simple means of identifying commonalities between different self-assembly processes, including identical processes.

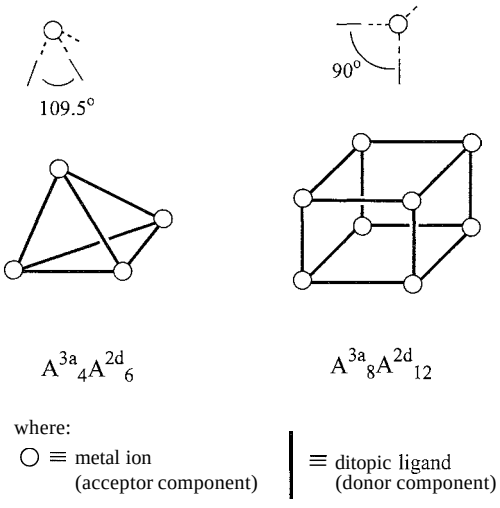

Fig. **6** Switchable molecular structures displaying the same stoichiornetries and component topicities.

near-identical processes, and processes involving common components.[29,30] Polygons and polyhedra that can be switched between structures are easily identified using this approach.[29] For example, illustrated in Fig. 6 are an $A_4{}^{3a}L_6{}^{2d}$ molecular tetrahedron and an $A_8{}^{3a}L_{12}{}^{2d}$ cube. Despite their different overall shapes, these structures have the same stoichiometry and component topicity and would therefore likely switch from one to the other if the directing angles of the angled component were toggled between 109.5" (tetrahedron) and 90° (cube).[29]

CONCLUSION

Self-assembly processes offer important opportunities to inexpensively fabricate novel, molecular-based structures and devices. Underlying all thermodynamic self-assembly processes is a set of common principles with a complexity that has not yet been fully exploited. Recent advances provided significant new insights into self-assembly. These are already generating new ways to manipulate self-assembly in the formation of coinplicated nonbiological entities. Developments such as these are mere precursors for what is still to come. Thanks to self-assembly, molecular engineering will undoubtedly take over from nanoscopic engineering as the dominant and topical theme of the day.

Semiochemistry

Antony M. Hooper
John A. Pickett
Rothamsted Research, Harpenden, Hertfordshire, United Kingdom

INTRODUCTION

A semiochemical, derived from the Greek word *semeion* meaning sign. is a chemical signal mediating interactions between organisms, either of the same species (pheromones) or between different species (allelochemicals). Examples of sex pheromones employed by mating moths are well known. Male moths. with their large antennae, locate females using an odor plume of sex pheromone. The first chemically characterized example was bombykol **1**, the sex pheromone of the silkworm moth *Bombyx mori*,[1] an organism still used as a study model (see below). Identifying the sex pheromones of insect pest species, particularly lepidopterous pests, led to pest inanagement strategies in agricultural systems that disrupt mating by the release of competitively high concentrations of the sex pheromone. An alternative strategy is illustrated by use of the aphid sex pheromone[2,3] to lure pests away from crops to areas where biological control or localized pesticide spraying can be used, minimizing the environmental iinpact of conventional pesticides.[4] Pheromones can elicit behaviors other than the familiar mating response. Alarm pheromones elicit escape behavior in aphids or muster an attack in social hymenopterous insects, such as honeybees and some ant species. The aggregation pheromone of the ladybird. *Coccinella septempunctata*, is an example of an epideictic or dispersal pherornone. The mosquito, *Culex quinquefasciatus*, has an oviposition pheromone. All these are important aspects of insect behavior that may be regulated by semiochemistry.

I - Bombykol

Allelochemicals are most notable in examples of host–plant and nonhost–plant selection, a process that is vital for phytophagous pest insects to locate food plants and avoid unsuitable or toxic hosts. Aphids have taxonomically unrelated summer and winter hosts. The bird-cherry-oat aphid, *Rhopalosiphum yadi*. is able to detect species-specific odors from each of its hosts, the bird-cherry tree. *Prunus padus*, in winter and summer cereal crops. One such allelochemical from the winter host is methyl salicylate 2, and the aphid's behavioral response changes from attraction in winter to repulsion, as it migrates to its summer host. Hematophagous insects such as mosquitoes or midges also use chemical odors from their animal hosts for location. These are examples of kairomones. which are defined as semiochemicals where only the receiver of the semiochemical benefits from the interaction. Insect antifeedants such as ajugarin are examples of allomones, compounds that benefit the emitter of the semiochemical. Ajugarin is not toxic at natural concentrations but prevents susceptible insects from feeding on the labiate plant, *Ajuga remota*. Synomones benefit emitter and receiver, for example, the attraction of pollinating insects to flowers; and apneumones are compounds emitted from nonliving material. It is common for semiochemical components to have multiple roles and exert effects on multiple trophic levels. Nepetalactone **3a** is the sex pheromone of the grain aphid, *Sitobion avenae*, but also attracts parasitic braconid wasps. e.g., *Praon* sp., that inject an egg into the aphid, which subsequently develops, consuming the host. Nepetalactone therefore acts as a sex pheromone and also as a kairomone. An even more sophisticated example is the release of isothiocyanates by cruciferous plants under attack from herbivores, such as the diamondback moth, *Plutella xylostella*. Herbivorous insect attack on the plant releases myrosinase enzymes (specific thioglucosidases) in the damaged plant tissue that catalyze the decomposition of glucosinolates to isothiocyanates. These compounds are repellent to many insects, but *P. xylostella* is adapted to feed on crucifers and is attracted by them. Furthermore, compounds such as allyl isothiocyanate 4 also attract parasitoids, such as *Cotesia xylostella*, that can destroy the herbivore, thereby acting as a synomone working in a tritrophic system.

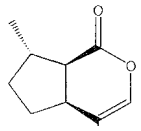
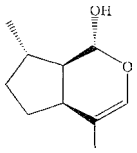
Semiochemical biogenesis employs biosynthetic pathways common to many organisms. and this, combined

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012785

with the requirements for most semiochemicals to be lipophilic, of low molecular weight, and, therefore, volatile. limits their structural diversity. As a consequence, behavioral response often depends on the detection of more than one semiochemical component in a blend. These blends are often detected at the same site of the antenna by co-located olfactory organs, and so the semiochemicals must be in the same odor plume to be recognized, verifying to the insect that they originate from the same source. Many species of aphid use nepetalactone **3a** and nepetalactol **3b** as their sex pheromone but respond to species-specific ratios. Also, the aphid alarm pheromone, (*E*)-β-farnesene **5** is a ubiquitous plant semiochemical, but in plants, it is generated along with *β*-caryophyllene, which is inhibitory to the behavioral response. Pure **5**, however, elicits the full-alarm response. Despite the existence of thousands of moth species, structural diversity of their sex pheromones is also low, and only a few hundred compounds, derived from fatty-acid metabolism, are used. By utilizing species-specific blends, as well as temporal, geographic. or habitat parameters, mating signals are not confused.



3 - Nepetalactone

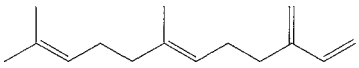


3b - Nepetalactol

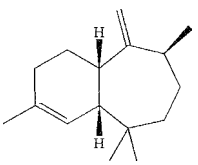
4

The use of single semiochemicals in the field is not usually sufficient for pest control, but by combining semiocheinicals, substantial protection can be achieved using an integrated approach called the push–pull system. The push is located in the crop and may comprise antifeedants, nonhost serniochemicals, attraction of predators or parasitoids, oviposition deterrents, or epideictic pheromones. The pull component comprises lures or trap areas away from the crop containing the sex pheromone, host odors, oviposition stimulants, or aggregation pheromones. The effectiveness of this approach can reduce broad-spectrum pesticide use by preventing, or even just delaying. the point at which pest populations reach economically damaging levels, so reducing the number of pesticide applications. Insect resistance to pesticides results from mutations that either allow enhanced detoxification of the chemical or that change the target site protein. These insects. which cannot be destroyed by the pesticide and so are at a significant selective advantage in treated areas, can subsequently multiply to produce a resistant population. Semiochemicals, however, affect insect behavior and prevent the damaging population explosions that occur in agricultural monocrops, so maintaining wild-type populations and avoiding a selection process comparable to pesticide use. Semiochemicals can, therefore, provide part of a successful, long-term pest-management strategy.

The primary difficulty in researching the field of semiochemicals is structure elucidation. Semiochemicals are produced in small quantities and are typically available in the range of subnanogram to microgram quantities and in complex mixtures. While modern NMR techniques of Microcell- or Microprobe-NMR using high-field instruments make the upper range amenable to elucidation, gas chromatography-mass spectrometry (GS-MS) is the usual analytical method. As structural data are limited and stereochemical data are severely limited from mass spectra, structure verification by chemical synthesis is almost always required. The structure of the sandfly *Lutzomyia longipalpis* sex pheromone was determined by GC-MS as methyl-α-himachalene **6**. however, syntheses of all four diastereoisomers and subsequent syntheses of both enantiomers of the correct diastereoisomer were required to determine the structure.[5] The synthesis of semiochemicals appears straightforward due to their low molecular weight. but it requires rigorous stereochemical control, as isomers (geometric, diastereomeric, or enantiomeric) can have different biological activities and interfere with the desired response. The field-scale of application also presents problems in the synthesis of the necessary quantities.



5



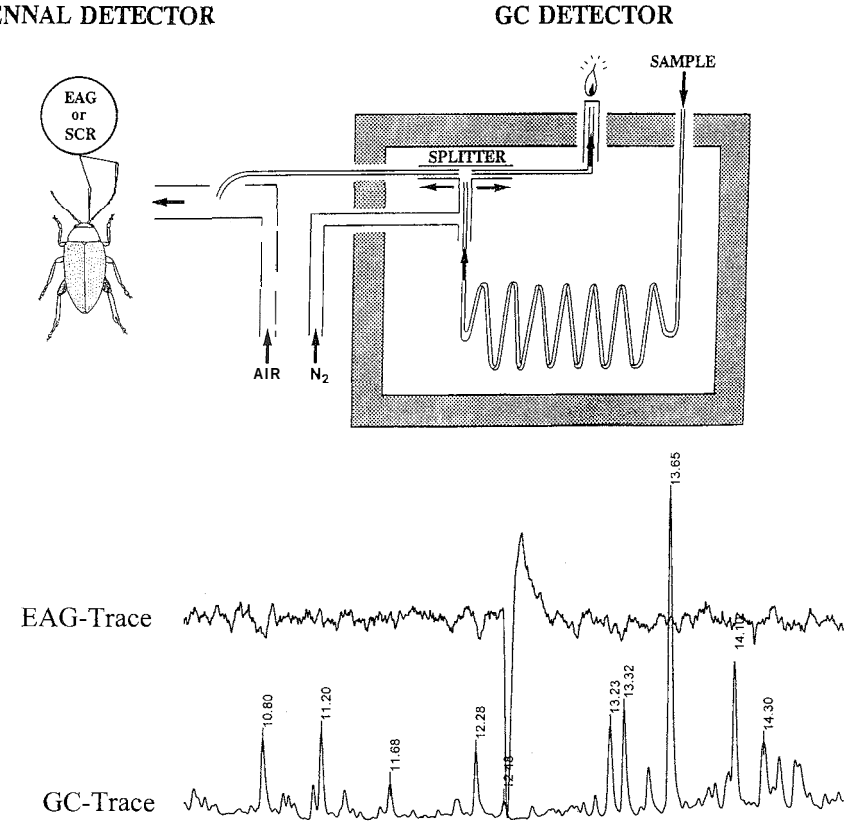


Fig. 1 GC-EAG response of the banana weevil, *Cosmopoiltes sordidus*. to host-plant volatiles

Biologically active isolates, especially plant volatiles. are extremely complex mixtures of compounds. By GC analysis, there may be 200–300 compounds. Insects, however, only detect and utilize a limited number of these, and as the compounds that insects need to detect are specific to a plant or insect, they are often not major peaks. presenting the problem as to which peaks should be analyzed. This problem has been tackled by a technique called gas chromatography coupled electro-antennography (GC-EAG), whereby the analytical GC effluent is split (Fig. I). One half is passed through the flame ionization detector as usual, while the other is simultaneously passed over an insect antenna that has electrodes attached to each end. Antennal response can be correlated to specific peaks. and these peaks are subsequently analyzed by mass spectrometry. This was developed further to a technique called single-cell recording (SCR). In this case, an electrode can be placed in an individual olfactory cell within the antenna. so locating the actual site of olfaction for particular semiochemicals.[6] These techniques show that the insect is capable of detecting a particular odor at the peripheral system and avoid the problems of demonstrating such detection through observing a behavioral response, which is only observed after the detection process is neurally processed and is less reproducible. Despite these techniques, electrophysiological responses are often observed to such vanishingly small quantities that peaks cannot be detected in the GC trace. The large number of compounds in the traces also means that although a compound in the active region may be identified, the activity actually comes from a much smaller co-eluting peak.

INSECT OLFACTION

Insect perception of volatile semiochemicals is mediated through olfactory sensilla, located mainly on the antennae. These sensilla have a porous cuticular surface through which semiochemicals can pass and make contact with the sensillum lymph. Semiochemicals are usually hydrophobic. organic chemicals. For land-living insects, these molecules must be transferred across the aqueous lymph to membrane-bound *G*-protein-coupled receptors (GPCRs) on the olfactory neurones, from which signal transduction occurs.[7] Transfer across the sensillum lymph is an evolutionary adaptation to terrestrial habitation and is mediated by odorant-binding proteins (OBPs). These are small (14–20 kDa), acidic,

water soluble. and highly concentrated (~10 mmol) in sensillum lymph. Initially it was thought that the function of OBPs was passive transport of any suitable hydrophobic, organic compounds across the aqueous sensillum lymph, and protection of the chemicals from degradative enzymes. However, it is now suggested that OBPs may bind a particular odorant specifically, or with at least some degree of specificity. and deliver it by dissociation at the receptor, or allow the receptor to recognize the entire odorant/OBP complex. Most current research is investigating the role OBPs play in molecular recognition of specific chemicals at the cuticular surface and at the interface with GPCRs, where molecular recognition must also reside.

ODORANT-BINDING PROTEINS

Insect OBPs were initially identified from lepidopteran species such as the tobacco hawkmoth. *Manduca sexta*, and silk moths, *Antheraea* sp.,[8] but they have now been found in examples from the orders Diptera (*Culex quinquefasciatus*—mosquito), Hymenoptera (*Apis melli*-,fern—honeybee). Coleoptera (*Exomala orientalis*—Oriental beetle), and Hemiptera (*Lygus lineolaris*—tarnished plant bug). The molecular techniques used to identify OBPs are numerous: as outlined in a recent review.[9]

OBPs are classed into three groups based primarily on sequence homology and tissue expression patterns:

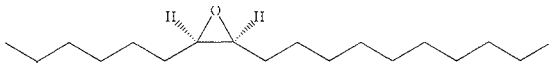
Pheromone-binding proteins (PBP). These are expressed mainly in male antennae and are concentrated in sensilla responding to pheromones (sensilla trichoidea in lepidopterans). although smaller quantities are commonly found in female antennae. They show little amino acid sequence identity between species, although they have higher homology if the insect pheromones are structurally related.

General odorant-binding proteins (GOBPs). These are expressed in male and female antennae and are localized in sensilla responding to food or host semiochemicals (sensilla basiconica in lepidopterans). They exhibit higher sequence similarity between different species, suggesting that they may bind to a broad range of common semiochemicals, though it is still possible they selectively bind particular chemicals. There are two groups of these. GOBP1 and GOBP2. that differ from each other in their C-terminal amino acid sequences, and both differ considerably from PBPs.

The amino acid sequences of OBPs show little homology between orders and no homology to analogous proteins found in vertebrate olfaction systems. implying convergent evolutionary processes. However. there is conservation of six cysteine residues in all insect OBPs, and these form disulfide bridges important for the protein structure. The cysteine pattern in insect OBPs can be generalized as X_{18}-C-X_{30}-C-X_3-C-X_{42}-C-$X_{8\ 10}$-C-X_8-C-X_{24-26}. There are other classes of small, putative binding proteins related to insect olfaction, including the rapidly expanding group of chemosensory proteins (CSPs). These have only four cysteines, and, as many CSPs are not antennal specific and there are no ligands yet identified, they are not examined further in this review.

Pheromone-Binding Proteins

Experiments to probe the specificity of PBPs to insect pheromones were carried out by chemical synthesis of pheromone analogues and measurement of the electrophysiological response of the insect antennae by EAG. This technique, however, only reveals the result of PBP binding and receptor response and does not reveal where any discrimination resides. Analogues of the gypsy moth sex pheromone. (7*R*,8*S*)-*cis*-2-methyl-7,8-epoxyoctadecane. or (+)-disparlure **7**, have been synthesized in attempts to create behavioral agonists, antagonists, or pheromone synergists to use in mating disruption of this pest species. Analogues with different methyl group or epoxide positions proved unsuccessful, and a study where electronic properties were analyzed by replacing the epoxide of (+)-**7** with various cyclopropanes or aziridine, revealed the overall system of detection at the antennal level to be highly stringent.[10] Studies probing the structural requirements of the sex pheromone of the turnip moth, *Agrotis segetum*, were done by synthesizing conformationally restrained analogues of the pheromone component, (*Z*)-5-decenyl acetate. The enantiomers of cis- and *trans*-3-(4-propyl-cyclopent-2-enyl)-propyl acetate (Fig. 2) mimic both enantiomers of the cisoid and *transoid* conformations of the sex pheromone.[11] Electrophysiological recordings from single sensilla showed the cisoid (1*S*,4*R*)-conformation to be two orders of magnitude more active than its enantiomer and three orders more than the *transoid* isomers, providing evidence of a cisoid conformation of the pheromone in its bioactive state. A complementary study in the same moth, A. *segetum*, tested analogues of (*Z*)-5-decenyl acetate, in which the acetate group was replaced by different polar functional groups.[12] By comparing molecular electrostatic potentials determined by ab initio calculations with



7 - (+)-disparlure

the results of electrophysiological single-cell recordings, the results indicated a probable H-bonding interaction of

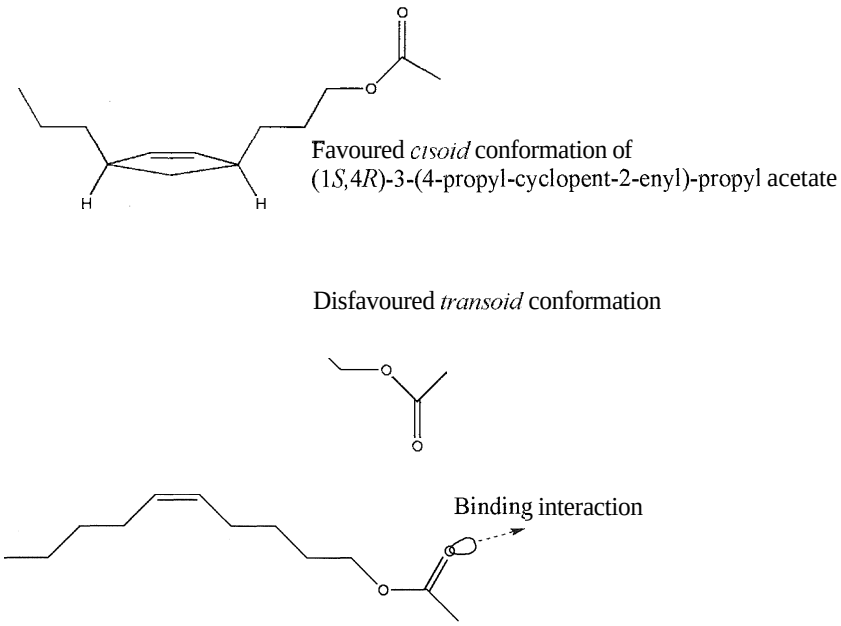


Fig. 2 (*Z*)-5-decenyl acetate and conformationally restrained analogues reveal structural requirements for peripheral detection by the turnip moth, *Agrotis segetum*.

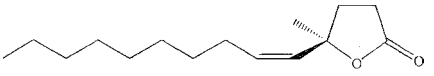
the carbonyl group in a direction pointing away from the hydrocarbon moiety (Fig. 2).

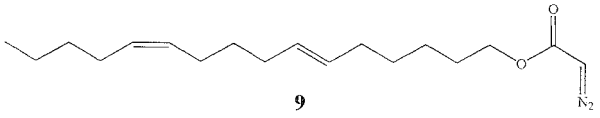
The question as to what degree molecular recognition resides at the OBP binding level remains. The insect is able to identify particular chemicals in an environment containing structurally related compounds, isomers, or even enantiomers, so how much molecular recognition resides at the OBP level? Many lepidopterous species use two or three compounds in their pheromone blends, often the same chemicals as related species but in different ratios, so it is possible that each component is recognized by a specific PBP. Incubation of Bombyx mori pheromone-binding protein (BmPBP) with its pheromone, bombykol 1, produced a complex stable enough to undergo mass spectrometric analysis to reveal a noncovalently bound complex at neutral pH (see the following section describing pH dependence).[13] However, other structurally related molecules also bound to the protein, albeit with lower binding efficiencies. Of three PBPs from the cabbage armyworm, *Mamestra* brassicae, only two isoforms bound the pheromone component (*Z*)-11-hexadecenyl acetate.[''' This PBP was also found in the female antennae at low concentration, belying the concept that only males can detect the pheromone. As mentioned before, the gypsy moth, L. *dispar*, uses (+)-disparlure 7 as its sex pheromone, but the (−)-enantiomer acts as an antagonist. Two recombinant PBPs from gypsy moth antennae reversibly bound with each enantiomer, but one PBP had a higher affinity to the (−)-enantiomer, and the other bound preferentially to the (+)-enantiomer. Two sibling moth species, A. *polyphemus* and *A*, pemyi, use the same three compounds in their sex pheromone blends. (*E*,*Z*)-6,11-hexadecadienyl acetate, (*E*,*Z*)-4,9-tetradecadienyl acetate, and (*E*,*Z*)-6,11-hexadecadienal. Three PBPs were isolated from each moth species and displayed a range of >1000-fold binding affinites measured for structurally related chemicals.[15] These PBPs also showed different binding affinities to different components of the pheromone blends, with *K*d values ranging from 0.6–30 μM. These examples, and others of lepidopteran PBPs that also bind their respective pheromones with Kd values of 0.1–10 μM, imply that an insect PBP will selectively bind its pheromone. However, in contrast to the ligand selectivity described above, only one PBP gene encoding an identical protein was isolated from two strains of the European corn borer, *Ostrinia nubilalis*, and from the closely related Asian corn borer, *O. furnacalis*. These insects use different pheromone isomers, suggesting that the molecular recognition here does not reside on the PBP.[16] In addition, two species of scarab beetle, the Osaka beetle (Anomala osakaaa) and the Japanese beetle (Popillia japonica), use opposite enantiomers of (*Z*)-5-(1-decenyl)oxacyclopentan-2-one 8 as their sex pheromone. The pheromone enantiomer of one species is a behavioral antagonist to the other species, yet the PBP from both species' antennae had the same binding affinity to both enantiomers,[17] suggesting that molecular recognition lies at the membrane receptor in this case. However, the finding that there are at least 38 OBP genes annotated in the *Drosophila melanogaster* genome[18] suggests some specificity between OBPs and particular ligands. In addition, more than 50 genes en-

coding putative receptors were also identified, so it may well be that semiochemical olfaction involves combinatorial interactions between OBPs and GPCRs and molecular recognition at both proteins.



8 - (*R*)-japonilure

Early attempts to characterize the binding site structure of PBPs were performed by Prestwich, who was the first to purify high levels of recombinant PBP from the moth Anfhemca *polyphemus*, by gene expression in *E.* coli. The active site of the PBP was probed by photoaffinity labeling using analogues of two components of the natural sex pheromone (6*E*,11*Z*)-hexadecadienyl acetate and (4*E*,9*Z*)-tetradecadienyl acetate. The photoaffinity labels prepared were [^{3}H]-(6*E*,11*Z*)-hexadecadienyl diazoacetate **9** and [^{3}H]-(4*E*,9*Z*)-tetradecadienyl diazoacetate. On photoactivation, these compounds degrade into a highly reactive carbene that forms a covalent bond, presumed to be with the nearest amino acid, i.e., one in the binding pocket. Subsequent degradation of the protein can identify this amino acid and its position in the protein sequence.[19] The 16-carbon label covalently bonded to a major hydrophobic domain comprising a helix-sheet-helix motif that shows sequence variation among insect PBPs and could explain the hydrophobic binding site of the alkyl chain. The bound amino acid, however, was threonine-44. found in a hydrophilic subfragment. next to arginine-46. a highly conserved amino acid. that could be involved in binding the acetyl group. The 14-carbon photoaffinity label was found bound to two sites in the binding pocket, one in the same region as the 16-carbon unit and one at aspartate-32. This is explained as a result of different chain lengths. allowing a different fit into the binding pocket. Indeed, the PBP binds the pheromone component (4*E*,9*Z*)-tetradecadienyl acetate poorly compared to the 16-carbon component. which may explain why the labeled pheromone analogue fits into the binding site less specifically.



9

PBP/Pheromone-binding mechanism

Analysis of recombinant bombyko! pheromone-binding protein. BmPBP, has given information on the protein structure and suggested a mode of action that is pH dependent. BmPBP can exist as a dimeric structure at neutral or slightly acidic or basic pH but dissociates at low pH and undergoes conformational change.[20] Single-crystal x-ray diffraction studies were carried out on the protein with bound bombykol, and they revealed some interesting structural features.[21] The structure contains many α-helices and has a novel protein fold different from that found in vertebrate olfactory proteins. The surface is covered in charged residues, as expected for a highly water-soluble protein, and it contains residues that may interact to form an asymmetric dimer. The monomeric structure shows bombykol bound in a large flask-shaped cavity with a very small opening. The residues most conserved between lepidopteran PBPs, including some highly conserved aromatic residues, form the hydrophobic surface of the cavity around the bound bombykol. The opening to the bombykol-binding pocket is small, and it is unclear from the x-ray structure how bombykol enters or leaves the binding pocket, as the hydroxyl end of bombykol is covered by a loop, stabilized by hydrogen bonding. that acts as a rigid lid. This lid. however, can be destabilized by a drop in pH, causing protonation of conserved histidine residues allowing release of the bound pheromone. Structural NMR studies show that BmPBP undergoes reversible conformational change on acidification between pH 6 and pH 4.9: and as expected, the more basic form generates better-dispersed NMR data, i.e., it is more structurally rigid, than the data from the acidified protein.[22] The BmPBP binds the pheromone only at neutral and basic pH. A. *polyphemus* PBP also only binds its pheromone above pH 5.6. There is evidence that the structural rearrangement of PBPs under acidic conditions may be more fundamental. The NMR studies of the BmPBP at pH 4.5 show a G-terminal helix occupying the pheromone-binding site.[23] Complementary reports from a hymenopteran (*Apis mellifera*—honeybee) OBP called ASP2, expressed in the yeast *Pichia* pastoris, found that ASP2 had cysteine residues identical to BmPBP and was dimeric at neutral pH.[24] The ASP2 protein bound a number of floral odorants. but this was reversed at pH 3 when the protein also became monomeric. The proposed mechanism is that the PBP binds the pheromone at neutral surface lymph pH. transports it across the aqueous sensilla lymph to the membrane-bound receptor. where lower pH at the membrane surface. or other local ionic conditions. cause the PBP structure to alter with concomitant release of the molecule that then elicits signal transduction.

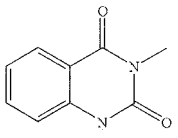
General Odorant-Binding Proteins

While many molecular genetic approaches to studying COBP proteins were reported, little has been achieved by chemistry-based studies. Current theories propose that these proteins bind either a wide range of semiochemicals

poorly or have a high affinity to one of a broad range of semiochemicals. This makes determination of ligands for study extremely problematic. So, work has generally focused on PBPs, where ligand identification (the sex pheromone) is simpler. A recombinant GOPB from the moth. *Manduca sexta*, could be photoaffinity labeled by the moth pheromone analogue [^{3}H]-(*E*,*Z*)-6,11-hexadecadienyl diazoacetate, but plant odors (3-3-hexen-1-01, geraniol, and limonene displaced it in competitive binding studies.[25] These same plant volatiles, however. were unable to displace the pheromone analogue when it was bound to its PBP. This suggests that the GOBP is tuned to a broad range of plant volatiles, although it is also possible that it binds highly selectively to a different semiochemical not used in the study. The GOBP also displayed similar properties to insect PBPs, as ligand binding was dependent on pH and salt concentration. and the protein structure was highly α-helical. In another study, a *D. melanogaster* mutant was created that lacked an antennal-specific gene containing six conserved cysteines named LUSH.[26] The nomenclature is derived from the mutant's attraction to abnormally high concentrations of ethanol. propanol. and butanol that repel wild-type flies. In low concentrations, these alcohols are attractive to both wild-type and mutant flies and are important semiochemicals in nature, as the flies feed on, and lay eggs in. fermenting plant material. where short-chain alcohols are present.

SEMIOCHEMICAL DEACTIVATION

After the olfactory receptor is activated, the semiochemical signal must be destroyed to prevent continued stimulation. Esterase, dehydrogenase. aldehyde oxidase, epoxidase, and glutathione-S-transferase activities have all been detected in the sensillum and could degrade the signal. A further example is found in the pale-brown chafer. *Phyllopertha diversa*, which uses 1,3-dimethyl-2,4-(1*H*,3*H*)-quinazolinedione **10** as its sex pheromone.



10

Degradative hydroxylation and dernethylation were observed. and a species-specific membrane-bound P450 system was found only in male antennae.[27] Signal degradation must be extremely fast, especially for insects locating odor plumes in flight. and it has been argued that enzymic methods are too slow to achieve this. An alternative model was suggested in A. *polyphemus*, where it is proposed that signal inactivation occurs by modification of the pheromone/PBP complex.[28] In this case, A. *polyphemus* PBP was found to exist in a reduced state with two disulfide bridges that bound the pheromone, [^{3}H]-(*E*,*Z*)-6,11-hexadecadienyl acetate, and oxidized in the presence of sensory hair material to a complex with three disulfide bonds. The concept is that oxidation of the pheromone/PBP coinplex occurs at the activated receptor, and the oxidized form traps the pheromone and prevents further stimulation. Subsequently, the complex is degraded enzymically.

CONCLUSION

The extraordinary ability of insect antennae to recognize particular odorants and blends of odorants in highly complex olfactory environments. through molecular recognition, has led to research into technologies to exploit this. Using live insects or excised antennae linked to electrodes, volatiles from a desired medium can be analyzed for specific signals. A mobile robot linked to a B. *mori* antenna was able to locate the organism's pheromone source.[29] Also. a company, Inscentine, is making efforts to detect food deterioration semiochemicals for quality control of supennarket foods.[30] In addition. fingerprint patterns using multiple antennae can be used to analyze anthropogenic signals, and American scientists are creating detectors for illegal drugs or explosives. This approach is vastly superior to other artificial nose technologies in that it relies on molecular recognition rather than simple physical properties. making it possible to analyze highly complex samples.

Siderophores

Robert C. Hider
Zu Dong Liu
King's College London, London, United Kingdom

INTRODUCTION

Siderophores are compounds produced by microorganisms for scavenging iron from the environment. They are low-molecular-weight compounds (500–1000 daltons) possessing a high affinity for iron(III) ($K_f > 10^{30}$), the biosynthesis of which is regulated by iron levels and the function of which is to supply iron to the cell. Because of these roles, siderophores are of interest to biomedical researchers who are working on treating anemia and helping recipients of blood transfusions. This article briefly describes the classification and chemical properties of siderophores, before outlining the research on siderophore transport and interactions with metals.

BACKGROUND

During the period 1949–1952. three different siderophores were isolated and identified as growth factors. namely. mycobactin 1, ferrichrome 2A and coprogen **3.** Snow, in a classic study, largely characterized mycobactin, correctly identifying its coordination groups and demonstrating that mycobactin possesses a high affinity for iron(III).[1,2] This seminal work was followed in 1960 by the discovery of the ferrioxamines 4.[3] A key observation concerning the mode of action of these growth factors was made by Garibaldi and Neilands in 1956,[4] when it was demonstrated that the production of ferrichrome A **2B** was enhanced by growing the organism *Ustilago sphaerogena* in a medium deficient in iron. This finding was subsequently confirmed for mycobactin and other hydroxamate siderophores. The first tricatechol siderophore. enterobactin ***5*** was independently isolated by Pollock and Neilands from *Salmonella typhimurium*[5] and O'Brien and Gibson from *Escherichia coli*.[6] The isolation and characterization of siderophores was greatly facilitated in recent years by the use of HPLC and mass spectrometry, thus, the number of well-characterized siderophores has risen to over 500. The majority of these molecules fall into ihe hydroxamate. catecholate. or hydroxycarboxylate classes and. despite considerable structural variation, chelate iron in a hexadentate fashion. In addition, there are some tetra-. tri-. and bidentate ligands that also function as siderophores.

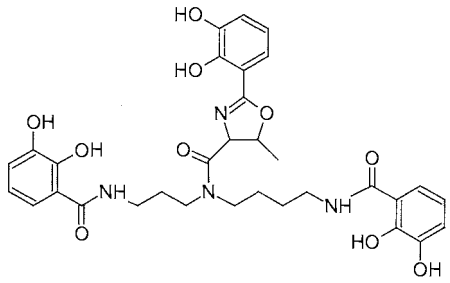
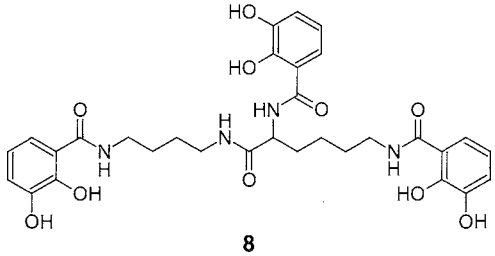
6

Iron is not a rare element, but its availability is limited by the inherently low solubility of iron(III); under aerobic conditions. the limiting concentration of ferric ions is close to 10^{-18} M at pH 7.0. For this reason. microorganisms evolved strategies for the solubilization and absorption of iron, iron being essentia! for all living processes. Siderophores are products of the vast majority of microorganisms, be they bacteria. or fungi. live in soil, fresh water. or the sea. For some microorganisms. a correlation was established between siderophore production and virulence.[7] The synthesis of all known siderophores is controlled by iron availability to the cell. Under conditions of high iron availability. the biosynthesis of siderophores and the corresponding transport proteins are repressed: however, as soon as the soluble iron levels drop below approximately 1 μM, siderophore synthesis and secretion are activated.



7



8

There is no evidence for siderophore-like molecules in multicellular animals, and with the exception of grasses and the related cereals, there is no evidence for the existence of siderophores in plants. Grasses secrete phytosiderophores,[8] for instance, mugeneic acid 6. into the soil under low iron conditions and. consequently. are able to thrive in alkaline soils.

Table 1 Hexadentate siderophores

Siderophore	*Organism*	*Structure*	Ligands
Enterobactin	*Escherichia coli*	**5**	Catechol
Agrobactin	*Agrobacterium tumefaciens*	7	Catechol and hydroxyphenyloxazoline
Protochelin	*Azotobacter*	8	Catechol
Desferrioxamine-B	*Nocardia*	**4**	Hydroxamate
Desferrioxamine-E	*Nocardia*	9	Hydroxamate
Ferrichrome	*Ustilago sphnerogena*	**2A. 2B**	Hydroxamate
Triacetylfusarine	*Fusarium roseum*	**10**	Hydroxamate
Coprogen	*Penicillium*	**3**	Hydroxamate
Exochelin	*Mycobacterium smegmatis*	**11**	Hydroxamate
Mycobactin	*Mycobacterium*	**1**	Hydroxamate and hydroxyphenyloxazoline
Pseudobactin	*Pseudomonas*	**12**	Catechol, hydroxamate, and a-hydroxycarboxylate
Aerobactin	*Klebsiella pneumonia*	**13**	Hydroxamate and a-hydroxycarboxylate
Rhizobactin	*Rhizobium meliloti*	**14**	α-Aminocarboxylate and a-hydroxycarboxylate
Mugineic acid	*Hordium vulgare*	6	α-Aminocarboxylate and α-hydroxycarboxylate
Rhizoferrin	*Rhizobus*	**15**	α-Hydroxycarboxylate

CLASSIFICATION OF SIDEROPHORES

The major chelating functions found in siderophores are catechol, hydroxyphenyloxazolone, hydroxamate, phenol, a-hydroxycarboxylic acid, α-aminocarboxylic acid, and thiazole (Tables 1 and 2).

Hexadentate Siderophores

The basic design of hexadentate siderophores is such that the bidentate functional units are placed at suitable distances in order to create a stable intermolecular complex. This spacing is achieved via cyclic and acyclic esters **(3, 5,** 10); by cyclic and acyclic α-amino acid amides (2. 12. 13) by cyclic and acyclic ω-amino acid amides (4. 9. 11), and by mixtures of ester and amide bonds (1). The structural framework can also be based on spermidine, related polyamines, and citrate. The advantage of a cyclic structure appears to be twofold. First, they are more resistant to attack by proteolytic enzymes. Second, due to a decreased entropy difference between the free ligand and the complex as compared with the acyclic analogue, they possess a higher affinity for iron(III) than their acyclic analogues. A wide range of siderophore–iron(III) complexes were subjected to x-ray diffraction studies.[9] As typified by ferrioxamine D 25, all possess a distorted octahedral coordination, the distortion being greater in complexes possessing non-equivalent ligands, for instance, mycobactin P. Although most hydroxamate siderophores possess three identical ligands. relatively few possess a threefold symmetry, examples being triacetylfusarine 10, desferrioxamine E 9, and enterobactin 5.

Table 2 Tetra-. tri-. and bidentate siderophores

Siderophore	*Organism*	*Structure*	Ligands
Rhodotorulic acid	*Rhodotorula*	**16**	Hydroxamate
Azotobactin	*Azotobacter vinelandii*	**17**	Catechol
Amonabactin	*Aeromonus hydrophilia*	**18**	Catechol
Uersiniophore	*Yersina enterocolitica*	**19**	Phenol. thiazole. and carboxylate
Desferrithiocin	*Streptomyces antibioticus*	**20**	Phenol, thiazole, and carboxylate
Chrysobactin	*Erwinia chrysanthemi*	**21**	Catechol
Aspergillic acid	*Aspergillus flavus*	**22**	Hydroxypyridinone
Pyridoxatin	*Acremonium*	**23A**	Hydroxypyridinone

Most hexadenlate hydroxamate and catecholate siderophores are stereochernically restricted to the ***cis*** isomers. The stereochemistry of a range of siderophore iron complexes was determined by x-ray and CD methods (Table 3).[10] These isomers are stable in aqueous solution. Although iron(III) phytosiderophore complexes have not beer, crystallized. structures of the analogous cobalt(III) complexes were determined. Again. a distorted octahedral geometry is observed but with two of the ligands being nitrogen atoms **26**.

Table 3 Stereochemistry of siderophore metallate(III) complexes

Siderophore	Structure	Stereochemistry
Ferrichrome	**2**	A-cis
Rhodotorulic acid	**16**	A-cis
Aerobactin	**13**	A
Mycobactin P	**1**	A-cis
N,N,N-triacetylfusarinine	**10**	A-cis (solid state); predominately A-cis (solution)
Ferrioxamine E	**9**	Racemate-cis
Ferrioxaniine B	**4**	Racemate-cis and *-trans*
Enterobactin	**5**	A-cis
Enantioenterobactin		***A-cis***
Agrobactin	**7**	A-cis

Tetradentate Siderophores

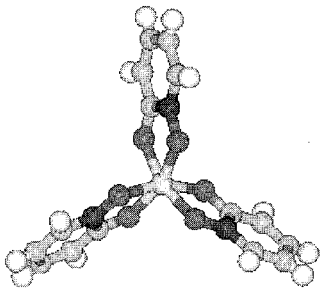
Tetradentate siderophores interact with iron(III) in three different manners, forming a 1:1 complex or a 3:2 complex (Fig. 1). The vacant coordination sites on the 1:1 complex can be occupied by a bidentate ligand forming a ternary complex. and thus, the coordination chemistry is more complex for this type of ligand when compared to the corresponding hexadentate molecule. The 3:2 complexes are generally favored at high concentrations ($>10^{-4}$ M), whereas the 1:1 complex will predominate at lower concentrations ($<10^{-6}$ M). For some tetradentate ligands, e.g., rhodotorulic acid **16**, the 1:1 complex is sterically forbidden, and only the 3:2 complex was characterized. With simple alkyl links between two bidentate functions. a chiral trihelical conformation is formed in the 3:2 complex.[111]

Tridentate Siderophores

As with tetradentate ligands, more than a single complex species can exist in aqueous solution, namely, the 1:1 and the 2:1 complexes. The 2:1 complex, for instance, ferrithiocin 27. will be favored under nonacid conditions and at high concentrations.

Bidentate Siderophores

The only well-characterized bidentate siderophores are based on the catechol or hydroxypyridin-2-one function. Some are probably intermediates in the synthesis of hexadentate siderophores. Nevertheless, they can be present at high concentrations in the immediate vicinity of secreting organisms and undoubtedly mobilize iron from insoluble ores. Bidentate catechols favor the 2:1 complex over the pH range 4.0–8.0, whereas the hydroxypyridinones 22 and 23 favor the 3:1 complex, which carries a net zero charge.[''''] The structure of the iron(III) complex of the parent 1-hydroxypyridin-2-one is a cis-distorted octahedron 28. By virtue of their neutrality and hydrophobicity, these ligands and their iron(III) complexes are toxic to some microorganisms and, as such, are recognized as antibiotics, e.g., aspergillic acid, 22.



28

CHEMICAL PROPERTIES

Thermodynamic Stability

Mexadentate ligands are likely to possess higher iron(III) stability constants than the corresponding tri- and bidentate ligands. due to entropy factors. However, the effect is

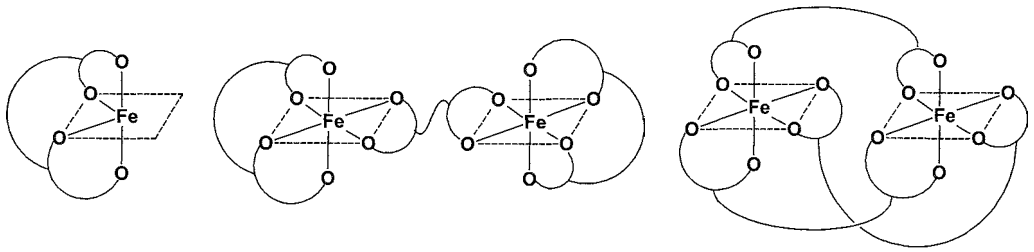


Fig. 1 Modes of iron(III) chelation by tetradentate ligands: A. 1:1 complex: B. 3:2 complex with ligands in nonequivalent positions; C. 3:2 complex with ligands in equivalent positions.

frequently suboptimal due to deviation from ideal stereochemistry and the associated influence on the enthalpy of the interaction. The smaller the conforinational space of the free ligand, the higher the stability of the complex: as the flexibility of the ligand and its corresponding iron complex decreases. so does the entropy difference. Thus, cyclic ligands typically possess a higher affinity than linear analogues and ligands with a good deal of preorganization in their structures, for instance, enterobactin 5, possesses particularly high affinities for iron(III). Irrespective of the framework. catechol and hydroxamate functions provide excellent iron(III) coordinating centers. as indicated in Table 4. The pM parameter provides a more reliable comparison of the affinity of the various ligands for iron(III) under physiological conditions.[''''] The pM is defined as pM = L o g $[Fe(H_2O)_6^{3+}]$, thus a large. positive value of pM corresponds to a low concentration of free Fe(III) and, hence, effective binding by the ligand. The most powerful ligands at pH 7.0 are the hexadentate triscatechols as exemplified by enterobactin (pM = 35); the hexadentate *tris*hydroxamates have appreciably lower pM values. typically 25–28. The substitution of a single hydroxamate function by a hydroxycarboxylate leads to a significant drop in the pM value, as indicated by aerobactin **13** (pM = 23). Due to the concentration dependence of the tri- and bidentate ligands, their pM values are lower than those of the hexadentate class (22–25). The amino carboxylate phytosiderophores also possess relatively low pM values. typically in the range of 17–18.

Kinetic Stability

As the affinity of hexadentate siderophores for iron(III) is so high, the dissociation rate of iron from the complex is extremely low at neutral pH values. Thus, the exchange of iron between two siderophores is also exceedingly slow. The halftime for exchange of ^{59}Fe between desferrioxamine-B 4 and ferrichrome-A **2B** (4 mM, pH 7.4) is over 200 h, although the rate can be increased by acidification of the medium. Tri- and bidentate siderophores are more kinetically labile. and this results from the relative ease of removing one of the ligands from the complex.[14] With bidentate ligands, even at pH 7.0. there will be a trace of the 2:1. ligand:iron complex, and thus, the reactions indicated in Eqs. 1 and 2 reach equilibrium rapidly. For this same reason, the iron complexes of bidentate hydroxamates, in contrast to those of hexadentate hydroxamates, undergo rapid racemization in aqueous solution.

$$L_3Fe \rightleftharpoons L + L_2Fe \quad (1)$$

$$L_2Fe + L' \rightleftharpoons L_2L'Fe \quad (2)$$

Thus, the role of bidentate siderophores may be to solubilize iron and, by virtue of their kinetic lability, then donate the iron to the more kinetically inert hexadentate siderophores. for specific delivery to the secreting organism.

Redox Activity of Catechol Ligands

In contrast to hydroxamates, catechols are susceptible oxidation. The oxidation products, semiquinone and quinone. are also able to coordinate cations. but generally with reduced affinity. Assignment of a formal oxidation state to the coordinated metal is not always unambiguous; as the orbitals involved are delocalized over the metal and at least one ring. The electronic structure of the iron chelate ring can be viewed in terms of three isoelectronic forms 29. These various complex types can be induced

Table 4

Siderophore	Ligands	Denticity	$K_{Fe^{3+}}$ (M^{-1})	pFe^{3+a}
Enterobactin **5**	Catechol	6	49	35
Protochelin **8**	Catechol	6	44.6	29

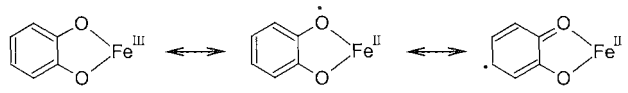
Aerobactin 13	Hydroxainate and α-hydroxycarboxylate	6	22.5	23
Mugineic acid 6	a-Aminocarboxylate	6	18	17
Rhizoferrin 14	a-Hydroxycarboxylate	6	25.3	20
Rhoclotrulic acid 16	Hydroxainate	4	31.2	22
Ainonabactin 18	Catechol	4	34	26
Desferrithiocin 20	Phenol. thiazole. and carboxylate	3	29.6	20
2,3-Dihydroxybenzoic acid	Caiechol	2	42	15
Aminochelin	Catechol	2	41.3	17.6
1-Hydroxy-4-methoxy-3-methyl-pyridin-2-one 23B	Hydroxypyridinone	2	28	16

[a]The pFe^{3+} is defined as log $[Fe^{3+}]$ when $[Fe^{(III)}]_{Total} = 1$ μM and $[Ligand]_{Total} = 10$ μM, pH 7.4.

electrochemically by the addition or removal of electrons via an electrode surface or a chemical agent. Thus, iron catechol complexes are capable of undergoing intramolecular electron transfer reactions. Such internal redox reactions are strongly influenced by pH, thus at pH 7.0. the iron(III) catechol complex is most stable, but under more acidic conditions: for instance, pH<5.0, the corresponding iron(II) semiquinone complex becomes the dominant species.[15]



29

TRANSPORT OF IRON–SIDEROPHORE COMPLEXES

Bacteria

A large proportion of bacterial siderophore uptake studies were centered on enteric bacteria as typified by E. *coli* and S. *typhimurium*. These bacteria possess a cell wall consisting of an outer membrane layer and a peptidoglycan layer. The former acts as a molecular sieve-type barrier, and the latter confers mechanical stability. Thus, the metabolically active cytoplasmic membrane is protected against bile salts and hydrolytic enzymes found in the mammalian gastrointestinal tract. The outer membrane consists of a lipid bilayer, rich in lipopolysaccharide and porins, which renders the outer membrane freely permeable toward small hydrophilic molecules. The region between the outer and cytoplasmic membranes is termed the periplasmic space and contains approximately 20% of the total cell water. As iron(III) siderophores possess molecular weights in excess of 600, their ability to permeate porin structures is low, and specific carrier proteins are necessary. Studies with mutants provided evidence for independent carriers being associated with iron–enterobactin, iron–hydroxamates. and iron–citrate (Fig. 2).[16]

The outer membrane proteins, for instance FecA. FepA, and FhuA, were recently characterized by x-ray crystallography and shown to be homologous structures with molecular weights in the region of 80.000.[17,18] The basic structure consists of a transmembrane β-barrel consisting of 22 transmembrane β-strands. The barrel is "corked" by a globular domain constructed from a mixed α-helical/β-strand framework. There is also an extracellular domain that covers the surface of the barrel and is fully exposed to the extracellular environment. The different proteins are selective for particular iron complexes. for instance, FepA (ferric-enterobactin permease) is selective for iron–enterobactin. The affinity of the outer membrane receptors for the iron–siderophore complexes is high (0.5–50 nM), and thus, they are able to scavenge the complexes from the environment. The complexes bind to the top of the β-barrel, and as a result of a conformation change in the cork domain, which is transmitted by the TonB protein. are translocated to the periplasmic space."'' Here they are picked up by binding proteins

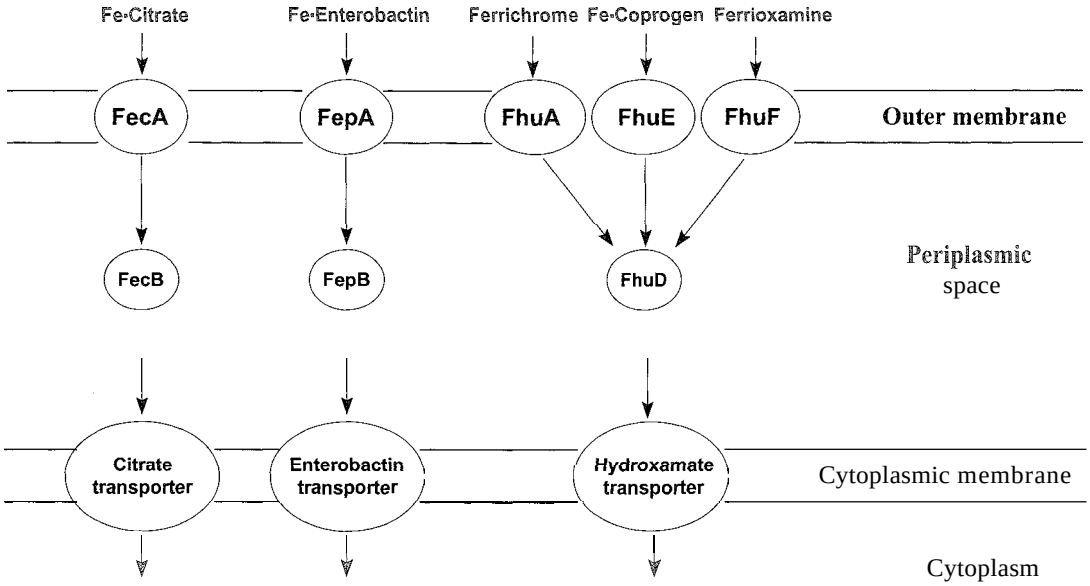


Fig. 2 Iron(III) transport system in E. coli and other enterobactriaceae. The donation of the iron–siderophore complex to the periplasrnic binding protein is facilitated by the cytoplasmic protein TonB. The cytoplasmic iron–siderophore transporters function via a typical ABC-type mechanism. which is driven by ATP hydrolysis.

with μM affinities. e.g., FepB, and translocated to the cytoplasmic membrane. where they are transported to the cytoplasin by ABC-type transporters.

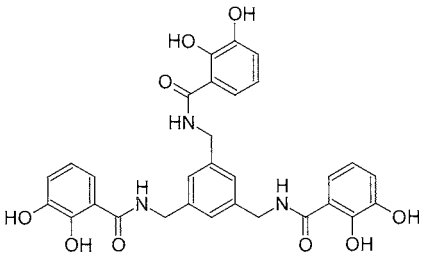
Inevitably. the field is dominated by studies centered on the two organisms. E. coli and *S. typhimurium*, although with the discovery of the plasmid-mediated aerobactin system,[20] other bacterial families are monitored, for instance, *Shigella flexneri*. Virulent strains of *Vibrio anguillarum* contain a plasmid that influences the efficiency of iron uptake by the organism. When grown under low iron conditions, these strains induce the synthesis of outer membrane proteins, in the 80,000 molecular weight range. In similar fashion. Vibrio *cholerae*. *Aeromonas salmonicida* (a fish pathogen), and *Agrobacterium tumefaciens* (a plant pathogen), all induce similar siderophore transport systems when grown under conditions of low iron availability. Many enteric bacteria possess transport systems for exogenous siderophores, for instance, E. coli possesses the Fhu complex of transporters even though it does not normally produce hydroxamate siderophores. This property. together with the ability to harbor plasmids for the synthesis and transport of siderophores, for instance. aerobactin. demonstrates the considerable evolutionary pressure experienced by bacteria to obtain iron from the environment.

Mycobactin species produce a range of siderophores, the water-soluble exochelins (for instance, exochelin MS **11**), mycobactin P **1** (a hydrophobic siderophore, which is not secreted from the organism), and the carboxymycobactins (which are also secreted) (Table 5). The carboxymycobactins are similar to mycobactin P, the only difference being the introduction of a ω-carboxyl function on the central lipid substituent. It is proposed that the exochelins and carboxymycobactins scavenge iron from the environment and donate it to mycobactin P. which acts as an intracellular ion store.[21,22]

Iron(III) complexes of hexadentate siderophores are kinetically and thermodynamically stable, which although being ideal for their scavenging roles. presents problems to the organism with respect to iron release. Redox processes were implicated in this mechanism, as the resulting iron(II) siderophore complexes are kinetically and thermodynamically much less stable than the corresponding iron(III) complexes. Furthermore, such a mechanism renders it possible to reutilize the siderophore and renders it unlikely for an organism to assimilate aluminum. another common tribasic element in the environment. Aluminum is not susceptible to a reductive release mechanism. The enzyme ferrisiderophore reductase is widely distributed. It was suggested that such a mechanism involving catecholate siderophores is not possible due to their extremely low redox potential (−750 mV). This is much lower than a typical intracellular reductant, NADH (−320 mV). As a consequence, the involvement of a siderophore esterase was proposed. However, there is no firm evidence for the existence of such an esterase, and such a mechanism would fail to explain how iron is released from the iron(III) complex of MECAM, a synthetic analogue of enterobactin 5. MECAM 30 can donate iron to *E.* coli and related microorganisms.[23] If the reduction process is carried out in the presence of a powerful iron(II) sink, for instance. protoporphyrin, then such a reduction is readily achievable under physiological conditions. as demonstrated by Byers and coworkers.[24]

Table 5 Microorganisms possessing multiple siderophores

Organism	Siderophores
Mycobactin smegmatis	Mycobactin P **I**, carboxymycobactin. and exochelin MS **11**
Ustilago	Ferrichrome **2A** and ferrichrome-A **2B**
Neurospora	Coprogen **3** and ferricrocin
Fusarium	Fusarine-c and nialonichrome
Aspergillus	Triacetylfusarine **10** and ferricrocin
Azotobacter vinelandii	Protochelin 8. aminochelin 24. and azotochelin **17**



30

Fungi

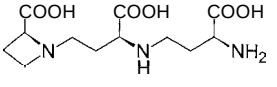
Fungi are eukaryotic organisms and possess a single cytoplasmic membrane. usually surrounded by a hyphal wall. This hyphal wall does not contain an integral lipid membrane. and thus. unlike enteric bacteria. the iron only has to permeate a single bilayer structure. Siderophores were isolated from many fungi classes. including Basidiomycetes (*Ustilago*), Ascomycetes (*Neurospora* and *Rhodotorula*), Zygomycetes (*Rhizopus*), and Deuteromycetes (*Penicillum*, *Aspergillus*, and *Fusarium*).[25] In general. fungi secrete siderophores into the environment. some are able to donate iron to the external surface of the membrane. whereas others are transported into the cytoplasm as an intact iron(III) complex. This latter process involves active transport and is dependent on the presence of membrane potential and ion gradients. Many fungi

secrete more than one siderophore (Table 5). The function of multiple siderophores is not clear. but their syntheses appear to be under independent control. Under different environmental conditions. the secretion of one or another of the siderophores will predominate. With some pairs. one will be a more potent scavenger for polymeric inorganic iron and will exchange iron prior to cellular uptake. Sorne siderophores are used as storage molecules for iron and do not rapidly donate iron once gaining entry to the cell. Iron is released from siderophores via specific ferrisiderophore reductases. *Neurospora crassa* produces coprogens and ferrichromes (Table 5), and whereas the fersichrome-type siderophores release their bound iron rapidly,[26] iron(III) coprogen is not rapidly reduced and remains largely unchanged in the cytoplasm, possibly acting as a storage form of iron. With *Fusarium roseum*, two different siderophore classes are produced: the fusarines and malonichrone. It is likely that the negatively charged malonichrome is a more efficient scavenger than the fusarines and, thus, is only induced under conditions of extreme iron scarcity. A similar phenomenon probably occurs with *Ustiligo*, which produces ferrichrome **2A** and the superior scavenger ferrichrome A **2B**.

Structure activity studies with the cyclic hexapeptide siderophores demonstrate that modification of the amino acid sequence in the cyclic peptide does not appreciably influence the ability of the resulting siderophore to transport iron. However, the nature of the hydroxamate acyl substituent has a major influence. the presence of one or more *trans* anhydromevalonic acid residues severely inhibits the process. Furthermore. the chiral nature of the iron complex has a dominant influence, the cyclic hexapeptide siderophore receptor with a marked preference for the Λ complex.[27]

Graminaceous Plants

Grasses, cereals, and rice secrete phytosiderophores into the soil when grown under iron-deficient conditions, for instance. alkaline soils. The iron–phytosiderophore complex is then transported via the root cells to the phloem,[28] where the iron is transferred to nicotianamine **31.** a molecule closely related to mugineic acid 6 and translocated to the rest of the plant tissues. Many phytosiderophores are hydroxylated, and this results in a lowering of the pK_a values of the amino functions and, hence, reduces the ability of protons to compete with the binding of iron.



31

Such trends have relevance to the ability of different cereals to grow in acidic soils. It is probably significant that barley and rye. which are relatively resistant to iron-induced chlarosis, produce highly hydroxylated phytosiderophores.[29]

INTERACTION OF SIDEROPHORES WITH METALS OTHER THAN IRON

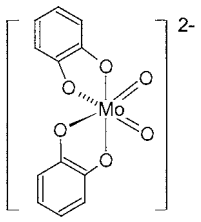
Aluminum and gallium form trivalent cations with similar radii to that of iron(III) and, therefore, possess high affinities for siderophores. Gallium is a scarce metal, and therefore. competition with iron in the biosphere in unlikely. In contrast, aluminum is plentiful, and although it binds less tightly to hydroxainate ligands than does iron(III), it possesses a similar affinity for catecholato ligands. The stability constants (β_3) of iron(III) and aluminum(III) for acetohydroxamic acid are 10^{28} and 10^{22} and for catechol are 10^{44} and 10^{46}, respectively. Thus, there is the possibility that aluminum could be absorbed by phenolate siderophores. However, its release from the siderophore, unlike iron, would not be facilitated by a reduction step. Thus, absorbed aluminum would tend to remain bound to the siderophore and not be available for protein coordination. For these reasons, it is unlikely that aluminum enters mammalian food chains via microorganisms. Some actinides, for instance, plutonium(IV), by virtue of possessing similar charge densities to that of iron(III), also possess high affinities for hydroxamate and catechol siderophores.

Three other metals. namely, copper. vanadium. and molybdenium, possess appreciable affinities for siderophores. It is possible that siderophores or siderophore-like molecules are involved in the microbial transport of these metals. Copper(II) forms stable complexes with hydroxamate siderophores (for instance, schizokinen, desferrioxamine B. and desferrithiocin) and catechol siderophores (for instance, enterobactin). However, copper(II), unlike iron(III), also possesses a high affinity for amino acids and small peptides, and this property renders it unlikely that copper uptake is dependent on siderophore-mediated transport.

Molybdenum VI

Molybdenum behaves differently than most metals that are essential for living processes, in that it exists predominantly in an anionic form in neutral aqueous solution. The reason for this difference is that the most stable valence state of molybdenum in aerobic aqueous solutions is six. Because the Mo(VI) cation possesses an extremely high charge density (radius = 0.73 A), it reacts with water,

forming the MoO_2^{2+} and MoO_4^{2-} species. The MoO_2^{2+} cation does not behave as a typical divalent cation insofar as it binds anions strongly and thus is more like a trivalent cation. The effective charge on the molybdenuin atom is 3.6^+, and therefore, the surface of the cation not occupied by oxygen atoms is similar to that of iron(III). Not surprisingly, therefore, molybdenum(VI) forms complexes with catechol 32, which possess a characteristic yellow color (λ_{max}=325 nm).



32

The nitrogen fixing organism *Azobacter vinelandii* was demonstrated to produce a range of molybdenum-binding catecholates, which also function as siderophores. for instance, azotochelin 17 and protochelin 8. The levels of molybdenum in culture medium have a dramatic influence on siderophore production (Fig. 3).[30] At high concentrations of molybdate, the production of the tetradentate siderophore **17** is reduced to zero and replaced by the hexadentate siderophore, protochelin 8. In the presence of high molybdate levels. the tetradentate molecule is an inefficient scavenger of iron(III) hydroxide due to the formation of a molybdenum complex. In contrast, the hexadentate siderophore is still able to scavenge iron, as one catechol function is free when the molecule binds molybdate. Thus, the frequently observed toxicity of high molybdate levels is likely to be a result of iron deficiency (Mo–Fe antagonism). However. this effect will be minimized in the presence of hexadentate catecholate siderophores. Other nitrogen fixing organisms, for instance, *Azospirillum lipoferum* and *Paracoccus denitrificans*, produce catechol siderophores and molybdenum accumulation was demonstrated to be dependent on the iron status of these organisms.

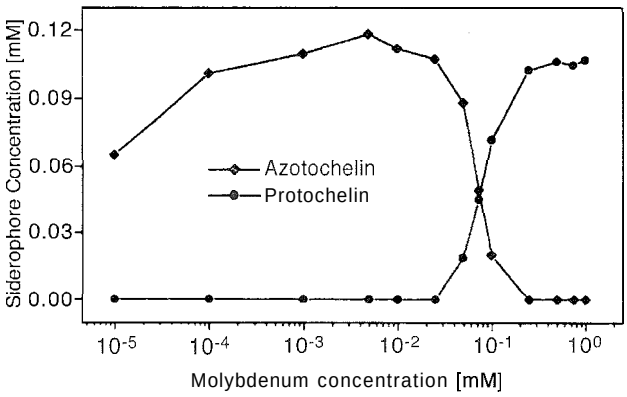


Fig. **3** Effect of rnolybdate on azotochelin 17 and protochelin 8 production by A *vinelandii* as determined by HPLC

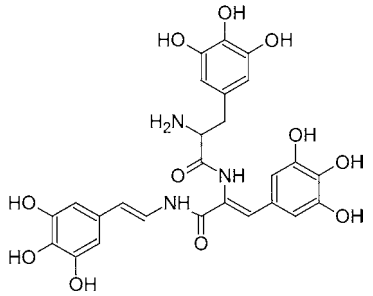
Vanadium ascidians (sea squirts), possess the ability to sequester and reduce vanadium in specialized blood cells termed vanadocytes. Vanadium is present in these cells at high concentrations, most probably in the simple mononuclear form $[V^{(III)}SO_4(H_20)_5]^+$. Tunichromes 33, which are produced by ascidians, possess a rigid backbone and, as a result. are unable to form stable tetradentate or hexadentate monomeric vanadium complexes: unlike enterbactin **5.** which binds V^{IV} avidly. As a result. it is more likely that tunichrome acts as a transient ligand and reductant of vanadium(V), which is accumulated by the organisms as the vanadate anion,[31] leading to its ultimate storage as V^{III} in vanadophoric granules of low pH.



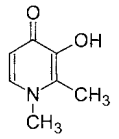
33

CLINICAL APPLICATION OF SIDEROPHORES AND ANALOGUES

Selective Iron Chelation

Currently, there is considerable demand for a highly specific chelator of iron. which is suitable for clinical administration to iron-overloaded patients. The most widely adopted method of treating β-thalassaemia, is regular blood transfusion. and this leads to iron overload. In 1962. Sephton Smith demonstrated that desferrioxamine **B** 4 given intramuscularly to iron-overloaded patients. increased the excretion of iron in the urine.[32] However, early experiences with this hydroxamate siderophore were disappointing, and it was not until regular bolus injections were introduced that any consistent success was obtained. Following this. administration of the drug by slow continuous infusion was introduced. and although unpleasant. the treatment is effective.[33] Desferrioxarnine is also used in the treatment of acute iron poisoning and for the removal of aluminum. Unfortunately, desferrioxamine is not orally active, and it has become increasingly important to identify a nontoxic orally active

iron chelator. A wide range of siderophores were investigated together with close synthetic analogues, for instance, **5,** 16, and **20**. In order to achieve good oral bioavailability, molecules with molecular weights <500 are required, and this excludes most of the hexadentate siderophores. However, the bidentate 3-hydroxypyridin-4-ones were demonstrated to be effective, and deferiprone **34** is now an approved medicine in Europe.[34]



34

Iron-Transport-Mediated Drug Delivery

Some natural antibiotics contain a siderophore structure, for instance, δ_1-albomycin **35,** which is produced by *Streptomyces subtropicus*. The linear tripeptide portion chelates Fe(III) and, thereby, is able to utilize the iron-transport system of a range of microorganisms. Subsequent to uptake, peptidases localized in the cytoplasmic membrane hydrolytically release the toxic thioribosyl moiety. In principle, this property can be used for selective drug delivery. Preliminary studies indicated that substantial modification of the siderophore framework can be tolerated by microbial iron-transport systems.[35,36] Surprisingly, simple modifications can be made to cephalosporin molecules, which endow them with the ability to interact with microorganism iron-transport mechanisms. Thus, simple incorporation of a catechol moiety, as in 36, endows this molecule with enhanced activity against *Pseudomonas aeruginosa* when compared with other cephalosporins.[37]

Simultaneous Binding of Cations and Anions

Bradley D. Smith
Joseph M. Mahoney
University of Notre Dame, Notre Dame, Indiana, U.S.A.

INTRODUCTION

Synthetic receptors for cations or anions have potential applications in many different chemical technologies, and a large number of receptor designs have been evaluated over the past three decades. Many of these synthetic receptors are uncharged molecules that operate in organic solvents. Under these conditions, the target salts may exist as associated ion pairs that can hinder the single-ion recognition process. Two strategies can be employed to simultaneously bind both ions of a target salt. The dual-receptor strategy uses a binary mixture of anion and cation receptors: alternatively, a single ditopic receptor can be designed with specific cation and anion binding sites. These salt-binding receptors can be organic or organometallic molecules. They are prototypes for more complicated self-assembly systems that may eventually be used as components in molecular machines.

IONS AND ION PAIRS

An important goal in supramolecular chemistry is to develop high-affinity synthetic receptors for specific target ions. Because the target ion is necessarily accompanied by a counterion. the recognition process can become complicated, because salts do not exist as free ions in most organic solvents, instead they are present as solvent-separated ion pairs, contact ion pairs. or aggregated contact ion pairs (Fig. 1).[1] Thus. for a receptor to associate with a target ion. it must compete with the counterion. Historically, this situation was avoided by using noncompeting counterions such as tetralkylammonium cations or tetrarylborate anions. However. in many real-life separation or sensing situations. the luxury of noncompeting counterions is not available, and ion pairing of the target ion with its counterion can lead to diminished receptor/ion association constants. For example, titration of the simple acetate receptor. *N*-octyl-*N*′-phenyl urea, in DMSO with tetrabutylammonium acetate leads to an association constant of $K_{acetate}$=310 M^{-1}. Repeating the titration experiment in the presence of one molar equivalent of sodium tetraphenylborate lowers $K_{acetate}$ to 90 M^{-1}.[2] In chis case. the sodium forms an ion pair with the acetate, which lowers the receptor1 acetate association constant. The associated sodium cation sterically hinders the receptor/acetate interaction. and it lowers the acetate's effective charge by a polarization effect or a shielding effect.

DUAL-RECEPTOR STRATEGY

One way to alleviate this counterion-induced inhibition of receptorlion binding is to use a dual-receptor strategy, that is. a binary mixture of anion and cation receptors.[3–6] Examples of dual-receptor strategies reported so far include mixtures of crown ether 1 and tripodal amide 2 to extract $CsNO_3$,[3] and a mixture of cation-binding calixarene **3** and anion-binding calixpyrrole 4 to bind butylammonium chloride (Chart 1).[4] A major advantage of the dual-receptor strategy is structural simplicity and the associated economic savings. Thus, dual-receptor systems should be useful for industrial solid/liquid extraction and membrane transport of salts.

DITOPIC RECEPTORS

An alternative to the dual-receptor strategy is to design a single ditopic salt receptor that simultaneously binds the cation and the anion.[7] A potential advantage gained by covalently linking the anion- and the cation-binding sites is the possibility of binding cooperativity. That is. the binding of the first ion to the receptor alters the receptor's affinity for the second ion. Positive cooperativity is when the presence of the first ion raises the receptor's affinity for the second ion, whereas negative cooperativity is the reverse. Many of the early ditopic salt receptors described in the literature have spatially separated cation and anion binding sites. so that the anion and the cation are not in contact with each other when they are bound to the receptor.[8–10] As a result; cooperative binding effects are expected to be small. One of the earliest ditopic salt receptors is Compound **5,** which has two crown ether rings to bind metal cations such as K^+ and a Lewis acidic UO_2^+ center to bind anions such as $H_2PO_4^-$.[8]

$$M^+ + A^- \rightleftharpoons M^+A^- \rightleftharpoons [M^+A^-]_n$$

Fig. 1 Salts can exist as free ions. ion pairs, or aggregated ion pairs in organic solvents. (Reprinted with permission from Ref. [9]. Copyright 2000. American Chemical Society.)

Positive cooperativity is produced when the binding of an ion alters the ditopic receptor structurally (induced fit) or electronically (receptor polarization) in a way that improves binding of the counterion. The induced-fit concept is particularly intriguing. because it is a central feature in the allosteric effect used by many enzymes and biological receptors. An early example of a flexible receptor that uses an induced-fit strategy to simultaneously bind K^+ and Cl^- is Compound 6.[11] The central polyamine linker wraps around a Cl^- ion, which brings the two crown ether rings together to bind a K^+. A more recent example is the dibenzo-30-crown-10 derivative **7**, which acts in reverse; that is. the receptor wraps around a K^+ ion and forms a preorganized binding site for diphenylphosphate anion.[12] A receptor that probably uses both induced-fit and polarization effects. is the tripodal *tris*(amido benzo-15-crown-5) 8. which simultaneously binds Na^+ and ReO_4^-.[13] In this case, the presence of the Na^+ improves the receptor's affinity for ReO_4^- by a factor of 20.

A variation of the receptor polarization effect is the binding strategy shown by schematic Complex 9. In this case; the binding of an ion to one face of an appropriately designed receptor polarizes (and perhaps preorganizes) the receptor so that it can bind the counterion to the opposite face with increased affinity. Two examples that use this strategy are the macrocyclic phosphine oxide 10, which can simultaneously bind a monoalkylammonium cation and Cl^-,[14] and the cyclopeptide **11**, which simultaneously binds an alkyltrimethylammonium cation and tosylate anion[15] (Chart 2).

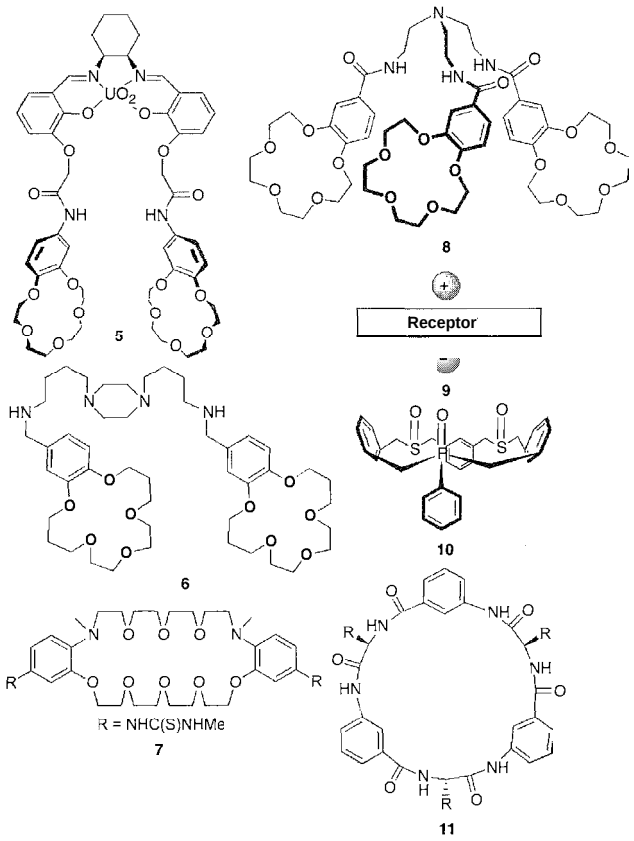

Chart 2 Ion-pair recognition using ditopic salt-binding hosts.

ORGANOMETALLIC DITOPIC RECEPTORS

A number of organometallic receptors were developed to take advantage of the anion coordination ability of inorganic atoms. A conceptually important early example is the crown boronate 12, which can simultaneoirsly bind cations such as K^+ and anions such as F^-. The F^- forms a strong coordinate bond with the boron, and the K^+ associates with the crown ether ring.[16] More recently. the simple monodentate ligand, 3-*t*-butylpyrazole, was found to act as a ditopic receptor for Zn(II) halide salts.[17] The system self-assembles to form Complex 13 with one halide anion coordinated to the zinc and the other hydrogen bonded to the pyrazole NH.

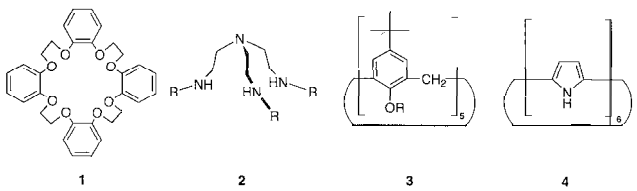

Chart 1 Compounds 1–4 used for dual-receptor recognition of cations and anions.

DITOPIC RECEPTORS THAT RECOGNIZE ASSOCIATED ION PAIRS

Another way to view salt binding is to accept the fact that salts prefer to form ion pairs and. thus. develop ditopic receptors that bind salts as associated ion pairs (Fig. 2). Two examples are the macrobicycles 14 and **15** with juxtaposed anion- and cation-binding sites. In the case of 14, the presence of Na' cation enhances Cl binding by about a factor of 10. An x-ray crystal structure of the **14**·NaCl complex shows that the salt is bound as a solvent-separated ion pair.[18] The Na^+ sits in the crown ring, and

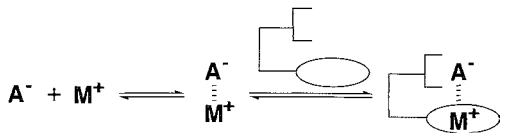

Fig. 2 Ion-pair recognition using ditopic salt-binding hosts. (Reprinted with pennission from Ref. [9] Copyright 2000, American Chemical Society.)

the C l is hydrogen bonded to the two receptor NH residues with a chloroform molecule sandwiched between the two ions. The positive binding cooperativity for this receptor is due to the anion interacting with the cation via the bridging chloroform. The binding cooperativity effect is greatly magnified in the case of the smaller macrobicycle **15**, because the NaCl salt is bound as a contact ion pair."'' This increases the Cl^- ion's electrostatic attraction to the receptor/Na^+ complex. In the case of **15**, the receptor/salt complexes are so stable that they can survive column chromatography using silica gel and weakly polar solvents (Chart 3).

CONCLUSION

In the future, salt-binding receptors are likely to be employed in various separation and sensing applications. It appears that both design strategies, dual-receptor mixtures, and single ditopic receptors, should be useful. Salt binding is a relatively new topic in supramolecular chemistry, and it is likely to be actively pursued in the near future. Hints of possible new research directions are provided by two examples from the recent literature. The first is the self-assembled pseudorotaxane **18**, which is prepared by simply mixing ion-pair **16** with macrocycle **17**[20] (Chart 3). This work and a related report[21] show how salts can be employed as "molecular glue" to assemble complex supramolecular structures. The second example. illustrated in schematic form in Fig. 3, is a permanently interlocked [2]rotaxane with salt-binding ability.[22] In polar DMSO solvent, the rotaxane is conformationally mobile, with the wheel rotating slowly around the axle. This motion is stopped by the presence

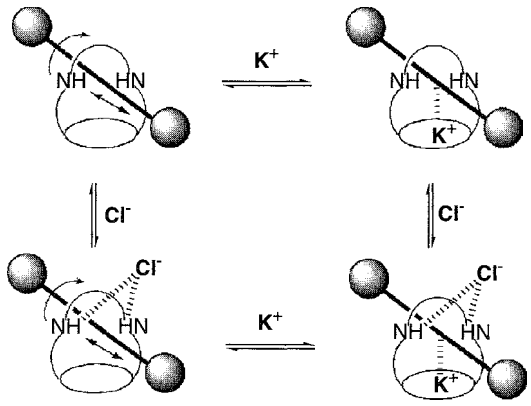

Fig. 3 In polar aprotic solvent, a salt-binding [2]rotaxane populates multiple axle/wheel orientations. Binding Cl^- does not measurably alter the rotaxane's dynamic properties, whereas binding K^+ freezes out a single coconformation (molecular brake). (Reprinted with permission from Ref. [22]. Copyright 2002, Elsevier Science.)

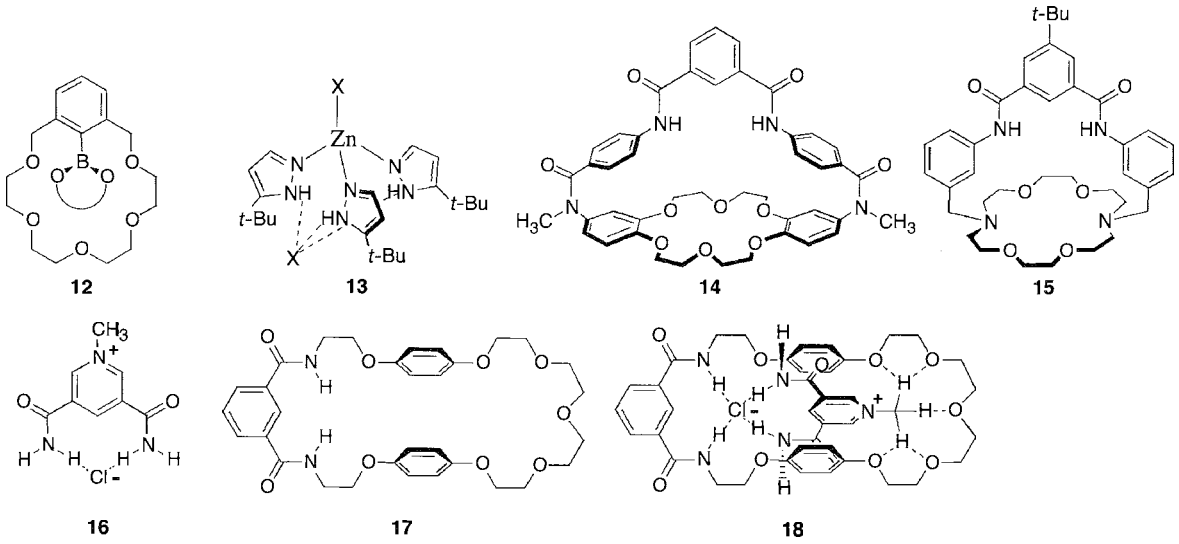

Chart 3 Compounds 12–15 are recent examples of salt receptors. Compounds 16–18 are examples of salt recognition as a method of supramolecular self-assembly.

of K^+ ions that bind to a crown ether unit in the wheel. Binding Cl^-, however, does not measurably alter the rotaxane's dynamic properties. This supramolecular system can be viewed as a potential molecular machine component. with dynamic properties that can be regulated by chemical effectors.

Simultaneous Binding of Cations and Neutral Molecules

Michaele J. Hardie
University of Leeds, Leeds, United Kingdom

INTRODUCTION

The simultaneous binding of cations and neutral molecules within a single host–guest system usually involves a metal as the cationic species, although there are a handful of examples involving an organic cation. Molecules that include metal cations but also bind neutral molecules may do so through a number of mechanisms, including coordinating the neutral guest with a metal cation that is bound within a host; binding the cation and neutral guest in different host receptor sites; and making the metal cation an intrinsic part of the molecular architecture of the host molecule (a metallohost). which includes the metal-templated self-assembly of a receptor molecule that subsequently binds a neutral molecule. Simple macrocyclic coordination complexes, such as metallated crown ethers, porphyrins, and phthalocyanines, where neutral ligands bind to the metal in axial positions, may also be regarded as simultaneous binding of cations and neutral molecules. These will not be considered here. Also, pseudomacrocyles, which are metal-assembled macrocycles analogous to traditional organic macrocycles. will not be presented. Metallohosts were extensively reviewed in recent years,[1–3] hence only a few representative recent examples will be highlighted herein. The main focus of this article will be host molecules that simultaneously bind cations and neutral molecules in different receptor sites.

TRADITIONAL HOST MOLECULES

Crown Ethers

The earliest reported examples of a system binding cations and neutral molecules simultaneously employed traditional inacrocyclic host molecules, such as calixarenes 1, which are described more fully below, and cyclic polyethers. Incorporating pyridyl or Schiff base groups into crown ethers leads to macrocycles with two possible binding modes.'" in the complex 2,6-pyrido[27]crown-9.$LiClO_4$.urea, both the Li^+ cation and urea are encapsulated within the crown ether cavity with interactions between them. In contrast, the Ni^{2+} complex of a Schiff-base-derived crown ether 2 has the Ni^{2+} immobilized at the Schiff-base binding sites in a square-planar geometry, with a water guest molecule bound in the macrocyclic cavity and showing no association with the metal. Uranyl cations UO_2^{2+} may likewise be bound within the Schiff-base cavity of Schiff-base-derived crown ether macrocycles, and the uranyl complex may be used as a metallohost that binds neutral molecules in the macrocyclic cavity through interactions with the uranyl cation and polyether oxygens. Guests include urea, formamide, dimethyl sulfoxide (DMSO) and (2-pyridylmethyl)urea.[4]

2

The crown ether tetrabenzo-24-crown-8 shows selective binding of large alkali metals Cs^+ and Rb^+ in preference to the smaller Na^+.[5] On complexation of Cs^+ or Rb^+, the tetrabenzo-24-crown-8 organizes into a cage-like structure about the cation, with the crown ether backbone resembling the seam of a tennis ball. The alternating benzo groups are thereby arranged to face one another, creating two molecular clefts. Neutral molecules may be bound within the clefts.[5,6] When crystallized from aqueous dioxane, host–guest species $[M(\text{tetrabenzo-24-crown-8})(\text{dioxane})_2(H_2O)_n]^+$, where $M=Cs^+$ or Rb^+, were isolated.[5] A dioxane molecule occupies one cleft of the assembly, while the other cleft contains dioxane and water guest molecules. Remarkably. a similar complex can be found with a traditionally "noncoordinating" sol-

DOI: 10.1081/E-ESMC 120012716

vent as the neutral guest molecule.[6] The complex [Cs(tetrabenzo-24-crown-8)(1,2-dichloroethane)$_2$](NO$_3$).(H$_2$O) forms a cage-like structure about the cation, with two molecular clefts. A molecule of 1,2-dichloroethane occupies each cleft, with weak bidentate coordination to the Cs^+ cation via the chlorine atoms, Fig. 1. Notably, the 1,2-dichloroethane molecules bind in preference to the nitrate anions, despite there being no obvious steric reason for this. It is postulated that this is more electronically favored, as some slightly electropositive hydrogen atoms of the 1,2-dichloroethane are within 3 A of an arene ring. Furthermore, the authors propose that the structure of the complex in the solid state persists in solution on the basis of liquid–liquid extraction studies. A distinguishing feature of these molecular clefts is that the cation is easily dissociated or replaced from the crown ether and may not be an intrinsic part of the host assembly, noting that the unmetallated acetonitrile complex of tetrabenzo-24-crown-8 has a similar conformation to acetonitrile molecules bound within the molecular clefts.'''

Calixarenes and Related Host Molecules

Traditional host molecules, the calix[*n*]arenes **1**, are cyclic phenols bridged by –CH_2- groups [$RC_6H_4(OR')CH_2]_n$ (*R'*=H in unsubstituted calixarene) that may adopt different conformations according to the value of *n* and the substituents *R* and R'. The most common calixarenes are *n*=4, and they have several important conformations, including the cone conformation or 1,3- alternate. In the cone conformation. calix[4]arenes possess a molecular cavity capable of binding cationic or neutral guest molecules, and additional host functionality can be imparted by the judicious use of functional groups at the lower rim of the calixarene. the R' position, allowing neutral and cationic guests to be bound simultaneously.

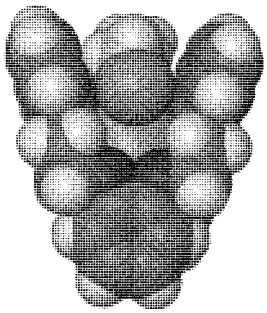

Fig. 1 Space-filling diagram showing the binding of 1,2-dichloroethane to Cs^+ within a molecular cleft from the crystal structure of [Cs(tetrabenzo-24-crown-8)(1,2-dichloroethane)$_2$](NO$_3$)·(H$_2$O). Minor disorder of the 1,2-dichloroethane was omitted. This diagram was adapted from Ref. [6].

An early example of this is found in *p-tert*-butylmethoxycalix[4]arene *R*=C(CH$_3$)$_3$, *R'*=CH$_3$, where in the solid state, a Na^+ cation is bound by the methoxy groups at the lower rim of the calixarene, and a molecule of toluene is contained within the molecular cavity.[7] The neutral calixarene *p-tert*-butyl-ethylacetatecalix[4]arene may likewise bind Wa or K^+ as a 1:1 complex. and this facilitates the transfer of these ions across a water-1,2-dichloroethane interface.[8] The crystal structure of the Na^+ complex reveals that the Na^+ is bound within the tetraethyl acetate cage of the calixarene lower rim in a distorted cube coordination geometry. Despite the presence of a tetraphenylborate anion. which is known to cooperatively occupy the upper-rim molecular cavity of alkali metal calixarene complexes, a molecule of ethanol is included as a loosely bound guest molecule. The smaller alkali metal ion Li^+ is bound by the lower-rim ether oxygens of the unsymmetrically substituted calixarene, 5,7-*bis*(9-fluorenyl)-25,26,27,28-tetrapropoxy calix[4]arene.[9] Although in a cone form, the metal-free calixarene has a pinched conformation that does not allow for the inclusion of guest molecules within the molecular cavity. Binding of the Li^+ cation opens the calixarene to a pseudo-C_{4v} cone conformation, however. simple complexation of a neutral guest molecule is not observed. Instead. the metallocalixarene dimerizes to give a capsule assembly that complexes a molecule of toluene (Fig. 2). The capsule is stabilized by interactions with the toluene and π–π interaction between fluorenyl groups of the different calixarenes.

Molecular capsules may likewise be formed by related host molecules such as calixresorcinarenes. Tetraethylresorcin[4]arene, for instance, forms a capsule-like assembly when cocrystallized with tetraethylammonium cations.[10] The capsule is composed of a neutral resorcin[4]arene and an anionic monodeprotonated resorcin[4]arene molecule hydrogen bonded in a head-to-head fashion via eight water molecules. In contrast to the capsule described above, the cationic guest molecule. tetraethylammonium, is bound within the capsule, and the neutral ethanol molecules form an interdigitating association with the lower rim of each tetraethylresorcin[4]arene molecule.

An entirely different mode of alkali metal cation inclusion is found in the complex {Cs(*p-tert*-butylcalix[4]-arene-H)(CH$_3$CN)}.[11] Notably, there is no lower-rim substitution, and the calixarene is monodeprotonated to form a phenoxide. The Cs^+ cation is not bound by the phenolic/phenoxide oxygen atoms but rather is contained within the molecular cavity of the calixarene. The Cs–C distances are sufficiently short to suggest a polyhapto coordination of the Cs^+ to the four aromatic rings of the calixarene, which is consistent with delocalization of the phenolate charge over the rings. The neutral CH$_3$CN guest molecule coordinates with the included Cs^+ cation.

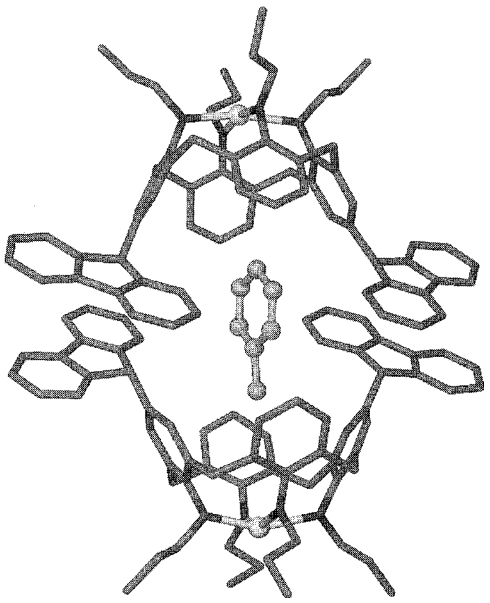

Fig. 2 X-ray structure of the molecular capsule formed by two Li[5,7-*bis*(9-fluorenyl)-25,26,27,28-tetrapropoxy calix[4]arene]$^+$ cations dimerizing around a toluene guest molecule. Diagram adapted from Ref. [9].

Transition or post-transition metals may be bound at the lower rim of a calixarene to form a metallocalixarene that may act as a metallohost. Calixarenes have a tendency to bind UO_2^{2+} cations, for example. A well-characterized recent example is the uranyl complex of (*p-tert*-butyltetrathiacalix[4]arene-H)$^{4-}$, where the $-CH_2-$ bridges of the calixarene are replaced by –S–. The UO_2^{2+} cation is bound by the four phenoxide O in a square plane. Further complexation of guest molecules is not precluded by one of the uranyl O atoms being directed into the molecular cavity from the lower rim of the calixarene, and a molecule of *N,N'*-dimethylformamide is found in the upper-rim cavity.[12] The zinc complex of the functionalized calix[6]arene hexa-*tert*-butyl-trimethoxy-tris{(1-methyl-2-imidazolyl)methoxylcalix[6]arene} has a cone conformation, with the Zn^{2+} cation coordinated by the tris(imidazolyl) groups on the lower rim and an aquo ligand.[13] The labile aquo ligand is constrained inside the molecular cavity of the calixarene and can be substituted for other neutral ligands. The hydrophobic calixarene cavity acts as a selective molecular funnel, allowing only guest molecules with complementary steric factors to be bound. Other examples of metallocalixarenes include a series of anionic {(*p-tert*-butylcalix[4]arene-4H)W≡CR}$^-$ hosts that host neutral solvent molecules."'' These may be linked into *bis*(calixarene) ditopic receptors by the binding of other metal cations such as Ag^+ and Mg^{2+}, which act as bridges.[14]

There are a number of other examples of similar ditopic metallocalixarenes binding neutral molecules. such as the crystalline complex $[NH_2(CH_3)_2][Mo_2(\eta^4\text{-}p\text{-}tert\text{-butylcalix[4]arene-}4H^+)_2]\cdot 4NC_5H_5$, where the anionic calixarenes are bridged by a $[Mo{\equiv}Mo]^{6+}$ moiety. and a molecule of pyridine is bound within each calix[4]arene molecular cavity.[15] An unusual example of a ditopic metallocalixarene that binds an organic cation and a neutral molecule is the anionic receptor {di-*p-tert*-butylcalix-[4]areneditungstate(III)}$^{2-}$, where a $[W{\equiv}W]^{6+}$ core is bridged by two fourfold deprotonated *p-tert*-butylcalix[4]-arene molecules.[16] The x-ray structure reveals that one calix[4]arene moiety binds a dimethylammonium countercation, while the other binds a molecule of acetonitrile. Interestingly. in the Mo analogue, both calix[4]arene molecular cavities are occupied by dimethplammoniurn cations. and acetonitrile molecules occupy holes within the molecular packing of the crystal structure.[16]

The water-soluble *p*-sulfonatocalix[*n*]arenes also form calixarene-based metallohosts that may bind transition or alkali metal cations at their upper-rim sulfonate groups. Representative examples of such chemistry are discussed below. The crystalline complex $Na_8\{Co(H_2O)_4(p\text{-sulfonatocalix[5]arene})_2\}.2CH_3C(O)N(CH_3)_2\cdot 37H_2O$[17] features two calix[5]arenes in cone conformations coordinating to a single $Co(H_2O)_4^{2+}$ moiety through sulfonate groups in a cis fashion. The calix[5]arenes are oriented in a face-to-face manner that results in the formation of a "supercavity." One *N,N'*-dimethylacetamide guest molecule is bound within each calix[5]arene host molecule. ^{1}H-NMR studies indicate that the coordination complex breaks up in solution. and there was no evidence of complexation of the *N,N'*-dimethylacetamide guest by the calix[5]arene. This is in direct contrast to the related Ni(II) complex $Na_8\{Ni(H_2O)_4(p\text{-sulfonatocalix[5]arene})_2\}.2NC_5H_5\cdot 38H_2O$, which in solution exists as a fluxional coordination complex with intracavity complexation of the pyridine guest molecules.[17] The complex $\{[Sc_2(OH)_2(H_2O)_8][Sc(H_2O)_4]_2[p\text{-sulfonatocalix[4]arene-H}]_2\text{-}([18]\text{crown-6})\}.16H_2O$ features a two-dimensional (2-D) coordination polymer formed through bridging coordinate interactions between $[Sc(H_2O)_4]^{3+}$ and lower-rim phenolate calix[4]arene oxygen atoms, and $[Sc_2(OH)_2(H_2O)_8]^{4+}$ and upper-rim sulfonate groups.[18] The neutral host molecule 18-crown-6 acts as a guest molecule in this structure. being bound within calix[4]arene capsule-like dimers in a similar manner to the binding of toluene by 5.7-*bis*(9-fluorenyl)-25,26,27,28-tetrapropoxy calix[4]arene that was discussed above.

Calixarenes may also be linked through covalent interactions to form ditopic receptors, such as in the symmetric linking of two *p-tert*-butylcalix[4]arene molecules via ethylene linkages to form a calix[4]tube. The calix[4]tube shows remarkable selectivity toward K^+ cations.[19] with K^+ bound within the central ethylether cage of the calix[4]tube. Molecular mechanics calculations suggest that the uptake of K^+ cations requires an

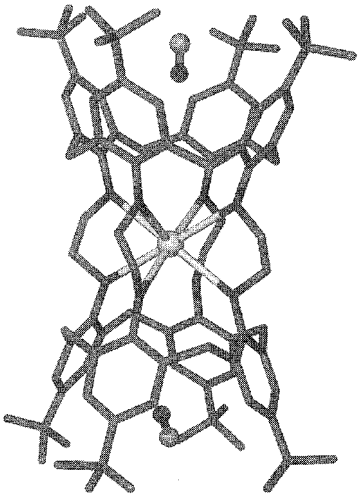

Fig. 3 X-ray structure of a calix[4]tube, with K^+ bound in the ethylether cage and ethanol guest molecules within the calixarene molecular cavities. Diagram adapted from Ref. [19].

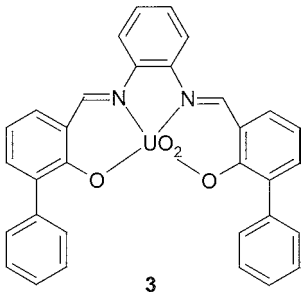
initial complexation of the K^+ within the calix[4]arene cavity, with subsequent channel transportation to the ethyleiher cage. A crystalline species $\{K(calix[4]tube)\}^+ \cdot I^- \cdot 3CHCl_3 \cdot 4CH_3OH \cdot H_2O$ was isolated and structurally characterized with the host–guest species shown in Fig. 3. The K^+ cation is 8-coordinate with a flattened cube geometry, and each calix[4]arene receptor binds one molecule of ethanol.

Another family of calixarene-based ditopic receptors are the 1,3-calix[4]arene-*bis*(crown ethers). where the calixarene is locked into the 1,3-alternate conformation, and substrate binding normally occurs at the crown ether loops. These may form mononuclear or dinuclear complexes with alkali inetal cations, or may bind neutral guest molecules. The unsymmetrical 1.3-alternate calix[4]arene-1,3-crown-6;2,4-(1,2-phenylene)-crown-6 forms a 1:1 complex with Cs^+. The crystal structure shows that the cation is bound only within the adapted phenylene-crown-6 loop, and a molecule of acetonitrile is bound within the unmodified crown-ether loop.[20]

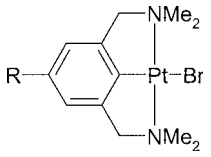
OTHER METALLOHOSTS

As described above. metallocalixarenes and metal-crown-ether complexes may act as host systems for neutral guest molecules. Many other types of coordination complexes may also act as host molecules, either through the formation of molecular cavities within the complex that may bind neutral molecules, or molecular clefts, where vacant coordination sites on the metal cation may be employed to bind neutral molecules. the latter termed metalloclefts. Recent examples of such chemistry are discussed below.

The structured binding sites of metalloclefts mean that they are often highly selective hosts. An example is the salophen-uranyl-based metallocleft **3,** which complexes neutral molecules. provided that the two phenyl groups of the host are parallel to one another. The salophen-uranyl unit may be employed as a catalyst for Michael additions, and the high steric requirements of the metallocleft of **3** result in it acting as a highly selective supramolecular catalyst.[21] Metalloclefts of Type 4 selectively bind SO_2 molecules and may be incorporated into dendritic materials that show catalytic activity.[22]



3



4

Self-assembly processes are employed to link molecules together to create molecular hosts. Metal-templated self-assembly was used to create supramolecular systems, where neutral molecules are bound by the metal complex that acts as a metallohost, however, without direct interactions between the metal cation and guest molecule. unlike in the metalloclefts discussed above. The molecular recognition or receptor sites can be intrinsic parts of the molecular building biock, or the receptor site can be created within the supermolecule.[2,3] An example of the former situation is seen with a 2.2'-bipyridine-substituted calix[5]arene.[23] Two calix[5]arenes self-assemble around an Ag^+-cation to bring the two molecular cavities into close proximity. The Ag^+-*bis*(calix[5]arene) is capable of binding large neutral guest molecules. and an intracavity 1:1 complex with fullerene-C_{60} was characterized by nuclear magnetic resonance (NMR) and electrospray ionization mass spectrometry (ESIMS). Binding of the larger fullerene-C_{70} was likewise demonstrated by ESIMS.[23]

Complexes that are capable of binding neutral molecules but where the molecular building blocks have no intrinsic binding properties may be constructed through similar self-assembly processes.[3] An example is the ligand 5. where binding of transition metal cations via the

alcohol and deprotonated carboxylic acid groups results in a water-soluble host with a pre-organized cavity, which binds hydrophobic guest molecules such as naphthalene.[24] The spiro-bridged bis-phenanthroline ligand **6** forms a self-assembled cyclic tetranuclear complex $[Cu_4\mathbf{6}_4]^{4+}$ with Cu(I).[25] The bis-phenanthroline ligands are arranged in a face-to-face arsangement in solution and in the solid state. effectively forming a molecular cavity. In ^{1}H-NMR experiments, anthracene guest molecules were demonstrated to be bound within the tetranuclear complex, and a 1:1 host–guest complex was formed in solution. Similarly, self-assembly processes result in the formation of a hexahedral coordination cage $[(NH_2CH_2CH_2NH_2)Pd]_{15}\mathbf{7}_6^{30+}$, a molecular capsule. The hexahedron has two open sites where guest molecules may enter or exit: encapsulating two molecules of CBr_4.[26] Related coordination cages may be employed as nanoscale reaction vessels, leading, for instance. to stereoselective reactions. An example is the quantitative formation of the *syn* dimer of acenaphthylene in a [2+2] photodimerization of guest acenaphthylene bound within the octahedral coordination cage $[(NH_2CH_2CH_2NH_2)Pd]_6\mathbf{8}_4^{12+}$.[27] In many cases, the manner of metal-cation-directed self-assembly of a metallohost is dependent on neutral guest molecules present during the self-assembly processes. Such templating effects are particularly predominant in coordination polymers. Discrete metallohelicates also provide some recent examples of this effect. For instance, triple helicates of stoichiometry M_2L_3 formed by bridging *bis*-bidentate ligands and octahedral metals may form helical or *meso* structures. When H_2L is the *bis*-hydroxypyridinone ligand 9, $[M_2L_3]$ complexes (M=Al, Ga) may form as either a *meso* or a helicate structure, where the helicate structure is stabilized by the incorporation of a guest water or DMSO. Furthermore, on addition of guest molecules in solution, a *meso*-helicate equilibrium is established, indicating that the structures are interconvertible.[28]

FRAMEWORK MATERIALS

Negatively charged solid-state framework materials may show inclusion behavior where both countercations and neutral molecules are included. The most obvious example is the zeolites and related materials, however, a discussion of the inclusion characteristics of these materials is beyond the scope of this article. A relatively new field where such inclusion behavior may be observed is based on coordination polymers. Most coordination polymers are cationic or neutral, however one exception is

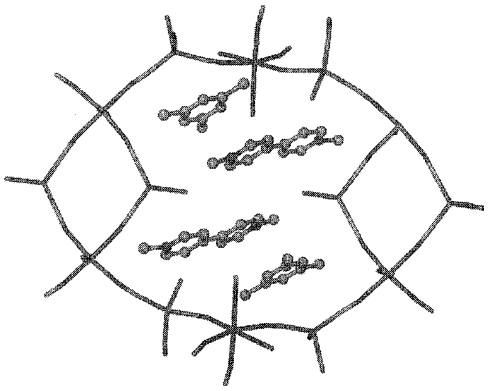

Fig. 4 Neutral mesitylene and cationic 1,1′-dimethyl-4,4′-bipyridicium $[MV]^{2+}$ guest molecules contained within a $[Cd_3(CN)_6Cl_2]^{2-}$ framework—from the x-ray structure of $[MV]^{2+}[Cd_3(CN)_6Cl_2]^{2-}.C_6H_3(CH_3)_3$. Diagram adapted from Ref. [29].

the series of mineralomimetic structures formed by cadmium cyanide derivatives, where the framework is anionic. In these cases, clathrate complexes with the simultaneous inclusion of cationic and neutral molecules may result. An interesting recent example is the clathrate complex $[MV]^{2+}[Cd_3(CN)_6Cl_2]^{2-}.C_6H_3(CH_3)_3$, where MV^{2+} is methylviolopen (1,1′-dimethyl-4,4′-bipyridinium).[29] The $[Cd_3(CN)_6Cl_2]^{2-}$ host framework has bridging cyanide ligands and terminal chlorides with an overall infinite three-dimensional structure. Cavities within the framework structure are occupied by methylviologen dications and mesitylene molecules that form a MV^{2+}-mesitylene charge-transfer complex. The crystal structure of $[MV]^{2+}[Cd_3(CN)_6Cl_2]^{2-}.C_6H_3(CH_3)_3$ reveals that the MV^{2+} acceptor and mesitylene donor molecules stack in a near coplanar manner and are very close, with an interspacing of 3.30(1) Å, (Fig. 4). Similar MV^{2+}-aromatic donor charge-transfer complexes are found in related polycyano–polycadmate clathrate complexes, with ethylbenzene, anisole, phenol: cresol, aniline or pyrrole in place of mesitylene.[29]

CONCLUSION

The simultaneous binding of cations and neutral molecules can be achieved by different types of molecular hosts or assemblies. Traditional host molecules such as crown ethers and calixarenes can complex both a cation and neutral molecule within different receptor sites. Metallohosts, where a metal cation is an intrinsic part of the host assembly, can complex neutral molecules within molecular clefts or capsule arrangements. Negatively charged framework materials such as mineralomimetic metal cyanide polymers may feature cavities that simultaneously contain both cations and neutral molecules.

Soft and Smart Materials

Dmitriy V. Soldatov
National Research Council Canada, Ottawa, Ontario, Canada

INTRODUCTION

The term "soft materials" refers to a large group of bulk materials where the inorganic, organic. or composite components link weakly through van der Waals forces, hydrogen bonding, additional coordination, or other secondary interactions. The term "smart materials" is attributed to materials that possess at least two functions: to sense an external signal ("sensor function") and to respond to that signal with a useful response ("actuator function"). An intrinsic feature of soft and smart materials is their resemblance to living systems, such that the former models supramolecular organization inherent in biological material, whereas the latter can mimic important functions in living organisms. Soft supramolecular materials form the basis for the rational design of a new generation of smart materials.

SOFT SUPRAMOLECULAR MATERIALS

The range of soft supramolecular materials embraces a variety of crystalline supramolecular compounds;[1] organic–inorganic nanocomposites;[2] partially crystalline or glassy low-dimensional organic polymers;[3] materials formed by nanoparticles and self-assembled supramolecular layers;[*] and liquid-like systems such as liquid clathrates, liquid crystals, and gels.[*] All of these materials exhibit supramolecular organization of varying complexities, with a prominent hierarchy of covalent, specific, and weak nonspecific interactions among their components. An example of soft supramolecular materials of practical interest are the naturally occurring clathrate hydrates. a huge reservoir of hydrocarbon fuel deposited in the world's permafrost regions and offshore on the continental margins. The water molecule, a species containing two covalent bonds, forms a host hydrate framework linking water molecules to each other by hydrogen bonds. while guest hydrocarbon molecules are retained in the cavities of the framework due to van der Waals forces.

Since the structures of the first materials having supramolecular organization were identified by Powell half a century ago,[6] extensive efforts produced entire generations of inclusion compounds. micro- and mesoporous sorbents, coordination polymers, and other supramolecular materials.[7–9] Clathrate chemistry provided a historical breakthrough in the intentional production of thousands of soft supramolecular materials and in a comprehensive understanding of their natures, structures, and properties.[10] The best-known classes of such materials include Hofmann-type clathrates; Werner clathrates; clathrate hydrates; inclusion compounds of urea, thiourea, and selenourea; cyclodextrins; calixarenes; gossypol; hexahosts: hydroquinone; phenol and Dianin's compounds; graphite intercalates; natural and pillared clays; and others. Such studies contributed to the birth of supramolecular chemistry, with relevance to a new understanding of the world of materials that was emphasized with a Nobel Prize.[11]

The general principle for building all soft materials is the bulk supramolecular assembly or aggregation of building units into a regular structure, with strong bonding within building units and weaker bonding between them. The nature of the building units may vary from simple molecules to nanoparticles, and the forces linking the units may vary from coordinative to van der Waals. On the one hand, weaker bonding among the building units allows for the variation of the units within the same type of material and, on the other hand, makes soft supramolecular materials sensitive to external conditions and leads them to have a propensity for structural or conformational changes, a property characteristic of biologically active materials. Therefore, the most attractive features of soft supramolecular materials, from a practical point of view, are their wide variability, easy conversion from one structure to another, and active response to external stimuli."

The variability of soft supramolecular materials makes it possible to modify each into a family of analogs, where a sought property will change by small steps over a wide range. An illustration of this is given by Werner complexes—the first metal complexes utilized for creating supramolecular materials in the 1950s and 1960s.[12,13] About 10 different metals (M), 15 anionic groups (X), and >100 organic ligands (A) were incorporated successfully

[*] Note that a number of supramolecular materials of practical importance today, such as zeolite inclusion compounds. microporous silicas. and most 3D coordination polymers. do not satisfy one or more of the listed conditions.

into this host of general formula $[MA_4X_2]$ to give hundreds of new host receptors, each able to include a variety of guest components. Detailed studies made it evident that for every guest. a characteristic host receptor specifically selective toward the particular guest, could be found. Shown in Table 1 experimental data. a few entries of many such available, strongly support the above statement.''']

The variability of soft supramolecular materials also provides a basis for their rational design. Although crystal structure prediction is a difficult problem, some crystal engineering approaches, such as Etter's rules[14] and the concept of the supramolecular synthon,[15] were successfully applied. A fascinating example of intentional design by the systematic variation of a component is given by the guanidinium disulfonates.[16] The sulfonates in the pillars (Fig. la) form a two-dimensional hydrogen-bonded network with guanidinium cations (Fig. lb), the pillared interlayer space being available for the hydrophobic inclusion of guest aromatics (Fig. lc). A library of pillars controlling the interlayer space from 3–17 Å with ~1 Å increments provides a diverse set of soft organic frameworks with systematically adjustable pore characteristics.

The existence of several energetically similar forms for the same compound is another typical feature of soft supramolecular materials. This property is a result of the weak linkage between building units and the variety of ways the units can assemble into a structure. A small change in external conditions can lead to another thermodynamically stable form, or. a little change in preparative conditions can lead to another kinetically stable product. The problem may show as polymorphism for forms having the same (polymorphs) overall composition, or pseudopolymorphism. where the components are present in different proportions. or as so-called supramolecular isomerism[18] for forms having the same composition of the host framework. Water exemplifies such a structural diversity. giving rise to dozens of ice and hydrate frameworks, each appearing under specific conditions of temperature and pressure with different guest types and transforming into each other as conditions change.[19,20]

The ability of soft supramolecular materials to respond to changing external conditions with dramatic structural reorganization reveals tremendous potential for their applications. Liquid crystals were utilized extensively in liquid-crystal displays and thermometers, optical imaging, and recording. Evidence for a growing practical interest in soft supramolecular materials is provided by the rapid evolution in design of microporous metal–organic frameworks. Three generations of frameworks were distinguished:''' 1) ''unstable to the loss of included guest'': 2) ''stable frameworks, reversibly losing and readsorbing guest species without undergoing a change in phase or morphology''; and 3) ''dynamic structures that change their frameworks responding to external stimuli.'' This last type of ''third generation,'' or ''dynamic.'' frameworks is also referred to. by other authors, as ''soft''[17] or ''flexible''[22] frameworks. In the context of a general tendency for materials science to move toward innovation and design,''' the growing interest in soft supramolecular materials can be seen in the concepts of functional materials and smart materials.

FUNCTIONAL AND SMART MATERIALS

Functional materials are major output targets of contemporary supramolecular design. Functional materials possess a certain designed functionality, making possible their implementation as elements in specific processes. Molecular magnets,[24] catalysts,[25] molecular sieves and chemical sensors,[26] materials displaying useful optical and conductivity effects.'''' ion-exchange materials,~''' materials switchable on molecular level through

coordination.'''' isomerization,[30] and other reversible in situ changes[22] are only a few examples of supramolecular materials that may be qualified as being functional.

Smart materials are functional materials that, according to essential definition,'''' function as both sensors and actuators. In other words, smart materials must possess at least two important functions inherent to living organisms: to sense an external signal (sensor function) and to respond to that signal with a useful response (actuator function). The first generation of smart materials comprises mainly covalently bonded materials exhibiting useful physical properties: ferroelectrics, piezoelectrics. electrostrictors. relaxor ferroelectrics. magnetostrictive actuators. shape-memory metals. and others.[31]

An example of a smart material is one developed by Toyota.[32] The multilayer piezoelectric ceramic inside an automobile shock absorber has about five layers for sensing road vibrations. The multilayer stacks positioned near each wheel of the auto also have about 100 layers that act as the actuator, all part of the same ceramic. After analyzing the vibrational signals, a voltage is fed back to the actuator stack, and a response occurs by pushing on the hydraulic system of the auto to cancel the vibration.

Soft supramolecular materials. with their high sensitivities to environmental conditions and easy responses to environmental changes. thus possess the qualities that make their implication as smart materials a rnatter of an appropriate engineering solution. An essentially endless variability of soft supramolecular materials, arising from the vast variability of their organic and inorganic components and multitude of ways that these components can be assembled to form a 3D structure, allows that it should be possible to create a proper material for any particular task and provides an area where the rational design of such materials can be foreseen. The above reasons provide convincing evidence that progress in the chemistry of soft supramolecular materials predestines the appearance of a new generation of smart materials.

Examples of soft supramolecular materials that are ''smart'' as they interact physicaily with the environment are available.[27,33] More complicated are systems in which the interaciion involves a chemical process.[28,29] A further advantage of soft materials, though, is that they allow even more complex process schemes to be organized. as exemplified by one-way cycles.[34,35]

A one-way cycle involving dense (α-form) and microporous (0-form) polymorphs of a host compound, and an inclusion form, is shown in Fig. 2: Step 1—The α-form converts into the inciusion form in an atmosphere of a suitable guest template; Step 2—The inclusion form converts into the empty β-form by means of guest template removal: this process is driven thermodynamically and is reversible; Step 3—The β form. which exists for kinetic reasons, collapses into the more stable α-form upon applying certain conditions. an irreversible step. Mainly because of the last stage. the complete cycle α form $\rightarrow$ inclusion form $\rightarrow \beta$ form $\rightarrow \alpha$ form may be run only in one direction.

Smart sorbents are a vivid application of one-way cycles; such a sorbent was recently developed on a basis of a copper complex.[22,36] It is the microporosity of the material that arises or disappears as a response to external stimuli. The a-form of the complex is not active as a sorbent with respect to many guest sorbates (e.g., xenon, methane. propane). Consecutive application of a helium flow containing a guest template and then a flow without the guest template (Steps I and 2 in Fig. 2. respectively) transforms the α-form into an empty β-form that acts as a

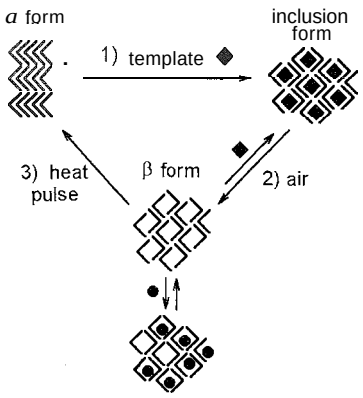

Fig. 2 One-way cycle: the phase interconversion scheme: 1) Guest template (diamonds) converts α-form into inclusion form: 2) ternplate removal gives the empty β-form that can work as a sorbent by including other guests (circles): and *3)* a heat pulse induces collapse of the empty β-form back to the u-form.

versatile sorbent with a pore diameter of —6 A. The application of a short-term heat pulse or appropriate catalyst returns the system to the "inactive" α-form. All of the processes proceed in situ, quantitatively, do not include any solvents, and may be controlled according to the degree of switching by an operator. The system is ‘‘smart,'' not only instantly responding to certain conditions but also recognizing the sequence under which the conditions change.

CONCLUSION

Soft supraniolecular materials are an extensive class combining organic, inorganic, and composite materials, where nonvalent interactions constitute at least one of several levels of bonding among the components. Recently, these materials attracted a great deal of attention because of their variability and mimicry of living matter. These properties predestine the appearance of soft supramolecular material libraries in the near future that exhibit useful functions, including those of living organisms. The ultimate targets in the engineering of new soft supramolecular materials start with functional materials for sensors, conductors, magnets. and catalysts. Smart materials are at the next level of complexity. as these materials combine the abilities of sensing external signals and responding to the signals with useful responses. Further levels may include materials with a learning or tuning function, that is. materials that become smarter with age. and materials able to choose and make correct decisions where multiple choices exist.

Solid-State Nuclear Magnetic Resonance Spectroscopy

John A. Ripmeester
Christopher I. Ratcliffe
National Research Council Canada, Ottawa, Ontario, Canada

INTRODUCTION

Nuclear magnetic resonance (NMR) spectroscopy evolved into a major technique for the characterization of materials in just about all areas of chemistry. Most researchers and students will be familiar with solution applications, where chemical shifts and J couplings of spin $^1/_2$ nuclei can be used for simple spectral analysis of reaction products as well as the complex multidimensional techniques used to determine the structure and conformation of molecules as complex as proteins. A fundamental strength of NMR spectroscopy is that there is one-to-one correspondence between a chemically distinct nucleus and a chemically shifted line in the resonance spectrum: thus, spectra are quantitative fingerprints of the material under investigation.

DIFFERENCES BETWEEN SOLIDS AND LIQUIDS

In the solid state, WMR spectroscopy differs from solution spectroscopy in a number of ways. The main one is that in solution spectroscopy, all anisotropic interactions are averaged by rapid molecular motion, so that usually only the two aforementioned interactions, chemical shifts and J couplings. survive at their isotropic averages. However, because in the solid state molecular motion is seldom isotropic, all spin interactions behave as second-rank tensors. This means that interactions such as the chemical shift depend on the orientation of a molecular fragment with respect to the magnetic field, and on the details of the motion of the fragment. In single crystals, this then gives rise to an orientation-dependent chemical shift spectrum, and for powdered samples, where all orientations are allowed. a powder pattern results. Overlapping powder patterns cause obvious problems in resolving contributions from inequivalent nuclei, so much effort is spent on developing methods that give better-resolved spectra.

Another factor in solid-state spectroscopy is that some interactions not encountered in the spectral analysis of liquids contribute to the solid-state spectrum. These include the through-space coupling of magnetic spins, known as the nuclear dipolar interaction, and the quadrupolar interaction between the nuclear electric quadrupole moment and the electric field gradient. Although both complicate the spectra, each contributes unique information and different possibilities for probing the solid state.

NMR SPECTRA IN SOLIDS

Below, we present a brief account of solid-state NMR spectroscopy that will point the interested researcher to more detailed accounts. General references are given[1–8] that will give the interested reader a detailed account of a variety of solid-state NMR topics. Refs. [1,2] give an encyclopedic overview of NMR spectroscopy that is updated regularly.

Spin—1/2 Nuclei

Carbon and hydrogen are of particular importance in supramolecular chemistry. as both organic and metal–organic components are in prominent use. A closer examination of these two nuclei provides a good starting point for discussion of all spin $^1/_2$ nuclei.

The proton (^{1}H) is an abundant nucleus (99.8%), it has a large magnetic moment, and hence, a high NMR frequency. The dipolar coupling between protons is the main broadening interaction and varies as $\gamma^2(3\cos^2\theta - 1)/r^3$ (where γ = magnetogyric ratio of the proton, r = internuclear distance, and θ = angle between the internuclear vector and the magnetic field direction), so that the ^{1}H spectrum of most organic compounds is a line. usually featureless. as broad as 10–50 kHz. Because the chemical shift range is small (−20 ppm), if fine structure is seen, it almost always arises from dipolar couplings. For certain geometries, this allows for the analysis of internuclear distances. Sufficiently rapid molecular motion averages the dipolar couplings, thus narrowing the resonance line. Only center-of-mass diffusion reduces the dipolar coupling to zero. Molecular motions also affect the rate at which nuclear magnetization is lost, and from studies of the relaxation time as a function of temperature, the activation energy E_a for a motion can be obtained. Chemical shift information for ^{1}H. therefore, is difficult to

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC *120012821*

obtain directly, and recourse must be taken to specialized techniques. The ^{1}H spins can be manipulated by multiple pulse cycles that remove homonuclear dipolar couplings. The chemical shift tensors that result can then be averaged to their isotropic values (plus a set of spinning side bands that are separated from the main resonance by the spinning frequency) by application of magic angle spinning (MAS). This involves rotating the sample rapidly about an axis that is inclined to the magnetic field at 57.3°, known as the "magic angle," the angle where $(3\cos^2\theta - 1)$ vanishes. The CRAMPS experiment (Combined Rotation and Multiple Pulse Sequence) combines the two approaches to produce high-resolution ^{1}H spectra in solids.

If the dipolar couplings are not too large, or if they were partially averaged by molecular motion, fast MAS (−35 kHz) used by itself can be employed to obtain a high-resolution spectrum. In such cases, many of the complex experiments designed for liquids can be applied to these "soft" solids.[2]

The ^{13}C nucleus, on the other hand. at 1% natural abundance, is considered to be a "rare" nucleus. The main line-broadening mechanisms are the anisotropic chemical shift and dipolar couplings to protons. In order to observe a high-resolution spectrum. it is necessary to apply high-power ^{1}H decoupling (50–100 kHz, values that are considerably larger than the dipolar coupling) and to apply MAS to average the chemical shift tensors to their isotropic values. The usual way of recording ^{13}C-NMR spectra is to transfer polarization from an abundant nucleus, usually ^{1}H to the rare ^{13}C nucleus. This double-resonance experiment is referred to as CP/MAS (cross-polarization with magic angle spinning). Although it is usually easier to generate a spectrum this way rather than by generating ^{13}C magnetization directly by applying a single pulse at the "63 frequency and decoupling the ^{1}H, quantitation is more difficult, as the spectral line intensities depend on the strength of dipolar coupling, the length of the cross-polarization sequence applied. and the ^{1}H spin-lattice relaxation time in the rotating frame, which all must be taken into account when performing a CP/MAS experiment.

Other "rare" nuclei for which spectra can be recorded in the same way as for ^{13}C include "Si. ^{15}N, ^{31}P, ^{77}Se, ^{125}Te, ^{113}Cd, and ^{129}Xe.

Quadrupolar Nuclei (Spin > 1/2)

By far. the majority of nuclides with spin are quadrupolar nuclei ($I > 112$). It should be remembered that for a spin I, there are $21 + 1$ energy levels and $2I$ allowed transitions. Of those with spin $\mathbf{I} = 1$. ^{2}H is by far the most popular. The magnetic moment of ^{2}H is a factor of 7 smaller than that of ^{1}H, resuliing in a lower resonance frequency and much smaller homonuclear dipolar couplings. The quadrupolar interaction. usually 300 KHz or less, is then a small perturbation on the Zeeman energy levels. giving rise to a quadrupolar fine structure. In a single crystal, each inequivalent ^{2}H nucleus gives rise to a doublet with a separation chat depends on the orientation of the quadrupolar coupling tensor in the magnetic field.

In a powder, because all orientations are allowed. the spectrum is broadened into a characteristic powder pattern that can be analyzed in terms of a quadrupole coupling constant (C_Q) and an asymmetry parameter (η). One attractive feature is that at low-to-medium magnetic fields, the quadrupolar coupling is the only interaction required to interpret the spectra; at higher fields, the chemical shift anisotropy must be taken into account as evident from asymmetry in the spectrum. The main use of ^{2}H-NMR is to study dynamics of molecules or molecular fragments, usually as a function of temperature. Dynamics cause narrowing of the line shapes as the quadrupolar coupling tensor reorients in the magnetic field. and details of the motion can be worked out from the shapes of the narrowed lines. The rate of motion and. thus, the line shape depend on temperature, and by fitting line shapes to dynamic models at specific rates, activation energies (E,) can be obtained from Arrhenius plots of rate versus $1/T$. Another property of ^{2}H-NMR. which can be of use in supramolecular chemistry. is that C_Q is a sensitive indicator of the strength of hydrogen bonds: the stronger (and hence, shorter) the bond, the smaller C_Q is for the ^{2}H atom in the bond.

Most quadrupolar nuclei are half-integral spins. and these have a central transition, affected by the second-order quadrupolar coupling. plus a set of satellite transitions with splittings related to the first-order quadrupolar coupling. A full discussion of the spectroscopy of half-integral quadrupolar nuclei is beyond the scope of this article, but the key features of the second-order central line shape are its inverse dependence on the magnetic field strength. a second-order shift (from the isotropic shift). and the fact that MAS alone will not coinpletely remove the anisotropy.

SOLID-STATE NMR SPECTROSCOPY AND SUPRAMOLECULAR CHEMISTRY

Structure, Disorder, and Dynamics

Why should a supramolecular researcher be interested in solid-state NMR spectroscopy?[7,9] After all, with advances in diffraction methods, it would appear that many if not most problems can be solved by crystallographic methods. A chief distinction between NMR and diffraction is that the former is a local-order technique. whereas the latter is a long-range-order technique. One

piece of information related to long-range symmetry in crystalline materials obtainable from NMR is that not only chemical inequivalence but also crystallographic inequivalence give rise to splittings in the spectrum. In this way, it is often possible to get a snapshot of the unit cell contents. and this has, on occasion, been used to guide the choice of space group.

In many complex supramolecular systems, usually still considerably less complicated than biological systems, there may be problems of disorder that are often dynamic. It must be remembered that for diffraction models. all disorder is projected back into the unit cell, whereas NMR spectroscopy will be sensitive to the local symmetry in all parts of the crystal. Thus. it is possible that the lattice symmetry for a diffraction-derived structural model can be higher than that indicated by NMR, as the former is affected by space averaging. For example. in Dianin's compound with *p*-xylene[10] (Fig. 1), with the x-ray structural solution. a spatially averaged sixfold symmetry of the host and disordered guest can be seen. If this were the true local symmetry, then each chemically (and crystallographically) distinct C should have only one resonance in the ^{13}C-NMR. whereas at room temperature, these resonances show splittings. indicating a static p-xylene disorder. The splitting pattern shows that each cavity lost its threefold axis and the center of symmetry: the high x-ray symmetry coupled with the observed disorder indicates that the distortions are not correlated through the lattice. The splittings disappear at higher temperatures as the disorder becomes dynamic. and on

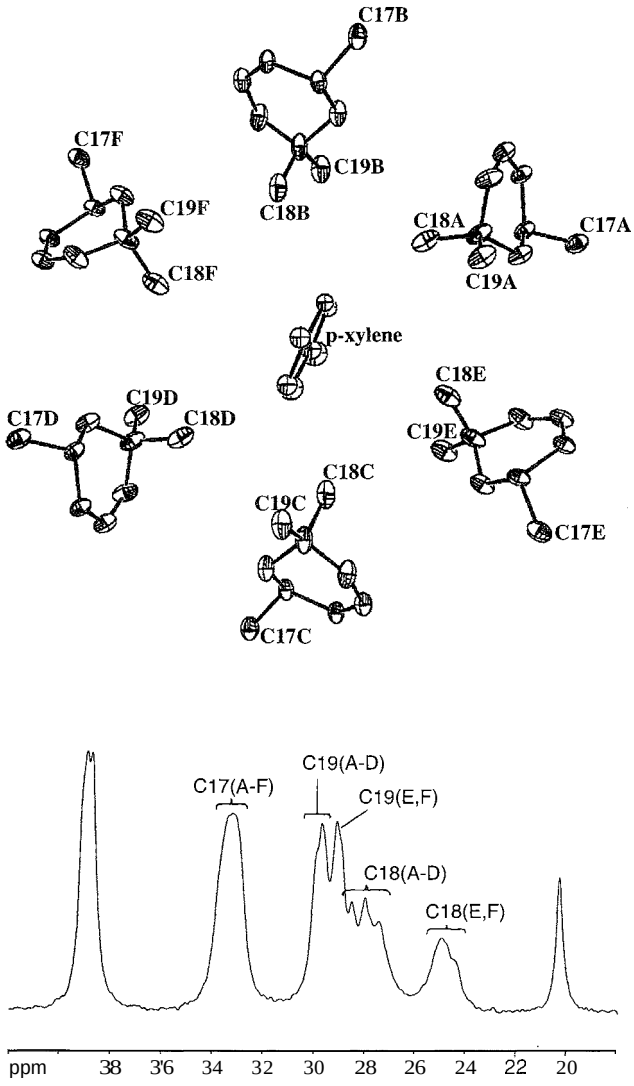

Fig. 1 Dianin's compound with p-xylene guest. (From Ref. [10].) (Top) Packing of six Dianin's host molecules around a p-xylene molecule. looking down the sixfold axis of the x-ray diffraction model (only part of each Dianin's inolecule is shown). (Bottom) Room-temperature ^{13}C-CP/MAS spectrum showing the multiple splittings for the methyl groups (18 and 19. pointing into the cavity) that arise because the p-xylene molecule is static. and the sixfold symmetry is lost.

time average each set of carbons becomes a sixfold equivalent. On the other hand, it is possible for the symmetry indicated by NMR to be greater than that derived from crystallography. This is often the case if there is sufficiently rapid molecular motion, and the NMR spectrum is affected by time averaging. For example, the ^{13}C-NMR of n-pentane in *t*-butyl-calix[4]arene shows only a single methyl resonance, rather than the two lines expected for the two distinct methyls seen in the crystal structure, one inside the calix cavity and the other outside.[11,12] The NMR, therefore, indicates dynamic exchange of the two ends of the pentane.

A great deal can be gained through the combined use of NMR and crystallography in a synergistic approach to refining structures. With NMR, we can determine if the disorder is static or dynamic and often define the exact nature and activation energies of the motions of both guest molecules and components of the host. Another contribution of NMR is in the detection of phase transitions and the possible involvement of dynamics and disorder in the transition process. Another example of where the combined use of NMR and x-ray diffraction led to a better understanding of the material and to an improved refinement of the structure is the toluene calix-[4]-arene inclusion compound.[13,14] At room temperature, the structure refines as P4/*n* in which the calix has a fourfold axis, and the toluene is disordered. Below a phase transition at 248 K (initially detected by NMR), the ^{13}C-NMR

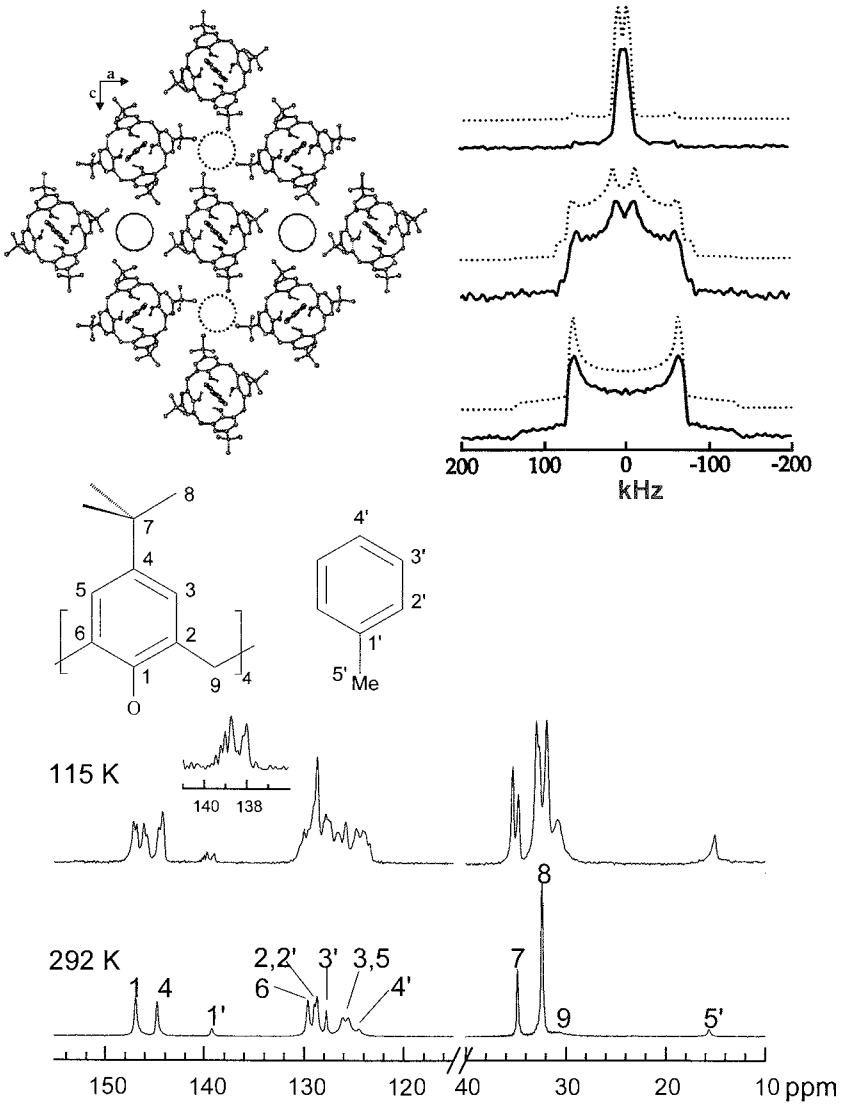

Fig. 2 (Top left) The 173 K P2/*c* structure of toluene-t-butyl-calix-[4]-arene, showing guest-induced twofold distortion of the host molecules. (From Ref. [14].) (Top right) ^{2}H-NMR line shapes, showing, from the bottom up, static (129 K), twofold flip (179 K), and fourfold rotation (337 K). (From Ref. [13].) (Bottom) The increased multiplicity of lines in the ^{13}C-CP/MAS spectra between 292 K and 115 K. (From Ref. [13].)

lines show splittings indicating a Iowering of symmetry. Shown by ^{2}H-NMR is that the toluene is static at 129 K, undergoes rapid twofold reorientation at 179 K and only goes into fourfold reorientation above the phase transition. An initial x-ray structure determination of this low-temperature phase appeared to show no difference from the room temperature phase (P4/*n*), but clearly this was not compatible with the NMR results. Further investigation of fine details in the diffraction data, including a set of superlattice lines, revealed a more complex structure in which the calix has twofold symmetry. P2/*c* (Fig. 2). Also of interest in this system and shown by x-ray and ^{13}C-NMR is the observation that 90–95% of the toluenes have their methyl groups inserted into the cavity, versus 5–10% out. For the external methyl, a weak line is observed close to the resonance seen for liquid toluene, whereas a stronger line is observed for the methyls in the cavity shifted by ~6 ppm to lower frequency, due to ring current effects from the aromatic rings of the calix.

To demonstrate static disorder in numerous cadmium cyanide host structures,[15,16] ^{113}Cd-NMR was used, because the number of resonances observed depends on whether the CN groups are ordered. statically disordered, or dynamically disordered (Fig. 3). The ^{13}C- and ^{15}N-NMR helped to establish or confirm connectivities in other mixed-metal cyanide frameworks, where it is more difficult to probe the metal nuclei directly. by making use of dipolar and J-couplings.[7,17] Likewise, ^{27}Al, ^{29}Si, and ^{31}P were used to establish connectivities in zeolite and aluminophosphate frameworks.[5,18,19]

Static line shapes arising from chemical shift anisotropy (CSA) and quadrupolar coupling also reflect the local symmetry of the nucleus. Isotropic lines occm for high-symmetry sites, such as tetrahedral, cubic, or octahedral, where these interactions are zero [e.g., in the ^{63}Cu-NMR of tetrahedral copper centers in $N(CH_3)_4$-$CuZn(CN)_4$ and $N(CH_3)_4CuCd(CN)_4 \cdot$guest framework~],'~whereas the lines have characteristic shapes for sites with axial symmetry or for lower-symmetry sites. In the case of ^{129}Xe. the sign of an axial CSA line shape also indicates whether the cavity is oblate or prolate.[20,21]

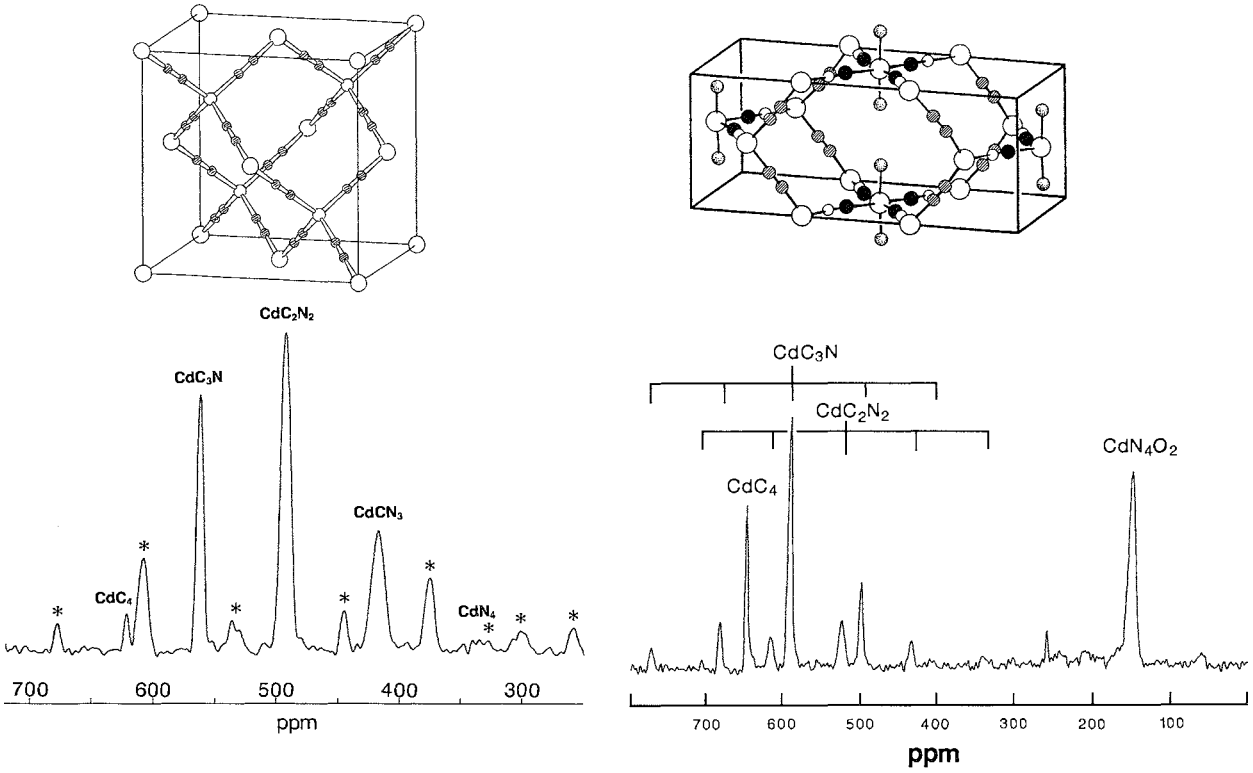

Fig. 3 (Left) The ^{113}Cd-NMR MAS spectrum of $Cd(CN)_2 \cdot C_6H_{12}$. The five lines arise from tetrahedral Cd attached to C_4, C_3N, C_2N_2, CN_3, and N_4, and indicate static disorder of the CN in the Cd–C–N–Cd linkages (* indicates spinning side bands). (From Ref. [15].) (Right) The ^{113}Cd-NMR CP/MAS spectrum of $Cd(CN)_2 \cdot 2/3\ H_2O \cdot$t-BuOH is shown. indicating ordering of the CN connecting the Oh Cd site to Td Cd sites (all N on the Oh Cd), with static disorder of the CN between Td Cd sites (the combs indicate the spinning side bands for CdC_3N and CdC_2N_2). (From Ref. [16].) X-ray structural studies previously established that this material could fall into one of five space groups. and a choice was made on the basis of the lowest *R*-factor. The NMR showed that this choice was not tenable and narrowed the choice to three of the five space groups. The structures of the frameworks are shown above the spectra: large open circles are Cd atoms; hatched circles are disordered C/N; and black circles are N atoms.

^{2}H-NMR is used extensively in studies of dynamics and disorder of guests and hosts in numerous supramolecular systems. These include clathrate hydrates, *t*-butylcalixarenes, cyclodextrins, metal cyanide clathrates, *tri-ortho*-thymotide, crown ethers, Dianin's compound, urea. thiourea, and numerous others. The benzene and pyridine t-butylcalixarenes provide an example where there is agreement between the orientations of the guest molecules with respect to the calix axis determined by NMR and diffraction, and where two guest molecules of similar shape have distinct differences in their dynamics.[22] It often comes as a surprise to the uninitiated that there can be large-scale motions in solids, yet solid-state NMR spectroscopy provided ample evidence of this over the years; a fine example being 18-crown-6, a large host macrocycle consisting of a ring of 18 atoms, which reorients rapidly in many of its solid complexes at room temperature.[23,24] In the malononitrile complex, the ring is

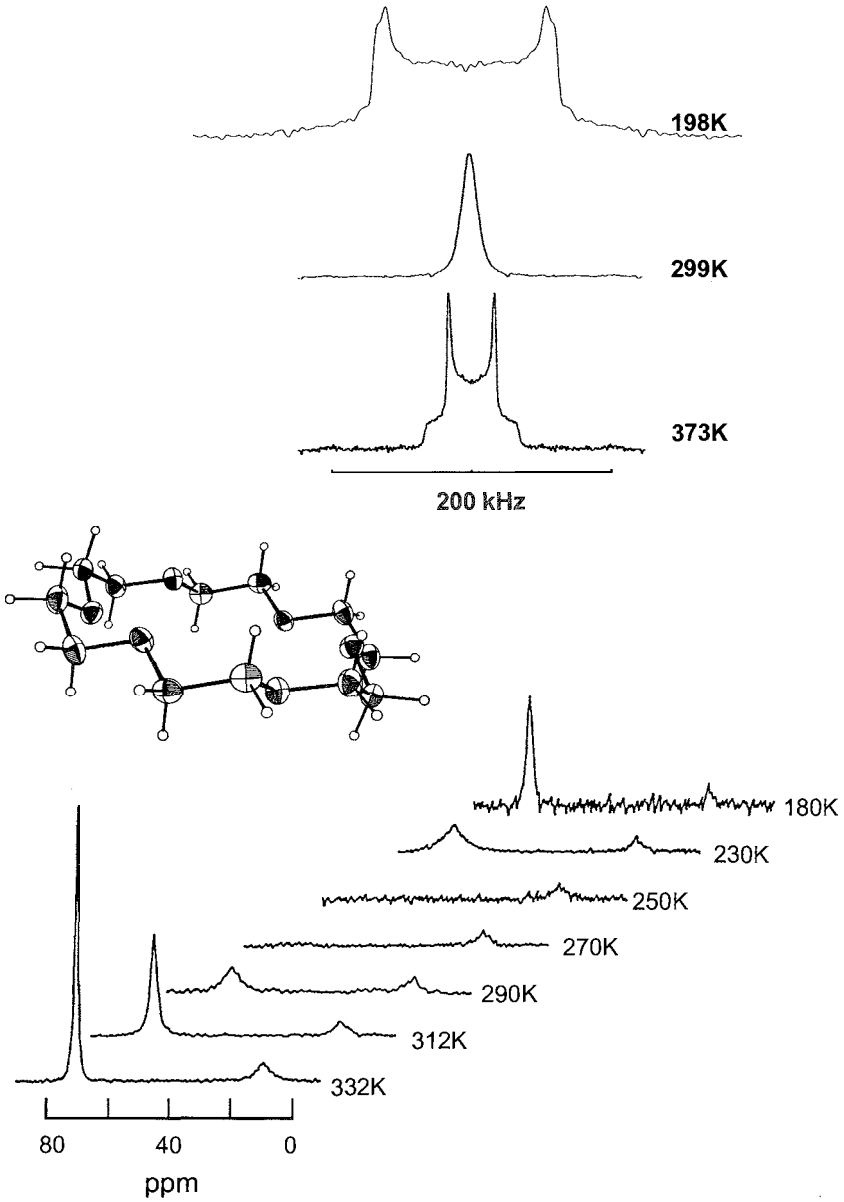

Fig. 4 The molecular merry-go-round in the solid complex 18-crown-6·$2CH_2(CN)_2$. (Middle) The ring adopts an almost D_{3d} symmetry. (Bottom) The ^{13}C-CP/MAS spectra as a function of temperature, showing fade-out of the resonance of the macrocycle carbons at 69.5 ppm near 250 K due to interference of incoherent reorientational motion with the coherent ^{1}H decoupling. (From Ref. [23].) (Top) The ^{2}H-NMR line shapes of the deuterated macrocycle as a function of temperature. indicating reorientation around the ring with a concomitant flip in orientation of each C–D bond between equatorial and axial. (From Ref. [24].)

in a D_{3d} conformation, and each $O—CH_2—CH_2$ unit rotates among adjacent sites around the ring. In the process, the CH_2 groups flip up and down. performing a motion resembling that of a merry-go-round (Fig. 4).

Similarly. effects of dynamics on line width and line shape can be observed for static NMR spectra of the following:

1. The chemical shift anisotropy, e.g., ^{13}C in CO_2 clathrate hydrate (which rhows a line considerably narrowed from that of a static CO_2 molecule,[25]), likewise for ^{77}Se in H_2Se clathrate hydrate[26] and ^{15}N in pyridine in *t*-butyl-calixarene.[22]
2. Noninteger quadrupolar nuclei. e.g., the central transition line shapes

   a. Of ^{17}O in water in THF clathrate hydrate, which narrows from a broad static quadrupolar line shape at 140 K to a line shape indicating rapid pseudoisotropic reorientation just below the melting point.

   b. Of alkali metals, such as ^{23}Na and ^{87}Rb in zeolites, which show isotropic lines that retain a field-dependent second-order shift, which indicates that these lines arise from dynamic averaging over sites with significant quadrupolar coupling.

The changes in line shape can often be used to derive details of the motions.

Evidence of dynamics can also be found in ^{13}C-CP/MAS spectra, where modulation of the $^{13}C—^{1}H$ dipolar coupling due to reorientation can interfere with the ^{1}H decoupling, causing broadening and a fade out of the signal over a specific temperature range (i.e., at specific rates of reorientation) (Fig. 4),[23,27] or prevent complete elimination of the resonances of carbons with attached ^{1}H in interrupted decoupling (also known as dipolar dephased or nonquaternary suppression) experiments.

Many supramolecular systems have pore spaces, usually, but not always. occupied by guest species. The ^{129}Xe-NMR can be applied to study the pore spaces or the exchange or competitive adsorption of guest species.

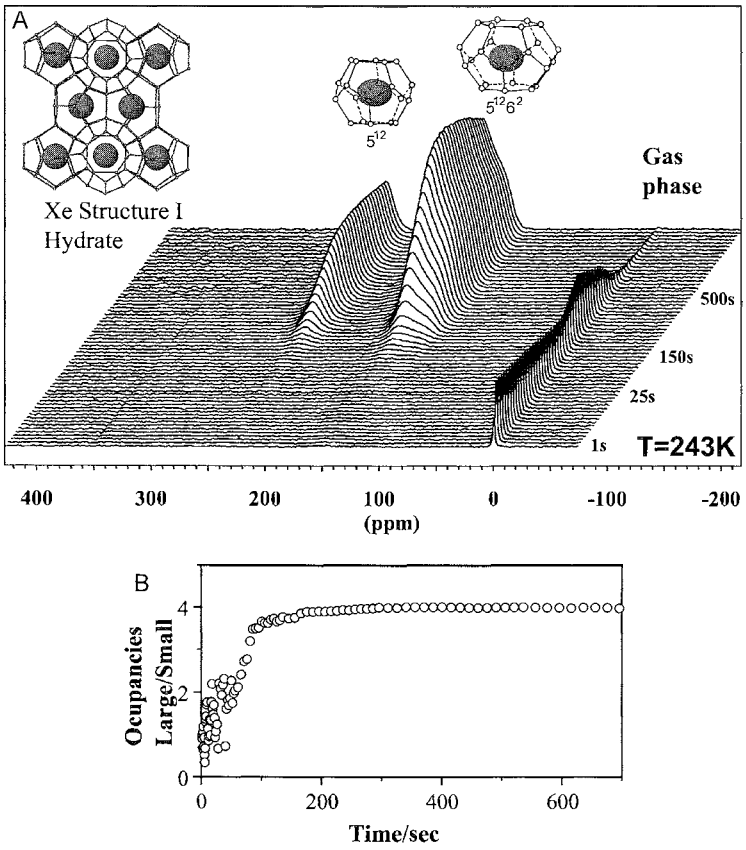

Fig. **5** Hyperpolarized ^{129}Xe-NMR spectroscopy of the formation of xenon hydrate on ice. (From Ref. [28].) (A) Single-scan spectra taken as a function of time, showing the development of Xe clathrate hydrate when HP Xe is admitted to powdered ice at 243 K. There is an initial induction period where only the gas line is observed. followed by a rapid rise of the lines due to Xe in the small and large cages of the clathrate hydrate. (B) The Xe-NMR intensity ratio of large:small cages shows an initial relative excess of Xe in small-cage environments. before eventually approaching the ratio in equilibrium Xe hydrate.

Although ^{129}Xe ($I = 1/2$) is a low-boiling gas under normal conditions, most of its NMR applications are in porous solids. The Xe atom is inert but highly polarizable. and as such. its chemical shift is sensitive to changes in its local environment: smaller cavities give larger chemical shifts. and the chemical shift anisotropy is sensitive to cavity shape. Thus. its signal, with the isotropic and anisotropic chemical shifts; is often diagnostic of whether the Xe atom behaves more like a trapped solid or adsorbed gas inside the pore system. The ^{129}Xe can also be hyperpolarized using optical pumping techniques such that its spin polarization is several orders of magnitude larger than the normal thermal spin polarization. This results in a greater NMR sensitivity. allowing for time-resolved studies of formation and decomposition processes. diffusion processes, and competitive adsorption between Xe and other guest molecules in supramolecular systems.[28,29] An example is shown in Fig. 5.

Of course, there are numerous other more sophisticated and hence less routine NMR experiments (refer to more specialized reviews[1,2,5,8] that can be applied to give information about supramolecular systems, such as the following:

1. The ^{1}H spin-counting technique can be used to determine the number of ^{1}H in a local cluster, and thus count the number of molecules in a cavity.[30,31]
2. Solid-echo double resonance (SEDOR) and rotational-echo double resonance (REDOR) techniques can be used to determine the proximity of the two types of nuclei, e.g., to determine which Na ions are closest to Al atoms in the framework of a zeolite, or to determine internuclear distances, or to help locate the position of a guest molecule relative to the host framework.[2,8]
3. MQMAS (Multiple Quantum MAS) is used to resolve resonances of noninteger quadruplar nuclei: complete narrowing of the second-order quadrupolar line shape cannot be achieved by MAS alone, but this is feasible when MAS is combined with multiple quantum pulse sequences.[2,5,8] This was used extensively in studies of zeolites.
4. Magnetic resonance imaging (MRI) can be used for diffusion measurements in porous systems, by monitoring the distribution of such nuclei as ^{1}H and ^{129}Xe as a function of time.[1,32]

CONCLUSION

It is clear that solid-state NMR has developed into a powerful tool for the supramolecular chemist who is interested in developing a true understanding of systems that are complicated and that, in fact, need to be flexible, responsive, or have dynamic components in order to be functional. On examining the development of NMR spectroscopy, it is remarkable that periodically there were major developments in hardware, software. or some fundamental aspects of spectroscopy. All of these led to increased prospects for spectroscopy as a research tool for the sciences. This is also the case for solid-state spectroscopy as it is applied to supramolecular chemistry, where the technique has now diffused from a few specialized labs into the mainstream. There is no reason to suppose that such developments will stop. Soon the impact of the general availability of higher fields to solid-state spectroscopists will give unprecedented sensitivity. thus giving access to smaller samples as well as nuclei that have lower sensitivity or low gamma. The wide range of fields will also allow for the development of complex spectroscopy of half-integral quadrupolar nuclei, thus giving the researcher a whole new range of probes for material studies as well as dynamic processes.

Solid-State Reactivity/Topochemistry

Leonard R. MacGillivray
Giannis S. Papaefstathiou
University of Iowa, Iowa City, Iowa, U.S.A.

INTRODUCTION

Topochemical solid-state reactions take place in a crystal lattice[1,2] and are typically initiated by irradiation [e.g., ultraviolet (UV) energy] or thermal annealing. Generally, for such reactions to occur, the reactive groups must be separated by <4.2 Å, consistent with the topochemical postulate.[1] Because the organization of the reactants usually dictates the stereochemistry of the products, topochemical solid-state reactions typically take place more selectively than in the liquid phase and, as a result, can give rise to molecules, and polymers, less obtainable, or completely inaccessible. in solution.[3] In recent years, the application of supramolecular chemistry[4] to control topochemical solid-state reactions was shown to provide control over the organization of reactants such that it is possible to conduct topochemical solid-state reactions, in a similar way to a classical approach to organic synthesis, by design. The primary focus of this article will be on two well-established topochemical solid-state reactions, namely, the UV-induced [2 + 2] cycloaddition reaction'"] and the thermal polymerization of diacetylenes,[2] to demonstrate how supramolecular chemistry may be utilized to control such processes.

THE TOPOCHEMICAL POSTULATE

Extensive crystallographic and photochemical studies by Schmidt involving polymorphs of cinammic acid led to topochemical postulates that may be used to predict whether a photoinduced [2 + 2] cycloaddition reaction will occur in the solid state (Fig. 1).[1] According to Schmidt, the nature of a crystal determines whether or not reaction will take place and determines the molecular structure of the product. Moreover, if a solid displays such reactivity, then the reaction will involve nearest-neighbor molecules and will occur with minimum atomic and molecular movement.'"] Thus. for the [2 + 2] photoreaction, the double bonds of the reactants should, as determined by Schmidt, be separated by <4.2 Å and aligned in parallel. Such separation and parallel alignment ensures that the p(z) orbitals of the double bonds are nearly colinear and overlap sufficiently to react. Notably, there are exceptions to these empirical rules, involving photoactive and photostable compounds.[5] Nevertheless, these postulates provided useful geometry criteria to predict whether a [2 + 2] photoreaction will take place in a crystalline solid.

FROM THE TOPOCHEMICAL POSTULATE TO CRYSTAL ENGINEERING

Following the emergence of the topochelnical postulate, a variety of studies were developed to identify molecules that crystallize in a necessary arrangement for [2 + 2] photoreaction.[6] In addition to the [2 + 2] photocycloaddition, such studies led to molecules that undergo other transformations. such as [4 + 4] photocycloadditions,[7] decarbonylations,[8] and Diels–Alder reactions,[9] giving molecular and polymeric products. In effect, such studies illustrated that it is possible for chemists to modify structure at the molecular level to affect a bulk physical property of a solid (i.e., reactivity). This strategy of identifying molecules so as to engineer structures and properties of organic crystalline solids has, in recent years, led to the emergence of the general field of crystal engineering, which has been systematized by Desiraju.[10]

ENGINEERING THE [2 + 2] PHOTOREACTION

Following the initial work of Schmidt, two general strategies for engineering solids that undergo the [2 + 2] photoreaction were developed. These strategies involved intramolecular substitution or auxiliary components to organize reactants for photoreaction.

Intramolecular Substitution

In the first approach, substitutents are covalently attached to reactants to steer molecules, upon crystallization, into a necessary arrangement for reaction.[11–15]

Schmidt, for example, revealed that chlorine groups, attached to an aromatic ring, tend to steer a molecule, by way of Cl···Cl interactions, such that it adopts a P-structure, wherein neighboring olefins are photoactive.[11]

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012761

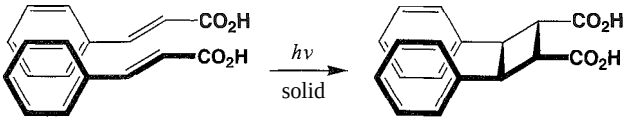

Fig. 1 Solid-state photodimerization of β-cinnamic acid.

Electrostatic[12] as well as donor–acceptor[13,14] interactions were also employed for steering the synthesis of molecules and polymers (Fig. 2a).

In a notable success, a J-shaped dicarboxylic acid was shown by Feldman to form a hydrogen-bonded molecular assembly held together by four O–H···O hydrogen bonds, wherein two olefins conform to the topochemical principle and are photoactive[15] (Fig. 2b). UV irradiation produced the expected photoproduct in quantitative yield. The covalently bound naphthalene unit served to preorganize the two double bonds within the discrete complex for reaction.

Auxiliary Components

In the second approach, an auxiliary component is employed to organize two olefins for [2 + 2] photoreaction. The auxiliary component is typically in the form of a molecule or cavity.[16–20]

Cavities based on cyclodextrins[16] and saponite,[17] for example. were used to organize olefins by way of van der Waals and electrostatic forces; respectively. In the former, the host accommodated the guests within a rigid tubular framework. while in the latter. the clay-like silicate accommodated the guests by swelling. In each case, the guest photodiinerized upon UV irradiation.

An auxiliary component that interacts with reactants by way of hydrogen bonds was also described (Fig. 3). Specifically, tetraaryl diols were shown by Toda to accommodate guests within cavities wherein the host interacted with two guests by way of two O–H···O hydrogen bonds.[18] The guests packed within the cavities such that two olefins of two guests conformed to the topochemical principle and, upon UV irradiation, photodimerized.

An approach that utilizes hydrogen bonds and electrostatic forces, in the absence of cavities, was also reported.[19,20] Specifically, Ito revealed the ability of flexible diamines (e.g., ethylenediamine) to undergo acid–base reactions with cinnamic acids, wherein each ammonium group forms an N^+–H···O^- hydrogen bond with a cinnamate. Combinations of acid and base were found to be photoactive, which was accounted for by the formation of three-component assemblies wherein each base, in a syn conformation. organizes two anions for reaction.

SOLID-STATE REACTIVITY AND CHEMICAL SYNTHESIS BY DESIGN

Although substituents and auxiliary components were successfully employed to achieve [2 + 2] photoreaction in the solid state. the ability to organize two double bonds in a solid for reaction has been a difficult challenge. This difficulty is largely due to insufficient knowledge of weak interactions that govern crystal packing (e.g., van der Waals forces). Reactions of homologous compounds $R'(CH_2)_nR''$ (n=1,2,3...), for example, were not found to be identical, in contrast to the liquid phase, for all values of n in the solid state owing to the sensitivity of molecular packing to unique electronic and steric demands of reactants.[1] Moreover; such sensitivity made

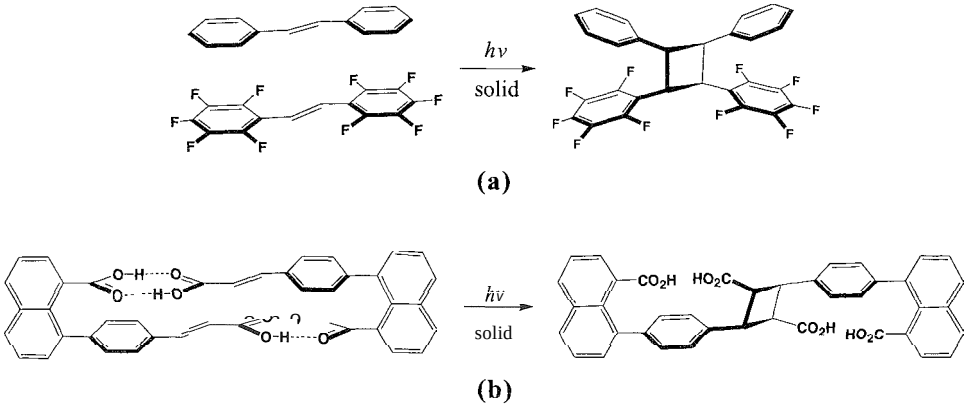

Fig. 2 The application of intramolecular substitution to control the [2 + 2] photodimerization in the solid state: (a) phenyl–perfluorophenyl interactions between two stilbenes and (b) a J-shaped dicarboxylic acid that self-assembles to form a hydrogen-bonded assembly.

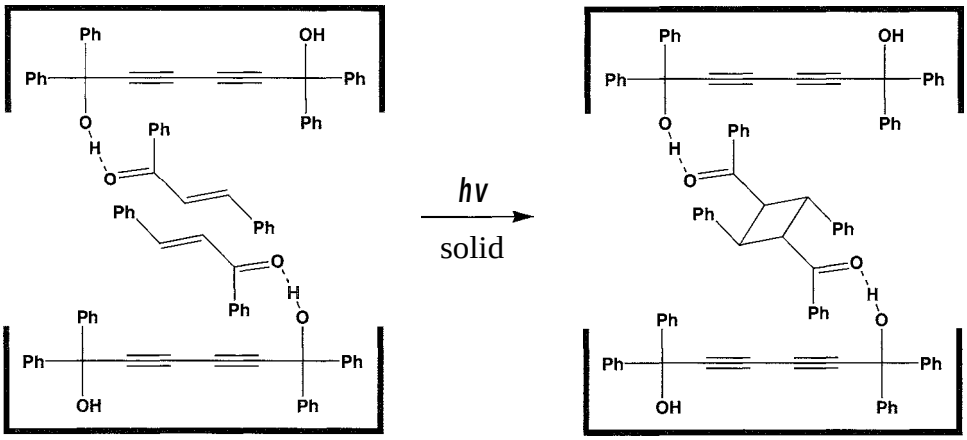

Fig. 3 The application of auxiliary components to control the [2 + 2] photodimerization in the solid state. A tetraaryl diol assembles to form a cavity and Interacts with olefins by way of hydrogen bonds.

it difficult to synthesize molecules in the solid state with degrees of freedom common to solution (e.g., reliability, functional group tolerance). In effect, products of solid-state [2 + 2] photoreactions were limited to specific topochemical strategies, a fact that has thwarted efforts toward an ability to conduct molecular solid-state synthesis by design.

SUPRAMOLECULAR CONTROL OF THE [2 + 2] PHOTOREACTION

To control the [2 + 2] photoreaction such that it is possible to conduct molecular solid-state synthecir by design, recent efforts were directed toward the application of supramolecular chemistry.[4] Specifically, the field of

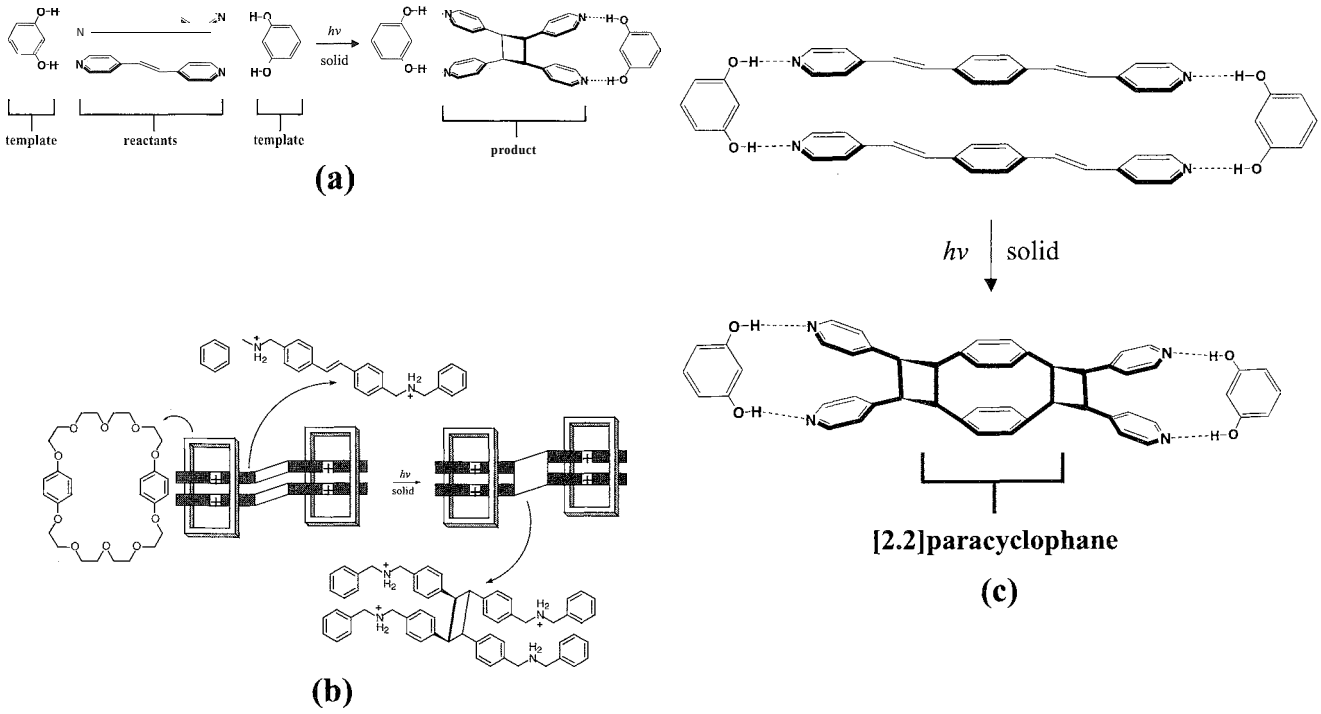

Fig. 4 The application of molecular receptors to achieve supramolecular control of the [2 + 2] photodimerization in the solid state. Control of reactivity using (a) resorcinol and (b) a crown ether, and (c) the targeted solid-state synthesis of a [2.2]paracyclophane using a resorcinol.

host–guest chemistry[21] was shown to provide access to molecules. termed molecular receptors, which recognize and preorganize molecules in the solid state for photoreaction. The receptors were shown to largely eliminate problems of intermolecular forces that made such topochemical reactions difficult to control by preorganizing the reactants. via noncovalent forces (e.g., hydrogen bonds), within discrete molecular assemblies for reaction.

MacGillivray, for example, demonstrated the ability of 1,3-dihydroxybenzene (resorcinol) and 1.8-naphthalenedicarboxylic acid (1,s-nap) to function as molecular receptors able to direct the [2 + 2] photoreaction by serving as bifunctional hydrogen bond donors in the solid state.[22,23] Specifically, cocrystallization of resorcinol or 1,8-nap with *trans*-1,2-*bis*(4-pyridyl)ethylene (4,4′-bpe) was shown to give discrete four-component molecular assemblies. 2(resorcinol)·2(4,4′-bpe) and 2(1,8-nap)·2(4,4′-bpe), respectively, held together by four O–H···N hydrogen bonds, wherein two double bonds of 4,4′-bpe are separated by <4.2 Å and are aligned in parallel (Fig. 4a). UV irradiation of each solid produced the expected photoproduct, *rctt-tetrakis*(4-pyridyl)cyclobutane (4,4′-tpcb), stereospecifically (yield: 100%). Owing to the ability of the receptors to organize the olefins linearly, the receptors were regarded as linear templates.[24]

A method that utilizes a crown ether to control a [2 + 2] photoreaction in the solid state has also been reported.[25] In particular, cocrystallization of *bis*paraphenylene[34]-crown-10 with a *bis*(dialkylammonium ion)-substituted stilbene was demonstrated by Garcia-Garibay and

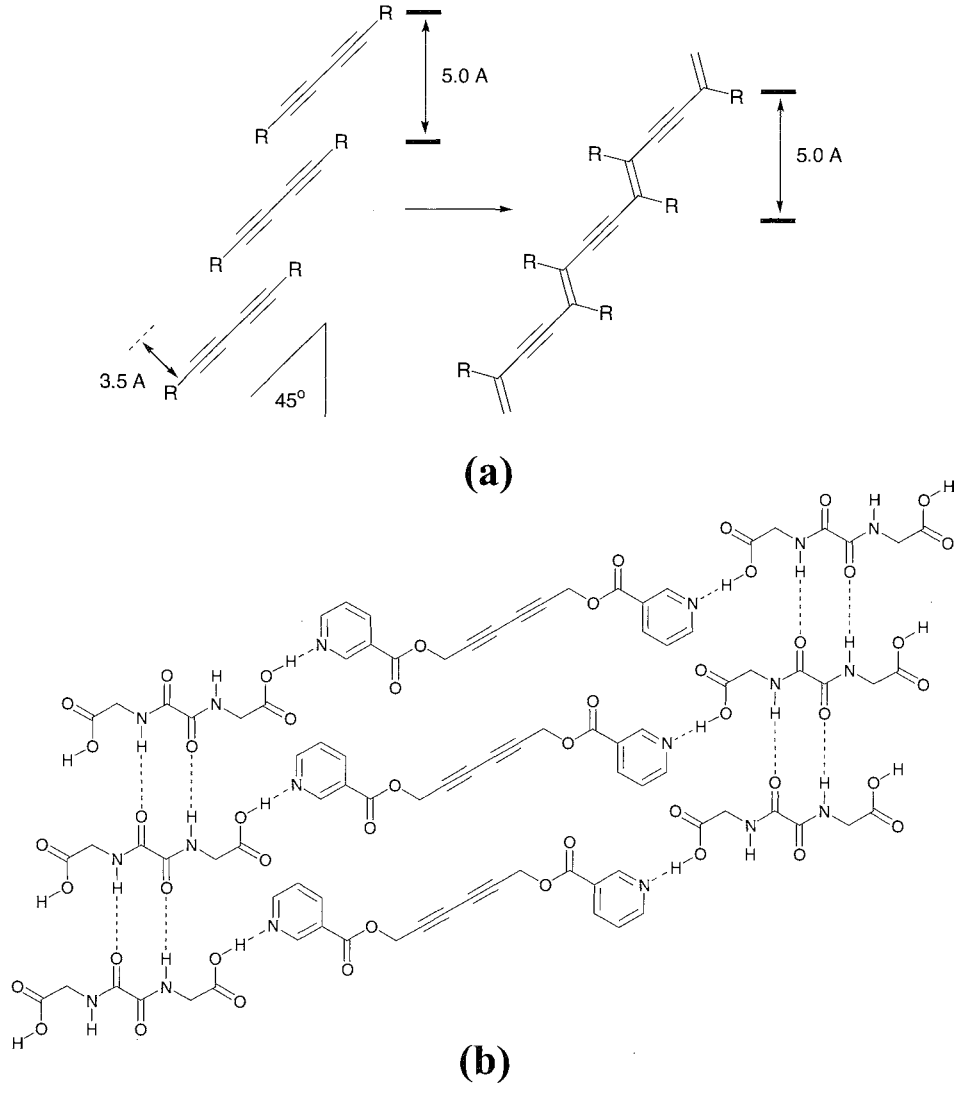

Fig. 5 Topochemical polymerization of diacetylenes in the solid state: (a) topochemical requirements and (b) a host–guest strategy for controlling polymerization of diacetylenes using an oxalamide of glycine as a supramolecular host.

Stoddart to give a 2:2 host–guest complex, wherein two olefinic bonds of two stilbenes are organized in a stacked geometry for photoreaction (Fig. 4b). UV irradiation of the solid resulted in a stereospecific solid-state photochemical dimerization that produced a single diastereoisomer. The stereochemistry of the photoproduct was determined by way of x-ray crystallography.

The ability of resorcinol to function as a linear template to organize reactants in the solid state for [2 + 2] photoreaction also led to a molecular solid-state synthesis by design.[22] Specifically. cocrystallization of 1,4-*bis*[2-(4-pyridyl)ethenyl]benzene (1.4-bpeb) with 5-methoxyresorcinol (5-OMe-res) yielded a four-component assembly. 2(5-OMe-res)·2(1,4-bpeb), wherein four olefins, as two reaction centers, conformed to the topochemical principle. UV irradiation of the solid produced. regio- and stereoselectively. a targeted [2.2]paracyclophane (yield: 60%) (Fig. 4c).

SUPRAMOLECULAR CONTROL OF DIACETYLENE POLYMERIZATION

The thermal polymerization of diacetylenes to form polydiacetylenes is also known to proceed under topochemical control in the solid state.[1] To achieve polymerization. reactant inonomers must be organized such that the carbons atoms of the reactive sites are generally separated by <3.8 Å. Thus. for a 1,4-topochemical polymerization to give a polydiacetylene, linear alignment of monomers with an intermolecular repeat spacing of approximately 5.0 Å and tilt angle of 45" with respect to the translation axis must be achieved[2] (Fig. 5a). Most diacetylenes, however. do not crystallize in accordance with structural requirements for solid-state polymerization.[1] Moreover, the application of host–guest chemistry to preorganize diacetylenes in molecular solids, similar to the [2 + 2] photoreaceion, for solid-state polymerization offered a solution to this problem.[26,27]

A host–guest strategy for controlling the polymerization of diacetylenes in the solid state was described by Fowler and Lauher.[26] Specifically. the method is based on the utilization of molecules that self-assemble into one-diiiiensional hydrogen-bonded β-networks. The networks serve as hosts by imposing a characteristic intermolecular repeat distance and tile angle upon the diacetylene guests such that the guests conform to topochemical requirements for solid-state polymerization. In particular, cocrystallization of the oxalamide of glycine with a *bis*-pyridyl substituted diacetylene was shown to impose a repeat distance and tilt angle of 4.97 Å and 43°, respectively, upon the diacetylene (Fig. 5b), an orientation suitable for solid-state polymerization.[26] The resulting oxalamide crystalline solids were observed to slowly polymerize crystal-to-crystal at room temperature to give the targeted diacetylene polymer. Notably, thermal annealing at a slightly elevated temperature increased the rate of conversion.[26] In addition to a diacetylene polymerization, the method was recently applied to an unprecedented solid-state topochernical polymerization involving a triacetylene.[27]

CONCLUSION

Topochemical solid-state reactions are, in general, more selective than liquid-phase reactions and can yield molecular and polymeric products which, in many cases, may be difficult, or impossible, to obtain in solution.[1,2] Owing to the ability of such reactions to occur under strict geometric requirements in an organized environment, topochemical solid-state reactions provided useful targets for applying principles of supramolecular[4] and host–guest[21] chemistry to direct such transformations. It is expected that as principles for controlling topochemical reactions using such host–guest design strategies continue to develop. it should be possible to routinely access molecules and polymers, as well as solid-state materials, less available by a more classical approach to covalent synthesis.[22–27]

Solvation Effects in Guest Binding

Mikhail Rekharsky
Entropy Control Project, International Cooperative Research Project (ICORP), Osaka, Japan

Entropy Control Project, International Cooperative Research Project (ICORP), Toyonaka, Japan

INTRODUCTION

A large variety of noncovalent weak interactions can take place in the solution of a guest. The guest–solvent interactions, or guest solvation, involve electrostatic (ion–ion, ion–dipole, dipole–dipole, dipole–induced dipole), van der Waals, hydrogen bonding, n – staking, and other weak forces that strongly depend on the physicochemical properties of the particular guest–solvent combination under consideration. As a consequence of the diversity of guest–solvent interactions, the association process of a guest with a supramolecular host can be dramatically altered or totally changed depending on the solvation properties.

WHAT IS GUEST SOLVATION?

The solvation of a neutral or ionic guest in any solvent, including hydration in aqueous solution, is represented by the process of guest transfer from the ideal gas to the solution. both in the standard state:

$$\text{Guest(gas)} \rightarrow \text{Guest(solution)} \quad (1)$$

The standard states correspond to a hypothetical ideal gas at atmospheric pressure (101,325 Pa) and a hypothetical ideal 1 M aqueous solution. The standard molar Gibbs free energy, enthalpy. and entropy changes for the above reaction are donated by symbols ΔG°, ΔH°, and ΔS°, respectively.

Certainly, it should be emphasized that the solvation of a supramolecular host is also altered upon switching from one solvent to another. Taking into account the generally more complicated structure and functionality of supramolecular hosts in comparison to guests, it should be stated that in many cases, the alteration of host solvation can lead to a more profound impact in its binding behavior.

The host–guest association process, incorporating solvent molecules, may be illustrated by a rather simple scheme shown in Fig. 1. The extent of the solvation, i.e., the amount and location/position of the solvent molecules as well as the strength of the host–solvent and guest–solvent interactions, critically varies depending on the nature of the solvent employed. However, in principle, the combined surface area of host and guest, which is accessible to solvent, is significantly reduced upon host–guest complexation, limiting the number of solvent molecules able to associate with the complex. Concurrently, a number of solvent molecules are released into the bulk solvent upon host–guest complexation, and therefore. the interaction of solvent molecules in the bulk solution also plays a crucial role in guest binding. More detailed discussion on this issue may be found in the literature.[1,2]

DESOLVATION UPON GUEST–CYCLODEXTRIN ASSOCIATION

One group of representative examples of host–guest desolvation upon association are the complexation reactions of cyclodextrin in water. Cyclodextrins (CDs), cyclic oligosaccharides composed of 6, 7, or 8 glycopyranose units, are truncated cone-shaped macrocyclic molecules with hollow, tapered cavities (Fig. 2) (see *Cyclodextrins* article for more details). In aqueous solution, the cavity is occupied by several water molecules that are excluded from the cavity upon inclusion of a proper guest. As a result of the α-1,4-linkage of each glucopyranose unit, all of the hydrophilic 2-. 3-, and 6-hydroxyl groups are located on the exterior of the hydrophobic cavity (Fig. 2), as is amply exemplified in the literature.[2,3] The most common binding mode of native and modified CDs with various guests involves penetration of the less hydrophilic (nonpolar) part of a guest molecule into the CD cavity, while the more hydrophilic. often charged. part of the guest stays just outside the primary or secondary rim of the cavity.

The diameters of simple aliphatic hydrocarbon chains match well with the size of α-cyclodextrin's (a-CD) hydrophobic cavity, which in aqueous solution contains in its interior several water molecules (Fig. 3). Sequential insertion of methylene groups of the hydrocarbon chain into the a-CD cavity is accompanied by expulsion of water molecules into the bulk solvent. In addition. several water

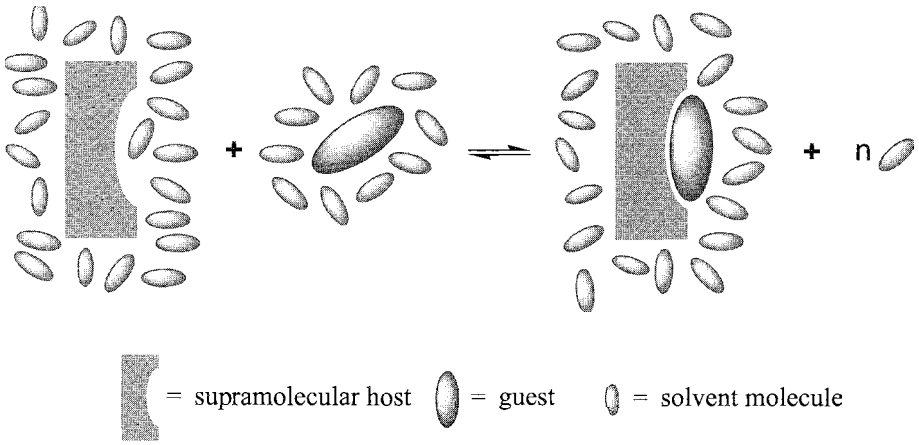

Fig. 1 Schematic drawing of host-guest deiolvation upon complex formation. (*View this art in color at www.dekker.com.*)

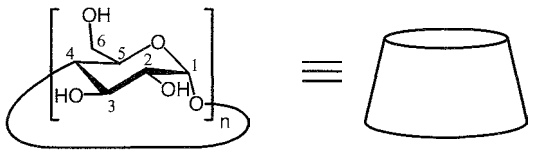
molecules that were located around the inserted methylene group in solution are also returned to the bulk solvent upon complexation. The longer the chain. the stronger the complexation.[3] Furthermore, the incremental change of the ΔG° value (as well as other thermodynamic parameters) for the complexation reaction is constant with the stepwise increase of the aliphatic chain length.'''

One of the intriguing issues observed in guest inclusion by native CDs is that only the specific part of the guest penetrating into the cavity contributes to the overall complexation thermodynamics. The introduction of a methyl group to the less-polar penetrating part of a guest consistently enhances the binding constant by a factor of 2–4, while the methylation of a charged group. such as an ammonium which stays outside the cavity upon complexation (Fig. 3), does not at all affect the complexation thermodynamics.[3] Furthermore, the chemical nature, structure, and even sign of the charged group do not play any significant thermodynamic roles upon cornplexation with native CDs as far as the same hydrophobic past of the guest is included in the cavity.''' This is obviously nonclassical. or unusual. thermodynamic behavior from the viewpoint of ordinary solute–solvent interactions or for the conventional solute transfer from water to nonpolar solvent.

Another major difference between conventional solute transfer and supramolecular association is the crucial influence of the shape of the guest molecule in the latter case. This is clearly demonstrated upon complexation of β-CD with 2- and 3-phenylbutyric acids. The apparently trivial variation in the methyl position results in a profound difference in complexation thermodynamics. Despite virtually the same hydrophobicity (i.e., the distribution ratio between water and nonpolar organic solvent). the affinity of 3-phenylbutyric acid toward β-CD (K=402–430 M^{-1}) is more than four times larger than that of 2-phenylbutyric acid (K=94–95 M^{-1}).[4,5] This difference arises from the significantly greater degree of steric hindrance occurring in the 2-phenylbutyric acid case. The crucial steric effect on guest binding is also found in the cornplexation of ortho-substituted phenyl guests. which always exhibit much lower complexation affinities toward β-CD than their *para* counterparts, due to the steric hindrance caused by the ortho-methyl group.[4,5] This is a good example of the critical role that steric factors play in CD complexation and in supramolecular association in general, highlighting the intrinsic difference between inclusion complexation by CD and classical hydrophobic processes (e.g., transfer from water to nonpolar organic media) (see Hydrophobic Effects article for more details).

EFFECT OF SOLVENT MOLECULE SIZE ON GUEST BINDING

As discussed above, improper molecular size and shape of a guest often prevent it from fully enjoying the most comfortable association with hosts such as cyclodextrins. In this light, it would be intriguing to investigate the effect



α-, β-, γ-Cyclodextrin (n = 6-8)

Fig. 2 Chemical structures of α-, β-, and γ-cyclodextrin (CD).

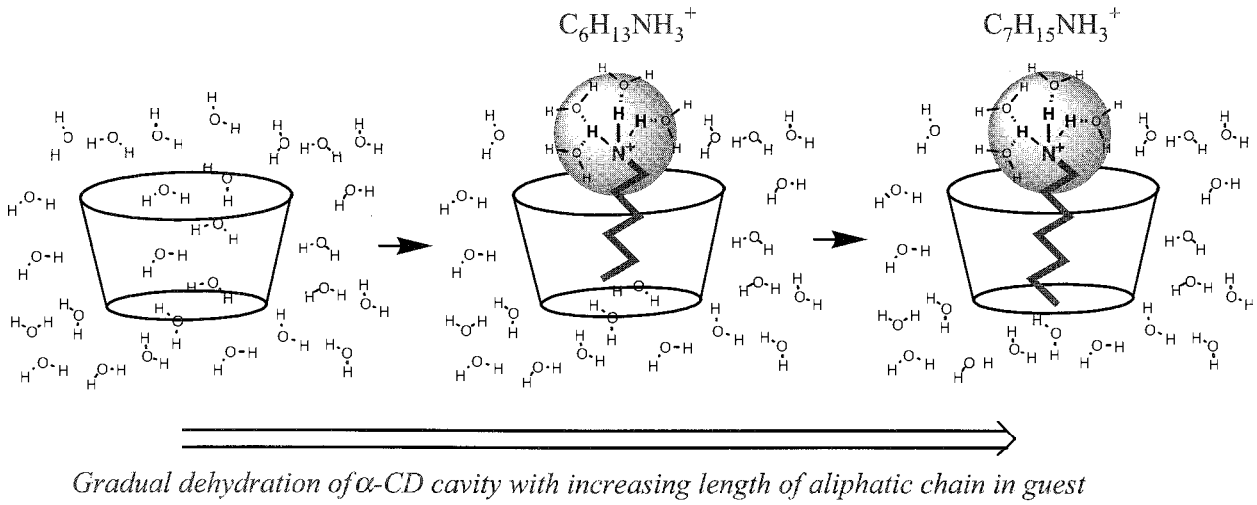


Fig. 3 Dehydration of r-CD cavity upon guest complexation. (*View this art in color at www.dekker.com.*)

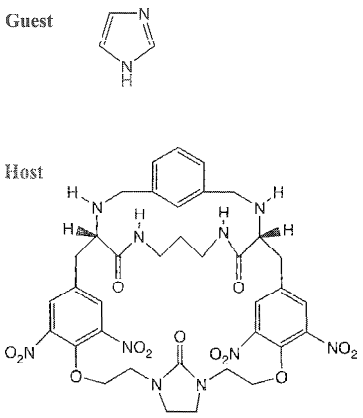
of the size and shape of the solvent molecule on supramolecular association. For instance, the cyclophane host (see *Cyclophanes* article for more details) with functionalized tethers, illustrated in Fig. 4, can bind a small guest such as imidazole in ethers and chlorinated hydrocarbons.[6] However. the binding constant for imidazole varies dramatically by two to three orders of magnitude from 29 M^{-1} in THF to 1067 M^{-1} in Me_4-THF and from 240 M^{-1} in CH_2Cl_2 to 128,000 M^{-1} in $CHCl_2CHCl_2$, critically depending on the size of the solvent used. Some of the solvent molecules are larger in size than the guest, and the relatively small binding site of the host is hardly accessible for the large solvent molecules, which facilitates the guest's access to the interacting site. Consequently, the association constant increases gradually with increasing size of the solvent molecule in both series of solvents, i.e., ethers and chlorinated hydrocarbons. Probably, the size/shape of the largest $CHCl_2CHCl_2$ molecule prevents it from entering the inner sphere of the host, thus giving the largest affinity of 128,000 M^{-1} in the absence of competitors for the binding site.

When the guest and host interact with the solvent, the guest binding is expected to become weaker. In the above case, both imidazole and the host (Fig. 4) can more strongly interact with ether solvents, in comparison to



Solvent	$K_a(M^{-1})$
CH_2Cl_2	240
$CHCl_3$	490

chlorinated hydrocarbons, through hydrogen-bond formation (see *Hydrogen Bonding* article for more details). Hence, the host–guest association is always much stronger in chlorinated hydrocarbons than in ethers of similar size.

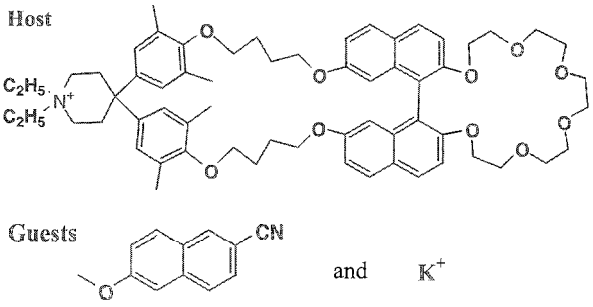
EFFECT OF SOLVENT POLARITY ON NONPOLAR ASSOCIATION

I? is also interesting to examine the solvent effect on the binding behavior of neutral nonpolar pyrene with the three-dimensional (3D) cyclophane host, as shown in Fig. 5, in a wide variety of solvents. Using this host–guest system. we can make a valuable comparison, because it was shown that in all solvents (Fig. 5) the coinplex has the same structure and geometry. and that the large cyclophane cavity is freely accessible to all solvents, assuring complete solvation.[7] The highest affinity for pyrene was observed in water and the lowest in nonpolar solvents such as benzene and carbon disulfide. A somewhat linear relationship was found between log K and the solvent polarity parameter $E_T(30)$, which was applied successfully to the interpretation of solvent effects observed for a variety of reactions and equilibria.[8]

Analogous correlations between solvent polarity and the strength of nonpolar interactions were found for other systems, such as for aromatic interactions in metal *tris*-bipyridine complexes.[9] These observations are consistent with the solvophobic nature of aromatic interactions. which is strengthened in polar solvents, lacking the ability to properly solvate to the nonpolar surfaces of the aromatic ring.

BINDING OF NEUTRAL AROMATIC GUEST VERSUS ION

Complexation of neutral hydrophobic organic guests and hydrophilic metal cations is usually characterized by different solvent dependencies. In this context. it is of interest to examine the binding behavior of the cyclophano-crown-ether host (shown in Fig. 6) in solvents of varying



Methanol content (% vol) in water	log K	
	K^+	6-Methoxy-2-naphthonitrile
40	1.1	3.6
60	1.9	2.6
80	2.0	2.1
100	3.2	1.4

Fig. **6** Interaction of potassium ion and 6-methoxy-2-naphthonitrile with cyclophane-crown ether host various water-methanol mixtures. (*View this art in color at www.dekker.com.*)

polarity.[10] Possessing crown ether and cyclophane moieties in a single molecule, the cyclophano-crown-ether host can simultaneously bind a potassium cation and 6-methoxy-2-naphthonitrile in a water–methanol mixture. Similar to the binding of pyrene by the 3D-cyclophane shown in Fig. 5, 6-methoxy-2-naphthonitrile forms a 160 times more stable complex with the cyclophane moiety in the more hydrophilic 60:40 water–methanol mixture than in pure methanol. In contrast, the affinity toward the potassium ion is enhanced 120 times in pure methanol compared to the 60:40 water–methanol mixture.

This opposite solvent polarity dependence is generally observed for solvophobically versus electrostatically driven complexation processes; see, for instance. the recent study by Mizutani et al.[11] This general phenomena is used to create a wide variety of supramolecular devices. such as molecular shuttles based on rotaxanes as well as other so-called .'molecular machines.''[12]

SOLVOPHOBIC THEORY AND SURFACE TENSION

Obviously, the simple unmodified 18-crown-6 (Fig. 7) (see *Crown Ethers* article for more details) is a better binder for potassium cation in water and methanol compared to the cyclophano-crown ether (Fig. 4). Nevertheless, the tendency of affinity is the same in both cases. Indeed, both hosts interact strongly with the potassium cation in methanol, while the affinity in water is relatively weak. The logarithm of the association constant of the potassium cation with the crown ether (Fig. 7)[13] correlates with the solvent surface tension (y), whereas the correlations with other solvent parameters such as relative permeability and dipole moment'''' are not as good. This is not the only case in which a direct correlation is observed between solvent γ and host–guest affinity. A linear correlation of ΔG° against γ was observed experimentally for several complexation reactions of cyclodextrin, e.g., indole + β-CD (1:1 complex)[15] and adainantanecarboxylate + β-CD (1:1 complex).[16]

According to the ''solvophobic theory.' originally proposed in Sinanoglu's pioneering papers.[17] the free-energy change of complex formation is regarded as a linear function of the solvent's surface tension (γ). To visualize this idea applied to the inclusion complexation of hydrophobic organic guests in CDs, one could imagine a sort of ''cavity'' or ''solvent cage'' that exists around the hydrophobic part of a guest in bulk water but disappears upon insertion of the hydrophobic part into a CD cavity. However, as is the case with the other hypotheses; the ''''slvophobic theory'' has limitations as to what it can explain, for instance, the higher complex stabilities in D_2O in comparison to H_2O are simply because the surface tension of D_2O is slightly smaller than that of H_2O.[18]

THERMODYNAMIC VIEW FOR GLOBAL UNDERSTANDING OF MOLECULAR RECOGNITION

In quantitatively discussing molecular recognition phenomena in various solvents from the viewpoint of supramolecular chemistry. it is indispensable to determine the thermodynamic parameters for the relevant (supra)-molecular system of interest. For a wide variety of chemical and biological molecular recognition systems, the thermodynamic quantities were already compiled: analyzed, and discussed in order to extract insights into the mechanistic profile of molecular recognition. However, most of the foregoing discussion and conclusions. though certainly self-consistent within the particular and closely related systems. unfortunately seem ad hoc in many cases and are not always applicable to other molecular recognition systems composed of different categories of host–guest combinations. Probably the most general thermodynamic approach to global understanding of molecular recognition is the comprehensive analysis of the compensatory enthalpy–entropy relationship observed in many supramolecular systems.

The enthalpy–entropy compensation in general has long been a hot topic in the chemical literature, because in principle. no explicit relationship between the enthalpy change and the entropy change can be derived from

Table 1 Slope (Y) and Intercept *(TASo)*of AH–TAS plots for suprarnolecular Interactions of natural and synthetic hosts with a variety of ionic. molecular. and biomolecular guests in homogeneous and heteiogeneouc solutions

fundamental thermodynamics. Nevertheless. the compensatory enthalpy–entropy relationship is often observed in activation and therinodynamic quantities determined for a wide variety of reactions and equilibria.

The linear AH–AS relationship observed experimentally leads to Eq. 2, where the proportional coefficient β has the dimension of temperature. From Eq. 2 and the differential form of the Gibbs–Helmholtz Eq. 3, we obtain Eq. 4.

$$\Delta H^\circ = \beta\Delta\Delta S^\circ \tag{2}$$

$$\Delta G^\circ = \Delta\Delta H^\circ - T\Delta\Delta S^\circ \tag{3}$$

$$\Delta G^\circ = (1 - T/\beta)\Delta\Delta H^\circ \tag{4}$$

Eq. 4 clearly indicates that, at the critical point. or so-called isokinetic or isoequilibrium temperature (β), the rate or equilibrium constant is independent of the enthalpic change caused by any alterations in substituent, solvent, and so on. It is interesting that such phenomena have been abundantly observed for a wide variety of reactions and equilibria.

ENTHALPY–ENTROPY COMPENSATION AS A PRACTICAL TOOL FOR UNDERSTANDING AND ANALYZING GUEST SOLVATION AND MOLECULAR RECOGNITION

From the compensatory enthalpy–entropy relationship, the $T\Delta S^\circ$ value can be linearly correlated with the AN^o value to give Eq. 5. When integrated. this gives Eq. 6. Subsequent combination with Eq. 3 affords Eq. 7.

$$T\Delta\Delta S^\circ = \alpha\Delta\Delta H^\circ \tag{5}$$

$$T\Delta S^\circ = \alpha\Delta H^\circ + T\Delta S^\circ_0 \tag{6}$$

$$\Delta\Delta G^\circ = (1 - \alpha)\Delta\Delta H^\circ \tag{7}$$

Thus. the slope (α) of the $T\Delta S^\circ$-versus-ΔH° plot (Eq. 6) indicates to what extent the enthalpic gain ($\Delta\Delta H^\circ$), which is induced by any alterations in host, guest, or solvent, is canceled by the accompanying entropic loss (AAS^o). In other words, only a fraction ($1r$) of the enthalpic gain can contribute to the enhancement of complex stability. On the other hand. the intercept ($T\Delta S^\circ_0$) represents the inherent complex stability (AC^o) obtained at AN^o=O, which means that the complex is stabilized even in the absence of enthalpic gain, as long as the $T\Delta S^\circ_0$ term is positive. From comparative analyses of the thermodynamic data for cation binding by three types of ionophores with different topologies and rigidities (i.e., glyme, crown ether, and cryptand),[19] the slope (α) and the intercept ($T\Delta S^\circ_0$) of the regression line were related to the degree of conformational change and to the extent of desolvation upon complexation. respectively. Using α and $T\Delta S^\circ_0$ as quantitative measures for changes in conformation and desolvation of both host and guest, diverse chemical and biological supramolecular systems can be analyzed consistently, despite the different weak interactions involved in each supramolecular system.[''']

The slopes (α) and the intercepts (TAS^o_0) obtained for a variety of supramolecular systems are presented in Table 1. It is obvious that conformational changes and desolvation

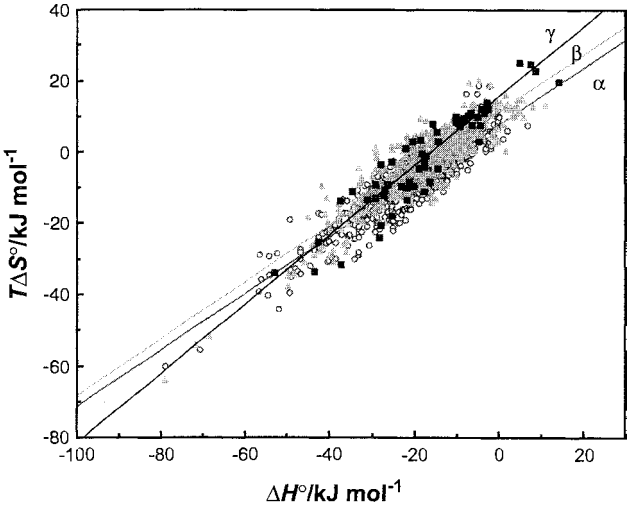

Fig. 8 Individual entropy compensation plots for natural a-, β-, and γ-cyclodextrins. (*View this art in color at www.dekker.com.*)

are much larger for the association reactions involving enzymes, antibodies, and DNA/RNA than for simple crown ethers. In accordance with that, the slope α and intercept $T\Delta S^\circ_0$ are larger for the former biological systems than for the latter synthetic systems. It should be emphasized that even closely related systems, such as cyclodextrins of different sizes (Fig. 8), can be consistently analyzed in terms of the slope α and intercept $T\Delta S^\circ_0$ as measures of the conformational changes and desolvation, respectively. The slope α and the intercept $T\Delta S^\circ_0$ increase from α-CD to P-CD and then to γ-CD in accordance with the increased conformational changes and extent of desolvation upon guest inclusion.

GRUNWALD THEORY OF ENTHALPY–ENTROPY COMPENSATION

The general concept and methodology developed by Grunwald et al.[20] provides us with a reliable tool for analyzing the complexation thermodynamic parameters and, particularly, for predicting the existence or nonexistence of meaningful enthalpy–entropy compensation in a particular set of limited thermodynamic data. The idea is based on the separation of overall complexation thermodynamic parameters into two terms: *nominal* and *environmental*. The nominal part (ΔG_{nom}, ΔH_{nom}, and AS_{nom}) is associated with the complexation of the solvated host with solvated guest to form a solvated host–guest complex. while the environmental part (ΔG_{env}, AH_{env}, and ΔS_{env}) is associated with water molecules involved in solvation/desolvation processes upon complexation. It was shown that ΔG_{env} is equal to zero in dilute solution, and thus, only AH_{env} and AS_{env} terms are subject to distinct enthalpy–entropy compensation.[21]

Recently, experimental confirmation of the Grunwald theory was achieved by comparing the qualities of differential enthalpy–entropy compensation plots for the exchange equilibrium between (*R*)- and (*S*)-enantiomers of chiral guests in β-CD's cavity (Eq. 8),[4] and the exchange equilibrium between native P-CD and 6-ammonio-6-dexoy-β-CD (am-β-CD) for chiral and achiral guests (Eq. 9):[5]

$$[\beta\text{-CD} \cdot \text{R}] + S = [\text{P-CD} \cdot \text{S}] + \text{R} \quad (8)$$

$$[\beta\text{-CD} \cdot \text{G}] + \text{am-}\beta\text{-CD} = [\text{am-}\beta\text{-CD} \cdot G] + \text{P-CD} \quad (9)$$

Differential thermodynamic parameters calculated for the hypothetical exchange equilibria (Eqs. 8 and 9) are used to build the compensation plot shown in Fig. 9a and 9b, respectively. Interestingly, despite the same accuracy level

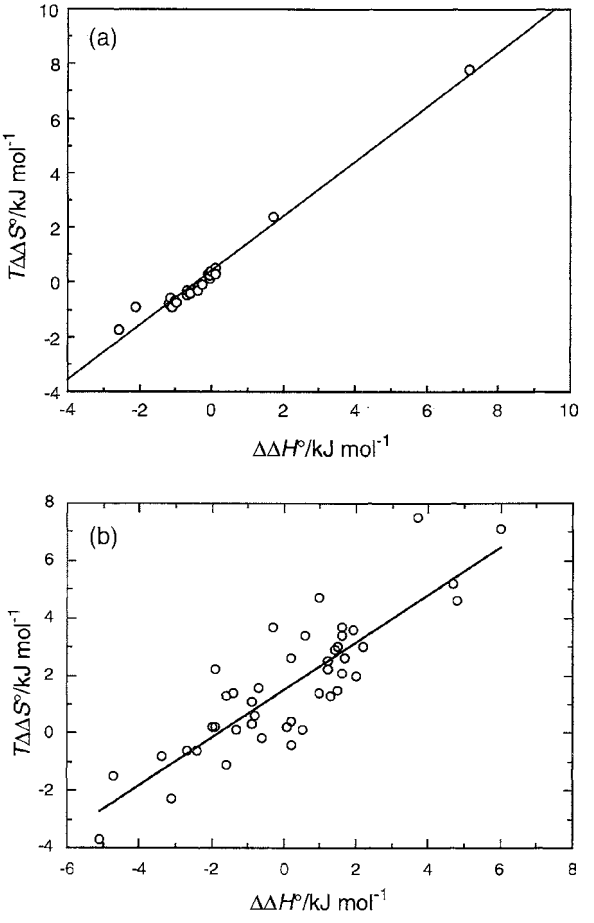

Fig. **9** (a) Compensation plot for differential entropy change ($T\Delta S^\circ_{D/L}$ or $T\Delta S^\circ_{R/S}$) against the differential enthalpy ($\Delta H^\circ_{D/L}$ or $\Delta H^\circ_{R/S}$) upon complexation of various D/L and *R/S*-enantiomeric pairs with β-cyclodextrin in aqueous buffer solution. (b) Compensation plot for differential entropy change ($T\Delta S^\circ_{am}$) against the differential enthalpy (ΔH°_{am}) upon transfer of various guests from β-cyclodextrin to 6-amino-6-deoxy-β-cyclodextrin in aqueous buffer solution.

and encompassing range of original data, the two compensation plots show strikingly different scattering levels. These compensatory enthalpy–entropy relationships are a direct experimental confirmation of the Crunwald's prediction that ΔG_{env} is equal to zero in dilute solution, and thus. only AH_{env} and AS_{env} are subject to the enthalpy–entropy compensation. It is obvious that a larger contribution from the nominal part (ΔG_{nom}, $A H_{nom}$, and $A S_{nom}$), associated with the particular complex structure, is expected for the host exchange from β-CD to am-β-CD than for the enantiomeric guest exchange in the same β-CD cavity.

CONCLUSION

It is demonstrated that, irrespective of the type of host. guest, and solvent systems employed, the solvation of the guest, host, and resulting complex plays a crucial role in supramolecular chemistry, where several weak interactions work together. However. the seemingly complicated solvation/desolvation behavior as well as the conformational changes upon suprainolecular interactions can be rationaliy understood, first by determining the thermodynamic parameters for a wide variety of chemical and biological supramolecular systems, and then by analyzing the compensatory enthalpy–entropy relationship that is frequently observed in weakly interacting supramolecular systems by applying the Grunwald theory.

Solvatochromism

Marcos Caroli Rezende
Universidad de Santiago de Chile, Santiago, Chile

INTRODUCTION

The term "solvatochrornism" describes a significant change in position or intensity of an absorption or emission band of a compound in solution, when the polarity of the medium is changed. A bathochromic (or red) shift of the absorption band with increasing solvent polarity is known as positive solvatochromism The corresponding hypsochromic (or blue) shift is termed negative solvatochromism.

Solvatochromic compounds exhibit large differences between the dipole moments of their ground and excited states. This behavior is commonly found in two families of compounds. Organic molecules where an electron-donating group is linked by a conjugated system to an electron-accepting fragment constitute the first group. Organometallic complexes composed of central metal and organic ligands with a π-electron system comprise the second important family.

Significant solvent-dependent spectral variations may also arise from self-aggregation of dyes in solution. The monomer rnay be solvatochromic. and it may not be easy to distinguish the contribution of self-aggregation to the observed solvatochrornism, especially in media where the dye is poorly soluble.

Because of their sensitivities to environmental changes. wide applications for solvatochromic compounds were found in the study of solute–solvent interactions, mainly in the characterization of bulk or microenvironments. Various polarity scales employing solvatochromic dyes as solvent probes were proposed. Because these empirical scales may be used to characterize any solvent or solvent mixture, solvatochromism played an important role in the study of a wide variety of solvent-dependent processes.

GENERAL PRINCIPLES

Spectra of a solvatochromic compound show significant shifts of absorption or emission bands in solvents of different polarities. Solvatochromism is thus a measure of the sensitivity of a compound to environmental changes, expressed by changes of its spectra in solution.[1,2] It is related with other environment-dependent spectral changes, such as thermochromisin and halochromism. In the former, spectral changes occur as a result of variations of the solvent temperature.[3,4] In the latter. spectral changes are observed by the addition of a salt to the solution. Depending on the nature of the ionic species capable of inducing absorption shifts, one may further distinguish a cationic and an anionic halochromism.[5,6]

These spectral changes may be ascribed to variations of solute–solvent interactions, when a given factor (solvent, temperature, or added salt) is changed. Because these are related processes. it is not uncommon for a solvatochromic compound to also show a thermochromic or halochromic behavior.

Solvent-dependent spectral changes are common in chemistry. However, only compounds that exhibit pronounced spectral changes are properly considered solvatochromic. A general requirement for this to occur is that large differences between the dipole moments of their ground and excited states must exist. The resulting solvatochromism may be explained in terms of the simplified scheme shown in Fig. 1.

According to the Franck–Condon principle. electronic excitation is much faster ($\sim 10^{-15}$ s) than solvent reorganization around the molecule ($\sim 10^{-12}$–10^{-10} s).

Therefore, the excited species has the same solvation pattern of its ground state. When large differences exist between the dipole moments of ground and excited states, the relative stabilities of the two solvated species change considerably with the solvent. Two possibilities exist: in case (a), the excited state of the solvatochromic compound is more polar than its ground state. Transfer to a more polar solvent has the result of stabilizing its excited state relative to its ground state. The new transition energy $\Delta E'$ is smaller than ΔE, and the cot-responding absorption band is shifted bathochromically (red-shifted) by a more polar solvent (positive solvatochromism).

Case (b) depicts the opposite situation, with a ground state more polar than the excited state of the molecule. In this case. increasing the polarity of the solvent has the effect of increasing the transition energy $\Delta E'$, and the corresponding absorption band is shifted hipsochromically (blue-shifted) in more polar media (negative solvatochromism).

This simplified scheme may be illustrated with two specific examples.[1,2,7]

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019192

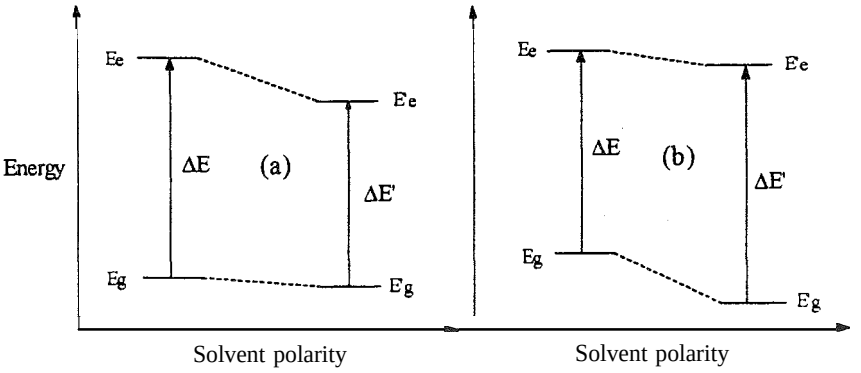

Fig. 1 The origins of positive (a) and negative (b) solvatochromism

Stilbene **1**, a hybrid of canonical structures (I) and (II), exhibits positive solvatochromism (Fig. 2). Its ground state resembles a neutral structure (I), with a calculated dipole moment of 9.85 D. Its more polar excited state, with the total electron density heavily concentrated on the acceptor fragment, has a calculated dipole moment of 23.5 D.

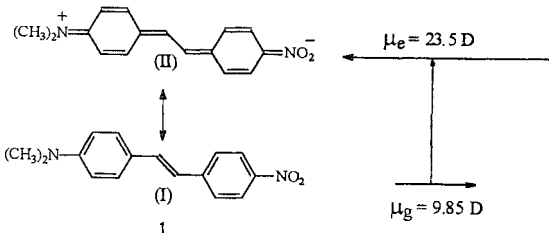
Compound 2 ($R_1 = R_2 = H$) shows an opposite behavior. Its zwitterionic ground state has a calculated dipole moment of 22.6 D, which is reduced in its quinoid, excited state to a value of 13.7 D. An increase in solvent polarity destabilizes the charge-transfer transition of this compound. shifting the λ_{max} value of its longest wavelength band hypsochromically, from 620 nm in nonpolar $CHCl_3$ to 442 nm in water (negative solvatochromism) (Fig. 3).

Similar considerations apply to the interpretation of solvatochromism in emission spectra. Here, however, the excited species may live long enough to allow for solvent rearrangement in its solvation shell. If. for example, the resulting solvated excited state has a larger dipole moment than it has in its ground state, it will be further stabilized, relative to its ground state, in a more polar environment. The emitted photon will have less energy with increasing solvent polarity, and a red shift of the fluorescence band will be observed.

Many emitting molecules may have two solvent-dependent excited states, arising from an intramolecular charge-transfer (ICT) and a twisted intramolecular charge-transfer (TICT) process. For these molecules, the existence of these two interconvertible excited states may give rise to two solvatochromic fluorescence bands.

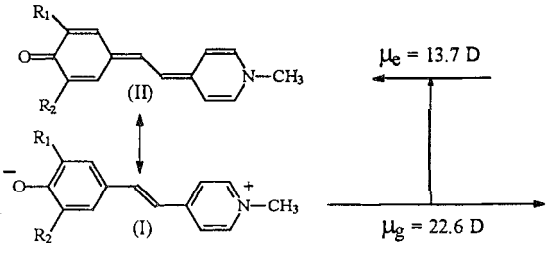
Significant solvent-dependent spectral variations may also arise from self-aggregation of dyes in solution. Monomer association gives rise to different dipolar species. according to their aggregation patterns in solution. Cyanines constitute a particularly well-studied example of such behavior.[8] The observed spectral shifts are ascribed to different aggregation patterns of the dye. *J*-aggregates generate red-shifted bands, while H-aggregates give rise to blue-shifted bands. A J-dimes results from an end-to-end stacking. in a head-to-tail arrangement. An *H*-dimer forms a sandwich-type arrangement. with a parallel plane-to-plane stacking. Several dyes form *J*- and H-aggregates in solution.

The solvatochromism of fullerene solutions was studied by several authors and constitutes an example of a difficult distinction between contributions from solute–solvent interactions of monomeric species and contributions arising from aggregation. The C-60 solutions are



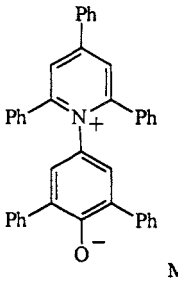
1

Fig. 2 Transition to a more polar excited state—positive solvatochromism.

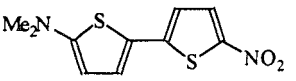


2

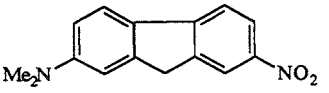
Fig. 3 Transition to a less polar excited state—negative solvatochromism.



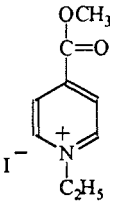
3



4

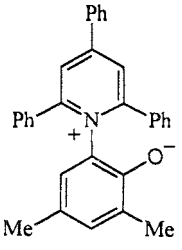


5

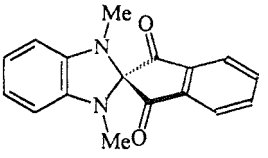


6

magenta in toluene, pink in fluorobenzene, and bluish-violet in anisol. In spite of changing color with concentration, solutions of C-60 in dimethoxybenzene follow the Lambert–Beer law, pointing to the absence of aggregates in solution.[9] Because transitions to the lowest excited states are forbidden by the highly symmetrical structure of the C-60 molecule, its spectral behavior must be ascribed to symmetry-breaking environmental interactions. The observed solvatochromism is then ascribed partly to complexation of the electrophilic C-60 molecule with π-electron-donating aromatic solvents and to the formation of aggregates.[10,11]



7

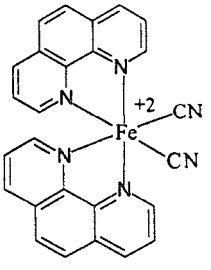


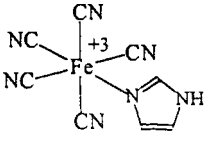
8

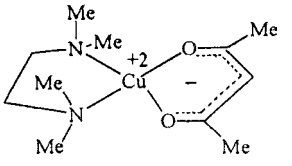
The requirements for a solvatochromic behavior are generally fulfilled by molecules exhibiting ICT excitations. Two families of compounds commonly behave in this way. The first comprises organic molecules with a donor and an acceptor fragment linked directly or through a conjugated π-system. Besides compounds **1** and 2, dyes **3–5** illustrate this general structural feature.[1,2] The ICT may also originate from the interaction of a donor–acceptor ion pair. Compound **6** is a classical example of this behavior.

Although coplanarity of the donor and acceptor fragments might be expected to be necessary for full conjugation and ICT. there are examples of solvatochromic compounds where these fragments are practically orthogonal. X-ray diffraction analysis of the strongly solvatochromic betaine **7** yielded a dihedral angle of 90° between the donor phenoxide and the acceptor pyridinium moieties of the molecule.[12] The CT band of the spiro dye 8, where donor and acceptor groups are mutually perpendicular, showed pronounced solvatochromism.[13]

A second important family of solvatochromic compounds comprises organometal complexes with ligands possessing a π-electron system.[1,2] The spectra of these cornpounds may exhibit more than one solvatochromic band. Two distinct processes may give rise to solvatochromism: a metal-to-ligand charge transfer (MLCT), where charge is transferred on excitation from the metal donor to an acceptor ligand, and a ligand-to-metal charge transfer (LMCT), where the opposite situation occurs. Compound **9** is an example of the former, and compound **10** is an example of the latter. The solvato- and halochromism of **11** arises from a transition from a square-planar to an







10

octahedral geometry. by interaction with an axial donor solvent or anion.[14]

THEORETICAL TREATMENTS

When developing theoretical models with which to interpret and predict the solvatochromic behavior of molecules. a distinction must be made between specific and nonspecific effects. The former are caused by specific interactions, such as complexation or hydrogen bonding with the solvent. The latter is a sum of different solute–solvent dielectric interactions.[15]

When only nonspecific effects are responsible for the solvatochromic behavior, the change of the molecule dipole moment upon excitation may be estimated from a continuum model.

For fluorescent molecules in nonpolar solvents of the same refractive index, solvatochromic shifts are governed by the change of the molecule dipole moment $\Delta\mu_{ge}$ and by a solvent polarity function $f(D)$, which depends on the static dielectric constant D of the medium.

$$f(D) = 2(D-1)/(2D+1) \tag{1}$$

For solvatochromic shifts between solvents 1 and 2, Eq. 2 applies, where $\Delta(E_{\text{flu}-\text{abs}})_{1-2}$ is the energy difference between the fluorescence and the first absorption bands, a_o is the radius of the solute molecule, and $\Delta f(D)_{1-2}$ is the difference between the polarity functions of the two solvents. This relationship. originally derived by Lippert,[16] allows for the calculation of $\Delta\mu_{ge}$:

$$\Delta(E_{\text{flu}-\text{abs}})_{1-2} = -(\Delta\mu_{ge})^2 a_o^{-3} \Delta f(D)_{1-2} \tag{2}$$

According to the McRae formalism,[17] the solvatochromic shifts in absorption frequencies of a molecule may be expressed as follows:

$$\nu_{\text{solv}} - \nu_{\text{vac}} = A[(n^2-1)/(2n^2+1)] + B[(\varepsilon-1)/(\varepsilon+2) - (n^2-1)/(n^2+2)] \tag{3}$$

where ν_{solv} and ν_{vac} are the frequencies of transition (s^{-1}) in a solvent and in the vacuum, respectively; n is the refractive index: ε is the dielectric constant of the solvent; and A and B are constants. The slope B may be obtained from a plot of transition frequencies in a series of solvents, and the excited-state dipole moment μ_e is estimated with the aid of the following relationship:[7]

$$B = 2[\mu_g(\mu_g - \mu_e \cos\phi)]/4\pi\varepsilon_o h a_o^3 \tag{4}$$

where ε_o is the permeability of the vacuum. h is Planck's constant. a, is the radiur of a spherical cavity occupied by the solute. μ_g is the ground-state dipole moment of the molecule, and ϕ is the angle formed by vectors μ_g and μ_e. The value of ϕ is often assumed equal to 180°.

Quantum chemical methods were employed with variable success in theoretical studies of solvatochromism.[18,19] Electronic transition energies of molecules in the gas phase may be calculated by ab-initio and semiempirical methods. The latter are more frequently used because of their much smaller computational cost and also because of the existence of programs. like CNDO/S and INDO/S, that were parametrized for spectral studies. Calculation of solvent effects poses a major problem in the prediction of solvatochromic shifts. Several methods exist that are based on a continuum model, where changes in the electronic levels of the molecule are treated as perturbations by the solvent dielectric constant. This model was extended to include the effect of an added salt.[20] Alternatively, the bulk solvent may be replaced by point charges.[21,22]

None of these treatments is capable of reproducing specific solute–solvent interactions, which become increasingly important in more polar, or in protic solvents. In this case. one has to resort to calculations involving supramolecules. formed by solute–solvent complexes.[23]

SOLVATOCHROMISM AND SOLVENT POLARITY

The use of solvatochromic compounds as polarity sensors in a variety of environments constitutes one of the most important applications of these molecules. Solvent polarity scales were designed that rely on the solvatochromic behavior of one or a set of compounds.[1,2]

In order to be a useful polarity indicator. a solvatochromic dye should meet a number of requirements. It should be easily available, stable on storage and in solution, soluble in extremely polar and nonpolar solvents. with a range of solvatochromic shifts as large as possible. High absorptivities should allow for the use of dilute solutions, so as to discard the possibility of aggregation. This last requirement is considered fulfilled if all solutions follow the Lambert–Beer law.

One of the first examples of a polarity scale based on a solvatochromic probe was Kosower's Z values.[24] defined as the transition energy of the longest wavelength absorption band of dye 6.

Transition energies of betaine 3 were used as the bases of the widely employed E_T (30) scale.[1,2] Its negatively solvatochromic charge-transfer absorption band is shifted by ca. 360 nm on going from diphenyl ether ($\lambda_{\max} = 810$ nm) to water ($\lambda_{\max} = 453$ nm). This high sensitivity prompted its use as a polarity indicator for over 350 pure solvents. besides a variety of solvent mixtures; micellar systems; and electrolyte solutions.

The large number of empirical polarity scales derived from solvatochromic sensors raises the question of the degree of correlation among them. In principle. there is no reason to expect a correlation between any pair of these einpirical scales. The solvatochromic behavior of a given compound reflects a sum of specific and nonspecific solute–solvent interactions that vary from probe to probe. Good correlations are to be expected only between scales based on solvatochromic compounds that present a similar response to a range of solvents. As a result of this, the concept of solvent polarity is elusive and the claims of a universal polarity scale based on solvatochromic probes cannot be maintained. Different solvents may assume different polarity values, according to the nature of the scale employed to define them.

One approach aimed at overcoming this relativity is the definition of polarity as a weighted sum of contributions from more specific effects. This approach, originally introduced by Kamlet, Abboud, and Taft,[25] distinguishes a hydrogen-bond donor, or acidity contribution (α values): a hydrogen-bond acceptor. or basicity contribution (β values); and a dipolarity-polarizability contribution (π^* values) of the solvent. Various probes were proposed for the measurement of these values. according to their nature as sensors for a given contribution. In order to isolate a particular effect. sets or pairs of homomorphic compounds are sometimes employed. Homomorphs are molecules that have the same, or closely similar geometries. and similar spectral responses. The spectral differences between a pair of hoinomorphs are due to the fact that one is capable of interactions with the solvent that should be absent. or nearly absent with the other. A cornparison of their spectra allows a distinction to be made between solute–solvent interactions that are shared by both probes, from those interactions characteristic of only one compound. An exainple of such a pair, employed to build a scale for acidity values, is the *o-tert*-butylstilbazolium betaine DBSB (2. $R_1 = R_2$ = t-butyl) and its homomorph TBSB (2. R_1 = t-butyl, R_2 = H), which were used in the classification of 121 organic solvents.[26] A comparison of the spectra of TBSB, a basic probe capable of interactions with hydrogen-bond-donor solvents. with DBSB, a homomorph where these interactions are absent because of the steric hindrance of the two t-butyl groups, allows for the quantification of the specific contribution of solvent acidity to the observed solvatochromism of the two probes.

The iron complex **9** is another example of a probe for solvent acidity. whereas the planar copper complex **11** was proposed as a basicity or β sensor.[27]

Compound 4, which displays large positive solvatochromic shifts and good solubility in a wide range of solvents. was proposed as a π^* probe.[28] Another example involves the homomorphic pair 2-(dimethylamino)-7-nitrofluorene (**5**)/2-fluoro-7-nitrofluorene that were suggested to be the basis of a solvent dipolarity-polarizability (SPP) scale.[29]

The use of solvatochromic compounds as polarity indicators may be extended to solvent mixtures and micellar systems. In this case, an additional difficulty is introduced in the assessment of systems that are not homogeneous from a microscopic point of view. The microenvironment actaally "seen" by the sensor does not correspond to the bulk characteristics of the medium. In a binary solvent mixture, a solvatochromic probe may be more solvated by one of the components, thus reflecting through its spectrum a solvent composition that may be different from that of the bulk mixture. In micellar systems. the solvatochromic response of a probe reflects the nature of its microenvironment and is dependent on the relative solubility of the sensor in the aqueous or the organic pseudophases, or in the micellar interphase.

APPLICATIONS **AND** FUTURE PROSPECTS

The use of solvatochromic compounds for characterizing common laboratory solvents was extended to other media. such as liquid organic salts[30] and supercritical solvent systems.[31] Solvatochromic probes were widely employed in the characterization of microenvironments. such as the interphase of micellar systems.[1,2]

By adsorbing or chemically binding a solvatochromic compound to a solid matrix. its surface polarity may be estimated, thus extending the applications of these compounds to the solid phase. A few examples include the evaluation of the surface polarity of various silicas[13] and polysaccharides.[33]

In the design of new materials for optical devices. crystal soivatochromism plays an important role in understanding intermolecular interactions in the solid phase.[34]

The field of nonlinear optical (NLO) materials constitutes another area of research related to the synthesis of solvatochromic compounds. Asymmetric molecules possessing donor and acceptor substituents linked by a π-backbone exhibit large hyperpolarizabilities, being potential candidates far NLO materials with interesting properties.[7] It is, therefore, not surprising that many solvatochromic dyes also exhibit NLO properties. Solvatochromism is an important property in the design of NLO-functionalized macromolecules.[7,11]

The development of chiro-solvatochromic compounds should lead to interesting applications. These probes should be capable of distinguishing pairs of enantiomers, as a result of stereoselective interactions. giving rise lo significant spectra! differences between solutions of the diastereomeric complexes. One may envisage simple and fast methods for the determination of the enantiomeric

purity of chiral compounds. based on the visual inspection of chiro-solvatochromic dyes. Such compounds might also present interesting chiroptical properties. So far, attempts to prepare such probes yielded solvatochromic compounds with little sensitivity to the chiral environment.[1,2,36,37]

CONCLUSION

The phenomenon of solvatochromism has caused a wide range of applications to be directed in chemistry, in the study of solute–solvent interactions. The design of new molecules with increased solubility and sensitivity to environmental changes will probably remain a subject of interest in the future, especially as probes in less-developed areas, such as, for example, the solvatochromic discrimination of a chiral environment. Theoretical approaches to the problem of describing the influence of the medium on the spectral behavior of these compounds will benefit from the availability of faster programs and computers. Finally, research on the solvatochromism of organic and organometallic compounds will remain an area of active interest, because of its connections with the development of new nonlinear optical materials.

Space Groups and Crystal Packing Modes

Chick C. Wilson
University of Glasgow, Glasgow, United Kingdom;
Central Laboratory of the Research Councils (CLRC) Rutherford Appleton Laboratory, Oxon, United Kingdom

INTRODUCTION

The internal symmetry of a crystal structure is described. The concepts of the unit cell and lattice are developed, leading naturally to a definition of symmetry elements and, hence. to the crystallographic space groups. The relevance of space groups and symmetry elements to the formation of the extended networks found in supramolecular chemistry is summarized. A discussion of common crystal packing modes follows, and the relevance of space group symmetry is discussed in this context.

THE CRYSTAL AND ITS INTERNAL SYMMETRY

The regularity of a macroscopic crystal gives a clear indication of the underlying construction. which describes the crystal structure as a convolution between the lattice. a conceptual array of points in space. and the motif (or basis). the structural unit repeated regularly at the lattice points. That is, the motif is placed at each lattice point in turn, the resulting function (the crystal structure) being the cumulative result of this folding together of the two components.

The geometry of the lattice is governed by crystallographic unit cell, a parallelepiped uniquely defined by six parameters: the lengths of the cell edges (a, b, c) and the angles between these (α, β, γ) (Fig. 1). The parallelepiped chosen is generally the smallest (or occasionally some more convenient) volume containing the unique structural component in the crystal. Repetition of this unit by translation through space forms the crystal. The unit cell contains the structural motif. The origin of each unit cell sits at one of the conceptual lattice points.

The Lattice

Replicating the unit cell through space along the directions of the three axes of the paralellepiped forms the complete crystal. containing all structural components. This is shown in Fig. 2, where one unit cell is shown to sit at each of the conceptual arrays of lattice points.

With the unit cell and lattice constructed, the remainder of the geometry of crystallography follows. For example, we can define sets of lattice planes according to the intercept of a plane within the unit cell with the three axes of the parallelepiped (Fig. 3). The lattice planes are defined by the Miller indices (hkl), where *hkl* are defined in terms of their intercept with the a, b, and c axes, respectively. The plane intercepts the *a*-axis at the position alh. the 0-axis at the position blk, and the c-axis at the position *c/l*. There are equivalent parallel lattice planes passing through all translationally related points in the lattice, and the set of lattice planes of this type is denoted (hkl). The related lattice direction [*hkl*] is the direction parallel to the line through the origin and the point (*ha*, kb, *lc*). For a cubic crystal, the [hkl] direction is perpendicular to the (hkl) planes. A considerably fuller description of geometrical crystallography is available in many other places.[1–7] It is worth mentioning at this point that the unit cell is bounded by the planes (100). (010), and (001), obvious from a brief study of Fig. 3.

The lattice is defined not only by the unit cell, principally by its external dimensions (defining the crystal system), but also by aspects of its internal constitution (defining the lattice type) and symmetry within the unit cell. There are seven crystal systems: triclinic. monoclinic. orthorhombic. tetragonal, cubic. trigonal, and hexagonal. These are defined on the basis of the external geometry of the unit cell. The constraints defining the crystal system can easily be summarized:

Crystal system	*Constraints on cell dimensions*
Triclinic	$a \neq b \neq c$; $\alpha \neq \beta \neq \gamma \neq 90°$
Monoclinic	$a \neq b \neq c$; $\alpha = \gamma = 90°$, $\beta > 90°$
Orthorhombic	$a \neq b \neq c$; $\alpha = \beta = \gamma = 90°$
Tetragonal	$a = b \neq c$; $\alpha = \beta = \gamma = 90°$
Cubic	$a = b = c$; $\alpha = \beta = \gamma = 90°$
Trigonal	$a = b \neq c$; $\alpha = \beta = 90°$, $\gamma = 120°$ or $a = b = c$; $\alpha = \beta = \gamma < 120°$
Hexagonal	$a = b \neq c$; $\alpha = \beta = 90°$, $\gamma = 120°$

The internal structure of the unit cell also plays a role in the definition of the lattice type. Unit cells containing a

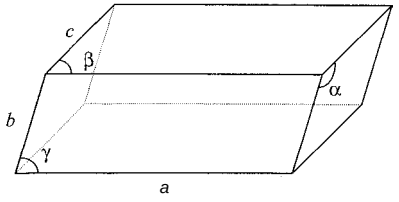

Fig. 1 The parallelepiped model used for a unit cell. The example shown is for a skew (triclinic) unit cell. with all lengths different and all interaxial angles non-90". The majority of unit cells found in nature are more regular than this example.

single lattice point are termed primitive. denoted **P.** Under certain circumstances: it is convenient to introduce unit cells that contain more than one lattice point. Such unit cells are called nonprimitive, and in general, the practical advantages to be gained from using nonprimitive unit cells can far outweigh the disadvantage of the larger unit cell volume.

Such nonprimitive or centered cells can occur in all crystal systems higher than triclinic and introduce an extra seven lattice types to those already defined by the crystal system. The conventional types of nonprimitive lattice are C-centered (C), with an extra lattice point in the center of the (001) face at unit cell position ($^1/_2,^1/_2$,0); body-centered **(I),** with an extra lattice point at the unit cell center at ($^1/_2,^1/_2,^1/_2$,); face-centered **(F),** with extra lattice points in the center of the unit cell faces at positions ($^1/_2{}^1/_2$0), ($^1/_2$0$^1/_2$), (0$^1/_2{}^1/_2$); and the rhombohedrai *R* setting of the trigonal lattice. There are also nonstandard settings of these, such as A-centered monoclinic cells, but these do not represent distinct lattice types.

There are thus 14 possible lattice types, termed the Bravais lattices:

Crystal system	*Lattice type*	*Number of lattice points*
Triclinic (one Bravais lattice)	P	1
Monoclinic (two Bravais lattices)	P	1
	C (or A)	2
Orthorhombic (four Bravais lattices)	P	I
	C (or A or B)	2
	I	2
	F	4
Tetragonal (two Bravais lattices)	P	1
	I	2
Cubic (three Bravais lattices)	P	1
	I	*2*
	F	4
Trigonal (one Bravais lattice)	R	3 or 1
Hexagonal (one Bravais lattice)	P	1

Symmetry Elements and Space Groups

Further symmetry occurs within the unit cell. This internal symmetry introduces relationships among the unit cell contents and can be due to rotation, reflection, and combinations of these with fractional translations. The internal symmetry of the unit cell allows the complete description of the entire contents on the basis of a unique structural unit, the asymmetric unit. Applying the internal unit cell symmetry to the asymmetric unit, followed by imposition of the lattice structure, leads to a complete description of the crystal.

The internal symmetry elements of the unit cell are of two types (Fig. 4): those involving purely reflections and rotations (symmorphic elements — mirror planes and rotation axes), and those additionally involving translational components (nonsymmorphic elements — glide planes and screw axes).

When the symmetry elements are introduced into the possible lattices, the symmorphic elements combine to yield a total of 32 so-called point groups, while inclusion of symmorphic and nonsymmorphic elements leads to the 230 crystallographic space groups. Space groups. symmetry elements, and other aspects of crystal symmetry are tabulated in great detail in the International Tables for Crystallography.[8]

CRYSTAL PACKING MODES

The periodicity conferred by the crystallographic symmetry described above also, of course, plays a major role in governing the intermolecular interactions that are so important in supramolecular chemistry. We now consider the implications for crystal packing modes. Crystal packing modes is a term used to describe the packing of molecular units inside a crystal structure. Specifically, the aim of their study is to find common patterns, with the aim of understanding, classifying. and potentially predicting the way in which these molecular units will pack to form crystal structures.

Crystal packing is governed by the interinolecular interactions between molecules, whether ionic, hydrogen bonds or other weaker nonbonded contacts. These intermolecular interactions are, in turn, governed by the relative disposition of molecules in the crystal, more often than not a consequence of the space group symmetry. An exception to this is when there are intermolecular interactions between distinct molecular units in the unit cell, usually in crystal structures with more than one formula unit in the unique part of the unit cell ($Z' > 1$).

There have been many attempts to categorize crystal packing modes and their implications for understanding and potentially predicting patterns of intermolecular

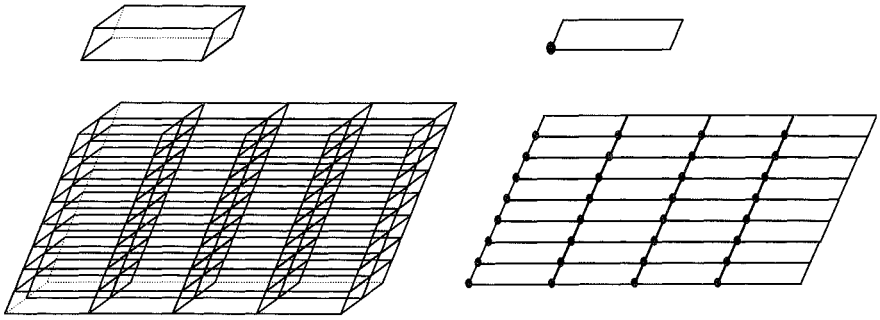

Fig. 2 The construction of a crystal from its unit cell (left) in three dimensions and (right) a two-dimensional projection, also showing the lattice points.

interactions, supramolecular assembly, and hence. crystal structures; from the earliest days of molecular crystallography.[1] The work of Kitaigorodskii[10,11] represented some of the earliest attempts at gaining insight into crystal packing via systematic studies of organic crystal structures. This included an enunciation of the principles of close packing and also set the initial framework for systematic analyses of crystal packing, using. for example, the Cambridge Structural Database,[12,13] which now contains over 250,000 organic crystal structures.

Several methods were adopted in attempting to describe and understand crystal packing and its implications for supramolecular chemistry. These include studies of commonly occurring intermolecular motifs, surveys of crystallographic databases. examinations of space group frequencies. analytical and predictive studies of simple molecular compounds and classes of molecules, and lattice dynamical and other computational/theoretical methods. The area was surveyed recently in the context of crystal packing[14] and its relation to supramolecular chemistry and crystal engineering discussed in many review articles. The latter subject is covered elsewhere in this volume, but is intimately related to the subject of this article. This is evident from the fact that the field of crystal engineering depends upon understanding the nature of intermolecular forces and their role in assembling molecular building blocks into extended structures and architectures.[15] A definition of crystal engineering by Desiraju brings home clearly this link between the topics. This definition of crystal engineering is "the understanding of intermolecular interactions in the context of crystal packing and in the utilisation of such understanding in the design of new solids with desirable physical and chemical properties."[16]

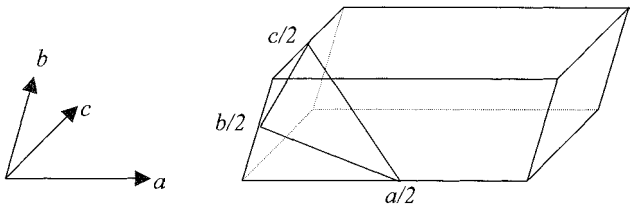

Fig. 3 A lattice plane and definition of its Miller indices. The plane shown intercepts halfway along each axis. It is described by the Miller indices according to $(a/2, b/2, c/2) = (a/h, b/k, c/l)$. This is. therefore, the (222) plane.

Commonly Occurring Intermolecular Motifs

Because the aim of supramolecular chemistry is to predict and control the arrangement of neighboring molecules or motifs by intermolecular forces, an understanding of how specific commonly occurring functional groups or motifs are likely to interact in the crystalline environment is important. Some of the earliest but still highly relevant studies in this area were carried out on carboxylic acids[17] and on primary[18] and substituted[19] ainides.

For carboxylic acid structures,[17] it is clear that for monocarboxylic acids, cyclic hydrogen-bonded pairs are the motif of choice (for achiral or racemic compounds: these are often generated by a syminetry center), while chains linked by O—H···O linear hydrogen bonds are also common. For chiral monocarboxylic acids, a chain motif is often formed along a twofold screw axis. Dicarboxylic acids tend to form chains in which the cyclic dimeric pair acts as the linking motif along the chains. In the other dimension. these carboxy-group-containing molecules tend to stack with neighboring units offset along either the C=O or C—OH bond direction. There also tend to be interplanar contacts via antiparallel arrangements of C—O bonds.

For amides R-$CONH_2$, the molecules generally form hydrogen-bonded rings linked by a pair of C=O···H—N hydrogen bonds that are then linked in several ways—by translation via NH···O bonds. by glide planes. or by a twofold screw axis. In cases where the dimer is not formed. helical motifs can be formed about a 2_1 screw

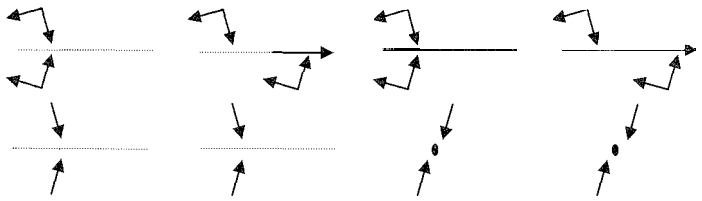

Fig. 4 The effect of four types of symmetry elements in elevation (upper) and projection (lower). From left to right are a mirror plane. a glide plane. a twofold rotation axis. and a twofold screw axis.

axis. and the molecules can also pack via a combined 2_1 axis and a translation axis (of length -5 Å) and by a hexameric, rhombohedra1 crown arrangement. For the diineric groups, parallel and antiparallel ribbon planes can be formed in the crystal packing. as can nonparallel ribbon planes. The detailed description of the formation of such motifs is given in the work by Leiserowitz and Hagler,[19] which also emphasizes the general principles of construction of crystal packing modes via various space group symmetry elements.

These two representative examples illustrate the type of general principle one seeks in trying to quantify crystal packing modes. They also illustrate the need for simple, general ways of classifying the ways in which molecules link together. Of several schemes advanced for such classification, perhaps the most widely applied currently is the graph set description of hydrogen-bonding motifs,[20] of particular relevance in supramolecular chemistry. as hydrogen bonds are frequently the sources of intermolecular interactions. In trying to look for similarities in patterns of crystal packing. it is also useful to have a means of classifying identical or similar organic molecules. This problem was tackled by Malman et al.[21] with their definition of isostructural systems (identical packing motifs of isometric. necessarily closely similar. molecules) and homeosrructural systems (similar packing motifs of nonisomeiric molecules). In a similar vein is the extensive body of work of Zorky et al.[22] This worli involved the concept of structural class as a descriptor of molecular packing arrangements in crystals. going beyond the normal definition of the space group in reflecting the topology of the molecular crystal.

Database Surveys and Space Group Frequencies

The Cambridge Structural Database (CSD)[12,13] contains deposited information from over 250,000 organic and organometallic crystal structures, and this can be extracted (mined) using powerful search tools, including fragment [one-dimensional(]-D), two-dimensional(2-D). and three-dimensional(3D)], unit cell and space group searches. These allow trends within motifs to be identified and followed, along with frequencies of occurrence of space groups. etc.,[22–24] and the implications of these for the formation of intermolecular interactions and supramolecular structures. Among the general conclusions of such surveys[1,2] are that space groups containing mirror planes occur if ail the mirror planes are occupied,[23,24] and that among rotation axes, only twofold axes are common in molecular systems.[23,25] The presence of inversion centers also tends to be favorable for crystal packing.

Among the 230 possible space groups. it is found that few are occupied with any great frequency among molecular crystal structures. For example, over 80% of structures in the CSD occur in the seven most common space groups: $P2_1/c$, $P1$, $P2_12_12_1$, $P2_1$, $C2/c$, Pbca. and Pnma.[26] However, space group frequencies depend on the type of compound in the crystal. as the intermolecular interactions will vary, governing the packing. For example, more ionic compounds, salts. and solvates are most likely to crystallize in high-symmetry space groups. Wilson found that normally. the relative frequency of occurrence of molecular compounds in particular space groups is governed by the ease of packing.[24] The presence of internal molecular symmetry and of symmorphism (lack of screw axes and glide planes) is an additional factor to take into consideration in such studies.

A further conclusion is that the occurrence of structures with $Z' > 1$ tends to be low. and the percentage of structures with this property tends to increase as the symmetry of the space group decreases, being most common in space group Pi. When there is more than one crysiallographically independent molecule in a unit cell. these molecules tend on the whole to have similar conformations.[27,28]

It is possible that as the number of structures in the CSD increases. general einpirical rules may become apparent that help predict particular packing patterns for certain types of molecules. Clearly, the principle of close packing (cosresponding to an energy minimum in the crystal) will always be important in governing the pacliing adopted. The principles of closest packing in molecular crystal structures are well illustrated by studies of the

distribution of molecular centers in crystallographic unit cells.[26] In these, there is a tendency for the preferred locations of these centers to cluster around positions between centers of symmetry or screw axes. Such studies also indicate the wide occurrence of layers of molecules and confirm the importance of close packing.

Studies of Simple Molecular Compounds

The study of crystal packing modes in simple molecular systems has long been seen as a tractable approach to quantifying the interactions underlying the adoption of packing patterns. Given their relatively simple shapes. fused ring planar aromatic hydrocarbons are an obvious case to choose, and these were studied on several occasions. The early work in this area[9,29,30] was extended in a series of studies by Gavezotti and Desiraju.[31,32] These studies examined the energetic and geometric factors controlling the packing of such condensed aromatics, using atom–atom and molecular–molecular packing energy calculations. It is found that the structures can be characterized in four structural types, called Herringbone, Sandwich-Herringbone, γ (a flattened Herringbone), and β (graphitic-like planes), which is determined by the relative orientation of molecular planes in the crystal. The major motifs present are built from stacks and glides of molecules.

The adoption of a particular structure type is found to depend on the relative importance of different intermolecular interactions — part of the molecule being likely to result in stack formation (C···C interactions) and part in the formation of glides (C···H interactions). In these simple molecules, some degree of prediction was found to be possible based on the assignment of a ''stacking'' ability or ''glide-forming'' ability to each atom in the molecule: equivalently, an overall molecular size/shape descriptor can be defined.

This work was extended to a study of the general crystal packing of hydrocarbons,[33] in which the correlation of packing energy with various parameters defining the molecular size/shape is exploited. These parameters include the total number of atoms. the number of carbon and hydrogen atoms. the van der Waals envelope volume and surface, the molecular mass, and the number of valence electrons. The best correlation is found to be between the packing potential energy and the number of carbon atoms in the molecule. A self-packing coefficient can be defined that describes the ''smoothness'' of the molecular envelope. high values of which tend to improve packing energy. More complex structures subjected to such packing analysis include those containing hexafluorobenzene or fluoranil,[34] nitrobenzene derivatives,[35,36] and the carboxylic acids and amides discussed

Computational/Theoretical Approaches

In addition to the packing energy calculations discussed above, there are many other examples of computational methods being used to quantify or interpret crystal packing modes. These included studies on the discrimination of the energies and stabilities of racemic crystals from equivalent chiral structures[37] and on the influence of directional molecular dipole interactions on crystal packing (in fact, this is found not to be as significant as was commonly supposed[38]). Recent systematic work on predicting the packing of paracetamol molecules showed the sensitivity of lattice energy minimization calculations to variations in the observed molecular structure.[39] Calculations were also used in studies of the important phenomenon of polymorphism — in particular, in this context: on the differing crystal packing modes that may be adopted by polymorphic forms of the same molecules.[40] It is found that many plausible structures have energies within a few $kJ.mol^{-1}$ of the global minimum, emphasizing the difficulty of reliable crystal structure prediction. The possibility of reducing the number of plausible predicted structures using calculations of other, macroscopic, properties was investigated.[41]

A related topic is the use of observed molecular conformation and crystal packing patterns for the deduction of possible mean molecular geometries, reaction pathways, and transition states. This so-called structure-correlation method[42] makes the assumption that observed molecular structures tend to adopt conformations and packing motifs that are close to low-energy regions in the solid state. These are, however, by no means fully quantitative[39] and, in particular, quantitative deductions from molecular conformations in different structural environments are not established. This point is emphasized in a study of the systematics of crystal packing in biphenyl structures.[44] in this case, close-to-planar conformations are found in crystal structures more often than would be expected — the effects of crystal packing would tend to favor this ''distortion'' to an apparently higher energy molecular conformation in a range of environments. However, there is a notable increase in dynamic and static disorder in these ''planar-distorted'' structures.

CONCLUSION

The study of crystal structure remains a vital underpinning component of much research in supramolecular chemistry in the solid state. The implications of crystallographic

symmetry for the solid-state packing of molecular systems are complex, with competing intramolecular, intermolecular, and lattice effects. The systematic study of crystal-packing modes yields vital clues about the relative influence of each of these on molecular association. and thus, toward a fuller understanding of crystal packing and crystal structure and the eventual goal of their prediction.

Spherands

john C. Sherman
University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

Soon after crown ethers came on the scene as the first synthetic host molecules capable of binding guests, cryptands followed, and soon thereafter, the spherands. The preorganization of these three classes of molecules follows the order of their invention, as does overall binding affinity, i.e., crowns<cryptands<spherands. Spherand **7** (Chart 1) is the prototypical spherand, but there are a number of subfamilies that will be discussed. Donald J. Cram, 1987 Nobel Laureate, was the creator of the family of hosts that he named spherands. The spherand story began shortly after the genesis of supramolecular chemistry, and it demonstrates how quickly the field matured. as complex syntheses and methods of characterization enhanced the rapid sophistication of host–guest chemistry.

PREORGANIZATION

The topic of preorganization is discussed in a separate article, and spherands were used there as an example of this principle. A further example is given here. Shown in Chart 1 are the structures of hosts, starting from a simple crown ether (**1**) and progressing to Spherand **7** via successive replacement of an aliphatic ether group with rigid anisole units (**2**–**7**). In Table 1, the binding free energies for selected cations are given.[1] Although guest selectivity changes (the anisole units are larger and create a smaller cavity), the general trend is still marked: increased preorganization increases overall binding affinity for the most strongly bound guest. Note that this is despite the sacrifice in ligand strength. That is, aryl ethers are poorer electron donors than aliphatic ethers due to delocalization of the lone pairs into the aromatic rings. The enhanced

Table 1 Binding affinities ($\Delta G°$, kcallmol) for guests by hosts in $CDCl_3$ saturated with D_2O at 25°C

Host	Li^+	Na^+	K^+
1	6.3	8.4	11.4
2	5.5	6.4	8.5
3	6.5	8.7	7.5
4	7.2	12.2	11.7
5	7.2	13.5	10.7
6	12.8	14.4	10.4
7	>23	19.2	

preorganization of the anisole groups more than compensates for this electronic loss, once the effect of preorganization kicks in at three anisole units.

SYNTHESIS

The highly strained spherands took great synthetic effort to bring to fruition. Cram had to invent a reaction to couple arenes in an efficient manner. The key development was the use of $Fe(acac)_3$ as the coupling agent. Thus, for example, spherand **1**·Li^+ could be prepared starting from arene **8**, *bis*-arene **9**, or *tris*-arene **10** (Chart 2), in 3, 7.5, and 28% yields, respectively, as follows: 1) BuLi; 2) $Fe(acac)_3$; 3) EDTA; and 4) HCl. Decomplexation to give free spherand **1** was achieved by heating the Li^+ complex in H_2O/MeOH at 125°C.[2]

CHARACTERIZATION

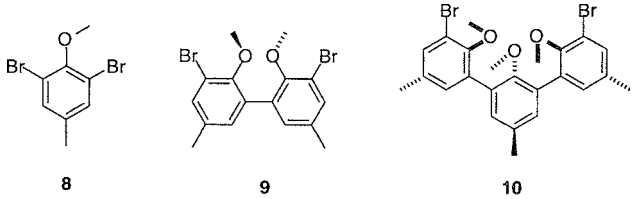
Spherands and their relatives are characterized like any organic molecule, largely by NMR and mass spectrometry, as well as by elemental analysis. The key binding experiment used to determine the free energy of complexation of cations is typically done via a picrate extraction procedure developed by Cram.[''] Picrate salts of the cation in question were partitioned along with the host between $CDCl_3$ and D_2O. The partition of the picrate, and thus the cation, was determined by UV/Vis spectroscopy. Thus. equilibrium constants and free energies of complexation were generated. This method is effective for binding energies in the range of 6–16 kcallmol. Beyond that. competition experiments are needed between the host in question with a host with known binding properties. In addition, rates of complexation and decomplexation were used to yield free energies of binding.[''''']

Another key tool for characterization of spherands and related species is x-ray crystallography. This is the definitive method for deriving structural information. Numerous structures of free and complexed hosts were obtained for this family of compounds. Such structures make it clear just how preorganized a host is and how significantly it is solvated. They also clearly depict the size and shape of the cavity.

Another crucial element in host–guest characterization is modeling. This is, of course, critical in the design stages, but there is an iterative process of design and characterization. Cram's key here was the use of CPK molecular models. Nothing can replace the visual effect of holding a physical model in your hands. Cram spent considerable time studying models and calibrating himself using the binding data and crystal structures he had at hand. With experience, binding energies could be predicted within a few kcallmol using CPK models. Even strain energy could be appreciated, as some models needed to be shaved to be built. Strain was also evident from analysis of crystal structures, as adjacent oxygens were often closer than the sum of their van der Waals radii (and had to be shaved in CPK models). In addition, the arene carbons and their substituents deviated up to 10° and 0.5 Å from the plane of the ring.[6] Such strain was largely relieved upon complexation of cationic guests, as **O—O** repulsion was eliminated.[6] The glut of data and the highly preorganized nature of spherands made them an attractive system for computational chemists to hone their force fields for supramolecular applications.[7]

CLASSES OF SPHERANDS

The closest member of the spherand family to the prototype (i.e., **7**) are the bridged spherands such as **11** (Chart 3).[2] Bridges of different lengths could be incorporated, even those containing an extra oxygen. The bridges could be *syn* or *anti*. as could the two methyl groups on the remaining anisoles. These bridges change the size and shape of the cavity. making some oxygen ligands closer to the guest, some farther. The effective diameter of Li^+ could be measured from crystal structures of its complex with various such spherands. and it ranged



8 9 10

Chart 2 Starting units to produce spherand 1.

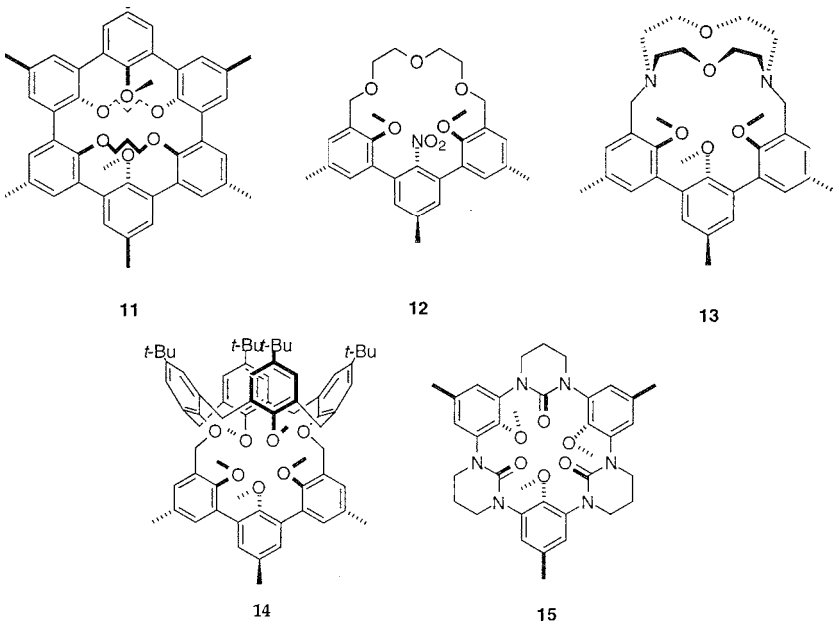


Chart **3** Compounds 11–15

as follows: 1.28 Å with five coordinating oxygens, 1.48 Å with six coordinating oxygens, and 1.72 Å with seven coordinating oxygens. These distances agreed with complexes found in the literature. though no other seven-coordinate lithium was known. The spherands, being the most preorganized ionophores, manifest the strongest binding and the highest selectivity of all alkali cation-binding hosts.[8] They also have the slowest decomplexation rates. For **7**·Li^+, heating to 400 K in MeOH/water is required for decompiexation. For **11**·Li^+, even such rigorous treatment is not sufficient for decomplexation. Thus, **11**·Li^+ can be considered a carceplex.[9]

The next class in the spherand family is the hemispherands. These consist of at least half preorganized ligands. Typically. the remainder of the host is a corand. that is. part of a crown ether. Compounds **4**–**6** fit in this category. The length of the corand could be varied. and functional groups were incorporated into the central aromatic rings of compounds such as **4**, in place of the methoxy group. This way. the ligating ability of a variety of functional groups could be explored. Functional groups such as nitro (e.g., **12**), N-oxide. amides, and esters were incorporated.[10] The hemispherands typically bind strongest to Na^+ and K^+, with binding energies typically 9–12 kcal/mol.[8]

Similar to the hemispherands are the cryptahemispherands. Instead of a corand part. there is a cryptand part; the rest of the host again is a highly preorganized spherand unit. Cryptahemispherand **13** binds Na^+ as a seven-coordinate ligand. The size and number of ligating sites can be varied considerably within this family, and complexes fi-om Na^+ to Cs^+ were studied.[8] Binding affinities for these guests are in the range of 19–21 kcal/mol for the best guests.[8]

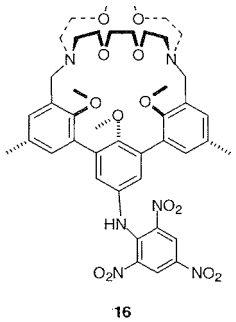
Loosely related to crytaheinispherands are the calix-spherands. e.g., **14**. in which as the name suggests, half a spherand is capped with a calixarene. Binding energies for K^+ of 14 kcal/mol were reported.[12]

Other classes of spherands were reported. Some will be discussed in other articles. such as those used for chiral recognition of amino acids and those used as rate enhancers for polymerization and acylation reactions.[8] The serine protease enzyme mimic developed by Cram made use of a unit that is worthy of mention here. Cyclic urea units were incorporated into spherands to give another subfamily of spherands, which manifest some unique features. In addition to alkali metal cations, spherands bind to ainmoniums. In these cases: instead of the guest being encapsulated in the cavity of the host. the guest perches like a tripod onto three of the potential ligating oxygens. Typically, binding of ammonium guests is lower than for the alkali cations (typically 3–4 kcal/mol), largely because of the differential binding geometries.[8] That is. the alkali cations can access six ligating oxygens. while the ammoniums can access only three. Thus, Cram developed the cyclic urea unit as a particularly strong ligand for ammoniums. as it is a strong hydrogen-bond acceptor. For example, *tris*-urea spherand **15** binds

ammonium and methyl ammonium with 14.4 kcal/mol, and the best guest, K^+, with similar affinity at 15.6 kcal/mol. Measurement of bond angles from crystal structures of relatives of tris-urea **15** led Cram to conclude that the oxygens of the ureas can adjust their hybridization as needed to the task at hand. i.e., to the needs of the guest in question.[13] This makes these spherands useful. In addition, they are highly soluble in organic solvents, and their complexation/decomplexation rates are high compared to hosts that bind guests with comparable affinity.[14]

A CHROMOGENIC IONOPHORE

Applications are always a strong selling point for a field. and nothing is more satisfying than when fundamental studies lead to a useful application, especially if the development of that application actually leads to more fundamental work. Creation of a sensor for a particular guest has and continues to be a common goal in applications of supramolecular assemblies. A particularly challenging problem is the detection of K^+ in blood serum. The problem is that there is $\sim$100-fold greater concentration of Na^+ over K^+ in blood serum. As K^+ is only slightly larger than Na^+, one cannot simply design a host with a cavity that is too small for Na^+. One cannot simply use the concept that two things cannot occupy the same space, at least without paying a large price. In this case, what one needs is a highly preorganized host that is complementary to K^+, and thus shows a high selectivity over Na^+; if it can conform (i.e., collapse) to a cavity complementary to Na^+, there will be little or no selectivity. Such a tall order in binding properties was available from the huge databank of spherands and related hosts that Cram and others (Jean-Marie Lehn in particular) developed over a period of 20 years. What remained was a way to turn such hosts into sensors. For a simple application, the hosts should change color upon binding K^+, and the assay should be fast. One does not want to have to wait days for equilibrium to take place to get a meaningful result. Thus; cryptahemispherand **16** (Chart 4) was developed and commercialized.[15] Cryptahemispherand **16** binds K^+ over Na^+ by a factor of 1500, the equilibrium is reached rapidly, and a chromophore was incorporated that gets activated upon binding of a metal cation (the host deprotonates). Cryptahemispherand **16** has a pK_a value of 7.05 in the presence of KBr, and a value of 7.75 in the presence of NaBr. Such a differential allows complexation of K^+ to be observed colorimetrically in the presence of 100-fold excess Na^+.[15]



16

Chart 4 Chomogenic ionophore 16.

CONCLUSION

Presented here is a brief summary of several decades of work. In addition to the original literature, the reader is directed to more comprehensive reviews.[2,16,17] The spherands and their immediate family begot many other supramolecular families, each of which is covered in subsequent articles in this encyclopedia. Thus, the spherands represent a daunting example of design and effort, synthetically, and in terms of characterization. This immense body of work is exemplary of how we can and should conduct our business in supramolecular chemistry.

Spontaneous Formation of Homochiral Supramolecular Architectures

S

Yasuhiro Ishida
The University of Tokyo, Tokyo, Japan

INTRODUCTION

The first observation of homochiral supramolecular architecture dates to Pasteur's historical experiment in 1848 on the resolution of sodium ammonium tartrate."' Since then, spontaneous formation of homochiral architectures attracted scientists' attention as an important phenomenon relevant to the emergence of biochemical homochirality. The origin of chirality in nature is of long-standing interest in physics, chemistry, biology, and geology.[2] However, answers to the following questions have not yet been provided: what is the first step of symmetry breaking, and how can an amplification of an apparently small initial enantiomeric excess be achieved? Although several hypotheses were proposed, homochiral segregation of a racemate and subsequent homochiral polymerization have been considered critical steps in biochemical evolution.[3]

Spontaneous separation of enantiomers also attracts practical attention because the phenomenon has a potential to provide attractive optical resolution methods, in view of simplicity and no requirement of chiral auxiliary. In fact, optical resolution by direct crystallization of racemates was operated on a large scale to prepare several economically important compounds, such as monosodium L-glutamate.[4] The key of the process is homochiral crystallization, where a racemic liquid or solution yields a mixture of crystals composed of only D or L isomers, so-called "conglornerate." In such a system, one can often sort the enantiomers by hand. or one can induce preferential crystallization of one enantiomer. This method cannot be applied for the resolution of racemates that undergo heterochiral crystallization, giving rise to crystals containing both enantiomers. However. the prediction of racemate types, the homochiral versus heterochiral packing, has been one of the most challenging subjects in this field, although more than 150 years have past since the discovery of Pasteur.[5]

Recent studies in supramolecular chemistry revealed that spontaneous separation of enantiomers is a phenomenon coinmonly observed in many phases, from the crystalline state to a dilute solution. Starting with early studies of the morphology of chiral crystals by optical microscopy, the scale for the observation of chiral supramolecular assemblies approaches that of the molecules themselves (Fig. 1). In the following sections. the achievements in this area, which would shed some lights on the unsolved problems as described above, will be summarized and compared. The examples of homochiral assemblies in heterogeneous systems. investigated by direct morphology observation are described in the second section. Then, described are the recent examples of homochiral architectures formed in homogeneous systems. which were characterized by various spectroscopic techniques. In the last section, the question of how to manipulate homochiral supramolecular architectures, in order to apply the attractive entities for practical use, is addressed.

HOMOCHIRAL AGGREGATES IN HETEROGENEOUS SYSTEMS

Homochiral Domain in Two-Dimensional Crystal

Pasteur's observation not only uncovered the existence of enantiomers but stimulated scientists' desire for direct observation of supramolecular chirality without resorting to diffraction techniques. Recent progresses in scanning prove that microscopy, such as atomic force microscopy (AFM) and scanning tunneling microscopy (STM), enable us to observe two-dimensional (2-D) chiral crystals at molecular resolution. Eckhardt and coworkers reported the first example of spontaneous separation of chiral phases in monolayer crystals. Langmuir–Blodgett films of a racemic tetracyclic alcohol (1), formed on the water surface, were transferred onto mica.[6] The AFM of the ordered films revealed the domains of mirror-image structures, indicating separation into domains of pure enantiomers. Such chiral symmetry breaking was also observed from achiral molecules. Zasadzinski and coworkers presented AFM images of monolayer crystals of calcium arachidate (2). where these achiral molecules separated spontaneously into lattices with'chiral packing of opposite handedness."'

DOI: 10.1081/E-ESMC 120019193

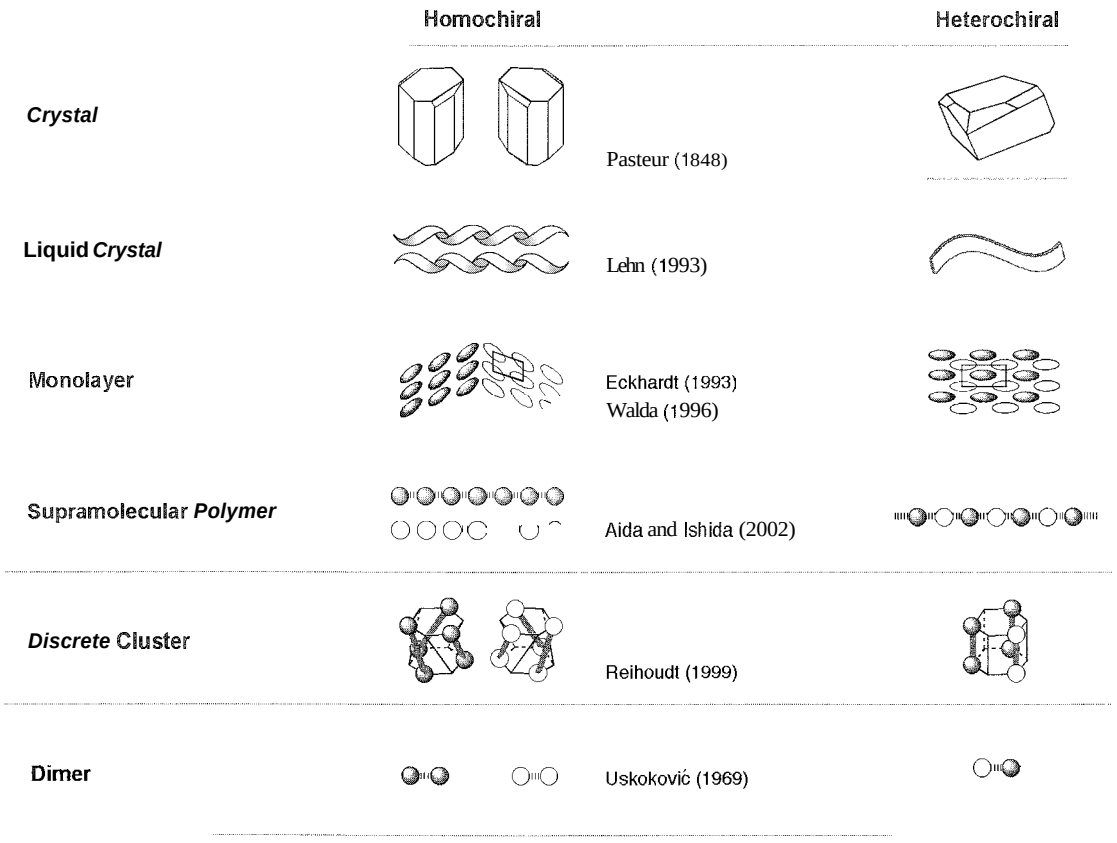

Fig. 1 Homochiral and heterochiral supramolecular architectures.

More recently, Walda et al. reported that a racemic mixture of mesogen *3* produced images of coexisting enantiomorphous domains, which were indistinguishable from the domains obtained from the enantiomerically pure materials (Fig. 2).[8] Observation of enantiomorphous domains in 2-D crystals can result from two different mechanisms:

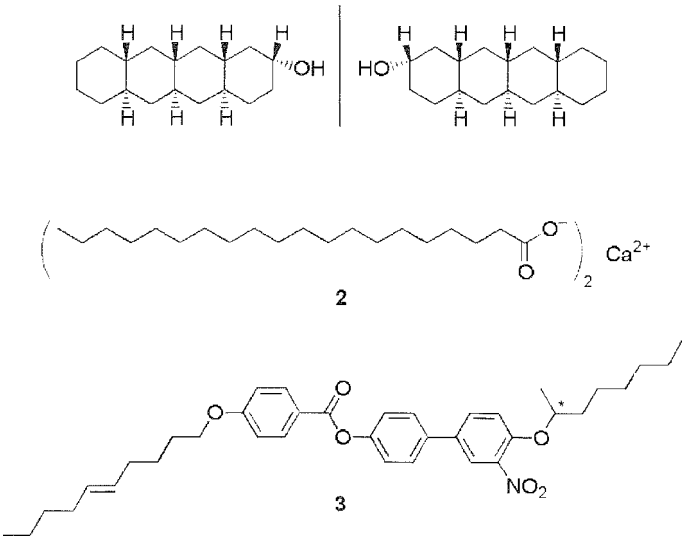
1. The racemic material spontaneously resolves into monolayer crystals of pure *R* and *S* material forming a 2D conglomerate.
2. Both enantiomorphous domains are composed of racemate packed in chiral orientation.

The crystals formed through these two mechanisms must be diastereomeric, but it is not possible to distinguish between these two possibilities by measuring physical properties such as optical activity. If resolution occurs, and the monolayer crystal domains are enantiomerically pure, the chiral images observed from the racemic material must be identical to those obtained from one or the other of the pure enantiomers. Over 100 images were analyzed for each material [enantiomerically pure (*R*)- and (*S*)-**3**, and racemic **3**], and the unit cells from the pure enantiomers and from the racemate were found to be the same within experimental error. These results provide strong evidence for chiral symmetry breaking to give a 2-D conglomerate.

Mesoscopic Superhelix in Liquid Crystal

Molecular chirality is sometimes amplified to chirality at the mesoscopic level, through the self-assembling process of a monomeric building block with low molecular mass.[9] Especially, helices with nanometric or micrometric pitches are fascinating entities for scientists, as they are often observed in crystalline fibers, liquid crystals, and physical gels. Chirality of such mesoscopic helices can be easily detennined by direct morphology observation using microscopy. Recent studies revealed that symmetry breaking can occur through superhelix-formation processes of racemic or achiral components.

Lehn and coworkers reported that a racemic mixture of monomeric components spontaneously formed long superhelices of opposite handedness that coexist in the same



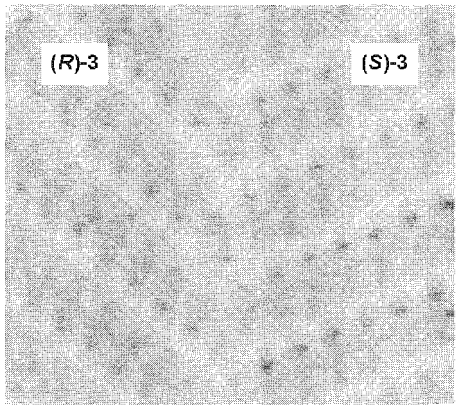


Fig. 2 A scanning tunneling microscopy (STM) image obtained from racemic **3** (nght) (Reproduced by permission of the American Chemical Society from Acc Chem Res. 1996, 29. 591–597.)

sample.[10] They designed mesogens consisting of two recognition units connected with D- and L-tartaric acid: Structures 4 and **5** derived from 2,6-diaminopyridine and uracile derivatives, respectively. Because 2,6-diaminopyridine and uracile moieties form a stable dimer via triple hydrogen-bonding interactions, equimolar mixtures of 4 and 5 lead to the progressive assembly of supramolecular–polymolecular entities (see the next section for more information on supramolecular polymers). Though the individual species L-4, L-**5**, D-**4**, and D-**5** were solids, the mixtures (L-**4**+L-**5**) and (D-**4**+D-**5**) showed liquid crystalline phases at room temperature. Electron microscopic observations of these mixtures revealed that (L-**4**+L-**5**) and (D-**4**+D-**5**) formed very long superhelical strings with right- and left-handed helicity, respectively [Fig. 3a (left) and (middle)]. Interestingly, in the case of a racemic mixture of L-**4**, L-5, D-**4**, and **D-5,** long superhelices of opposite handcdncss were formed [Fig. 3a (right)], which suggests the occurrence of spontaneous optical resolution in the supramolecular liquid crystalline polymers.

Since the discovery of the first liquid crystalline material in 1888, helicity has proven to be one of the most fascinating topics in this field.[9,11] Several liquid crystalline phases with helical structurc were reported, such as chlolesteric phase, blue phase, ferroclectric and antiferroelectric smectic phases, and helical smectic A phase. In most of these helical phases, at least a fraction of the constituent molecules have an asymmetric carbon, and it was long believed that chirality at a molecular level is a prerequisite to construct chiral architectures at the mesoscopic level. However, Watanabe et al. reported the first example of spontaneous helix formation in liquid crystalline systems comprised of achiral molecules.[12] They employed banana-shaped mesogene **6,** which showed thermotropic smectic phases. Interestingly, the achiral mesogen **6** formed a helical structure in the smectic phases. Although right- and left-handed helices were observed with equal probability in this system, they spontaneously segregated to form the domains of opposite handedness, which was confirmed by cross-polarized microscopy and circular dichroism spectroscopy (Fig. 3b). Moreover, millimeter-ordered homochiral domains could be grown, upon cooling the sample from isotropic melt to the smectic phase. It should be emphasized that such intriguing phenomena were specifically observed in the liquid crystalline state of such banana-shaped mesogens. Despite not yet knowing the precise mechanism, these phenomena are presumably attributed to the unique bent structurc of 6.

HOMOCHIRAL ASSEMBLIES IN HOMOGENEOUS SYSTEMS

Homochiral Dimer

In a solution of a chiral compound, the enantiomers should display identical physical properties, if any foreign optically active substance does not exist in the system. However, this notion holds truc only in on ideal dilute solution. To the extent that there is some degree of solute aggregation, chiral differentiation of enantiomers may be possible without the aid of any foreign optically active substance. As Uskoković and coworkers discovered in

1969 for the case of dihydroquinine,[13] diastcreoisomeric solute–solute interactions can cause nonraccmic mixtures of cnantiomcrs to give distinct NMR spectra. To date, several reports of this phenomenon appeared, most of which can be elucidated as the results of the dimerization of solutes via noncovalent interactions (Fig. 4a).[13-17] Enantiodiffcrcntiation through dimcr formation is of paramount importance, because this process should be involved in the formation of all homochiral aggregates.

Harger ct al. reported the discrimination by NMR spectroscopy of both enantiomers of alkylphenylphospinic amides **7**.[14] Thc observed spectra can be rationalizcd in tcrms of dimerization through hydrogen bonds [Fig. 4a (top)]. In this system; there was no marked preference for homochiral or heterochiral dirncrization, and the partner-exchanging was fast on the NMR time scale. In an cnantiomcrically unbalanced sample, thc major enantiomer was, on average, associated mainly with partners with thc same chirality, whereas the minor one was for the most part paired with partners of opposite handedness. Therefore; the major and minor cnantiomcrs were related differently to their time-averaged local environments and exhibited distinct NMR spectra. Hara et al. described the self-induced nonequivalence in the association of amino acid derivatives **8**.[15] In this case, thc homochiral dimer and the hctcrochiral dimcr gavc different signals in NMK due to thc same reason as the example of Hargcr, where dimcrization via hydrogen-bonding interactions again played an important role [Fig. 4a (middlc)]. At room temperature, stabilities of thc homochiral and the heterochiral dimers were cssentially thc same. I-Iowever, upon lowering the temperature, the homochiral dimer bccame relatively more stable compared with the heterochiral dimer, which was supported by NMR and IR spectroscopy.

Recently, Aida and Ishida demonstrated the example of exclusive homochiral-dimer formation, where the enantioselection mechanism was clearly elucidated by the number of hydrogen bonds [Fig. 4a (bottom)].[18] The hydrogen-bonded dimer motifs **10** and **11** were designed based on a xylyiene-bridged *bis*(cyclic dipeptide) 9. Conformational studies on cyclic dipeptides with benzylic side chains indicated that the aromatic groups "hover over" the diketopiperadine unit due to a dipole–dipole interaction. Hence, 9 having a p-xylylene bridge adopts an "*S*" -shaped conformation with the aromatic ring stacked by the two diketopiperadine units, which was confirmed by x-ray crystallography of L-**9** [Fig. 4b (top)]. Furthermore, crystallographic studies showed that 9 possesses arrays of two-amide functionalities, (NH⇒CO)⇒(CO⇒NH) and (CO→NH)⇒(NH⇒CO), on each edge of the "*S*"-shape. When the sequences and the shapes of the arrays are complementary, the two arrays can efficiently interact with each other through multiple hydrogen bonds. In fact, L-9 formed a columnar assembly in the crystalline state, via complementary hydrogen bonds at both edges of the molecule [Fig. 4b (bottom)]. Contrary to this, the association of **L-9** with D-**9** is expected to be unfavorable, because the steric requirement allows only one of the two diketopiperadine units to take part in the association event. By protecting either of the two edges of L-**9**, **L-10** and L-**11** were derived, which are expected to posses "S" -shaped (NH⇒CO)⇒(CO⇒NH) and "anti-*S*"-shaped (CO⇒NH)⇒(NH⇒CO) arrays, respectively. Because of the steric and sequential requisites for the association as described above, **10** and **11** should form a stable hetero dimer 10.11 only when they are homochiral [Fig. 4a (bottom)]. In fact, the amide–NH signal of L-**11**, upon mixing with L-**10**, showed a 1 ppm downfield shift due to the hydrogen-bonding interactions, whereas the signal was totally intact due to the addition of D-**10**. The association constant for the homochiral dimer L-**10**·L-**11** was estimated to be $5 \times 10^3\ M^{-1}$ by ^{1}H-NMR dilution technique. Such high stability is most likely due to the simultaneous participation of the two diketopiperadine units, because a

model compound possessing only a single diketopiperadine ring did not show any sign of hydrogen-bonding interactions under the same condition

Homochiral Discrete Cluster

Supramolecular approaches to self-assembly often rely upon reversible noncovalent interactions. These strategies inherently involve an error–correction process, and as a consequence, the thermodynamically favored structures are preferentially constructed.[19] Particularly in the self-association of racemic components, the error–correction process often leads to the selective formation of the homochiral clusters, although the diastereomeric clusters with similar stability are potentially formed as the final products.[20]

Enantiomeric self-recognition of biomolecules such as amino acids attracted exceptional attention, because symmetry breaking of these materials might play a significant role in a prebiotic process, which was proposed to explain the transformation from a racemic chemistry to a chiral biology.[3] Recently, Cooks et al. reported chiroselective self-directed oligomerization of serine (**12**).[21] An unusually strong magic number cluster of L-12, observed as the protonated, sodiated, or potassiated octamer, was identified by electospray ionization mass spectrometer (ESIMS). Tandem mass spectrometry results and ab initio calculations suggested that the serine octamer $(L\text{-}\mathbf{12})_8$ is composed of four dimeric units: the individual dimers are bound through carboxylic acid groups, while additional hydrogen bonding involving the hydroxyl and amino groups generates the final drum-shaped structure (Fig. 5a). Furthermore, preliminary results showed the formation of "clusters of clusters," which is predicted to arise as a result of oligomerization of $(L\text{-}\mathbf{12})_8$, held together by the "sticky ends" present on the top and bottom faces via hydrogen bonds between the amino and hydroxy groups. The most intriguing discovery about the octamer was its chiral dependence. Under ESIMS conditions, the relative abundance of the protonated $\mathbf{12}_8$ significantly depended on the enantiomeric composition of the sample. For example, the mass spectra recorded for solutions of enantiomerically pure L- and D-**12** were essentially identical, while the absolute intensity attributed to the octamer was reduced by a factor of five when using a racemic mixture. Furthermore, ESIMS spectrometry results of isotopically labeled samples (mixtures of L-[$^{13}C_1$]-**12** and D-**12**) confirmed the homochirality of the octameric cluster. These results may have implications for the evolution of homochirality of amino acids in living organisms.[3]

Such chiroselective oligomerization was also achieved in the self-organization of nucleoside derivatives. Davis

et al. employed a guanosine derivative 13 for cation-templated formation of homochiral clusters.[22] It is known that guanosine derivatives (G) self-associate to form quartets G_4 in the presence of cations M^{n+} (n= 1 or 2). Individual G_4-quartets, stabilized by hydrogen bonds between the base moieties: stack to give G_8-M^{n+} sandwiches and higher-ordered C-quadruplexes (Fig. 5b). For example. Ba^{2+} picrate ternplates the formation of a complex with eight equivalents of D-**13** bound to each Ba^{2+} picrate. X-ray crystallographic study indicated that the formation of a huge discrete cluster consisting of 16 units of D-13 associates around two Ba^{2+} cations to give a complex with four 6-quartet layers. This hexadecamer $(D\text{-}\mathbf{13})_{16}\cdot 2Ba^{2+}$ was composed of two coaxially stacked C_4-symmetric octamers, $(D\text{-}\mathbf{13})_8\cdot Ba^{2+}$, and the octamers are linked by four picrate anions that hydrogen bond to the "inner" *G*-quartets. The NMR studies indicated that the hexadecamer structure was retained in solution. While studying the structure and dynamics of *G*-quadruplexes, they discovered that Ba_2^{+} picrate directs enantiomeric self-recognition of 13. The homochiral hexadecainers with opposite handedness. $(D\text{-}\mathbf{13})_{16}\cdot 2Ba^{2+}$, and $(L\text{-}13)_{16}\cdot 2Ba^{2+}$, were predominantly generated by the treatment of a CD_2Cl_2 solution of racemic 13 with Ba^{2+} picrate. The ^{1}H-NMR spectrum of the mixture showed that the homochiral pair accounted for at least 90% of all of the diastereomers observed at equilibrium. In contrast, such enantiomeric recognition did not occur when the templating cation was the monovalent K^+, where NMR signals attributed to heterochiral diastereomers were observed. Taking advantage of the reversible nature of these nucleoside assemblies, the homochiral assemblies can be reconstructed: upon treatment of the diastereomeric $(D,L\text{-}\mathbf{13})_{16}\cdot 4K^+$ with Ba^{2+}, an equilibrium favoring the homochiral $\mathbf{13}_{16}\cdot 2Ba^{2+}$ was attained. Because Ba^{2+} and K^+ are similar in size, the cation's charge density is considered to be the major factor in controlling the enantioineric self-association at the supramolecular level.

Homochiral Supramolecular Polymer

Supramolecular polymers, 1-D aggregates of monomers formed via noncovalent interactions, attracted increasing attention as a new class of environment-responsive polymeric materials because of their reversible polymerization and depolyrnerization characteristics.[23] In general, monomers possess two interactive moieties at which they can be connected to each other via noncovalent interactions. in supramolecular polymerization, every chain-elongation process could be regarded as equivalent events, because the associations, monomer with monomer, monomer with polymer, and polymer with polymer. involve the same chemical process. In sharp contrast, through the formation of discrete clusters in a supramolecular manner. several types of association events should be involved, which are often complicatedly related to each other (see the previous section).

In the case of a chiral monomer, sequences of the resultant polymer should be directly influenced by the stereoselectivity of these interactive moieties."'' if the interactive moiety prefers homochiral association, two enantiomeric polymers of individual optical antipodes should be afforded. Contrary to this, when the interactive moiety possesses a strong tendency to adhere another monomer with opposite handedness, an alternative copolymer of each enantiomer is expected to arise. On the other hand, the monomer with no stereoselectivity will give a random copolymer. Studies on the supramolecular polymerization of racemic monomers are of significant importance, because these three extreme cases are regarded as the simplest models of the molecular arrangements in crystalline states. conglomerates, racemic compounds, and racemic mixtures. respectively.

In supramolecular polymerization of chiral monomers, molecular weights of polymers and distribution (MWD) are generally affected by the stereoselectivity of the association event as well as optical purity of the monomer.[16] Shown in Fig. 6b are three extreme cases of supramolecular polymerization of an enantiomerically unbalanced monomer (e.g., [D]>[L]). For nonstereoselective supramolecular polymerization, size-exclusion chromatography (SEC) profiles [monitored by absorption (UV) and circular dichroism (CD) detectors], shown in Fig. 6b (top). are expected, where MWD is unimodal, as in the case of polymerization of optically pure monomers, and should not change with [L]/[D], whereas the CD intensity response should reflect the enantiolneric purity of the monomer. Shown in Fig. 6b (middle) are SEC profiles, as expected for perfect homochiral supramolecular polymerization, where a bimodal MWD should result due to the formation of poly(L) and poly(D) with different molecular weights, depending on chiral monomer concentrations [L] and [D], respectively. According to a theoretical prediction, the CD response should initially be positive (or negative) but display a sudden drop to the baseline level at the beginning of the second peak, due to partial cancellation in ellipticity of poly(D) by Iower molecular-weight poly(L) ([D]>[L]). On the other hand, Fig. 6b (bottom) shows SEC characteristics as expected for perfect heterochiral supramolecular polymerization, in which a CD-silent copolymer with an alternating sequence of L- and D-monomers should be formed. In the SEC profile. D-monomer, which exists in excess with respect to L-monomer, should be observed as a CD-active, sharp peak at the end of the chromatogram.

Recently, Aida and Ishida demonstrated the first example of ''homochiral supramolecular polymerization,"

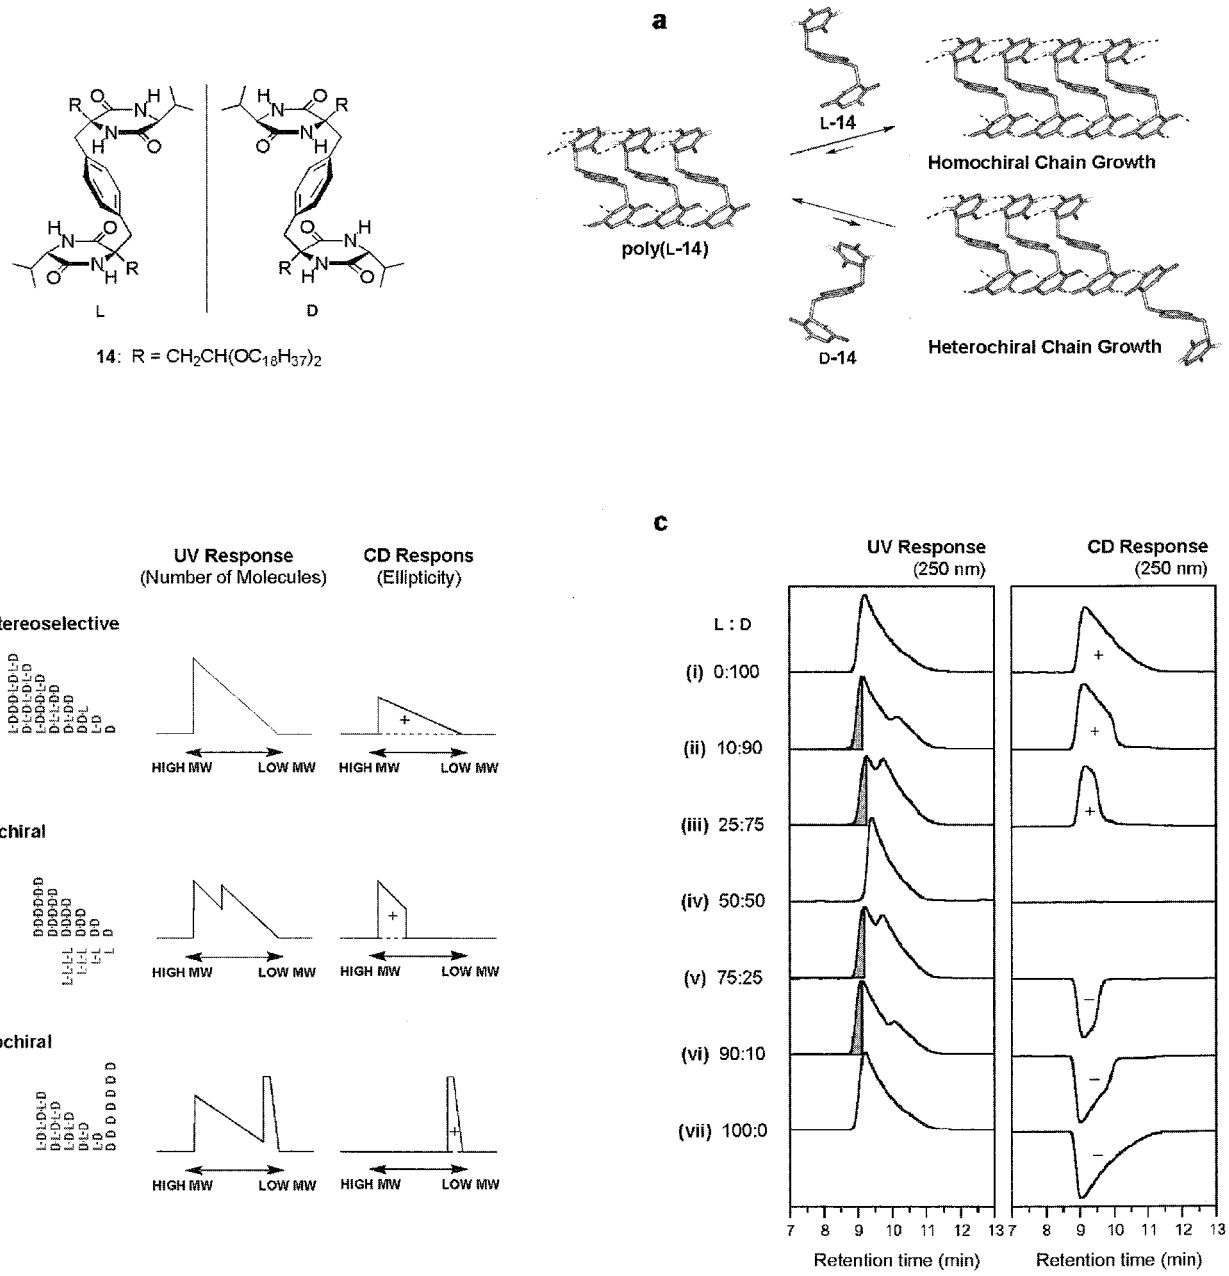

Fig. 6 (a) The homochiral supramolecular polymerization of **14**. (b) Size-exclusion chromatographic (SEC) profiles of an enantiomerically unbalanced (D-enriched) monomer, as expected for nonselective (top), homochiral (middle), and heterochiral (bottom) polymerization. (c) UV (left) and circular dichroism (CD) (right) responses in SEC traces of mixtures of L-**14** and D-**14**. (Reproduced by permission of the American Chemical Society from J. Am. Chem. Soc. **2002**, *124*, 14017–14019.) (*View this art in color at www.dekker.com.*)

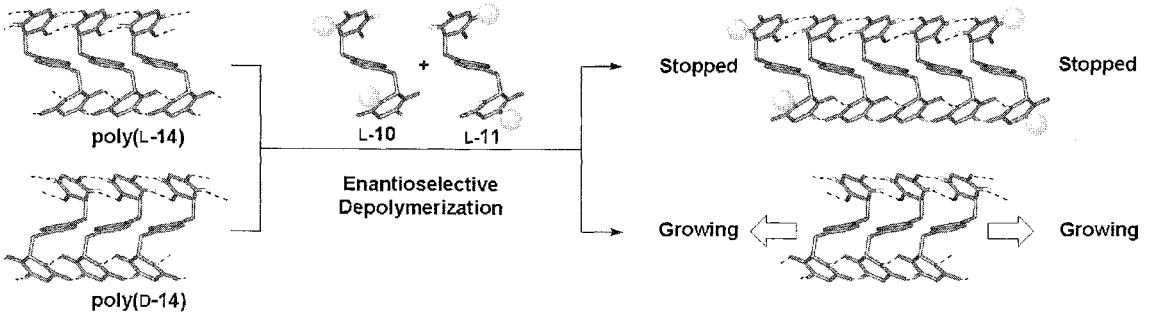
which can be regarded as the formation of a discrete 1D conglomerate (Fig. 6a).[16] The chiral monomer **14** was designed based on **9**, by introducing long alkyl chains to improve solubility. In aprotic solvents, **14** formed a supramolecular polymer via hydrogen-bonding interaction, which was confirmed by ^{1}H-NMR, FT-IR, SEC, and vapor pressure osmometry. As an inherent property of supramolecular polymer, significant dependence of the average molecular weight on monomer concentration was observed for poly-**14**. Noteworthy, the homochiral association of **14** interactions preferentially proceeds compared with the heterochiral one, and as a consequence,

racemic 14 in solution forms two enantiomeric supramolecular polymers of individual optical antipodes, poly(L-14) and poly(D-14). Such homochiral association is undoubtedly due to the same reason as the homochiral dimerization of 10 and 11 (see previous section entitled "Homochiral Dimer"). The SEC profile of the supramolecular polymerization of 14 was consistent with the expectation as described above (Fig. 6b,c). When the mole ratio [L]:[D] was gradually changed from 100:0 to 0:100 at a constant concentration of 14 (Fig. 6c), the two peak tops once merged at [L]:[D]=50:50 (Fig. 6c, iv), and then they were separated once again. The CD profiles of the chromatograms thus observed, were also consistent with what was expected for the homochiral supramolecular polymerization. When the SEC trace of an optically unbalanced mixture of L-14 and D-14 was monitored by CD detector. the chromatogram, initially with a positive sign, displayed a steep drop to the baseline level at the beginning of the second peak and remained almost unchanged thereafter (Fig. 6c. vi). By virtue of this homochiral supramolecular polymerization; enantiomerically pure L-14 and D-14 could be isolated from the fractions corresponding to the shaded parts of the chromatograms in Fig. 6c, ii, iii. v, and vi.

CONCLUSION

By means of various analytical techniques. we can observe homochiral supramolecular architectures in a wide range of phases, from the crystalline state to a dilute solution, as described above. If we want to apply these systems for practical use. such as in optical resolution of racemates, the next crucial subject is how to manipulate the homochiral assemblies. In the case of separation of conglomerates. one can often sort the enantiomers by hand, as was performed by Pasteur.[1] Although this method can be applied only when crystals have sufficient size to allow determination of their sign of rotation, an alternative technique named "preferential crystallization" was developed, which has its origin in 1866 in the work of Gernez.[4] He observed that a supersaturated solution of racemic dextrorotatory salt yielded only



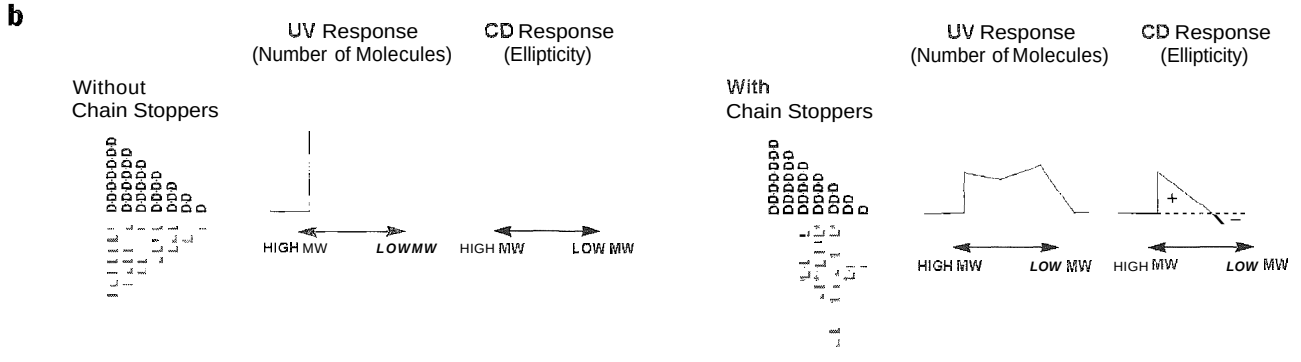


Fig. 7 (a) The optical resolution of poly-14 by enantioselective depolymerization with L-10 and L-11. (b) The SEC profiles of a racemic monomer for homochiral polymerization in the absence (left) and the presence (right) of chain stoppers. (View *this art in color at www.dekker.com.*)

L-isomer crystals, when a particle of L-dextrorotatory salt was seeded. However, in other phases than the crystalline states, attempts to manipulate homochiral assemblies were surprisingly limited.

As a preliminary result, Aida and Ishida demonstrated the optical resolution of a homochiral supramolecular polymer by controlling its MWD via the enantioselective depolymerization. As described above, 10, **11,** and 14 are expected to possess similar structures, because they are all derived from 9 (see the previous sections entitled "Homochiral Dimer" and "Homochiral Discrete Cluster"). Therefore, hydrogen-bonded homochiral complexes **10**·**14** and **11**·**14** are likely to be formed. Taking advantage of the reversible nature of hydrogen-bonded complexes, enantioselective depolymerization of the supramolecular polymer of racemic 14 was attained by using a mixture of L-**18** and L-**11** as chain stoppers (Fig. 7a). In this case, L-**10** and L-**11** could enantioselectively bind the two respective termini of poly(L-**14**), to reduce its molecular weight (Fig. 7a,b). For example, *SEC* traces of racemic 14 displayed a monodisperse chromatogram with a broad tail [Fig. 7b (left)], typical of noncovalent polymeric aggregates. In contrast, when an equimolar mixture of L-**10** and L-11 was added to a $CHCl_3$ solution of racemic 14, the *SEC* trace of the supramolecular polymer was considerably broadened due to two overlapped fractions [Fig. 7b (right)]: a fast-eluting (higher molecular-weight) fraction with a positive CD sign and a slow-eluting (lower molecular-weight) fraction with a negative CD sign. Because the CD signs of the L-forms of 14, poly-14, **10**, and **11** are all negative, and those of their D-forms are positive, the above observations strongly indicate that poly(L-**14**) in poly(*rac*-**14**) is enantioselectively depolymerized by the action of L-**10** and L-**11** to provide poly(L-**14**) with a lower molecular weight than that of poly(D-**14**).

ACKNOWLEDGMENTS

The works in homochiral supramolecular polymerization were carried out when I was a postgraduate student under the guidance of Prof. Takuzo Aida, to whom I am greatly indebted. I am also grateful to the JSPS Young Scientist Fellowship.

Stability Constants: Definition and Determination

Peter Cans
The University of Leeds, Leeds, United Kingdom

Alberto Vacca
Università degli Studi di Firenze, Sesto Fiorentino, Italy

INTRODUCTION AND DEFINITIONS OF STABILITY CONSTANTS

The following entry defines the commonly used stability constants (stepwise, overall. conditional, association, dissociation, and pK) and relates the values to a rigorous thermodynamic definition of equilibrium constants. In addition. the article briefly outlines experimental techniques (potentiometric titration, spectroscopic methods involving ultraviolet/visible, infrared, Raman, fluorescence. and nuclear magnetic resonance spectroscopy), together with the numerical methods and computer programs that can be used to derive stability constants from such experimental data.

THERMODYNAMIC DEFINITION

For a reaction of the type $pA+qB+.. \rightleftharpoons A_pB_{q..}$ a thermodynamic equilibrium constant, β^0_{pq} . is defined by the equality Eq. 1.

$$\{A_pB_{q..}\} = \beta^0_{pq..}\{A\}^p\{B\}^q.. \quad (1)$$

where {A) signifies the activity of a reagent, denoted by A, etc., and the species $A_pB_{q..}$ is said to be an adduct, or complex. A stability constant (or formation constant) is a particular kind of equilibrium constant that relates to the stability of a complex species.

Activities are, by definition, unit-less quantities. In practice it is more convenient to use concentrations. The activity. {A}. of a species A is related to its concentration, [A], by {A)=[A]γ_A, where γ_A is the activity coefficient that has units which are the inverse of the concentration unit. It follows that the thermodynamic stability constant can be defined by Eq. 2:

$$[A_pB_{q..}]\gamma_{pq..} = \beta^0_{pq..}[A]^p[B]^q..\gamma_A^p\gamma_B^q.. \quad (2)$$

The stability constant can be expressed as a product of two terms. a concentration quotient and an activity quotient, Eq. 3:

$$\beta^0_{pq..} = \frac{[A_pB_{q..}]}{[A]^p[B]^q..} \times \frac{\gamma_{pq..}}{\gamma_A^p\gamma_B^q..} \quad (3)$$

Stability Constants Based on Concentrations

If the activity quotient can be regarded as a constant, a stability constant can be defined as a concentration quotient, Eq. 4:

$$\beta_{pq..} = \frac{[A_pB_{q..}]}{[A]^p[B]^q..}$$

The activity quotient can be made effectively constant by performing the measurements in a medium of high ionic strength relative to the concentrations of the species involved in the equilibria. The stability constants obtained from measurements at relatively high ionic strength have the thermodynamic significance of setting that medium as the standard state: in terms of this definition of thermodynamic standard state, the activity quotient has a value of unity. This can clearly be seen in the relation between the stability constant and the standard free-energy change for the equilibrium: $\Delta G^0 = -RT\log_e\beta_{pq}..$. Thus, any stability constant has meaning only in terms of the standard state conditions.

Other forms of stability constant can be derived from the fundamental definition given in Eq. 2. For example, if one of the reagents is H^+, the hydrogen ion activity can be measured with a suitable electrode, and this will give rise to a mixed stability constant when the other species are represented by concentrations.

Conditional constants

A conditional constant is obtained when the measurements are made in the presence of a substance that affects the equilibria in a fixed way, but these effects are ignored. In fact, stability constants derived from measurements in an ionic medium are conditional in the sense that they are valid only under those experimental conditions. Each concentration term in Eq. 4 should be considered as the sum of the concentrations of all species that have the same stoichiometry in regard to the explicit reagents A,B.. but containing different quantities of the implicit reagents, such as the solvent or ions present in the ionic medium. The concentrations of the implicit reagents

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012822

usually remain constant as long as the solvent or ionic medium is not changed.

The term "conditional" (or alternatively, apparent or effective) constant is sometimes used in analytical chemistry and frequently used in biological chemistry. A conditional constant is a concentration quotient that applies only when the concentration of one or more reactants or products is fixed at a particular constant value. For example, when the equilibrium $M+H_nL \rightleftharpoons ML+nH$ is studied at fixed pH, an effective constant can be defined by Eq. 5:

$$[ML] = K_{eff}[M][H_nL] \quad (5)$$

where n may be nonintegral, and H_nL may represent an equilibrium mixture of species with $n=0$, 1, etc.[1]

Overall and stepwise constants

The equilibrium constant defined in Eq. 4 is an overall constant. A stepwise constant refers to an equilibrium in which a single reagent molecule or ion is added to a complex species or another reagent. For example, the equilibrium constant for $A_pB_{q-1}..+B \rightleftharpoons A_pB_q..$ is given by Eq. 6:

$$K^{B}_{pq..} = \frac{[A_pB_q..]}{[A_pB_{q-1}..][B]} \quad (6)$$

An overall constant is simply the product of the stepwise constants leading to the complex of given stoichiometry. For example, $\beta_{12}=K_1K_2$, where $K_1=[AB]/[A][B]$, and $K_2=[AB_2]/[AB][B]$. The logarithm of the overall constant is the sum of the logarithms of the stepwise constants: $\mathrm{Log}\beta_{12}=\mathrm{Log}K_1+\mathrm{Log}K_2$.

Association and dissociation constants

The stability constant given in Eq. 4 is an association constant. A dissociation constant is numerically equal to the reciprocal of the corresponding association constant. It is common practice to quote dissociation constants for acids (particularly organic acids), while association constants are used for complexes. For a monobasic acid, HL. there are no further complications. But for polybasic acids, the numerical order of the two sets is reversed. For example, for a dibasic acid, the first stepwise dissociation constant is equal to the reciprocal of the second stepwise association constant and vice versa.

Variation of stability constants with temperature

Equilibrium constants vary with temperature according to the following well-known expression (Eq. 7):

$$\mathrm{Log}K = \frac{-\Delta H^0}{2.303RT} + \frac{\Delta S^0}{2.303R}$$

If ΔH^0 is measured by means of calorimetry, the value of the equilibrium constant at a temperature other than that of the standard state can be calculated. It has to be assumed that ΔH does not vary with temperature, which is only approximately true. The same assumption is made when deriving AH' from stability constant values obtained at different temperatures—the so-called Van't Hoff method, in which Log$K$ is plotted against $1/T$ to give a straight line with slope $-\Delta H^0/2.303$ R. Use of this method requires stability constants of high precision, because the error on ΔH^0 is considerably magnified with respect to the error on Log$K$.

Variation of stability constants with ionic medium

When a stability constant is derived from measurements in an ionic medium. the value will vary when the medium is changed. This is a subject of considerable importance, because often the medium of interest is different from the medium of measurement; for example, in biomedical applications, the medium of interest is a biological medium such as blood, but that medium is unsuitable for stability constant measurements. Corrections for variation of ionic strength can be made by using the Davies equation (Eq. 8) to estimate activity coefficients:

$$\mathrm{Log}\ \gamma = -Az^2\{[I^{1/2}/(1+I^{1/2})] - 0.31I\} \quad (8)$$

where I is the ionic strength; A is the Debye–Hückel limiting slope; and z is the electrical charge on the species under consideration. A better approximation can be made by application of the theory of specific interactions between ions.[2]

TYPES OF MEASUREMENT

In order to derive a stability constant. it is necessary to measure one (or more) concentration (or activity). When that quantity is measured over a range of experimental conditions, the method of least squares may be applied to the data to yield one (or more) stability constant.

Potentiometric Measurements

The most common quantity measured is the hydrogen ion concentration. This is measured by means of a glass electrode. The response of the glass electrode is assumed to follow a near-Nernstian law (Eq. 9):

$$E = E^0 + s\ \mathrm{Log}[H^+] \quad (9)$$

E^0 and s (ideal value $2.303\ RT/F$) are calibration parameters. The recommended calibration procedure involves the titration of a known quantity of a strong acid with a

base of known concentration; this procedure ensures that the electrode is calibrated in terms of hydrogen ion concentration. The data can be analyzed using the program GLEE.[3] which employs Gran's method.[4]

The term pH in this context must be understood to mean $-\mathrm{Log}[H^+]$: from Eq. 9, $pH=(E^0-E)/s$. Another point to note is that in Eq. 9, the measured potential; E, is expected to depend linearly on the logarithm of the concentration, for the glass electrode deviations occur at low and high pH values. At low pH, the effect can be partly corrected by adding a term proportional to $[H^+]$ to Eq. 9. At high pH, an additional term, proportional to [OH]. may be added. These additional terms are loosely described as correction for variation in junction potentials, and the proportionality constant(s) may be determined empirically. At high pH. the glass electrode is susceptible to interference from Na^+ ions (it also becomes a Na^+ ion-selective electrode). For this reason. the use of KOH as alkali is preferable to the use of NaOH when using a glass electrode.

In a typical stability constant determination, an acidified mixture is titrated with alkali; after each addition, the pH is measured to produce a so-called potentiometric titration curve.

Absorbance Measurements

The second most common quantity measured is UV/Visible absorbance. obtained by means of a spectrophotometer. Optical density (OD), is assumed to follow the Beer–Lambert law Eq. 10:

$$OD = LC_{pq..}[A_pB_{q..}] \tag{10}$$

where L is the path length of the cuvette. and $\varepsilon_{pq..}$ is the molar absorbance of the complex $A_pB_q...$ For pure substances, ε can be determined directly from a set of experimental measurements, but for species that only exist in equilibrium, the molar absorbance must be regarded as an unknown quantity. Measurements may be performed at a single wavelength or at multiple wavelengths. If a reagent is added in a stepwise manner, a spectrophotometric titration curve will result.

NMR Measurements

In recent years, NMR spectroscopy has been used more for stability constant determination. It can be used in two different ways. In systems where exchange is slow, each species gives a separate NMR spectrum; the (integrated) intensity of the signal from any one set of chemically equivalent nuclei is related to the concentration of the species containing that set of nuclei. Where exchange is rapid, the separate resonances merge to a single resonance with a chemical shift, δ, that is the average of the individual shifts, weighted according to the fractional population of a single nucleus (Eq. 11):

$$\delta = \sum_j \frac{x_j C_j}{T_x} d_j$$

where T_x is the total concentration of the reagent containing the nucleus under consideration; x_j is the stoichiometric coefficient (p, q, etc., in the chemical formula) of reagent X in the jth chemical species; and d_j is its chemical shift in that species.

Other Measurements

Other indicators of a species' concentration include fluorescent intensity, infrared intensity, Raman scattering intensity, and electron spin resonance. These will not be discussed in detail.

METHODS OF CALCULATION

A Simple System

A simple system involves the protonation of a base. L, in the equilibrium $L+H \rightleftharpoons LH$. Working with concentrations and omitting electrical charges, the system is defined by Eqs. 12–14:

$$[LH] = K[L][H] \tag{12}$$

$$T_L = [L] + K[L][H]$$

$$T_H = [L] + K[L][H] \tag{14}$$

where T_L and T_H are the total (analytical) concentrations of the base L and mineral acid. Both T_L and T_H must be known experimental quantities. The [L] and [H] are called the free concentrations of the reagents L and H, respectively. The term LH is conveniently called a complex species. If [H] is measured by means of a glass electrode (Eq. 10), the three equations can be solved for the three unknown quantities [L], [LH], and K. However, rather than obtain a K value at each point in a titration curve, it is preferable to treat the whole data set by the method of least squares.

A General Procedure

The most general method is as follows. Each stability constant is defined by an expression of the type given in Eq. 4, and for each reagent there is an equation of mass balance. of the general form as follows in Eq. 15:

$$T_A = [A] + \Sigma p\beta_{pq..}[A]^p[B]^q.. \tag{15}$$

Then. if values of the stability constants are "known." there are as many mass-balance equations as unknown free concentrations of the reagents [A], [B], ... The solution of these nonlinear simultaneous equations provides the values of the free concentrations and thence, from the definitions such as Eq. 4, the concentrations of all the complex species. Armed with these concentrations, it is then possible to calculate quantities that correspond to the quantities observed and to minimize a sum of squared residuals (differences between observed and calculated values) with respect to the stability constants, that is, to use the least-squares method to find the values and standard deviations on the stability constants. A large number of computer programs for stability constant determination were published.[5] The discussion below concentrates on the programs most familiar to the authors and that are of a completely general nature, having no restrictions regarding the number of reagents, the stoichiometry of the complexes formed (p, q .. values), or the number of measurements collected.

The least-squares problem is also nonlinear and so must be solved by an iterative procedure. This means that initial values of the stability constants must be estimated before the iterations can begin. One way to obtain the estimates is by finding values for analogous compounds in one of two extensive stability constant databases.[6,7]

Potentiometric data

This form of data typically consists of one or more titration curves, each curve containing a number of data points of the form titre volume. electrode reading. The electrode is an ion-selective electrode (ISE). The most common electrode used is the glass-electrode, which is sensitive to the hydrogen ion, H^+, but other ISEs may be used just as well. The electrode potential is supposed to follow a modified Nernst equation. such as Eq. 9.

The computer program Hyperquad[5] may be used to determine stability constants from potentiometric data. This program employs the general procedure outlined above with the following specifics for implementation.

Solution of the mass-balance equations at any titration point provides the concentration of free hydrogen ions $[H^+]$ so that a potential can be calculated for Eq. 10. The objective function to minimize can be written (in simplified form) as $\Sigma w(E^{obs} - E^{calc})^2$. It is immediately obvious that the objective function contains no explicit reference to the stability constants. Therefore, in order to use the powerful Gauss–Newton method of minimization, it is necessary to perform an implicit differentiation. details of which can be found in the literature."]

Absorbance data

Hyperquad can also handle absorbance data. Indeed, Hyperquad can handle potentiometric and absorbance data obtained on the same solutions. With absorbance data the Beer–Lambert law (Eq. 10) applies at each wavelength where measurements were made. Nowadays. it is common practice to record complete spectra at fixed wavelength intervals, though in principle, measurements need only be made at a single wavelength. Once the free concentrations are found by solving the equations of mass balance, the molar absorbances can be obtained by solving the set of equations (Eq. 10) with measured absorbances in place of OD. This is a linear least-squares system, so no iteration or initial estimates are required. There is a linear least-squares system at each wavelength measured. Once the molar absorbances are deduced, the optical density may be calculated, and the (simplified) objective function $\Sigma w(OD^{obs} - OD^{calc})^2$ may be minimized. Once again, the stability constants are implicit parameters of the objective function.

Another computer program that can be applied to absorbance data is pHab.[8] The main difference is that pHab assumes that pH was set for each solution. This means that there is one less free concentration to calculate, but otherwise. the program functions in a similar manner.

These programs can also be used with fluorescence data on the assumption that the fluorescent intensity due to any species is a linear function of the concentration of that species. This assumption is usually valid for dilute solutions. but as the concentration rises, self-absorption, or quenching, causes deviations from linearity to occur.

NMR data

The data from slow-exchange systems can be treated as though it were absorbance data. When exchange is fast on the NMR timescale. the chemical shift of any given nucleus is given by Eq. 11. The computational procedure used in the computer program HypNMR[9] is similar to that used for absorbance data. Free concentrations are obtained by solving the equations of mass balance, and the individual chemical shifts are derived by means of a linear least-squares calculation. The objective function $\Sigma w(\delta^{obs} - \delta^{calc})^2$ is, once again, an implicit function of the stability constants.

Common Features

The three programs Hyperquad. pHab, and HypNMR use an objective function that contains weights. represented by the symbol w. Ideally: the weight associated with any measured quantity should be equal to the reciprocal of the variance on the measurement. When this is so, the objective function divided by the number of degrees of freedom (reduced objective function) has an expectation value of unity. This means that there can be an objective criterion of the goodness of fit. However. estimation of experimental errors is tedious and difficult. so the ideal weighting scheme is hard to realize in practice. When a

single type of measurement is made (e.g., NMR chemical shift), the weighting scheme has little bearing on the values to be calculated for the stability constants.

The programs provide a means for finding good initial values for the stability constants by manual fitting, with a display of observed and calculated values; the stability constants are adjusted by hand so as to reduce the systematic differences between observed and calculated values. This phase of the computation is important, because it serves to validate the choice of species taken to be present in the equilibria. In particular, in cases other than the simple one where only a 1:1 host:guest complex is formed, manual fitting will be useful to establish the stoichiornetry of the complexes formed.

CONCLUSION

The fundamental question to answer is as follows: Are the calculated values equal to the experimental values within experimental error? Implicit in this question is the need to have estimates of experimental error. With programs in the Myperquad suite, these estimates are entered as data such that the expectation value of the reduced objective function is unity. In practice, any value near unity (perhaps less than three) indicates an acceptable fit. However, other criteria should also be satisfied. In particular, the residuals (observed minus calculated values) should not show any systematic trend along a titration curve. The existence of a systematic trend implies the presence of a systematic error, most probably that the wrong set of chemical species was chosen to represent the equilibria.

Another indication of the quality of the results is given by the estimates of standard deviation on the stability constants. It should be remembered that these estimates depend only on random experimental errors. The 95% confidence limits are usually taken as ± 2 standard deviations. It should also be remembered that standard deviation refers only to precision. The accuracy of a derived stability constant is lower because of the inevitable presence of systematic errors in the measurements.

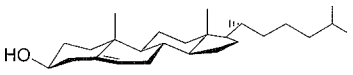
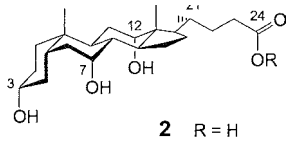
Steroid-Based Anion Complexation Agents

Anthony P. *Davis*
University of Bristol, Bristol, United Kingdom

INTRODUCTION

Supramolecular chemistry depends critically on preorganization, the correct and reliable positioning of functional groups and surfaces to achieve specific binding, etc. In principle, this may be achieved with flexible but conformationally biased architectures. However, in practice, it is difficult to operate without rigid spacers and scaffolds. While these roles are often filled by aromatic rings, fused aliphatic systems can be equally rigid and have certain advantages. For example, they are usually chiral and possess two valencies (and thus two orientations) at each nonbridging center. Also, they are readily available in the form of inexpensive natural steroids such as cholesterol **1** and cholic acid **2**.[1–4] In the field of anion recognition. the steroid nucleus has made notable contributions by providing a scaffold on which to mount polar functional groups. and lipophilic surfaces that can be used to maintain solubility in nonpolar media. This brief account of the area is divided into two parts, covering electroneutral anion receptors derived from cholic acid and positively charged steroid-based anion complexers.





2 R = H
3 R = Me

ELECTRONEUTRAL ANION RECEPTORS BASED ON CHOLIC ACID

The history of anion complexation in supramolecular chemistry is almost as long as that of cation binding.[5,6] However, it developed differently. Whereas the first cation-binding agents (crown ethers, cryptands, etc.) were electroneutral and compatible with organic solvents, the early anion complexers were cationic and highly hydrophilic.[7] It is only recently, perhaps since the early 1990s. that much attention has been paid to the design of electroneutral, lipophilic anion-binding molecules.

One obvious approach to electroneutral anionophores is the deployment of neutral H-bond donor functionality around a central binding site. However, the execution of this strategy is nontrivial. Anions are generally larger than cations, while convergent H-bond donor centers must be spaced more widely than, for example. electron pair donors (compare O—H· ·X^-· ·H—O versus O· ·M^+· ·O). Both factors imply that large, elaborate frameworks may be required. Moreover, most neutral H-bond donor groups are also H-bond acceptors, raising the pcssibility of intramolecular H-bonding within the receptor.

The steroid nucleus provides an attractive solution to these problems. It is extended, and thus able to support well-separated functional groups, and rigid, such that these groups cannot easily interact with each other. Of the readily available steroids. cholic acid 2 is especially useful.[1,2] It possesses a curved profile, with three codirected hydroxyl groups emerging from the concave α-face. This structure naturally lends itself to the creation of macrocyclic or cleft-type architectures with polar interiors and apolar exteriors. The hydroxyl groups may be differentiated and converted to a range of other functional groups, while the side-chain carboxyl affords further possibilities.

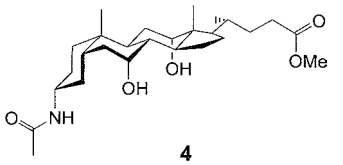
Cholic acid has been converted into a series of electroneutral anionophores targeted at inorganic anions. These may be divided into two categories: acyclic and macrocyclic receptors that exploit the H-bonding properties of (at least some of) the secondary hydroxyls, and acyclic podands in which all the hydroxyl groups were modifed to give alternative binding functionality. These two classes are considered separately below.

Hydroxysteroid Anion Receptors Derived from Cholic Acid

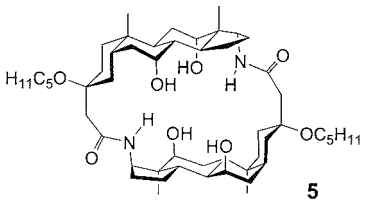
The hydroxyl groups already present in 2 are, of course, H-bond donors, so that simple esters such as 3 might be expected to have anion-binding properties. Indeed, 3 was found to associate with tetrabutylammoniurn (TBA) bromide, tosylate, mesylate. and hydrogen phenylphosphonate in benzene and benzene–hexane mixtures.[8,9]

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012780

However, there was no detectable complexation in $CDCl_3$ or more polar solvents. Some improvement resulted from the incorporation of a single -NH-CO group. Thus. the acetamido derivative 4 showed modest affinities for TBA chloride and bromide in $CDCl_3$ (K_a=53 and 36 M^{-1}, respectively).[9,10] Further, significant increases could be obtained using a more elaborate, cyclodimeric architecture. The cryptand ***5*** was specifically designed to encapsulate a small, spherical anion such as fluoride or possibly chloride. It was synthesized from 2 via degradation of the C21–C24 side chain, introduction of a short spacer plus an externally directed solubilizing group. and cyclodimerization. NMR titrations reveaied binding constants of 3320, 990, and 250 M^{-1} to TBA fluoride, chloride, and bromide, respectively.[10]



4



5

Steroidal Podands with Multiple NH Groups

As H-bond donors in supramolecular chemistry, NH units are far more versatile than OH groups. The third valence on the nitrogen can be exploited structurally and can also be used to tune the H-bond donor power. Accordingly, steroidal podands with three or more NH groups proved more effective than 4 or ***5***. Early studies involved the sulfonamide *bis*-carbamate 6 and the iris-sulfonamide **7**.[11] Both systems provide well-defined binding sites for anions. In 6, free rotation is possible about the C3–N bond. but the carbamate NH groups are preorganized to some extent through restricted rotation about the axial C7/C12-O bonds and the preference for *Z,Z*-conformations across the carbarnate units." In 7, restricted rotation about the C7/C12-N bonds (Eq. 1) holds the NH groups firmly in place for anion recognition. NMR titrations revealed the binding constants shown in Table 1, significantly higher than those for 5.

Table 1 Association constants (K_a, M^{-1}) of 6 and **7** with TBA Salts in $CDCl_3$ (NMR titrations)

Anion	*Complex* **with** 6	*Complex* **with** 7
F^-	15.400	Not determined
Cl^-	7200	92,000
Br^-	7200	9200
I^-	930	525
TsO^-	865	950

Data from Ref. [11]

The steroidal podand architecture clearly had potential for further development. Electron-withdrawing substituents could be used to increase H-bond donor potency, and further NH groups could be added. Progress was hindered by problems of measurement: at $K_a \sim 10^5$ M^{-1}, receptor **7** had already attained the upper limit compatible with NMR titrations. However, a solution was found in Cram's extraction-based methodology, whereby binding constants are determined from the ability of the receptor to extract a hydrophilic substrate from water into an organic medium.[12]b Once this method was calibrated for use with tetraethylammonium (TEA) chloride and bromide, it was possible to investigate a second generation of podands.[13,14] Receptors 8–13 feature a lipophilic side chain (to minimize loss during extraction experiments) and acidifying, nitrophenyl substituents. As shown in Table 2. the binding constants to TEA chloride and bromide increase through the series as the number of H-bond donors increases. The sequence also illustrates the

[a] *Ab initio* calculations on *O,N*-dimethylcarbamate (6–31G* basis set) indicate that the *Z,Z*-conformation lies 5.58 kJ mol^{-1} below the next lowest energy minimum.

[b] Alternatively, NMR titrations could have been continued in more competitive solvents, such as DMSO. However, it was thought preferable to retain the nonpolar medium, as being more relevant to (for example) biological membranes.

Table 2 Association constants (K_a, M^{-1}) of **8–13** with TEA chloride and bromide in water-saturated $CHCl_3$ (extraction measurements)

Receptor	Complex with TEACl	Complex with TEABr
8	3.2×10^6	1.1×10^6
9	3.4×10^7	2.9×10^7
10	4.77×10^8	2.26×10^8
11	1.05×10^9	3.24×10^8
12	6.60×10^{10}	1.68×10^{10}
13	1.03×10^{11}	2.59×10^{10}

Data from Refs. [13,14]

slight advantage of thiourea over urea groups in anion recognition. The affinities of the stronger receptors are exceptional; at the time of writing, the binding constant of 10^{11} M^{-1} for **13**+TEACl is the highest published value for an electroneutral, purely organic anionophore.

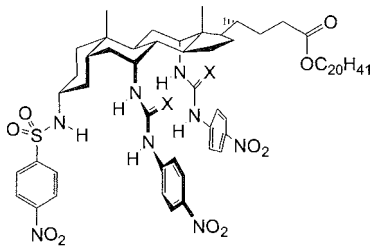
10 X = O
11 X = S

The advent of these powerful and highly lipophilic anionophores raises the possibility of new applications, for example, in the area of membrane chemistry. An early result is the discovery that **14** and **15** can serve as translocases for phospholipids. promoting the *trans*-membrane shuttling of polar, phosphate-containing head groups.[15]



12 X = O
13 X = S

STEROID-BASED ANION RECEPTORS WITH NET POSITIVE CHARGE

The steroid nucleus has also been exploited in a variety of positively charged anion complexers. These fall naturally into two categories: those employing guanidinium units as the major binding centers and those bearing protonated amino groups.

Steroidal Guanidinium Cations as Anion Receptors

The guanidinium cation is well-established as a center for carboxylate recognition, through formation of electroneutral, H-bonded complexes **16**. High affinities are observed, even in polar solvents.[16] Placed on a steroidal scaffold. a guanidinium group can therefore position a carboxylate within a well-defined (and chiral) environment created by other substituents. Cholic acid. once again. is an attractive starting material for such systems. Elaboration of the secondary hydroxyl groups can lead to a variety of receptors in which three independent contacts are made with a substrate. For example. a series of cations **17** was prepared with a view to enantioselective carboxylate recognition.[17,18] The receptors could be tested by straightforward extraction experiments, in which **17** served as both extractant and chiral NMR shift reagent. As shown in Table 3. good selectivities were observed with *N*-acetyl amino acids as substrates. Perhaps surprisingly. the asymmetrically derivatized receptors **17c–e** did not generally perform better than their symmetrically substituted relatives; indeed. symmetrically substituted **17b** gave (marginally)

Table 3 Enantioselectivities (L:D) shown by receptors **17a–e** in extraction experiments

Receptor	*N*-Ac-DL-alanine	*N*-Ac-DL-valine	*N*-Ac-DL-tryptophan
17a	7:1	7:1	7:1
17b	10:1	9:1	9:1

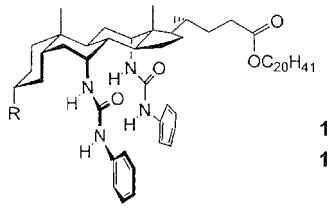
the best overall results. Receptor 18, a lipophilic variant of this system; proved capable of transporting *N*-acetylphenylalanine enantioselectively, with turnover. through nonpolar solvents. As well as the traditional "U-tube" apparatus. a "hollow-fiber membrane" separator was used in this work, raising the possibility of industrial-scale separations.[19]



14 R = H
15 R = OAc

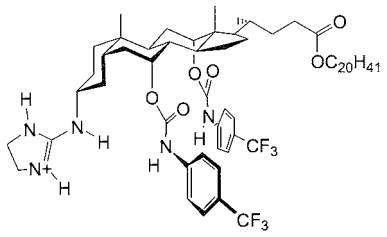
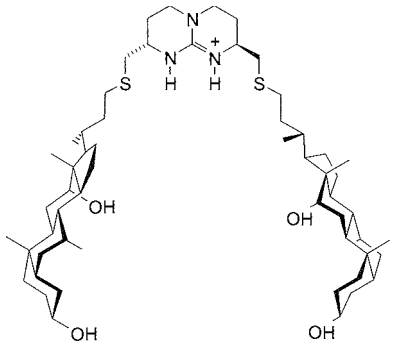
17a A = B = OCONHPh
17b A = B = $OCONHC_6H_4(p\text{-}CF_3)$
17c A = OH, B = OCONHPh
17d $A = OCONHBu^t$, B = OCONHPh
17e $A = OCONHC_6H_3(o,o\text{-}Cl_2)$, B = OCONHPh

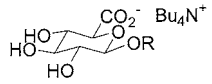
Two units of cholic acid were linked through a guanidinium moiety to create receptor **19**.[20] The targets in this case were glucuronic acid salts such as **20**. The steroidal units caused a small but significant increase in binding to *20* (K_a=7000 M^{-1} versus 2800 M^{-1} for a nonsteroidal control). A framework derived from corticosterone was used to position *bis*-guanidinium units relative to an imidazole, as in **21**. The imidazole was



18



19



20

expected to act as a general base, promoting cleavage of bound RNA. Dication **21** was capable of cleaving RNA models, although accelerations over background were only moderate.[21]

Protonated Aminosteroids

Finally, a range of steroidal polyamines were found to promote transport across cell/liposome membranes or bind to nucleic acids and promote gene transfection. Although these compounds have not in general been studied as receptors. their interactions with anionic centers are presumably central to their activities. For example, **22**[22] and **23**[23] were incorporated in vesicle membranes and shown to discharge pH gradients across the membranes. Their mechanisms of action are

uncertain. but symport transfer of H^+X^- is a likely option.

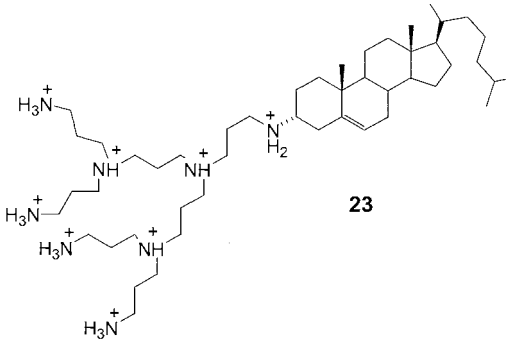
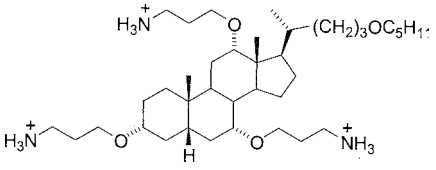
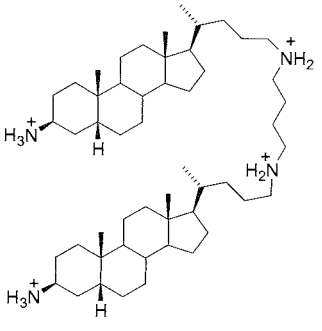
22



23



24



Triamine 24 and relatives permeabilize the membranes of gram-negative bacteria and possess antibiotic activity.[24] A series of polyamines derived from deoxycholic acid, lithocholic acid. or cholesterol were shown to strongly bind DNA.[25,26] Especially effective was 25, showing higher affinities than the natural DNA-complexer spermine.[25] Other steroidal amines were shown to act as cytofectins, promoting the delivery of DNA from liposomes to cell nuclei.[27] Examples are CTAP **26**[28] and the facial amphiphiles **27**[29] and **28**.[30]

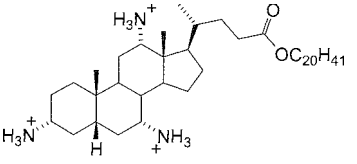
27



28

CONCLUSION

Steroid-based anion receptors show exceptional binding constants, encouraging enantioselectivities and a range of membrane-related activities. Much structural space remains unexplored. especially in the series derived from cholic acid 2. and further advances can be expected. In particular, the podand architecture of 6–15, 17. and 18 is amenable to variation through combinatorial chemist ~ ~ . and this technique may expand the scope and effectiveness of steroid-based anion recognition in years to come.

Strict Self-Assembly and Self-Assembly with Covalent Modifications

Bruce C. Gibb
University of New Orleans, New Orleans, Louisiana, U.S.A.

INTRODUCTION

At the most general level, the words "self-assembly" are used to identify the phenomenon whereby some kind of higher-level pattern emerges from the interactions of multiple simple components (Fig. 1). We are concerned here with the phenomenon of molecules coming together in a specific fashion so as to engender the formation of a higher species that is precisely defined at the molecular level. An example from the Fujita group is shown in Scheme 1.[1] To sets this particular type of self-assembly in its proper context. we should note that in the field of chemistry. ihe term "self-assembly" is used to describe two distinct types of processes. On the one hand, there are assemblies that lead to the formation of essentially infinite arrays, while on the other hand; there are assemblies such as that shown in Scheme 1 that lead to distinct, bounded species. Furthermore. within each of these categories, it is possible to make a further distinction that reflects the scale of organization. For example, for infinite arrays. we can consider processes such as crystallization,[2] where the molecules are ordered at the molecular level (ca. 10^{-9} m), or the formation of self-assembled monolayers[3] and bilayers,[4] where there is little order between individual molecules, but a larger scale of organization is evident across say the 10^{-6}m level. Likewise. the scale of organization for assemblies leading to distinct species can be broken down into similar categories. Briefly stepping out with the bounds of molecular assemblies. we can note the self-assembly of macroscale objects (10^{-3} m) is currently being investigated.[5] However, as far as the interaction of molecules to form distinct species goes, we can consider the formation of micelles[3] and vesicles[4] that constitutes assembly at the 10^{-6}m level, while the formation of the discrete molecular assemblies of interest here represents system ordered at the 10^{-9}m level.

The essential features of chemical assembly processes is that they share a common self-correcting mechanism.[6–8] In other words, strict self-assemblies are fully reversible, dynamic. systems that lead to a product that represents the global thermodynamic minimum for the system. Sometimes an additive or template"-"' is needed to boost the efficiency of the assembly. but this is the only true variable if we are speaking of strict self-assembly. *At* their *cores, strict molecular assemblies consist of subunits, product, and an equilibrium that relates the two.*

One addition to the assembly lexicon added a layer of complexity to the above definition. Thus, one of the seven different classes of self-assembly originally proposed by Lindsey.[11]—which are strict self-assembly processes (with or without a template) positioned in different chemical settings—is commonly known as "irreversible self-assembly." This term is used to describe two-step processes, whereby a strict self-assembly processes is followed by irreversible reactions that covalently knit together the array of subunits. As Whitesides noted, strictly speaking this term is a misnomer.[7] Hence, along with other types of post-assembly modified self-assemblies, we categorize these processes as "self-assembly with covalent modification." Postmodification generally comes in the form of a series of covalent bond formation steps and is of less interest to us here. The crux of any self-assembly process is the self-assembly.

Even within the strict confines given above. self-assembly processes come in all shapes and sizes. One of the results of this complexity is that defining self-assembly is difficult. Thus, although definitions from Hamilton,[6] Whitesides,[7] and Lehn[8] were highly influential in clarifying the *quality* of self-assembly, signs of confusion still appear in the literature. Perhaps part of the problem lies in Kelvin's dictum: if we cannot put a number to it, we do not understand it. Put another way, without a unifying quantitative description of self-assembly. our appreciation of self-assembly is limited. With the idea of a unifying quantitative description of self-assemblies, Lehn pointed out[12] that our approach must require a kind of molecular information science, of "molecular informatics." Hence, chemists have, over the last 15 years or so. been busy contributing to this information data bank. As this collection of data increases. it becomes possible to begin to quantify assemblies. This process is. in effect, writing the rule book that will ultimately allow inolecular subunits to be readily designed and synthesized for a required self-assembly. The purpose of this article is not to review the stream of data that was collected: there are many good reviews for this purpose.[8,11,13–17] Rather, it is to define self-assembly by bringing together the less well-appreciated examples of quantitative descriptions of

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012781

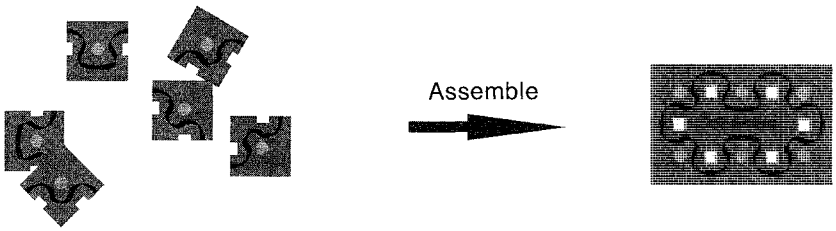

Fig. 1 Cartoon of a self-assembly process.

self-assembly, so that these can be tied into the well-established qualitative descriptions given above.

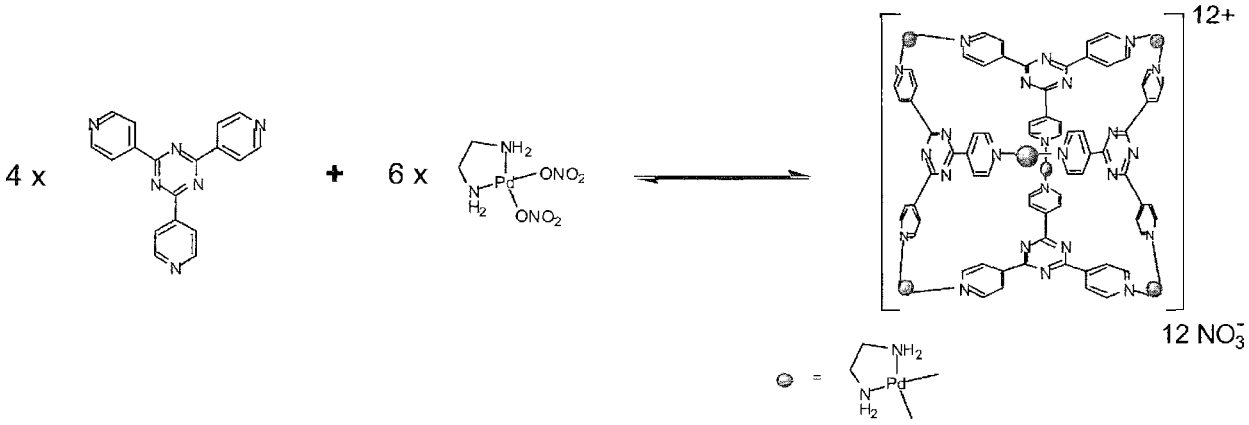
SELF-ASSEMBLY: THE CURRENT STATE OF AFFAIRS

To describe self-assembly, we need to consider the three components of any process: the subunits: the products, and the (complex) equilibrium that relates the two. As yet, there is no unification of these different aspects. Consequently. we will review the work from each category separateiy. In general. progress toward a quantitative description can be approached from two different fronts. The first of these is based on first principles. and produces detailed models that fully describe specific assembly processes. There are literally only a handful of systems described in this manner. For some recent examples, the reader is directed toward the literature.[18–20] The basis of the second approach is philosophically different. Here. the developing classifications are not derived from first principles but are symmetry based. In this way, they are applicable to more than one specific type of self-assembly. In this entry we focus on this latter methodology.

The Molecular Subunits

Molecules that constitute assembly subunits are generally described qualitatively. For example, the term, "possessing information'' is routinely used. What is this ''information''? A considerable amount of effort has gone into describing and classifying the assembly information contained within molecular subunits. Perhaps not surprising, the bulk of these descriptions has been applied to the most successful type of self-assembly to dace; self-assembly utilizing metal ions (acceptors) and coordinating ligands (donors). The assembly shown in Scheme 1 from the Fujita group is an admirable example.[21]

Assembly subunits can be broadly categorized as rigid or flexible. This absolute, and imperfect. distinction is made because, as we will see. the inherent flexibility in a subunit has a major impact in the way assembly (and assembly information) is viewed. Peter Stang and co-workers were some of the early pioneers in regard to the categorization of rigid subunits. Thus, they described[22] how rigid subunits coinprised of donor ligands and acceptor metal ions can be broken down into two kinds: those that are linear and those that are angular. Linear units can only be comprised of two donor–acceptor sites, but the angular subunits can have any number of sites



Scheme 1 A typical strict self-assembly from the Fujita group. (From Ref. [1].) (*View this art in color at www.dekker.com.*)

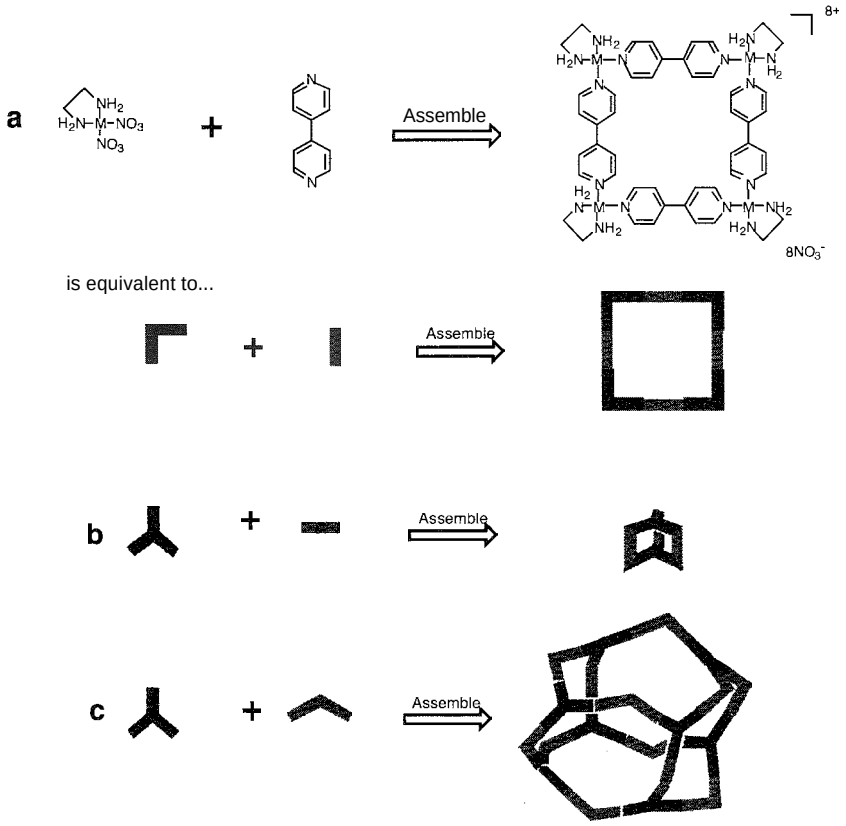


Fig. 2 Three successful assembly predictions from the combination of (a) four 90° angular units and four linear units: (b) two trigonal planar units and three linear units; and (c) Eight trigonal planar units and 12 109° angular units. **(View *this* art *in* color at *www.dekker.com.*)**

(>1), and possess any set angle between them. From this simple premise. it became possible to consider many assemblies arising from rigid subunits (Fig. 2).

Swiegers and Malefetse recently proposed[23] an extension to the Stang assembly analysis technique to precisely define the chemistry and geometry of each subunit. Consider the assemblies shown in Fig. 2. We can define each subunit as linear (*L*) and angular (A) and the blue and red subunits as acceptors *(u)*and donors (d), respectively. Having done this and taking the convention that the order of listing of subunits is acceptors, then mixed (acceptor–donor) subunits, then donors, we can classify these types of assemblies. Hence, the assembly in Scheme 1 is an $A_6^{2a}A_4^{3d}$ process, because it involves the coming together of six angular ditopic acceptors and four tritopic angular donors. Similarly, the assemblies in Fig. 2 are $A_4^{2a}L_4^{2d}$, $A_2^{3a}L_3^{2d}$, and $A_8^{3a}A_{12}^{2d}$, respectively. This approach to categorizing is useful, because it can be tied in with the categorizing of assembly products (vide infra) to reveal which type of assembly subunits are required for a target polyhedron with corners, edges. or faces that are formed from donors or acceptors. However, it must be noted that this approach was designed specifically for assemblies such as those shown in Scheme 1 or Fig. 2. Outside the bounds of these types of processes, the approach runs into problems. For example, the assembly shown in Fig. 3 cannot be described in this manner. Likewise. it will require modification if it is to be able to describe assemblies involving subunits such as proteins that interact via a multitude of moieties.

The above approach to describing subunits is difficult if the subunit possesses several degrees of rotational freedom or some other form of disorganization. How does one define, say, the ligation directionality of di-3-pyridyl ketone? Recently, Raymond and coworkers proposed rules that describe the assembly of their more flexible subunits.[24] In these cases, the organic subunits are relatively flexible and possess inultiple chelator groups. Hence, the principle focus of attention has not been on the directional relationships of the donor groups. but rather on describing the mode of ligation of the subunits to the metal ion subunits using coordinate vectors. chelate planes, and approach vectors (Fig. 3). Hence, the information contained within each subunit is not considered with the molecule or fragment in isolation, but in the context of the assembled species. Approaches to describe the assembly products (vide infra) have, therefore. much in common in this regard.

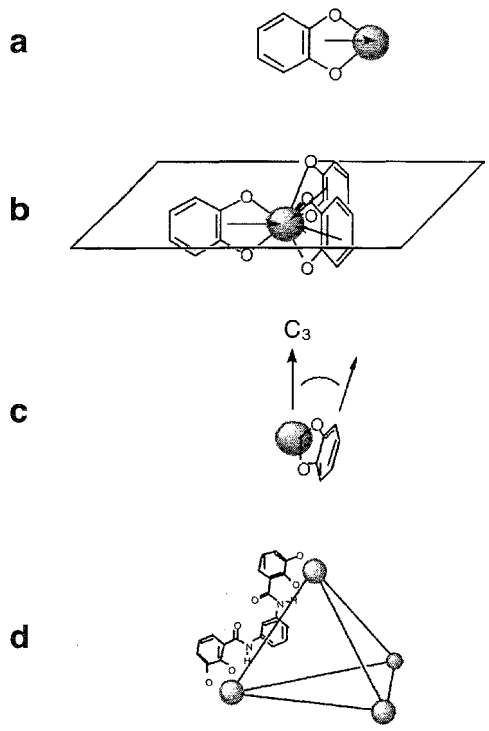

Fig. **3** *(a)The coordinate vector* for *catechol coordination to* a *metal center.* (b) *The chelate plane defined by a metal* ion *and the coordinate vectors in a tris-catechol complex. (c). The approach angle* for *each chelate of the tris-catechol complex.* (d) *A* M_4L_6 *tetrahedral cluster (adapted from Ref.* [24]). (*View this art in color at www.dekker.com.*)

Mirkin et al. recently worked on a slightly different metal-ion-directed self-assembly in which thermodynamically controlled covalent modification is applied to the product.[''''] In this approach. the assembly part of this, ''self-assembly with covalent modification,'' involves chelate donors and is perhaps best described with the Raymond analysis. However, in contrast, the postmodified products are probably best described using the method proposed by Stang. This double-barreled approach is not ideal and indicates that there is still a large amount of work to be done before a more uniformly applicable description of self-assembly is reached.

The Assembly Product

There are an infinite number of shapes that can be formed by self-assembly. How do we classify all of them? It may be possible to broadly classify assembly products as, e.g., star-shaped, but it is hard—at least from a chemist's point of view—to justify at the moment why snowflake-shaped assemblies need to be divided into different subclasses ad infinitum. There is, however, at least one exception to this ''classify assembly product or not'' quandary; spherical or quasi-spherical assembly products. As MacGillivary and Atwood pointed out,[25] in a chemical system, there are only so many ways in which subunits can be brought together to form these types of assemblies. This is fortunate, because with potential applications including catalysis, drug delivery, or molecular devices. hollow sphericallquasi-spherical assembly products are probably one of the most important classes of assembly product. Within this subgroup there are two general categories of products: arising from either two (curved) subunits, or those formed from more than three regular polyhedral subunits. The latter of these lead to assembly products based on the five Platonic solids, the 13 Archimedean solids, or one of the two (infinite) families of prisms and antiprisms. Classifying the assembly product in such a manner complements the categorization of the assembly subunits. In combination, they allow the visualization of which assembly subunits can potentially lead to which assembly products.

The Assembly Process

In a chemical sense. what relates molecular subunits with their assembly product? To answer this question precisely is to define self-assembly. From a qualitative standpoint, we can state that the two sets of molecules are related by a complex series of intertwining equilibria; some of them dead-ends. some of them leading as directly to the assembly product as possible.[26] As a step toward analyzing this type of complex system, we recently described a general, semiquantitative analysis of self-assemblies.[27] This probabilistic approach'' focuses on the options available to each molecular subunit as the assembly occurs and engenders a common frame of reference by which the efficiency of all assemblies leading to discrete species can be compared.

Because different assemblies involve the coming together of different numbers of subunits, quoting a yield for an assembly system tells us nothing about the efficiency of the assembly process. Yields tell us what went right during the assembly but not what potentially could have gone wrong with the process, and it is the difference between these that dictates assembly efficiency. To gauge the efficiency of a process, we need to measure the probability that an assembly will occur

''To the author's knowledge. the first consideration of probability of assembly in a self-assembling system (the folding of bovine pancreatic ribonuclease via the pairing of the eight sulfhydryl groups) was made by Anfinsen: Ref. [28].

successfully, and compare this to the actual yield of the process to see if it is better or worse than probability suggests. To determine the probability of assembly, two approximations must be made. First, the examination of possible assembly options must be constrained to the possibilities that can arise between the number of subunits that appear in the product. Put another way, to prevent an analysis into infinity, the possibility that molecules or random polymers larger than the product are formed must be assumed to be zero. This limits the analyses to a practical level. The other approximation also restrains the analyses and, perhaps more importantly, levels the playing field for all analyses. Thus, we assume that assembly occurs between subunits for which bond rotation is the only allowed motion, and that barring impossible molecular motions (such as moieties passing through moieties). all intermolecular and intramolecular processes occur on a flat potential energy surface. Thus, there is no bias because of conformational sampling of the subunit or supramolecular array, or bias because activation energies arising from the building processes are taken into account. These natural biases are, in actuality, what makes an assembly successful, and they are part of the actual yield of the assembly. The probability value calculated is therefore representative of a worst-case scenario, where the subunit is devoid of information. The approach centers around the construction of a standard probability tree that details the successful and the nonsuccessful pathways of assembly. This "assembly tree" leads to the calculation of a probability (p) for forming the product and, hence, a theoretical yield. An example best illustrates the approach. Consider the $A_6^{2a}A_4^{3d}$ assembly shown in Scheme 1 and its corresponding assembly tree (Fig. 4). Assembly is initiated by joining two triangular subunits by one metal ion (not shown) to form the first, bow-tie, intermediate. The probability of this occurring correctly is one in one. Note that although the assembly is reversible, for convenience, we assume that each step is irreversible. There is no going back: either we form an intermediate that can go on to form product, or we form an intermediate that cannot. Next, the bow-tie can undergo eight possible reactions: four intrainolecular and four intermolecular. All the intramolecular reactions lead to an intermediate that cannot go on to form product. These pathways are therefore terminated. All four intermolecular reactions give the same linear, trimer intermediate. Thus, the probability of this compound forming is 1/1 x 4/8, i.e., $\rho = 0.5$. Likewise, the probability of forming each of the three, next-generation, possible tetramers is 1/1 x 4/8 x 1/13 or one in 26 for the three-pointed star derivative, and two in 1/1 x 4/8 x 4/13 or two

Scheme *2* The formation of a [2]catenane and a *bis*-[2]catenane. (From Refs. [29,30])

in 13 for the linear and equilateral triangle species. Repeating this process until the product is formed, we can determine that the probability of successful assembly is $\rho=0.1301$ or 13%. In actuality, the product is formed quantitatively, and thus the ratio of these two values is 7.68. The actual yield is 7.68 times better than probability suggests. We call this ratio the assembly number (AN). The higher the assembly number the better.

By considering the probability of assembly, it is possible to evalute the effifiency of different assemblies. Consider the formation of the [2]catenane[29] and the *bis*-[2]catenane[30] shown in Scheme 2. The first is isolated in a yield of 70% and the second in a yield of 31%. However, by forming the corresponding assembly trees. it is possible to determine their respective AN values as 1.4 and 3.72. It is the formation of the *bis*-[2]catenane that is more efficient.[27]

Whether or not an assembly follows a theoretical assembly tree can only be determined by garnering information about intermediates in the process—a difficult task for complex assemblies.[26] Nevertheless, as a starting point to assembly analysis, assembly trees offer information regarding the statistically prevalent species in an assembly mixture. They suggest where we should start looking when wishing to determine the mechanism of an assembly. Moreover, in addition to the information they provide regarding the efficiency of a process, assembly trees represent unique fingerprints for specific types of assembly. Hence, they represent a powerful means by which assemblies can be analyzed and categorized.

CONCLUSION

It is apparent that although chemical self-assembly is defined in qualitative terms, there is still a considerable amount of work to be done to quantify self-assembly. However, advances are being made in the categorizing of assembly subunits, assembly products, and the chemical relationships between the two. On another front, specific systems are beginning to be described from first principles. These advances amount to an increasingly more accurate definition of self-assembly in chemical systems. They also constitute a developing rulebook with which we will ultimately be able to manipulate the increasing pool of knowledge of "molecular informatics."

Strong Hydrogen Bonds

Christer B. Aakeröy
Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

Hnterrnolecular forces are ultimately responsible for the way in which discrete molecular building blocks are assembled into infinite architectures and crystalline materials, and for providing the necessary specificity and selectivity in host–guest chemistry. Although it is important to acknowledge that every crystal structure and host–guest interaction is the result of a subtle balance between a multitude of noncovalent forces; the hydrogen bond remains a crucial element in supramolecular chemistry. In this article, some of the parameters that are commonly used when characterizing and examining strong hydrogen bonds, particularly in the context of supramolecular solid-state chemistry. will be outlined.

BACKGROUND

Strong Hydrogen Bonds—What Are They?

The strength and directionality of the hydrogen bond,[1–5] as compared to other intermolecular forces, account for its significance and has made it the most important interaction in molecular recognition and crystal engineering. Despite the fact that hydrogen bonds are employed regularly and successfully as structure-directing forces in natural and synthetic supramolecular systems,[6] there is still considerable debate about how to define a hydrogen bond and how to distinguish between "weak," "moderate." and "strong" hydrogen-bond interactions.[7–11] in many ways, such classifications will suffer from a considerable degree of arbitrariness, as it is impossible to find boundaries with experimental or theoretical methods that correspond to real physical distinctions. Hydrogen bonds. in general. as well as weak hydrogen bonds are covered elsewhere (see articles on hydrogen bonding and weak hydrogen bonds). The main focus of this section will be on "strong" hydrogen bonds. Defined in Scheme I are the geometric parameters that will be used throughout this section. Despite the lack of fully satisfactory definitions, hydrogen bonds that are frequently referred to as being strong display many common traits in terms of their properties and behaviors. Strong hydrogen bonds tend to display significant infrared (IR) shifts (over 25%) for the D—H bond. large downfield 'H-WMR shifts (14–22 ppm). and bond energies over 50 kJ/mol. In the solid state, common features include a lengthening of the D—H bond (0.08–0.25 Å), short H···A distances (1.2–1.5 Å), and 0 in the range of 170–180° (these numbers should be taken as guiding values only).[12] Strong hydrogen bonds are often referred to as low-barrier hydrogen bonds. because they involve a single-minimurn potential energy well or a double-well with a small barrier. Such interactions: which usually involve charged species. have a significant covalent component. They tend to form when a proton is shared by two strong bases. as demonstrated by the charge-assisted hydrogen bonds between bifluoride ions. $[FHF]^-$, which have bond energies greater than those displayed by some covalent interactions.[13] For the purpose of this section, a strictly operational "definition" of strong hydrogen bonds will be employed: only hydrogen bonds that involve O. N, or X heavy atoms (where X=F, Cl, or Br) and display some of the structural or spectroscopic features listed above will be considered as strong (and no distinction between hydrogen bonds involving neutral and charged species will be made).

Relevance of Strong Hydrogen Bonds

Strong hydrogen bonds are important stabilizing factors in enzymes and are relevant to proton-transfer reactions in biological systems.[7–9] For example. a key step in many enzyme-catalyzed processes is the formation of a thermodynamically unfavorable enolate in the presence of an acid catalyst. The required stabilization energy may be provided when a weak enzyme···substrate hydrogen bond is replaced with a strong enzyme···intermediate hydrogen-bond interaction.[14] Strong O—H···O and N—H···O hydrogen bonds are also responsible for the formation of α-helices and β-sheets in proteins, base pairing in nucleic acids. and many protein–nucleic acid interactions.[10] It was suggested that the formation of strong hydrogen bonds is instrumental in ester hydrolysis catalyzed by cholinesterases.[15] Strong hydrogen bonds were also implicated as possible conduits for magnetic exchange interactions,[16,17] and near-symmetric $N—H^+\cdots N$ hydrogen bonds are observed in proton sponges.[18] Strong hydrogen bonds are important in some

ferroelectric materials,[19] which is indicated by changes in transition temperatures that occur upon deuterium substitution. They are also known to play key roles in several structures that display pyrelectricity (polarity induced by heating). piezoelectricity (polarity induced by pressure). and ferroelasticity (polarity induced by mechanical stress).[19]

DETECTING HYDROGEN BONDS

In a generic hydrogen bond, D—H···A, the overall thermodynamic effect is a lowering of the potential energy as compared to the sum of the energies of the two isolated monomers. In addition. as the distance between the two species decreases and the D—H···A interaction approaches its maximum stability, there is a corresponding weakening of the covalent D—H bond. Consequently. it is possible to employ a variety of spectroscopic. crystallographic, and thermodynamic tools (in addition to the use of high-level ab initio or density functional theory)[20] in the study and detection of strong hydrogen bonds.

Infrared Spectroscopy

Changes in molecular geometries that take place when hydrogen bonds are formed can be studied using vibrational spectroscopy, but the relative strength of a hydrogen bond can also be determined due to its behavior in the IR region.[7,9] For weak hydrogen bonds. the bands are not far removed from those in a discrete D—H system, however, a strong hydrogen bond gives a broad band in the 1600–3000 cm^{-1} region, with three discernible maxima. Particularly strong hydrogen bonds give a broad band below 1600 cm^{-1}, which is indicative of a highly polarizable system. Even with this information, it is sometimes difficult to analyze and interpret IR spectra that involve strong hydrogen-bond interactions, as the region below 1400 cm ' tends to be overlaid with a large number of other absorption maxima. By selectively replacing hydrogen atoms with deuterium. it is often easier to accurately assign correct hydrogen-bond modes; the isotope frequency ratio ν_{AH}/ν_{AD} varies as a function of internuclear separation.[22]

Possible correlations between the chemical nature of the donor and the acceptor, and the resulting hydrogen-bond behavior were examined extensively.[1–5] For example,[23] a systematic study of the mid-and far-IR regions for a series of carboxylic acid···pyridine complexes (in chloroform) showed that even the weakest acid in this sequence, acetic acid, forms a 1:1 complex with pyridine held together by a short O—H···N hydrogen bond. The potential energy of this hydrogen bond is described by a highly asymmetrical double-minimum curve. With increasing acidity (or decreasing temperature), the O—H···N hydrogen bond becomes stronger. the O···N distance shortens, and the potential energy curve has a more symmetric appearance. The height of the barrier between the two minima in the potential-energy curve decreases with increasing acid strength. In the trifluoroacetic-acid–pyridine complex. the equilibrium is shifted toward the right-hand side of the equilibrium, O—H···N⇌O^-···$^+$H—N. The partial proton transfer is most efficient when the acceptor and the donor have similar proton affinities (PA), and the dissociation energy of D—H···A decreases as ΔPA increases. The gradual physical changes that take place (as a function of variations in the donor strength of D—H). can be monitored effectively using IR spectroscopy. However, this study also shows that there is a continuum between the relatively weak acetic acid···pyridine hydrogen bond and the charge-assisted O^-···$^+$H—N hydrogen bond.

NMR Spectroscopy

The findings from the use of nuclear magnetic resonance (NMR) spectroscopy for interrogating systems with strong hydrogen bonds can be divided into four categories: changes in chemical shifts, hydrogen-bond dissociation and exchange times, relaxation processes, and location of hydrogen atoms in crystalline materials. When a hydrogen-bond donor, D—H. is in close proximity of a suitable hydrogen-bond acceptor. the corresponding ^{1}H-NMR signal is shifted to higher frequencies, consistent with deshieiding of the proton. Observed shifts are significantly larger for species capable of forming strong hydrogen bonds, cf. HF and H_2O.[7–9]

By correlating hydrogen-bond distances (obtained from neutron-diffraction data) with chemical shift tensors obtained from solid-state ^{1}H-NMR spectroscopy, it was shown that there is a linear relationship between the O···H distance and the anisotropic chemical shift. The observed shifts translate to −20 ppm per 1.0 Å change in O···H distance.[24] The change in chemical shift for

strong hydrogen bonds can also distinguish single-minimum systems from the double-minimum, low-barrier type.[25] For example, the following data were found for the hydrogenphthalate ion: $\delta(H)=21.00$; $\Delta\delta(H,D)=-0.15$; and $\Delta\delta(H,T)=-0.25$ ppm (the negative change indicates a single-minimum hydrogen bond). Whereas for acetylacetone, the following was determined: $\delta(H)=16.1$: $\Delta\delta(H,D)=0.61$; and $\Delta\delta(H,T)=0.83$ ppm, which is typical of a hydrogen bond with a double-well energy profile.

Crystallography

The presence or absence of hydrogen bonds in a crystalline material is often inferred by applying one or several geometric criteria such as D···A and H···A distances shorter than their combined van der Waals radii [e.g., R(O···O) <3.10 A. r(H···O) <2.75 Å, R(N···O) <3.25 Å, θ (D—H···A) greater than 90–120°, etc.]. Unfortunately, there is still debate about which values to use for van der Waals radii. and it has become clear that rigid applications of geometric criteria as a way of identifying hydrogen bonds is inadequate, especially when examining weaker interactions.

A way around these difficulties can be provided by systematic statistical studies of extant structural data obtained from the steadily growing Cambridge Structural Database.[26] Such efforts provide a crucial base from which our understanding of hydrogen-bond interactions can be further developed. By correlating geometric parameters of hydrogen-bond interactions with the nature of the participating donor and acceptor moieties, several important trends were identified.[27] An increase in H···A distance is likely to be accompanied by large deviation from linearity of θ. And, O—H···O interactions are more often close to linear geometries than are N—H···O hydrogen bonds.

There is also an inverse relationship between the covalent O—H and the intermolecular H···O distance in an O—H···O hydrogen bond. In the case of strong D—H···A hydrogen bonds, the D···A distances are typically significantly less (>0.3 A) than the sum of the combined van der Waals radii of D and A. Furthermore, the proton is normally located near the center of D···A. Of course, any reliable examination of geometric parameters involving the hydrogen atom requires access to neutron-diffraction data: the large neutron-scattering power of hydrogen-atom nuclei means that they can be located with the same accuracy as many heavier atoms.

Electron-density maps (obtained through a combination of neutron-diffraction, x-ray diffraction, and high-level theory) can offer unique insights into the subtle, but significant, electron rearrangements that accompany the formation of hydrogen bonds.[28,29] In hydrogen bonds of weak and intermediate strengths, it is common to approximate the electron distribution in the bond to a simple superpositioning of the electron densities of the individual. unperturbed, donor and acceptor moieties. In essence, these interactions can be adequately represented by an electrostatic model, because attractive charge transfer and repulsive exchange interaction are small and tend to cancel each other. In strong hydrogen bonds, the charge distribution is more symmetrically arranged. as there is less charge buildup on either side of the proton, as well as in the D—H bond and in the H···A region.

Theory and Physical interpretations

Because electrons are responsible for all chemical bonding, it is desirable to discuss hydrogen-bond interactions in terms of quantities that directly describe electron densities rather than concepts like σ-and π-bonding, electronegativity, etc.[20]

The total interaction energy of a hydrogen bond can be partitioned into four (sometimes five) constituents. The sum of these terms should represent the total energy difference, ΔE_{HB}, between the hydrogen-bonded system at equilibrium and the total energy of the isolated, unperturbed, components. The electrostatic contribution represents the energy change that would take place if two isolated components. D—H and A. were positioned in such a way that the geometry represents the hydrogen-bonded complex, D—H···A, but without perturbing their respective charge distributions and without any electron exchanges taking place. The polarization energy represents the energy gain that would arise if the charge distributions of the isolated components were deformed to resemble the charge distribution of the hydrogen-bonded complex (still without allowing for any charge transfer between D—H and A). The charge transfer contribution represents the energy change that would result from electron transfer between D—H and A. The notion of "covalency" in a hydrogen bond is related to the latter term; charge transfer results in a buildup of charge in the overlap region, where it is shared between the original components D—H and A. The dispersion energy (another stabilizing component) is the energy change resulting from the correlated motion of electrons on D—H and A. The only destabilizing term. the exchange energy between D—H and A. essentially corresponds to the repulsion that arises when too many electrons are located within the same region of space (a violation of the Pauli exclusion principle)—this exchange energy also prevents the system from collapsing. The way the energy is partitioned in a positively charged hydrogen bond is similar to the situation in a neutral system, with the main difference being that there is a decrease in exchange contribution. This is due to the fact that wave functions in positive ions

are more compact, resulting in less overlap between donor and acceptor moieties.

Through high-level calculations. it was shown[30] that there is a linear relationship between the strength of O—H···O hydrogen bonds and the difference in proton affinity. ΔPA, of the donor and the acceptor (there is also a correlation between O···O distance and strength). Single-well or low-barrier double-well hydrogen bonds tend to arise when $\Delta PA \approx 0$ (this is corroborated by IR studies).

STRENGTH OF THE HYDROGEN BOND

As so many different donor and acceptor moieties can participate in a strong hydrogen bond. it is not surprising that the strengths vary considerably. The hydrogen-bond energy (increased stabilization) is typically defined with respect to the lower-energy coinponents [D—H] + [A] or [D] + [H—A]. Strong hydrogen bonds involving neutral species tend to be in the range of 10–65 kJ mol^{-1}, but for charge-assisted interactions. the range of bond strengths rises to 40–90 kJ mol^{-1}.[13] The strongest known hydrogen bonds typically involve $[FHF]^-$ anions with commonly reported values of 155–252 kJ mol^{-1},[31–34] which is comparable to the strength of covalent single bonds.

Interionic Hydrogen-Bond interactions

Despite conflicting reports,[35] interion O—H···O^- interactions of the type often observed in monoanions of dicarboxylic acids. dihydrogenphosphates, and hydrogensulfates. behave similarly to strong hydrogen bonds between molecular species.[36] The IR absorption spectrum of potassium hydrogenoxalate displays the expected features of a strong (and stabilizing) hydrogen bond. There is also a significant lengthening of the covalent 8 — H bond distance (as determined by single-crystal neutron diffraction).''' Finally, the C—O bond distance of the acceptor moiety of the anion is significantly longer than the C—O bond distance of the moiety that does not participate in the near-linear O—H···O^- interaction. In addition, solution WMW studies of hydrogenoxalate anions demonstrate that interactions between anions display characteristics that one would conventionally associate with strong hydrogen bonds, e.g., significant shortening of the O···O distances.[38] These results have important ramifications for supramolecular synthesis, because they show that charge-assisted hydrogen bonds between anions can be employed as active structure-directing tools. The commonly observed short intermolecular distances are not the result of a ''least-destabilizing'' arrangement.

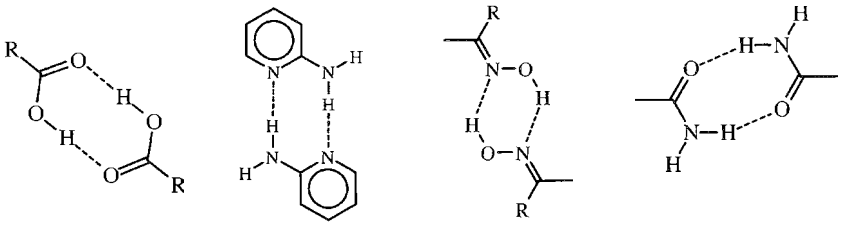
SPECIFIC EXAMPLES OF STRONG HYDROGEN BONDS AND THEIR BEHAVIORS

Strong O—H^+···O hydrogen bonds are typically associated with oxonium ions, H_3O^+. Other ''hydrated protons.'' like the diaqua oxonium ion. $H_5O_2^+$, often appear in structures of strong mineral acids.[39]

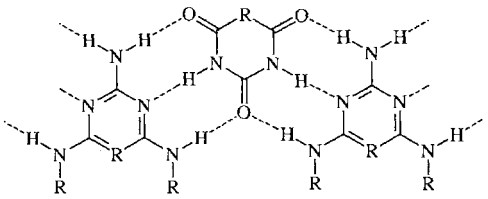
Strong O—H···O hydrogen bonds between neutral species are well known from crystal structures of β-diketo enols and certain dicarboxylic acids. The shortest O···O distances are associated with intramolecular interactions (exemplified by pyridine 2.3-dicarboxylic acid). The increased strengths of such interactions are the result of a resonance contribution. This n-bond cooperativity or resonance-assisted hydrogen bonding[40] involves multiple bonds. whereas the cooperative effects between hydroxyl groups in carbohydrates and cyclodextrins are usually described as σ-bond cooperativity.[41] Resonance-assisted hydrogen bonds also contribute to the stability of heteromeric interactions. e.g., 2-pyridone ··2-aminopyrimidine, and are therefore particularly important in inolecular recognition processes involving purines and pyrimidines.

Strong N—H^+···N hydrogen bonds are characteristic of proton sponges, fused-ring diamines with extraordinarily high basicities.[''' These molecules readily accept a proton, which interacts simultaneously with two nitrogen-based lone pairs that face each other. These hydrogen bonds range from very short (possibly centrosymmetric) to conventional hydrogen bonds without significant lengthening of the covalent N—H bonds.

The N—H···N^- hydrogen bonds were studied crystallographically, as exemplified by intramolecular N—H···N interactions between adjacent acetamido



Scheme 2 Some examples of self-complementary hydrogen-bond interactions



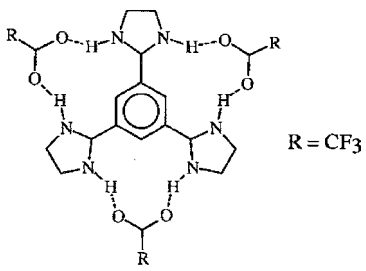
Scheme 3 A typical hydrogen-bonded tape generated by hydrogen bonds between complementary aminotriazine-··barbituric acid building blocks.

moieties (where one of the acidic protons was removed). In addition, ab initio calculations estimate that the $[H_3N\cdots H\cdots NH_3]^-$ complex has a hydrogen-bond energy of 56 kJ/mol, which is 48 kJ/mol less than the calculated value for the corresponding positive complex ion.[42]

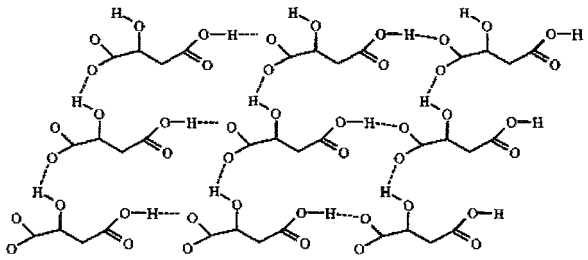
STRONG **HYDROGEN BONDS** AND **SUPRAMOLECULAR ASSEMBLY**

One of the most well-known hydrogen-bond motifs is the carboxylic acid dimer. This particular intermolecular interaction is not only present among simple organic acids (there are few examples of chain-like, catemeric interactions between carboxylic acids), but self-complementary head-to-head carboxylic acid dimers are also often observed in coordination compounds as well as in organometallic species.[43] The availability of these robust and transferable intermolecular interactions (Scheme 2) allows for the assembly of discrete building blocks into extended networks of well-defined and predictable connectivities.

The improved understanding of interinolecular interactions. hydrogen bonds in particular. is invaluable to the development of crystal engineering — an interdisciplinary area concerned with the rational design, synthesis, and assembly of functional materials through noncovalent interactions.[44] Several aspects of this field are covered extensively elsewhere (see articles on hydrogen bonds,



Scheme 4 Six charge-assisted N—H···O hydrogen bonds give rise to a tetrameric structure.



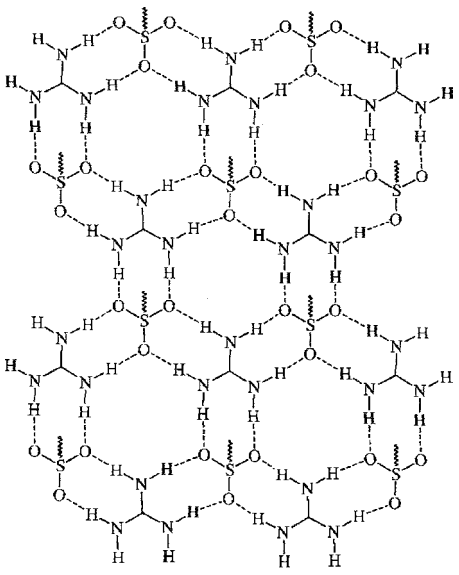
Scheme 5 Charge-assisted O—H···O hydrogen bonds between hydrogenmalate anions lead to an infinite sheet.

weak hydrogen bonds, crystal engineering with hydrogen bonds) and a few examples of hydrogen-bond-directed crystal, engineering are given below.

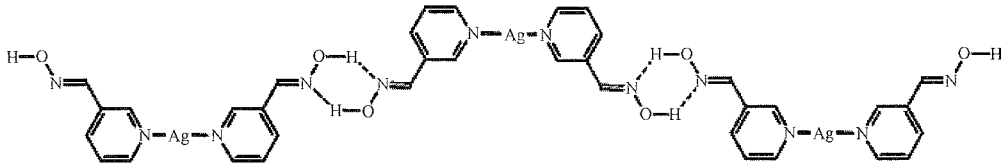
Construction of Extended Organic Architectures

The complementarity of some triaminotriazines (and related heterocycles) and barbituric acid was employed extensively in the assembly of a variety of discrete multicomponent structures as well as of extended ribbons, tapes, and rosettes (Scheme 3).[45–48] A collection of strong hydrogen bonds can impart sufficient stability to allow these structures to stay intact in solution as well as in the gas phase.

It was shown[49] that anions of trimesic acid generate hydrogen-bonded lamellar structures with alkyl- or aryl-substituted ammonium moieties.[50] The complementarities



Scheme 6 Charge-assisted N—H···O interactions in a guanidinium/sulfonate system produce highly reliable layers (shown face on).



Scheme 7 Infinite chain of Ag(I)(3-aldoximepyridine)$_2$ cations held together by oxime···oxime dimeric hydrogen bonds.

of pyrimidine-2.4.6-triamines and 1,3,5-triazine-2,4,6-triones were used to create infinite ribbons that were subsequently connected into sheets via ammonium ··carboxylate hydrogen-bond interactions.[''] A combination of directional hydrogen bonds and electrostatic interactions between complementary units (dicarboxylic acids and cyclic bisamidine) were also employed in the design of discrete and infinite assemblies.[52,53] Charge-assisted N—H···O hydrogen bonds were utilized in the construction of tetrameric structures from a *tris*(imidazoline) base and four carboxylate anions (Scheme 4).[54] Charge-assisted interactions were also instrumental in building two-dimensional ionic networks using chiral hydrogen-*L*-malate ions (Scheme 5).[55]

The most thoroughly studied supramolecular organic host framework capable of reversible incorporation of guests is arguably the guanidinium/organic sulfonate-two-component system.[56–58] The host structure is built with the aid of complementary hydrogen-bond sites on guanidinium cations and substituted sulfonaie anions, leading to robust infinite hydrogen-bonded sheets (Scheme 6).

Strong Hydrogen Bonds and Extended Inorganic Assemblies

Hydrogen bonds also enabled the directed assembly of coordination complexes into extended architectures.[59–63]

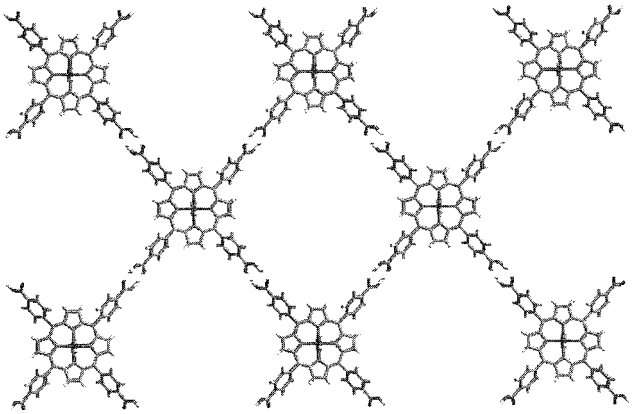


Fig. 1 Metal porphyrins assembled into infinite square grids through O—H···O hydrogen bonds between adjacent carboxylic acids.

For example, self-complementary oxime···oxime and amide···amide interactions[64–66] were used to propagate the inherent linear geometry of some Ag(I) complexes into infinite chains (Scheme 7).

Ligand-based, charge-assisted carboxylic acid···carcarboxylate hydrogen bonds in combination with Pt(II) ions. produced square grids that extend infinitely in two dimensions.[67] Even porphyrin complexes were connected into flat, grid-like networks through amide··amide and acid··acid hydrogen-bond interactions (Fig. 1).[68–70]

CONCLUSION

The concept of molecular recognition has a profound impact upon our understanding of a wide range of fundamental events, e.g., biomolecular activity. crystallization processes, and physicochemical signaling mechanisms. The relevance of strong hydrogen bonds to such phenomena remains unchallenged, and it is likely that further studies of the nature of such interactions will have important ramifications for supramolecular chemistry as a whole.

INTRODUCTION

Layer perovskite materials of the type $(RNH_3)_2MX_4$ and $(NH_3RNH_3)MX_4$ (M = divalent metal ion; X = Cl^-, Br^-, or I^-) form an extensive family of organic–inorganic hybrid materials. These contain layers of corner-sharing metal-halide octahedra separated by layers of organic cations. The metal ions employed have typically been from the first transition series or the heavier members of group 12 and group 14 elements, although a number of other divalent ions as well as trivalent ions have also been incorporated. With the appropriate choice of M and X ions, it is possible to incorporate a large variety of organic R groups into these materials. Often, the R groups play a passive role in the behavior of these materials, but much of the current research focuses on systems where there may be synergistic interactions between the organic and inorganic subsystems.

The compounds containing magnetic transition metal ions were extensively studied as model low-dimensional ferro- or antiferromagnetic systems. Variations in the size and shape of the organic groups are used to modify the strength of intra-and interlayer exchange coupling. When the metal is Sn^{2+} or Pb^{2+}, the systems are semiconductors that can be of use in device applications. The labile, ionic nature of these compounds allows for many of the hybrid materials to be processed using solution techniques.

A common feature of these hybrid materials is structural phase transitions involving the onset of disorder of the organic *R* groups. For compounds containing long-chain aliphatic *R* groups, this led to organic layers being studied as crystallographic models for lipid bilayers. Another interesting application is to use the inorganic layers as templates to hold unsaturated organic groups in favorable juxtaposition for photopolymerization.

STRUCTURAL CHARACTERISTICS OF LAYER PEROVSKITE MATERIALS

The parent perovskite rtructure has the formula AMX_3, where A and *M* are metal ions, and X is a monatomic anion.''' The structure consists of a three-dimensional (3D) network of corner-sharing MX_6 octahedra, while the A cations fill the 12-fold coordination holes within the 313 framework, as shown in Fig. 1a. The oxide perovskites can incorporate a broad range of A and *M* metal ions and have been extensively studied because of their interesting and useful physical properties. With the halide perovskites, it is possible to incorporate small organic cations in the A sites when the M cation has a large ionic radius.[2] However, the dimensionality of the framework must be reduced in order to extend this framework to incorporate larger organic cations. This is typically accomplished by slicing out a $(MX_4^{2-})_\infty$ (100) sheet, as seen in the left-hand diagram in Fig. 1b. The 12-fold holes in the parent AMX_3 structure now become eightfold square cavities that decorate each face of the inorganic framework. These have appropriate size to accommodate the $-NH_3^+$ moieties of the organoammonium cations. In this manner, $(RNH_3)_2MX_4$ layers are formed in which the inorganic frameworks are sheathed by the organic R groups. The crystalline materials thus formed are fragile, because only van der Waals interactions occur between these sheathed layers. If 3D stability is desired. diammonium cations (right-hand diagram in Fig. 1b) may be used to provide a covalent linkage between the inorganic frameworks.[3] In a few cases, a zigzag inorganic framework is observed, where the slices of the AMX_3 parent structure are cut out parallel to the (110) direction.''' Another variation. observed when a small A' ion such as $CH_3NH_3^+$ is present, has a multilayered inorganic framework of stoichiometry $(A)_2(A')_{n-1}M_nX_{3n+1}$.[5]

The inorganic framework is able to accommodate most divalent metal ions that can assume octahedral coordination geometry. From the first transition series, structures with Cr^{2+},[6] Mn^{2+},[7] Fe^{2+},[8] and Cu^{2+}[3] are known (Fig. 2a). However, the perovskite structure is not found with metal ions that have a strong preference for tetrahedral geometry or have a small radius. For metal ions like $Mn^{2+}$and Fe^{2+}, the bridging M–X distances are relatively invariant. so the sizes of the eightfold cavities vary little from compound to compound. In contrast. the

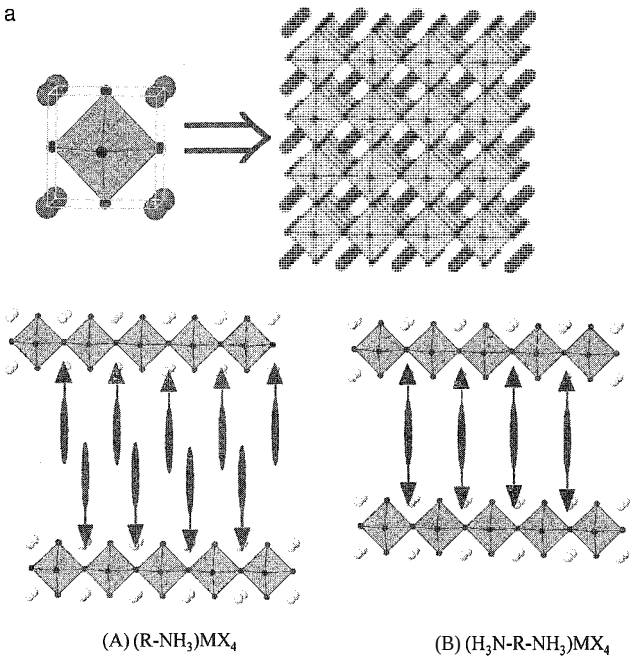

Fig. 1 (a) The cubic AMX_3 perovskite structure. (b) Single-layer perovskites with (A) monoammonium (RNH_3^+) of (B) diammonium ($^+NH_3RNH_3^+$) organic cations. (*View this art in color at www.dekker.com.*)

Cu^{2+} and Cr^{2+} ions are subject to a tetragonal elongation of their octahedral coordination due to the Jahn–Teller effect. This leads to an asymmetrical *M–X···M* linkage, with one normal *M*–X bond and one longer semi-coordinate *M···X* bond. The length of the semicoordinate bond is variable over a range $\geq$0.8 A. Thus, these lattices can adapt to accommodate more complex organic cations. For the main group metals. Cd^{2+},[9] Sn^{2+},[10] and Pb^{2+} [10] salts were prepared. Other more unusual metal ions that were incorporated include Eu^{2+}[11] and Pd^{2+}.[12]

The $-NH_3^+$ hydrogen-bonding linkage into the eightfold square cavity provides the interesting topological challenge of inserting an objeci with threefold symmetry into a cavity with fourfold symmetry. As a result. the C–N bond tips so that the $-NH_3^+$ is able to hydrogen bond to both the bridging and terminal halide ions. Two limiting cases exist: hydrogen bonds to two terminal and one bridging halides (the 2b,1t scheme) or to one terminal and two bridging halides (the 1b,2t scheme). The former is illustrated in Fig. 2b. These two schemes result in different conformations for the hydrocarbon backbone attached to the ammonium ion. These interactions have two effects on the inorganic framework. A $\sqrt{2} \times \sqrt{2}$ superlattice (or more complex) is produced that involves a 45° rotation of the in-plane crystallographic axes. The second effect is to cause the *M–X–M* bonding interactions to be nonlinear. This leads to a washboard effect for frameworlis based on transition metals. as seen in Fig. 2a. With Group 14 metal ions. an in-plane bending occurs. Both distortions adapt the eightfold cavities to the shape of the organic *R* groups.

The inorganic framework provides a template to which the organic *R* groups must accommodate. For *M* = first row transition metal and X = Cl or Br, the edges of the cavity typically range from 5.1–5.5 A. Thus. primarily straight-chain hydrocarbon groups can be accommodated. However, for the Jahn–Teller active ions. the variable length of the semicoordinate *M···X* allows for greater flexibility in the length of the sides of the cavity. Thus, these salts can accommodate *R* groups with simple ring systems. For cornpounds based on the larger metal or halide ions, the cavity edges now range from 6.0–6.4 A. This allows the incorporation of more complex *R* groups. In order to give sufficient flexibility to accominodate these more complex organics. it is conventional to tether them to the $-NH_3^+$ moiety via methylene or ethylene linkages.

PHYSICAL PROPERTIES AND APPLICATIONS OF HYBRID LAYER PEROVSKITES

Magnetic Properties

Because of their interesting magnetic properties. hybrid layered perovskites containing transition metal ions were

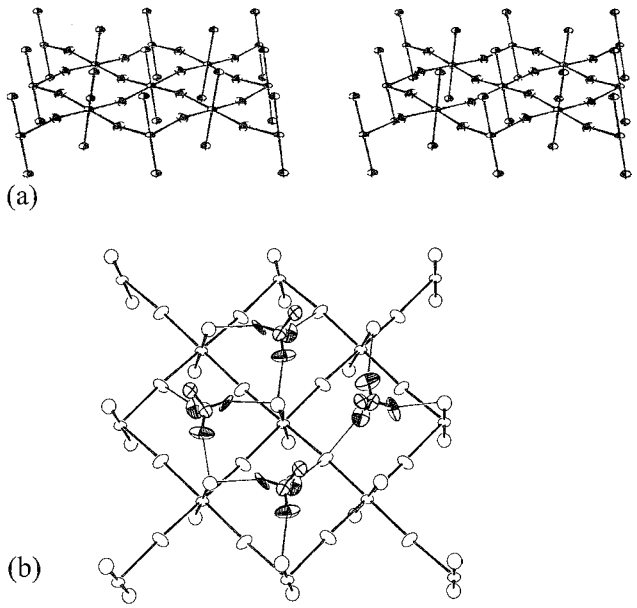

Fig. 2 The structure of $(NH_3C_3H_6NH_3)MnCl_4$ showing (a) the inorganic framework and (h) the 2t.1b hydrogen-bonding scheme (Adapted from Ref [8])

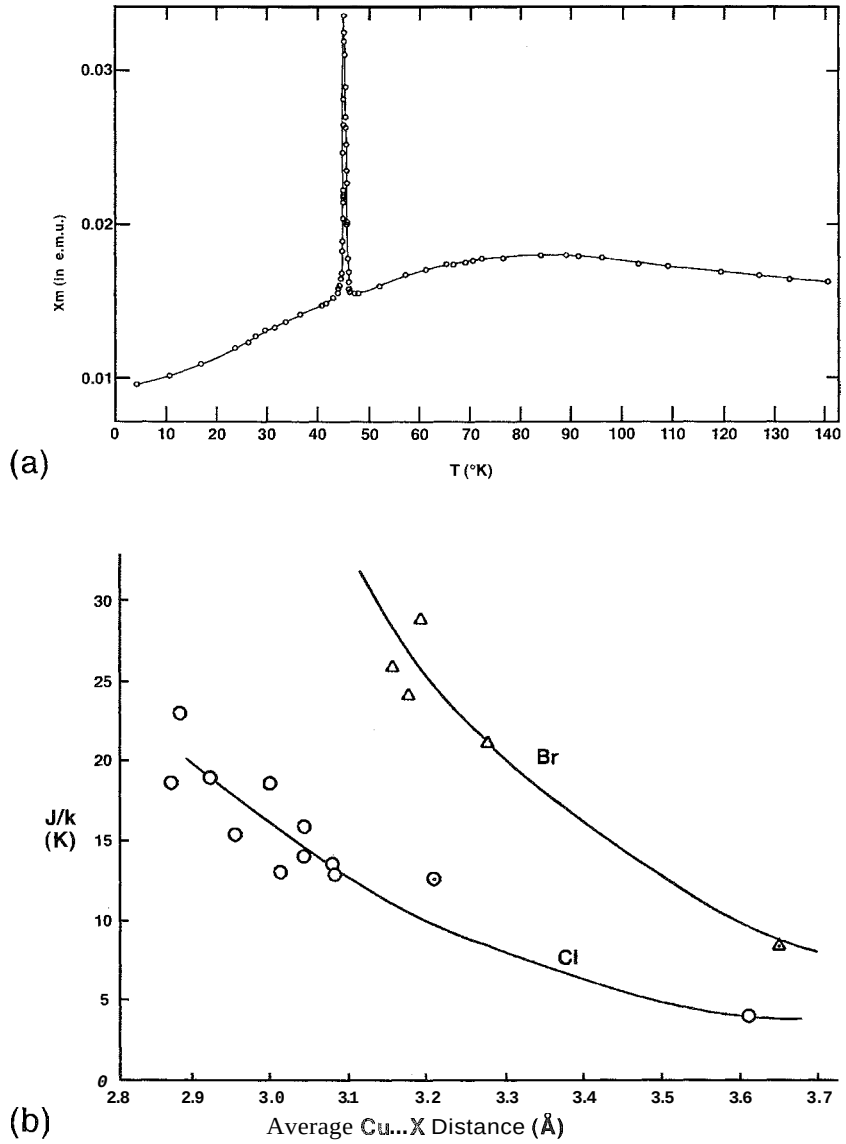
the most intensely studied. The corner sharing of the octahedra within the inorganic framework gives direct *M–X–M* superexchange pathways between the metal ions. while the organic sheathing of the layers generally restricts the interactions between the layers to those of dipolar nature. Thus, they are excellent realizations of two-dimensional (2D) magnetic systems. The ability to change spin quantum number and magnetic anisotropy through variation of the metal and halide ions has made these extremely interesting systems to study. In the Mn^{2+} salts, the symmetric Mn–X–Mn pathways lead to antiferromagnetic exchange coupling.[13] With the $S = 5/2$ ground states, the Mn^{2+} salts provide excellent model systems for classical 2D antiferromagnetic coupling. Short-range antiferromagnetic correlations lead to a maximum in the magnetic susceptibility in the 80–90 K range (Fig. 3a), with the onset of long-range magnetic order occurring at 40–50 K. Because of the nonlinear nature of the Mn–X–Mn exchange pathways, adjacent spins are not precisely antiparallel, so these actually show canted antiferromagnetic behavior. The creation of domain wall movements in these canted antiferromagnetic systems at the 3D ordering temperature leads to the spike seen in Fig. 3a. For the $S = 2$ Fe^{2+} systems, the presence of zero field-splitting leads lo further complications in describing the details of the antifersomagnetic-coupled 2D layer.[14]



Fig, 3 (a) Magnetic susceptibility of $(CH_3NH_3)_2MnCl_4$ (Gerstein, B.C.; Chang, K.; Willet, R.D. *J. Chem. Phys.* 1974, *60,* 3454). (b) Correlation of interlayer exchange coupling with the Cu···X distance in $(RNH_3)_2CuX_4$ salts. (From Ref. [4].)

Ferromagnetic interlayer coupling is found in salts of the Jahn–Teller active d^4 Cr^{2+} and the d^9 Cu^{2+} ions. The antiferrodistortive nature of the tetragonal elongation of the octahedra within the layers leads to orbital arrangements that favor ferromagnetic interlayer coupling within the layers in these systems. The type of 3D ordering will depend upon the nature of the coupling between the layers. Dipolar and superexchange interactions between layers usually lead to antiferromagnetic coupling. However, examples with ferromagnetic 3D ordering are known. The Cr^{2+} salts typically undergo 3D ferromagnetic interlayer ordering around 40–45 K. pointing the way to the possibility of high T_c molecular magnets.[6] $(MeNH_3)_2CuCl_4$ (among other Cu^{2+} salts) orders at 8.9 K.[15] The Cu systems were extensively studied as realizations of the quantum (S = 1/2) 2D ferromagnetic interlayer. The strength of the FM intralayer exchange coupling (and thus the ordering temperature) was shown to decrease monotonically (Fig. 3b) as the length of the semicoordinate Cu···X distance increases.[3] Magnetization and, electron paramagnetic resonance (EPR) studies showed that the spins align normal to the layers in the Cl salts and in the plane in the Br salts. This is due to the role of the ligand spin-orbit in determining the anisotropy of the magnetic interactions.[14] lor the diammonium $(NH_3RNH_3)CuCl_4$ series. it is found that as n decreases, strong interlayer antiferromagnetic superexchange coupling occurs via so-called "two-halide" Cu–X···X–Cu interaction~.~'~'

PHASE TRANSITIONS

The combination of different hydrogen-bonding schemes and the possibility of thermal reorientation of the part or all of the organic R groups leads to the potential for multiple phase transitions in these materials. The R = n-propyl series (M = Mn, Cu, Cd) exhibits interesting behavior. with multiple transitions and the presence of modulated phases. The phase transitions in the Cu^{2+} salt involve not only disorder of the cations but also perturbation of the inorganic framework.[17,18] In the low-temperature phase. the n-propyl groups form an ordered arrangement that leads to a pseudohexagonal arrangement for the terminal methyl groups. However. the disorder in the high-temperature phases causes packing of the methyl groups to mimic the square arrangement of the underlying ammonium groups. The high-temperature phase differs from the lower-temperatme phase in three significant ways: the average orientation for the N–C bonds is parallel to the normal to the plane; the bridging Cl atoms are not displaced from the planes; and the cations are disordered. An incommensurate phase, found at intermediate ternperatures, is characterized by the superposition of a wave-like sinusoidal displacement of each layer.[17,18] The displacements in adjacent layers are out of phase, so the distance between layers is also sinusoidally modulated.

The diammonium salts can also undergo phase transitions. The high- and low-temperature phases of $(NH_3C_3H_6NH_3)MnCl_4$ have the usual $\sqrt{2} \times \sqrt{2}$ superlattice of the inorganic framework and 2t,1b hydrogen-bonding scheme.[19] In the high-temperature phase, the cations are disordered across a mirror plane. with a rotation angle of 40° between the two orientations. However, the intermediate phase has a 2 x 2 superlattice. The cations are again disordered across a mirror plane. The hydrogen bonding is intermediate between the 2t,1b and 1t,2b schemes, so the angle between the two orientations is only 20°.

The phase transitions in compounds with long-chain R groups—C_{10} or longer—were touted as analogues of the phase transitions in lipid bilayers.[20] However, a major difference exists between the two systems. Although the R groups in the perovskites can undergo various types of motion. the-NH_3^+ head groups are anchored to an inorganic framework. Nonetheless. some similarities exist. The perovskite materials typically show two primary thermal anomalies. one with $\Delta S_{tr} \sim$ 5–10 cal/mol-K and the second with $\Delta S_{tr} \sim$ 30–40 callmol-K. The sequence in which these anomalies occurs depends on the length of the hydrocarbon chain and the size of the

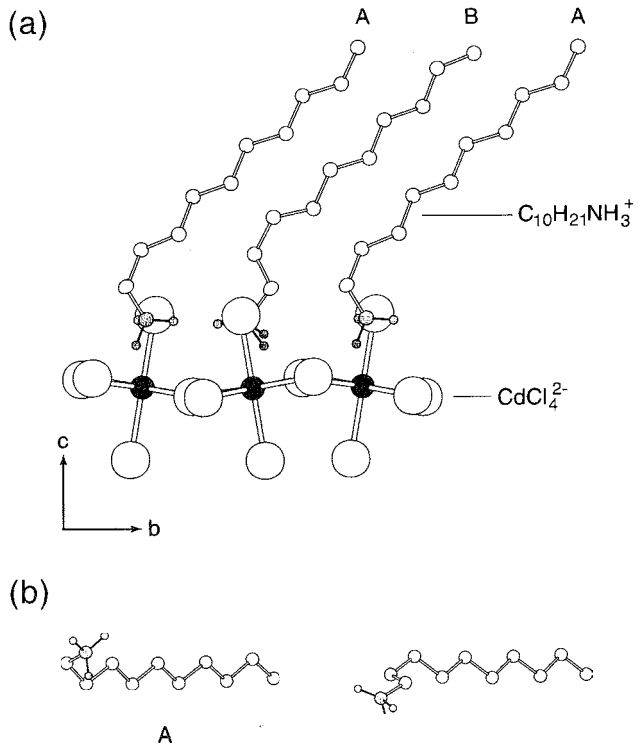


Fig. 4 The room-temperature structure of $(C_{14}H_{29}NH_3)_2CdCl_4$. (From Ref. [27].)

inorganic framework. In the low-temperature phase, the majority of hydrocarbon chains are in extended *trans* conformations that are tilted 30–40° from the normal to the plane, although some *gauche* bonds exist near the head group to accommodate the packing of the chains (Fig. 4). The major thermal anomaly corresponds to "chain melting"—the introduction of *gauche-trans-gauche* kinks into the chain and a realignment of the chains perpendicular to the layers.[21] When the smaller anomaly occurs first, this corresponds to a twofold flipping motion of the *trans* portions of the chains. When it occurs after the chain melting, it corresponds to a twofold disorder of the melted chains due to disorder of a gauche bond by the head group. Thus, these studies helped to shed light on the possible behavior in lipid layers.

Electrical Properties

Hybrid layer perovskites designed with metals from Group 14 possess a variety of favorable properties for the fabrication of electronic devices. These metal halides have excitonic transitions related to their band gap, which result in spectral transitions dependent on the metal cations and halides contained within the inorganic sheet of the perovskite. The 2D A_2MX_4 perovskite structure as well as the dielectric modulation between the organic and inorganic layers allows for strong exciton binding energy and observation of the electroluminescence at room temperature. The exciton binding energy and the oscillator strength also lead to strong photoluminescence,[10,22,23] nonlinear optical effects,[24,25] and tunable polarization absorption.[26] The Pb^{2+} perovskites demonstrated thermal and mechanical stability as well as room-temperature photoluminescence in the visible range,[27] while the Sn^{2+} perovskites possess high carrier mobility.

Incorporation of AEQT, the cation of the oligothiophene derivative 5,5‴-*bis*(aminoethyl)-2,2′:5′,2″:5″,2‴:5‴,2‴-quaterthiophene into the lead halide perovskite framework results in a characteristic absorption/emission of the given material. The organic-inorganic framework is tethered between the layers of PbX_6 octahedra by the ethylammonium groups of the dication. The AEQT is held between the metal-halide sheets in a herringbone arrangement with respect to the other AETQ cations in the lattice (Fig. 5). Organic-inorganic light-emitting diodes (OILED) were fabricated using thin films of the (AEQT)$PbCl_4$ perovskite.[28–30] The OILED devices based on (AEQT)$PbCl_4$ emit bright green-yellow light (λ_{max} = 530 nm) in a well-lit room when the devices are forward biased under ambient conditions.

Organic-inorganic TFTs (thin-film field effect transistors) were formulated as low-cost alternatives for the development of display and storage technologies.[31] The semiconducting organic-inorganic perovskite, $(C_6H_5C_2H_4NH_3)_2SnI_4$ [$(PEA)_2SnI_4$], was used in the fabrication of TFTs using solution-processed thin films (Fig. 6).[31] Devices fabricated from the $(PEA)_2SnI_4$ perovskite are *p*-channel transistors with field effect mobilities of 0.61 $cm^2/V\text{-}s$ and I_{on}/I_{off} ratio of $\sim 10^6$.[32] Flexibility in the choice of the inorganic anion and the organic cation

allowed for the development of processable TFTs. The $(PEA)_2SnI_4$ perovskite contains alternating layers of corner-sharing SnI_6 octahedra and PEA cations. The $-NH_3^+$ group present on PEA cation hydrogen bonds to the SnI_6 octahedra, and weak van der Waals interactions between the PEA groups hold the layers together. The weak interactions between the layers allow the material to be solution processed.

Enhanced physical properties of materials where the thickness of the inorganic layer sheathed between the organic cation layers is of interest in the fabrication of devices with conductive properties. A semiconductor ⟷ metal transition is observed for tin(II) compounds $(C_4H_9NH_3)_2(CH_3NH_3)_{n-1}Sn_nI_{3n+1}$ as a function of increasing n value. The n = 1 compound $(C_4H_9NH_3)_2SnI_4$ is a large band-gap semiconductor with a room-temperature resistivity of approximately 10^5 Ωcm.[5] Increasing the value of n results in reduced resistivity of the material, with metallic behavior seen for materials $n \geq 3$. The 3d perovskite $(CH_3NH_3)SnI_3$ (n = ∞) is a low-carrier-density p-type metal with a room-temperature Hall mobility of approximately 50 $cm^2V^{-1}s^{-1}$ and a carrier density of approximately $10^{19}cm^{-3}$.[32] As the number of inorganic layers increases, the conductivity also increases.

CONCLUSION

The family of layered perovskites designed with divalent cations grew from systems, which use organic cations as placeholders in the lattice, to materials that can be tailored to possess unique properties. Systems were developed with specific properties inherent to the organic and inorganic components. Crystal engineering was used with the layers structure to design materials with potential commercially useful properties, such as magnetic and electronic characteristics. The recent developments in magnetic materials and device fabrication of TFTs and OILEDs highlighted the practical applications that can be explored with the ability to consistently work in the same structural framework.

Supermicroscopy: AFM, SNOM, and SXM

Steven De Feyter
Frans C. De Schryver
Katholieke Universiteit Leuven (K.U.Leuven), Leuven, Belgium

INTRODUCTION

The development of scanning probe techniques is a blessing for the study of suprarnolecular structures. These supermic oscopy techniques open new ways not only to visualize the architecture of supramolecular structures but also to allow insight into chemical and physical processes related to their supramolecular identities with unprecedented spatial resolution.

The birth of scanning probe techniques revolutionized the way small objects or domains can be visualized. Common to all scanning-probe techniques is a tiny probe that scans a surface at a very small distance from it, and the interaction between probe and object is translated into a signal. The ultimate control in positioning is achieved by using piezoelectric elements. Since the invention of the scanning tunneling microscope (STM),[1] several experimental schemes were developed that allow detection of a great variety of interactions between probe and surface. Probably. atomic force microscopy (AFM) is the most popular.[2] Among those techniques. scanning near-field optical microscopy (SNOM)[3,4] takes a special place due to its optical resolution below the diffraction limit. All of these techniques have in cominon that they almost exclusively probe surface structures and properties. A major benefit of these techniques with respect to other surface characterization techniques is their noninvasiveness. Moreover, these techniques can be used under a large variety of experimental conditions, such as ultrahigh vacuum, under ambient conditions, in liquids. and at different temperatures.

In general. these supermicroscopy tools can be used for the investigation of two types of supramolecular structures> based upon the way they are "deposited" on the subst ate. On the one hand, these techniques can be exploited to investigate supramolecular assemblies that form in. e.g., solution, and that do not lose their structural integrity upon deposition on the surface. On the other hand, these techniques are also ideally suited to probe the supramolecular structures with forination is driven by the presence of the substrate. in any case, one has to take into consideration that upon deposition of supramolecular structures from solution. their nature can be affected substantially by the deposition process due to, for instance, adsorbate–substrate interactions and changes in concentration; and one should not neglect the role of the substrate.

SCANNING TUNNELING MICROSCOPY

STM for Structure Elucidation

In STM. a metallic tip is brought very close to a conductive substrate. and by applying a voltage between both conductive media. a tunneling current may result (Fig. 1). The exponential distance dependence of the tunneling current provides an excellent means with which to control the distance between the probe and the surface. High resolution (atomic) can be achieved, but the use of this probe technique is limited to conductive substrates. Of major importance is its ability to probe not only bare surfaces such as metals or semiconductors but also molecules, which are physisorbed or chemisorbed on these conductive surfaces. However, due to the specific nature of probing. only very thin molecular layers can be investigated.

Reducing the mobility of the molecules is a prerequisite for successful STM imaging. This can be achieved by working at low temperatures. Under these conditions. submonolayer assemblies can be investigated. Some examples include the formation of surface-supported supramolecular structures with size and aggregation patterns that are rationally controlled by tuning the noncovalent interactions between individual adsorbed molecules. Using low-temperature ultrahigh vacuum scanning tunneling microscopy. it was shown that porphyrin molecules adsorbed on a gold surface form monomers, trimers, tetramers. or extended wire-like structures. based upon dipole–dipole interactions."' Other examples include the formation of wire-like structures by hydrogen-bond formation[6] and the two-dimensional self-assembly of supramolecular clusters (containing precisely 10 molecules) and chains formed by 1-nitronaphthalene.[7] In the latter case. it was shown that these clusters could be manipulated (translated) while maintaining their structural and chiral integrities.[8]

Another way to reduce the mobility is by forming two-dimensional monolayers under ambient conditions. Adsorbate–substrate and adsorbate–adsorbate interactions lower the molecular mobility and are responsible for the two-dimensional ordering, ''Dry'' monolayers can be formed by drop casting and evaporation or by the horizontal lifting technique.[9] It is also possible to measure

in liquids. With respect to sample preparation, the latter approach is attractive, as one needs only to apply a drop of a solution on the substrate, and by physisorption, a two-dimensional layer can be formed.[11] Examples include the study of supramolecular grids[11] and catenanes.[12] Within our research group, the "liquid" approach was extensively used to investigate and to control the formation of two-dimensional supramolecular structures by dicarboxylic acid type and urea-containing compounds.

Shown in Fig. 2a is a STM image of a monolayer of a 5-alkyloxy-isophthalic acid derivative physisorbed from 1-phenyloctane on the graphite surface. The larger bright spots in this functionalized hydrocarbon monolayer correspond to the aromatic moieties. The darker regions in the image correspond to the alkyl groups, which are interdigitated over their full length and aligned with their long axis parallel to the graphite substrate. The distance between adjacent isophthalic acid moieties allows for intermolecular hydrogen bonding within a lamella and between adjacent lamellae. In Fig. 2b, the ordering of an isophthalic acid derivative with a semifluorinated alkyl chain is shown (model: Fig. 2c). There is a clear change in contrast along the alkyl chain, illustrating the chemical sensitivity of STM. When isophthalic acid derivatives are

dissolved in 1-octanol or 1-undecanol, solvent molecules are often incorporated in the monolayer (Figs. 2b–c). The 1-octanol molecules are codeposited and are stabilized by hydrogen bonding. Some functionalized hydrocarbons may display stabilizing hydrogen bonding along the lamella axis. For example, in monolayers of alkylated terephthalic acid derivatives (Fig. 2d), the terephthalic acid groups (bright) are linked by hydrogen bonds, and the alkyl chains, which are oriented perpendicular to the lamella axis, are interdigitated. This interdigitation allows for a two-dimensional stabilization.[17] For those systems lacking interacting groups at the termini of the alkyl chains, quasi-discrete supramolecular structures can be formed, even in liquid conditions. Urea groups are capable of forming up to four hydrogen bonds. Therefore, for the symmetrically substituted monourea compound. lamellae are formed, and the intermolecular distance (0.46 nm) is determined by hydrogen bonding (Fig. 2e). On the other hand, the interaction between adjacent lamellae is rather weak. For example, some *bis*-urea derivatives showed stable lamella formation.[14] In combination with relatively strong adsorbate–substrate interactions. the lamellae were stabilized enough to prevent or limit molecular diffusion on the graphite support. and isolated lamellae could be observed (Fig. 2f).

STM as Probe for Supramolecular Chirality, Dynamics and Reactivity

These simple examples illustrate how by carefully designing the molecules. one can control the supramolecular patterns in two dimensions. We took advantage of the control of the supramolecular patterns formed by these types of molecules to carry out reactions at the liquid–solid interface. In addition to investigations related to the structure of the two-dimensional assemblies, topics such as chirality, dynamics, and light-induced reactions can be studied. For instance, chirality is known to often have a major influence on the handedness of supramolecular structures formed in solution. and its effect also shows up in two-dimensional layers and in clusters. In general, it is found that enantiomers form enantiomorphous monolayers or clusters (the monolayers or clusters formed by enantiomers are related to each other by mirror symmetry). The same holds for achiral compounds, but now both mirror-image-related structures—monolayers or clusters—are formed. Of course, in these kinds of investigations, the study of the behavior of racemic mixtures is also of main interest.[8,15,16] Supramolecular structures, both in solution and on solid supports exposed to solution, are often "equilibrium structures" and show continuous exchange with the reservoir of building blocks. The STM is ideally suited to probe the dynamics in physisorbed supramolecular structures. For instance. assemblies formed at the liquid–solid interface are in dynamic equilibrium with the supernatant solution, and STM is the ideal tool to investigate desorption and adsorption dynamics in those supramolecular assemblies. To elucidate these dynamic processes, one can take advantage of the chemical sensitivity of STM by incorporating marker molecules in the supramolecular assembly.[17] Reactivity can be controlled by the structures of the supramolecular assemblies. For example, the photodimerization of two cinnamate derivatives was investigated at the graphite–liquid interface (Figs. 2g–i). The symmetrically substituted derivative was found to pack in two patterns, and photodimerization was observed upon in situ illumination. On the other hand. an asymmetrically substituted cinnamate derivative was found not to photodimerize, which could be related to a different supramolecular packing, inducing too great of an intermolecular distance between the reactive centers.[18]

ATOMIC FORCE MICROSCOPY

In contrast to STM. in AFM, forces exerted by the sample on the tip (or vice versa) are recorded, and several detection schemes are possible. The AFM scans a sample with a sharp tip, which is mounted on a cantilever spring (Fig. 3). The cantilever senses the interaction forces between tip and sample. A distance sensor monitors the reflection of the cantilever. Nowadays, beam deflection is nearly the only used detection scheme. The laser beam is reflected onto a segmented photodiode. As the deflection of the cantilever changes, the laser spot on the photodiode will shift accordingly. The detected deflection is then converted into an AFM image. Due to the flexibility of AFM with respect to the nature of the samples that can be studied and the measuring conditions (ambient conditions, liquids. etc.), AFM is intensively used. In most

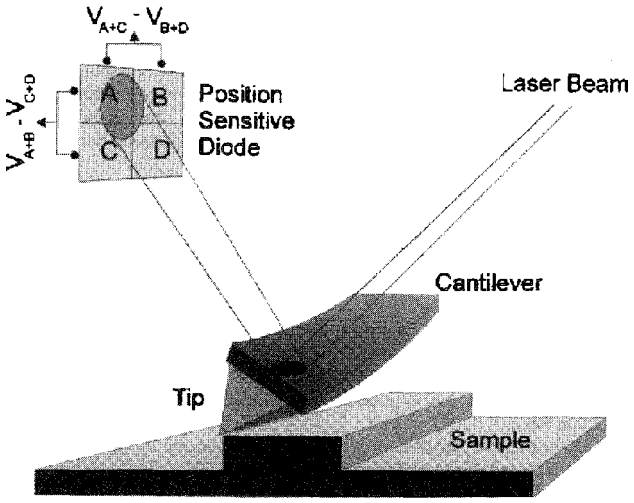

Fig. 3 An AFM setup.

applications, AFM is used as a topography sensing tool, but in certain measuring conditions, AFM is also sensitive to the mechanical properties of the sample, such as adhesion and stiffness.

The AFM was used to investigate various supramolecular structures. An example includes the study of the vertical profiles along the molecular long axes within a microtube made up of a boloamphiphile, which illustrates the usefulness of AFM for studying the molecular packing as well as the morphological dimensions of supramolecular assemblies.[19] Another recent study focused on the aggregation process of conjugated (sexithiophene)/nonconjugated [poly(ethylene glycol)] rod–coil copolymers[20] They all show regular arrangements of microfibrillar structures. This fibrillar morphology appears to be a typical signature of the organization of these conjugated copolymers in the solid state. If, on the other hand, this compound is deposited on the surface of a silicon wafer, thin fibrils are also formed, but they present a helical shape. The influence of substrates is a factor one has to be aware of. For instance, we investigated by means of noncontact AFM, individual polyphenylene dendrimers and their self-assembled nanostructures, prepared by spin coating and solvent casting on various substrates, such as mica: silanized mica, and graphite.[21] Besides globular clusters and monolayers, the polyphenylene dendrimer self-organizes into micrometer-long nanofibers on a graphite surface (Figs. 4a–c). Fibrillar nanostructures were also visualized on a silanized mica surface, while on a mica surface, the dendrimers only aggregate into globular structures. On the other hand, alkyl-substituted polyphenylene dendrimers do not form fibers but monolayers, including complex two-dimensional arrangements and suprarnolecular ordering.[22]

Of course, the use of AFM is not restricted to the investigation of supramolecular structures in the material sciences. 'Xrtificial" biomaterials were also recently probed by AFM. For instance, two-dimensional crystalline forms of DNA that self-assemble from synthetic DNA double-crossover molecules were assembled, and their patterned crystals were visualized by AFM. Intermolecular interactions between the structural units are programmed by the design of "sticky ends" that associate according to Watson–Crick complementarity.[23] Recently, biohybrids, formed by the association of two biotinylated polystyrene

molecules and streptavidin (leading to the formation of "giant amphiphiles"), were investigated.[24] In addition to AFM imaging (Figs. 4d–f). the nature of the monolayers was characterized by confocal fluorescence microscopy imaging of dye-labeled hybrids. The combination with optical techniques brings us to the last technique discussed in this entry (SNOM). The analysis of supramolecular structures becomes more powerful when topography data can be related to spectroscopy data.

SCANNING NEAR-FIELD OPTICAL MICROSCOPY

The SNOM combines the possibilities of AFM and optical microscopy. On the one hand, it allows for probing of the surface and obtaining information on the topography. On the other hand, in aperture SNOM, the probe contains an aperture, and the sample can be illuminated locally (Fig. 5). The diameter of the aperture at the end of the probe is typically of the order of 50–100 nanometer, and therefore. the illuminating spot is not diffraction limited. Both transmission and tluorescence in combination with polarization provide appropriate contrast mechanisms.

There are a number of excellent reviews on SNOM[25,26] and its applications in the study of organic materials.[27] The reader is referred to these reports for detailed information on the technique and some of its applications. We focus on some of our results on the use of SNOM for illustrating its usefulness in the study of supramolecular structures.

Porphyrin Wings

'The formation of ring-like structures was observed in the evaporation process of organic solutions containing porphyrin derivatives.[28] In particular, the deposition of these solutions on a substrate led to micron-scale ring-shaped arrangements of the solute/dispersed materials. Using SNOM, a deeper insight into the morphology and the local optical properties of solvent-evaporated porphyrin thin films was reached. Evaporation of a 10^{-6} M solution of PtP (Figs. 6a,b) in $CHCl_3$ on glass yielded symmetric rings for which the topography and fluorescence images are highly correlated. The ring diameter ranges between 100 nm to 10 μm, while the height of the rims, determined from the SNOM topographic image, varies between 10–300 nm. The fluorescence intensity measured inside the rings equaled the background value, indicating the absence of porphyrin material at these positions. The use of a more dilute solution (10^{-7} M) resulted in the formation of incomplete ring-shaped assemblies that were made from individual isolated structures which were observed in the topography and in the fluorescence image (Fig. 6c). A further characterization of the films in terms of the local optical properties and molecular organization was perfoimed using fluorescence polarization imaging. Similar experiments were performed using samples prepared by evaporation of another porphyrin derivative (BP_6)/$CHCl_3$ (Fig. 6a) solution. For the samples studied before annealing, the images corresponding to the different polarization configuration were identical (images are not presented). On the other hand, the annealed sainples exhibit strong polarization contrast. When the fluorescence intensity distributions in the rings are compared to what was found for PtP, a much smoother profile is observed. For the BP_6 samples, the intensity distribution depends, over a longer range, on the excitation polarization with parallel emission polarization. When the excitation polarization is oriented horizontally in the image (Fig. 6e), the upper and lower parts of the rings have a relative higher intensity than the left and the right parts of the rings. Turning the excitation polarization 90° (Fig. 6f) results in

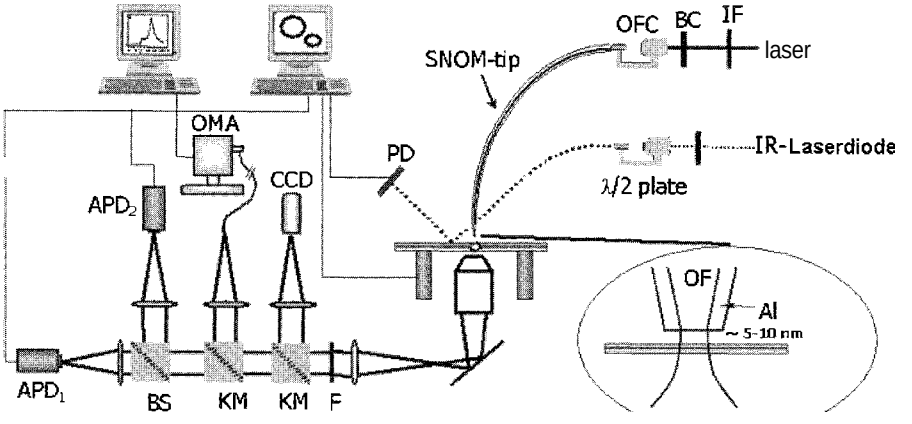

Fig. 5 Experimental setup of SNOM: The inset is a zoom of the optical fiber end. (Chem. Com. 2001. 7, 585—Reproduced by permission of the The Royal Society of Chemistry.)

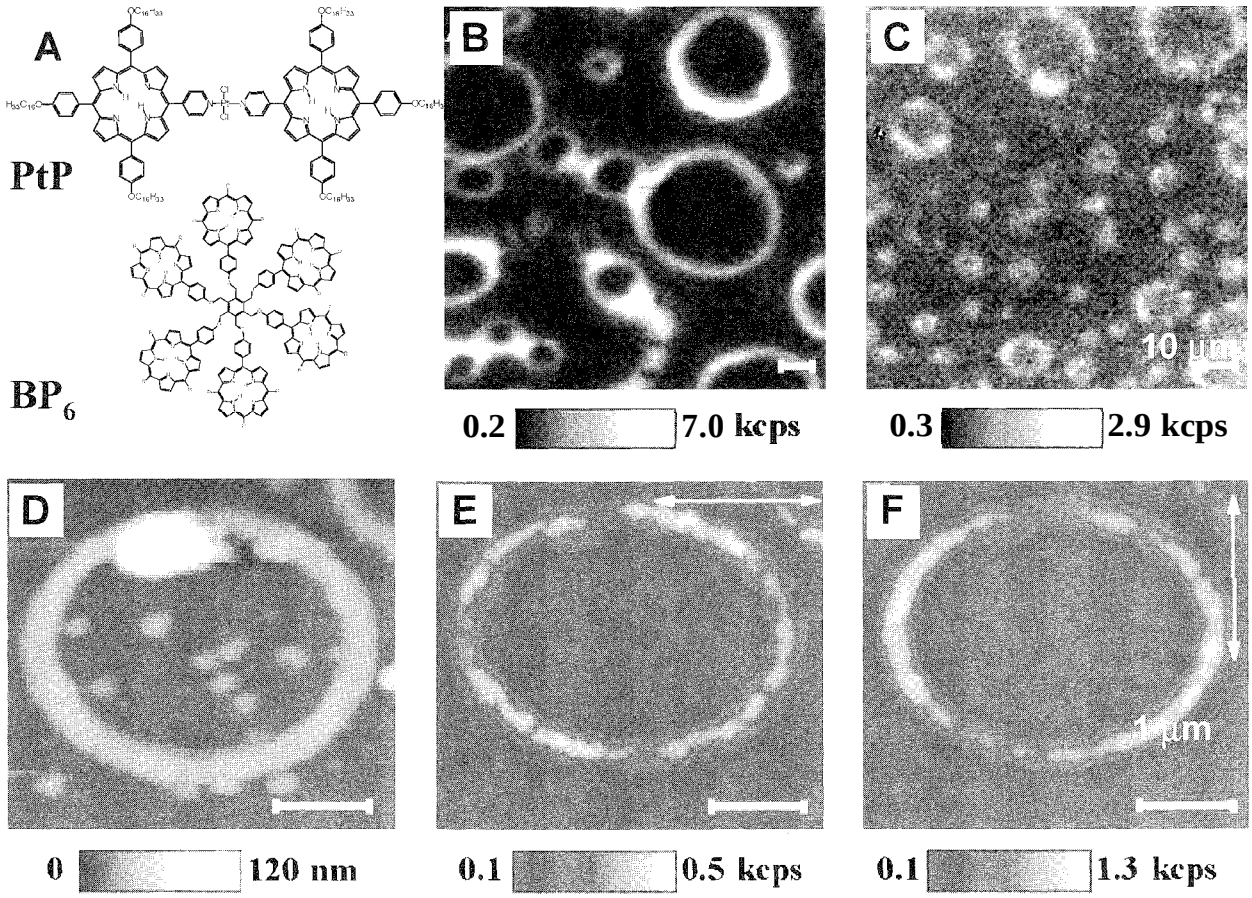

Fig. 6 (a) Porphyrinc derivatives. (b,c) SNOM fluorescence images of evaporated films of PtP/$CHCl_3$ solutions on glass by solvent casting at different concentrations. Scale bar is 10 μm. (d,e,f) A set of SNOM topographic and fluorescence polarization images acquired from a BP_6/$CHCl_3$ solution on glass. The orientation of the excitation polarization is indicated with the white arrows on the images. All tluorcscence images arc acquired with a parallel polarization configuration. Scale bar is 1 μm. (Chein. Com. 2001, 7, 585—Reproduced by permission of the The Royal Society of Chemistry.)

higher fluorescence intensity for the left and right parts of the ring. The observed fluorescence pattern can only be explained if there is a preferential orientation of the molecules in the rings. Using polarized excitation results in a preferential absorption of the excitation light at the positions where the polarization and the absorption dipole of the chromophore are parallel. This results in higher fluorescence intensity at the respective positions. If the molecules are schematically presented as disks, the orientation should be preferentially perpendicular to the sample plane. A possible arrangement of the disks in the rings could be one with the planes parallel or perpendicular to the radial of the ring.

CONCLUSION

In summary, the invention and development of scanning-probe microscopy techniques opened new ways to study supramolecular systems on solid supports The strength of these techniques is the local natures of the probing modes and their general applicability, even under ambient conditions, combined with the high resolution

Supramolecular Chemistry: Definition

Jonathan W. Steed
University of Durham, Durham, United Kingdom

INTRODUCTION

It is an almost impossible task to write a useful definition of supramolecular chemistry. The field is ever changing as it advances, and researchers will have their own understanding and sets of terminology. Rather than trying to limit the field or "claim" certain areas, what follows will attempt to be a simple introduction for the newcomer into the sorts of areas in which the concepts of supramolecular chemistry, broadly defined, may be of some use. In short, here are some things to think about to get you started.

In this article, for a practical exploration of the definition and scope of supramolecular chemistry, we will consider the viewpoint within the following interrelated subfields, all of which lend something to our understanding of supramolecules:

- Molecular host–guest chemistry.
- Solid-state host–guest chemistry (also known as inclusion or clathrate chemistry).
- Crystal engineering.
- Supramolecular devices.
- Self-assemblylself-organization.
- Soft/smart materials.
- Nanochemistry/nanotechnology.
- Biological chemistry.

BACKGROUND

In 1978, Jean-Marie Eehn introduced the modern concept of supramolecular chemistry, which he defined as the "...chemistry of molecular assemblies and of the intermolecular bond,"[1] although the term itself made a much earlier appearance (in *Webster's Dictionary* in 1903). Traditionally, phrases such as "chemistry beyond the molecule." "the chemistry of the non-covalent bond," and "non-molecular chemistry" or even "Lego chemistry" were also used to describe the field. In the beginning, supramolecules mainly comprised two components. a host and a guest, which interact with one another in a noncovalent fashion (Fig. 1). The area rapidly evolved to encompass molecular devices and molecular assemblies. More recently (2002), Lehn added a further functional definition: "Supramolecular Chemistry aims at developing highly complex chemical systems from components interacting by non-covalent intermolecular forces."[2] The current emphasis is thus on increasing complexity and, hence, increasingly sophisticated functionality, and on the information stored in molecular coinponents that allows this complexity to be achieved.

Fundamentally, supramolecular chemistry concerns the mutual interaction of molecules or molecular entities with discrete properties. This interaction is usually of a noncovalent type (an "intermolecular bond," such as a hydrogen bond, dipolar interaction or x-stacking). Key to many definitions of supramolecular chemistry is a sense of modularity. Supramolecules, in the broad sense: are aggregates in which a number of components (of one or more type) come together, either spontaneously or by design, to form a larger entity with properties derived from its components. These aggregates can be of the host–guest type in which one molecule encapsulates the other, or they can involve mutually complementary, or self-complementary, components of similar size, in which there is no host or guest (Fig. 2).

The broad general field of interactions between molecules is, in fact, of relevance to a number of loosely related disciplines, both within chemistry and at the interface of chemistry with biology, condensed matter physics, and materials science. Some of these disciplines—particularly solid-state clathrate chemistry and biological chemistry (see articles of further interest)—predate the rise of modern supramolecular chemistry. as shown by the rough timeline of some supramolecular milestones given in Table 1. It would be inappropriate to describe workers in this diverse group of disciplines as supramolecular chemists. However. the evolving language and framework provided by supramolecular chemistry facilitates cross-fertilization and communication between disciplines concerned with the interactions between molecules (of whatever size and chemical composition). Moreover. a great deal can be learned by the comparative study of such loosely related areas, and the juxtaposition may inspire important new areas of activity.

MOLECULAR HOST–GUEST CHEMISTRY

A host–guest complex was defined by Donald Cram,[3] who shared the 1987 Nobel Prize in Supramolecular Chemistry, in the following way:

> Complexes are composed of two or more molecules or ions held together in unique structural relationships by electrostatic forces other than those of full covalent bonds. . .molecular complexes are usually held together by hydrogen bonding. by ion pairing, by π-acid to π-base interactions, by metal-to-ligand binding, by van der Waals attractive forces, by solvent reorganizing. and by partially made and broken covalent bonds (transition states). . .High structural organisation is usually produced only through multiple binding sites. . .A highly structured molecular complex is composed of at least one

Table 1 Timeline showing some milestones of interest in supramolecular chemistry

1810—Sir Humphrey Davy: Discovery of chlorine hydrate
1823—Michael Faraday: Formula of chlorine hydrate
1841—C. Schafhäutl: Study of graphite intercalates
1849—F. Wohler: β-Quinol H_2S clathrate
1891—Villiers and Hebd: Cyclodextrin inclusion compounds.
1893—Alfred Werner: Coordination chemistry
1894—Emil Fischer: Lock and key concept
1906—Paul Ehrlich: Introduction of the concept of a receptor
1937—K.L. Wolf: The term *Ubermolekül* is coined to describe organized entities arising from the association of coordinatively saturated species (e.g., the acetic acid dimer)
1939—Linus Pauling: Hydrogen bonds are included in the groundbreaking book *The Nature* of *the Chemical Bond*
1940—M.F. Bengen: Urea channel inclusion compounds
1948—R.M. Powell: X-ray crystal structures of β-quinol inclusion compounds; the term "clathrate" is introduced to describe compounds where one component is enclosed within the framework of another
1949—Brown and Farthing: Synthesis of [2.2]paracyclophane
1953—Watson and Crick; Franklin and Wilkins: Structure of DNA
1953—Max F. Perutz: Structure of hemoglobin
1956—Dorothy Crowfoot Hodgkin: X-ray crystal structure of vitamin B_{12}
1959—Donald Cram: Attempted synthesis of cyclophane charge-transfer complexes with $(NC)_2C{=}C(CN)_2$
1961—N.F. Curtis: First Schiff's base macrocycle from acetone and ethylene diamine
1964—Busch and Jäger: Schiff's base macrocycles
1967—Charles Pedersen: Crown ethers
1968—Park and Simmonds: *Katapinand* anion hosts
1969—Jean-Marie Lehn: Synthesis of the first cryptands
1969—Jerry Atwood: Liquid clathrates from alkyl aluminium salts
1973—Donald Cram: Spherand hosts produced to test the importance of preorganization
1978—Jean-Marie Lehn: Introduction of the term "Supramolecular Chemistry" defined as the "...chemistry of molecular assemblies and of the intermolecular bond"
1979—Gokel and Okahara: Development of the lariat ethers as a subclass of host
1981—Vogtle and Weber: Podand hosts and development of nomenclature
1987—Award of the Nobel Prize for Chemistry to Donald J. Cram, Jean-Made Lehn. and Charles J. Pedersen for their work in Supramolecular Chemistry
1996—Atwood, Davies. MacNicol. and Vogtle: Publication of *Comprehensive Supramolecular Chemistry* containing contributions from many key groups and summarizing the development and state of the art
1996—Award of the Nobel Prize for Chemistry to Kroto, Smalley. and Curl for their work on the chemistry of the fullerenes
2003—Award of the Nobel Prize for Chemistry to Agre and MacKinnon for their work on channels in cell membranes

> host and one guest component...A host–guest relationship involves a complementary stereoelectronic arrangement of binding sites in host and guest...The host component is defined as an organic molecule or ion whose binding sites converge in the complex...The guest component as any molecule or ion whose binding sites diverge in the complex...

The key point here is the convergent arrangement of binding sites on a host molecule. This disposition is deliberately introduced during the host synthesis and is an intrinsic property of the host. A preorganized host such as the spherand 1 (which binds a Li' guest) will maintain a convergent arrangement of binding sites at all times, irrespective of the presence of guest species. More flexible hosts such as [18]crown-6 (2) display some flexibility and may undergo a conformational change to a more convergent geometry upon guest complexation (metals such as K^+ in the case of 2) (Fig. 3).

Hosts such as 1 and 2 use their molecular cavity (whether preorganized or binding induced) to bind effectively to metal cations and were among the first modern host systems, The range of guest species is not limited to cations, however, and can include hosts for anions (e.g., **3,** which binds effectively to Cl^-[4]) or neutral molecules as in cavitands such as 4 that complexes CS_2.[5]

SOLID-STATE HOST–GUEST CHEMISTRY

Solid-state host–guest chemistry dates to the discovery of chlorine clathrate hydrate by Davey in 1810 and represents cocrystallization of two or more chemically

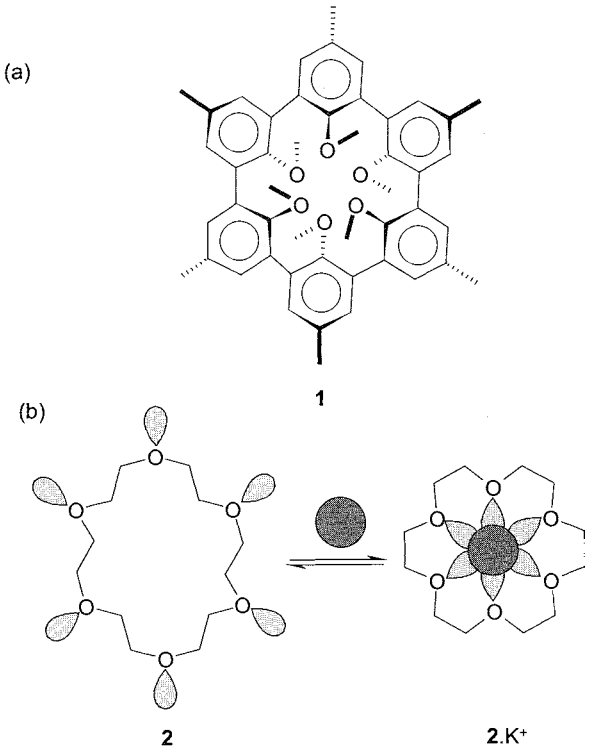

Fig. 3 Molecular hosts (a) preorganiaed spherand. (b) flexible crown ether—in polar solvents. the oxygen lone pairs point outwards to interact with solvent but converge upon guest binding. (*View this art in color at www.dekker.com.*)

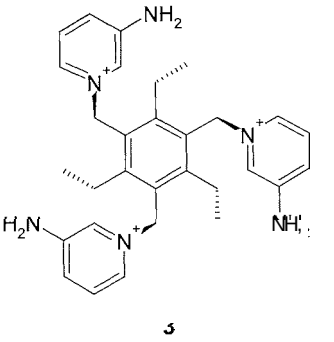
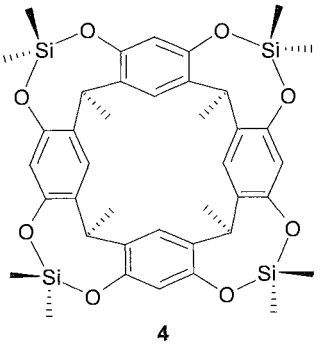
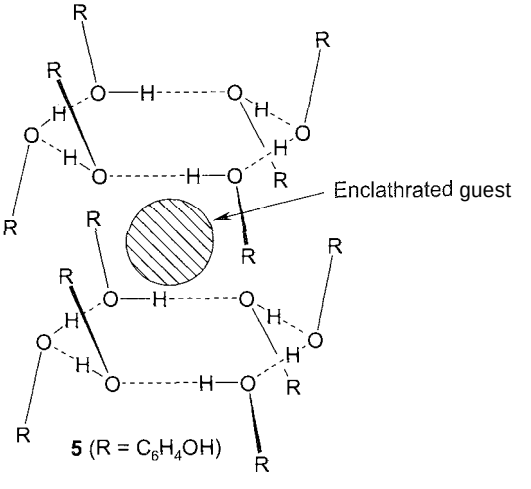
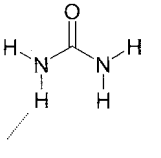
distinct species. The nature of solid-state host–guest complexes was first elucidated by Powell in the 1940s using x-ray crystallography. He introduced the term "clathrate" to indicate a guest molecule trapped in a cavity formed by the host, formally a kind of inclusion compound "in which two or more components are associated without ordinary chemical union, but through complete enclosure of one set of molecules in a suitable structure formed by another." More recently. Vogtle and Weber[6] proposed the division of host–guest complexes into two general categories according to the relative topological relationship between guest and host. Cavitands may be described as hosts possessing intramolecular cavities. This means that the cavity available for guest binding is an intrinsic molecular property of the host and exists both in solution and in the solid state. Compounds 1–4 fall into this category. Conversely, clathrands are hosts with extramolecular cavities (the cavity essentially represents a gap between two or more host molecules) and is only of relevance in the crystalline or solid state. The host–guest aggregate formed by a cavitand is termed a cavitate, while clathrands form clathrates.

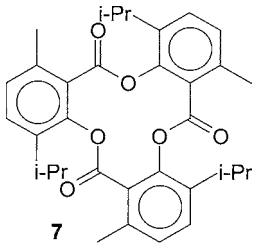




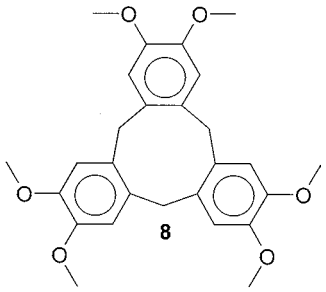




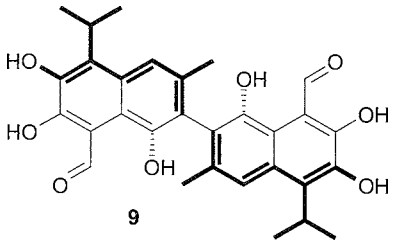
In principle, any cocrystal may be regarded as a clathrate: however. there are certain well-known classes of host molecules that regularly and reliably form solid host–guest clathrate-type compounds. and in many cases, these materials were extensively studied for a number of decades. Typical examples include hydoquinone (5), urea (6), tri-o-thymoiide (7). cyclotriveratrylene (8), gossypol (9), perhydrotriphenylene (10), etc. Urea clathrates are perhaps the most well-known with the urea molecules forming double-helical hexagonal channels via N H . ·O═C hydrogen bonds. The channels are able to include long, linear guest species such as *n*-alkanes (Fig. 4). Guests do not usually interact with the channel walls, and packing is often incommensurate. However, Hollingsworth et al. reported a number of complexes of ketone guests in which host–guest interactions result in interesting stress-induced orientational changes.[7]



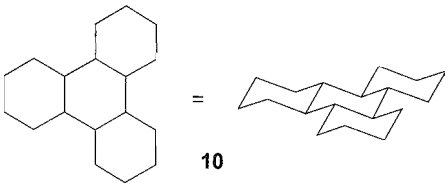
7



8



9



10

An interesting example of the interplay between solid-state clathrands and solution-phase cavitands is provided by cyclotriveratrylene (CTV, 8). In the solid state, the "saucer-shaped" CTV molecules stack one on top of another in the two most common phases (x and β),[8] and hence, while the molecules possess shallow molecular cavities, they do not include guests such as solvent molecules, which instead are located in voids between host stacks. However. larger guests such as buckminsterfullerene C_{60},[9] organometallic sandwich compounds,[10] or carboranes[11] form intracavity inclusion compounds, and the association persists in the solid state, with potential applications, for example, in the selective purification of fullerenes.[12] Thus, CTV is both a cavitand and a clathrand. The cavitand behavior of CTV is highlighted by the chemistry of the double-CTV cryptophanes that form very stable solution complexes with a variety of halocarbon guests.[13,14]

CRYSTAL ENGINEERING

In a recent article."'' Dario Braga summed the impact of supramolecular concepts in the following way:

> The supramolecular perception of chemistry generated a true paradigm shift: from the one focused on atoms and bonds between atoms to the one focused on molecules and bonds between molecules. In its burgeoning expansion the supramolecular idea abated, logically, all traditional barriers between chemical subdivisions (organic, inorganic, organometallic, biological) calling attention to the collective properties generated by the assembly of molecules and to the relationship between such collective properties and those of the individual component.

In the context of crystal engineering. he goes on to say the following:

> When applied to crystalline solids, the paradigm shift leads directly from supramolecular chemistry to crystal engineering. What is a (molecular) crystal if not an organized entity of higher complexity held together by intermolecular forces (J.M. Lehn)? Who can deny that the collective properties of such a giant supermolecule are the result of the convolution of intermolecular non-covalent bonding between molecular/ionic components with the periodicity of the crystal.

So, while traditionally crystal engineering had its birth in the "topochemistry" of Schmidt,[16] or even the earlier ideas on control of crystal packing presented by Pepinsky in 1955,[17] the modern discipline is simply supramolecular chemistry applied to periodic molecular solids. The aim is the rational design of interesting or

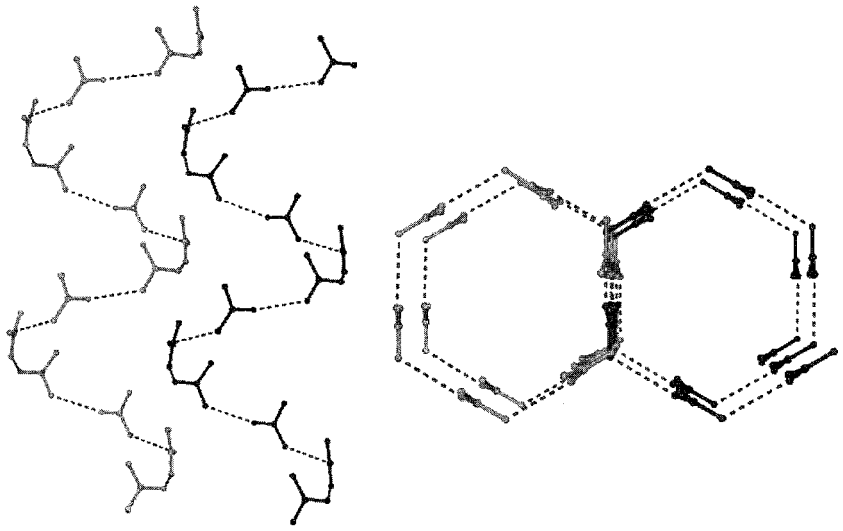


Fig. 4 The hexagonal urea host channel. Two urea helices viewed from the side of the channel and along the channel axis

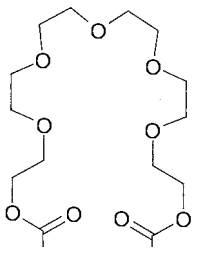
functional crystalline materials. For example, a recent report by Hosseini et al. of the University of Strasbourg, France, demonstrated the designed synthesis of a double helical chain in the solid state via the assembly of ligands such as **11** and Ag^+ (Fig. 5).[18] Hosseini advocates the use of the term "molecular tectonics" instead of crystal engineering to emphasize the building block nature of the discipline (see article on *Tectons: Definition and Scope* in this *Encyclopedia).*

There is also continued interest in the systematic placement of reactive groups in the solid such that their chemical reactivities are determined by the reactants' spatial relationships.[19] This was the original premise of Schmidt's topochemistry and has important implications in modern solventless ("green") synthesis[20,21] and even mechanochemistry.[22] For example, work by MacGillivray resulted in the solid-phase photochemical synthesis of paracyclophane **12** by a strategy termed "template switching" (Fig. 6).[23]



The crystal engineering community is also at the forefront of work into new kinds of intermolecular interactions. Recent single-crystal neutron diffraction studies revealed detailed information on OH···π interactions[24] and on unconventional hydrogen bonds to metal centers as well as MH···HX-type interactions, where MH is a hydridic metal hydrogen moiety, and HX contains protic hydrogen.[26,27]

Supramolecular Devices

A supramolecular device is a molecular-level system that acts or carries out a function of some kind in the same way as a larger-scale device, such as an electronic component (switch, rectifier) or mechanical object (motor, spring). The basis for the device's operation can be supramolecular in the sense that two or more components interact in a noncovalent manner. This is the case with rotaxane **13** (Fig. 7), in which the paraquat-derived macrocycle switches back and forth between the two biaryl "stations" in response to changes in pH. The interaction between the paraquat "train" and the two stations on the polyethyleneglycol "track" is entirely supramolecular and involves n-stacking. charge transfer, and CH···O hydrogen bonds.

In the construction of molecular devices, however, the focus is on the functional interactions between the components rather than the chemical nature of their connectivity. This means that a supramolecular device can be an entirely covalent molecule if it possesses characteristics of a supramolecular nature. Thus, a supramolecular device may be defined as a complex system made up of molecular components with definite individual properties.

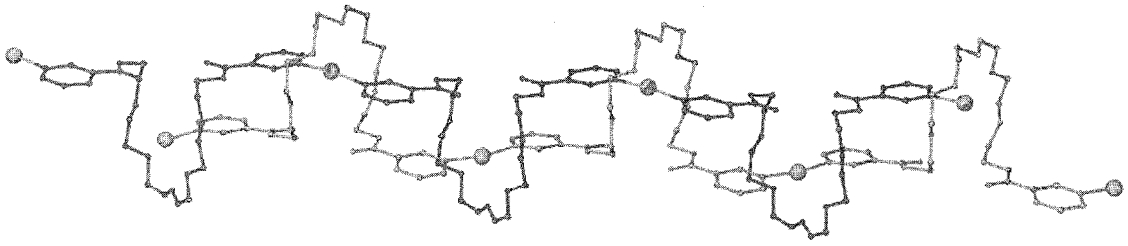


Fig. 5 Double-helical polymer chain formed from an interaction of Ag^+ with **11**. (From Ref. [18].) ***(View** this art **in** color at www.dekker.com.)*

These properties are intrinsic to the molecular component. whether they are part of the device or not. Another way of saying this is that the interaction energy between the components of the supramolecular device must be small compared with other energy parameters relevant to the system. It does not matter, therefore, how the components are connected in the device (covalently, hydrogen bonded, coordination interaction, etc.); all that matters is that each component should contribute something unique and identifiable with that component alone. within the system. If this does not hold true, and the functionality of the system is identifiable with the molecule as a whole, as opposed to the individual parts, then the complex is best thought of as a "large molecule" and is not supramolecular.

The relative unimportance of the nature of the bonding is illustrated by compounds 14 and **15**, both of which are devices designed to transport a photoexcited electron from the zinc porphyrins to the Fe(III) center, reducing it to Fe(II).[28] In the case of 14, the link between the two compounds is noncovalent, whereas in **15**, it is covalent. Remarkably. not only are both systems effective at carrying out this process, but the photoelectron transfer rate constants of 8.1×10^9 and 4.3×10^9 s^{-1} for 14 and 15, respectively, suggest that the carboxylic acid double hydrogen bond is more effective at transmitting the excited electron than the σ-framework in **15**. despite the fact that some dissociation might occur in solution.

Self-Assembly and Self-Organization

Strict supramolecular self-assembly involves the spontaneous formation of a multicomponent aggregate under thermodynamically controlled conditions based on information encoded within the individual building blocks (tectons). The aggregate might comprise only one kind of molecule (as in the multiple copies of the same protein that comprise the coat of many viruses, such as the tobacco mosaic virus) or more than one type of component. In the latter case, the different components are usually mutually complementary. Strict self-assembly implicitly

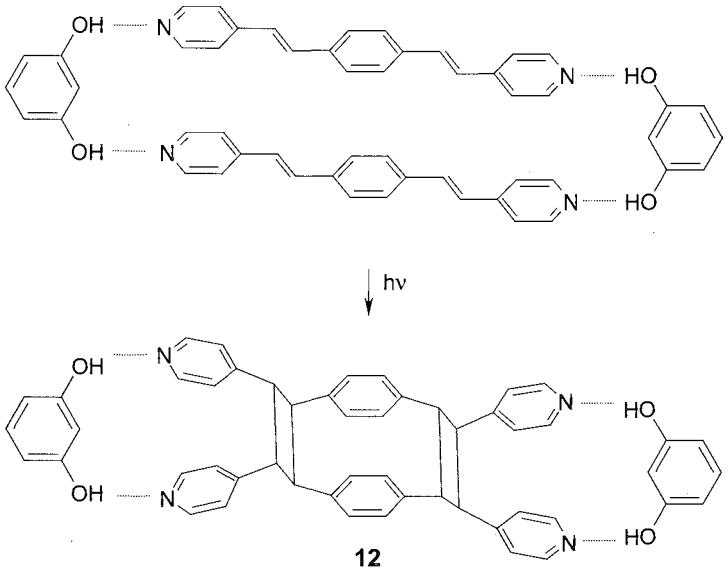

Fig. 6 "Template switch" synthesis of tetrapyridylparacyclophane 12. (From Ref. [23].)

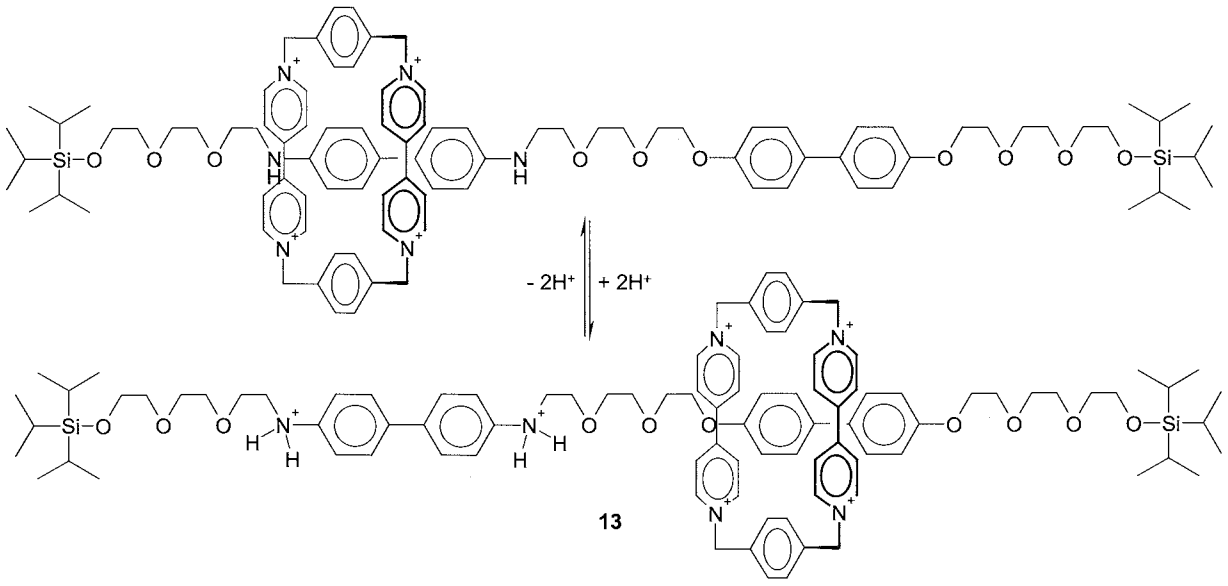

Fig. 7 The pH switched molecular switch based on a two-component rotaxane.

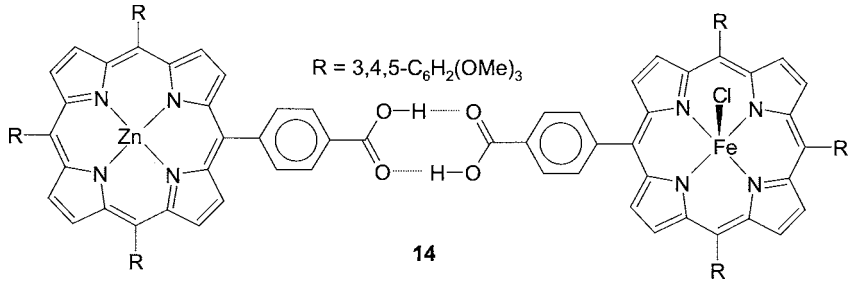
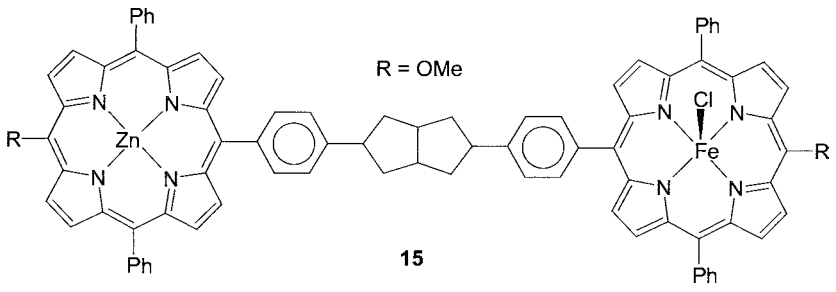
carries with it the notion of reversibility of intercomponent bond formation in that the final aggregate is the most thermodynamically stable structure under the prevailing conditions. This means that there is an in-built error-checking mechanism—malformed aggregates are less stable than the true minimum energy structure and decompose and are reassembled correctly if sufficient time is allowed to pass. Self-assembly processes may be regarded as the result of a series of supramolecular templated steps that build the aggregate. In turn, the interactions and synergy of self-assembled components, leading to collective behavior and, ultimately, intelligent "soft" functional systems, may be regarded as self-organization. The hierarchical sequence of templation leading to self-assembly leading to self-organization represents the ideal manifestation of the supramolecular information concept outlined in the introduction.

One simple and elegant example of supramolecular self-assembly is the synthesis of a molecular cube by Jim Thomas from the University of Sheffield, U.K.[29] Starting from the simple geometric observation that a cube comprises eight corners and 12 edges (a ratio of





2:3), Thomas et al. reacted $\{Ru([9]aneS_3)Cl_2(OSMe_2)\}$ as a "corner" with 4,4′-bipyridyl as an "edge" in a *2:3* ratio. The result was the displacement of the chloride and $OSMe_2$ ligands to give the predicted molecular cube $[\{Ru([9]aneS_3)\}_8(\mu\text{-}4,4'\text{-bipyridyl})_{12}]^{16+}$ **16**. Thomas' faith in the tenets of self-assembly were demonstrated by the fact that the reaction had to be allowed to reflux for a month before reaching the thermodynamically most stable cube structure. In this particular case, the ''supramolecular'' interactions are relatively covalent ruthenium(II)-pyridyl interactions, and the cube structure **16** is formally a molecule, or a coordination complex (albeit a fancy one) rather than a supramolecule in the strict sense. However, the slow but inevitable thermodynamically reversible formation of the Ru-N interactions obeys all of the same supramolecular rules that the hydrogen-bond-driven self-assembly of the DNA double helix does. The concepts are transferable even if the chemistry is hugely different.

Soft/Smart Materials

The term "materials" carries with it images of durable solids; organic materials like plastics and polymers, or inorganic materials like semiconductors and coatings. More generally, however, the term "material" can be applied constructively to any (usually solid) chemical compound with interesting or useful physical properties. We can readily distinguish between hard materials (often inorganic) and soft materials (often organic). Soft materials are held together by supramolecular interactions, such as hydrogen bonds, van der Waals forces, or other weaker intermolecular bonds. Hard materials involve much less easily deformed ionic or covalent interactions. A great deal of supramolecular chemistry, particularly the types of activities we termed crystal engineering above, represents de facto the design and synthesis of soft materials.

A smart material is a material that can, in effect, make a decision based on external stimuli. In other words, it is able to sense an external event such as an electrical signal, change in pH, or irradiation, and respond with an action of some kind (change in binding behavior, cooler, conformation, etc.). The ability of supramolecular chemists to use intermolecular interactions to design and construct soft materials (perhaps via self-assembly) may pave the way to the tailored design of smart materials. The concept has been articulated by Dima Soldatov of the Steacie Institute, Canada, and a wealth of detail is contained in his article in this *Encyclopedia* (see *Soft and Smart Materials).*

Nanochemistry/Nanotechnology

The prefix nano-refers to objects with dimensions approximately of the order of a nanometer (10^{-9} m). Broadly speaking, there are two approaches to the nanoscale dimension — "synthesizing-up" and "engineering-down." The engineering-down approach includes the latest in modern techniques for producing electronic components and originates in a bulk sense. Engineering-down to the nanoscale involves doing the same sorts of things that an engineer or artisan does on a macroscopic scale but using specialized techniques in order to miniaturize. In contrast, the synthesizing-up approach is modeled on biology, particular biological self-assembly, and aims to produce nanoscale functional components (perhaps with molecular device or molecular-scale computing applications in mind) by chemical synthesis. The first reports of functional molecular computing using supramolecular species have already begun to appear.[30] Somewhere in between these two complementary approaches to the preparation of new systems come a variety of scanning-probe-microscopy-based techniques such as STM and AFM (see articles on *Supermicroscopy: AFM, SNOM, and SXM* and *Scanning Tunnelling Microscopy).* Because they operate on the nanometer scale, these techniques give unique insight into molecular behavior. Microscopists are not necessarily innocent observers, however, and microscope tips may be used to carry out molecular manipulations and redox chemistry. Tips may even be modified by attaching a probe molecule and using molecular recognition to examine a surface. Chemical reactions may even be carried out by physically pushing individual molecules into close mutual proximity using an STM tip.[31] Chemical assembly, thus, represents one facet of the preparation and study of nanoscale materials, and it is particularly through the concepts of self-assembly and self-organization that the nanoscale world can be addressed by chemists in a well-defined and molecularly precise way.

Biological Chemistry

The world of biological molecules is governed almost entirely by supramolecular chemistry: hydrogen bonding, van der Waals, π-stacking, and hydrophobic interactions responsible for protein secondary and tertiary structure; enzyme–substrate binding and transition-state stabilization; viral and oligonucleotide self-assembly; intracellular sensing and signaling; semiochemistry — supramolecular concepts are everywhere. Of course, biochemistry is a vast, well-established and distinct field that dwarfs abiotic supramolecular chemistry. To date, much of the inspiration in the latter discipline has come from biology, however, and supramolecular chemistry is beginning to contribute to the understanding and mimicry of biochemical systems. While the language of biochemistry is often distinct from the parallels in supramolecular chemistry, no supramolecular chemist can function without a rudimentary knowledge of biological principles. Indeed, in his article in this *Encyclopedia* on *Terminology in*

Self-Assembly, Gerry Sweigers goes a long way toward bridging the gap.

CONCLUSION

In this article. a brief survey is provided of some critical areas in which the concepts that underlie supramolecular chemistry have found utility and application. It is a moot point whether all such chemical systems should be described using the adjective "supramolecular." Indeed, Ian Dance of the University of New South Wales made a spirited argument in favor of strictly limiting the use of the term ''supramolecular'' to systems that involve the "philosophies and strategies of grand assembly." The term "grand assembly" is taken to mean "a strategy of controlled organization of multiple separate components." This definition is particularly designed to exclude "intermolecular" chemistry (well-known weak and long interactions between molecules) and more or less elaborate metal coordination compounds that may be described by the language of coordination chemistry.[32] The crucial point is that in any discussion of science. nomenclature and language should be precise and unambiguous. On the other hand, concepts should be flexible and widely applicable.

Supramolecular Electrochemistry

Angel E. Kaifer
University of Miami, Coral Gables, Florida, U.S.A.

INTRODUCTION

The field of supramolecular chemistry is concerned with a large number of systems ranging from simple host–guest complexes to more complicated solution assemblies, as well as two-dimensional (organized monolayers) and three-dimensional assemblies (crystalline solids). Noncovalent interactions play an important role in the kinetic assembly and thermodynamic stabilization of all these systems and constitute their most distinctive feature. Electron-transfer reactions can obviously be affected by supramolecular structures, but the reverse is also true. It is possible to alter the structure and the thennodynamic stability of supramolecular assemblies using electrochemical (redox) conversions. In other words, electron-transfer reactions can be utilized to exert some degree of control on supramolecular aggregates. Provided in this article is an overview of the interplay between supramolecular structure and electron-transfer reactions.

REDOX CONTROL ON HOST–GUEST COMPLEXES

Consider a host–guest complexation equilibrium and assume that the guest (G) is redox active, while the host (H) is not. Obviously, redox or electrochemical reactions on the guest introduce pronounced changes in electric charge and hydrophobic character. These changes usually translate into considerable changes in the stability of the corresponding host–guest complex (HG). In other words, changes in the oxidation state of the guest will affect the equilibrium constant (K) for the formation of the complex. The best way to represent the coupling between the electron-transfer and binding processes is through a square scheme. such as that shown in Scheme 1.

In Scheme 1, K and K' represent the binding constants corresponding to the association of each of the oxidation states of the guest with the host, and E^o_f and E^o_c represent the formal potentials for the electron-transfer reactions (taken arbitrarily as oxidations in the scheme) of the free and complexed guest. These thermodynamic values are related by the following equation:

$$K/K' = \exp[nF(E^o_c - E^o_f)/RT] \quad (1)$$

where n is the number of electrons transferred, F is Faraday's constant, R is the ideal gas constant, and T is the Kelvin temperature. Clearly revealed by this equation is that the molecular recognition of the guest by the host may affect its formal potential (E^o versus $E^{o\prime}$). In fact, other electrochemical parameters may also be affected by the complexation reactions. For instance, voltammetric peak currents, which depend on the effective diffusion coefficients of the electroactive species, are usually depressed by molecular association phenomena, as the diffusion coefficient of the complex is lower than that of the free components. In general terms, this means that electrochemical techniques are useful experimental tools for the study of host–guest binding interactions, provided that there is a redox-active center (electrophore) in the guest, the host or both.[1]

The chemical literature already contains numerous examples of redox control on host–guest binding interactions, and the topic was the subject of several reviews.[2–6] In this article, selected examples that illustrate particularly well the possibilities of the research field will be presented. As a first example. let us consider the cobaltocenium ion (Cob^+), an 18-electron organometallic complex that can be reversibly reduced to its neutral form, cobaltocene **(Cob).** The reduced form is hydrophobic and is an excellent guest for the water-soluble host β-cyclodextrin (β-CD), which has a cavity that also has an inner surface with pronounced hydrophobic character. In contrast to this, the positively charged cobaltocenium is not bound by the β-CD host in aqueous solution.[7] This system illustrates the idea of electrochemically enhanced binding, as the initial and more stable form of the electroactive guest is not significantly bound by the host, but its one-electron reduction triggers the formation of an inclusion complex (see Scheme 2), with stability that is derived from the hydrophobic character of the guest in its reduced form.

The positive charge on the cobaltocenium ion makes it an excellent guest for water-soluble, anionic calix[6]arene hosts. Specifically, the hexasulfonatocalix[6]arene (1^{8-}), with its structure given in Scheme 3, was shown to bind two Cob^+ ions on the equivalent binding sites indicated by the arrows.[8,9] Therefore, one can think of an aqueous solution containing cobaltocenium, and the two hosts, β-CD and calixarene 1^{8-}, as a redox-switchable system in which, initially, two Cob^+ ions form a 2:1 complex with

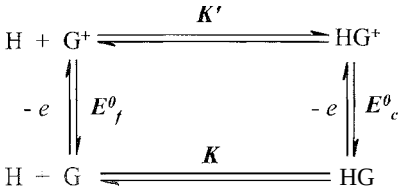
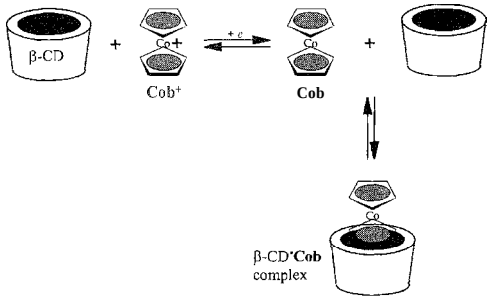


Scheme 1 Square scheme showing the redox and complexation equilibria that describe the interactions between a redox active guest (G) and an electroinactive host (H).

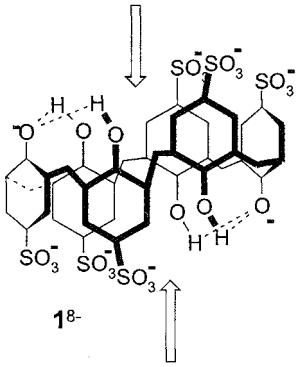
the anionic host $\mathbf{1}^{8-}$. Upon a one-electron reduction of the guest to the neutral Cob form. the predominant bimolecular species in the solution is the 1:1 inclusion complex β-CD.Cob. This example clearly illustrates a case in which the oxidation state of the guest determines host selection for complex formation. as well as the stoichioinetry of the resulting complex.

The Cob^+/β-CD host–guest system can also be adapted to the preparation of much larger supramolecular aggregates in the solution phase. For instance, multiple cobaltocenium groups can be covalently attached to the periphery of dendrimers. In these macromolecules. the reduction of the peripheral cobaltocenium units takes place in just one voltammetric wave. regardless of their number (dendrimers with 4, 8, 16, and 32 cobaltocenium units were prepared).[9] This finding reveals that all the reducible cobaltoceniurn units are equivalent and show no degree of electronic communication with one another on the dendrimer surface. When the reduction takes place in the presence of excess β-CD host. the reduced cobaltocene units are complexed by the freely diffusing hosts. Thus, the dendrimer can be considered as a molecular scaffold for the organized assembly of the CDs upon cobaltocenium reduction (see Scheme 4), and this provides another interesting example of electrochemically driven self-assembly.

A completely different example illustrates the flexibility of this general approach. For instance. the tetracationic

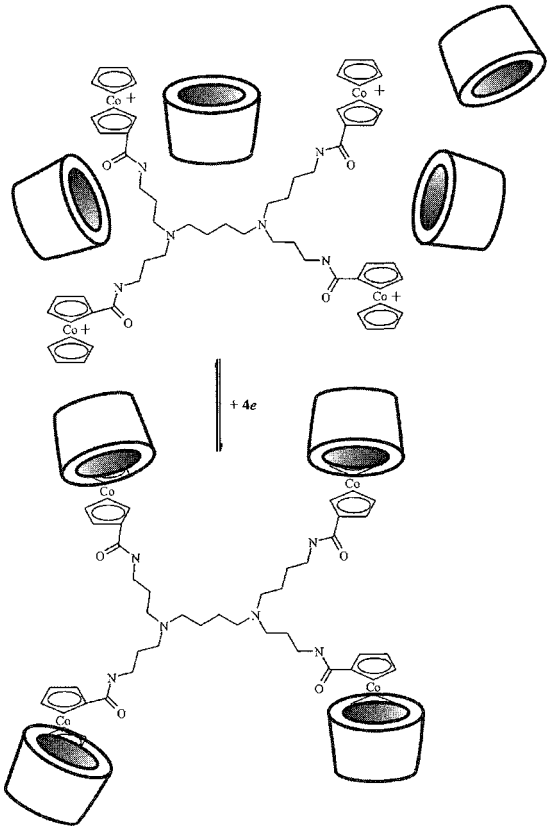


Scheme 2 Interplay between electron transfer and complexation equilibria in the cobaltocenium/β-CD system. **(View *this art in color at www.dekker.com.*)**



Scheme **3** Molecular structure of the anionic host hexasulfonatocalix[6]arene at neutral pH. The arrows point to the two pockets for the binding of cationic species.

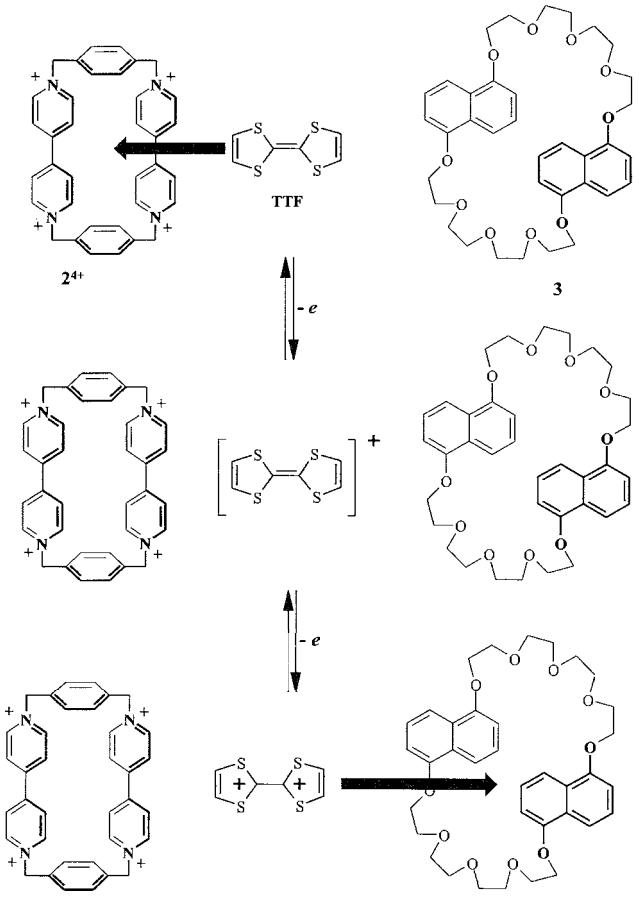
cyclophane host [$\mathbf{2}^{4+}$, *bis*(paraquat-*p*-phenylene)], forms a stable inclusion complex with the guest tetrathiafulvalene (TTF). in which the stability of the complex is rationalized by a combination of solvophobic forces and charge-transfer interactions between the π-donor guest and the



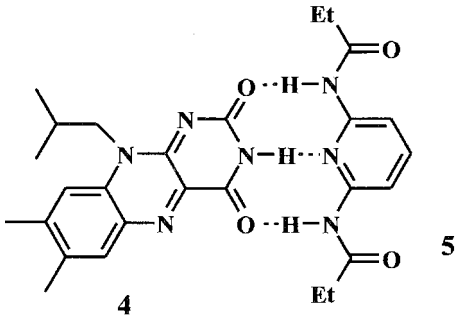
Scheme 4 Electrochemically triggered self-assembly of β-CD hosts around a dendrimer with four peripheral cobaltocenium units.

π-acceptor (4,4′-bipyridinium) residues of the host.[10] In this case, oxidation of the guest to its cation radical leads to complex dissociation due to the loss of π-donor character by the guest, and, perhaps more importantly, the coulombic repulsion between the tetracationic host and the cationic guest. The binding affinity can be restored, because the one-electron oxidation of the TTF guest is fully reversible (Scheme 5). Furthermore, the stability of the TTF–cyclophane complex can also be decreased by the one-electron reduction of the two 4,4′-bipyridinium residues on the cyclophane host. This system exhibits additional features due to the possibility of further oxidizing the cation radical TTF^{+} to yield a dication TTF^{2+}, which constitutes an excellent guest for the crown ether **3**.[10] Therefore, the three accessible oxidation states of TTF have different selectivities for these two hosts, and conditions can be found to form either complex or none.

Hydrogen-bonding interactions are extremely important in living systems, and their redox control has been the subject of a good number of interesting reports. For instance, Rotello and coworkers extensively investigated



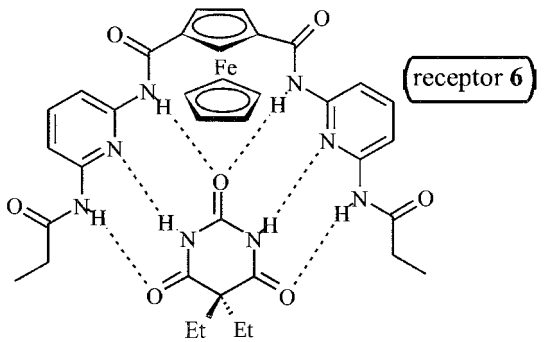
Scheme 5 Redox control on the guest properties of TTF in the presence of two possible hosts (2^{4+} and **3**).



Scheme 6 Hydrogen bonding between flavin 4 and diamidopyridine derivative **5**.

the binding interactions between the flavin 4 and the 2,6-diamidopyridine derivative **5** (Scheme 6).[11] In CH_2Cl_2 solution, the three-point hydrogen bonding between these two compounds leads to a shift of +155 mV in the one-electron reduction of the flavin to its anion radical. This reflects the enhanced binding constant between $4^{-}\cdot 5$ as compared to that observed for $4\cdot 5$. The binding pair between flavoprotein models, such as 4, and a number of diaminopyridine and diamidopyridine derivatives was extensively investigated, as it has considerable importance to understanding the wide range of redox potentials observed in flavoproteins.[12]

Tucker and coworkers prepared and investigated the ferrocene-containing host 6, which was specifically designed to recognize and bind urea and barbiturate derivatives (Scheme 7).[13] This host binds barbital in organic solvents forming a 1:1 complex, with a crystal structure that was reported. However, the ferrocene residue in 6 does not act as an effective voltammetric reporter for the binding, because the formal potential for ferrocene oxidation shifts only by ~20 mV in the presence of excess barbital guest. Drawing from this example, we can conclude that the design of redox-active hosts as



Scheme 7 Hydrogen bonding between receptor 6 and barbital.

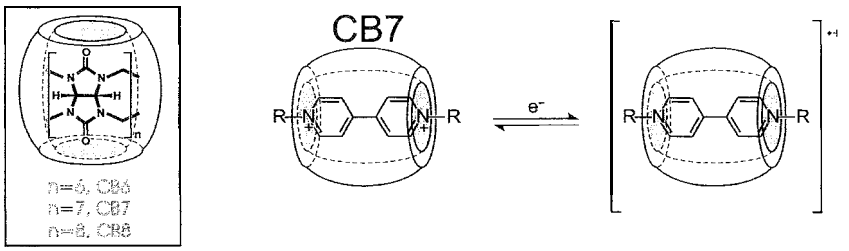
voltammetric sensors poses special requirements, because it is highly desirable that the sought-after binding event will shift the formal potential of the reporter electrophore *as much as possible. To* accomplish *this goal, the molecular design must focus on two fundamental points: 1) the binding site and the* redox *center must be spatially very close; and* 2) *the binding event must alter the microenvironment around the* redox *center or cause a considerable change in the electronic density of the electrophore.*

Typically, redox *conversions in the host or the guest give rise to pronounced changes in the stability of the corresponding complex. The* β-CD/Cob^+ *host–guest system and any complexes between n-donor compounds and host* 2^{4+} *constitute excellent* examples *of electrochemically induced complex formation or dissociation. Furthermore, in cases where the guest's electron-transfer reaction is associated with substantial changes in the host–guest affinity, the actual electron-transfer step takes place on the free guest. not on the inclusion complex, as both species undergo dynamic equilibrium in the solution. This somewhat surprising fact was first demonstrated by Evans and coworkers in a* seminal *study of the electrochemistry of ferrocenecarboxylic acid in the presence of the host* β-CD.[14] *The author's groups reached similar conclusions on electrochemical investigations of the host–guest systems between several* ferrocene *derivatives and* β-CD[15] as *well as the* cobaltocene/β-CD system.[7] *However, recent work on the complexation of methylviologen* (MV^{2+}) *by the host* cucurbit[7]uril (CB7) *shows different behavior (see Scheme* 8).[16] *The* CB7 *inclusion complex of* MV^{2+} *exhibits a high binding constant* ($\sim 1 \times 10^5$ L/mol) *in aqueous media. However, a one-electron reduction of the guest to its cation radical* MV^+ *decreases the binding constant by* a *modest factor of only two. As a result of the high stability of both complexes, the electrochemical behavior of the* MV^{2+}/MV^+ redox *couple in the presence of one equivalent of* CB7 *does not show any signs of coupling with* association/dissociation *chemical steps, which reveals that the electron-tranfer process actually takes place on the inclusion complexes.*

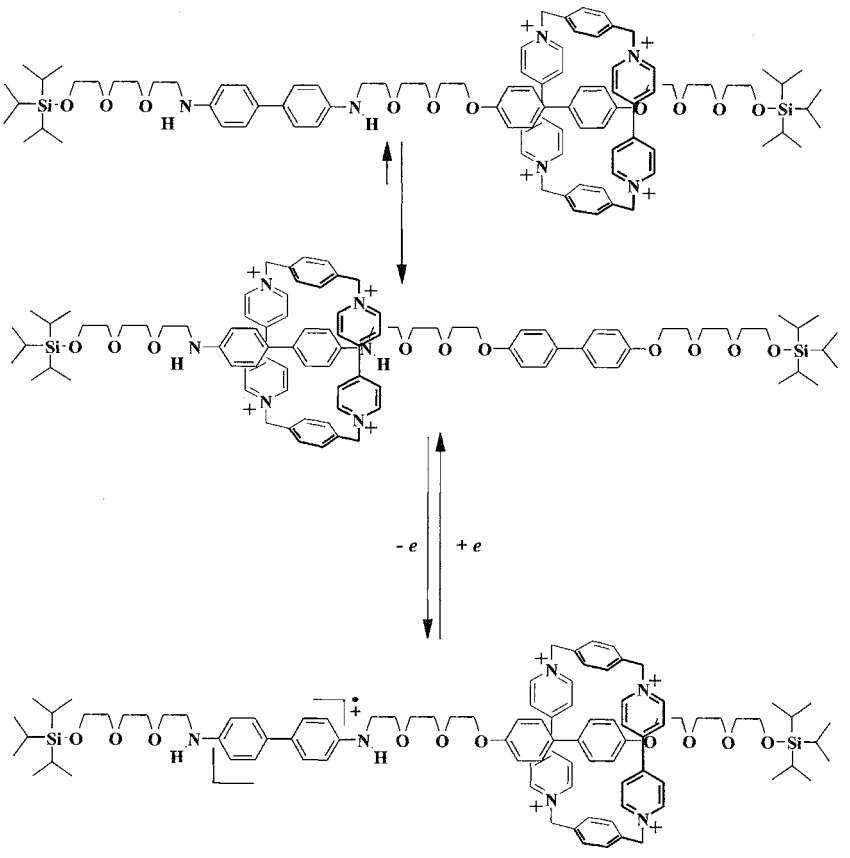
REDOX CONTROL OF ROTAXANES AND CATENANES

Rotaxanes are molecules that consist of one or more macrocyclic rings (wheels) threaded by a linear component (axle) with bulky stopper groups at both ends. The sliding, back-and-forth motion of the macrocyclic *rings is spatially limited by the stopper groups, which prevent axle–wheel dissociation. A catenane is composed of two or more interlocked macrocycles. The relative positions of the interlocked components in these fascinating molecules can be determined to some extent by noncovalent interactions, and thus, the possibility to exert interactive control by* redox *conversions quickly became a goal in the development of molecular machines. A review of the extensive work in this area* is available.[17] *Here, we will discuss* some *key examples.*

In collaboration with Stoddart, the authors' group reported in 1994 *a rotaxane in which the relative position of the wheel could be controlled by chemical and electrochemical* methods.[18] *This rotaxane contains two n-donor stations in the axle: benzidine and biphenol. The* macrocyclic *wheel fcyclophane* 2^{4+}) *interacts preferentially with the benzidine station. Thus, at* 299 *K in* CH_3CN *solution, 84% of the rotaxanes have the wheel located around the benzidine station, and* 16% *have it around the biphenol group (Scheme 9). At higher temperatures, the exchange between these two translational conformers is too fast in the NMR timescale, and the lines broaden extensively. Electrochemical experiments demonstrated that the one-electron oxidation of the benzidine station to form its cation radical results in the effective translation of the wheel over to the biphenol station.''''* The *wheel sliding motion is mostly due to the coulombic repulsions that the oxidized, positively charged benzidine station exerts on the tetracationic wheel. Switching back to the original situation is possible, as the* electrochemical *oxidation of benzidine is reversible under these conditions. A nice aspect of this rotaxane is that similar control on the wheel position can be attained by proton-transfer reactions, as the protonation of the benzidine station leads*



Scheme 8 *Electron transfer between the* CB7 *inclusion complexes of* MV^{2+} and MV^+. *The structure of three* cucurbituril *hosts* (CB6, CB7, *and* CB8) *is* shown *in the* insert *at the right.*



Scheme 9 Electrochemical switching of the average location of the wheel component (cyclophane 2^{4+}) in the rotaxane. taking advantage of the reversible oxidation of the benzidine station in the axle.

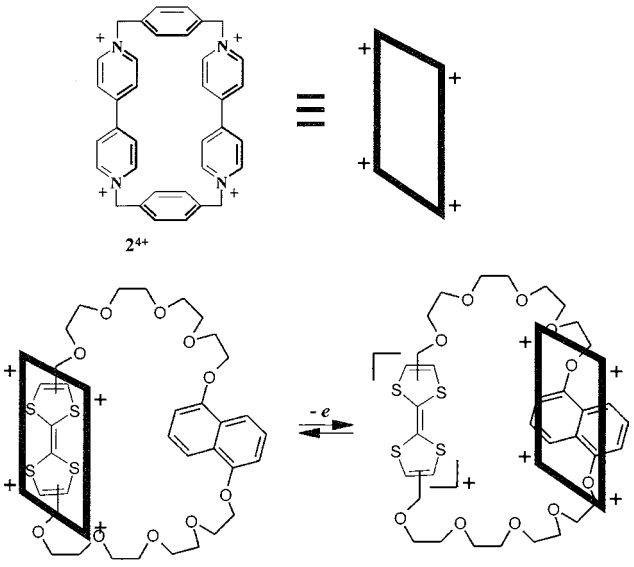
to wheel binding on the biphenol's region of the axle. Therefore, this rotaxane clearly exhibits properties corresponding to a molecular machine that can be switched by electrochemical and chemical means.

Similar electrochernical and chemical control on the conformation of catenanes was reported by the groups of Stoddart and Balzani. A prominent example is given in Scheme 10. The catenane in question is composed of two macrocyclic rings; the first is the already familiar electron-acceptor cyclophane $\mathbf{2^{4+}}$, while the second contains TTF and binaphthol aromatic donor units.[19] Given that TTF is the strongest π-donor, the most stable conformation of the catenane has the TTF unit sandwiched between the two bipyridinium units of the electron-acceptor ring. However, electrochemical (or chemical) oxidation of the TTF unit gives rise to a conformational change, as the catenane structure minimizes the coulombic repulsions between the oxidized TTF^+ and the tetracationic cyclophane ring by inserting the binaphthol unit between the bipyridinium groups and leaving the TTF^+ unit "alongside." This process is completely reversible, and the reduction of TTF^+ back to TTF returns this unit to the "inside" position.

These examples show how redox conversions can be utilized to control internal motions and the relative positions of functional groups in interlocked structures, such as catenanes and rotaxanes. Recently, the groups of Stoddart and Heath demonstrated that these compounds can be used to build monolayers, anchored with phospholipid counterions, which exhibit properties like those of solid-state. electronically addressable, switching devices.[20]

ELECTROCHEMISTRY **OF ENCAPSULATED** WEDOXCENTERS

Most redox proteins contain a redox-active group that is partially or completely buried inside their polypeptide backbones. Clearly, this design is meant to discriminate between possible electron-transfer partners, in such a way that only those approaching the protein at the right locations will be allowed to exchange electrons with the redox functional group. Therefore. the electron-transfer reactions of encapsulated redox centers are the subject of considerable current interest.[21–23] Most groups

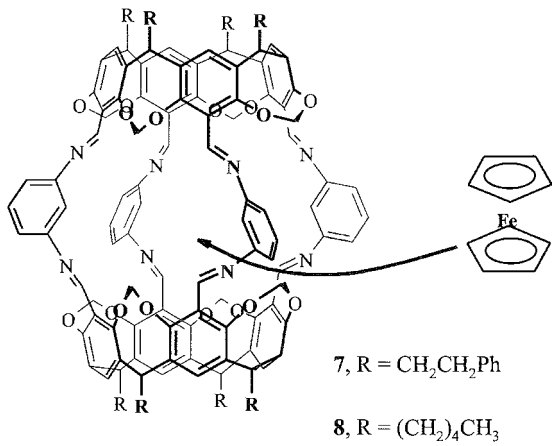


Scheme 10 Electrochemical switching of the average location of the 2^{4+} macrocycle in the catenane, taking advantage of the reversible oxidation of the TTF unit on the other macrocycle.

approached this problem by preparing large macromolecules containing redox-active groups covalently attached to their cores. In particular, this approach was popular in dendrimer chemistry, and a number of dendrimers with electroactive cores were synthesized and their electrochemical properties investigated.[23] Generally; dendrimer growth around a redox-active center results in the quick attenuation of the corresponding electron-transfer rates: although dendrimers with viologen cores appear to be exceptions to this trend.[24] This research topic is still open, and much work must be done to fully understand the effects of dendrimer encapsulation on the electrochemical properties of the redox cores.

An alternative way to attack this problem would rely on noncovalent encapsulation. In other words, use host–guest interactions to trap a redox active guest inside an electroinactive host. However, full encapsulation is not so easy to accomplish. and. as mentioned before, many complexes dissociate once the redox-active guest undergoes electron transfer. As a result of these complications, the literature contains few examples of truly encapsulated redox guests by noncovalent means. A few years ago; the author's group reported the electrochemistry of ferrocene fully encapsulated inside Cram's hemicarcerands.[25] This is a case of constrictive binding in which the complex is formed at high temperatures, at which the collisions between the fersocene (Fc) and the host molecules may lead to ferrocene encapsulation in the central cavity of the host, by sliding through one of the equatorial portals in the hemicarcerand. Cooling of this solution to room temperature effectively traps the Fc guest inside the host. We prepared hosts 7 and 8 (Scheme 11) and their respective ferrocene inclusion complexes, as previously described by Quan and Cram.[26] While $Fc\cdot 7$ was only soluble in tetrachloroethane. $Fc\cdot 8$ was soluble in dichloromethane and tetrachloroethane. Guest release from $Fc\cdot 8$ in CD_2Cl_2 was monitored at 25°C by ^{1}H-NMR spectroscopy. The half-life for the dissociation process was found to be slow enough ($t_{1/2}$ > 300 h) and to provide a long time in which to perform the electrochemical experiments with the encapsulated guest.[27]

Voltammetric experiments with $Fc\cdot 7$ in $C_2H_2Cl_4$ and $Fc\cdot 8$ in $C_2H_2Cl_4$ and CH_2Cl_2 were performed, and the results were compared with those obtained with free ferrocene in the same media. The data showed that encapsulation shifts the half-wave potential for fessocene oxidation to more positive values. Also, fersocene encapsulation by either host leads to a decrease in the diffusion coefficient and the standard rate constant for the heterogeneous electron transfer.[27] The observed effect on the potential values can be rationalized by the poor solvation provided by the inside walls of the host to the oxidized. ferrocenium ion. On the other hand, the observed decrease of the diffusion coefficient is easily explained by the increase in the molecular weight (and size) experienced by fersocene upon encapsulation inside the massive host. Finally, the decreased rate of electron transfer is probably the result of the increased average distance between the electrode surface and the ferrocene center upon its encapsulation. These results are similar to those obtained with dendrimer systems containing a redox center covalently attached to their cores,[21–23] which reveals general agreement between two different types of experiments. In any instance, additional work is necessary to fully understand



Scheme 11 Structures of Cram's hemicarcerands 7 and 8 for the constrictive encapsulation of ferrocene.

the ways in which encapsulation and site isolation affect electron-transfer reactions in synthetic systems and, by extension. in natural ones.

SUPRAMOLECULAR CHEMISTRY *AT THE ELECTRODE–SOLUTION INTERFACE*

Another area of work that received considerable attention in the last few years focuses on the design of the molecular architecture at the electrode–solution interface and the utilization of supramolecular interactions and effects to increase the selectivity of the electrode response. For instance, several years ago, the author's group prepared self-assembled monolayers on gold containing β-CD units.[28] The electrode-immobilized CD cavities were shown to bind ferrocene at low concentrations, increasing the sensitivity of the electrode and making possible the electrochemical detection of ferrocene under those conditions. Reinhoudt and coworkers extensively worked on the design and preparation of supported monolayers containing preformed binding sites.[29] The recent efforts of Nupp and coworkers also deserve mention in this area. This group developed electrode coatings based on cavity-containing coordination compounds. These film coatings are then capable of molecular sieving,[30] that is, they can size-select the electroactive materials for access to the underlying electrode surface, where they can undergo electron transfer.

CONCLUSION

The work summarized in this article relates to some of the most exciting areas of supramolecular chemistry. The interdependence of electron-transfer reactions with supramolecular interactions is at the core of the development of switchable molecular devices. Furthermore, research in areas of supramolecular electrochemistry may open the way for technological applications such as responsive (intelligent) materials. A possible impact in the field of electrochemical sensors is also readily visualized from the work described here.

Supramolecular Isomerism

Martin Schröder
Neil R. Champness
The University of Nottingham, Nottingharn, United Kingdom

INTRODUCTION

Described in this article is the phenomenon of supramolecular isomerism, using examples derived from coordination framework materials. The terminology, as applied to this complex area, is discussed via the description of ''isomerism'' within one-, two-, or three-dimensional arrays.

DEVELOPMENTS

The construction of crystal-engineered frameworks using either coordinative bonding or hydrogen-bonding interactions is an extremely topical area of inorganic and materials chemistry. In the case of coordination frameworks, notable advances have been made in understanding the factors that influence network topology using the building-block methodology as originally advanced by Robson et al.[1] This straightforward concept of using transition metal geometries to develop extended arrays is highly adaptable, but framework structures can be readily influenced by weaker supramolecular forces and by the coordinating ability of the anion.[2] Thus, it is possible for different forms of the extended array to be formed in which the same molecular components are used to construct the array, but different connectivities or orientations are observed. The realization that different forms, or '.isomers,'' of highly related compounds can be formed led to a dilemma of how such compounds can be described most usefully. Confusion, and conflicting opinions. have resulted in a variety of terminologies being used in the literature, which we seek to clarify in this article.

TERMINOLOGY

A large number of terms have been used to describe forms of isomerism in extended supramolecular arrays observed in the solid state. These include architectural isomerism,[3] topological isomerism,[4] and older terms that have specific and often well-defined meanings, including polymorphism, pseudopolymorphism, and structural isomerism.[5]

The term ''supramolecular isomerism'' was first used by Zaworotko[6] to describe distinct forms of highly related coordination polymer materials. This is complicated by the observation that supramolecular isomerism for a given network system is commonly combined with a variation in guest solvent molecules within the extended structure. Variation of guest molecules within a framework does not, of course, define new supramolecular isomers of the framework if the latter is unchanged. In a recent review, Zaworotko et al.[7] stated that supramolecular isomerism is closely related to the ''well-documented subject of polymorphism in crystalline solids.'' Zaworotko defined supramolecular isomerism in this context as ''the existence of more than one type of network superstructure for the same molecular building blocks'' and related the phenomenon ''to structural isomerism at the molecular level.''

Supramolecular isomerism represents a broad term for which the following subdivisions need to be considered:

Class I. Frameworks built from the same molecular components using the same interactions, i.e., supramolecular synthons (M-L, H-bonding, etc.), giving rise to the same localized connectivities but different framework topologies.

Class II. Frameworks built from the same molecular components using different interactions, i.e., supramolecular synthons (M-L, H-bonding, etc.), giving rise to different framework topologies.

Class III. Frameworks built from the same molecular components but with different noninteracting guest molecules giving rise to different framework topologies.

All of these subdivisions of supramolecular isomerism can be related to previously used terminology; thus, Class I can be considered as polymorphism; Class II as structural isomerism, and Class III as pseudo-polymorphism.

Other subsets of these classes also exist that can be considered as further forms of supramolecular isomerism but that are perhaps more usually associated with molecular species. Therefore, the term supramolecular isomerism offers little additional information. In particular, conformational changes of one, or more; of the molecular

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012924

constituents of the extended array can lead to isomerism of the supramolecular array. Similarly, it is possible to prepare chiral frameworks for which two enantiomers can be envisaged and often isolated. Another form of isomerism. classified as a subset of supramolecular isomerism, is catenane isomerism, which distinguishes between catenatedlinterpenetrated and noncatenated/interpenetrated forms.

We will now discuss the classes of supramolecular isomerism using illustrative examples to show the complexity of the issues that arise in this area.

Class I—Polymorphic Supramolecular Isomers

We define polymorphic supramolecular isomers as supramolecular frameworks built from the same molecular components using the same interactions, i.e., supramolecular synthons (M-L, H-bonding, etc.). in all isomers giving rise to the same localized geometries but different framework topologies. To illustrate this terminology, we outline three examples of this class of isomerism.

Two distinct polymorphic supramolecular isomers of $\{[Ag(4\text{-}CNpy)_2]BF_4\}_\infty$ (4-CNpy = 4-cyanopyridine) have been reported.[8] In both isomers, each Ag(I) cation is coordinated by two pyridyl and two nitrile donors. In the first isomer, the Ag(I) cation adopts a flattened tetrahedral environment in which both pyridyl and nitrile donors adopt conventional Ag—W bond lengths, [Ag—$N_{(pyr)}$, 2.270(6) A: Ag—$N_{(CN)}$, 2.350(10) Å]. Propagation of the polymer via the 4-cyanopyridine ligands from these tetrahedral nodes results in the formation of a three-dimensional diamondoid assay (Fig. la), which exhibits fourfold interpenetration.

The second isomer of $\{[Ag(4\text{-}CNpy)_2]BF_4\}_\infty$ shows a distorted square-planar geometry at Ag(I) with different bond lengths for Ag—$N_{(pyr)}$ and Ag—$N_{(CN)}$, [Ag—$N_{(pyr)}$, 2.175 Å; Ag—$N_{(CN)}$, 2.71(1), 3.06(1) Å]. Thus, the two Ag—$N_{(CN)}$ contacts can only be considered as weak interactions. Polymeric propagation via the bridging ligands in this isomer results in a two-dimensional sheet structure of (4,4) topology (Fig. lb), in contrast to the three-dimensional diamondoid assay observed in the first isomer. The difference in polymeric dimensionality of the two compounds, i.e., two- versus three-dimensional, is therefore a direct result of the different geometries adopted at the Ag(I) cation, square-planar versus tetrahedral.

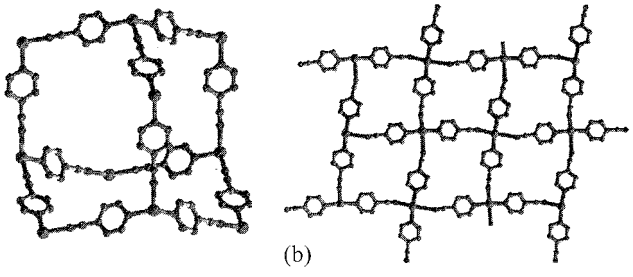

Fig. 1 Class I supramolecular isomers of $\{[Ag(4\text{-}CNpy)_2]BF_4\}_\infty$, in which the flexible Ag(I) coordination geometry leads to three-dimensional diamondoid (a) or two-dimensional (4.4) grid structures.

Cu(TCNQ) (TCNQ = 7,7,8,8-tetracyanoquinodimethane) exists as two polymorphic supramolecular isomers; which have been described as polymorphs by the original authors.[9] The two isomers exhibit distinct morphologies, needle (A) and platelet (B), and different magnetic and charge-transport properties. Interestingly. Isomer A can be converted to Isomer B by simply suspending Isomer A in MeCN solution for several days. Structural characterization of the two isomers shows that they exist as doubly interpenetrated three-dimensional coordination polymers in which the Cu(I) center is bound by four nitrile donors from four separate TCNQ ligands. The isomers exhibit subtly different four-coordinate geometries that lead to significantly different three-dimensional topological arrangements. Whereas, in Isomer A, neighboring TCNQ ligands around the Cu(I) center are rotated through an angle of 90° with respect to each other, in Isomer **B**, infinite assays of coplanar TCNQ molecules are arranged in the same orientation but in two perpendicular planes.

The series of compounds $[M(dca)_2(pyz)]_\infty$ (M = Mn,[10,11] Co [10] Ni,[10] Cu [12] Zn;[10] dca = dicyanamide, pyz = pyrazine) forms two distinct isomers termed the α and β forms. In both cases. the M(II) cation is coordinated by four dca nitrile donors and by two pyrazine donors that adopt a *trans* assangement. Thus, essentially the same coordination sphere is adopted at the M(II) cationic network node. In the case of the Cu(II) salt, Jahn–Teller distortion is observed via elongation of two of the dca nitrile–copper Cu—N bonds.[12]

In α-$[Cu(dca)_2(pyz)]_\infty$, the dca ligands bridge each Cu(II) cation to four nearest-neighbor metal nodes forming a square-grid framework derived from $[M(dca)_2]_\infty$ units. The pyrazine ligands link these $[M(dca)_2]_\infty$ square-grids into a three-dimensional α-Po network (Fig. 2a) which exhibits two-fold interpenetration. In contrast, in β-$[Cu(dca)_2(pyz)]_\infty$, the dca ligands bridge metal centers via double bridges such that each M(II) is only linked to two other metal nodes leading to $[M(dca)_2]_\infty$ chains. These chains are then linked through bridging pyrazine ligands to give two-dimensional sheets with a square-grid topology, if one considers the double-bridges as a single link (Fig. 2b). Interestingly. in the case of $[Cu(dca)_2(pyz)]_\infty$, the α form can be converted. over a period of hours. to the β isomer by suspension of the α

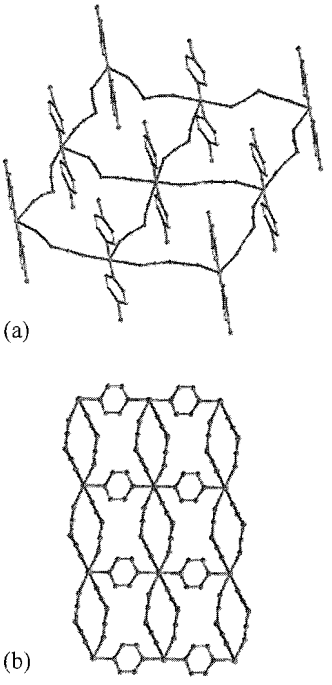

Fig. 2 Class I supramolecular isomers (a) α-$[M(dca)_2(pyz)]_\infty$, a three-dimensional coordination framework with ʏ-Po topology and (b) β-$[M(dca)_2(pyz)]_\infty$. a two-dimensional framework (M = Mn, Co. Ni, Cu, Zn) (*View this art in* color *at www dekker com*)

form in aqueous solution: this interconversion of phases is not observed for other metal cations.

Class II Structural Supramolecular Isomers

We define structural supramolecular isomers as supramolecular frameworks built from the same molecular components using different supramolecular interactions. Examples of structural supramolecular isomerism in coordination polymers are relatively rare, which probably reflects the requirement of inultiple interactive modes being present in a single building-block, ligand, or hydrogen-bonding moiety.

The complex [Cu(SCN)(dpt)] [dpt = 2,4-*bis*(4-pyridyl)-1,3,5-triazine] exhibits structural supramolecular isomerism. with the two isomers adopting either a three-dimensional lattice A or a one-dimensional ribbon polymer B.[13] Isomer A exhibits N_3S binding via two dpt ligands and two S C N anions. The chains of (CuSCN), are single stranded and are linked via bridging bidentate dpt ligands (Fig. 3a); therefore, SCN^- anions and dpt ligands lead to polymer propagation. The (CuSCN), chains on opposing ends of any given dpt ligand are orthogonally disposed. leading to the three-dimensional framework structure with a $6^5.8$ topology [$Cd(SO_4)$-type structure]. Such frameworks have been previously observed for coordination polymers with bridging bipyridyl ligands, but this structural type is more commonly associated with square-planar metal centers.[14 15]

Isomer **B** of $[Cu(SCN)(dpt)]_\infty$ exhibits a one-dimensional ribbon polyiner structure constructed from dpt-decorated (CuSCN), stair-polymers (Fig. 3b). Each Cu(I) center adopts a N_2S_2 coordination sphere formed by three SCN^- anions and a single dpt ligand. In contrast to Isomer A, each dpt ligand is only monocoordinated and, therefore, is not involved in polymer propagation.

Class III Pseudopolymorphic Supramolecular Isomers

We define pseudopolymorphic supramolecular isomers as supramolecular frameworks built from the same molecular components but with different noninteracting guest molecules giving rise to different framework topologies.

The complex $[(CuI)_2(bpds)]_\infty$ [bpds = *bis*(4-pyridyl)-disulfide] adopts two different structural motifs depending upon the solvent of crystallization. In both cases, the $[(CuI)_2(bpds)]_\infty$ consists of Cu_4I_4 cubane tetramers linked by two bpds ligands to form a square-shaped cavity.[''] When crystals of $[(CuI)_2(bpds)]_\infty$ are grown from $EtCN/CH_2Cl_2$, the tetrahedral Cu_4I_4 cubane junctions are linked by bpds ligands to give a necklace structure, $\{[(CuI)_2(bpds)] \cdot 0.5\ EtCN\}_\infty$ (Fig. 4a). The tetrahedral geometry of the Cu_4I_4 cubane results in alternating square-shaped units being orientated perpendicular to each other in adjacent links of the necklace, with the square-shaped cavities packed to give channels that accommodate EtCN molecules.

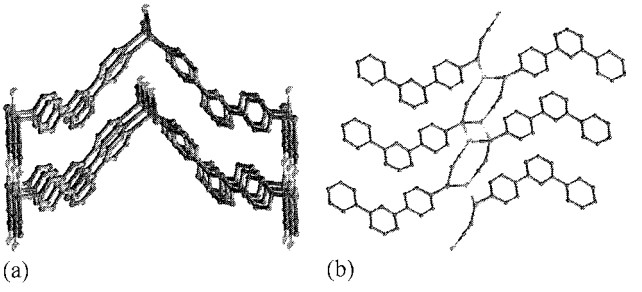

Fig. *3* Class II supramolecular isomers of $[Cu(SCN)(dpt)]_\infty$. in which the different $(CuSCN)_\infty$ motifs lead to the formation of three-dimensional (a) or one-dimensional (b) coordination polymers. (*View this art in* color *at www.dekker.com.*)

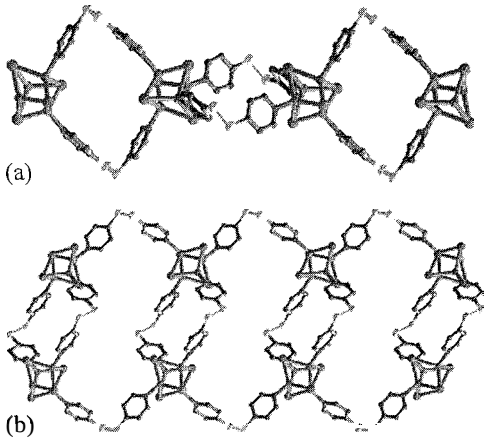

Fig. 4 (a,b) Two Class III supramolecular isomers of $[(CuI)_2(bpds)]_\infty$ [bpds = *bis*(4-pyridyl)disulfide] in which Cu_4I_4 cubane tetramers are linked via bridging bipyridyl ligands. (*View this art* in color *at www.dekker.com.*)

Use of $MeCN/CH_2Cl_2$ as the crystallization solvents results in a different isomer; $\{[(CuI)_2(bpds)] \cdot 0.5\ MeCN\}_\infty$. As in the first isomer discussed. Cu_4I_4 cubane tetramers are linked by two bpds ligands to form a square-shaped cavity. However. the tetrahedral junctions of these cubane units now allow these squares to interlink via two further bpds ligands. forming a tubular polymer (Fig. 4b). Despite interdigitation between adjacent tubular polymers, the packing arrangement allows the formation of two criss-crossed channels occupied by MeCN solvent molecules. Powder X-ray diffraction studies confirm that the formation of each isomer is exclusively dependent on solvent of crystallization. As both isomers of $[(CuI)_2(bpds)]_\infty$ are formed under similar reaction conditions, but with a change in the nitrile solvent. it is reasonable to conclude thatr there are oniy relatively minor, but significant. energy differences in the formation of the two polymers.

A wide family of network architectures can be formed when $M(NO_3)_2$ (M = Co, Ni, Cd) salts are reacted with bridging bipyridyl ligands.[6,16–23] Many of these compounds adopt a seven-coordinate geometry in which the metal center is coordinated by two chelating nitrate anions, leaving th ee sites for pyridyl ligation, arranged in a *mer* configuration in the equatorial plane of a pentagonal bipyramid. These compounds have a T-shaped asrangement of pyridyl sites and have been shown to adopt a range of coordination polymer architectures, including ladder,[16,23] bilayer,[17,18,20,21] three-dimensional architectures,[19] herringbone,[22,23] and brick-wall[23] motifs. Systems that exhibit architectural flexibility are particularly likely to exhibit supramolecular isomerism, and this is the case for the family of compounds, $[Co_2(NO_3)_4(4,4'\text{-bipy})_3]_\infty$. The supramolecular isomerism exhibited by this particular system was extensively studied, and it was shown that the architecture adopted by $[Co_2(NO_3)_4(4,4'\text{-bipy})_3]_\infty$ is highly dependent on the nature of guest species included in the host. Thus. $Co(NO_3)_2$ reacts with 4,4′-bipy in either MeOH/$CHCl_3$ or MeOH/MeCN to afford the complex $\{[Co_2(NO_3)_4(4,4'\text{-bipy})_3] \cdot solv\}$, (solv = MeCN or $CHCl_3$), which exhibits a ladder motif, Isomer A (Fig. 5a).[16] Despite the cavity between the rungs of the $[Co_2(NO_3)_4(4,4'\text{-bipy})_3]_\infty$ ladder being large enough to allow interpenetration of further ladders. the structure exhibits no such interpenetration but rather includes guest solvent molecules, $CHCl_3$ or MeCN in the two reported instances.

In contrast, reaction of $Co(NO_3)_2$ with 4,4′-bipy in the presence of CS_2[17] or H_2O[18] affords a molecular bilayer motif. Isomer **B**, in which each Co(II) center still acts as a T-shaped connecting junction. The guest molecule, CS_2 or H_2O, is clathrated within the framework and presumably acts as a template for the formation of the bilayer motif.

Reaction of $Co(NO_3)_2$ with 4,4′-bipy in the presence of pyridine and benzene templates leads to the formation of a further structural motif.[19] In this case, a three-dimensional lattice (Fig. 5c) is observed which again is a supramolecular Isomer C of the ladder structure. In this structure, the T-shaped connections are arranged such that pairs are oriented at 180° with respect to each other and then at 90° to the adjacent pair of connections. This affords a complicated three-dimensional lattice that is triply interpenetrated, leaving channels that are occupied by guest benzene solvent molecules.

These three distinct architectures of the $[Co_2(NO_3)_4(4,4'\text{-bipy})_3]_\infty$ family all contain guest solvent molecules,

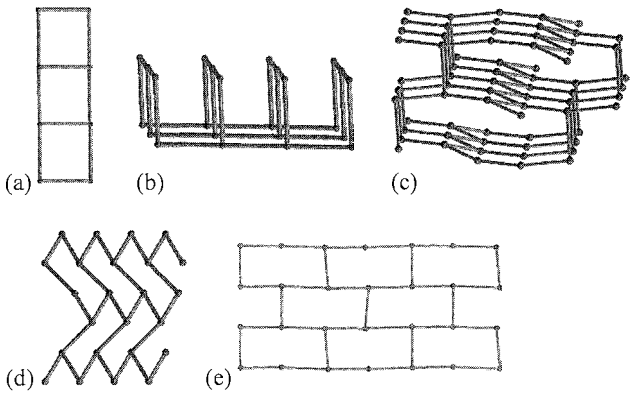

Fig. 5 Coordination frameworks constructed using a T-shaped connecting unit: (a) ladder: (b) bilayer: (c) three-dimensional framework; (d) herringbone; and (e) brick-wall motifs. (View *this* art *in* color *at* 1tww.dekker.com.)

MeCN, $CHCl_3$ (ladder),[16] CS_2, H_2O (bilayer),[17,18] benzene (three-dimensional framework)[19] and, thus, can be considered pseudopolymorphic supramolecular isomers. Of course, it is a debatable point as to whether the guest molecules are "noninteracting." At the least, the molecules will act as shape templates encouraging the formation of one supramolecular isomer over another or will act as kinetic templates. However, one method of assessing the extent of host–guest interaction is to investigate the ease of guest removal and the stability of the guest-free framework. In this respect, it is notable that the bilayer motif of $[M_2(NO_3)_4(4,4'\text{-bipy})_3]_\infty$ (M = Co, Ni, Zn) shows that not only is this structure robust to guest removal, but it also adsorbs N_2, CH_4, O_2,[18] CO_2, N_2O, MeOH,[20] and EtOH.[20,21] This indicates that host–guest interactions are not sufficiently important in the final product such that upon guest removal the host framework is structurally robust.

The reactions of $Co(NO_3)_2$ with the elongated analog of 4,4′-bipyridine, 1,2-*bis*(pyrid-4-yl)ethyne, have also been studied, and supramolecular isomers have been prepared.[22,23] Two isomers have been structurally characterized, the familiar ladder motif (Fig. 5a) and a herringbone structure (Fig. 5d), both using a $Co(NO_3)_2(py)_3$ as a T-shaped junction. The two isomers can be produced from the same reaction mixture (MeOH/MeCN),[22] but samples of pure ladder material can be isolated from an acetone–EtOH mixture.[23] The ladder structure is analogous to those observed previously. except that the ladders interpenetrate in a perpendicular fashion to afford a polycatenated three-dimensional structure. Each square-space between the rungs of the ladder is filled by two other square units from two further perpendicular ladders. In the case of the second, "herringbone" isomer triple parallel interpenetration gives rise to a polycatenated two-dimensional sheet.[22] Powder x-ray diffraction studies of the products from simple precipitation reactions of 1,2-*bis*(pyrid-4-yl)ethyne and $Co(NO_3)_2$ yield intriguing results.[23] If an acetone solution of $Co(NO_3)_2$ is added to a solution of the ligand in EtOH, then pure samples of the interpenetrating ladder compound are isolated, but if the addition process is reversed, then powder x-ray studies reveal that the product is ca. 20% ladder and 80% of a further structural motif, the brick-wall (Fig. 5e). The brick-wall structure is highly related to the herringbone motif but with a different orientation of the rectangular cavities within the structure. These results further reinforce the subtle differences between the different supramolecular isomers based on the $Co(NO_3)_2$ unit.

Reaction of $Co(NO_3)_2$ with 1,2-*bis*(pyrid-4-yl)ethane in a 1:3 ratio affords three different pseudopolymorphic supramolecular isomers of formula $\{[Co_2(NO_3)_4(1,2\text{-}bis(\text{pyrid-4-yl})\text{ethane})_3] \cdot x(\text{guest})\}_\infty$, depending upon the ternplating conditions used.[6] In all three cases the

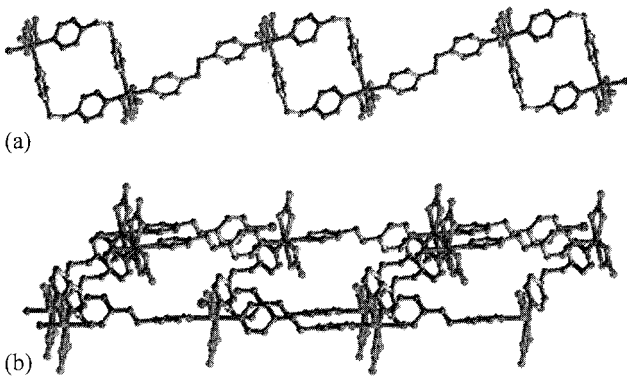

Fig. 6 Class III supramolecular isomers of $\{[Co_2(NO_3)_4(1,2\text{-bis(pyrid-4-yl)ethane})_3] \cdot x(\text{guest})\}_\infty$, (a) isomer exhibiting ligands with both *gauche* and *anti* ligand conformations to afford a one-dimensional polymer; (b) isomer again containing both *gauche* and *anti* ligand conformations. but in this case. forming a two-dimensional bilayer structure. *(View this art in color at www.dekker.com.)*

Co(II) cation is coordinated by two nitrate anions in a bidentate fashion to form a T-shaped $Co(NO_3)_2(py)_3$ junction, but the 1,2-*bis*(pyrid-4-yl)ethane ligand is flexible and can adopt either *gauche* or *anti* isomers. When crystallized from MeOH/MeCN, the complex illustrated in Fig. 6a is isolated, in which two ligands adopt a *gauche* arrangement and link two $Co(NO_3)_2$ units in a square-shaped unit which are then linked by ligands in the *anti* arrangement into a one-dimensional polymer. In complete contrast, if the crystallization process is performed in MeOH/MeCN but in the presence of a ferrocene-templating agent, then a molecular bilayer structure is formed. For every ligand in a *gauche* conformation, two ligands in an *anti* conformation are observed in the structure. The ligands in the *anti* configuration bridge T-shaped $Co(NO_3)_2$ junctions in a linear arrangement, and these chains are then linked through the *gauche* ligand to form the bilayer structure (Fig. 6b). By varying the solvent combination to MeOH/$CHCl_3$, a more familiar molecular ladder motif (Fig. 5a) is formed in which the ligands adopt *anti* conformations. As with the 4,4′-bipy analog of this complex, the spaces between the rungs of the ladder are filled with guest $CHCl_3$ solvent molecules that inhibit interpenetration of adjacent ladders. The supramolecular isomerism observed in these cases arises by variation of the conformation of the 1,2-*bis*(pyrid-4-yl)ethane ligand building block. Zaworotko described this type of supramolecular isomerism as ''conformational supramolecular isomerism.''[7] With the aim of simplifying the terminology in this area, we suggest that the example of supramolecular isomerism described in this family of compounds be classified as pseudopolymorphic supramolecular isomerism (i.e., Class III), as many instances

of supramolecular isomerism will also exhibit minor differences in the arrangements of the ligand or other building blocks within the overall network structure.

CONCLUSION

It is clear from the examples discussed that supramolecular isomerism can be encountered in a range of systems. Such isomerism is particularly important when there are only subtle energy differences between highly related structures. This is clearly the case when the metal coordination environment remains the same in the different isomers (Class I and III), and so the differences in structure arise purely through different orientations of metal nodes within the coordination polymer. For Class II, structural supramolecular isomerism. it is rare to observe such a subtle balance between different metal coordination spheres, and this is reflected in the small number of examples of this type of isomerism.

In conclusion. we seek in this article to clarify the terminology used to describe supramolecular isomerism observed in coordination polymer frameworks. The terminology used has wider implications and can readily be applied to hydrogen-bonded arrays and also to non-polymeric architectures.

Supramolecular Libraries

Sijbren Otto
Jeremy K. M. Sanders
University of Cambridge, Cambridge, United Kingdom

INTRODUCTION

Over the two last decades, the pharmaceutical industry has gone to great lengths in the development of combinatorial methods for drug discovery. Although combinatorial chemistry has perhaps not been able to live up to the overstretched expectations, it claimed its rightful place as another tool among the diverse approaches toward drug development. Combinatorial methods are now starting to penetrate other fields of science, where they can be efficient tools for exploring structural space just beyond the boundaries of what we know; understand, and can predict. in this article, we summarize the progress made using combinatorial libraries of noncovalent assemblies. These libraries were mainly developed for the discovery of supramolecular receptors for small guest molecules, although some work was also carried out on the complementary approach, where libraries of noncovalent assemblies were screened for affinity for biological targets.

COMBINATORIAL LIBRARIES OF NONCOVALENT ASSEMBLIES

Supramolecular assemblies held together by noncovalent forces have some unique characteristics. Even the strongest of the noncovalent forces (metal–ligand coordination and hydrogen bonding) tend to be weak enough to allow, under relatively mild conditions, for the exchange of the building blocks that make up the assemblies. This reversibilitp ensures that, upon mixing different supramolecular building blocks together. the composition of the resulting library is typically controlled by thermodynamics rather than by kinetics. Hence, most libraries in which building blocks are held together by noncovalent interactions are dynamic combinatorial libraries (DCLs).[1–3] Because of the possibility of interchange of building blocks. DCLs are able to respond to external influences. For instance, other noncovalent interactions can be used to shift the equilibria (and. hence, the library distribution). Thus, after introduction of a guest into a DCL of hosts. binding of the guest to the best available host will lead to stabilization of this host, which induces a shift in the equilibrium. The best host will be amplified at the expense of the inferior receptors (Fig. 1). Screening the libraries for the best receptors is then simply a matter of comparing product distributions before and after addition of the guest.

RECEPTORS FROM LIBRARIES OF NONCOVALENT ASSEMBLIES

In early work in 1995, just before the concept of dynamic combinatorial chemistry was first explicitly recognized,[4] Hamilton et al. screened a combinatorial library of ruthenium *bis*(terpyridyl) complexes.[5] From five differently substituted terpyridine ligands, a series of 15 different coordination complexes was synthesized and isolated. The library was screened for affinity for dicarboxylate or diammonium guests using microcalorimetry or picrate extraction. and several receptors were identified (Fig. 2).

More recently. Morrow and coworkers developed a dynamic combinatorial approach to identify complexes that extract metal ions [Zn(II) and Cd(II)] from an aqueous phase into organic solution.[6] Diversity was achieved on a covalent level and on a noncovalent level: metal ions were extracted into the organic phase by coordination to two Schiff base ligands, each of which was assembled from an aldehyde or ketone and an amine through reversible covalent bond formation. In a more recent study, the authors used a set of 25 acylhydrazones as ligands.[7] Although. in theory. diversity in these systems can be achieved through hydrazone exchange as well as metal–ligand exchange, the former process was found to be too slow for practical use. Under thermodynamic control, the product distribution of the libraries will be biased toward the most stable complexes. This might be beneficial, as extraction efficiency is likely to be correlated with complex stability. However, other factors not directly correlated to stability, such as the solubility of the complex in the organic phase, will influence the efficiency of extraction.

Huc, Lehn. and coworkers used the coordination of bipyridine ligands to Cu(I) or Pd(II) metal centers to form four-coordinate tetrahedral or square-planar complexes, respectively.[8] Mixing two bipyridine ligands. one with and one without hydrogen-bonding capabilities, resulted in the formation of a small dynamic library of three

possible ternary complexes. Introduction of guest molecules presenting complementary hydrogen-bond recognition motifs resulted in modest shifts in the equilibrium in favor of complexes that maximize host–guest hydrogen bonding.

Work on combinatorial supramolecular libraries nearly exclusively uses metal–ligand interactions to hold the assemblies together. Crego Calama, Timmcrman, Reinhoudt, and coworkers, however, used well-known complementary hydrogen-bond motifs to build up supramolccular structures of impressive complexity. Three calix[4]arene units (1a) each functionalized with two melamine groups and six complementary barbiturate building blocks (2) self-assemble cooperatively into a $\mathbf{1}_3\mathbf{2}_6$ superstructure that is held together by 36 hydrogen bonds (Fig. 3). By starting from two different calixarene building blocks (not shown) the researchers were able to build a small DCL.[9] NMR studies indicated rapid exchange of building blocks at room temperature. In a separate study, the authors prepared a calixarene functionalizcd with two melamine and two Zn-porphyrin units (**1b**).[10] The Zn-porphyrins have an affinity for nitrogen ligands, giving the resulting structures potential receptor properties. Mixing the barbiturate 2 with the parent calixarene 1a and the porphyrin-functionalized calixarene **1b** generated a small DCL of four superstructures with different numbers of Zn-porphyrin recognition sites. Addition of a tripyridine guest (3) resulted in a shift of the equilibrium in favor of the host–guest complex $(\mathbf{1b})_3\mathbf{2}_6\mathbf{3}_2$, forcing the remaining 1a to form $(\mathbf{1a})_3\mathbf{2}_6$. After addition of the guest, no mixed **1a1b** structures could be detected.

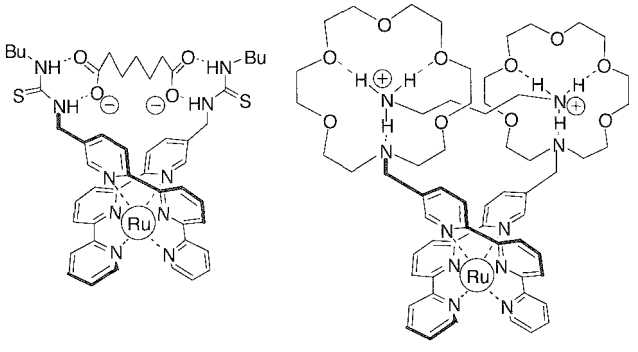

Fig. 2 Some of the first receptors identified using a combinatorial approach. (Adapted from Ref. [5].)

In recent work in our laboratories, we used the efficient coordination of phosphine ligands to Rh(III) porphyrins to construct DCLs of mixed-metal arrays of Zn(II)- and Rh(III)-porphyrins (Fig. 4).[11] The porphyrin building blocks 4 and **5** are bifunctionalized, thus allowing access to a theoretically unlimited range of linear and macrocyclic oligomeric structures. Using the interaction of Zn-porphyrins with the nitrogen ligand 4,4′-bipyridine led to the selection and quantitative amplification of host–guest complex 6.

The last two examples demonstrate convincingly how host–guest interactions can quantitatively transform a complex mixture into the optimal host, illustrating the power of dynamic combinatorial chemistry for selection and amplification of the fittest receptors.

DYNAMIC LIBRARIES OF NONCOVALENT CAGE COMPOUNDS

Cage-like compounds are among the more complex supramolecular structures and are formed through the connection of tripodal or even more complex building blocks in a specific manner. It is perhaps one of the areas in supramolecular chemistry that has benefited most from noncovalent thermodynamically controlled synthetic methods.

Rebck and coworkers extended their studies on the hydrogen-bond-bascd self-assembly of tetrameric capsules around guest molecules using a combinatorial approach.[12] Starting from two different monomers, a small dynamic library of guest-filled capsules was produced. The distribution of capsule compositions was analyzed by MS and found to depend on the nature of the guest, with methylquinuclidinium cation as the most

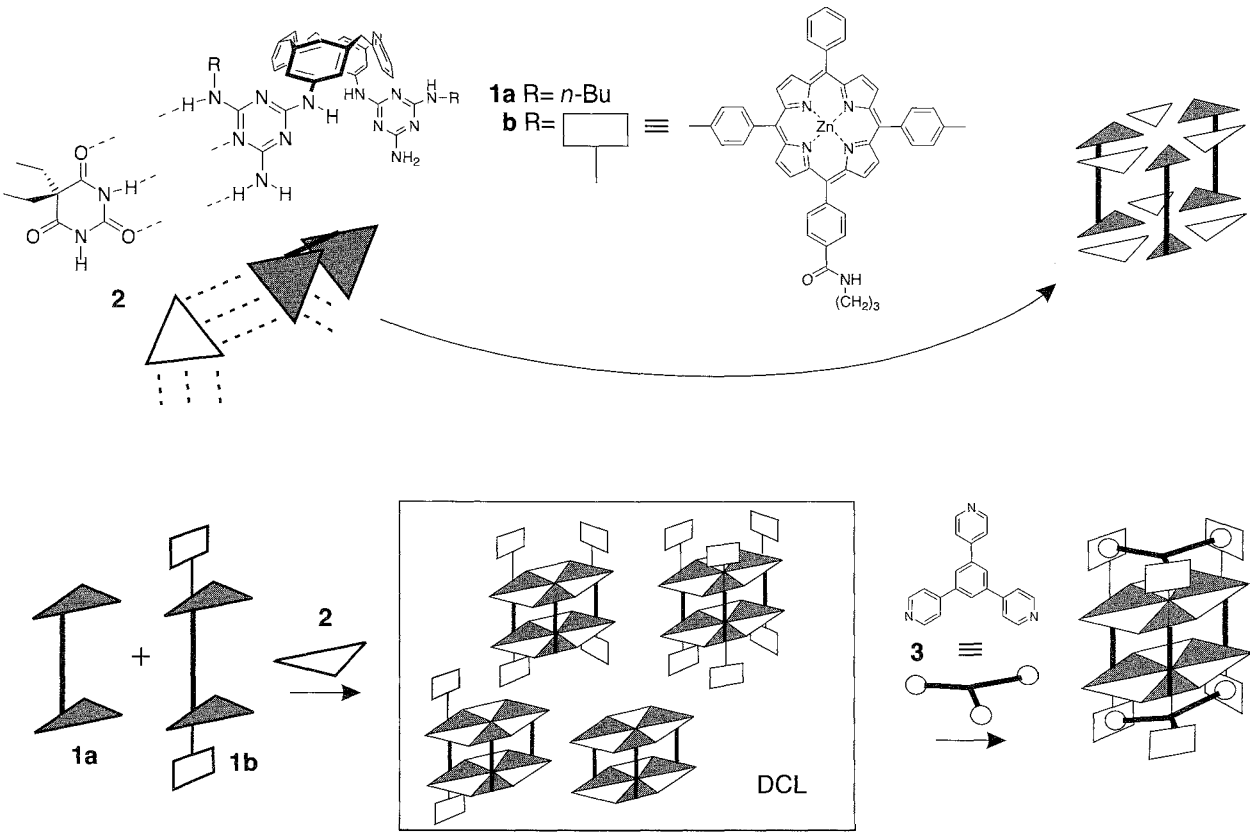

Fig. 3 Self-assembly of three calix[4]arenes (1a) functionalired with two melamine groups and six complementary barbiturate building blocks (2) into a $(\mathbf{1a})_3\mathbf{2}_6$ superstructure. Mixing in of another calixarene building block functionalized with Zn-porphyrin units (1b) generates a small DCL of four superstructures. Addition of a tripyridine guest (3) shifts the equilibrium in favor of the host–guest coinplex $(\mathbf{1b})_3\mathbf{2}_6{\cdot}\mathbf{3}_2$. (Adapted from Refs. [9] and [10].)

selective guest amplifying the formation of the largest capsule. Similar, but less clear-cut, changes in product distribution were observed in a more diverse library made from five (or seven, when counting enantiomers separately) building blocks.

Raymond and coworkers published a thorough study of a series of dynamic libraries made from dipodal biscatecholate ligands linked together by Ga(III) metal centers.[11] The ligands are predisposed to assemble into tetrahedral Ga_4-ligand$_6$ complexes. The kinetics of equilibration and equilibrium distribution of a 12-component dynamic library made from two different ligands were analyzed in detail. Analysis by ESI-FTICR-MS of larger libraries made by mixing three different ligands confirmed the

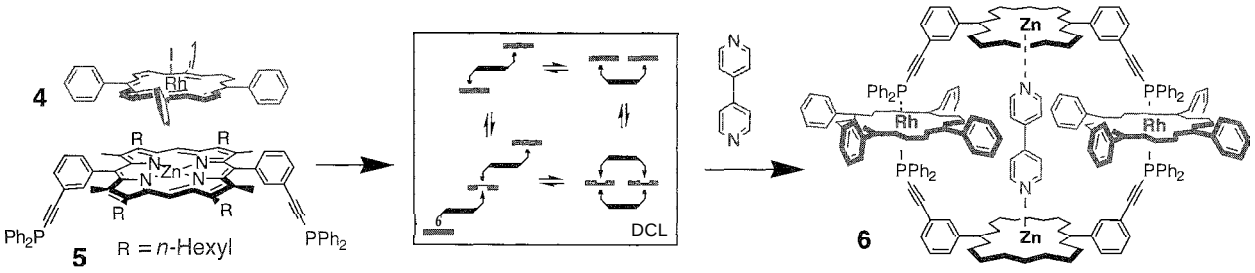

Fig. 4 A dynamic combinatorial library of cyclic and linear arrays of mixed metalloporphyrins which. upon addition of a 4.4′-dipyridine guest. transforms quantitatively into a macrocyclic porphyrin tetramer. (Adapted from Ref. [1 I].) (*View* this *art in color at www.dekker.com.*)

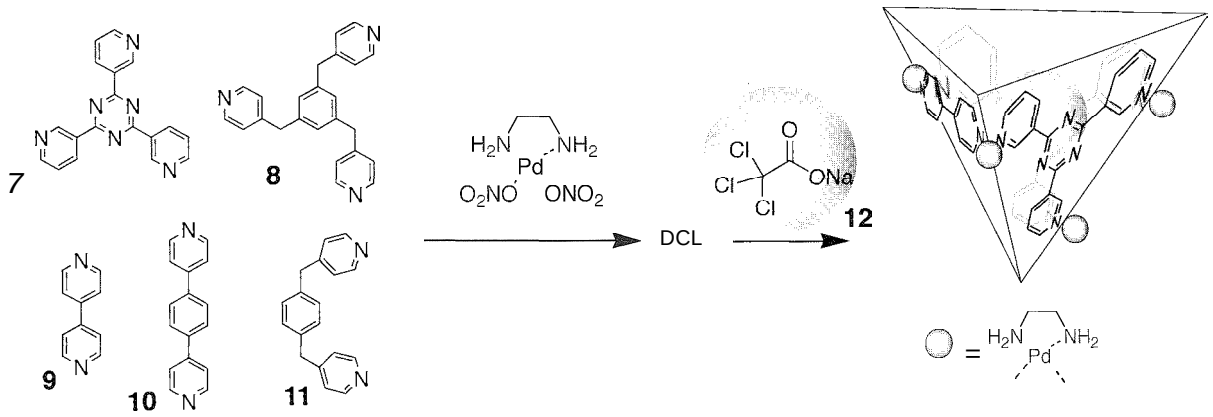

Fig. 5 Mixing di- and tripyridyl ligands (7–11) with Pd(en) produces a diverse dynamic combinatorial library of cyclic and cage coordination compounds. Exposure of this library to sodium trichloroacetate (12) results in the amplification of a new receptor. (Adapted from Ref. [17].)

presence of most of the statistically most probable products. Although the capsules are known to bind Et_4N^+ ions indiscriminately, screening of these libraries for more specific host–guest systems has yet to be performed.

Albrecht and coworkers used Ga(III) and Zn(II) centers to link ligands containing two bidentate hydroxyquinoline units.[14] In the absence of any guests, dynamic libraries of metal–ligand complexes were formed that were not further characterized. However, upon addition of Na^+, K^+, Rb^+, or NH_4^+ ions to the Ga(III)–ligand solutions. well-defined structures were formed containing three ligands held together by two Ca centers surrounding a central cation guest. Similar structures were observed upon addition of Li^+, Na^+, or $K^+$to the Zn(II)–ligand solutions. Receptor amplification is driven by the interaction of the six oxygen atoms of the three ligands with the central cation.

In elegant work, Fujita and coworkers extensively explored Pd-pyridyl interactions to build capsule-like structures. In one of the first dynamic combinatorial approaches toward encapsulation. an asymmetric tripodal pyridine ligand was used to construct an equilibrium mixture of two isomeric complexes containing two ligands held together by three bridging Pd centers.[15] Exposure of this equilibrium mixture to globular guest molecules such as $CBrCl_3$ and CBr_4 induced a shift toward one of the isomers, whereas flatter guests (xylene and 1.3.5-benzenetricarboxylic acid) amplified the other capsule isomer. This selectivity was rationalized on the basis of differences in the shapes of the two isomeric capsules. In a separate study. another slightly larger tripodal ligand was added to the prototypical library, increasing the number of two-ligand capsules to four.[16] Significant shifts in the capsules distributions were observed upon adding suitable guests. For instance. $CBrCl_3$ was now found to selectively amplify the formation of the heteroligand capsule. Recently. Fujita and coworkers increased capsule diversity further by mixing two tripodal pyridine ligands (**7** and 8) with three dipodal ones (**9**–**11**) (Fig. 5*)*, once again using Pd centers to link the ligands together.[17] The authors were able to identify a new receptor for sodium trichloroacetate (12) from this full-grown DCL. Analysis of a difference NMR spectrum obtained by subtracting the spectrum of the library in the absence of guest from that in the presence of guest led to the identification of the selected building blocks. A second round of similar NMR experiments was necessary to obtain the building block stoichiometry. The newly discovered receptor was found to consist of two units of **7** bridged by one unit of **9** (Fig. 5).

NONCOVALENT LIBRARIES AND BIOLOGICAL SYSTEMS

The discussion of noncovalent libraries has so far been limited to cases where a guest selects its optimal receptor from a library of hosts. When targeting biological systems, the reverse approach of screening a library of guests against a macromolecular host becomes relevant.[18] Several cases were reported where a macromolecule amplifies the formation of its best binder.

Sasaki and coworkers used coordination of *N*-acetyl galactose (GalNAc) functionalized bipyridine ligands to a central Fe(II) ion to generate a small dynamic library of four $(ligand)_3Fe$ complexes differing in the spatial arrangement of the three GalNAc units[19] (Fig. 6). The

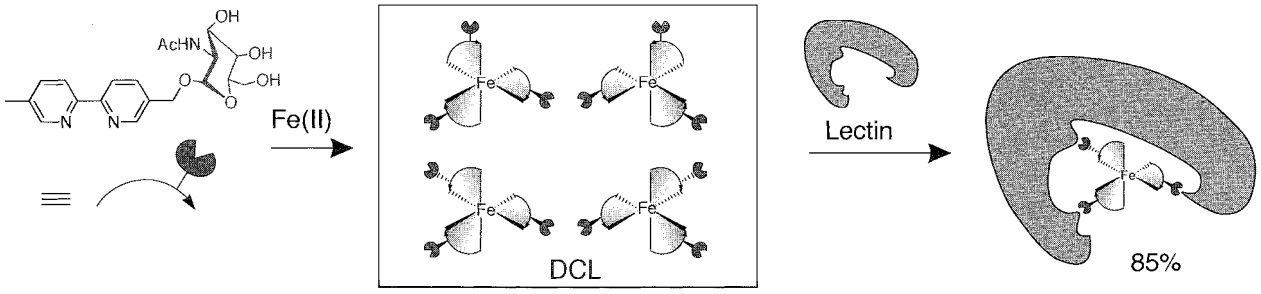

Fig. 6 Mixing Fe(II) with a bipyridine ligand functionalized with a N-acetylgalactose residue produces a small dynamic library of coordination compounds. Exposure of the library to a lectin leads to selection and amplification of the strongest binding complex. (Adapted from Ref. [19].) (*View this urt* in color *at www.dekker.com.*)

authors screened this library against two different lectins (proteins with carbohydrate-binding sites; the two lectins used were known to have affinity for GalNAc). They found that exposure of the library to one of the lectins led to the amplification of the Fe complex with the highest affinity for the protein, whereas the second lectin selected and amplified a different complex.

Miller and coworkers targeted DNA using libraries of metal–ligand complexes.[21,22] A DCL was made through coordination of different salicylaldimine ligands to a central Zn(II). Exchange between library building blocks can take place through metal–ligand exchange as well as through breaking and forming the covalent C=N bond in the ligands. The library was screened against double-stranded DNA immobilized on a cellulose resin. The optimal DNA binders were identified by monitoring depletion of the selected building blocks from solution as a result of binding to the immobilized DNA. In more recent work,[23] the same group also targeted RNA using libraries made from square planar Cu(II) complexes containing one or two salicylamide ligands. A dynamic library was prepared using six such ligands carrying different amino-acid sidegroups. The library was exposed to an RNA hairpin sequence contained within a dialysis tube. The selected ligands were identified by monitoring their depletion from the library solutions. As the total concentration of library members was much higher than the RNA concentration, several rounds of exposure to RNA were required to observe significant effects. The authors found that the Cu(II) complex of the salicylamide derived from histidine bound the RNA hairpin with nanomolar affinity and with remarkable 300-fold selectivity over the homologous DNA sequence. Unfortunately, the experimental setup does not allow for quantification of the level of amplification of the selected complex.

Dynamic libraries of noncovalenl assemblies can also be used to address issues related to protein folding. In this case, no additional guest or host is added to the system, but molecular recognition occurs internally, leading to the amplification of the most stable folded arrangement. In one of the first studies in this area, McLendon and coworkers grafted short α-helical peptides onto bipyridine ligands.[24] Three such ligands differing in hydrophobicity were allowed to compete for the binding sites on an octahedral Fe(II) center, producing a small dynamic library of three-helix bundles. The authors found that the most hydrophobic helix was preferentially incorporated in the bundles, leaving the remaining two less hydrophobic helices behind in solution. Denaturation studies on the analogous but more robust Ru(II) complexes, that were synthesised independently, confirmed that the amplified three-helix bundle is the most stable. These results demonstrate that dynamic combinatorial chemistry is a useful tool to identify the global minima in free-energy landscapes.

FIXATION OF NONCOVALENT STRUCTURES

The use of noncovalent interactions for the assembly of libraries of supramolecular assemblies has one serious disadvantage: the resulting structures are inherently labile, because they are held together by relatively weak bonds. This will limit their practical utility as receptors or selective binders to macromolecules. Hence. there is a need for methods of fixation of the noncovalent structures after selection and amplification have taken place. One approach is to equip the building blocks with functional groups that can be used to covalently link them together after selection has taken place. This strategy was used successfully by Reinhoudt and coworkers to stabilize their hydrogen-bond-based assemblies.[25] The calixarene building blocks (1 in Fig. 3) were equipped with terminal alkenes that can undergo ring-closing metathesis to form stable assemblies that are held together by alkene bonds.

Another approach was reported by the groups of Eliseev[26] and Constable[27] who made elegant use of the difference in kinetic stability between Co(II) and Co(III) complexes. The former are kinetically labile and can be used to generate dynamic libraries of different metal–ligand complexes. However, upon oxidation to Co(III), ligand exchange becomes very slow, and the resulting complexes are kinetically inert. An admirable feature of this system is that the change in oxidation state does not affect the coordination geometry around the Co center.

CONCLUSION

The key concept of dynamic combinatorial chemistry—molecular recognition-induced amplification of the fittest—has laid dormant in the literature for decades. For instance, there are many examples where a complex of interest crystallized from a mixture of "hopeless" and unintentional diversity. Nevertheless. researchers have. in the past, largely steered away from making use of complex mixtures and. instead, focused on more "well-behaved" systems that were easier to study. It was not until the concepts of dynamic combinatorial chemistry were first articulated that interests shifted, and efforts are now made to actively generate diverse and complex mixtures and screen them for components that are good at recognition. As illustrated by some of the examples in this review, the first successes have appeared, illustrating that handing control back to the (right) molecules can be a fruitful approach.

INTRODUCTION

Following a classical view, supermolecules assemble because of recognition properties that are expressions of molecularly stored information in the interacting partners.[1,2] Noncovalent, weak interactions (e.g., hydrogen-bonding, van der Waals. and electron donor–acceptor) are generally recognized to assist the structural organization of a supermolecule. Metal-coordination may represent a type of stronger interaction, frequently responsible for the building up of multicomponent arrays that can still be regarded as supermolecules.[3] According to a largely shared understanding, in an assembly of weakly interacting molecular components, the local properties are preserved, and the overall behavior cannot be reduced to the simple sum of the intrinsic properties of each component. In other words, a supermolecule shows a richer spectrum of properties with respect to the components; this happens because the additional properties basically rest on the intercomponent interactions. This outcome has nothing to do with holistic effects; instead it is traceable to molecularly stored information at the component level that went unexpressed until formation of the multicomponent assembly.[4]

ARE THERE SEVERAL CLASSES OF SUPERMOLECULES?

Discrete local and overall properties may also be identified in multicomponent systems. where electronically isolated molecular moieties, recognized as the active components, are connected by covalent bonds.[1,2] In this sense, this type of molecule can be regarded as a second class of supramolecular systems. Mere. the bridges are bound to play a structural role while providing only a small degree of electronic communication between the active components. When such electronic mediation is sufficiently weak, the bridged multicomponent system becomes similar to a self-assembled supermolecule. The extension of the concept of supramolecular system to include covalently connected assemblies proved to offer the remarkable advantage that a spatial assangement of the various components can be designed and subsequently made through suitable synthetic procedures. In this way, it is frequently possible to deal with components at fixed geometry, a key requisite in view of successful studies of the intercomponent processes originated after placing light energy at one of the components.

Molecular assemblies made of interlocked components like catenanes, knots, and rotaxanes[6–8] crucially rely on weak forces and covalent bonds and can be considered a further step forward along a higher degree of complexity of the organized matter (i.e., a hierarchically superior step). With such systems, provided some of the interlocked components can store energy (supplied by chemical, electrochemical, or photochemical methods), it is possible to spark off cycles of intercomponent displacements (see below).

Supramolecular photochemistry is the science of the interaction between light and supermolecules. It has to do with the consequences on the structural and electronic organization of the supramolecular system of the extra energy placed by light within it[9] and with the signaling properties of light.[10] Below, we introduce a distinction between photoactive and innocent units of a supermolecule. Then, we briefly describe a few selected cases from the literature. These, in our opinion, illustrate the type of approach followed in supramolecular photochemistry and. at the same time, show how fertile the supramolecular approach is in combination with the use of light. The examples are from solution chemistry; for the experimental details (e.g., type of solvent, concentrations employed, and so on), the reader should consult the original work. Of course, behind and next to the few examples we deal with in the following. there currently stand broad, diversified, and extremely important areas of study that we have not mentioned.

PHOTOACTIVE AND INNOCENT COMPONENTS

The understanding of the light effect relies on the clear-cut attribution of individual component-based properties and on properties regulated by the intercomponent interactions taking place within the assembly. Having in mind an extended view of supramolecular systems. we

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012792

recall notions that are of help to understand their behavior under illumination. The primary event that triggers any subsequent process is obviously light absorption. This may occur selectively, i.e., depending on the frequency of the radiation, some of the components may be excited and others may not. Thus, to a first approximation, the light-absorbing subunits may be regarded as photoactive; for the others, an innocent behavior seems foreseeable (the bridging units, when present, are always expected to exhibit an innocent behavior, otherwise one is not dealing with a supermolecule but with a big molecule).[9]

This is, however, an oversimplified approach, at least from four different viewpoints that we illustrate with reference to Fig. 1 (here. cases for two-component systems are examined; extension to a higher number of components is given for granted). First, a molecular subunit undergoing no direct light absorption and apparently regarded as innocent, may play some role from an electronic viewpoint (for instance, a perturbation effect over the electronic properties of other subunits) (Fig. 1a). Second. use of radiation of sufficiently high frequency can lead to population of excited levels spatially centered on all subunits (i.e., in this case, all subunits are photoactive against absorption). Cascade steps, both of intra- or cross-component nature, can then take place and finally lead to population of the lowest-lying excited level. The cascade paths take place with various degrees of efficiency as governed by the electronic properties of the involved subunits, including those presumed to be innocent (Fig. 1b). Third (a clear-cut case), because of intercomponent interactions, one may observe the appearance of electronically excited levels not present in the separate components; of course, this corresponds to the manifestation of an additional property according to the basic supramolecular approach. For instance, donor–acceptor interactions frequently result in low-lying excited levels of intercomponent nature, which may be involved in light absorption and light emission events (Fig. 1c). Four, and most important, a light-absorbing subunit temporarily stores an excess of energy. Provided some energetic requirements are met, this may result in a transfer of energy (Fig. 1d) or electron (Fig. 1e. f) to and from, respectively, the other unit, which being not photoactive with regard to light absorption turns out to be not innocent.

In conclusion, the definition of a subunit as innocent with respect to the interaction with light should be employed after careful inspection of the spectroscopic properties of the supermolecule and of the separated components. and after monitoring the occurrence of light-induced processes. As a practical short-cut, use of light at a selected frequency (for instance, a low-frequency radiation to selectively excite the lowest-available electronic levels of a supermolecule, both of localized or

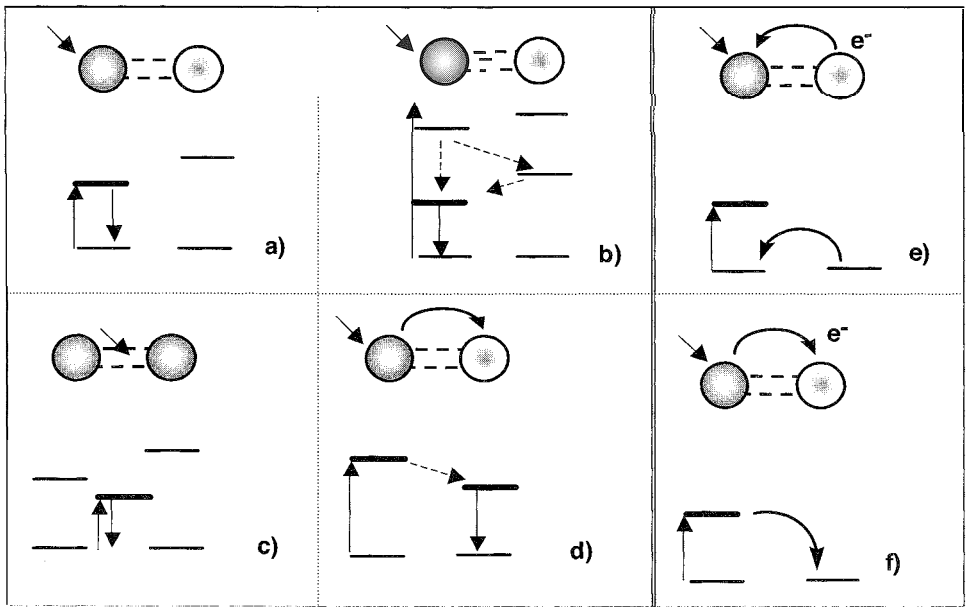

Fig. 1 Photoactive (dark sphere) and innocent (empty sphere) units and possible intercomponent effect? in self-assembled or covalently-linked two-component systems undergoing illumination: for the cases in which (a) one unit absorbs and emits light: (b) both units process the absorbed light; (c) photoactivity is of intercomponent origin: and (d) the unit that absorbs light transfers excitation energy to the other unit. which becomes emissive: and an orbital description for the case in which (e) the photoactive unit undergoes reduction: and (f) the photoactive unit undergoes oxidation.

intercomponent origin) and observation of luminescence properties (a localized emission is identified upon comparison with the luminescence properties of a suitable reference molecular unit) may lead to the understanding of which subunits precisely display a photoactive behavior and which can be regarded as innocent.

SYSTEMS POWERED BY LIGHT: LOOKING FOR THE STOWAGE OF CHEMICAL ENERGY

Extension of the dyad schemes of Fig. 1 to triads and multicomponent systems with carefully balanced electrochemical and spectroscopic properties has led to remarkable achievements along the mimicking of the fundamental processes of light energy collection and storage (via charge separation. CS) taking place in natural systems.[11,12] Dealt with in Fig. 2 is a representative example that conveniently illustrates the approach followed by studying light-induced processes in covalently-linked multicomponent systems.[13] In the figure, the behavior of a porphyrin-fullerene dyad-type reaction center ($P\text{-}C_{60}$) is compared with that of a carotenoporphyrin-fullerene triad ($C\text{-}P\text{-}C_{60}$). For the latter, the presence of the third component results in a two-step sequential transfer of electron; with an overall final quantum yield of charge separated state, Φ_{cs}, not far from unit. The chemical energy stored within the final CS state of the triad is less than that of the dyad, 1.1 versus 1.39 eV, respectively. However. the storage time. τ_{cs}, is three orders of magnitude longer. 340 ns versus 480 ps. respectively. which suggests an easier utilization of its energy content. In line with a supramolecular view. the energy schemes of Fig. 2 are drawn by combining the spectroscopic and electrochemical properties of the single components.

A related area in supramolecular photochemistry has to do with the transduction and collection of excitation energy in the presence of a convenient energy gradient. This type of process is frequently a multistep one and was

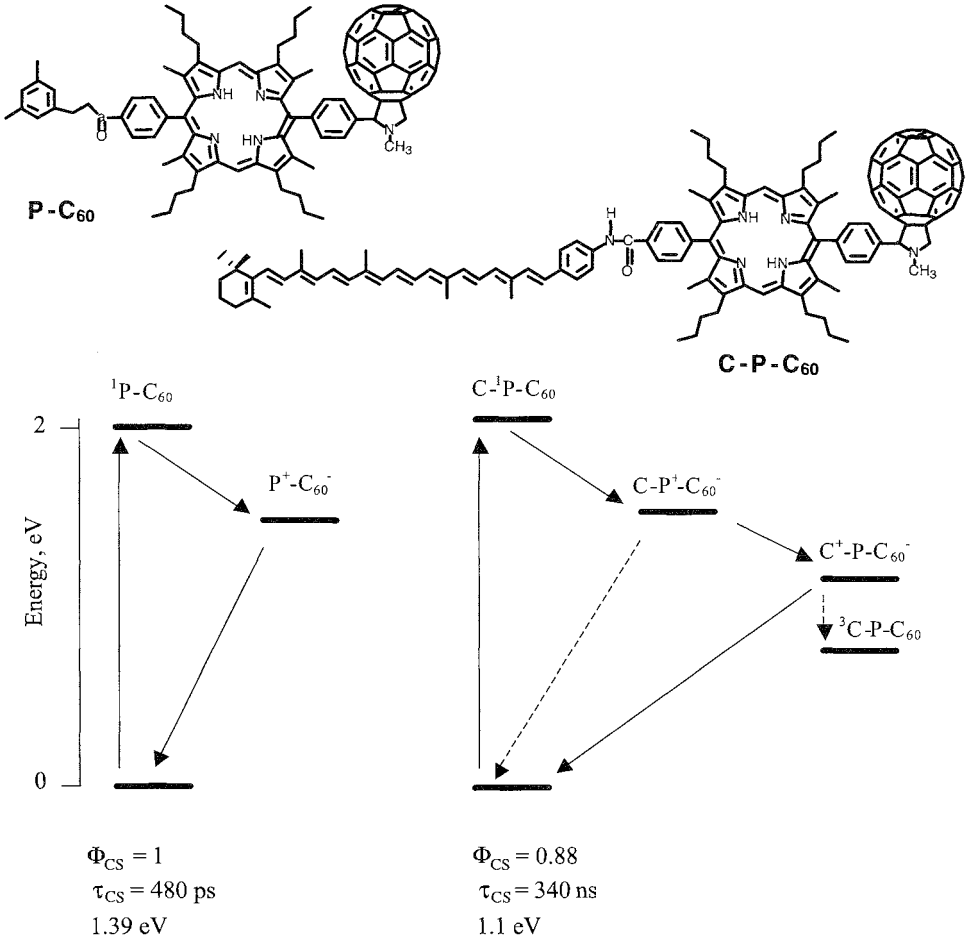

Fig. *2* Artificial photosynthesis: photoinduced storage of chemical energy inspired by the behavior of natural systems;[11,12] comparison of the performance of a dyad and related triad.[13]

extensively studied in linear and dendritic-type assemblies. In the former case, it can be initiated by light absorption at one terminal of the linear system (usually termed molecular wire). and after vectorial transfer of the excitation, it can lead to final population of excited states localized at the opposite terminal.[14] Cases are also known where a vectorial energy migration takes place along chromophores linked to a polymer backbone.[15] In dendritic-type systems, light absorption may take place at one peripheral/central unit and result in the subsequent energy conveyance at a central/peripheral unit.[16] The final localization of the excitation at the periphery or at the center of the assembly can be driven by carefully organizing and integrating the active components.[17,18] As an example, the behavior of a polyphenylene-framed, rigid-shape system performing a periphery-to-center excitation collection is depicted in Fig. 3.[18] The active components are naphthalene dicarboxmonoiimide (N), perylene dicarboxmonoimide (P), and terrylene tetracarboxdiimide (*T*). These components exhibit conveniently

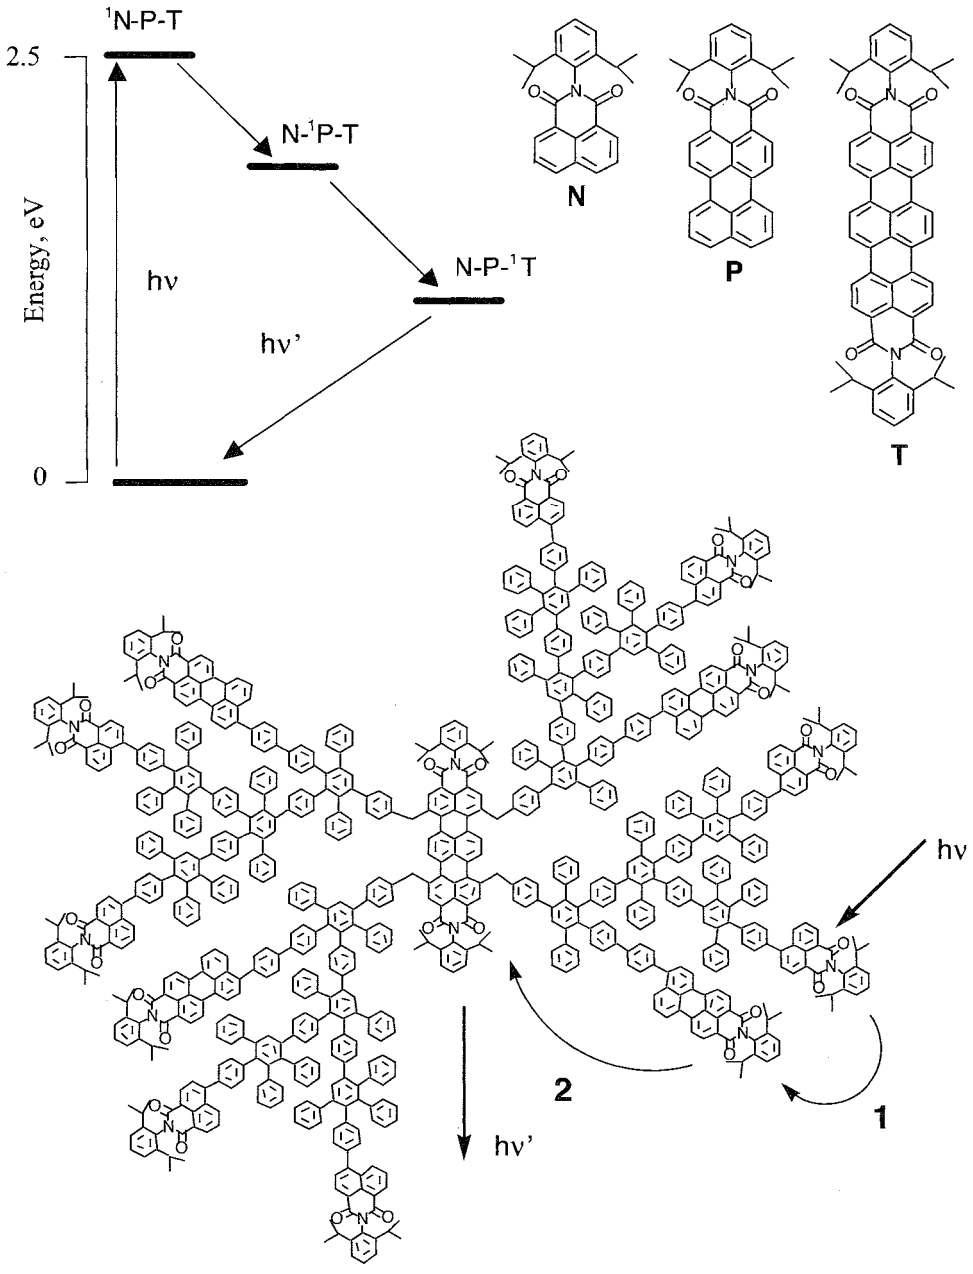

Fig. 3 A two-step periphery-to-center excitation energy collection driven by the energy gradients between the excited levels of the three luminactive components.[18]

scaled luminescent levels, and from the luminescence properties of the dendrimer, it is inferred that upon excitation of a peripheral *N* chromophore, a two-step, nearly quantitative final collection at the single central T unit is taking place. Clearly, assemblies may be envisaged that combine the funnelling of excitation energy at one component of a dendritic array with its subsequent utilization for performing CS steps. a scheme that is reminiscent of the behavior of natural systems.[11 12]

SYSTEMS POWERED BY LIGHT: MACHINES AT THE MOLECULAR LEVEL

Numerous interlocked assemblies were designed in connection with attempts to gain control of rotational and translational motions at the molecular level. a stepping stone toward possible outstanding development. As regards light-operated cases, a representative shuttling scheme for a rotaxane-based "molecular abacus" is depicted in Fig. 4.[21] As active components, the rotaxane axle contains a $[Ru(bpy)_3]^{2+}$ photosensitizer (which also plays the role as a stopper) and two MV-type electron-accepting stations exhibiting a slightly different accepting aptitude [bpy is 2.2'-bipyridine. MV is 4.4′-bipyridinium (methylviologen)]. An electron-donor ring, a macrocycle containing two dioxybenzene units, is wired around the axle that is terminated by a tetraarylmethane group as a second stopper. The streamed arrangement of the two accepting stations sets up the stage for molecular displacements based on donor–acceptor interactions through the following steps: a) positioning of the macrocyclic ring according to the more favorable donor–acceptor interactions; b) the better acceptor turns into the worse acceptor by the photoinduced event, electron transfer; and c) displacement of the ring. This half-cycle is expected to be followed by restoration of the starting a) position after some time. Actually, the timing of the various steps represents the most critical factor within the scheme of Fig. 4. This is basically due to the fact that the ring displacement is usually exceedingly slow compared to the light-triggered events. Despite these difficulties, successful systems were reported

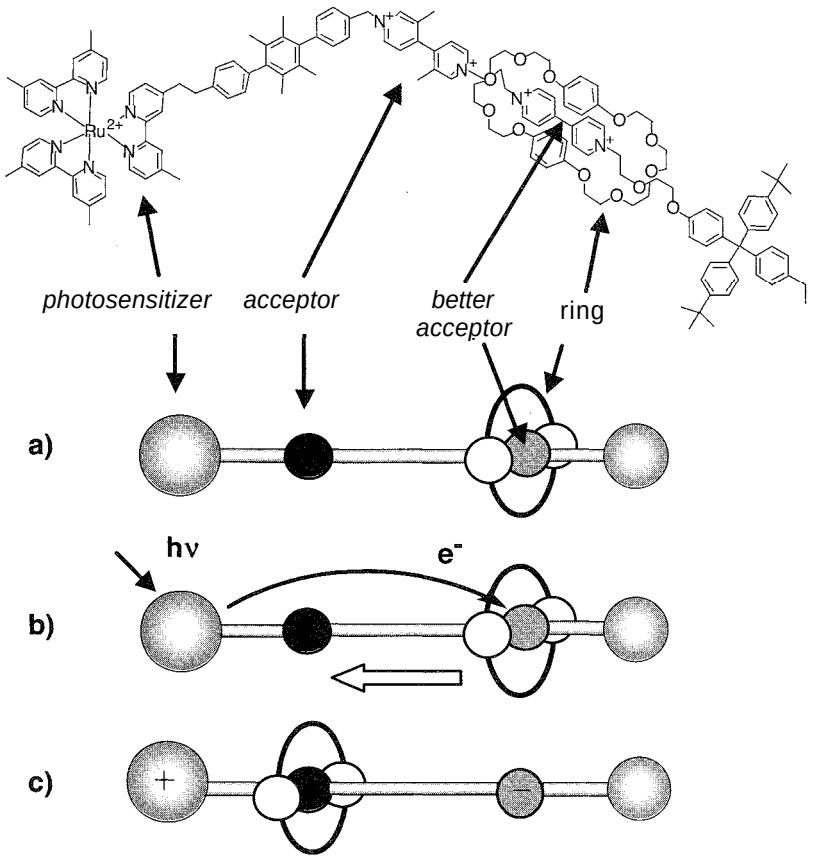

Fig. 4 A light-driven "molecular abacus" with movements that are mediated by the covalent bonds and are stationed by the establishment of weak (donor–acceptor) interactions.[21]

where the light-induced intercomponent displacements are fast in comparison to the competing deactivation processes.[22,23]

SENSING AND SIGNALING BY LIGHT UPON MOLECULAR RECOGNITION

Biomedical applications as well as environmental and food quality control fostered the development of systems for easily sensing and fast reporting the presence of a chemical species, the analyte. With this purpose, a variety of supramolecular sensors were designed in the last decade, able to signal binding of a substrate via large changes in the overall optical properties. These structures generally possess a receptor for associating the analyte, a spacer, and a signaling unit that converts the recognition event into changes of the light absorption or emission features of the system. Receptors such as crown ethers, functionalized calixarenes, cryptands, podands, chelators, and coronands are expressly designed for recognition of cations: polyammonium derivatives and functionalized metal ions are suitable for anions, whereas aromatic moieties of calixarenes and cyclodextrins easily bind neutral species. Various intercomponent interactions may work, such as H-bonding, hydrophobic forces, electronic effects, donor–acceptor interactions, metal coordination, and covalent bond formation.

Because of their intrinsic higher sensitivities and selectivities, the luminescent sensors are considered to be convenient. The signaling events rely on emission quenching or enhancement related to photoinduced electron transfer (PET sensors), on new emissions originating by excimer or exciplex formation, on changes in λ_{max}, quantum yield, and lifetime of the luminescence by intramolecular charge transfer (PCT sensors).[24,25]

Compared to systems based on a single interaction, cooperative sensors based on multiple, concerted, intermolecular interactions between the components exhibit higher discrimination capabilities and enhanced functions.[26,27] As examples for this class of sensors, two systems, both based on the absorption/luminescence properties of the porphyrin nucleus: are illustrated in Fig. 5. Structure (a) represents a ditopic receptor where cooperative binding of a cation by the amide-appended calixarene and of an anion by the Zn-porphyrin allows recognition of complete binary metal salts.[27] Structure (b) incorporates two cyclodextrin cavities and relies on the modification of the Fe(III) complex spectroscopic properties by inclusion of guests in these hydrophobic sites.[28] This species is able to sense the presence of benzylmercaptane and 1-adamantanecarboxylate in four

different binding conditions. Empty cavities, singly-occupied cavity, doubly-occupied cavities in homo- or heterocomplexes are easily distinguished by UV/Vis spectra. The system coupled sensing properties with catalytic action, by trapping an oxidizable substrate near an activated iron center or carrying out biomirnetic electron transfer reactions with quinones as guests.[29,30]

Cooperative binding in supramolecular sensors is a main requirement for obtaining other sophisticated, environmentally effective, functions like the selective transport of molecules.[26]

FROM OPTICAL SIGNALS TO LOGIC FUNCTIONS FOR MOLECULAR ELECTRONICS

As seen above, thanks to a suitable structural organization and functional integration of the components, the energy addition via light input can start useful energy conversion processes within a supermolecule. These may be exploited to achieve various types of luminescent sensors[24,25] and switches[31,32] and may lead, along with increasing complexity of components and their integration; to the development of nanoscale devices for information processing and molecular computing. In principle, these devices may be based on logic gates that combine the effect of chemical inputs on the optical output (luminescent signals) of a suitable chromophore. Nowadays, optical functions of two inputs are amenable to AND, OR, XOR, WAND, NOR, and XWOR behaviors via exploitation/inhibition of electron- or energy-transfer processes involving the excited luminescent level of the selected chromophore. Two simple model examples are illustrated in Fig. 6.[33,34] For the upper case, amine protonation or reception of Ca^{2+} by the carboxylate groups prevents the occurrence of photoinduced electron transfer from these fragments to the excited anthracene unit; for the bottom case, protonation of the bpy unit or its coordination with Zn^{2+} results in the quenching of the anthracene-based fluorescence. This probably happens because H^+ and Zn^{2+} cause a stabilization of the lowest-lying levels of bpy so that an anthracene-to-bpy energy-transfer step becomes energetically allowed. Notably, the implementation of elaborate electronic functions at the

molecular level is further made possible by the combination in series or in parallel of the two-inputlone-output gates of the type shown in Fig. 6.[33,34]

CONCLUSION

In supramolecular chemistry, concepts like recognition and self-organization based on the expression of molecularly stored infosmation appear to be strictly derived from a biomimetic approach, the one taught at the school of nature.[2,4,35] Supramolecular photochemistry, with the emphasis placed on the use of energy consequent to its spatial localization at some selected and active component of a molecular array, appears to enforce prospects along the design of artificial systems, where preorganization of the stereochemical features holds the spotlight. For the supramolecular science, it is reasonable and tempting to envisage developments toward systems of higher degrees of complexity that incorporate more infosmation. This means that they can display improved self-organizing abilities (which are stored in the components) and that novel molecular architectures are at once made available because of the designing abilities of molecule makers, the chemists. These developments are sometimes claimed to possibly include molecular adaptive and evolutive schemes,[35,36] until now an exclusive power of nature, exerted over time scales of hundreds of millions of years.[37] We shall soon see what the future brings.

Supramolecular Polymers

Alberto Ciferri
University of Genoa, Genova, Italy

INTRODUCTION

Conventional linear polymers are characterized by main-chain covalent bonds and by nonbonded interactions among groups localized at specific sites of repeating units. Supramolecular polymers (SPs) recently investigated display purely nonbonded interactions or unconventional combinations of covalent chains and supramolecular interactions. Novel structures, properties, and applications are displayed by SPs with respect to conventional polymers. The study of this exciting class of new inaterials is of interest for the formation of nanostructures with prescribed molecular order assembling hierarchically to mesoscopic dimensions, for the understanding of self-assembling processes in complex biological systems, and for the use of concepts cutting across traditional boundaries between colloid, polymer, and solid-state science.

DEFINITION, CLASSIFICATION

A classification of several systems described as SPs was recently presented.[1,2] For the fully supramolecular polymers (Class A) the interactions holding the unimers along the main-chain are of a supramolecular nature. These polymers are open, self-assembled, equilibrium sequences of bifunctional unimers polymerizing to a high degree of reversible supramolecular polymerization (DP) according to mechanisms significantly different from those of conventional polymers. Unimers can be of several forms and sizes: from small molecules to covalent polymers terminated by supramolecular bonding units. In the latter case, a SP should be regarded as a "polymer of polymers." Assembly of multifunctional unimers results in multidimensional structures. Class B includes self-assembled, closed structures such as aggregates of a small number of molecules (supermolecules), helical, globular, and side-chain associations of monofunctional sites. Class C includes self-assembled systems based on supramolecular structures irreversibly associated to covalent polymers, as in the case of dendrimeric chains or single-stranded globular proteins. Finally. engineered (as distinct from self-assembled) supramolecular structures. ofien involving covalent polymers, are included in Class D.

GENERAL ASSEMBLY PRINCIPLES

Localized Interactions

For all types of SPs, the stabilization of well-defined structures is due to combinations of interactions that may be localized at specific atomic groups of the unimers, or more uniformly distributed over the assembly surface. In all cases, shape complementarity is an integral part of the process of molecular recognition. Detailed quantitative assessment of the role of classical localized interactions (Coulombic. van der Waals, hydrogen. and solvophobic bonds) is described in the literature of low-molecular-weight host–guest complexes.[3] In the case of SPs, most important types of localized interactions are based on H-bonds, charged groups, π–π stacking, or metal-ion coordination.[2–6] Several combinations of these interactions may addiively contribute to the overall contact energy. H-bonds are a primary source of stabilization due to their strong directionalities allowing positional control. For multiple H-bonds, the product of single-binding constants may be increased or decreased by parallel (e.g., AAA–DDD) or antiparallel placements.[4–6]

Solvents may compete or enhance the formation of localized bonds. For instance, H-bonds are stronger in apolar solvents, ionizable groups are sensitive to pH. and π–π interactions are not largely affected. Solvents also display nonlocalized effects on the formation of supramolecular bonds, as described below.

Site Distribution, Unimer Functionality, Assembly Dimensionality

The number of sites per unimer *(S)* and their distributions control the functionalitjj (F) of the unirners and the dimensionality of the assembly. Complementarity of shapes and interaction. localized at the north and south contacting surfaces of bifunctional unimers, results in the formation of unidimensional (linear) assemblies (Fig. 1a: $F = 2$, $S = 2$). Functionalities greater than 2 result in the formation of more complex geometries (Fig. 1b).[1] Helical supramolecular chains are expected when two additional sites are located on the same side (i.e., NE and SE) of the unimer.[7] Planar assemblies are expected when four sites are distributed along the circumference of a disk,

S > 2): (c) linear polymers, branching. and termination for various F and S; and (d) assembly of unimers with different shapes and functionalities.

or the equatorial plane of a quasi-spherical unimer.[8] Three-dimensionally ordered arrays are expected if N and S interacting sites increase (longitudinally) the functionalities of the planar systems.

Supramolecular unimers can be of large size, and often more than one binding site occurs over each complementary surface (cf. Fig. lc). If full compensation occurs. there will be no alteration of the functionality of the unimer or the dimensionality of the assembly. Multiple sites on properly designed complementary surfaces have a high probability of being mutually compensated. Should a mismatch occur, or unimers with different functionalities or numbers of sites be mixed. alterations in the above assembling patterns are expected, i.e., termination or random network formation. as shown schematically in Fig. lc. More complex patterns are expected upon mixing unimers differing in shape, functionality, and bond type (Fig. 1d). These situations are not yet under active investigation: computational and simulation methods (algorithmic assembling) might be used for describing assemblies of increasing complexities.[9]

Smoothed-Out interactions

Wonlocalized interactions play a unique role in the assembly of SPs. particularly in their hierarchical evolution from nano to mesoscopic dimensions. One type of smoothed-out interaction is described by thermodynamic parameters of compatibility between solute and solvent species (i.e., the χ parameter). and another type is related to thermodynamic parameters describing excluded volume effects for unimers and growing SPs.[6,10]

Incompatibility

The *solvophobic bond*[11] describes the poor affinity of a nonpolar solute (i.e., a hydrocarbon) for a polar solvent (i.e., water). The ensuing phase separation amounts to a recognition of compatible components and hence is a driving force for self-assembly.[6] If the solute is a ditopic, amphiphiiic molecule (i.e., a surfactant[11] or a block copolymer[12]) dissolved in a selective solvent, the combined incompatibility of the components leads to micellization.[6,11,12] For ditopic molecules in the absence of a solvent. the inacroscopic phase separation expected for the unconnected components is replaced by a microsegregation in domains separated by the surface comprising the intersegmental bonds. A detailed mean-field theory satisfactorily explains the self-assembly of amorphous diblock copolymers into hexagonal, lamellar, and other phases by a balance of the thermodynamic incompatibility of components and their relative sizes and flexibilities.[13]

Excluded volume

The tendency to reduce excluded volume leads to a driving force for the orientation of rods having length/diameter ratio $X = L/D > \sim 6$.[14] and for the stacking of thin disks ($0 < L/D < 0.1$[15]). This hard interaction effect is detectable even in diluted isotropic solution and leads, above a critical concentration, to an orientational transition to

nematic and higher-order phases. Excluded volume is therefore an important driving force for self-assembly. It is important to stress the predicted differences between rod- and disk-like particles.[10] The relatively large axial ratios indicated above for rod-like mesogens suggest that only rigid assemblies or covalent polymers with large DP will attain the nematic phase. On the other hand, a strong tendency to form nematic phases is exhibited even by low MW disk-like unimers, provided their thicknesses are sufficiently small.

Assembling Mechanisms

The general thermodynamic formalism regarding growth of supramolecular aggregates was highlighted by Israelachvili.[16] The growth of two- and three-dimensional systems can be described as a true phase transition (crystallization): the aggregation number tends to infinity above a critical aggregate concentration (CAC). Unidimensional assemblies (linear. helical, columnar. including spherical micelles), may instead display large cooperativity above the CAC but not a true transition: size distributions will occur. In line with the above considerations, three distinct mechanisms were identified for unidimensional growth.[6]

Multistage Open Association (MSOA) is the basic step-by-step process (not involving critical nucleus or cooperativity) similar to the molecular polycondensation of bifunctional monomers.[17] Each step is described by a single binding constant K that includes all possible contributions to the contact energy and determines (Fig. 2a) the rate of increase of DP with unimer concentration. Detailed calculations[1,4,6] reveal that values of $K > 10^6$ M^{-1} are needed to produce SPs exhibiting DP in the range of interest (>100) in diluted (<1%) solutions. For H-bonded polymers, the above condition requires a minimum of three bonds (S=6, $F=2$, assuming a value of $K \sim 500$ M^{-1} for a single H-bond[18]).

Helical growth (HG) occurs when a sequence of linear steps according to MSOA leads to a critical concentration C^* at which cooperative helical growth begins (Fig. 2b). Because more bonds per unimer are expected in the helical than in the linear chain, the sudden increase of DP at $C > C^*$ is described by a constant $K_h > K$ and by the familiar Zimm–Bragg cooperativity parameter.[11,12] The original theory was developed by Oosawa for the nucleus schematized in Fig. 1b and applied to the $G \rightleftharpoons F$ transformation of actin.[7] A recent extension by van der Schoot and coworkers,[13] applied to helical assemblies of discotic molecules, does not require the specification of the critical nucleus.

Growth-coupled-to-orientation(SLC), also described as the open supramolecular liquid crystal,[20] is an inter-

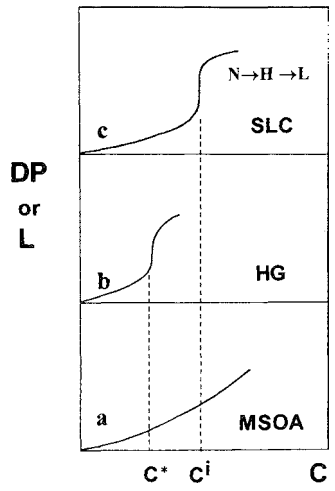

Fig. 2 Growth mechanisms. Schematic theoretical variation of DP (or length) with unimer concentration for linear supramolecular polymerization according to (a) multistage open association; (b) helical growth: (c) growth-coupled-to-orientation. C^* and C^i are critical concentrations corresponding to (b) and (c). Occurrence of liquid-crystalline phases (N. H, L) is indicated. From Ref. [1]. Copyright 2002 Wiley-VCH.

assembly cooperative process occurring at a critical concentration C^i at which growth of bifunctional unimers occurs siinultaneously with the formation of a nematic phase (Fig. 2c). The sudden increase of DP at C^i is controlled by suitable combinations of contact energy and rigidity (persistence length) of the formed assembly.[20–23] The original theory,[21] developed for linear assemblies of cylindrical micelles in nematic solutions, was later extended to discotic molecules displaying hard interactions and showing nematic. hexagonal, and higher-order phases.[22,23] Theory predicts that the nematic phase may be skipped for particular combinations of contact energy and rigidity.[23]

CLASS A SPs

Representative examples of linear, helical. and columnar assemblies are summarized in Fig. 3.[1,4] The growth mechanism. the magnitude of the solution DP, and the nature of the main contact forces are evidenced. The figure highlights essential features of supramolecular polymerization. Note, for instance, how the geometry of the assembly is not necessarily related to the growth mechanism or the nature of contact forces. In particular. Polymers **1** and **3** assemble through the MSOA mechanism, but one is a linear chain. and the other is a columnar stack of disks. Polymers 4 and 6 assemble through the HG mechanism, but one is a double helical chain, and

9		SCL	---	π-π Solvophobic

Fig. *3* Class A SPs. 1: Ureidopyrimidone-based linear chains;[4,24] 2: porphyria-based linear chains;[25] **1:** folic acid tetramers columnar stacks;[1,26] 4: actin double-helical chains;[6,27,28] 5: helicene helical chains;[29,30] 6: C_3-symmetrical molecules forming helical columnar stacks;[7] 7: uracyl or pyridine-terminated anthracene forming linear chains;[5] 8: surfactant micelles linear polymers;[6,21] 9: 2,3,6,7,10,11-hexa(1,4,7-trioxoacetyltriphenylene) columnar stacks.[8]

the other is a columnar helix. Polymers **7,** 8, 9 assemble through the SLC mechanism, but 7 is a linear chain, 8 is a linear micelle, and 9 is a columnar stack of disks. Also to be noticed is the difference in the structure of the disk-like unimer in Polymer **3:** a superrnolecular tetramer,[26] and in Polymer 9: an amphiphilic molecule. The cooperative growth of Polymer 6 is attributed to a conformational transition from a flat to propeller shape in each disk, allowing maximization of interaction.''' The chirality of the unimer is usually expressed and reinforced in helical SPs.[4,26,30,31] Not included are "tubular" polymers containing a large central cavity and based on MSOA stacking of peptide rings,[32] or on a spiralization (HC) of globular proteins, as in the case of microtubules,[6] and helical assemblies of oligomeric foldamers such as m-phenylene ethylene.[33,34]

The extent of polymerization (DP) appears to be directly related to the strength of contact forces and cooperativity effects. In particular, Polymer 1 attains DP well above the value reported for other MSOA polymers due to the large dimerization constant ($K = 6 \times 10^7\ M^{-1}$ in $CDCl_3$)[4] of ureidopyrimidone forming four (self-cornplementary) Id-bonds. The still larger DPs reported for Polymers 4 and 8 reflect the occurrence of cooperative growth mechanisms, HG and SLC, respectively (reported DPs refer to dilute isotropic solutions for MSOA or HG and to relatively concentrated anisotropic phases for SLC). It is theoretically predicted that DP will increase with unimer concentration, the largest DPs being expected in the undiluted state. If the assembly becomes oriented in a nematic phase, a sequence of transitions to hexagonal columnar and lamellar phases upon increasing concentration represents a hierarchical ordering to mesoscopic

Planar systems resulting from a crystallization process are exemplified by self-assembling S-layers (Fig. 4a), the protective monolayers for the external surface of bacterial cells.[8] The constituent proteins have a quasi-spherical shape with an equatorial distribution of H-bonding sites (Fig. 1b) and an additional site on the south pole, allowing weaker electrostatic anchoring to the cell membrane. Proteins were isolated and reassembled in vitro as single free-standing monolayers over inert surfaces. revealing a tendency for this system to form open planar assemblies. More complex is the behavior of the in vivo assembly when features of a dynamic closed-surface crystal are exhibited. The curvature and finite size effects are controlled by the curvature of the bilayer cell membrane to which the protective layer is anchored. The assembly $\longleftrightarrow$ disassembly process of the crystalline layer responds to cell growth and division by incosporating fresh protein at dislocation sites (intussusceptive growth). Nanotechnology applications of S-layers were described.[8]

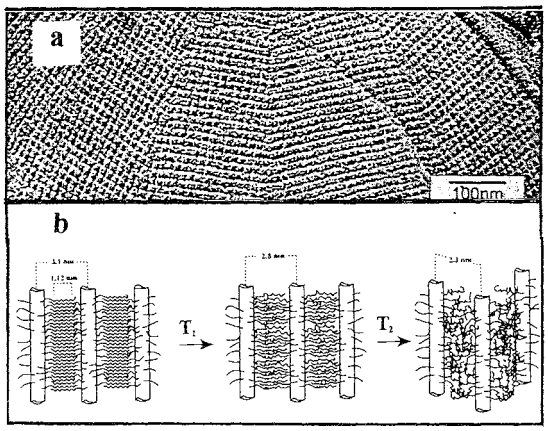

Fig. 4 (a) A planar assembly of S-layers showing square symmetries and edge dislocations (sites for intussusceptive growth). From Ref. [8]. Copyright 2000 Marcel Dekker. (b) Thermal transition for a three-dimensional assembly of comb-like PαAA-18. Loosely interdigitating clusters occur in the LC phase between T_1 and T_2. From Ref. [35]. Copyright 1995 ACS.

Three-dimensional assemblies of spheres with a symmetrical distribution of equivalent sites (cf. Fig. 1b) form regular crystalline arrays. More interesting are situations in which a geometrical anisotropy of the unimer or differences in the recognition pattern of different components exists allowing consideration of modes of growth along longitudinal and transverse directions. An interesting example is a comb-like polymer poly(α-*n*-alkyl-β,L-aspartate) (Fig. 4b) based on a helical backbone and aliphatic side chains.[35] At the highest temperature investigated, the flexible segments were completely molten within a nematic phase, due to orientation of the helical backbones. At lower temperature; another LC phase was observed in which rigid helices were correlated by interdigitation with partly molten side chains. At still lower temperatures, the latter crystallized in a separate hexagonal lattice. Thus, it appears that a supramolecular unimer based on an elementary cluster of helices correlated by interdigitating side chains was a precursor of the solid-state structure.'''' This led to the suggestion of describing systems showing complex and mesoscopic structuralization in terms of supramolecular polymerization of specifically designed building blocks.[1,10] A similar concept was used to describe the solid-state organization of interpenetrating nets.[36] The future evolution of this concept for building patterns of increasing complexity could be handled by methods of molecular computing[''' ((Fig. 2c) and cellular automation.[37]

The SPs in Class A exhibit strong growth (DP may exceed that of conventional polycondensation[1,17]) and labile bonds. DPs may reversibly change by altering concentration. temperature, and other external variables.

The linear systems conforming to the MSOA mechanism exhibit relatively minor changes of DP in response to the above variables. Rheological data offer compelling evidence for the persistence of polymer-like behavior in spite of reversible polymerization.[24,38] Therefore, applications in areas expanding the uses of conventional polymers were suggested.[1,4,5,24,39] In particular, the following applications were suggested: easier processing despite a large DP: topology control in networks; tunable, smart, self-repairing materials; increase of DP for covalent polymers: recycling; supramolecular block copolymers; and chiral and sequential control promoted by the high selectivity of molecular recognition.

In the case of helical SPs, when major length changes occur in response to the above variables. microengines mimicking the mechanical behavior of biological systems and engineered for new practical applications were suggested. Particularly important is the coupling of an external stimulus, or a chemical reaction, to the assembly–disassembly process, thus extending the use of SPs materials to complex, coupled systems.[6,27,28] For instance, ATP hydrolysis causes an alteration of polymerization–depolymerization rates at the two ends of a growing actin filament. As a result, the polymer translates.[27,28]

Interesting nonlinear optical properties were shown by chiral helicenes (5) forming LB films with larger second-order susceptibility than corresponding racemic structures.[29] Nanotubes based on cyclic peptides[32] were reported to form membranes with ion-selective channels.

CLASS B SPs

Scheme 10a in Fig. 5 represents the formation of low-MW closed assemblies such as host–guest complexes, supermolecules, and cyclic oligomers. Examples include the supermolecules 11 and 12 and the cyclic folic acid tetramer (**3** in Fig. 3). These compounds aroused interest due to their pronounced thermotropic behaviors compared to the unbound components. The enhancement of liquid crystallinity for Complex **11** is explainable by general consideration of soft interactions in low-MW mesogens.[41] More complex is the case of Complexes 12 and **3** that. due to discotic shape, can form columnar stacks. A close relationship between liquid crystallinity and columnar growth was anticipated.[4,5,26] However. recent analysis[11] showed that columnar growth of the folate tetramer receives only a minor contribution from contact forces. The large excluded volume effect of thin disks is the main driving force for liquid crystallinity and self-assembly.

Scheme 10b in Fig. 5 represents the formation of closed side-chains SPs. Electrostatic binding of salts and

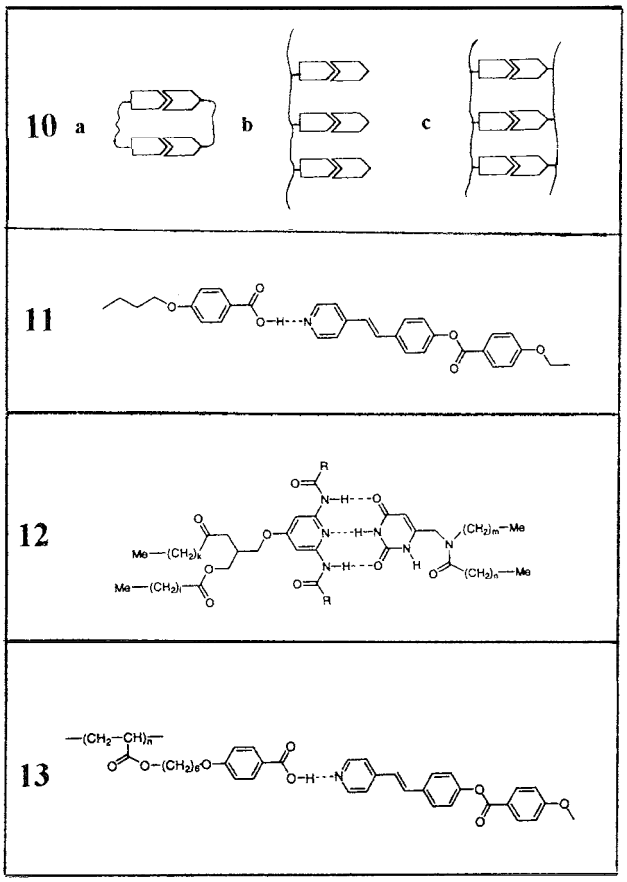

Fig. 5 Class B SPs. 10: Schemes for (a) closed low-MW assemblies; (b) side-chain polymers: and (c) multichain assemblies; 11: supermolecule of 4-butoxybenzoic acid and stilbazole;[40,42] 12: supermolecule of derivatives of 2.6-diaminopyridine and uracil;[5] 13: polyacrylate with hexyloxy benzoic acid side chains H-bonded to stilbazole.[42]

amphiphilic molecules to polyelectrolytes or polar polymers is an important topic of supramolecular interaction but is not usually described in the context of supramolecular polymers. Side-chain binding of small mesogens through H-bonding was pioneered by Kato and Fréchet.[42] Example **13** in Fig. 5 illustrates how the interaction of the supermolecule 11 can be transferred to a covalent polymer. In this case, a broad nematic phase occurred over a wider temperature range (140–252°C) than that for the individual components.

Scheme 10c in Fig. 5 represents the forination of closed supramolecular assemblies involving two (or a small number) covalent chains. There may be direct recognition of complementary groups attached to complementary chains. or ditopic units may be used to link (by electrostatic charge or H-bonds) identical chains. Conspicuous examples of this type of assembly are described in the literature of multistrand proteins and nucleic acids

but. again. are not usually described in the context of supramolecular polymers. It is to be noted that complete internal compensation of all sites carried by the polymers must occur for a closed structure to develop. Residual uncompensated sites still allow growth to occur, causing a mixed behavior of closed and open systems. For instance, the stoichiometry of the tropocollagen triple-helix is strictly defined. but occurrence of uncompensated chain-ends and reduction of electrostatic repulsion cause side-by-side and head-to-tail aggregation of triple-helices at neutral pH. Ultimately, network structures may be formed.

Formation of H-bonding between synthetic polymers is used as a way to improve compatibility in blends.'''' Interesting examples of switching from closed to open assemblies are the reversible transformation of the structure of folic acid **3** into linear ribbon-like aggregates (by salt concentration changes),[44] and of cyclic octapeptides into linear chains (by UV radiation).[32]

CLASS C SPs

Polyrotaxanes and poly[2]catenanes, exemplified by 14 and **15** in Fig. 6, are a class of mechanically interlocked macromolecules[45–47] deriving from the extensively studied low-MW compounds **16**.[48,49] Polyrotaxane **14**. prepared from the condensation of tetraarylmethane-based diols and acid chlorides in the presence of a crown ether, attained $M_n \sim 25.000$ with rings mechanically trapped between two large tetraarylmethane groups. The poly[2]catenane **15**, prepared from a bisfunctionalized [2]catenane, attained $M_n \sim 800.000$ including numerous mechanical linkages. Interest in this unconventional type of polymers is due to the possibility of inducing relative movements of their noncovalently bound components under the action of external stimuli. In Scheme **16**, rings of dibenzol[24]crown-8 can flip around interactions localized at the NH_2^+ centers. Relative motion can be triggered by electrochemically or photocheinically induced reduction/oxidation reactions.[49] Molecular microengines and abacuses may thus be conceived.

The components of the "shish-kebab" composite (17) based on α-cyclodextrin rings over poly(ethylene oxide)[50] are not irreversibly interlocked as for true Class C SPs. The assembly belongs to the class of clathrates (inclusion compounds) that have interest for separation processes. Single chains are confined in small channels (diameter -6 Å) for a wide variety of crystalline adducts. These systems suggests that smoothed-out effects assist rhe formation of host–guest polymeric assemblies in addition to localized interactions. The nonlocalized effects may arise from the suppression of undulation modes of the polymer due to the presence of rings. and from excluded volume effects favoring elongated assemblies."]

A covalent polymer (18) was synthesized starting from dendritic 7-oxanorbornene macromonomers. The solid-state structure of the polymer revealed helical columnar stacks of disks. Each disk included four tapered monodendrons (spanning two repeating units), with the main chain running in the central cavity and complying with the supramolecular organization of side chains.'''''''' The formation of columnar stacks of disks was documented for other monodendritic, tapered units having a crown ether at the focal point. When the latter was replaced with an oligoxyethylenic segment connected as a side chain to a polymethylacrylate chain, the columnar stack was transformed into a helical column.

The organization of tapered monodendrons, connected or not to a covalent chain, can be regarded as a model roi. the assembly of the tobacco mosaic virus, 19. included for comparison in Fig. 6. Here, the guest is a RNA molecule: and the host is a hollow column composed of 2130 identical tapered protein molecules following a helix with 16.3 units per turn.'''' The whole structure can be disassembled by pH change and reassembled with and without RNA. In the latter case. however, the spiralization is lost, and the host is simply a stack of disks, each including 17 protein units. It appears. therefore, that a polymer hosted in the cavity of a columnar stack induces spiralization, irrespective of the nature (covalent or supramolecular) of the bond with the host. The model of internal crank-shaft coupling features of Class A and Class C systems is suggested.[20] Additional features of biological assemblies were reproduced by polymers with dendritic side chains.[51,52] In particular, spherical assemblies. modeling icosahedral virus. were obtained with low-DP dendritic polymers.

The self-assembled monolayers 20 (SAMs) are two-dimensional assemblies of short hydrocarbon chains [i.e., decanethiol HS(CH2)10X] grafted to a planar surface [i.e., AU(111)].[54] A covalent bond actually occurs between the head-group HS and gold. The organization of alkyl segments involves. with increasing coverage, a phase with molecular axes parallel to the surface and a final phase with all *trans* segments tilting $\sim 30°$ from the normal axis. Properties and applications of SAMs are influenced by the nature of the terminal functional group and by subsequent chemical transformations, including the attachment of polymers. Patterning of SAMs is most conveniently done by microcontact printing, confinement in areas of nanometric dimension was verified by AFM. Applications are in areas of nanotechnology: molecular electronics. optical devices, biological and chemical sensors, and tissue engineering.

CLASS D SPs

Engineered assemblies may be produced by controlled addition of components, chemical reactions or additives, external forces such as flow fields, and dissipative processes.[6] Supramolecular interaction still assists the final organization, but the assembly mechanisms are outside the theoretical framework discussed above. Thus, only a few examples will be outlined.

The complexation of complementary polyelectrolytes can allow the formation of assemblies attaining macroscopic dimensions. Spherical skins may, for instance, be

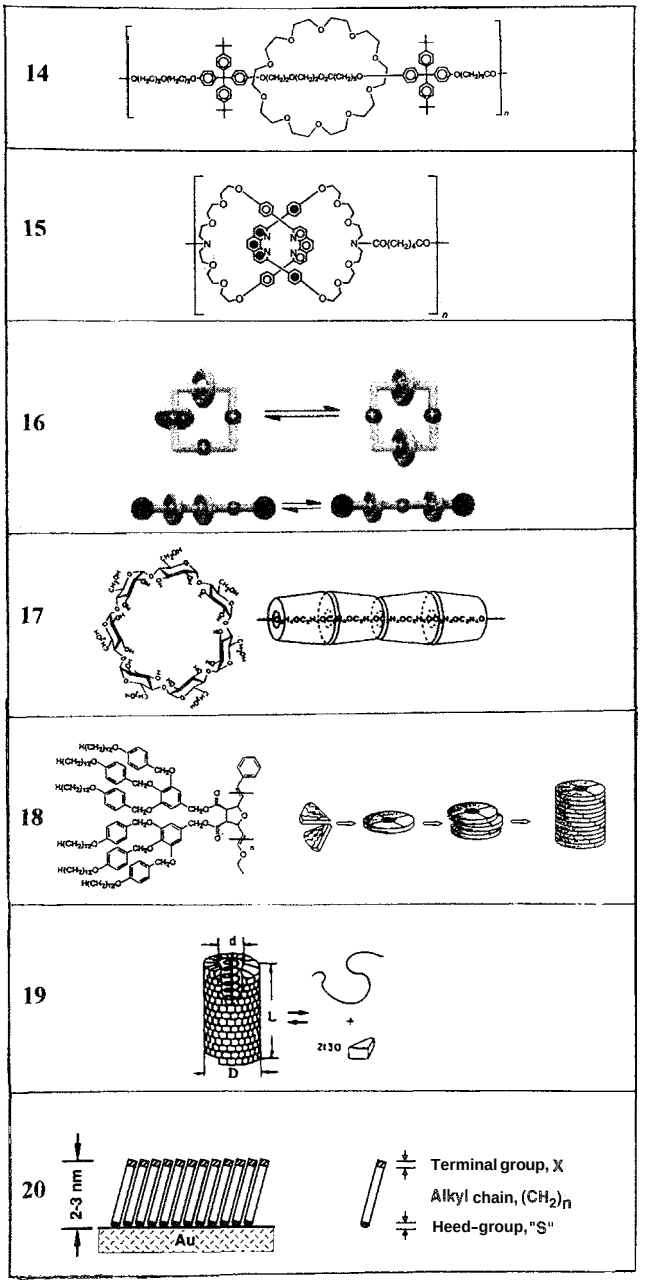

Fig. 6 Class C SPs. 14: Polyrotaxane;[45,46] 15: poly[2]catenane;[45,47] 18: linear dendritic hybrid chain from 7-oxanorbornene monomers substituted with two tapered monodentrons;[52] and 20: SAMs of n-alkanethiolates on gold.[54] Structures 16: [3]catenane and [3] rotaxane with two dibenzol[24]crown-8 rings;[48] 17: α-cyclodextrin+poly(ethylene oxide);[50] and 19: tobacco mosaic virus[**] are included for comparison.

produced by letting drops of a polycation solution free fall into a solution of a polyanion.[55] The theoretical basis for the forination of micellar-like aggregates within a gel of complementary polyelectrolytes was discussed.[55] Stratified deposition of complementary polyelectrolytes, colloids.~bola-type amphiphiles may be achieved by alternating deposition of components anchored to a suitable surface; for instance, a substrate compatible with poly-(styrene sulfonate) alternatively dipped in poly(allylamine hydrochloride). and PSS solutions.[56,57] Uncompensated sites and intermediate rinsing steps prevent uncontrolled coprecipitation. The method has several advantages over the classical LB deposition and was applied to a wide variety of systems. It allows micropatterning and tailored performance in applications such as biocompatibility, biocatalysis, and integrated optics and electronics.[56,57]

DNA nanotechnology allows the fabrication of nanostructured composites based on gold particles regularly distributed within a DNA matrix.[▾▾▾] Complex functionalities leading to branched and two-dimensional matrices lead to programmable nanodevices extending the assembling modes from periodic to algorithmic ones.[9]

Supramolecular Stabilization

Dmitriy V. Soldatov
John A. Ripmeester
National Research Council Canada, Ottawa, Ontario, Canada

INTRODUCTION

Supramolecular stabilization means stabilization of certain chemical species. their different forms, and assemblies in a particular supramolecular environment. Supramolecular stabilization is responsible for the existence of "energetically unfavorable" conformations. different spatial isomers, unexpected oligomers, "unstable" molecules. highly reactive radicals, elements in unusual oxidation states. certain ionic species, and so on, in supramolecular phases. Such species decompose. change, or equilibrate with alternative forms once they are brought out of their "stabilizing" environment. The best-known chemical reaction based strictly on supramolecular stabilization is the so-called "blue reaction." where iodine reversibly polymerizes in the presence of starch.

Supramolecular stabilization provides an excellent opportunity to store highly reactive species or to obtain species not available by traditional methods in high concentration. The phenomenon plays an important role in stabilizing drugs and may be useful in the creation of new methods of separation and purification. the design of new functional and smart materials. and the development of new approaches to chemical and biological research.

KINETIC VERSUS THERMODYNAMIC STABILIZATION

Kinetic and therinodynamic stabilization are intrinsically distinct and. therefore. should be treated separately. Kinetic stabilization occurs because of the restrictions that a supramolecular environment superimposes on highly reactive species. These restrictions increase the activation barrier for decomposition routes. thus increasing the lifetime of the species. Typical restrictions include the isolation of reactive species from each other or from other possible issues relating to their instability: oxygen, water, light, radiation, and so on. Thermodynamic stabilization occurs because of a change in the energy balance created by the supramolecular environment. thus favoring formation of stabilized species. This can be attributed to a specific set of noncovalent interactions, such as van der Waals forces, hydrogen bonding, additional coordination, or other secondary interactions. Although each individual interaction is weak. the cumulative contribution of multiple intermolecular contacts may have an impact significant enough to stabilize supramolecular complexes or solids with "unusual" chemical species.

Kinetic stabilization is iinportant for increasing the useful lifetime of drugs. The active drug content of various pharmaceutical formulations decreases with time upon heating, oxidation, hydrolysis. and self-degradation. The guarantee of chemical and mechanical stability for a pharmaceutical product for periods of at least 2 years is a key factor for marketing the product. Stabilization of photosensitive drugs by inclusion in cyclodextrins was reported."' The stabilization of prostaglandins and other pharmaceuticals using cyclodextrins is successful, and inclusion products are marketed in Japan and other countries.[2] Kinetic stabilization plays an important role in the chemistry of radicals. For example, stabilization or destabilization of nitroxides in redox processes and hydrolysis in the presence of cyclodextrins is well documented."'

Thermodynamic stabilization reflects a drive to the lowest overall energy of the final phase. This tendency may cause flexible chemical species to change in order to accept the most favorable geometry in context of the resulting supramolecular environment. Thermodynamic stabilization falls into several types. depending on the kinds of species that are stabilized. The most common types are dealt with below.

SPECIES THAT CAM BE STABILIZED

Conformational Isomers

Three experimental observations provide good estimates of how strongly molecular geometry is influenced by surroundings in molecular crystals. The first observation is "contact conformational isomerism.." where different conformations are encountered for the same molecule in a single phase.[4] The statistical analysis of crystals having two or more symmetrically independent molecules in the same structure reveals that about 20% contain molecules with different conformations.[4] A second observation is

DOI: 10.1081/E-ESMC 120013466

conformational polymorphism, the existence of different conformations of the same molecule frequently observed in polymorphs.[5] A third observation is conformational isomerism induced by a guest template. the appearance of different conformations of the same molecule in a range of inclusion compounds.[6–8]

Monomers, Oligomers, Polymers

First described in the literature in 1814,[9] the "blue reaction" of iodine with starch is the best-known example of a polymerization process induced by supramolecular stabilization. Structural studies indicate that amylose (the linear fraction of starch) forms a helix with six glucose residues per turn to include guest iodine molecules.[10] Inside this helix, iodine molecules form a polymeric chain with a periodicity of 3.1 Å, which is much shorter than the nonbonded distance between iodine atoms (4.3 Å) but greater than the single I–I bond distance (2.7 A).[11] The amylose–iodine reaction is widely used in analytical chemistry and was utilized for the solubilization and purification of carbon nanotubes.[12]

Oligomerization of metal complexes induced by a template drastically changes properties of materials. Exposure of a polymeric copper(I) complex to toluene vapor leads to the disappearance of its blue emission and the appearance of yellow emission because of the formation of a new tetrameric complex which forms an inclusion compound with guest toluene.[13] Nickel(II) dibenzoylmethanate monomer, a brown diamagnetic material. rearranges into a trimer, green paramagnetic material. in the presence of benzene, as the trimeric form accommodates guest benzene in its void space.[14] The material transformations described above are reversible and selectively sensitive to a specific transforming template and, therefore. may be used in the design of functional and smart materials.

Spatial Isomers

Several types of isomers can be stabilized in supramolecular solids,[11] and the temperature. or the presence of various templates, may factor in switching molecules from one isomer to another. These may be inorganic ions,[16] polar molecules like water,[17] or typical organic molecules like *o*-xylene.[18] Guest-induced stabilization of stereo- (*cis–trans*) isomers has the most potential: stereoisomers are usually similar in energy (because they have the same set of chemical bonds), but they can form different inaterials (due to dramatic differences in molecular geometry).

The utility of the stabilization of spacial isomers is vividly illustrated by a system of two conjugated polymorphs of a copper β-diketonate complex.[15,19] The *r*-form of the complex contains cis and *trans* units that assemble into a dense structure, whereas the β-form contains only *trans* units that assemble into a microporous framework (Fig. I). Therefore, the α-to-β (or reverse) transition involves cis-to-trans (or reverse) isomerization on a molecular level and switches on (or off) the microporosity, an integral property of the material. The identification of appropriate conditions that control the isomerization made it possible to utilize the system as a first smart sorbent, that is. a sorbent with microporosity that may be switched off and on in situ by an operator.[20]

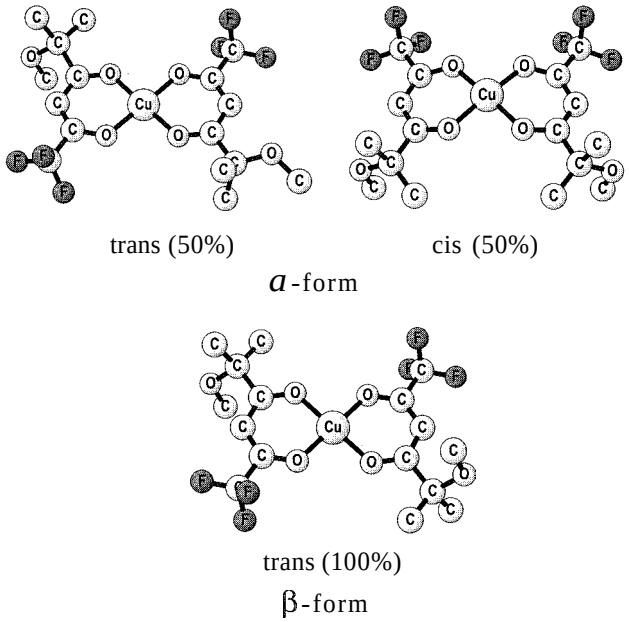

Fig. 1 Isomer distribution in the two polymorphs of (1,1,1-trifluoro-5,5-dimethyl-5-methoxyacetylacetonato)copper(II). The n-form has *trans* and cis isomer units, whereas in the P-form, they are all *trans*. For clarity, fluorine atoms are dark.

Host *Molecules*

The stabilization of host molecules in van der Waals clathrate matrices is referred to as "contact stabilization,"[21–23] This type of stabilization is most striking, as the molecule can exist only in a "stabilizing" supramolecular environment and cannot form a stable solid phase without a template. In other words, a favorable set of noncovalent interactions prevents the molecule from decomposition.

Contact stabilization is observed in the binary system pyridine (Py)–cadmium nitrate. The phase diagram of the system[24] indicates formation of an inclusion coinpound $[CdPy_4(NO_3)_2]$*2Py (Fig. 2). The compound comprises molecules of the $[CdPy_4(NO_3)_2]$ host complex[25] (Fig. 3)

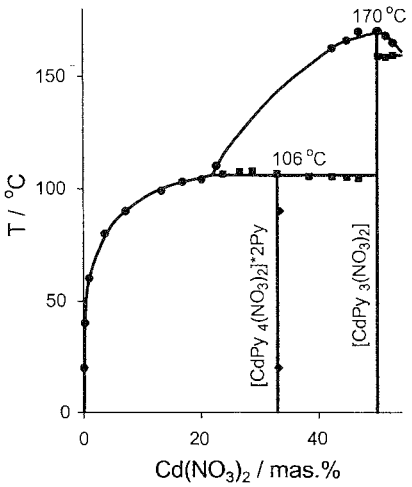

Fig. 2 The phase diagram of the pyridine (Py)–cadmium nitrate system (fragment). The host complex $[CdPy_4(NO_3)_2]$ does not exist in the system as a solvent-free compound.

that build a crystal with guest pyridine included in cavities. As follows from the phase diagram, the host complex does not form an individual phase; the molecules of the $[CdPy_4(NO_3)_2]$ complex exist only in the inclusion compound and instantly decompose upon removal of the guest component:

$$[CdPy_4(NO_3)_2]*2Py = [CdPy_3(NO;),] + 3Py$$

In quantitative terms,[26] the contact stabilization phenomenon appears when the stability of a molecule is comparable with the stability of its decomposition products, and noncovalent interactions in a particular solid phase play a decisive role favoring or disfavoring formation of the molecule.

Guest Species

The stabilization of highly reactive or easily dissociating guest species included in host molecules or in a host framework is related to the contact stabilization phenomenon. Various fluoride complexes of boron, silicon. and germanium are stabilized through creation of favorable hydrogen bonds with crown ethers.[27] Oxonium and other ions of biological significance are stabilized in calixarenes or coordination polymers, such as H_3O^+,[28] $H_5O_2^+$,[29] $H_7O_3^+$,[30] and $N_2H_7^+$.[31]

MOLECULAR VERSUS SUPRAMOLECULAR STRUCTURE

In the past. chemists underestimated the importance of noncovalent interactions, resulting in much confusion. The development of supramolecular concepts in chemistry made it possible to understand and rationalize a number of experimental observations. One such example is the so-called "hexapyridine metal complexes," representing dozens of compounds with the general formula MX_2*6Py (M is a metal(II), X is (–1) anion, *Py* is pyridine or its derivatives). A priori, these compounds were described as complexes where six pyridine ligands coordinate to the central atom M with ionic packing comprising $[MPy_6]^{2+}$ cations and A^- anions. Recent studies revealed that this is not the case.[32] The compounds should be described by the formula $[MPy_4X_2]$*2Py, as the *X* anions and only four pyridines are coordinated to the central atom, whereas the remaining two pyridines are included as guest species. Therefore. the compounds contain only neutral species in their van der Waals lattices. Exclusively using the language of chemical bonds, it would be difficult to explain why such poor ligands as nitrate or perchlorate compete with pyridine for the coordination sites around the metal center.[26] It is the noncovalent interactions that are responsible for the fact that hexapyridine metal species are rarely observed in the solid state. while the chemical analogue hexaammine complexes are common.[33]

STABILIZATION OF MOLECULAR ENSEMBLES

In a broader sense, supramolecular stabilization is responsible for the regular arrangement of species in supramolecular structures. The following examples show some of the applications of the phenomenon.

Inclusion compounds of urea[34] display linear arrays of guest species inside cylindrical channels. This property makes it possible to conduct stereoregular poiymerization

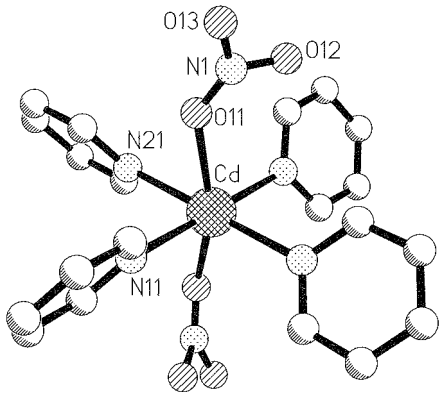

Fig. *3* Structure of the $[CdPy_4(NO_3)_2]$ coinplex molecule in the clathrate phase.

reactions of included species inside the channels. Another application is to constrain polymers in the ordered environment of the urea tunnel structure to simplify the spectroscopic and diffraction properties of the polymers. Orienting unsaturated molecules in certain supramolecular environments with appropriate hydrogen bonding makes it possible to conduct stereoregular condensation reactions in the solid phase in quantitative yield.[35] In more detail, the subject is reflected in other topics, see for example the following topics in this *Encyclopedia*: inclusion reactions and polymerization; hydrogen bonding; inclusion compounds; polarity in crystals; preorganization and complementarity; soft and smart materials; solid-state reactivity and topochemistry; and strong hydrogen bonds.

CONCLUSION

Supramolecular stabilization is an important concept that needs to be introduced when considering the influence of the supramolecular environment on the structures and stabilities of chemical species. The kinetic component of the phenomenon is responsible for increasing or decreasing the lifetime of chemical species included in host structures. The thermodynamic component of the phenomenon explains the existence of unusual, or one of many possible, chemical entities in supramolecular solids. Our current understanding of these phenomena allows a number of experimental facts to be explained and makes qualitative predictions possible in some cases. Further development of these concepts to more quantitative levels will allow improved predictions and the purposeful design of desired species stabilized in supramolecular environments.

Surfactants, Part I: Fundamentals

John F. Scamehorn
David A. Sabatini
Jeffrey H. Harwell
University of Oklahoma, Norman, Oklahoma, U.S.A.

INTRODUCTION

Surfactants are important, or even crucial, in a wide variety of phenomena, including wetting, surface tension reduction, micelle formation, solubilization of organic solutes in micelles, emulsification: dispersion formation. adjusting solution rheology, and foaming. The two articles on ''Surfactants'' in this encyclopedia are split into "'Fundamentals.' and "Applications," with fundamental aspects of surfactant behavior being discussed in this article. The article in which a certain topic appears is arbitrary, because fundamental and applied aspects of surfactant behavior are involved in certain topics (e.g., wetting. emulsification, adsorption on solids). The purpose of this article is to outline the important physical behavior of surfactants, primarily in aqueous solution, because this is where most studies have been done.

OVERVIEW

The term "surfactant" is a contraction of "surface active agent." because a characteristic of surfactants is their tendency to adsorb or concentrate at interfaces between bulk phases. such as at the water–air surface or at the solid–liquid surface.

A surfactant molecule is composed of two basic parts: a water-soluble (hydrophilic) head group and an oil-soluble (hydrophobic) tail group, as shown in Fig. 1. While the tail group is often a hydrocarbon chain. the head group can be charged or uncharged. The basic surfactant structure is illustrated by sodium dodecyl sulfate in Fig. 1. The anionic sulfate is the head group. the linear dodecyl chain is the tail group. and sodium is the counterion (ion of opposite charge to the head group). Based on the hydrophilic and hydrophobic regions of surfactant molecules. they are sometimes referred to as amphiphiles or amphipaths.

In aqueous solution: the driving force for a surfactant's tendency to adsorb at interfaces and to form aggregates is the incompatibility of the tail group with water. Because of their hydrophobic nature, tail groups tend to insert themselves into a hydrophobic phase, or tend to self-assemble by forming aggregates in which the tails intertwine to form a hydrophobic environment from which water is largely excluded. If the tails cannot distribute into an oil-like phase. they essentially form their own oil phase, a process known as hydrophobic bonding. This term should not be misconstrued to imply that chemical bonds are formed between tail groups; rather, aggregation permits the hydrophobic tails to escape from water, eliminating this unfavorable tail–water interaction.

Shown in Fig. 2 are several of the many aggregates formed by surfactants. For these systems, unaggregated surfactant (monomer) is in equilibrium with the aggregate. If an aqueous solution of surfactant is in contact with air. the surfactant molecules adsorb at the air–water interface as a monolayer, with the head groups immersed in the water and the tails sticking in the air phase. If the aqueous solution forms an interface with a hydrophilic solid (e.g., cotton fabric or a clay). under select conditions, bilayered aggregates. known as an admicelles, will form on the surface. In this case. the head groups of the first layer of surfactant can have attractive interactions with the solid surface (e.g., electrostatic attraction or hydrogen bonding), and the second surfactant layer has head groups exposed to the water. In admicelles, the tail groups interact to form a hydrophobic interior.

The surfactant can also form aggregates in solution, such as micelles and vesicles. The spherical or cylindrical micelles shown in Fig. 2 have a core of interacting tail groups, coated by the head groups exposed to water, a configuration in which both dichotomous regions of the surfactant molecules can be in favorable environments. In contrast. if the surfactant is dissolved in an organic solvent. reverse or inverse micelles can form. where the tail group is at the micelle surface exposed to the solvent, and the head groups are exposed to a droplet of water at the reverse micelle core. Vesicles have structures similar to cell membranes, and in solution, the phospholipids of the cell membrane spontaneously fo m vesicles. Surfactants can form many other aggregated structures, only a few of which are shown in Fig. 2. In each case, the basic driving force for self-assembly is for each of the surfactant molecule's dissimilar parts to be in a favorable

environment: for aqueous solutions, this means that the tail group should avoid contact with water.

While the tail group of commercial surfactants can be fluorocarbon or silicon based. the vast majority of surfactants have a hydrocarbon group as the tail. This hydrocarbon tail Is generally derived from natural sources like animal fat or vegetable oil, or from synthetic sources like petroleum derivatives. The head groups can vary dramatically between surfactants. Based on their head groups, surfactants are normally classified into five major classes. as illustrated in Fig. 3. Anionic surfactants are the largest volume of surfactants produced, with the linear alkylbenzene sulfonate (EAS). shown in Fig. 3, being the largest volume anionic surfactant produced commercially. For LAS. the head group is the negatively charged sulfonate group. while the linear alkyl chain (approximately 12 carbons in length) with the benzene ring is the tail group. The counterion (sodium) completely disassociates from the surfactant when the surfactant dissolves in water. As with many commercial surfactants. LAS is a coinplex mixture of hornologues with varying alkyl chain lengths, and isomers with varying points of benzene ring attachment to the alkyl chain. This natural heterogeneity produces performance advantages compared to a single surfactant molecule, including improved water solubility. In contrast to anionic surfactants. cationic surfactants, like ihose based on quaternary ammonium, have a positively charged head group. Nonionic surfactants typically have a polymeric group or an uncharged hydrophilic group like poly(ethylene oxide) as the head group (see Fig. 3). Zwitterionic surfactants have positive and negative charges on the head group. Amphoteric surfactants have a head group with a pH-dependent charge. The amine oxide shown in Fig. 3 is zwitterionic at high pH, but becomes cationic as protonation occurs at low pH. Because amphoteric surfactants are generally zwitterionic at some pH. and zwitterionic surfactants are often amphoteric. in practice, the terms zwitterionic and amphoteric are used as synonyms, and the term ampholytic is used to describe both surfactant types.

MICELLES

As illustrated in Fig. 4. a number of surfactant properties experience discontinuity in slope at a specific concentration called the critical micelie concentration (CMC). Below the CMC, an insignificant concentration of micelles is present. and essentially all the surfactant is present as monomer. Above the CMC. incremental surfactant forms micelles, and the monomer concentration remains nearly constant. Surfactant molecules contribute differently to a given property when present as monomer versus in a micelle. accounting for the discontinuity in slope in Fig. 4. The monomer concentration is often nearly proportional to the thermodynamic activity of the surfactant, and it is this activity that determines such properties as adsorption at interfaces. surface tension reduction, and precipitation. Monomer concentrations become nearly constant above the CMC (for single-component surfactants), resulting in many physical properties plateauing above the CMC. For example. as shown in Fig. 4, surface tension at the air–water interface levels off above the CMC—this is the dominant method of measuring the CMC. Even practical properties. such as

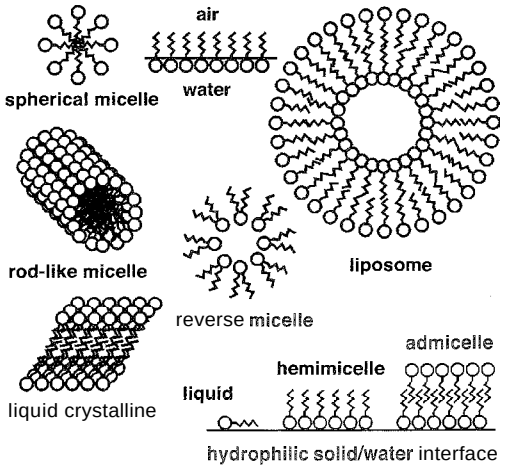

Fig. 2 Examples of surfactant aggregates.

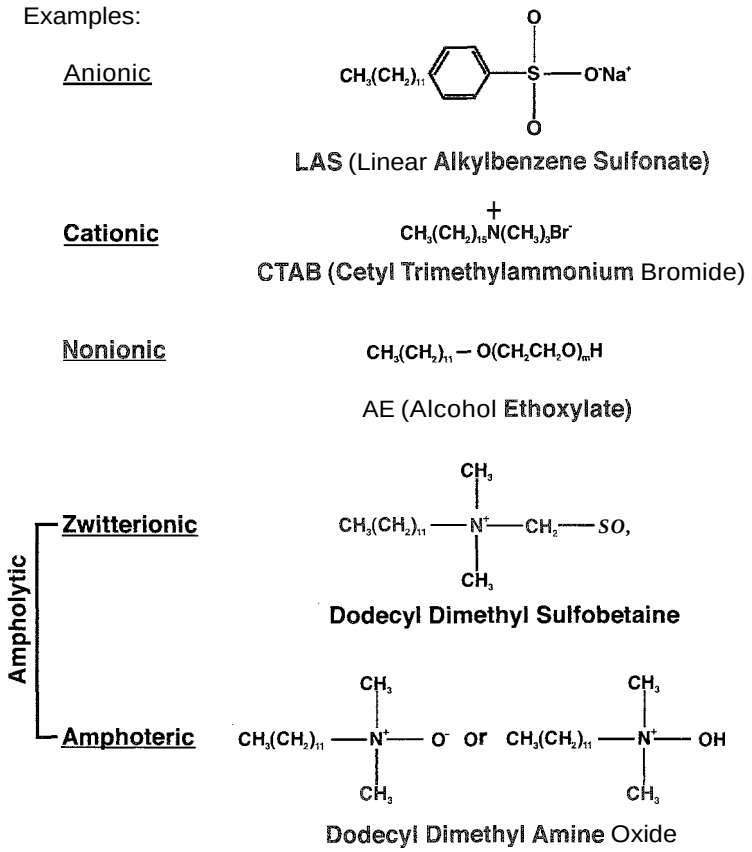

Fig. 3 Major surfactant groups.

particulate soil detergency, can plateau above the CMC. Charged or ionic surfactants contribute less to equivalent conductance in micellar form than as a monomer, resulting in the change in slope for this variable illustrated in Fig. 4; conductance is used to measure CMC of ionic surfactants at low ionic strength. Because the organic solutes dissolve (partition) into micelles (a phenomena called solubilization), the aqueous solubility of organic solutes increases with surfactant concentration above the CMC; conversely, surfactants do not significantly affect the aqueous solubility of organic solutes below the CMC, as illustrated in Fig. 4.

As illustrated in Fig. 2, micelies can be classified as normal (tail groups forming the core and head groups coating this oil-like interior) in aqueous solution; or reverse (inverse) where the tail groups are on the micelle exterior exposed to an organic solvent. There are fewer studies of reverse micelles compared to those on normal micelles, because the vast majority of surfactant applications are in aqueous solution, and normal lnicelles are much easier to form than reverse micelles. The focus in this article will be on surfactants in aqueous solution, due to this emphasis and space limitations.

A typical spherical micelle in aqueous solution has an average number of surfactant molecules, or aggregation number, of 40–100. The diameter of a spherical or cylindrical micelle is around 4–6 nm for typical surfactants. The shape of the micelle depends on surfactant molecular structure, solution ionic strength, temperature, and presence of organic solutes in solution, among other factors.

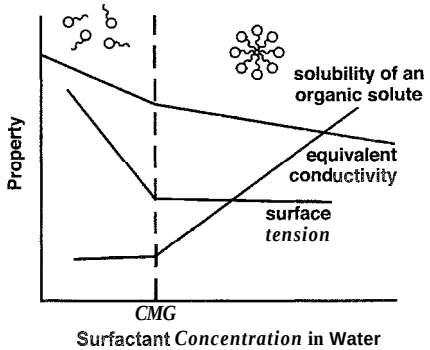

Fig. 4 Some properties of aqueous surfactant solutions related to CMC.

For example, micellar structures commonly transition from spherical to cylindrical to planar to reverse micelles as the tail group length decreases, branching of the tail group increases, diameter of the head group decreases, ionic strength of solution increases (for ionic surfactants), or surfactant concentration increases. This can be understood in terms of how the surfactant molecules best fit together to form the aggregate. For a large head group and small diameter tail group. each surfactant can be approximated as a cone, which best fits together as a sphere in water. As the tail group becomes more branched, each surfactant molecule becomes more like a cylinder in shape, which aggregates best as a planar structure. As the tail group becomes even more branched. the molecules can invert to form reverse micelles. with the head group surrounding a droplet of water in the reverse micelle interior. This transition in aggregate type is shown in Fig. 5. The shape of the micelle can influence important physical properties. For example. cylindrical micelles (particularly when they become long or thread-like) can substantially increase solution viscosity, even at a fairly low surfactant concentration, a phenomenon sometimes used in shampoos.

It is easy to think of micelles as stable species when viewing depictions such as that in Fig. 2. However, micelles are dynamic structures. The average lifetime of a surfactant molecule going into and out of the micelle is normally on the order of 1–10 μsec, and the average lifetime of an individual micelle is commonly around 1–10 msec. Thus, at a given condition, the fraction of surfactant present as monoiner versus micelles is that at equilibrium. because equilibration times are so fast. This rapid kinetics can affect such processes as foaming or wetting, where the micelles act as reservoirs for surfactant monomer and replenish this monomer readily. as it is used by adsorbing at an interface.

While rnicelles are the most studied surfactant aggregate. the driving force for forming other surfactant aggregates often mirrors those for micelle formation. Thus, knowledge of how variables affect the CMC can provide guidance on the anticipated effect of variables on. e.g., the surfactant aggregate adsorbed on solids or at the air–water interface as monolayers. The analogous behaviors between aggregates composed of surfactants give substantial importance to knowledge of micelle formation tendencies. Thus. as a broad generalization, the CMC is the single most important physical property of water-soluble surfactants in aqueous solution.

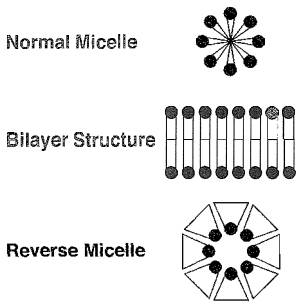

Fig. 5 How tail group share can influence micelle shape

The thermodynamics of micelle formation is unusual compared to formation of condensed or structured phases in systems not involving contact between water and hydrophobic groups. For example, when a vapor condenses to form a liquid, the entropy decrease is compensated for by a large endothermic effect. so a condensed phase can be in equilibrium with a vapor phase. The heat of micelle formation is not large; while it can be endothermic or exothermic. it is always small. In micelle formation, the entropy decrease for surfactants in the aggregate is offset by an entropy increase in another part of the system, the water. Water forms highly structured layers. known as iceberg structures. adjacent to the hydrophobic groups of surfactant monomer. When the ice-like sheath is disrupted as the monomer moves into a micelle, the increase in disorder as these structured water molecules become ordinary bulk water. approximately offsets the increase in order of the surfactant molecules as they form the structured micelles. The overall result is that the entropy change for the system is small when micelles form, consistent with small heat changes and resultant lack of free energy change when micelles form at the CMC. with the monomer in equilibrium with micelles. Sometimes. micelle formation is referred to as entropy-driven in the surfactant literature. This is a misleading term and results from the lack of the large entropy decrease normally associated with formation of a condensed phase, rather than a large entropy increase upon micelle formation. which the term implies.

There are two basic approaches to modeling the thermodynamics of micelle formation. The mass action model views the micelles as reversible complexes of the monomer that are aggregating and predicts the sharp change in tendency of incremental surfactant to form micelles instead of monomer at the CMC: this sharp transition is a consequence of the relatively large number of molecules forming the aggregate. The mass action model predicts that micelles are present below the CMC but at very low concentrations. The ocher major model used to describe micelle formation is the pseudophase separation model, which views micelles as a separate thermodynamic phase in equilibrium with monomer. Because micelle formation is a second-order phase transition. micelles are not a true thermodynamic phase. and this model is an approximation. However. the assumption that there are no micelies present below the CMC, and that the surfactant activity becomes constant above the CMC. is close to reality. and the mathematical simplicity of the pseudophase

separation model is attractive. In fact, some version of the pseudophase separation model is predominantly used in modeling mixed surfactant systems (almost all practical applications involve surfactant mixtures). The distribution of the different surfactant components between monomer and micelle can be calculated using solution-mixing models to describe surfactant mixing in mixed micelles; regular solution theory is frequently used and results in simple mathematical relationships with a single parameter describing nonideality of mixing.

Micelle fornmtion is enhanced (the CMC is lowered) by increasing the length of the hydrophobic gioup due to the increased tendency for hydrophobic bonding. For ionic surfactants, the repulsion between the like-charged head groups at the micelle surface must be overcome by hydrophobic bonding for the micelle to form. So, for a given tail group, the CMC of nonionic surfactants can be an order of magnitude or more below an ionic surfactant, because no electrostatic repulsion must be overcome for nonionic surfactants to form micelles. For ionic surfactants, the CMC decreases as this repulsion force decreases; this can be induced by increasing solution ionic strength or by inserting nonionic hydrophilic groups between the charged head groups by using a mixture of nonionic and ionic surfactants. This type of synergism from the use of surfactant mixtures is observed in many properties of the surfactant system, and use of surfactant mixtures is one of the most common ways to adjust properties and performance.

LIQUID CRYSTALS/SURFACTANT PRECIPITATION

As the surfactant concentration increases above the CMC, many surfactants form solutions in which the micelles are no longer randomly distributed but are organized into structures called liquid crystals. Surfactants form four main types of liquid crystals, as shown in Fig. 6. Hexagonal liquid crystals involve cylindrical micelles packed hexagonally, where six micelles surround a central micelle. Lamellar liquid crystals are composed of bilayers of surfactants separating layers of water. Cubic liquid crystals are also known as the viscous isotropic phase. These are called cubic because they were originally thought to be composed of spherical micelles packed in a cubic structure. The current view is that there are two types of liquid crystals called cubic, although neither exhibits cubic packing. One of these is the discontinuous cubic liquid crystal, where oblong micelles are arranged in a highly structured fashion. Bicontinuous cubic liquid crystals have a continuous bilayer of surfactant extending through solution as a "plumbing-type" of structure separating the water, which is also a continuous phase; hence, the term bicontinuous.

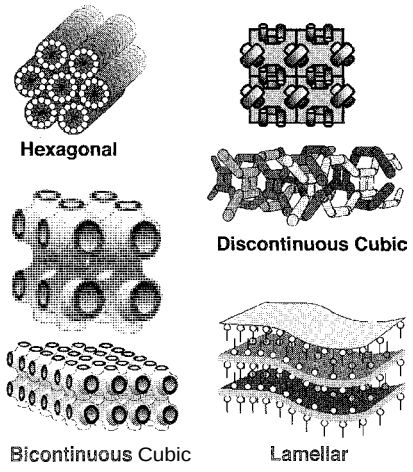

Fig. 6 Classes of surfactant liquid crystals

As the surfactant concentration increases, surfactant structures commonly transition as follows: spherical micelles, cylindrical micelles, discontinuous cubic liquid crystals, hexagonal liquid crystals; bicontinuous cubic liquid crystals, and lamellar liquid crystals. However, viscosity increases in the order as follows: lamellar liquid crystal, hexagonal liquid crystal, and cubic liquid crystals, with both types of cubic liquid crystals being the most viscous (cubic liquid crystals are commonly deduced to be present from high viscosity). Lamellar liquid crystals can exhibit relatively low viscosity despite high surfactant concentrations due to the existence of shear planes, along which the aggregated surfactant layers can move easily. The cylindrical micelles in hexagonal liquid crystals can shear past each other, but there are no shear planes in discontinuous cubic liquid crystals and bicontinuous surfactant structures, which must be broken for flow to occur, so both types of cubic liquid crystals exhibit high viscosity. Liquid crystal formation or transition of one type of liquid crystal to another can be induced by other variables, such as ionic strength and temperature. Liquid crystals have substantially longer lifetimes than micelles; transitions between different liquid crystal types often occur in a few seconds. Optical microscopy under polarized light is often used to detect liquid crystals, because hexagonal and lamellar liquid crystals are birefringent.

As the temperature of an aqueous solution of nonionic surfactants is increased, at some temperature, called the cloud point, the solution transitions from a one-phase to a two-phase system. If the solution is allowed to equilibrate, a coacervate phase (highly concentrated in surfactant, as much as 70 wt %) and a dilute phase separate. The solution appears cloudy at the cloud point, because an emulsion of coacervate phase exists in the dilute

phase. The cloud point is an important temperature for nonionic surfactant solutions; for example, nonionic surfactants are used above their cloud points in automatic dishwashing formulations to promote low foaming. In addition, optimum laundry detergency is observed around the cloud point.

If the solubility product of a charged surfactant monomer with an ion of opposite charge is exceeded, precipitation will occur. Hydrophobic bonding in the surfactant precipitate causes precipitation to occur at low counterion concentrations, particularly if the counterion is multivalent. Hard water cleaning has always been challenging, because hardness ions (calcium or magnesium) readily form a precipitate with many anionic surfactants. Surfactant precipitation is generally undesirable, because when the surfactant is present as a crystal, it is unavailable for adsorption at interfaces and interfacial tension adjustment, or for forming other aggregates. such as micelles and vesicles. When the surfactant is a fatty acid or soap, the precipitate formed is called soap scum. The use of anionic and cationic surfactant mixtures is limited by their tendency to precipitate over a wide concentration range. Precipitation can be avoided by manipulation of the surfactant structure so that the molecule will not fit well into a crystal lattice. for example, by making the tail group more highly branched and increasing the solubility product. As shown in Fig. 7, another strategy is to synergize micelle formation, thereby reducing the CMC and monomer concentration. Because the surfactant activity is reduced, a higher counterion concentration (called hardness tolerance in this case) is required to exceed the solubility product. Micelle formation can be made more favorable by adding nonionic or amphoteric surfactants to ionic surfactants, by increasing ionic strength of nonprecipitating counterions for ionic surfactants, etc. Manipulation of conditions to favor one type of aggregate over another is a common technique used by surfactant technologists to improve system performance. Recently introduced industrial surfactants are designed to preferentially fonn micelles rather than precipitate, for example, by judiciously introducing branching in the hydrophobe; this is an example of molecular engineering to manipulate surfactant physical properties and system performance.

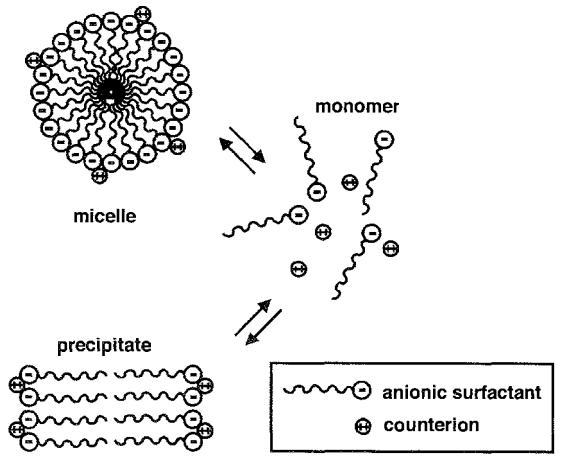

Fig. 7 Equilibria between anionic surfactant precipitating with a hardness cation and surfactant monomer and micelles.

SURFACE TENSION REDUCTION/FOAMS/WETTING

One of the most important properties of surfactants is their ability to reduce surface or interfacial tensions between bulk phases: which results from their surface activity or adsorption at the interface. Surface tension is the energy per unit area required to create new surface area and is the consequence of dissimilarity between phases. When a vapor and liquid are in equilibrium for a single-component system, as the critical point is approached. the vapor–liquid surface tension approaches zero as the two phases become identical. Surface tensions result from the reduction in intermolecular interactions when a molecule is moved from bulk phase to a surface and a reduction in interaction with nearest neighbors of the same structure. Surfactants reduce surface tensions due to their tendencies to adsorb at the surface. and they act as linkers to make these phases more compatible with each other. This is illustrated in Fig. 8 for an air–water interface. At room temperature, air–surfactant-free water surface tension is about 72 mN/m (same as mJ/m^2), while a typical air–alkane interfacial tension is 30 mN/m. When a surfactant monolayer adsorbs at the air–water surface, the head groups are immersed in or adjacent to the water, while the tail groups stick in the air. The 72 mN/m air–water interface was replaced by a head group–water interface and a tail group (oil-like layer)–air interface. The sum of the surface tensions of these two new interfaces is that of an oil–air surface (about 30 mN/m) and a head group–water surface (very low surface tension). As a result of the surfactant linking the air and water phases, the surface tension is reduced from 72 mN/m to about 30 mN/m. Surfactant-induced surface tension modification is used in a wide range of applications. For example, air–water surface tension reduction is important to processes such as wetting of an aqueous solution on a hydrophobic surface or production of foam; interfacial tension reduction at an oil–water interface is important in the removal of oily soil from fabric in laundry detergency.

The air–water surface tension decreases with increasing surfactant concentration below the CMC and

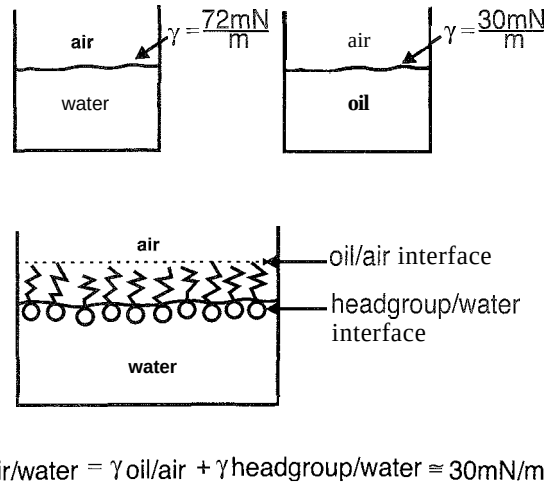

Fig. 8 Using adsorption to lower surface tension of water: surfactant acts as linker between phases.

plateaus above the CMC for single-component surfactants. Because the tendency of the surfactant to adsorb at the air–water interface and its tendency to form micelles is affected similarly by changes in many conditions, the plateau surface tension does not vary greatly within a homologous series of surfactants. For example, as the number of carbons within a linear hydrocarbon tail group increases. to attain a specified surface tension, a lower surfactant concentration is needed, but the concentration at which no further surface tension reduction occurs (the CMC) is also lowered. As a result. the plateau surface tensions between meinbers of a homologous series vary little with alkyl chain length of the surfactant. Similar trends are true for other variables that synergize micelle formation. such as increasing ionic strength for ionic surfactants or adding a nonionic surfactant to the ionic surfactant. This is illustrated for the addition of NaCl to an aqueous solution of the cationic surfactant cetylpyridinium chloride in Fig. 9. It is difficult to attain a plateau air–water surface tension of less than about 25 mN/m with hydrocarbon-based tail groups in surfactants. Silicon-based hydrophobic groups allow surface tensions as low as 20 mN/m, and fluorocarbon-based hydrophobic groups exhibited surface tensions as low as 13 mN/m.

When a droplet of liquid is on a solid surface, the contact angle describes whether the droplet wets the surface (spreads) or beads up, as shown in Fig. 10. A contact angle through the droplet of 0° would correspond to wetting and 180° to dewetting. As a liquid spreads over a solid surface and the contact angle decreases. a liquid–vapor surface and a solid–liquid surface are created. and a solid–vapor interface is destroyed. This process is made thermodynamically favorable when surfactant adsorbs at the two newly created interfaces. reducing their surface tensions; total system energy decreases upon wetting in this case. as illustrated in Fig. 10. In part because it is easily measured, liquid–vapor surface tension is often considered the dominant force that affects wetting of an aqueous solution on a hydrophobic solid, and surfactants cause an increased tendency to wet due to surface tension reduction. The most effective wetting agents in water are fluorinated surfactants, followed by silicon surfactants. Wetting is important in many applications, including spreading of an aqueous solution of herbicide sprayed on crops in agriculture, spreading of inks on a plastic film upon printing. and spreading of a detergent solution over dishware in automatic dishwashing. to name a few.

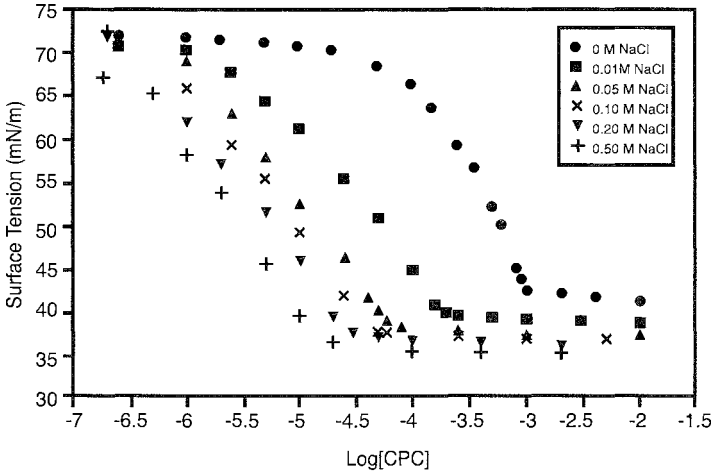

Fig. 9 Surface tension of cetylpyridinium chloride (CPC) solutions at different salinities.

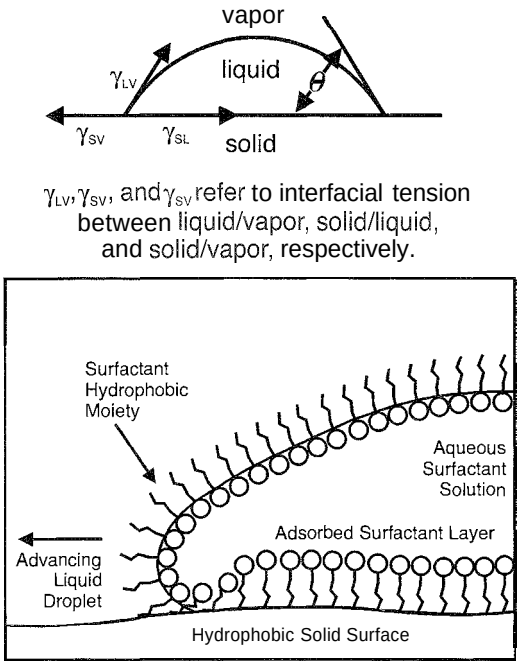

Fig. 10 Contact angle (0) for liquid wetting a solid and role of surfactant adsorption in aiding spreading (0 decreases).

Foams are dispersions of gas in a liquid. The thin-liquid film (film lamellae) separating the discrete gas bubbles is continuous. Surfactants are critical to effective foam formation and stability for two basic reasons: 1) the reduction in liquid–vapor surface tension reduces the energy required to creaie the large surface areas in a foarn; and 2) the adsorbed surfactant monolayers on each side of the film lamellae repel each other. thereby opposing thinning and the ultimate rupture of the film, as shown in Fig. 11. If the head groups are ionic, there is electrostatic repulsion between the charged monolayers: if the head groups are large polyethoxylate nonionic groups, steric (space-filling) repulsion exists between layers. These electrostatic and steric repulsive forces, generically referred to as a disjoining pressure, are crucial to stabilization of the foam. Because electrostatic forces are often stronger than steric forces. ionic surfactants are generally the best foaming agents. Foam stability is particularly good when using mixtures of ionic and zwitterionic surfactants, because they form stable monolayers. Fortnation of cylindrical micelles or liquid crystals in the foarn lamellae can increase viscosity in the film and increase foam stability. As a foam ages and the liquid drains from the liquid film. the foam becomes dryer, and the gas bubbles transition from spheres to polyhedrons. The minimum free energy of a foaming system occurs when the foam breaks. demonstrating the instability of these systems. Foams can be formulated. however. to be stable for months or even years. One foam of academic interest has ultrathin liquid films separated by gas bubbles. so thin that no light reflects from them. and they appear to be black. These black films were first observed by Newton and can be stable. because repulsive and attractive forces between the two surfaces of the liquid film can be in balance. This is a quasiequilibrium state. however; at equilibrium. these black film-based foams will break due to the large energy gained by the system when the film surface area is destroyed.

Surfactants improve foam formation by inducing film elasticity. which is helpful when the film is stretched as a gas bubble emerges from a liquid solution to become part of the foam matrix. As the film stretches, differentia! surfactant adsorption at the interface leads to surface tension gradients and healing of the film (so it thins with approximately uniform thickness). The optimum surfactant concentration for foam formation (although not foam stability) is around the CMC.

Water-insoluble surfactants (particularly silicoa-based) can act as antifoams (prevent foarn formation) or defoamers (break existing foams) due to displacement of water-soluble surfactants from the air–water interface. resulting in inelastic adsorbed monolayers. poor foam formation, and poor resistance of an existing foam to rupture upon stretching (due. for example, to mechanical vibrations). So, surfactants can help make or help break foams, depending on the desired effect.

EMULSIONS/MICROEMULSIONS

Emulsions and microemulsions are widely used in a range of products. including pharmaceuticals, cosmetics, food products. and cleaning. to name but a few. as well as in industrial operations. such as in the production of

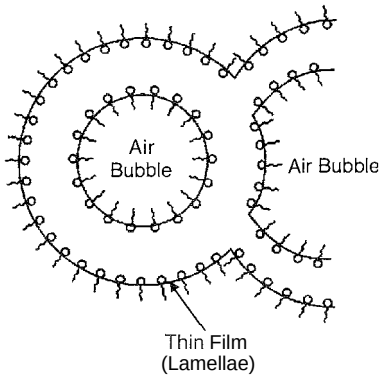

Fig. 11 Formation of surfactant monolayers at the air–water interface that stabilizes foam.

emulsion polymers. An emulsion, or macroemulsion, is a thermodynamically unstable mixture of oil and water. Surfactants can help to stabilize these emulsions for months, or even years, depending on the desired shelf life for a given product. By contrast, a microemulsion is a thermodynamically stable system. The surfactant selection approach to stabilize a macroemulsion and to form a microemulsion are similar in some ways but different in others. The discovery that microemulsion formation and macroemulsion stability are linked is rapidly changing the designs of macroemulsion surfactant systems.

Macroemulsions are opaque dispersions of an oil and water phase, taking on a milky-white appearance when the oil is colorless (as in the case of milk). The milky-white appearance results from the emulsion droplet size, typically on the order of 0.5–1.0 microns, which is large enough to scatter visible light. Stable macroemulsions cannot have droplets much larger than this, as the buoyant forces that result from the oil–water density difference will cause the droplets to "cream out," rising to the top of the continuous phase. By contrast, microemulsions are generally transparent, a result of their much smaller droplet size—larger than a micelle, 4–6 nm, but much less than 100 nm. As microemulsion systems approach or exceed this upper limit. they evidence a blue-white or hazy appearance; this region is sometimes known as a miniemulsion, or swollen micelles.

Droplet size plays an important role in macroemulsion stability. Forming a macroemulsion requires energy input because of the increased interfacial area between the oil and water phases (Fig. 12). Conversely, as the emulsion breaks and the system returns to the original state, energy is released. In the example in Fig. 12, 31 J of work is required to form one micron droplet of 100 mLs of heptane in 1 L of water. If smaller droplets were desired, more energy input would be required because of the increased interfacial area. At the same time, smaller emulsion droplets experience less buoyancy effect and creaming (coalescence as the droplets rise to the surface). Surfactants help the emulsion process in two important ways: 1) by reducing the interfacial tension, surfactants decrease the energy input required to form a certain droplet size (or, for the same energy input, smaller droplets are formed); and 2) as surfactants accumulate at the oil–water interface, they provide electrostatic or steric hindrances to droplet coalescence. It is by producing smaller emulsion droplets and hindering the coalescence process that surfactants help to form stable macroemulsions. Once a macroemulsion breaks, energy must again be added to reform the macroemulsion.

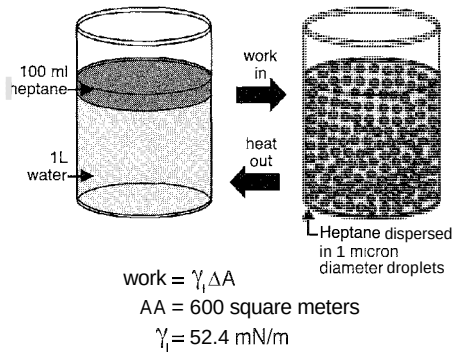

Fig. **12** An example of energy required to form a macroemulsion.

As a general description, a microemulsion is a homogeneous phase that contains a substantial fraction of both oil and water, their mixing being induced by the dissolved surfactant. In contrast with macroemulsions, microemulsion systems form spontaneously in solution. As with micelles, microemulsions are thermodynamically stable. As a result, in contrast to macroemulsions, microemulsion formation is reversible. For example, if changes in a system parameter (e.g., temperature) alter the microemulsion system, when the system parameter returns to its original state, so does the microemulsion system. In contrast to macroemulsions, a microemulsion forms virtually independent of the volume of the oil phase, but once formed, the microemulsion enhances the aqueous solubility of the oil phase. Most often, an excess oil phase persists in the presence of a microemulsion phase—the oil and water phases do not completely mix.

Macroemulsions can occur in two basic forms: oil in water (O/W) or water in oil (W/O). In an O/W emulsion, the system has bulk properties of a water phase, and thus behaves like oil droplets dispersed in a water continuous phase. Conversely, for a W/O emulsion, the system has properties of water dispersed in a continuous oil phase. An obvious questions is: how does one design a surfactant system to form or stabilize an O/W or a W/O emulsion'? A traditional rule-of-thumb, Bancroft's Rule, indicates that an O/W emulsion will result when the emulsifying agents (surfactants) are more soluble in the water phase, while W/O emulsions result when the emulsifying agents are more soluble in the oil phase. The more quantitative hydrophilic–lipophilic balance (HLB) is an indicator of a surfactant's water or oil solubility. Surfactants with relatively high HLB values (e.g., 16 or greater) are highly water soluble. while relatively low HLB values (e.g., six or less) indicate surfactants that are oil soluble. As expected, increasing the surfactant tail length decreases the HLB, while increasing the number

of ethylene oxide groups or going from a carboxylate to sulfate or sulfonate head group increases the HLB. As the HLB of a surfactant, or surfactant mixture. decreases between these extreme values, it transitions from being water soluble (micelles) to oil soluble (reverse micelles). This transition occurs at intermediate HLB values (approximately eight to 12, depending on the oil). An emulsion has its highest stability when the HLB of the surfactant is tailored to the HLB of the oil. In this case. the surfactant concentrates at the oil–water interface, lowering the interfacial tension and providing electrostatic and steric hindrances to emulsion coalescence. If the surfactant is too oil or too water soluble (the HLB is too low or too high). the surfactant will preferentially be in the oil or water phase rather than at the interface stabilizing the emulsion. Surfactant mixtures help optimize the MLB. increase the surfactant packing density at the oil–water interface, lower the interfacial tension, and enhance the electrostatic/steric hindrances to coalescence. all of which improve emulsion stability. The HLB method is widely used. because it provides a single value that characterizes the water solubility of a surfactant or mixtures thereof. Within a class of surfactants. the lower the HLB. the greater the tendency to form aggregates from aqueous solution [such as micelles (reduced CMC), precipitate (for ionic surfactants. higher Krafft temperature)]. form monolayers at the air–water interface, etc. However, at the same HLB, surfactants from different classes (e.g., anionic versus nonionic) can behave differently.

One limitation of the HLB concept is its failure to account for variations in system conditions from that at which the HLB is measured (e.g., temperature. electrolyte concentration). For example. increasing temperature decreases the water solubility of a nonionic surfactant. ultimately causing phase separation above the cloud point. an effect not captured in a temperature-independent HLB value. When both water and oil are present. the temperature at which a surfactant transitions from being water soluble to oil soluble is known as the phase inversion temperature (PIT). Below the PIT, nonionic surfactants are water soluble, while above the PIT. they are oil soluble. Thus, from Bancroft's rule. a nonionic surfactant will form an O/W emulsion below its PIT and a W/O emulsion above its PIT. Likewise, increasing salt concentrations reduces the water solubility of ionic surfactant systems. At elevated salt concentrations, ionic surfactants will eventually partition into the oil phase. This is illustrated in Fig. 13. which shows aqueous micelles at lower salt concentrations and oil-phase inverse micelles at higher salt concentrations. Increasing the system temperature will likewise cause this same transition for nonionic surfactant systems.

Interesting things happen in the region where a surfactant transitions from being water soluble to oil soluble. At the incipient point of transition. the surfactant dislikes the water and the oil phases and prefers to be at the interface, but there is not sufficient room at the interface to accommodate all of the surfactant. In this case, a new phase forms, which we call a middle-phase microemulsion. The middle-phase microemulsion combines virtually all of the surfactant with portions of the oil and water phases, giving it an intermediate density. and exists in equilibrium with virtually surfactant-free oil and water phases. Middle-phase microemulsions appear at the intermediate salt concentrations shown in Fig. 13. Unlike oil–water emulsions. which break given sufficient time, a middle-phase microemulsion system is thennodynamically stable and does not break with time (given that system conditions remain constant). Winsor referred to this middle phase as a Type III microemulsion. as opposed to Type I (micelles) and Type II (inverse micelles) microemulsions. Middle-phase microemulsions have several highly desirable properties; including ultralow interfacial tensions with the water or the oil phases, potentially less than 10^{-4} mN/m, and ultrahigh solubilization potentials for oil or water, potentially two to three orders of magnitude higher than in simple micellar systems. as illustrated in Fig. 13. To illustrate the remarkable ability for oil and water to coexist in a middle-phase microemulsion. a few weight % surfactant can cause equal amounts of oil and water to be contained in the microeinulsion.

While the middle-phase microemulsion appears at a discrete point in the temperature or salinity scan, system properties change continuously through the scan. As illustrated in Fig. 13. the interfacial tension decreases

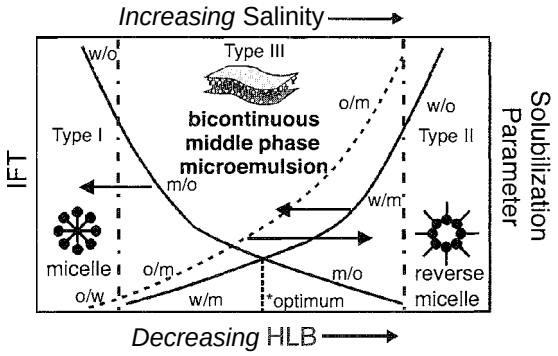

Fig. 13 Effect of electrolyte concentration on Winsor microemulsion type (salinity scan). w: water: o: oil: m: microemulsion: solubilization parameter: volume of oil solubilized per mass of surfactant.

continuously as the system transitions through the Type I region toward the Type III boundary, and it will decrease by orders of magnitude prior to the appearance of a middle-phase microemulsion. Likewise, the solubilization potential will increase by an order of magnitude or more prior to the appearance of a middle phase. We refer to the Type I microemulsion region just before a Type III microemulsion forms as the supersolubilization region.

As the surfactant concentration increases. there is more surfactant in the middle-phase region. Because the surfactant is accumulating at the oil–water layers within the middle phase, as the surfactant concentration increases, the volume of the middle phase must increase to accommodate the additional surfactant. Eventually, at elevated surfactant concentrations. the volume of the middle phase grows sufficiently to consume all of the oil and water phases, and we are left with a single-phase microemulsion. In this Winsor Type IV microemulsion, the oil and water become miscible, the system interfacial tension reaches a global minimum. and the solubilization potential reaches a global maximum. In order to form a single phase, a Type IV microemulsion requires elevated surfactant concentrations, but the improved performance may warrant additional costs for certain applications. As a microemulsion transitions from a Type I toward a Type III system, micelles become swollen. and eventually, a bicontinuous structure forms with a monomolecular surfactant film separating regions of oil from regions of water. (See Fig. 13.) Hence. water and oil are continuous; this bicontinuous structure is present, not only in middle-phase microemulsions containing approximately equal volumes of oil and water. bur also as we approach the Type I or II microemulsion boundaries within the middle-phase region.

Emulsion stability is also a function of surfactant concentration. As discussed above. if the surfactant HLB is not tailored to the HLB of the oil, the surfactant will be in the oil or water phase rather than accumulating at the interface. But in addition to having the right surfactant system (HLB matched to the oil phase), there must be sufficient surfactant present to cover the interfacial area of the optimally sized emulsion droplets. In addition to saturating the oil–water interface: enough surfactant must be added to maintain the aqueous CMC, as this equilibrates with the desired level of surfactant at the interface. If the surfactant concentration is less than this optimal concentration. then larger emulsion droplets will occur, and increased buoyancy forces will result in a shorter shelf life than desired. Thus, optimal emulsion stability requires selecting the right surfactant system. as guided by the HLB concept, and the right amount of this surfactant system, as estimated from the oil–water interfacial area and the area per head group of the surfactant present as an adsorbed monolayer.

CONCLUSION

The tendency of surfactants to adsorb at interfaces and self-assemble results in unique physical properties and behavior. Formation of micelles, liquid crystals. macroemulsions, microemulsions. and foams, as well as surface tension reduction and improving wettability of aqueous solutions, are just a few phenomena exhibited by surfactants. This behavior is of both fundamental interest as a unique subset of physical chemistry as well as leading to many practical applications.

INTRODUCTION

Surfactants are used in many applications, including consumer products. industrial products and processes, and environmental remediation. The total annual value of surfactants is on the order of $\$6 \times 10^9$. As an example of the commercial importance of applications in which surfactants are crucial, the worldwide annual market for detergent or cleaning products. in which surfactants are an important component, is approximately $\$60 \times 10^9$. The two articles on ''Surfactants'' in this encyclopedia are split into "Fundamentals" and "Applications," with this article discussing applied aspects of surfactant behavior. The article in which a certain topic is included is arbitrary. because fundamental and applied aspects of surfactant behavior are involved (e.g., wetting, emulsifying. adsorbing on solids). The purpose of this article is to extend the discussion of fundamental surfactant behavior from Part I, to discuss some applications, like detergency and surfactant-based separations. and to describe environmental aspects of surfactants that influence their use in applications.

SURFACTANT ADSORPTION ON SOLIDS/DISPERSIONS

Surfactants tend to accumulate at the solid/liquid interface just as they accumulate at the vapor/liquid and liquid/liquid interfaces. Surfactants also tend to form aggregates at the solid/solution interface, just as they tend to form inicelles in solution. Bilayered aggregates of adsorbed surfactants are called admicelles.

Shown in Fig. I is a typical adsorption isotherm for a single-component surfactant adsorbing from an aqueous solution surface for which the head group of the monomer has an attractive interaction, such as an anionic surfactant adsorbed on a positively charged surface. The *x*-axis is the equilibrium concentration of surfactant in solution, and the y-axis is the amount of adsorbed surfactant. in moles or molecules or mass per area or adsorbent weight.

The surfactant adsorption isotherm is usefully divided into four regions. Region I is called the Henry's Law Region, where adsorption is proportional to concentration. In Region I. monomers adsorb independently on the solid surface, without cooperation or competition for adsorption sites, because the number of available adsorption sites greatly exceeds the number of adsorbed molecules. Region II is characterized by the formation of admicelles (adsorbed bilayers) in patches on the surface. The Region I/Region II transition is marked by a sharp increase in the slope of the adsorption isotherm. as the surfactant molecules begin to cooperate, and hydrophobic bonding causes formation of admicelles. The Region II/Region III transition is characterized by a competition between admicelles for available formation sites, as the number of adrnicelles can approach the number of sites available for admicelles. Thus, while Region II is dominated by cooperative interactions between surfactant monomers to form admicelles, Region III is dominated by competition between the admicelles for the available surface area of the solid. Region III may not exist in some systems where surface coverage of admicelles is sparce. Region IV begins as the monomer concentration in solution reaches the critical micelle coacentration (CIVIC). Because the last admicelle forms at the same chemical potential as the first micelle to form. surfactant added above the CMC goes into forming more inicelles with little change in the chemical potential of the surfactant molecules. resulting in a nearly constant adsorption above the CMC in Region IV. The level of adsorption above the CMC is often called the plateau adsorption. In cases where the head group has a neutral or even repulsive interaction with the surface. as might occur with a hydrophobic surface or with a surface having the same charge as the head group, the admicelles will tend to be local monolayers called hemimicelles. with a tail-down, head-out configuration. In this case. the driving force for self-assembly is less than that for the systems shown in Fig. 1. so a gradual increase in surfactant adsorption with concentration instead of an abrupt transition upon surface aggregate formation is observed. However, adsorption still plateaus above the CMC in these cases.

It is hard to overstate the observation that the admicelle has properties similar to a micelle. Counterion binding on the adrnicelle is nearly identical to that on the micelle:

B -- *Longer* alkyl *chain length or higher electrolyte concentration (for ionic* surfactants) than A

CAC -- Critical Admicelle *Concentration*

Fig. 1 A typical surfactant adsorption isotherm on a hydrophilic surface from water.

admicelles will soiubilize organic solutes, a phenomenon called adsolubilization. to about the same extent as the same solute is taken up by a micelie. A consequence of this is that the transition from Region I to Region II—often called the CAC, or critical admicelle concentration in analogy to the CMC—will decrease with added electrolyte in nearly the same manner as the CMC decreases for ionic surfactants. In Fig. 1, Isotherm B can represent the same surfactant as in Isotherm A. adsorbing on the same surface; Isotherm B is shifted to the left. because added electrolyte reduced the CAC along with the CMC. Isotherm B could also represent a surfactant with a larger hydrophobic g oup than Isotherm A. As with added electrolyte for ionic surfactants, increased hydrophobicity lowers the CAC and the CMC and shifts the Isotherm to the left. For all concentrations of surfactant between the CMC and the CAC, the adsorption for Isotherm B is higher than the adsorption in Isotherm A: however. because the electrolyte or increased hydrophobe size lowered the CMC, the CMC occurs at a lower surfactant concentration. and the level of adsorption above the CMC is practically unchanged. Above the CMC, the plateau adsorption level may be at or near complete biiayer coverage but may be significantly less if there is not a strong interaction between the surface and the hydrophilic group of the surfactant.

While ionic surfactants will always adsorb strongly on surfaces oppositely charged to the head group. nonionic surfactants adsorb strongly on some substrates, like silica (due to hydrogen bonding), but have low adsorption on substrates like alumina. A nonionic surfactant may adsorb to form a complete bilayer on silica but may not even begin to form admicelles on alumina. Anionic and. nonionic surfactants can form monolayers (hemirnicelles) on hydrophobic surfaces and can form admicelles on hydrophilic surfaces.

All hydrocarbon mixed surfactant systems with dissimilar head groups. such as ionic/nonionic, ionic/amphoteric, and anionic/cationic, tend to have increased adsorption relative to the pure component adsorption at the same surfactant concentration. This synergisin is analogous to the effect of mixed surfactant systems in forming low CMC surfactant mixtures. It is easier to form a mixed admicelle rather than a pure component admicelle, just as it is easier to form a mixed micelle.

Adsorption of surfactant at the solid/solution interface is important in technologies such as ore flotation (a separation process). stabilization of dispersions. wetting. and surface cleaning. Surfactants are important components in paints. drilling muds; printing inks, and ceramic green bodies. There are many similarities in the phenomenologies of dispersions and emulsions. In both phenomena, adsorption of surfactants at the solvent interface lowers the interfacial energy and also imparts steric and electrostatic repulsion between particles; this inhibits aggregation of the particles, thus preventing the buoyant force on the aggregate from becoming significant enough to reduce the stability of the dispersion. The role of the adsorbed surfactant layer in stabilizing a dispersion of hydrophobic particles (e.g., carbon black) is illustrated in Fig. 2. In emulsions, in contrast to dispersions. optimization of the surfactant systems results in smaller liquid droplets. so that the buoyant force becomes negligible. For solids, the particle size does not adjust when surfactants are added (although surfactants can cause small particles to agglomerate into assemblies or flocs—this is not the same as adjusting the primary particle size). This means that for solid particles too large to be suspended by Brownian motion, the negative buoyant force will cause the particles to settle. no matter

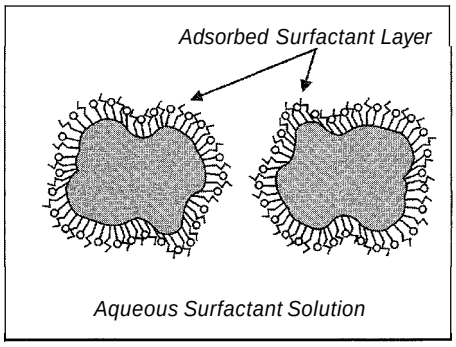

Fig. 2 The role of adsorption in solid/liquid dispersions

how effectively the surfactant adsorbs at the particle/solution interface.

Despite the central role of surfactants in stabilizing solid/liquid dispersions. the most important variables affecting dispersion stability are the particle size and the volume fraction of the solid. These variables essentially determine the strategy to be used to form a stable dispersion of the particles in liquid. Only in the case of a low volume fraction of submicron particles will surfactant adsorption on the surface, and the resulting electrostatic and steric repulsion between the particles, be sufficient to form a stable suspension of dispersed particles. When the solid particles are too large to be suspended by Brownian motion, as is generally the case for particles of micron size or larger, if the particles are completely, uniformly dispersed, then the dispersion stability remains low. To form stable suspensions in such systems, it is important that the particles have a small amount of "stickiness" between one another. Sticky particles form high volume fraction aggregates that, even though too large to be suspended by Brownian motion, form a large volume fraction clay or floc that is readily redispersed by shear forces and does not form a dilatant (shear thickening or nonredispersable) clay. Formation of high volume fraction aggregates that keep one another suspended is easier as the volume fraction of the solid increases.

There is a strong correlation between surfactant concentration and cossesponding adsorption, and the type of dispersion obtained. Consider, for example, an aqueous suspension of silica particles to be stabilized by adsorption of a nonionic surfactant. The silica particles have a negatively charged surface above pH 2; consequently, submicron silica particles at neutral pH tend to remain suspended even in the absence of added surfactant, because the charged surfaces repel one another. When the particles are greater than a micron in size; however, the density of silica (specific gravity of two) causes rapid settling of the particles, despite their electrostatic repulsion. Addition of surfactant to a level where the surfactant equilibrates in Region I of the adsorption isotherm has little effect on the suspension because of the low level of adsorbed surfactant. When the surfactant equilibrates in Region II, however, the silica particles begin to aggregate. The aggregation is caused by the simultaneous coadsorption of individual admicelles on two silica particles. resulting in the formation of an admicelle bridge linking the particles together. So, when the surfactant adsorption density is such that surfactant-covered patches on one particle interact substantially with bare patches on other particles, the surfactant can decrease dispersion stability or cause aggregation. The extent of aggregation and the size of the aggregates will vary throughout Region II, and there will generally be an optimum level of surfactant for stabilizing the dispersion. Once the surfactant adsorption level reaches Region III, however, a high fraction of adsorption sites can become filled. and there can be a decrease in aggregation. By the time the plateau or Region IV adsorption is reached, the adsorbed nonionic surfactant admicelles cause steric repulsion of the particles, and a stable dispersion can result.

In selecting a surfactant for use in modifying dispersions, the most important consideration is whether or not the surfactant adsorbs on the solid. Ionic smfactants adsorb best on oppositely charged surfaces of oxides like silica, alumina, or titanium dioxide. The opposite charge is determined by the pH of the solution. For example. silica gels generally have what is called a point-of-zero charge (PZC) between pH 2 and pH 3. Below pH 2 the silica surface is positively charged, and anionic surfactants will adsorb best; above pH 3 the silica surface will be negatively charged, and cationics will adsorb best. In contrast, zinc oxides generally have a PZC around pH 9. Below pH 9 the zinc oxide has a positively charged surface, and anionic surfactants adsorb best and are better able to affect the stability of zinc oxide dispersions. Above pH 9 the zinc oxide will have a negatively charged surface, and cationic surfactants will adsorb best and be more effective.

As in the earlier example. where nonionic surfactant decreases then increases dispersion stability of silica as surfactant concentration increases from Region I on the adsorption isotherm to the CMC. ionic surfactants can exhibit the same qualitative behavior with hydrophilic solids. If the surfactant has an opposite charge to that of the particle (e.g., anionic surfactant with alumina at pH below its PZC of 9), adsorption of surfactant can reduce the absolute value of electrical potential of the particle, reducing electrostatic repulsion between particles and reducing dispersion stability. As surfactant concentration and adsorption are increased further, the surfactant adsorption density can cause the net charge on the particle to change from positive to negative (or vice versa), a phenomena known as charge reversal. Further increases in surfactant concentration, up to the CMC, can increase charge density on the particles. increase electrostatic repulsion, and increase dispersion stability. Charge reversal is possible, because hydrophobic bonding in admicelles can overcome electrostatic repulsion between charged surfactant head groups. So charge reversal can be yet another factor causing surfactant to act as an agglomeration agent or as a dispersant, depending on concentration. Dispersion stability approximately plateaus above the CMC, because surfactant adsorption also plateaus (Region IV in Fig. 1). Unlike hydrophilic particles, where dispersion stability can exhibit a minimum with surfactant concentration, the higher the adsorption (higher concentration up to the CMC), the greater the dispersion stability of hydrophobic

particles in water (see Fig. 2), because electrostatic and steric stabilization improve with increasing surfactant adsorption. In designing dispersed systems. relating equilibrium surfactant concentration to the CMC is crucial. rather than using empirical rules related to a wt% of dispersant recommended for a given system.

DETERGENCY

Detergency can be defined as removal of unwanted materials from a solid surface. Most detergent applications occur in aqueous solution. although in laundry dry cleaning. organic solvents are used. We will restrict discussions here to water-based systems. Detergent products include laundry detergents (mostly powders, liquids. tablets), hand dishwashing detergents, automatic dishwashing detergents, hard surface cleaners, shampoos, bar soaps and body washes for cleansing of the skin, carpet cleaners, glass cleaners, car washes, and many other products. While a universal formulation could do a reasonable job of cleaning most surfaces, the consumer demands high performance. so products are designed for specific applications with differing compositions. Surfactants are a key component in the detergency process. In some applications (e.g., inexpensive bar soaps, most hand dishwashing detergents). surfactants are the only additive responsible for cleaning.

Unwanted materials (or soils as they are referred to in detergency) to be removed from the substrate are normally classified as oily, particulate, or solid non-

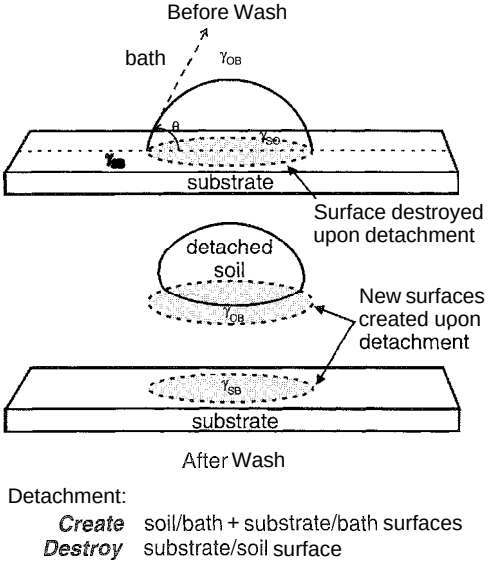

Fig. 3 Destruction and creation of surfaces upon oily soil detachment.

Time

Fig. 4 Removal of oily soil by the roll-up mechanism.

particulate. Oily soils are any liquid substances that can spread out or bead up (contact angle change) on the substrate; motor oil or vegetable oils are typical model oily soils used in detergency studies. Particulate soils are hard particles such as carbon black (model hydrophobic soil) or clay (model hydrophilic soil). Solid nonparticulate soils are sebum from human skin. which can contain enough crystallinity (due to fatty acids) so they do not flow, yet they do not remain intact as discrete particles like particulate soils. Soils are different from stains; stains involve a chemical bond between the contaminant and substrate (e.g., blood, coffee, blueberries), whereas soils are attracted to the substrate by physical forces like van der Waals, electrostatic, and hydrophobic forces. Enzymes and bleaches are generally used to treat stains, whereas surfactants are critical to removal of soils. Substrates to be cleaned are generally classified into textiles or hard surfaces (e.g., dishes, kitchen counters), although there are a number of surfaces that do not fall into either of these categories. Another way of classifying substrates is as hydrophobic (e.g., synthetic clothing, polyethylene food storage containers) or hydrophilic (e.g., cotton fabric, ceramic dishes). This latter classification is mechanistically more convenient, as illustrated by the example that the toughest detergency challenge is oily soil on a hydrophobic surface.

The general principle of surfactant action to remove soils from a surface is illustrated for oily soil in Fig. 3. When the soil is detached from the substrate, the surface between soil and substrate is destroyed. but two new surfaces are created—that between soil and bath and between substrate and bath. Detachment will be thermodynamically favorable when the sum of the interfacial tensions of the two new surfaces is less than that of the destroyed surface. A primary function of surfactants is to adsorb at the soil/bath and substrate/bath interfaces and reduce these interfacial tensions to make detachment more thermodynamically favorable. As surfactants adsorb and modify interfacial tensions, the contact angle (8 in Fig. 3) increases. and the contact area between soil and substrate decreases. As shown in Fig. 4, this results in the

"roll up" mechanism of detergency as the oily droplet rolls up and detaches. However, as shown in Fig. 4, when the substrate/bath interfacial tension is not sufficiently reduced, a phenomena called snap-off can occur where the oil droplet becomes elongated. forms a neck. and only part of the drop is removed. For particulate soil detergency. surfactants act to adsorb onto the newly created soil/bath and substrate/bath interfaces, reducing these interfacial tensions to make detachment more thermodynamically favorable. However, because removal is all or nothing in this case, there are no contact angles or roll-up mechanisms. As shown in Fig. 5. for solid nonparticulate soil, the surfactant diffuses into the soil and loosens pieces of the soil. thereby promoting detachment of these dispersed particles. Thus, the surfactant acts as a dispersing agent as well.

Whatever the type of soil removed, once this soil is detached from the substrate, barriers must be set up to inhibit reattachment or redeposition. The chemicals used to achieve this are known as antiredeposition agents. Surfactants can achieve this by adsorbing onto the detached soil and setting up electrostatic and steric barriers to redeposition. For example, anionic surfactant can adsorb onto a particle to induce a negative charge. and the resultant repulsion of these particles from negatively charged cotton. Nonionic surfactants can adsorb onto the surface of oily soil droplets, form a macroemulsion, and set up steric barriers to redeposition. In practice. water-soluble polymers (e.g., sodium carboxymethylcellulose) are used for antiredeposition. but the mechanisms are electrostatic and steric stabilization.

Anionic surfactants are generally most effective in removing particulate soils, while nonionic surfactants are most effective at removing oily soils. Cationic surfactants adsorb strongly onto negatively charged fabrics like cotton and act as fabric softeners. as they set up an adsorbed monolayer with hydrophobic groups sticking out to give a smooth feel to the fabric.

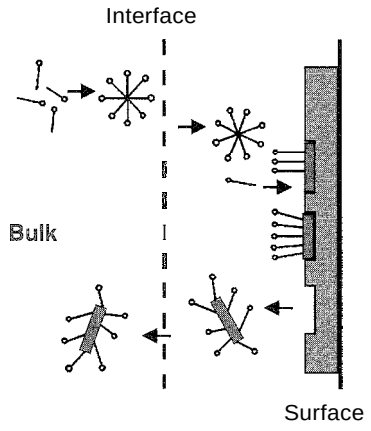

Fig. 5 Detergency of solid nonparticulate soil

INDUSTRIAL APPLICATIONS OF SURFACTANT-BASED SEPARATIONS

Separation techniques using surfactants are valuable in industrial operations and in analytical chemistry. We will briefly discuss several industrial applications of surfactant-based separations to illustrate how surfactants are used in such important operations as wastewater clean-up and recovery and purification of valuable materials.

Detergency aside, ore flotation is the largest industrial use of surfactants. Ore is mined. crushed into small particles, mixed with water, and placed into a flotation cell. In the froth flotation process, as illustrated in Fig. 6. surfactant is added to the slurry, and air is bubbled into the solution through a sparger at the bottom of the vessel. Surfactant adsorbs at the air/water interface as a monolayer and (under the right condition) adsorbs as a bilayered structure onto the valuable ore (colligend) that is to be collected. When the air bubble collides with the ore particle, the minimum free energy corresponds to the configuration shown in Fig. 6, where the surfactant acts as a bridge between the air and ore surfaces. Surfactant is chosen that does not adsorb well onto the mineral to be rejected (gangue), which then does not stick to the air bubbles and stays suspended in the water. The colligend is carried up to the foam (called a froth in this case). where it is suspended in the froth and carried overhead as the froth flows over a weir or is skimmed off. Depending on the ore type, anionic surfactant or cationic surfactant is chosen; pH is a crucial parameter for maximizing adsorption of surfactant onto the colligend. Calcium is sometimes added as an activator with anionic surfactant. coadsorbing or acting as a bridge between the ore surface and the surfactant. Foam stabilizers are sometimes added to make the froth strong enough and stable enough to hold the ore particles.

During paper deinking, ink removal permits recycling of the paper as secondary fiber. Paper is pulped (blended into small pieces), and the ink is detached from the paper by immersing in a surfactant solution, which is basically a detergency process. In flotation deinking, the slurry of paper fiber and ink is placed in a flotation cell (same type of equipment as used in ore flotation), and air is sparged through the solution. As with ore flotation. under the correct conditions. certain materials (in this case, ink) attach to the air bubbles as they rise through solution. leaving the paper fibers behind for reuse. Nonionic surfactants are often used in the detachment step. while fatty acids. with calcium as an activator. are often used in the flotation operation. The calcium synergizes the anionic surfactant adsorption onto ink.

As illustrated in Fig. 7. in micellar-enhanced ultrafiltration, surfactant is added to water at concentrations well above the CMC. Dissolved organic solutes (e.g., chlorinated organic pollutants) and multivalent ionic solutes

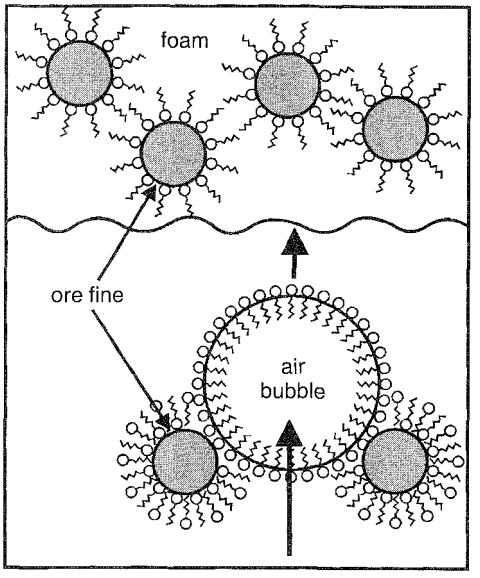

Fig. 6 Froth flotation for ore separation.

(e.g., cadmium, copper, chromate, arsenate) are incorporated into the micellcs via solubilization and counterion binding, respectively. When solubilizing nonionic organic solutes, any type of surfactant can be used, but surfactants of opposite charge to the target multivalent ions arc used for their removal. The solution is then treated by ultrafiltration, with membrane pore sizes sufficient to block or reject micelles. The solution passing through the membrane contains only unsolubilized solute, unbound counterions, and monomeric surfactant. If insufficient concentration reduction is attained, the process can be staged. One intriguing application is the use of optically active surfactants or solubilized ligands to selectively remove biologically active enantiomers in a bioseparation.

In surfactant-enhanced subsurface remediation, surfactant solutions are pumped through a subsurface contaminated with organic pollutants, such as a chlorinated solvent (e.g., trichloroethylene) or components from a fuel spill (e.g., gasoline). The pollutant is trapped between soil grains due to capillary forces. As illustrated in Fig. 8, a concentrated surfactant solution is pumped between the injection and recovery wells. The flush solution is treated above-ground and reinjected. There are two mechanisms by which the surfactant solution enhances pollutant removal: solubilixation into micelles; and sufficient reduction of interfacial tension between the organic phase and the aqueous phase so the organic droplets are mobilized or removed intact from the pores. Which mechanism is desirable depends on the pollutant and aquifer characteristics. For organics less dense than water (LNAPLs, or light-nonaqueous-phase liquids), the more efficient mobilization process is generally desired, but for organics heavier than water (DNAPLs, or dense-non-aqueous-phase liquids), solubilization may be favored, because if mobilized, the organics might sink into previously uncontaminated aquifer regions and get retrapped. So, solubilization capacity and the ability to attain ultralow interfacial tensions are crucial properties of the surfactants, in addition to high hardness tolerance and low adsorption onto the soil. In addition, the residual surfactant left behind must be biodegradable, often under anaerobic conditions. Cationic and nonionic surfactants tend to have unacceptably high soil adsorption. Ethoxylated anionic surfactants, gemini surfactants, and branched-tail surfactants are three types of popular surfactants for this application. For economical operation for multiple pore volume flushes (greater than four), the surfactant has to be reused. In above-ground operations, the flush solution is treated to remove the organic pollutant (for volatile organics, pervaporation or air stripping can be used; for nonvolatile organics, liquid–liquid extraction can be used) and to concentrate the surfactant that was diluted during

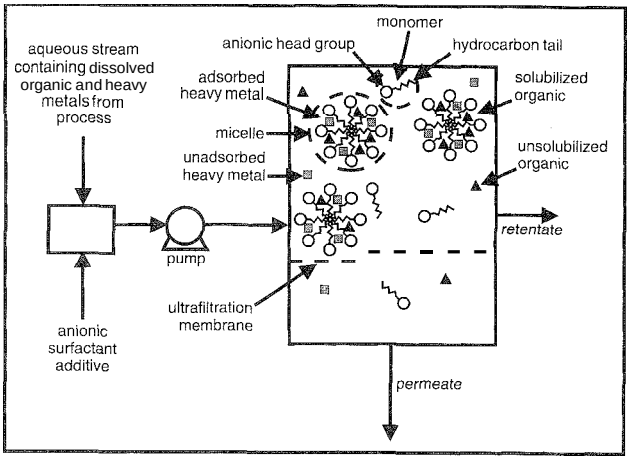

Fig. 7 Micellar-enhanced ultrafiltration

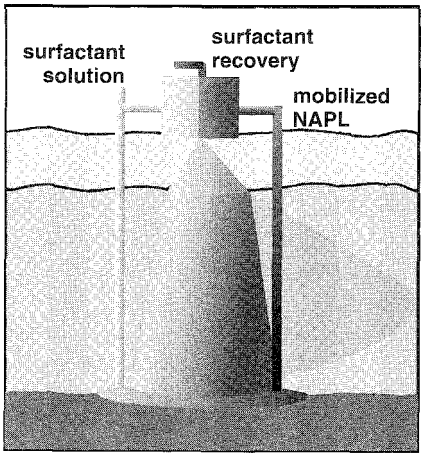

Fig. 8 Recovery of organic contaminant by surfactant-enhanced subsurface remediation.

the subsurface operation by the use of micellar-enhanced ultrafiltration. These operations further constrain surfactant selection, because excessive foaming makes stripping difficult, and micelles must be big enough to be ultrafiltered. Following the flushing operation, bioremediation is often used to remove the small residual pollutant concentration in a polishing step.

ENVIRONMENTAL AND HEALTH ISSUES

Over the past several decades, chemical impacts on the environmental and human health have been an increasing concern. Fortunately, the human toxicity of surfactants is relatively low compared to many other environmental contaminants. However, surfactants can be toxic to aquatic life at relatively low concentrations (1–10 mg/L) and can cause foaming in rivers at even lower concentrations. It was through these effects that the deleterious effects of surfactants were first observed in the environment. Introduction of the highly branched (tetrapropyl) alkylbenzene sulfonate (ABS), which is highly resistant to biodegradation in wastewater treatment plants, resulted in the widespread occurrence of surfactants in the environment. This had not been a problem before, because soaps are readily biodegradable. To help combat this situation. ABS was replaced by linear alkylbenzene sulfonate (LAS), which readily biodegrades in wastewater treatment plants. Once again, surfactant being discharged into the environment reached acceptable levels. This shift from tetrapropyl to linear ABS started a trend to eliminate ali branching in surfactant molecules. Recently. it was found that a mild degree of branching in the tail group can lead to performance advantages without sacrificing biodegradability. The majority of surfactant biodegradation work focused on aerobic environments. However, recently, the fate of surfactants in anaerobic environments is receiving increased scrutiny.

Nonionic surfactants have the lowest oral toxicity. while cationic surfactants have the highest toxicity, and anionic surfactants have an intermediate toxicity. One measure of toxicity is the lethal dose for 50% fatality (LD_{50}). The LD_{50} of nonionic surfactants with rats (1000–25,000 mg/kg) is slightly higher than that of anionic surfactants (700–15,000 mg/kg), which is higher than that for cationic surfactants (300–600 mg/kg). By contrast to surfactants, the LD_{50} of dioxin, a highly toxic compound, is 0.02 mg/kg. The high LD_{50} values for hydrocarbon-based surfactants indicate how safe they are to consumers or industrial workers. Fluorinated surfactants are recalcitrant to biodegradation and can bioaccumulate in the liver, leading to toxicity.

Surfactants can also cause irritation to skin. mucous membranes, etc. This irritation tends to be greatest for cationic surfactants, with decreasing irritation from anionic to nonionic and amphoteric surfactants. The irritation also tends to be greatest for 12-carbon alkyl groups and decreases with increasing ethoxylation of nonionic surfactants. This same trend is observed for a wide range of surfactant impacts on the environment and human health. In addition, for certain systems, the irritant results from an impurity or by-product of the surfactant manufacturing process rather than the surfactant.

Likewise, in some surfactant systems, the environmental or toxicity concern results from an additive or impurity in the formulation rather than the surfactant. Sultone or chlorosultone impurities in some anionic surfactants can lead to irritation. As another example, polyphosphates used to be commonly added to detergents as builders (i.e., to bind calcium and magnesium and prevent hardness precipitation of the surfactant). In some surface water bodies, phosphorous scarcity limits the growth of algae: discharging additional phosphorous into such water bodies can cause algal blooms and eutrophication. For this reason, phosphate builders were removed from many detergent systems, in some cases being replaced with zeolites for hardness sequestration. But there is some uncertainty as to how much impact phosphate builders have on the environment as compared to other phosphorous sources, and many areas of the world still use phosphates in formulations.

CONCLUSION

Surfactants are used in a wide range of industrial and consumer applications from washing fabric to remediating polluted water. Understanding and applying the fundamental properties of surfactants is resulting in a continuing expansion of practical uses of surfactants.

Swelling Clays (Smectites) and Nanofilms

Robert A. Schoonheydt
Katholieke University Leuven, Leuven, Belgium

INTRODUCTION

Smectites or swelling clays are almost ideally suited for fabrication of functional nanofilms. Self-assembling, also called fuzzy assembling or layer-by-layer assembly, and the Langmuir–Blodgett technique were explored. The functionality is introduced in the nanofilrns by ion exchange of amphiphilic molecules. In that way, films with nonlinear optical properties were prepared. Highly dispersed organoclays are also used in nanocomposites of polymers and in coatings to increase the mechanical strength, the photostability, and the heat resistance. and to prevent leakage.

SMECTITES

Clay is a general term for inorganic inaterials in the nano- and micrometer-size range that show plasticity.[1] Clay minerals form the crystalline fraction of clays. They belong to the class of the phyllosilicates. This class is subdivided into 1:1 and 2:1 clay minerals. The elementary sheet of the 1:1 clay minerals consists of a layer of SiO_4 tetrahedra and one layer of Al- or Mg-octahedra, which share a layer of oxygen atoms. In 2:1 clay minerals, the Al- or Mg-octahedral layer is sandwiched between two SiO_4 tetrahedral layers. Isomorphous substitution of Si^{4+} with trivalent cations. mainly Al^{3+}, or Al^{3+} in the octahedral layer by Mg^{2+} or Mg^{2+} in the octahedral layer with Li^{+} leads to negative layer charges compensated by exchangeable cations. When the isomorphous substitution amounts to 0.2–0.6 e per unit cell formula of 2:1 clay minerals. we have smectites or swelling clays. They are the subject of this article. Typical unit cell formulae are given in Table 1.

The superscripts IV and VI stand for the tetrahedral and octahedral layers. respectively. Smectites with Mg in the octahedral layer are called trioctahedral: those with an Al-octahedral layer are called dioctahedral.

SWELLING

The elementary sheets form aggregates. and the exchangeable cations are located at the surfaces of the sheets in the interlamellar spaces.[2] Depending on the size and charge of the cations. one or two layers of water molecules are associated with the exchangeable cations in the interlamellar space. In liquid water. additional water molecules are taken up, leading to the swelling of the aggregates. The limiting case is that of complete swelling into elementary clay sheets or platelets. which diffuse independently of each other in the aqueous suspension. Whether such a state can ever be achieved is a matter of debate. Two opposing forces determine the extent of swelling: on the one hand, the cations, which attract water molecules through ion–dipole interactions; on the other hand. the interaction exchangeable cation-negative layer charge. The former promotes swelling; the latter prohibits swelling. As a consequence. most extensive swelling is observed for the smallest monovalent cations, Li^{+} and Na^{+}. but swelling decreases significantly with increasing cationic radius (Cs^{+}). Di- and trivalent cations have strong interactions with the negative lattice charge, which limits the degree of swelling: the ion–dipole interaction is too weak to overcome the ion-negative lattice charge attraction.

Swelling is an extremely important property of the smectites. because it makes the interlamellar surface available. e.g., ion exchange with almost any type of cation. be it organic or inorganic. Cationic surfactants such as long-chain alkylammonium cations are selectively ion exchanged and form well-defined supramolecular assemblies at the surface. depending on the negative charge density of the clay mineral and the length of the alkyl chain. These so-called organoclays[3] are hydrophobic, swell in suitable organic solvents, e.g., methanol or ethanol. and form stable suspensions in these organic solvents. In principle. it is possible to prepare smectites with well-defined hydrophobicity or hydrophilicity. This property together with the nano/micrometer size of the elementary clay sheets is at the basis for the development of functional nanomaterials. starting from natural or synthetic smectites.

CATIONIC DYES

Cationic dyes such as methylene blue. rhodamine B or 6G, and many others are extremely selectively adsorbed by ion exchange.[4] The reaction is instantaneous. The dyes form aggregates around the smectite particles in aqueous

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012831

Table 1 Typical unit cell compositions of smectites

$(Si_8)^{IV}(Al_{3.34}(Mg_{0.66})^{VI}O_{20}(OH)_4\ M^+_{0.66}\ mH_2O$: montmorillonite
$(Si_{7.34}Al_{0.66})^{IV}(Mg_6)^{VI}O_{20}(OH)_4M^+_{0.66}\ mH_2O$: saponite
$(Si_8)^{IV}(Mg_{5.34}Li_{0.66})^{VI}O_{20}(OH)_4\ M^+_{0.66}\ mH_2O$: hectorite

suspension, from which the dye molecules slowly redistribute over the surface of the smectite particles.[5] The extent of redistribution and the time scale of the event depend on the type of clay. This means that aggregation and desaggregation phenomena of the elementary clay sheets and the layer charge (position and amount) come into play. The result is that a mixture of monomers, dimers. and aggregates of dye molecules are usually present on the clay surface. The relative proportion of each of these species depends on the loading, the particle size of the smectite, and the location of the isomorphous substitution (octahedral layer versus tetrahedral layer). Two additional interesting observations were made in the study of smectite–dye systems in aqueous suspensions:

1. When water is removed, the dye aggregates redistribute into monomers.[6] This means that in excess water, dye–dye interactions dominate, while in the absence of water, dye–clay particle interactions dominate.
2. The hyperpolarizability of adsorbed methylene blue in a methylene blue–smectite suspension is 11 times higher than that of methylene blue in a methanolic solution.[7] This effect disappears with increasing loading. Thus, two effects play a role: weak electronic interaction of the methylene blue molecule with the clay surface and organization of the dye molecules at the surface.

FILMS

The nanosize of the elementary sheets (1 nm thickness). ion exchange, swelling. and hydrophobic and hydrophilic balance are the basic properties of smectites for layer-by-layer construction of nanofilms and the development of nanodevices. Films can be prepared by casting and spin coating. However. the two most important techniques. which allow a layer-by-layer construction of the nanofilms, are self-assembling (SA) or fuzzy assembling (FA) and the Eangmuir–Blodgett (LB) technique.

Self-Assembling (SA), Fuzzy Assembling (FA), or Layer-by-Layer Assembling (LBL)

Self-assembling is based on the Coulombic attraction between negative and positive charges. In that way. nanocomposite films of oppositely charged polyelectrolytes can be constructed, but the technique can also be applied with smectite particles, because the elementary sheets are negatively charged. Multilayered nanofilms can be constructed by alternate deposition of a layer of a cationic polyelectrolyte and of a layer of smectite particles on a suitable substrate such as glass, quartz, Si, or mica. The latter is preferable, because it is also a 2:1 phyllosilicate with a very high negative charge density and therefore not swellable in water. The cationic polyelectrolyte is strongly adsorbed from a dilute aqueous solution on the surface of the mica sheet. After washing and drying of the polyelectrolyte film, a dilute suspension of a smectite is deposited. The smectite particles are retained by electrostatic attraction with the cationic polyelectrolyte. Excess smectite is washed away, and the film is dried in air. This procedure can be repeated several times to produce multilayer films of the type $(PE/clay)_n$, where PE stands for polyelectrolyte and n is the number of layers.[8] A linear increase of the film thickness with the number of deposited layers is obtained. The average layer thickness is proportional with the concentration of the polyelectrolyte in the solution used for deposition. The clay particles are essentially single sheets (no aggregates) that are randomly oriented in the layer and are partially overlapping. They also form a submonolayer, which means that they do not completely cover the surface. As a consequence, the films have a significant roughness, which is proportional to the amount of polyelectrolyte. This observation gives a hint for the mechanism of film formation. In a thick layer of polyelectrolyte, there is a high density of positive charges, giving a medium with high ionic strength. When a dilute clay suspension is deposited, the high local ionic strength causes clay particle aggregation, thus increasing the roughness. This is schematically shown in Fig. 1. In a thin layer of polylectrolyte molecules, the positive charge density is low, as is the ionic strength; and the polyelectrolyte molecules are stretched. Clay particles will mainly deposit as individual sheets, aggregation is minimal, and the roughness of the film is minimal. The main advantages of such a layer-by-layer assembly are simplicity, control of thickness on the nanometer scale, universal applicability, and easy incorporation of a functionality.[9] This functionality is necessary if the nanofilms are going to be implemented into a device. Two strategies were described in the literature.

In the first. developed by us,[10] a layer of clay mineral particles is covered with the cationic polyelectrolyte poly(diallyldimethylammoniumchloride) (PDDA) and subsequently with the anionic, noncentrosymmetric dye 4-{4[*N*-allyl,*N*-methylamino]phenylazo} benzene sulphonic acid (NAMC). Thus, the monolayer consists of clay/PDDA/NAMO. It is supported on a glass substrate. derivatized with 3-aminopropyl-trimethoxysilane (APTS)

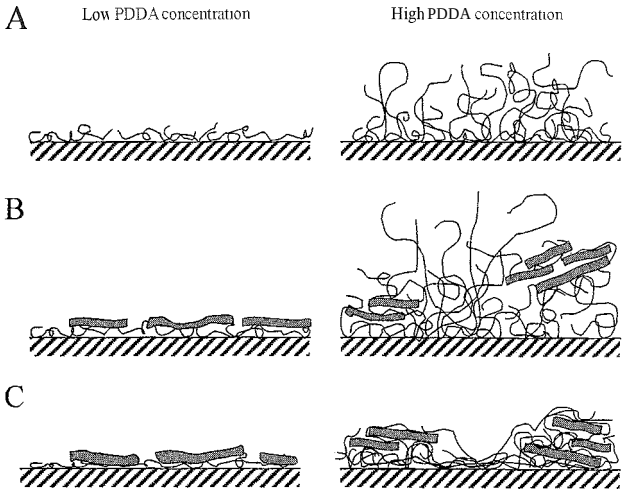

Fig. 1 Model of self-assembling of clay mineral particles (represented as gray slabs) and PDDA (represented as thin curled lines) on a substrate. (A) PDDA only: (B) PDDA + clay mineral particles in the presence of water: and (C) dried film of PDDA + clay mineral particles.

or *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethylammonium chloride (TMSPA) and exhibits nonlinear optical properties (Fig. 2). The amount of PDDA is the most important parameter, determining the intensity of the second harmonic signal. $I_{2\omega}$. The type of clay and the type of derivatization of the glass substrate seem to have a less pronounced influence on the $I_{2\omega}$ signal. The NAMO molecules are probably adsorbed with their SO_3^- groups toward the positive charges of the PDDA. If the latter molecules are more or less stretched on the surface of the clay, a noncentrosymmetric organization of the NAMOs can be realized. At high PDDA loadings. a stretched configuration of the PDDA molecules is impossible at the clay surface. Chains of PDDA stick out of the clay surface in different directions and adsorb NAMO molecules. The positive charges on PDDA are randomly distributed, as are the NAMO molecules, and the noncentrosymmetric organization fades away, leading to a decrease of the $I_{2\omega}$ signal.

LBL assembling is not restricted to two-dimensional particles such as smectites. Spherical particles, which carry some negative charge, can also be organized in nanofilms. Such particles include Fe_3O_4, CdTe, PbS, and TiO_2.[9] Thus, the assembly can be $(PDDA/Fe_3O_4)_n$ with $n=1-30$. Smectite layers can also be included, thus giving, e.g., $(PDDA/clay/PDDA/Fe_3O_4)_{30}$ or $(PDDA/clay/PDDA/CdTe)_{20}$. The smectite particles have at least two positive effects: avoidance of interpenetration of the Fe_3O_4 or CdTe layers or isolation of the magnetite layers and the CdTe layers from each other, thus strongly influencing the magnetic properties (Fe_3O_4) and the luminescence properties (CdTe) of the nanofilms.[11]

A special case is that of the free-standing nanofilms.[12] In this case, the glass substrate is covered with a layer of cellulose acetate (CA). This layer is partially hydrolyzed, thus generating negative charges, on which PDDA and Fe_3O_4 or PDDA. smectite. PDDA and Fe_3O_4 can be deposited, thus giving films of composition glass/CA/PDDA/Fe_3O_4 or glass/CA/PDDA/clay/PDDA/Fe_3O_4. The film is peeled off, and cellulose acetate is dissolved in acetone without damage to the nanofilm. The latter is freely suspended in acetone and maintains its magnetic properties.

Langmuir–Blodgett Technique (LB)

In the LB technique, a monolayer of amphiphilic molecules, prepared at the air–water interface, is transferred to a substrate, thus giving a monomolecular film. The molecules must be solvable in a volatile, water-insoluble (organic) solvent. but not, or to a very limited extent. in water. Thus. when the solution of the molecules in the organic solvent is spread over the surface of water, the solvent evaporates, leaving a monolayer of molecules at the air–water interface. This monolayer can be compressed and transferred to a substrate. When the molecules are replaced by colloidal. nanosized particles. monolayers of these particles on a substrate are obtained. Smectites are especially well suited for the LB technique. The elementary clay sheets are about 1 nm thick and a few tens to hundreds nm wide and long. In the alkali- or alkaline earth form. they are hydrophilic, but by ion exchange with suitable amphiphilic cations. they become hydrophobic. There are then two ways to prepare monolayers of smectite clay particles by the LB technique.

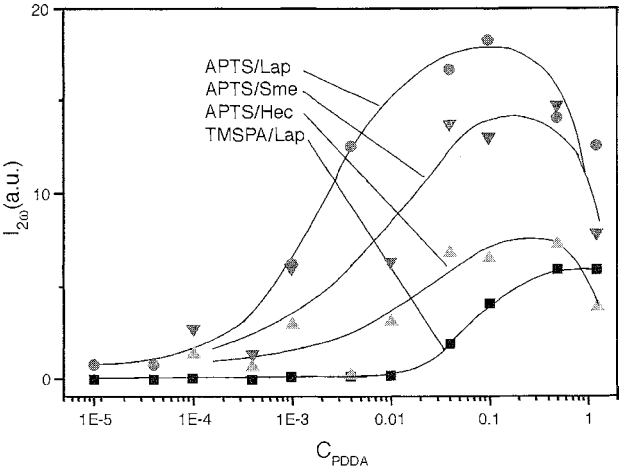

Fig. 2 Intensity of the second harmonic signal versus the amount of PDDA offered in solution (C_{PDDA} in moles/L) for the film: glass/clay/PDDA/NAMO. Lap= laponite; Hec= hectorite; Sme= synthetic saponite: APTS=3-aminopropyltrimethoxysilane: and TMSPA=trimethoxysilylpropyltrimethymammonium.

The first starts with the preparation of a hydrophobic smectite, which forms a colloidal suspension in chloroform. This suspension is spread over the water surface in the EB trough, chloroform evaporates almost instantaneously, and the remaining monolayer of clay particles is transferred to a hydrophobic glass plate.[13] The procedure is laborious because of the preparation of the organophilic smectite. In addition, it is not at all evident that the aggregates of organophilic smectite particles swell in chloroform to such an extent that they break up into individual elementary sheets necessary for the monolayer film formation. An alternative and, in principle, easier approach is schematically shown in Fig. 3. The LB trough is filled with a dilute aqueous suspension of smectite particles. The amphiphilic cations are spread at the air–water interface. The organic solvent evaporates, and the amphiphilic cations undergo an ion exchange reaction with the elementary clay sheets at the air–water interface. Thus, a monolayer smectite sheet–amphiphilic cations is formed at the air–water interface, which is compressed and transferred on a substrate (e.g., glass) by vertical or horizontal dipping. The advantage of this procedure is that the preparation of the organoclay is avoided. A dilute aqueous suspension of a Na^+-smectite guarantees that the smectite suspension contains a large fraction of individual eleinentary clay sheets. This is proven by visualization of the smectite particles in the monolayer film with AFM.

The technique was developed with octadecylammonium cations as amphiphiles. However, short-chain, water-soluble alkylammonium cations can also be used.[14,15] In that case, some of the alkylammonium cations are picked up by the eleinentary clay sheets and stabilized at the air–water interface and some dissolve in the aqueous subphase. In any case, the alkylammonium-smectite sheet can be compressed at the air–water interface and transferred to the substrate. This proves that the ion exchange reaction between the smectite particles and the alkylammonium cations at the air–water interface is an extremely fast and selective reaction. Multilayers can be prepared, and their formations can be followed by measuring the intensities of the C–H stretching vibrations of the ion-exchanged alkylammonium cations. The linear increase of the intensities with the number of deposited layers indicates that, on average, the same amount of eleinentary clay sheets and alkylammonium cations are deposited in each layer.

If functional films are to be made. the alkylammonium cations have to be replaced, at least partially, with functional molecules. Thus, if the optical isomers or the racemic mixture of $[Ru(phen)_2(dcC_{12}bpy)](ClO_4)_2$ (phen=1.10-phenanthroline; $dcC_{12}bpy$=4,4′-carboxyl-2.2'-bipyridyl didodecylester). is used as an amphiphile. monolayer and multilayer films are obtained that have nonlinear optical properties.[16] That means that they generate a second harmonic signal upon illumination with a Nd-YAG laser. When the Ru complex is diluted in octadecylammonium cations. the signal intensity increases quadratically with the number of layers deposited. indicating that films with noncentrosymmetric organization of the Ru complexes are realized. This is not the case in the absence of octadecylamrnonium cations. The latter observation suggests that in the absence of octadecylammonium cations, the Ru complexes form aggregates at the clay surface. In principle then, one can control the organization of amphiphilic cations at the smectite surfaces and tune it into the desired direction. Amphiphilic dyes can also be used. If the right couple of dyes is used, energy transfer can be realized in the films. This has been shown for 3.3'-dioctadecyloxacarbocyanine and octadecyl-rhodamine B.[17] The former is the donor. Upon excitation around 460 nm, the fluorescence of rhodamine B in the region 500–580 nm is monitored. The advantage of the clay films is that they stabilize the dye molecules against degradation by light and that the organization of the molecules can be monitored in the presence of octadecylamrnonium cations.

With a single layer of elementary clay sheets and a single layer of adsorbed molecules, one can now start studies of the clay sheets with x-ray techniques,[18] vibra-

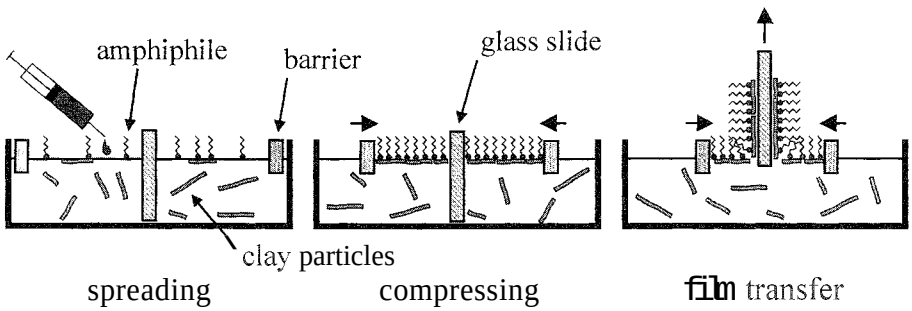

Fig. 3 The preparation of clay mineral-amphiphilic cation films by the Langmuir–Blodgett method.

tional and electronic spectroscopies. The same holds for the adsorbed molecules.

Highly Dispersed Organoclays

One of the essential conditions for formation of smectite nanofilms is the presence of elementary clay sheets in the system. This is not only the case for LB and SA films, discussed above, but also for a number of modern developments in fabrication of devices and formulations of polymeric materials. Thus, Ecke and Decher[19] fabricated organic light-emitting devices (OLEDs) with an isolating barrier of single sheets of montmorillonite in the active medium between the two electrodes. This isolating montmorillonite layer plays a key role in the electrooptical properties of the device, increasing the light output. But the exact mechanism of action of the isolating montmorillonite layer is not yet known.

Single clay layers or 100% dispersion of the clay in polymer matrices is also the ideal situation in which to obtain nanocomposite materials with enhanced mechanical properties. This was achieved by researchers at the Pennsylvania State University[20] with a semifluorinated organic surfactant to modify the montmorillonite, which is subsequently compounded with polypropylene (functionalized with, e.g., maleic anhydride). In The Netherlands,[21,22] the clay is intercalated with polyethyleneoxide block copolymer. This material is swollen in the monomer (methylmethacrylate). which polymerizes to poly(methylmethacrylate) by radical polymerization. The swelling ensures complete dispersion of the clay.

Organophilic clays can also be homogeneously dispersed in coatings, giving them improved corrosion resistance, thermal stability. and barrier properties (decreased permeability toward water and oxygen). If the organic modifier of the clay is a dye, improved color stability against. e.g., UV irradiation, is obtained.[23,24]

Organoclays in an adequate solvent provide microenvironments for formation of quantum-sized semiconductor particles, such as CdS and ZnS.[25] Finally, they are excellent adsorbents of pesticides, which leads to improved stability of the pesticides: higher resistance against photodegradation and reduced leaching into water.[26]

CONCLUSION

It has been convincingly shown that functional nanofilms on the basis of smectites can be prepared. Properties that must be under control are complete swelling of the clay minerals into individual elementary sheets, selective and fast ion exchange of functional molecules, and organization of the molecules at the clay surface.

These nanofilms open two directions of research. First and for the first time they allow the fundamental study of single elementary clay mineral sheets and of their adsorbed molecules. Second. there is still a long way to go from nanofilms to devices. These hurdles can only be solved by research. Thus, there is a bright future for more research on clay minerals.

INTRODUCTION

Many molecules tend to be involved in a pattern of several intermolecular interactions of comparable relative strength. the structure of the resulting aggregated system being determined by the balanced cooperation of these interactions. The relative relevance of these interactions often depends on the properties of the partners with which the molecules are connected. This is the case of molecules that can give rise to weak interactions only. In contrast. there are molecules with interactions that are dominated by particular associative forces that induce the self-assembly of an organized network with specific architectural or functional features. In 1991. James D. Wuest proposed naming these molecules tectons. from the Greek, τεκτων. which means "builder" and is the root of such words as architect."] Water is among the simplest tectons.[2]

Tectons interact with their neighbors in strong and well-defined ways, as they inherently possess the molecular structure and intermolecular recognition features to predictably self-assemble into crystalline networks. The interactions pattern of a tecton is robust enough to be exchanged from one network structure to another, thus securing generality and predictability in self-assembly processes. Within their structure. tectons contain the recognition sites and a specific assembling algorithm that will operate when complementary sites are available. Tectons can be considered to consist of peripheral "sticky sites" that direct molecular association, as well as of scaffolds that hold the sticky sites in pa ticular orientations. Together, these features help tectons control how their neighbors are positioned, despite the competing effects of other intermolecular interactions that are weaker and less specific."] Tectons must fulfil energy and structural criteria (interaction robustness and scaffold geometry. respectively). An effective method for making tectons is to attach selected functional groups that are known to participate reliably in specific intermolecular interactions to geometrically suitable molecules."" Various interactions are used to direct association. thanks to their strength, directionality, and specificity. e.g., metal coordination. hydrogen bond. and halogen bond.

The concept of tecton can be better understood if contrasted with the concept of supramolecular synthon. Paraphrasing Corey's historic definition of synthon,[5] Desiraju defined that a supramolecular synthon is a structural unit within a supermolecule that can be formed or assembled by known or conceivable synthetic operations involving intermolecular interactions.[6] The supramolecular synthon concept is backwardly oriented (i.e., is useful in supramolecular retrosynthesis) and focuses on the part of a supermolecule that is formed or can be formed through an intermolecular interaction. The tecton concept is forwardly oriented (i.e., is useful in supramolecular synthesis) and focuses on a molecule that predictably gives supermolecules, thanks to its tailored structure and robust binding sites.

Various derived terms were also introduced. Molecular tectonics is the art and science of supramolecular construction using tectonic subunits[7] and describes the chemical construction of systems with an order higher than the molecular scale."" The term "metallatecton" is used to indicate tectons having a metal ion coordinated in their core,[9,10] but its employment could be extended to indicate all the tectons where a metal is present [see the discussion of metal coordination presented later in this article[11,12]]. The term tecton is also used to address synthetic polymers [13] and DNA strands.[14] When structures of inorganic frameworks are considered. the word tecton is used to address oligomeric groups of polyhedra that enable a desired topology to be formed.[15]

TECTONS

Metal-ligand dative bonds are always highly directional. While their strength spans over a wide range. depending on the nature of the species involved, in most cases. metal coordination overpowers a number of weaker interactions. Being a dominant supramolecular interaction. it is perfectly tailored for the design and synthesis of tectons. The studies of Peter J. Stang on the self-assernbly-driven formation of high-symmetry coordination cages are simultaneously elegant in their simplicity and in their complexity and are particularly well-suited for a case

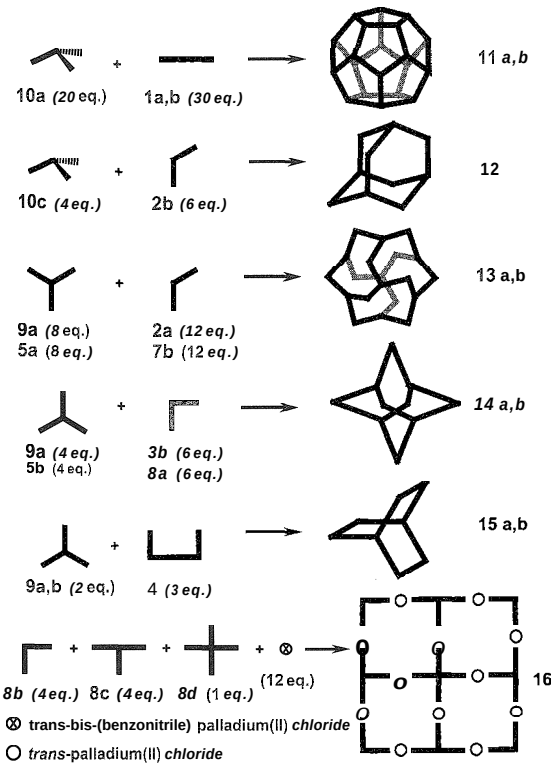
history on tectons exploiting inetal coordination."[1,12] Stang's paradigm is the recognition between two complementary tectons. one bearing the metal sites and the other bearing the ligands. Two libraries of tectons were prepared (Scheme 1). Platinum atoms are typically used as metal sites, and the nitrogen atoms of pyridine moieties are used as ligand sites. Less frequently. palladium atoms and cyano groups are also employed with comparable success.[16] Metal tectons (1–5) and ligand tectons (**6–10**) can be classified as functions of the recognition sites number; namely. they can be differentiated into ditopic tectons (**1–4**, 6–8a.b). tritopic tectons (5, 8c, 9, P0), and tetratopic tectons (8d). A further differentiation can be made in relation to the angle between the recognition sites. Ditopic 180° tectons are typically obtained by the 1,4-difunctionalization of a benzene ring (1a) or by the 4-functionalization of a pyridine (6a). If metric engineering requires the distance between the recognition sites to be tuned, ethylene. acetylene. and benzene spacers are used (Pb, **6b**,**c**).[17] Ditopic 120° tectons are obtained by interposing an sp^2 atom between two para-substituted benzenes (2a) or pyridines (7a). Siinilarly, ditopic 108" tectons are obtained by intei-posing an sp^3 atom (2b, 7b,c). Ditopic 90° ligand tectons are formed by appending two 4-pyridyl residues in positions 5,10 of a porphyrin system (8a,b). When a third and fourth 4-pyridyl substituent are added in positions 15 and 20 of the porphyrin scaffold, the tritopic and tetratopic 90" tectons **8c** and **8d** are obtained. respectively.[18] The 90° ditopic metal tectons (3a,b) are obtained by resorting to dicoordinating platinum or palladium ions. Metal tectons with different topicity and geometry are obtained by using other metals with different numbers or geometries of coordination. For instance, Ag(I) is frequently used as a ditopic 180° metal tecton in the coordination of pyridyl ligands[19] and Cu(I) as a tetratopic tetrahedral tecton for oligo(2,2′-bipyridine) ligands.[20] Tritopic tectons with either a planar (5 and 9) or a tetrahedral (10) arrangement of the "sticky sites" were also developed. The 1,3,5-trisubstitution of a benzene core is the standard approach to tritopic planar tectons, while the trisubstitution of a methane (10a–c) or adamantane (10d) moiety affords tetrahedral tectons. Once again, their metrics are controlled by using rigid acetylene and phenyl spacers.

By combining tectons 1–10 as the bricks of a molecular Lego, Stang obtains several cage molecules, and among them, some of the Platonic and Archimedean solids (Scheme 2). On self-assembly. the pyridyl or nitrile nitrogen atoms replace the triflate, or nitrate, residues at the metal. Dodecahedranes **11** are formed by self-assembly of 30. 180° ditopic tectons **1** and 20, 108° tritopic tectons 10, yields being nearly quantitaiive independent from the metric of the employed ditopic tecton. The same three-dimensional geometries can be obtained



Scheme 2

by switching the donor and acceptor sites between ditopic and tritopic tectons. For instance. cuboctathedrons 13 and truncated tetrahedrons 14 can be obtained by self-assembly of metal tritopic tectons ***5*** with ligand ditopic tectons **7** and 8 or of ligand tritopic tectons 9 with metal ditopic tectons 2 and **3.** Selective self-assembly of different tectons can also occur. When 12 equivalents of *trans*-bis(benzonitrile)palladium(II) chloride are mixed with four equivalents of '1-shaped" tectons 8b. four equivalentss of ''T-shaped'' tecton 8c, and one equivalent of "X-shaped'' tecton 8d, a 21-membrered discrete square array is obtained, where the "L-shaped" tectons form the corners of the array, the ''T-shaped'' tectons the sides, and the ''X-shaped'' tecton the central core.[18]

Hydrogen bonding is the most frequently occurring interaction in self-assembled systems of living organisms. forcefully indicating the outstanding power and effectiveness of the interaction. It is not surprising that several tectons were developed by exploiting hydrogen bonding. As described above, tectons based on metal coordination bear donor or acceptor sites. On the other hand. tectons exploiting hydrogen bonding bear both donor and acceptor sites, and it is important that an equal number of complementary sites be present so that robustness and predictability during the self-assembly process are maximized. In most cases, tectons exploiting hydrogen

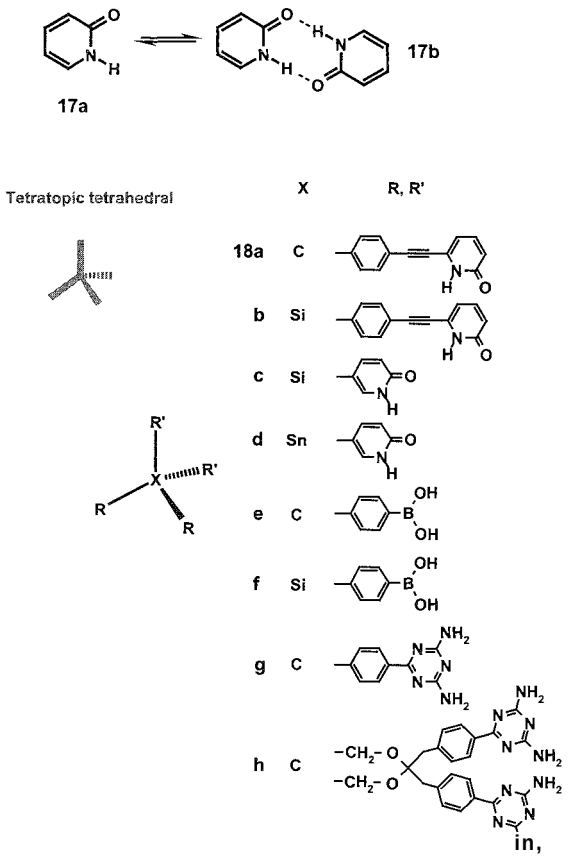
bonding were built by endowing them with the ability to participate in multiple intermolecular hydrogen bondings. Simple. well-known hydrogen-bonding motifs, which were carefully studied and shown to be particularly strong and reliable, were selected and repeatedly inserted on a core to construct the tectons via a modular approach.

In the solid state and in solution, 2(1*H*)-pyridinone (**17a**) shows a well-established tendency to self-associate and to form cyclic hydrogen-bonded dimers (**17b**, Scheme 3). This preference is used effectively to control the association of more complex derivatives that incorporate multiple 2-pyridiaone groups[1] and have some of the desirable properties of zeolites, including high structural integrity, potential large void volumes, and adjustable microporosity. Compound **18a** is a tetratopic and tetrahedral tecton that have four 2-pyridone groups appended to a methane core through phenylacetylene spacers. The intermolecular hydrogen bondings of these tetrahedrally oriented pyridones direct the self-assembly of a diamandoid network. The enormous voids in this structure are filled by a combination of interpenetrating, independent, diamondoid networks and enclathrated molecules of carboxylic acids (acetic, propionic, butyric, or valeric acids). The hydrogen-bonded networlts are porous enough to permit the exchange of the acid (e.g., valeric by acetic acid) and robust enough to remain intact. Compound **18b**. where the tetrahedral core is a silicon atom, also crystallizes in diamondoid interpenetrated networks. The Si—C covalent bond is approximately 0.33 Å longer than the C—C bond, and the intertectonic separation in the crystal of **18b** is approximately 0.7 Å larger than that in the crystal of **18a**. The structural similarity between **18a** and 18b extends also to functional properties, as **18b** also enclathrates carboxylic acid molecules in the void channels of the crystal.[7] To have contracted diamandoid networks, the tecton **18c** was constructed. Its smaller size results in a decreased intertectonic separation (11.7 Å) and reduced interpenetration (twofold in **18c**. sevenfold in **18a**. eightfold in **18b**) but leaves unchanged the ability to selectively enclose carboxylic acid guest molecules in the void channels. When the silicon core of **18c** is replaced by a more flexible tin core (**18d**), the direct hydrogen bonding of pyridone rings still links each tecton to four neighbors, but because the core is more susceptible to angular deformation. cyclic quartets are present instead of diamondoid networks. Nevertheless, functional properties are retained. and carboxylic acid molecules are once again enclosed in the channels.[21]

Also, simple aryl boronic acids form cyclic hydrogen-bonded dimers in the solid state. Tetraboronic acids **18e,f**, bearing four $-B(OH)_2$ groups oriented tetrahedrally by cores derived from tetraphenylmethane and tetraphenylsilane, afford isostructural. fivefold interpenetrated, and diamandoid networks held together by hydrogen bondings of the $-B(OH)_2$ groups. Both networks present void channels available for the inclusion of disordered guests, and their crystallization affords inclusion compounds of approximate composition $18 \cdot 5CH_3COOC_2H_5 \cdot xH_2O$.[22]

The 2,4-diamino- and the 2.4.6-triaminotriazine (melamine) motifs proved particularly effective in tecton construction. The pentaerythritol derivative **18g**, having four 2,4-dimethylaminotriazine residues appended to the tetrahedral core through flexible spacers. affords crystals where, despite the eightfold interpenetration, 60% of the volume is available for including guests. which can be exchanged quantitatively without loss of crystallinity.[3] A similar inclusion behavior is shown by other tectons bearing four tetrahedrally oriented 2,4-diaminotriazine residues, e.g., **18h**.

In synthetic chemistry; the reactivity profile of a functional group is inherently invariant, as only some of its marginal aspects are affected by the overall structure of the molecule in which the functional group is inserted. Similarly. the interactions pattern of a tecton is strong enough to be exchanged from one network structure to another. but some slight changes may occur as a function of the properties of the partner with which it is interacting.

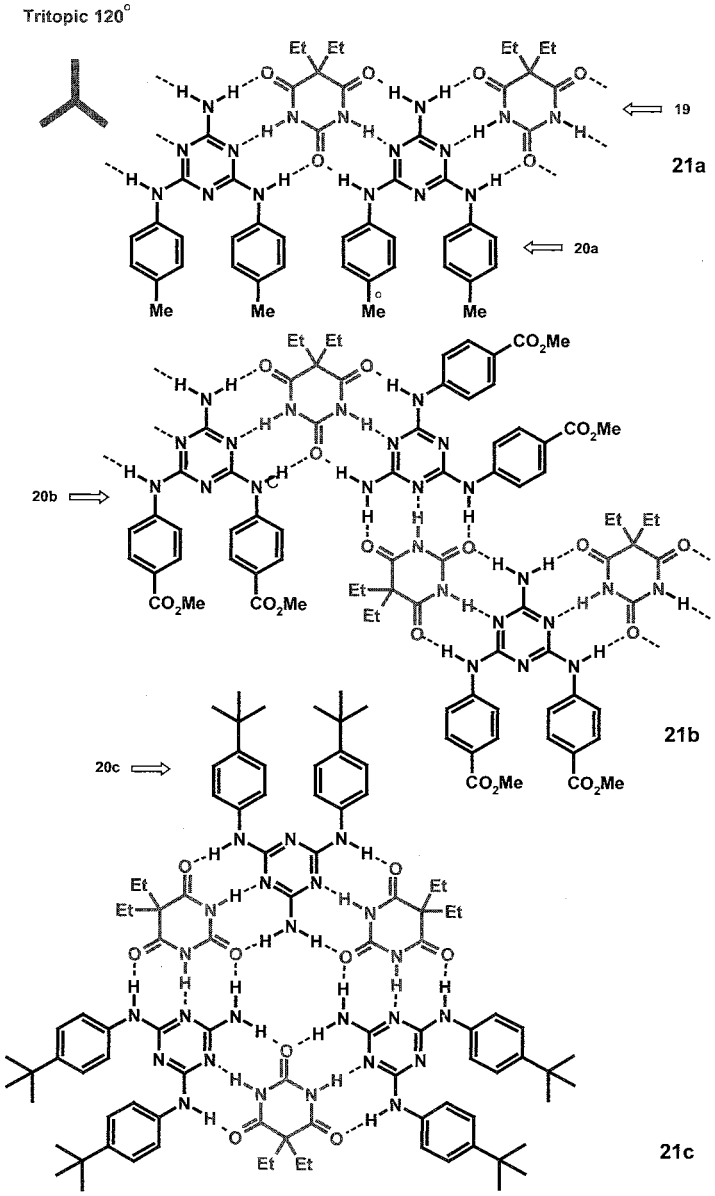


Scheme **3**

The pairing of melamines and barbituric acids, two tritopic 120° tectons, gives a telling example.[23] 5,5-Diethylbarbituric acid (**19**) cocrystallizes with *N*,*N*′-bis (4-methylphenyl)melamine (**20a**) to form the linear, polymeric, tape-like array **21a** (Scheme 4). On replacement of the methyl group of the melamine subunit with the sterically bulkier carbomethoxy substituent, as in **20b**, the crinkled tape **21b** is generated in the solid to relieve unfavorable lateral nonbonding interactions that would be present in a hypothetical linear tape. Placing highly encumbering *tert*-butyl substituent on the melamine subunit, as in **20c**, effects the production, in the solid state, of the rosette-like supermolecule **21c**.

All tectons described above give rise to nonionic hydrogen bonds. Other tectons form intermolecular recognition patterns dominated by directional hydrogen bonds and strong but less directional ionic interactions. This is the case, for instance, of cyclic *bis*-amidinium dications interacting with dihydrogenophosphate anions, iso- or terephthalate dianions, fumarate, pyromellitate, or acetylenedicarboxylate dianions.[24]

Halogen bonding[25] is another directional, strong, and selective interaction that allowed several iodo-substituted compounds. and to a lesser extent their bromo analogues, to work as reliable tectons. The "sticky sites" here are the halogen atoms. Chlorine atoms give rise to



weak halogen bondings that do not dominate the associative forces driving self-assembly processes. Bromine atoms give stronger halogen bonds, but in the reported tectons, the bromines are usually appended to electron-withdrawing scaffolds in order to strengthen the interaction.[26] Iodine atoms give strong halogen bonds, and a wide diversity of tectons was described where the iodines were bound to cores, which are quite different from the structural point of view.

Strategies employed to prepare halogen-bonding based tectons strictly parallel those described above for metal-coordination-based tectons. 1,4-Difunctionalization of a benzene ring affords ditopic 180° tectons (**22a–c**, Scheme 5). Perfluoroalky chains, due to limited conformational flexibility, behave as rigid bars, and α,ω-diiodoperfluoroalkanes **23a–d** are ditopic 180° tectons for which the metric can be controlled by simply varying the difluoromethylene units number. Ditopic 108° tectons are obtained by interposing an sp^3 atom between two pam-substituted benzenes (**24a,b**), and 1,2-difunctionalization of a benzene ring affords ditopic 60° tectons **25a,b**. Tetrabromomethane 26 is a tetratopic and tetrahedral tecton.

Several one-dimensional and infinite chains are formed when ditopic halogen tectons 22–25 interact with ditopic electron donor tectons (Scheme 6). Noncovalent copolymers **27a–h** are formed when **22a–c** interact with dipyridyl 6a and its analogues **6b** and **6d**, where an (*E*)-ethylene and ethane spacer separate the two pyridine rings. X-ray analysis of these one-dimensional chains shows a remarkable crystal packings arrangement consistent with the self-assembly being dominated by the algorithm of the starting tectons.[27,28] Infinite chains are also obtained on the interaction of **6a** with the ditopic halogen tectons **24b** and **25a,b**. Because the geometry of the supramolecular chains is controlled by the geometry of the "sticky sites" on starting tectons, the noncovalent copolymers given by **24b** and **25a,b** show a wave-like or screwed arrangement rather than the linear arrangement of **27a–h**. 1,4-Diiodobenzenes **22a,c** also afford one-dimensional infinite chains when interacting with ditopic tectons, where the electron donor sites are oxygen atoms (e.g., 4,4′-dipyridyl *N*,*N*′-dioxide and 1,4-dinitrobenzene, **27i,j**)[27,29] or sulfur atoms (e.g., 2-mercapto-1-methylimidazole, **27k**).[30] Similarly, α,ω-diiodoperfluoroalkanes **23a–d** give infinite chains **28a–g** upon interaction with a wide variety of ditopic tectons, where the electron donor sites are either neutral (e.g., primary, secondary, and tertiary amines, anilines, pyridines, ethers) or anionic (e.g., fluoride or iodide anions).[31] In all reported structures, the perfluoroalkyl chains adopt a twisted *trans* conformation and behave as rigid, linear spacers of the two terminal "sticky sites."

When the tetratopic and tetrahedral halogen tecton 26 interacts with an electron donor with a similar topicity and geometry, for instance, hexamethylenetetramine, diamondoid networks are obtained.[6] The tecton **24a** bears two iodine atoms (halogen-bonding donor sites) and two nitro groups (halogen-bonding acceptor sites) that are oriented after a tetrahedral geometry. On crystallization, the system behaves as a tetratopic and tetrahedral tecton and affords a fivefold interpenetrated diamondoid network.[32]

Finally, tectons based on two other interactions types were reported.

The van der Waals interactions-driven recognition processes between diconcave and diconvex tectons afforded one- and two-dimensional inclusion networks.[33] Calix[4]arene units in the cone conformation offer preorganized and tuneable hydrophobic pockets that include a wide variety of neutral molecules. Fusion of two calix[4]arene units in the cone conformation and in a face-to-face arrangement (by bridging their eight OH groups with two silicon atoms), gives diconcave tectons, the "sticky sites" of which are the two cavities arranged in a divergent fashion. Mexadiyne and p-xylene are used as diconvex tectons. Being included in the calixarenes cavities thanks to van der Waals interactions, these hydrocarbons work as connectors and form one-dimensional networks.

With metals, tetracyanoethylene can work as a polydentate ligand via several different bonding modes. In addition, with a number of organic π systems, it sustains π–π stacking interactions as a result of a combination of electrostatic and charge-transfer interactions. In this last context, it was considered a tecton prone to give, in the

CONCLUSION

The term tecton does not address a "yes-or-no phenomenon." It is applied to molecules with interactions that thanks to energetic and structural characteristics, are dominated by particular associative forces that induce the self-assembly of organized networks with specific architectural or functional features. The term pinpoints aspects of the suprainolecular behavior of molecules. As is always the case in behavioral matters and in dominance affairs, the use of the term is somewhat subjective. This becomes more true when the extremity of weak interaction patterns is approached, and the possibility of exchanging the pattern from one network structure to another becomes more remote. For this reason and with the aim to avoid a biased selection, the tectons described in this article were. in most cases, drawn from the compounds already named in this way in the primary scientific literature.

Nevertheless, the term can be applied and should be applied to many other molecules and whenever the pertinent aspects of the supramolecular behavior of molecules have to be stressed. For instance. purine and pyrimidine bases are reliable tectons. as their intermolecular recognition patterns are predictably defined by the well-known hydrogen bonds to which they give rise. However, to the best of our knowledge, they were never named in this way. The introduction of the term tecton declared the need for molecules with predictable and invariant self-assembly features. Identifying new tectons can be equated to devising molecules to be discussed in a graduate textbook of supramolecular chemistry or to be included in a hypothetical "Aldrich catalogue for supramolecular chemistry..

The Template Effect

Daryle H. Busch
University of Kansas, Lawrence, Kansas, U.S.A

INTRODUCTION

Template reactions have been used to produce new molecules with remarkable chemical architectures." The field of macrocyclic ligand chemistry and the closely related field of cage-like ligand chemistry had their beginnings in their template synthesis as the new concept ligands of their era. As the sophistication of templates grew, interlocked molecular structures emerged, including catenanes (interlocked rings), rotaxanes (axle inolecules locked in cyclic molecules by large end groups), oligocatenanes and oligo-rotaxanes of various kinds, and molecular knots (see Fig. 1).

DEFINITION AND ILLUSTRATION OF THE TEMPLATE EFFECT

By definition,[2] "a molecular template organizes an assembly of atoms, with respect to one or more geometric loci. in order to achieve a particular linking of atoms." Such a template plays an active role in the construction of a new molecular entity, and this involves two essential features: 1) the template organizes some specified assembly of atoms, thereby influencing their chemical reactions; and 2) the results of this organization are found in some spatial, geometric. and topological relationships built into the structure of the new molecule.[2,3]

The basic concept of the template effect is illustrated by the first example of such a reaction (Fig. 2). In this seminal case, the template effect results from the binding to the nickel(II) ion of the ligand that is precursor to the macrocyclic product. The ideal behavior results from the fact that the tetradentate ligand is just the right size to wrap around the metal ion (complementarity); the sulfur nucleophiles of the ligand are still active while bound to the metal ion, while the nitrogen donors are not; and the length of the xylylene unit in the α,α-dibromo-*o*-xylene reagent is right for spanning between the two sulfur nucleophiles (again, complementarity). Finally. the coordination sphere of the metal ion has an appropriate geometry, square planar, bringing the sulfur nucleophiles into adjacent locations. Here is what happens. The metal ion wraps the long ligand molecule about itself, binding to all four donor atoms, S and *N*. and bringing the two, still reactive, terminal donors (sulfur atoms) into adjacent positions. This new metal complex encounters one of the α,α-dibromo-*o*-xylene molecules, and a bound sulfur nucleophile displaces Br from one end of that reagent. This produces an intermediate in which the second active functional group, the second sulfur atom. is ideally located to displace the second bromide, closing a ring that now encircles the metal ion. Thus, a neighboring group effect favors ring closure and formation of only a single product in a system that ordinarily would have given a useless mixture of products, including linear oligomers and polymers, rings of various sizes, and mixed oligomer/ring structures.

This first example not only illustrates the template effect, but it also shows certain elements of a molecular template. The metal ion serves as an anchor that holds certain groups of atoms in place, and it also bends a long linear molecule into what is usefully termed a molecular turn. These are basic elements of a molecular template. Anchoring the ligand to the metal ion in the form of a molecular turn facilitates tying the ends of the turn together with a complementary reagent; and that results in the formation of a large ring that encircles the metal ion. It follows that the essential elements for the formation of a macrocycle by a template reaction are an anchor, a molecular turn, and its complement.

A less obvious part of the template concept is that. once formed, the products of these template reactions are not dependent on the template that guided in their generation. Thus, the macrocyclic ligands formed by template reactions of the kind shown in Fig. 2 can be removed from their metal ions and moved to other chemical applications. The great promise of the template effect rests on that fact. Templates facilitate the synthesis of complicated molecular architectures composed solely of the light atoms typical of organic molecules.

KINETIC AND THERMODYNAMIC TEMPLATE EFFECTS

Two different kinds of template effects have long been known. One of these is an equilibrium phenomenon and is

"For a brief history of the field see Ref. [1]

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012668

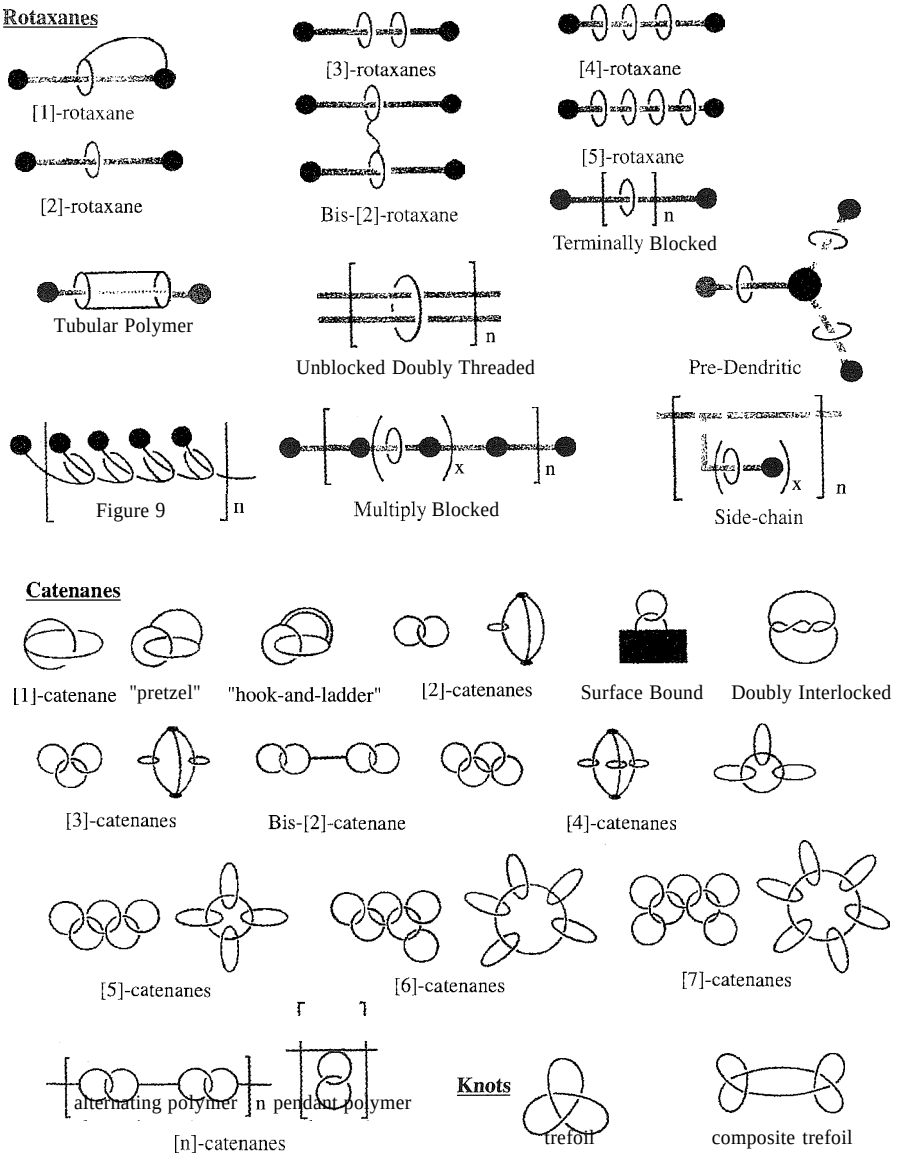

Fig. 1 Rotaxanes, catenanes, and knots formed by template reactions.

therefore of thermodynamic origin, while the other is mechanistic: or kinetic, in its fundamental nature. The example in Fig. 2 exemplifies the kinetic template effect. As described, the template controls a sequence of reaction steps by constraining reactant molecules. Examples of the thermodynamic template effect were first invoked when, as a result of a chemical reaction, a metal complex of a new ligand was discovered, and that new ligand was known to be unstable in the absence of the metal ion.[4] The organic components chat form the new ligand are capable of equilibrating to form a variety of products, but one of them binds to the metal ion much more strongly than do the others. Consequently, the metal ion sequesters that product and shifts the equilibrium in the direction of its for-mation.

COMPONENTS OF **TEMPLATES**

Maximum value of templates will be achieved only through an intimate understanding of how they function. As pointed out in the discussion of Fig. 2, a template for macrocycle formation need only consist of a molecular turn, an anchor, and a complementary reagent to link the two ends of the turn. Anchors and turns recur repeatedly in template reactions and are among the most important

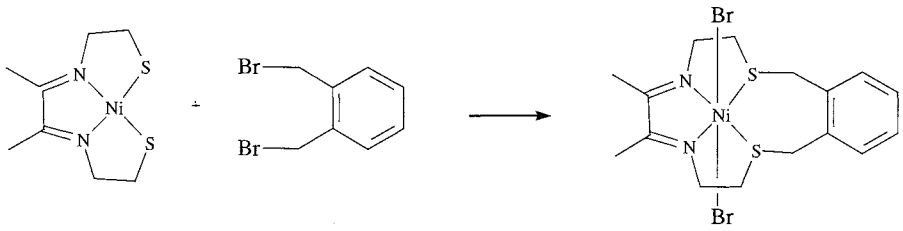

Fig. 2 The seminal example of a template reaction; the product is a coordinated macrocycle.

basic elements of a template.[5] Shown in Fig. 3 are a number of important examples. In Fig. 3a, two turns are united by an anchor to create another basic element of templates. a crossover. Crossovers template the formation of catenanes (interlocking rings) and rotaxanes (axles threaded through rings. with the ends of the axles blocked). If a linking group makes a ring from one of the turns, a rotaxane is formed. If two linking groups convert both turns to rings, a catenane if formed. Shown in Fig. 3b is how closing a fused pair of turns, using a fused linker, produces a bicycle, or cage-like molecule. Linearly connected pairs of turns that are mutually inverted can be used in pairs, with pairs of anchors, as a template for tying a trefoil knot (Fig. 3c). Further doubling of the number of turns and anchors to eight and four: respectively. led to the formation of molecules having the configurations of square knots and granny knots. In addition to anchors, turns, and crossovers, threading are elements of general applicability in templates. Threading of an axle molecule through a cyclic molecule obviously produces a rotaxane. Almost as simply; if a turn is threaded through a ring, and the two ends of the threaded turn are then linked, a catenane is formed. Further. a second way to generate a trefoil knot is by threading through a loop created by a crossover using a single linear molecule. The product is a mathematically acceptable knot if the ends of the molecule are then joined. Multiple crossovers anchored onto a single ring lead to oligocatenanes.

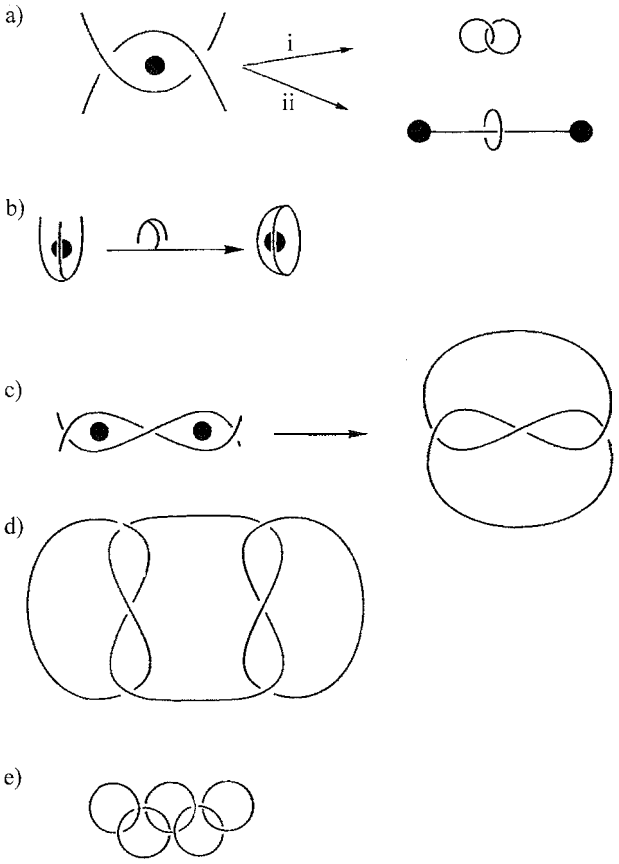

Fig. **3** Elements of molecular templates: (a) a crossover reacts with a linker to give (i) a catenane and (ii) a rotaxane; (b) a fused turn closed with a fused linker gives a macrobicycle; (c) two anchors and two pairs of inverted ditopic turns template a trefoil knot: (d) composite knots require two two-anchor templates; and (e) oligocatenanes can be formed with multicrossover templates on a single anchor.

VARIOUS USES OF THE TERM ""TEMPLATE"

The word "template" occurs in the vocabularies of biochemists, materials scientists, synthetic chemists, and elsewhere. reflecting broad usage in the chemical literature. Here, template refers to controlling the outcome of a chemical reaction, commonly in chemical synthesis, by organizing components that are being united or rearranged in the templating process—all on the molecular scale. Thus. the formation of very small, but macroscopic, fibrils and tubules within molds provided by the pores of a membrane does not qualify as the product of a molecular template reaction—the scale is not molecular. On the other hand. the astounding control over pore size in aluminosilicate molecular sieves[6] and the molecularly imprinted macroporous polymers[7] represent limits of the realm of molecular templates. In biology, the word has been applied to the biosynthesis of DNA and other natural

products. However. the obvious extension into the realm of continuous hydrogen-bonded supramolecular arrays is supramolecular chemistry, but not template chemistry. Beautiful and complicated architectures in which metal ions participate in their backbones, including polymers. cages, catenanes of metallocycles, inetallo-macrocycles. and dendrimers make use of the metal ion coordination spheres in determining supramolecular structures. but they do not involve template reactions. Fisher's "lock and key" concept (e.g., enzyme/substrate selectivity) is sometimes suggested as the equivalent of the molecular template. That is incorrect; the key is the complement of the lock, and this is an excellent example of complementarity,[8] not a template. Also, foundational components upon which other moieties may be appended are sometimes referred to as templates. Such components might better be called platforms; one is adding superstructure, not conducting a template reaction. The critical aspects of a template reaction are the creation of a structure that is otherwise difficult to produce, often for reasons of entropy. and that would still exist if the anchoring component were removed.

PRIMARY EXAMPLES

Metal Ion Templates

The seminal example (Fig. 2) produced a family of macrocyclic complexes in high yield with no apparent byproducts, in accord with the expectations of a well-designed template.[b] This was followed by the use of inetal ion anchors for the template syntheses of hundreds of macrocycles varying from nine-membered tridentate rings, through a plethora of tetradentate rings. to 24-membered and greater rings with as many as eight donors, that is best known for binding two inetal ions simultaneous ~Macrobicycles were first produced using metal ion templates[10] to make the cage complexes. Many hexadentate cage ligands having only saturated amine donors were produced by template reactions.[b] Cyclidenes, bicyclic ligands of a different kind, were produced using inetal ion templates.[12] They are bicycles, but they contain two distinctive cavities, one having four donor atoms that binds a metal ion. while the second is essentially hydrophobic and provides a cave-like site for binding a second species, either a ligand for the metal ion or an organic molecule that might be a substrate.

The first template synthesis of catenanes[13] made use of ligands that were turns and a copper(I) ion as anchor (Fig. 4). Terminal phenolic functions provided the reactive sites to combine with linking groups and produce two interlocked inacrocycles, a catenane. The same copper(I) anchor and the same molecular turns were used in the tying of knots[b] using multicentered templates (Fig. 5).

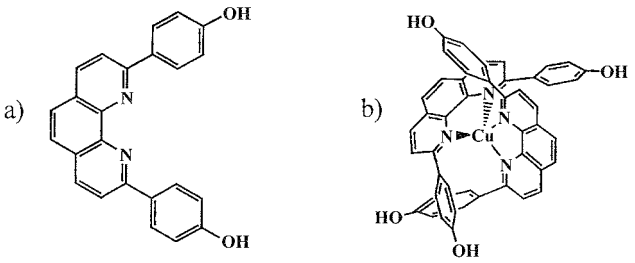

Fig. 4 Sauvage's template composed of two molecular turns bound to a copper(I) anchor: phenolic functions were reaction sites for ring closures and catenane or rotaxane formation.

Hydrogen-Bonded Templates

Although elegant results were obtained with metal ion templates, the ultimate applications of rotaxanes. catenanes, knots. and the production of the as yet unavailable polymers. molecular braids, or woven molecular materials will depend oil simpler materials, such as those presently found in synthetic fibers. Arguably the most likely candidate for an anchor in such long-term developments will be a proton. or multiple protons, anchoring axles, or turns through hydrogen bonding. The early demonstration that the ammonium ion forms a complex with a crown ether was harbinger to these systems.[15] The difficulty of the threading process was emphasized by low yields in the early work, for example. a system that yielded 30% for a [2]rotaxane gave only 10% for the corresponding [3]-rotaxane.[16] For high-yield syntheses. the threading and the blocking reactions must be efficient. Such a successful synthesis was reported in 1998, with the yield of a [3]-rotaxane at 84%.[17]

A high dilution reaction that might have been expected to produce a macrocycle, serendipitously yielded an entirely new kind of catenane (Fig. 6) and led to the characterization of a different family of hydrogen-bonded templates.[18] Structural and isomer studies led to the conclusion that the threaded macrocycle is the critical intermediate in the catenane formation. making this a classic template process.[19]

Templates with More Complex Anchors

Short tube-shaped cyclodextrins, consisting of six (α), seven (β), or eight (γ) x-1.4-linked D-glucose units. act as

[b] An earl) review of macrocyclic ligand chemistry. (Ref. [9].)

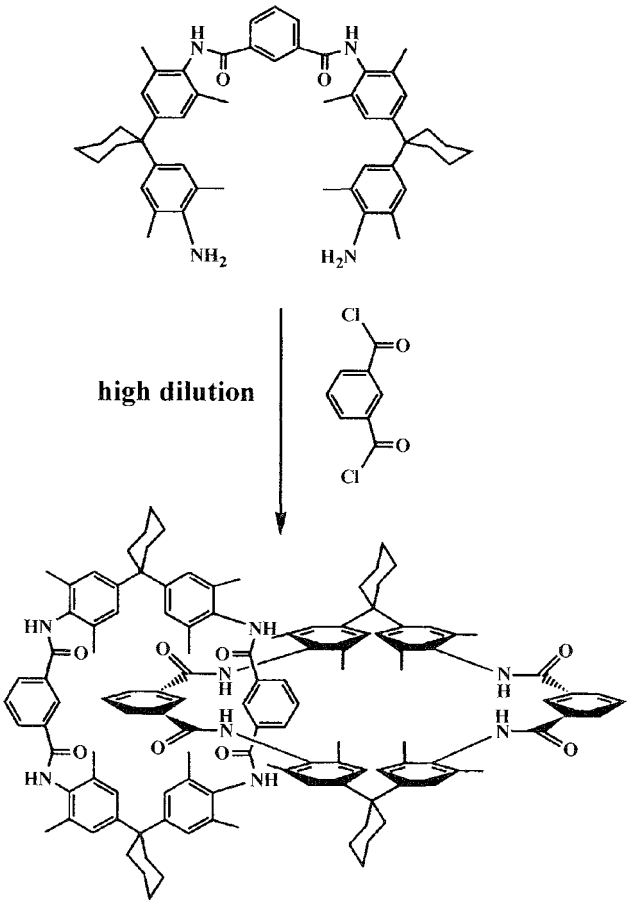

Fig. 6 The hydrogen-bonded amide template and its first catenane product.

anchors in a broad range of template reactions. The cyclodextrins bind an axle molecule within their cylindrical cavities through a combination of weak intermolecular interactions such as hydrophobic effects, van der Waals interactions, and hydrogen bonds, the latter at the periphery of the cavity. Although their guest–host complexes have been studied for many years,[20] its use as the anchor in template formation of catenanes and simple rotaxanes is relatively recent. Remarkably, linear polymers heavily laden with threaded β-cyclodextrins were prepared as early as 1976 and have been studied extensively. In a particularly striking example of a template reaction, cyclodextrin rings strung along a linear polymer were bound together by reaction of their peripheral OH groups with epichlorohydrin. Removal of the polymer anchor then liberated the first synthetic tubular polymer.[21]

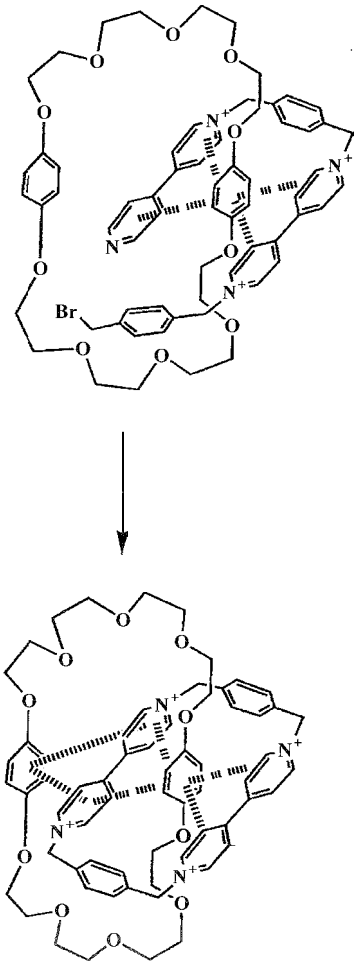

Fig. 7 The $\pi-\pi$ template in use to form a catenane.

As the above example illustrates, the discovery of a new template can lead to voluminous chemistry with exciting new results. Such has been the case with the development of templates based on guest–host complexes between derivatives of the electron-deficient herbicide paraquat and π-donor molecules like *bis-p*-phenylene-34-crown-10.[22] Powerful noncovalent forces lead to appreciable yields of predictable products. The strong interactions between the π-systems may be viewed as playing the role of the anchor. In some cases, more complicated interactions create tums from the mutually attracted molecules, but a phenylene-linked bis-paraquat wraps about an electron-rich aromatic ring forming a prototypical molecular turn. The latter stages of [2]-catenane formation in such a system are shown in Fig. 7. These systems have been used to produce oligo-catenanes up to a [7]-catenane,[23] Olympiadane, the [5]-catenane, being best known.'''' An enormous assembly of interlocked molecular structures has been designed and synthesized using this template, including functional species not previously described here, like molecular switches.

CONCLUSION

It is remarkable how much new chemistry emerges when a new molecular template is discovered. This is especially true of the discovery and development of a new molecular turn. Sauvage's turn and Stoddart's turn have been exceptionally productive in leading to new molecular architectures. New turns will continue to create new opportunities. For example, there is no turn specific for cyclodextrins. although it is reasonably clear how to proceed in attempts to design such a potent addition to the toolbox of parts for interlocked molecules.

Other new kinds of fundamental elements for template chemistry await development. A relatively new arrival[25] is what has been called the divergent turn.[3] This requires re-labeling the previously known turns as convergent. Convergent turns extend across the anchor with which they associate in a molecular template, whereas divergent turns extend away from their anchor. Illustrated in Fig. 8a is a divergent turn. Shown in Fig. 8b is how a divergent and convergent turn might be combined to produce noninterlocked rings of different sizes. Shown in Fig. 8c is how using a half-blocked divergent turn along with a convergent turn could result in a blocked trefoil knot. The latter concept, knots stabilized by blocking groups after the fashion of rotaxanes, appears not to have been tested in the laboratory as yet. Envisioned in Fig. 8d and 8e is the use of a combination of divergent/convergent turns to produce new interloclied figure eights. A possible new template element. the templated loop. may be used to

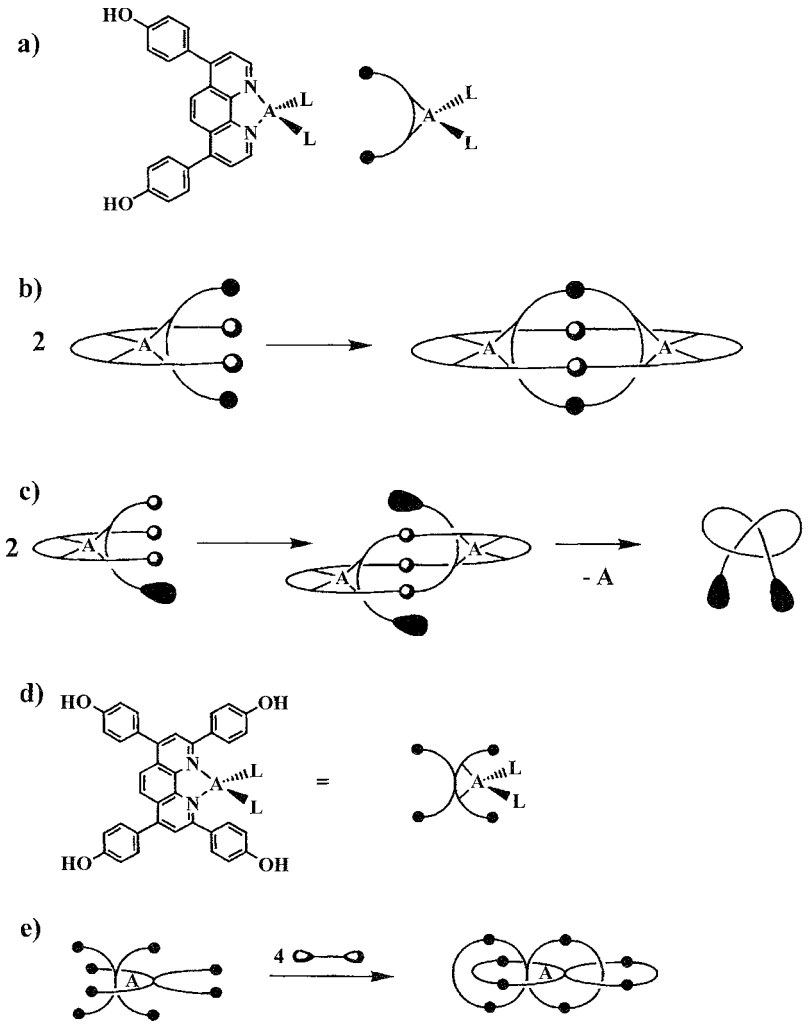

Fig. 8 (a) A hypothetical divergent turn; (b) combining convergent and divergent turns in a template produces a complex with a ring in a ring; (c) a knot designed after a rotaxane. using divergent and convergent turns: (d) and (e) a hypothetical combined convergent and divergent knot gives an interlocked set of figure eights.

form temporary rings for threading, and this might be helpful in the formation of still more complicated architectures as the field advances.

The development of rack complexes[26] and the overlaps of strands observed in a star-shaped circular double helicate[27] give promise of the eventual success of attempts at molecular weaving, an ultimate goal of interlocked molecular structures. Through molecular weaving and molecular braids, the development of materials may be possible that multiply the strengths of covalent bonds. The three-dimensional equivalent of a woven material is easily envisioned on the molecular scale and may present microscopic structures with no macroscopic counterparts. Molecular switches, traditional and Boolean, and molecular-scale inactive information storage remain viable goals of chemistry controlled at the inolecular level by templates.

Thiourea inclusion Compounds

Kenneth *D. M. Harris*
Cardiff University, Cardiff; Wales

INTRODUCTION

It has been known since 1947[1] that thiourea forms crystalline inclusion compounds in the presence of appropriate guest molecules. These thiourea inclusion compounds have a tunnel host structure (Fig. 1) that is similar in some respects to the urea tunnel structure but has a larger cross-sectional area. As a consequence, the urea and thiourea host structures typically accommodate different types of guest molecules. with the thiourea host structure able to incorporate larger guest molecules that cover a more diverse range of chemical types. For example, the thiourea tunnel structure can include guest inolecules such as cyclohexane and its derivatives, ferrocene and other organometallics, and compounds containing aromatic rings. Such guest molecules do not generally form inclusion compounds with urea. Empirical generalizations on the characteristic features of guest molecules that form inclusion compounds with thiourea have been discussed elsewhere.[2–4]

The host structure in thiourea inclusion compounds is generally rhombohedral or monoclinic. For guest molecules that have fairly isotropic shapes (such as cyclohexane, chlorocyclohexane, and ferrocene). the host structure at ambient temperature is usually rhombohedral. and the guest molecules generally exhibit reorientational dynamics. In many cases, this rhombohedral structure transforms (via one or more solid-state phase transitions) to a monoclinic structure at sufficiently low temperature. On the other hand, guest molecules with a more planar shape (such as 2.6-diethylnaphthalene: 2,3-dimethylbutadiene; and 1,5-cyclooctadiene) tend to favor the monoclinic host structure at ambient temperatme, with the guest molecules constrained to adopt an ordered arrangement. Lowering the symmetry from rhombohedral to monoclinic is associated with a deformation of the tunnel, leading to greater orientational ordering of the guest molecules.

While the tunnel in conventional urea inclusion compounds is fairly cylindrical (with fairly constant cross-sectional diameter), the thiourea tunnel structure contains bulges and constrictions at different positions along the tunnel. As a consequence, it is often more appropriate to regard the thiourea host structure as ''cage''-type rather than ''tunnel''-type, and many properties of thiourea inclusion compounds can be understood more directly on this basis. Thus, the guest molecules in thiourea inclusion compounds usually occupy specific preferred sites along the tunnel, cossesponding to one guest molecule per cage and a stoichiometric guest/thiourea molar ratio of 1/3. Thus, most thiourea inclusion compounds have a commensurate relationship between the host and guest substructures.

In this article, an overview of structural aspects of thiourea inclusion compounds is provided and some of the interesting properties of these materials are elaborated upon, such as the dynamic and conformational properties of the guest molecules, chemical reactions, and applied aspects. Also highlighted are the types of techniques and approaches that have been used in order to acquire an understanding of these properties. Several review articles[5–7] have been published on thiourea inclusion compounds, and contain comprehensive lists of references to the original literature in this field.

STRUCTURAL PROPERTIES

Structural Aspects of ''Conventional'' (Rhombohedral) Thiourea Inclusion Compounds

The host structure[8–10] in ''conventional'' thiourea inclusion compounds is rhombohedral [usual space group $R\bar{3}c$; $a \approx 15.5$–16.2 Å, $c = 12.5$ Å (hexagonal setting)] and exhibits a significant variation in tunnel diameter on moving along the tunnel, with constrictions (minimum diameter ca. 5.8 Å) and bulges (minimum diameter ca. 7.1 Å). In most thiourea inclusion compounds, the guest molecules occupy specific sites along the host tunnel, corresponding to one guest molecule within each ''cage'' in the host structure and corresponding to the commensurate relationship $c_h = 2c_g$ (where c_h is the periodic repeat distance of the host structure along the tunnel, and c_g is the periodic repeat distance of the guest molecules along the tunnel). Thus, there are two guest molecules within the periodic repeat distance of the thiourea host structure along the tunnel, leading to a guest/thiourea molar ratio of 1/3. The well-defined positioning of the guest molecules at specific locations within each tunnel gives rise directly

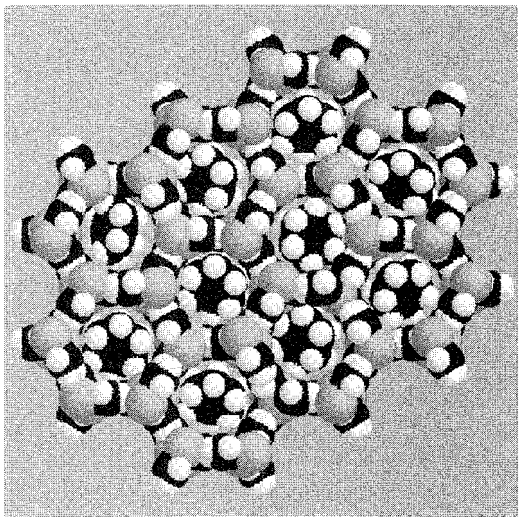

Fig. I Structure of the cyclohexane/thiourea inclusion compound at ambient temperature, showing 10 complete tunnels (with van der Waals radii) viewed along the tunnel axis. Guest molecules have been inserted into the tunnels, illustrating orientational disorder. The positions of the guest molecules are not actually determined from x-ray diffraction data at ambient temperature. (View this art *in color at www.dekker.com.*)

to three-dimensional (3-D) positional ordering of the guest molecules controlled by the 3-D periodicity of the host structure. However, in many cases, as discussed below, there is orientational disorder of the guest molecules.

Much progress has also been made in understanding the structural properties of conventional thiourea inclusion compounds below their phase transition temperatures. The rhombohedral structure of the high-temperature phase usually transforms to a monoclinic structure in the low-temperature phase[7] and is associated with changes in the dynamic properties and the degree of ordering of the guest molecules. Powder x-ray diffraction studies of the chlorocyclohexane/thiourea[12] and cyclohexane/thiourea[13] inclusion compounds have highlighted the advantages of using powder diffraction techniques when transformation to the low-temperature phase is associated with crystal twinning.

Structural Aspects of Some Thiourea Inclusion Compounds with Monoclinic Host Structures

As discussed above, a number of thiourea inclusion compounds have monoclinic structures that can be considered as distorted forms of the conventional (rhombohedral) thiourea tunnel structure. Two examples of inclusion compounds in this category are discussed here.

In the monoclinic structure of the 2,3-dimethylbutadiene/thiourca inclusion compound,[14] the planar guest molecules are arranged longitudinally (rather than stacked) within the tunnels and occupy 6.3 A per guest molecule along the tunncl. The cross-sectional dimensions of the guest molecules perpendicular to the tunnel are ca. 4.0 Å $\times$ 7.0 Å, and the tunnel is considerably deformed from the regular hexagonal cross section found in the conventional (rhombohedral) thiourea inclusion compounds, but with the same N — H. ·S hydrogen-bonding scheme. The guest molecules do not exhibit orientational disorder with respect to the tunnel axis. In the monoclinic structurc of the 2,6-diethylnaphthalene/thiourea inclusion compound,[15] the cross section of the tunnel is a deformed hexagon, and the asymmetric unit comprises three thiourca molecules and half the 2,6-diethylnaphthalene molecule. Thus, in contrast to the conventional thiourea inclusion compounds, there is one guest molecule per unit repeat distance of the host structure along the tunnel, and the molar guest/thiourea ratio is 1/6.

CASE STUDIES: STRUCTURAL AND DYNAMIC PROPERTIES OF SOME SPECIFIC THIOUREA INCLUSION COMPOUNDS

Cyclohexane/Thiourea

In many respects, the cyclohexanetthiourea inclusion compound is regarded as the prototypical example of conventional thiourea inclusion compounds, and its properties have been investigated widely. At ambient temperature, cyclohexanetthiourea has the conventional rhombohedral thiourea host structure,[8] and the cyclohexane guest molecules are located at the sites of 32 symmetry along the tunnel. Three distinct phases have been identified:[7,9,10] Phase I (above 149 K) is rhombohedral (space group $R\bar{3}c$); Phase II (149–129 K) is monoclinic (space group $P2_1/a$, with twice the volume of the rhombohedral unit cell); and Phase III (below 129 K) is also monoclinic (space group $P2_1/a$), with a discontinuity in the lattice parameters between Phases II and III at 129 K. The phase transition between Phases I and II is second order, and the phasc transition between Phases 11 and III is first order. A comprehensive investigation of the structural and symmetry properties associated with these phase transitions has been reported,[13] including the application of Landau theory to establish a detailed understanding of the mechanisms of the phasc transitions.

Early studies of the dynamic properties using wide-line solid-state ^{1}H-NMR of cyclohexane/thiourea-d_4[11,16] concluded that molecular motion of the guest molecules occurs in all three phases I–III. More details of the dynamic processes have been elucidated subsequently

from ^{2}H-NMR studies of cyclohexane-d_{12}/thiourea,[17,18] although confiicting interpretations of the dynamic properties have emerged from these studies. The most comprehensive study of the dynamics of cyclohexane/thiourea to date[13] has involved the application of single-crystal ^{2}H-NMR techniques. In Phase I, the dynamic properties of the cyclohexane guest molecules are described by a model of jumps of the C_3 symmetry axis of the molecule among six equiprobable orientations (corresponding to the D_6 point group symmetry of the site occupied by the guest molecules within the host structure), together with rapid reorientation of the guest molecule about its C_3 axis. The dynamics in Phase II involve reorientation of the C_3 axis of the guest molecule among six inequivalent orientations, although with specific relationships between these orientations. Order parameters driving the transition from Phase I to Phase II have been identified. and the orientational ordering process in Phase II has been elucidated. In Phase III, an abrupt ordering of the C_3 axis of the guest molecule takes place, due to freezing the motions of this axis relative to the host structure, although rapid reorientation of the guest molecule about its C_3 axis still occurs at the temperatures investigated within this phase. The information obtained on the dynamic properties together with the structural information obtained from powder x-ray diffraction studies were both important in developing a detailed description of the phase-transition mechanisms in this material. Molecular dynamics simulation studies[19] have also been exploited to understand the dynamic properties of cyclohexane/thiourea.

Ferrocene/Thiourea

At ambient temperature. ferrocene/thiourea has the conventional rhoinbohedral thiourea host structure.[10] The Fe atoms of the fessocene guest molecules occupy the sites of 32 symmetry within the host tunnel, and the cyclopentadienyl rings are disordered. Heat capacity measurements[20] have suggested that there are five phase transitions (at ca. 147, 160, 171, 186, and 220 K) between 13–280 K, which led to the proposal that the transitions at 147 K and 160 K are associated with reorientational order–disorder processes involving the molecular axis of ferrocene.

Early studies of the dynamic properties focused on ^{1}H-NMR of ferrocene/thiourea-d_4,[21] from which it was concluded that the fivefold axes of the ferrocene molecules are frozen in a number of nonequivalent orientations at low temperature. and that the phase transition at 160 K is associated with the onset of reorientational motion of these axes. Anisotropic ^{13}C-NMR chemical shielding spectra,[22] ^{57}Fe Mossbauer spectroscopy,[23] and solid-state ^{2}H-NMR[24] studies have also shed significant light on the orientational and dynamic properties of the guest molecules. The most recent ^{2}H-NMR study of fessocene-d_{10}/thiourea[25] proposed that there are four distinct orientations of the ferrocene guest molecules in the thiourea tunnel. In three of the orientations; the principal axis of the fessocene molecule is perpendicular to the tunnel axis, whereas in the fourth orientation, it is parallel to the tunnel axis. Below the phase transition at 160 K. the only motion effective on the ^{2}H-NMR timescale is rapid reorientation of each cyclopentadienyl ring about its C_5 axis. In this temperature regime, each fessocene molecule is confined (at least within the ^{2}H-NMR timescale) to one of the four molecular orientations defined above. The phase transition at ca. 160 K is associated with the onset of reorientational motion of the C_5 axes of the ferrocene molecules; between 165 and 220 K. the ^{2}H-NMR spectra are interpreted in terms of interchange of molecules between the three orientations perpendicular to the tunnel axis (with activation energy 6.4 kJ mol^{-1}) together with interchange between the perpendicular and parallel orientations (with activation energy 10.1 kJ mol^{-1}). The populations of these orientational states were determined as a function of temperature. At ambient temperature, the motion of the fessocene molecules is rapid on the ^{2}H-NMR timescale (i.e., frequency >10^7 Hz) and is still anisotropic, but by 340 K, the guest motion is effectively isotropic.

Carbon Tetrachloride/Thiourea

The CCl_4/thiourea inclusion compound has a rhombohedral host structure[26] (space group $R\bar{3}$; a = 15.54 A, c = 12.53 A) at 170 K. The crystal structure determination developed a model for the disordered CCl_4 guest molecules, with the carbon atoms of these molecules coplanar with the three sulfur atoms of thiourea molecules that point toward the center of the tunnel. Heat capacity measurements[27] between 15–300 K give evidence of a first-order phase transition at 41 K and a second-order phase transition at 67 K. Possible types of molecular disorder in the high-temperature phase have been related to the transition entropy and the molecular and site symmetries of the guest molecules. The heat capacity of the lowest temperature phase is unusually large, perhaps indicating very low-frequency vibrational modes or labile configurational excitation of the guest molecules. ^{35}Cl-NQR studies[28] have elucidated details of the dynamic properties of the guest molecules in CCl_4/thiourea.

Adamantane/Thiourea

Adamantane/thiourea has the conventional rhombohedra1 thiourea host structure.[29] In the crystal structure determination. the adamantane molecules were considered as

rigid bodies, and a model of twofold disorder of these molecules was invoked. Dynamic properties of the adamantane guest molecules have been studied by solid-state ^{2}H-NMR spectroscopy.[30] Motionally narrowed isotropic ^{2}H-NMR line shapes are observed throughout the temperature range studied (119–333 K), and ^{2}H-NMR T_1 measurements indicate that the guest molecules reorient on the picosecond timescale at 300 K. There is only one solid phace over the temperature range studied, and the effective barrier to overall reorientation of the adamantane guest molecules is estimated to be about 11 kJ mol^{-1}.

CONFORMATIONAL PROPERTIES OF THE GUEST MOLECULES

Guest molecules in solid host structures are often constrained to exhibit uncharacteristic conformational properties, which can be exploited inter alia as a means of carrying out spectroscopic characterization of such conformations. A classic illustration of such unconventional conformational behavior is provided by monohalogenocyclohexane ($C_6H_{11}X$; X=Cl, Br, I) guest molecules within the thiourea tunnel structure. For monohalogenocyclohexanes in liquid and vapor phases, the dynamic equilibrium between equatorial and axial conformations favors the equatorial conformation, and in the solid state (at sufficiently low temperature or high pressure), only the equatorial conformation is found. In contrast, however, when included as guests in the thiourea tunnel structure, $C_6H_{11}Cl$, $C_6H_{11}Br$, and $C_6H_{11}I$ exist predominantly in the axial conformation. These results have been established from infrared,[31] Raman,[32] and high-resolution solid-state ^{13}C-NMR[33,34] techniques. From the ^{13}C-NMR studies,[34] the mole fraction of the equatorial conformation is in the range 0.05–0.15, in contrast to the corresponding range (0.75–0.81) for the same molecules in $CFCl_3/CDCl_3$ (3:1) solution (all values quoted are for temperatures in the range 159–220 K). There is also a marked contrast between the conformational properties of these guests in the thiourea tunnel structure and in various zeolitic hosts, within which the equatorial conformation predominates. Bromine K-edge extended x-ray absorption fine structure (EXAFS) spectroscopy[35] has also confirmed that the axial conformation of bromocyclohexane predominates within the thiourea tunnel structure. This technique provides a direct measurement of the intramolecular Br···C(3) distance (3.27 Å), and on this basis, the axial and equatorial conformations may be distinguished directly. The ^{13}C-NMR results also demonstrate that for monohalogenocyclohexane guests in the thiourea tunnel at sufficiently high temperature, there is dynamic interconversion between the axial and equatorial conformations.

For guest molecules $C_6H_{11}X$, with X=CH_3, NH_2, and OH, the equatorial conformation is preferred (mole fraction 0.82–0.97) inside the thiourea tunnel structure.[34] Thus, for these guests, the conformational properties resemble those of the same molecules in solution, in contrast to the behavior of the monohalogenocyclohexane guests discussed above.

Further diversity of behavior is observed for fluorocyclohexane ($C_6H_{11}F$) guest molecules in the thiourea tunnel structure, for which there are approximately equal amounts of guest molecules in the axial and equatorial conformations. The conformational properties of this system and the ring inversion dynamics have been probed in detail[36] using a variety of different high-resolution ^{19}F-NMR techniques (with high-power ^{1}H decoupling) and triple-resonance ^{13}C-NMR experiments (with ^{1}H and ^{19}F decoupling).

A number of experimental techniques have also been used to show that certain disubstituted cyclohexanes can adopt uncharacteristic conformations inside the thiourea tunnel structure. For *trans*-1-bromo-2-chlorocyclohexane, intramolecular Br···Cl and Br···C(3) distances of 4.5 Å and 3.27 Å determined from bromine K-edge EXAFS spectra[35] demonstrate that the diaxial conformation is preferred. In contrast, the diequatorial conformation is preferred in dispersed phases.

CHEMICAL REACTIONS OF GUEST MOLECULES IN THIOUREA INCLUSION COMPOUNDS

Although the thiourea tunnel structure can accommodate guest molecules containing a diverse array of functional group types, reported studies of reactions in thiourea inclusion compounds have primarily concerned polymerization reactions. Classical work in this field[13] reported polymerization reactions of 2,3-dimethylbutadiene; 2,3-dichlorobutadiene; 1,3-cyclohexadiene; cyclohexadiene monoxide; iso-butylene; and vinylidene chloride. In all but the latter two cases, high-melting, crystalline polymers were obtained. There have been many subsequent reports of polymerization reactions carried out within the thiourea host structure. A computational study investigating the size requirements of polymers within the thiourea tunnel structure has also been reported.[37]

Another example of a chemical reaction within the thiourea tunnel structure concerns the Diels–Alder reaction between maleic anhydride and cyclopentadiene, which is reported to occur with high conversion and high stereoselectivity.[38] The two guest components were

cocondensed with the vapor of thiourea at 77 K. On subsequent heating, the Diels–Alder reaction occurs with 90% conversion, and more than 95% of the product comprises the *endo* isomer of the Diels–Alder adduct.

APPLIED ASPECTS OF THIOUREA INCLUSION COMPOUNDS

Nonlinear Optical Properties of *Thiourea* Inclusion Compounds *Containing* Organometallic *Guests*

It has been shown by Tam and coworkers[39,40] that thiourea inclusion compounds containing appropriate organornetallic guests can exhibit second-harmonic generation (SHG), i.e., doubling of the frequency of light as it passes through a material. Materials exhibiting SHG are important in a range of applications in optoelectronics and other fields. In order for a crystalline solid to exhibit SHG. the crystal structure must be noncentrosymmetric. If the crystal structure is centrosymmetric, the SHG will be zero, even if the constituent molecules have high second-order hyperpolarizabilities (β). The organometallics [e.g., (η^6-C_6H_6)$Cr(CO)_3$] studied have large values of β, but the structures of their "pure" crystalline phases are centrosymmetric and therefore do not exhibit SHG. Under the proposal that dipole organization may be favored inside the thiourea host structure, a large number of thiourea inclusion compounds containing organometallic guest molecules were prepared, and several of these materials were found to exhibit significant SHG. Structure determination of the SHG-active crystals confirmed the expected dipole organization of the guest molecules. For example, the crystal structures of (η^6-benzene)$Cr(CO)_3$/thiourea, (η^4-trimethylenemethane)$Fe(CO)_3$/thiourea, and (η^5-cyclohexadienyl)$Mn(CO)_3$/thiourea are isomorphous (space group R3c), and contain head-to-tail arrangements of the guest molecules along the tunnel. This work suggests, inter alia, that inclusion compound formation may be a widely applicable strategy for the formation of SHG-active materials. It was also shown that the SHG activity of these materials arises predominantly from the organometallic guest molecules, rather than the thiourea molecules (which also have significant β).

Application *of a Thiourea* Inclusion Compound *as* **an** Analyzer for **X-ray** Polarization Analysis

In the case of visible light, studies of polarization are dominated by the use of dichroic filters (e.g., the Polaroid sheet), for which photons with polarization parallel to a certain axis in the material are preferentially attenuated over those with polarization perpendicular to this axis. In principle, materials analogous to the Polaroid sheet may be developed for applications as dichroic filters in other regions of the electromagnetic spectrum, and there is interest in the development of materials for analysis of polarized x-ray radiation (which may be produced, for example, from a synchrotron radiation source). A suitable dichroic filter would be a crystal for which the absorption of polarized x-rays depends significantly on the orientation of the crystal, and such materials are of interest in a range of applications, such as in studies of magnetic x-ray scattering. Recently, it has been shown[41] that the 1-bromoadamantane/thiourea inclusion compound exhibits essentially optimal properties as a dichroic filter for polarized x-ray radiation (with x-ray energy close to the bromine K-edge). In this inclusion compound. the thiourea molecules form a tunnel host structure that differs to some extent from the conventional thiourea host structure. Within the repeat distance (24.75 Å) along the tunnel, there are three crystallographically independent 1-bromoadamantane guest molecule sites, corresponding to a guest:thiourea molar ratio of 1/4. At each site, there is disorder between two orientations (with essentially equal occupancies) of the guest molecule, but importantly, the C—Br bond of each guest molecule lies parallel to the thiourea host tunnel. It has been shown theoretically that this structural feature promotes optimal perforinance of such materials as dichroic filters for polarized x-rays.

CONCLUSION

As discussed above, the fact that thiourea inclusion compounds display a wide range of interesting structural and dynamic properties is well established. As with many solid inclusion compounds: structural constraints imposed upon the guest molecules by means of confinement within the host structure can confer properties upon the guest molecules chat differ significantly from those of the same molecules in dispersed phases. In view of the fact that the thiourea host structure can incorporate a diverse range of guest species, in terms of size, shape, and chemical functionality, there appears to be considerable potential for the design of thiourea inclusion compounds for applications in a range of scientific fields, and significant future developments in this regard may be anticipated.

Torands

Thomas **W. Bell**
University of Nevada, Reno, Nevada, U.S.A.

INTRODUCTION

The term "torand," derived by combination of "toms" and "ligand," denotes a macrocyclic ligand in which the perimeter of the large ring is completely formed by fusion of smaller rings. Three kinds of torands are currently known, dodecahydrohexaazakekulene (**1**, $R^1 = R^2 = H$)[1,2] and its substituted derivatives,[3–7] "expanded" torand 2 (R = butyl) containing 1,8-naphthyridine units,[5,6,8,9] and mixed pyridine/pyrrole macrocycle **3** (R = butyl), an expanded porphyrin.[5,6] The structures of these torands are shown in Fig. 1, along with those of related molecules. The latter include kekulene (**4**),[10] cyclosexipyridine (**5**),[11] Shiff-base pyridomacrocycles **6** and **7**,[4,5,12] and a heterohelicene molecular coil (**8**).[7,13,14] These systems are included in the following discussion of the background for torands. Current methods for synthesis of torands **1** and 2 are presented, followed by a summary of their binding properties. Torand **1** forms complexes with a wide variety of metal cations, including alkali metals, and expanded torand 2 binds guanidinium cation via hydrogen bonds. These relatively rigid hosts form stronger complexes than less highly preorganized analogues.

RELATED MOLECULES

Kekulene (4)

The ^{1}H-NMR spectrum[10,15] and crystal structure[16] of kekulene (4) disproved the concentric [18]annulene/[30]annulene character implied by the resonance form shown in Fig. 1. Instead, kekulene is better represented by a D_{6h}-symmetric structure including six benzenoid sextets.[16,17] Computational studies confirmed the semilocalization of π electrons in six benzene rings[17] and also produced current-density maps contradicting the annulene model."[17] Torands of Type **1**, formally dodecahydrohexaazakekulenes, have six pyridine rings in the same positions as the six benzenes of the D_{6h} kekulene structure. Fully unsaturated torands were not reported, but a D_{3h}-symmetric hexaazakekulene with three inner and three outer nitrogen atoms is known.[19] Lacking solubilizing substituents, this macrocycle only has appreciable solubility in strong acids. An insoluble dodecahydrodiazakekulene may have been prepared from the corresponding dodecahydrodioxoniakekulene.[20] Kekulene (4) represents only one of a hypothetical family of "cycloarenes" derived by fusion of benzene rings to form macrocyclic hydrocarbons.[15] To date, **1** and "expanded" torand 2 are the only known torands formally derived from cycloarenes.

Cyclosexipyridine (5)

The ultimate bridged-pyridine macrocycle,[21] cyclosexipyridine (**5**), was a synthetic target for numerous research groups for decades prior to the 1983 reports by Newkome and Lee[11] and Toner[22] on the parent and diaryl-substituted systems, respectively. These two communications did not give full details pertaining to synthesis and characterization and implied contrasting solubilities and sodium-scavenging properties. A thorough investigation of the synthesis of threefold symmetric triarylcyclosexipyridines was reported recently by Masciello and Potvin.[23] The *tris*(*p*-tolyl), *tris*(4-chlorophenyl), and *tris*(4-*tert*-butylphenyl) derivatives of **5** were obtained as mixed Na^+ and K^+ complexes and were insoluble amorphous solids. On the other hand, the *tris*(4-neopentoxyphenyl) analogue is soluble in nonaromatic solvents and was characterized (NMR, UV/Vis, and matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS)) as a 5:2 mixture of Na^+ and K^+ complexes. Thus, the tendencies of cyclosexipyridines toward problematic aggregation and alkali metal sequestration are well established.

Schiff-Base Pyridomacrocycles (6 and 7)

Metal complexes of Schiff-base macrocycle **6**[4,5] can be prepared by cyclocondensation of pyridine-2,6-dicarboxaldehyde with benzene-1.2-diamine in the presence of Sr^{2+}[24,25] Pb^{2+}, or Cd^{2+}.[26] The metal-free macrocycle is prepared by replacement of Sr^{2+} with K^+,[24] followed by decomplexation with excess 18-crown-6.[12] While 6 adopts the circular conformation shown in Fig. I in complexes with Sr^{2+}[25] and other metals, the cavity collapses in the absence of a guest.[5,12] Despite this conformational flexibility, 6 binds both Na^+ and K^+ better than 18-crown-6 in dimethyl sulfoxide (DMSO), and it is

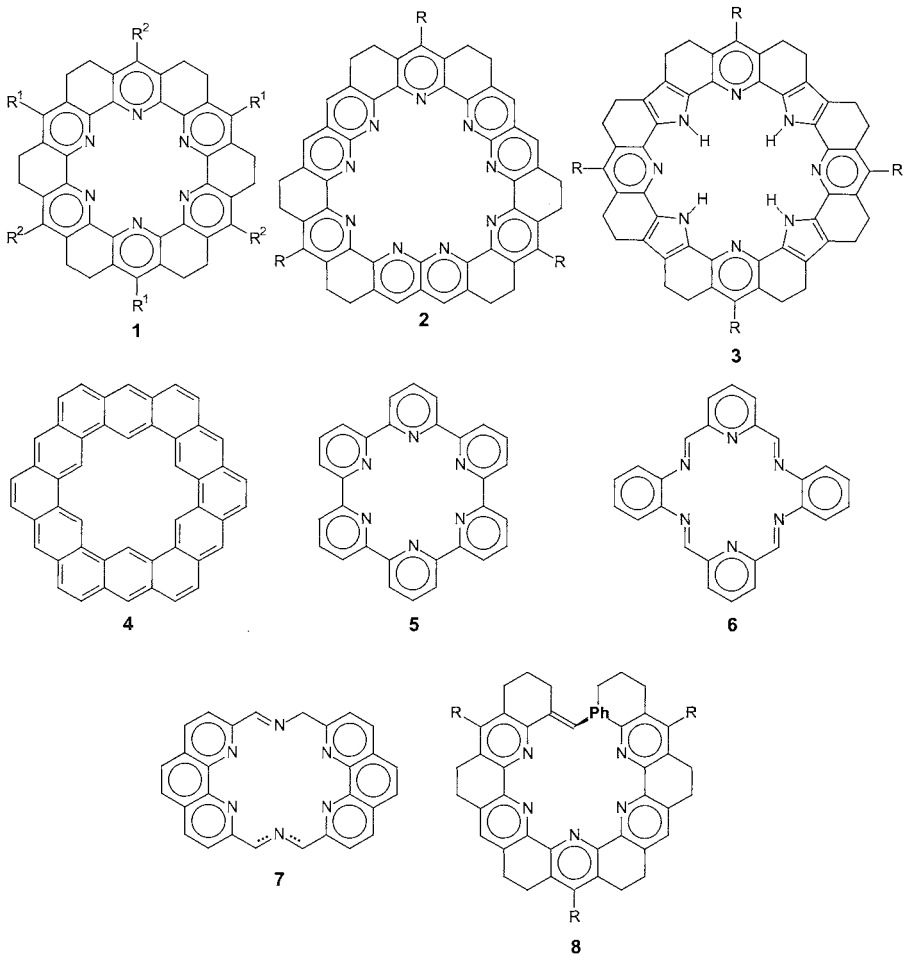

Fig. 1 Known torands (1–3) and related molecules: kekulene (4), cyclosexipyridine (5). Schiff-base pyridomacrocycles (6 and 7), and a molecular coil (8).

slightly selective for K^+ over Na^+.[25] Condensation of 1,10-phenanthroline-2,9-dicarboxaldehyde with 2,9-*bis* (aminomethyl)-1,10-phenanthroline in the presence of strontium triflate gave a *2:*1 mixture of diimine macrocycles (7) as very stable Sr^{2+} complexes.[4,5] These complexes of 6 and **7** are among the first complexes of "hard" alkaline earth ions with hosts containing only "soft" nitrogen donors.[21] This apparent contradiction is, however. consistent with the large dipole moments associated with pyridine and imine ligand sites[24,25] and the importance of ion–dipole interactions in the stabilization of alkaline earth (as well as alkali metal) complexes.

Molecular Coils (8)

Torand 1 consists of alternating, angularly fused pyridine and six-membered carbocyclic rings. When this molecular architecture is applied to open-ended systems, the ends overlap when a total of *12* rings is reached, or when a benzylidene group is introduced as a steric barrier in an 11-ring system, as in **8**.[7,13,14] This expanded heterohelicene. or "molecular coil." and a 13-ring analogue lacking the benrylidene group were synthesized.[7,13] While the metal-free ligands were isolated, they were found to sequester Na^+ or Ca^{2+} from chromatographic sorbents (silica or alumina). Careful examination of sodium binding by **8** revealed that a double-helical 2:2 complex was formed.[14] These results underscore the affinities of preorganized polypyridines toward alkali metal and alkaline earth cations.

TORAND SYNTHESIS

Dodecahydrohexaazakekulenes (1)

A lengthy synthesis of the parent dodecahydrohexaazakekulene (1, $R^1 = R^2 = H$) was reported by Ransohoff and Staab.[1] The final, macrocyclization step apparently gave the torand in 3% yield as a sparingly soluble solid,

which was characterized only by mass spectrometry and ^{1}H-NMR spectroscopy. Anticipating solubility problems with the parent torand, Bell and Firestone developed a method for synthesis of butylated heptacyclic terpyridines[27] and applied it to tributyldodecahydrohexaazakekulene (1, R^1 = H. R^2 = butyl).[3] The rnacrocyclization step in both approaches involved the reaction of two components to form a *bis*(pyrylium) dicationic intermediate. In the Ransohoff/Staab case, a single compound representing about half of the torand ring was dimerized. In the case of the Bell/Firestone synthesis, two different octahydroacridines each comprising one-third of the torand were combined, then the final third was incorporated during macrocyclization. The strategy is illustrated in Fig. *2,* which shows current approaches to both the parent and tributyl torands.

Two routes were originally developed for the synthesis of intermediate diketone 18 (*R*= butyl).[3,28] One involved introduction of the two carbonyl groups by oxidation of the corresponding dibutyl heptacyclic terpyridine.[27] The other route is similar to that shown in Fig. 2, except that 14 was prepared by pyrolysis of the trimethylhydrazonium derivative of 12. An improved method for this ''1/3+1/3'' coupling reaction involves condensing the HCl salt of Mannich derivative 13 with ketone 12 and ammonium acetate, giving heptacyclic terpyridyl 14 in 70% yield. The synthesis of 9-butyloctahydroacridine (9) and its conversion to N-oxide 10 are part of an Organic *Syntheses* procedure,[29] and various routes to diketone 18 are documented in an article describing its complexation properties.[28] The overall yield of the tributyl torand is 3% for the 11-step synthesis shown in Fig. 2.[6] The route was also applied to the unsubstituted torand (1, $R^1 = R^2$ = H), in which case the overall yield is *2%*. The synthesis of torand I is tedious, but the route shown in Fig. 2 can be used to prepare gram-quantities of the trifluoroinethanesulfonate (triflate) salt. The triflate salt of the tributyl torand can be converted to the free-base form by reaction with tetrabutylammonium hydroxide in butanol/acetonitrile.[30]

Similar pyridine annelation reactions were used to produce cleft-shaped molecules and torands bearing substituents capable of modifying their solubilities and aggregation properties. For example, 9-(4-t-butoxybutyl) octahydroacridine was prepared and used to synthesize corresponding disubstituted heptacyclic terpyridines and an undecacyclic quinquepyridine similar to 8.[31] Several β-arylenones resulting from condensation of ketone 12 (*R*= butyl) with aromatic aldehydes were condensed again with 12 and ammonium acetate to give. after oxidation, analogues of 14, in which the central pyridine ring bears a phenyl, 4-methoxyphenyl, 4-chlorophenyl. or 4-nitrophenyl substituent.[32] By an approach analogous to that shown in Fig. 2, this method was applied to the synthesis of triaryltrialkyltorands (1, R^1 = butyl, R^2 = aryl), which were obtained in 15–30% macrocyclization

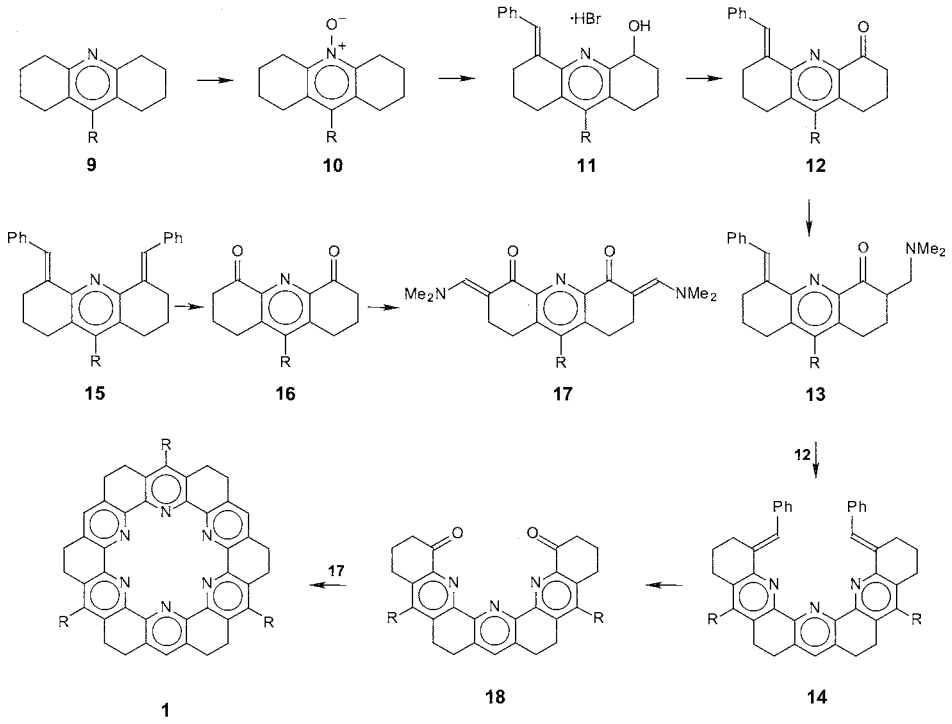

Fig. 2 Synthesis of dodecahydrohexaazakekulene torands (*R*=H or butyl)

yield.[6,7] Substituents in the four-positions of the three aryl groups may potentially be used to introduce ionic groups or steric barriers.

Expanded Torand 2

Angular fusion of six-membered rings produces torand 1 with an 18-membered central ring; incorporation of three linearly fused pairs of pyridines produces three 1,8-naphthyridine units and a larger cavity defined by a 24-membered ring in torand 2. Annelated 1.8-naphthyridines are conveniently prepared by Friedlander condensation of 4-aminopyrimidine-5-carboxaldehyde (19, Fig. 3), with a cyclic ketone, hydrolysis of the pyrimidine ring, and Friedlander condensation of the resulting *o*-aminoaldehyde with a second ketone.[''''] This method was applied to benzylideneketone 12 (R = butyl) to synthesize expanded torand 2, as shown in Fig. 3. as well as a nonmacrocyclic (or U-shaped) analog.[5,6,8,9] The macrocyclization step involves trimerization of ketoaminoaldehyde 22, which is obtained by ozonolysis of 21, the hydrolysis product of Friedlander derivative 20. The cyclotrimerization yield (50% max.) is sensitive to the amount of cesium hydroxide used to promote the reaction. Torand 2 precipitates as a complex with cesium and is obtained as the free ligand after removal of the metal by boiling in water.

TORAND COMPLEXATION

Metal Cations

Torand 1 (R = butyl) forms remarkably strong complexes with alkali metal salts. Lithium, sodium. potassium, and cesium picrate are completely extracted from water into chloroform, indicating that the stability constants of their 1:1 complexes exceed $10^{''}$ M^{-1}.[5,30] Competition experiments were performed by adding [2.2.1]- or [2.2.2] cryptand to solutions of the 1:1 complexes of 1 with alkali metal picrates, following the binding equilibrium by ^{1}H-NMR spectroscopy under slow exchange conditions. The resulting logK_s values were calculated: Li^+, 13.4; Na^+, 14.7; and K^+, 14.3. [5,30] As shown in Fig. 4, under these conditions, torand 1 binds Na^+ and K' with higher affinity than does cryptahernispherand 23, spherand 24, [2.2.2] cryptand (25). or naphtho-18-crown-6 (26). The cavity of 1 is more open than those of the other hosts, so these findings refute the notion that encapsulation is required for strong binding. Moreover. the low size-selectivity of 1 contradicts the usual preference for the metal that best fits the cavity. The torand cavity radius is nearly fixed at a previously estimated value of 1.3 Å, and the hexacoordinate radii of potassium, sodium, and lithium are 1.38, 1.02, and 0.76 Å, respectively.[5]

The stability constants of the 1:1 alkali metal picrate complexes of diketone 18. heptacyclic terpyridyl 27 and flexible terpyridine 28 were estimated by liquid–liquid extraction,[28] and the resulting logK_s values for Na^+ and K^+ are also given in Fig. 4. The affinities of 18 and 27 for these alkali metals are remarkably high for hosts containing only five or three ligand atoms, respectively. In water-saturated chloroform, pentadentate host 18 binds Na^+ and K^+ more strongly than do most crown ethers. Compared to naphtho-18-crown-6 (26), 18 binds Na^+ 4000 times better, and K^+ 40 times better. Even tridentate host 27 extracts alkali metal picrates into chloroform, whereas flexible model system 28 is ineffective under the same experimental conditions. The potent complexation

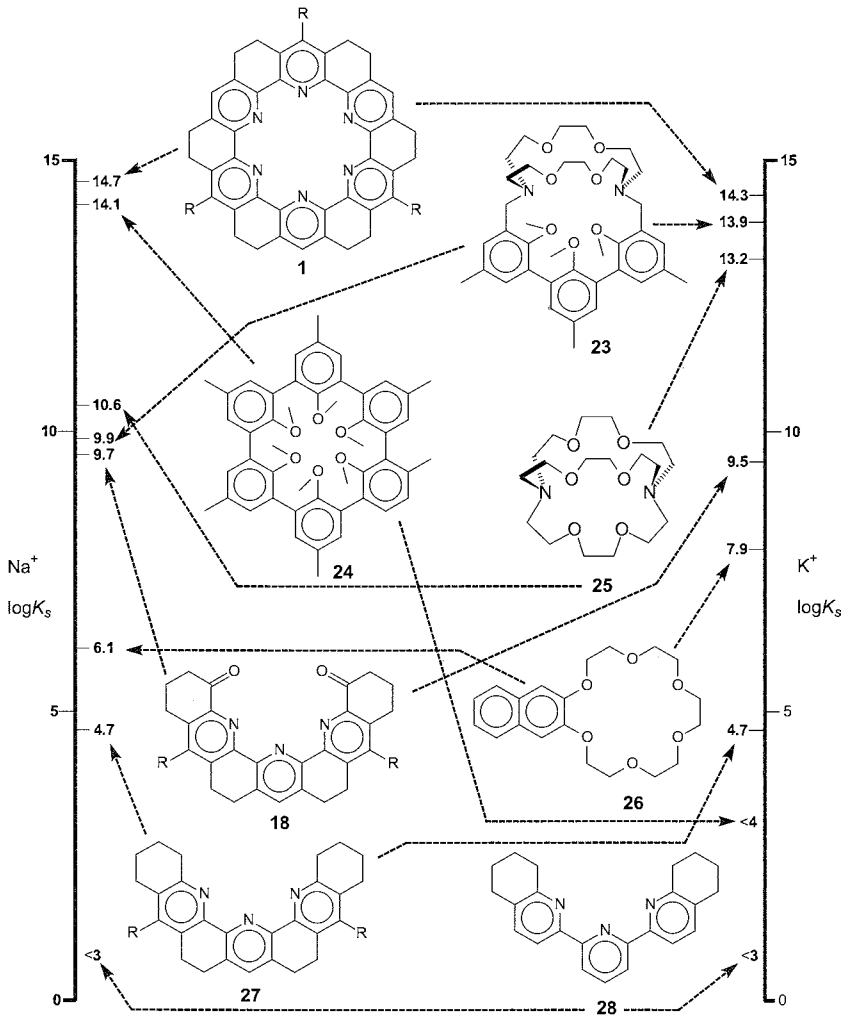

Fig. 4 Stability constants ($\log K_s$) of sodium and potassium picrate complexes in H_2O-saturated $CHCl_3$ (or D_2O-saturated $CDCl_3$) for torand 1. cryptahemispherand 23, spherand 24. cryptand ***25.*** terpyridyldiketone 18. crown ether 26, preorganized terpyridyl 27. and flexible terpyridyl 28 (R = butyl in **1. 18**, and 27).

abilities of heptacyclic terpyridyl hosts 18 and 27 can be attributed to enforced orientation of relatively large ligand functional group dipoles toward the center of the molecular cleft. As observed for torand **1**. selectivity is modest. Diketone 18 binds sodium and potassium slightly better than lithium, rubidium, and cesium, whereas 27 shows a slight preference for lithium among all the alkali metals.[28]

The x-ray crystal structures of the lithium, potassium. and rubidium picrate complexes of torand 1 (R = butyl) were determined.[5,34–37] and the structures of the potassium and rubidium complexes are shown in Fig. 5. In ihese two complexes. the metal atoms rest in the center of the cavity of 1, which adopts the staggered pseudo-D_{3d} conformation predicted by molecular modeling.[34,35] Potassium is clearly an excellent fit to the torand cavity, because it lies only 0.23 Å out of the best plane of the six nitrogen atoms. with K–N distances ranging from 2.73–2.85 Å. Potassium has a seventh contact to picrate, suggesting that the cavity radius of 1 should be revised to nearly 1.46 A, the ionic radius of seven-coordinate potassium.[5] The torand adopts the same conformation in $1 \cdot Rb^+$, but rubidium lies 1.06 Å out of the best nitrogen plane. and picrate is bidentate.

In contrast to K^+ and Rb^+, lithium picrate crystallizes with torand 1 as a 2:2 complex containing three water molecules.[36,37] The two torands are coaxially stacked and threaded by a hydrated dilithium chain: H_2O–Li^+–H_2O–Li^+–H_2O. Each lithium cation binds unsyinmetrically to two of the six nitrogens in each torand, and two water molecules complete the tetrahedral Li^+ coordination sphere. No anion coordination is observed, and hydrogen

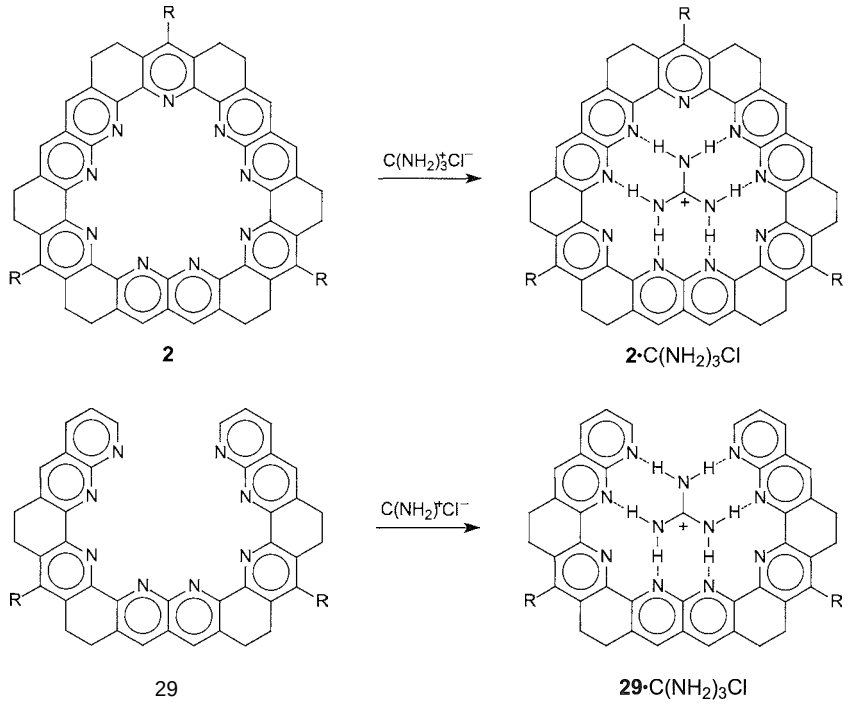

Fig. 6 Complexation of guanidinium by expanded torand 2 and flexible analogue 29

bonding between Li^+-coordinated water molecules and vacant N binding sites apparently enhances the stability of the supramolecular assembly. Torand stacking interactions are also implied by the cation response of thin films of torand **1** at the air–water interface.[38] Even though **1** is substituted only with three butyl chains, it is sufficiently hydrophobic to form compressible thin films on water. Surface pressure/molecular area isotherms are dramatically affected by metal cations in the aqueous subphase. Transitions at 100–120 $Å^2$/molecule suggest the formation of stacked-torand dimers in the presence of Li^+, Cs^+, and Pb^{2+}.[7,38] Despite the relatively large cavity size of **1**, and unusual hexagonal planar ligand geometry, complexes are formed with metal cations throughout the periodic table.[5] Fluorescence of protonated **1** is quenched upon binding certain metals (e.g., Pb^{2+}), so it might be useful as a sensor for detection of metals in solution.[39]

Organic Guests

Torand **2** (*R*= butyl) presents a nearly ideal array of hydrogen-bond-accepting pyridines for complexation of the guanidinium cation, as shown in Fig. 6. This nearly perfect registry of host and guest geometries led conceptually to the family of "hexagonal lattice receptors" for organic guests.[39] Flexible U-shaped host **29** has nearly the same array of pyridine rings as **2**. but its minimum energy geometry is expected to be nonplanar, placing the terminal nitrogen nuclei nearly 7.3 Å apart.[8,9] Thus, **2** should bind guanidinium with little change in host conformation, while **29** must adjust to a more planar conformation in the complex. Accordingly, the UV/Vis spectrum of **2** shows no significant response to complexation, while **29** binds guanidinium with bathochromic shifts of the longer wavelength absorption maxima.[8,9,39] Both *2* and **29** quantitatively extract guanidinium chloride into anhydrous CH_2Cl_2. Titration studies led to calculation of a stability constant of 2×10^6 M^{-1} for **29**·$C(NH_2)_3Cl$ in 95:5 ethanol/CH_2Cl_2,[39] and the stability constant of **2**·$C(NH_2)_3Cl$ is apparently even higher.

CONCLUSION

Torands and closely related molecules, such as cycloarenes, sexipyridines, and expanded heterohelicenes (molecular coils). still constitute a relatively small group of known compounds. The main reason for this is purely synthetic: fusion of multiple rings requires many synthetic steps; and low-yield macrocyclization reactions compound the problem. Clearly, better methods are needed for the synthesis of torands to enable more complete exploration of their complexation properties and other potential uses. Easier synthetic access would pave the way for application of these rigid molecules as, for example, scaffolds, dendrimer cores, mesogens, and nanoscale molecular devices. The binding properties of partial structures of torands also demonstrate the value of preorganization in supramolecular chemistry. Fused-ring hexagonal lattice receptors can form strong complexes, and macrocyclic structures may not be necessary or desired for many applications.

Tröger's Base Derivatives

Gerd Kaupp
University Oldenburg, Oldenburg, Germany

INTRODUCTION

Troger's base derivatives (5,6,11,12-tetrahydro-5,11-methanodibenzo[b,f][1,5]diazocines) are V-shaped or roof-shaped chiral bases. They are potential concave receptors. The angles between the two aryl rings vary from 92" to 104° in the crystal. Calculated ab initio DFT (density functional theory) values for isolated molecules are larger (112° for Troger's base). These compounds are frequently synthesized from primary aromatic amines and formaldehyde or in related synthetic procedures. Numerous derivatives (the Chemical Abstracts Service (CAS) Registry file contains 532 entries at present) are known, and 24 of them are well characterized by x-ray crystallography. The racemates can be optically resolved to give pure enantiomers that racemize slowly in acidic inedia via reclosure of iminium intermediates. Troger's bases can be used for optical inductions.

They were complexed with heavy-metal salts and quaternized with alkylating agents. The quaternary salts are better hosts for formation of inclusion complexes with various guests. The receptor qualities and molecular as well as chiral recognition capabilities rely on the armature function for larger clefts and for larger pockets in trögerophanes via embedding in large ring systems when they exert their armature function. This leads to biological and pharmaceutical actions that are promising for medical treatments.

Various related ring systems of the *nor*, *iso*, and *homo* types are available. and most of them show promise for applications in supramolecular chemistry. The V-shape in all of these systems is the common structural motif.

SYNTHETIC ASPECTS

Tröger's base [**I** (Fig. 1). R=CH_3, X=H] (5,6,11,12-tetrahydro-2,8-dimethyl-5,11-methanodibenzo [b,f][1,5]diazocine) was first obtained from *p*-toluidine, formaldehyde, and acid in 1887.[1] The yields are not very high in that procedure but may reach 70% under carefully selected conditions.[2] Numerous derivatives, including double Troger's bases. were prepared by this one-pot approach. however, only p-substituted aniline derivatives were successful.[3] The unsubstituted system nor-Troger's base **3** (Fig. 1) (**1**, R=X=H) required a bromine-lithium exchange of **I** (R=Br, X=H) followed by hydrolysis[4] or a four-step synthesis from anthranilic acid methylester. The last step is the reaction of the tetrahydrodibenzodiazocine 4 (Fig. 1) with formaldehyde.[5] An elegant synthesis starts with commercial 1,3,5-triphenylhexahydrotriazine (2. Fig. 1) (easily synthesized from aniline and paraformaldehyde in boiling xylene), which is dissolved in trifluoroacetic acid to provide a 90% yield of **3** in a one-pot cascade reaction.[6] Further derivatives of Tröger's base were synthesized in a corresponding manner, using triaryl-2 with free *o*-position.[6]

The intermediate labile iminium salt was isolated as its chloride in a gas–solid reaction between 2 and HCl. Water vapor produced 3 and aniline after final neutralization.[6] Racemic Troger's base derivatives can be optically resolved by chromatography at chiral stationary phases.[7] Absolute configurations of Troger's bases **1** were determined and recently corrected: (−)-(*R,R*)-**1**; (+)-(*S,S*)-**1**.[8] The configurational stability decreases upon monoalkylation.[9,10] Alkylations provide monoquaternized salts, complexations of (+) or (±)-Tröger's base with heavy metal salts (e.g., $HgBr_2$) yield 2:1 complexes that were characterized by x-ray crystal structure determination (e.g., 5. Fig. 1).[10] An enantiopure 1:1 complex **6** (Fig. 1) of Troger's base was formed with methyl rheniumtrioxide and was equally characterized by x-ray crystal structure analysis.[11] X-ray structures were reported for Troger's bases with condensed aromatics, such as **7** (Fig. 1)[12] and for the bis-Troger's base 8 (Fig. 1).[13] Highly functionalized (*R,R*)-Tröger's bases, such as 9, (Fig. I), and also their (*S,S*)-enantiomers were prepared.[14] A polycyclic Troger's base **10** (Fig. 1) is easily obtained by acid-catalyzed self-condensation of *o*-aminobenzaldehyde.[15] Several derivatives are known.

INCLUSION **REACTIONS**

Troger's bare **11** (Fig 2) includes 1.4-dioxane (1 0 33 ratio) [16] Mole versatile are inclusions of the quaternary salt 12 (Fig 2) (X=*I*) which includes toluene *p*- and *m*-xylene. p- and *m*-chlorotoluene, diethyl ketone, cyclohexanol. dioxane. and THF The characteristic ratios vary

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120019139

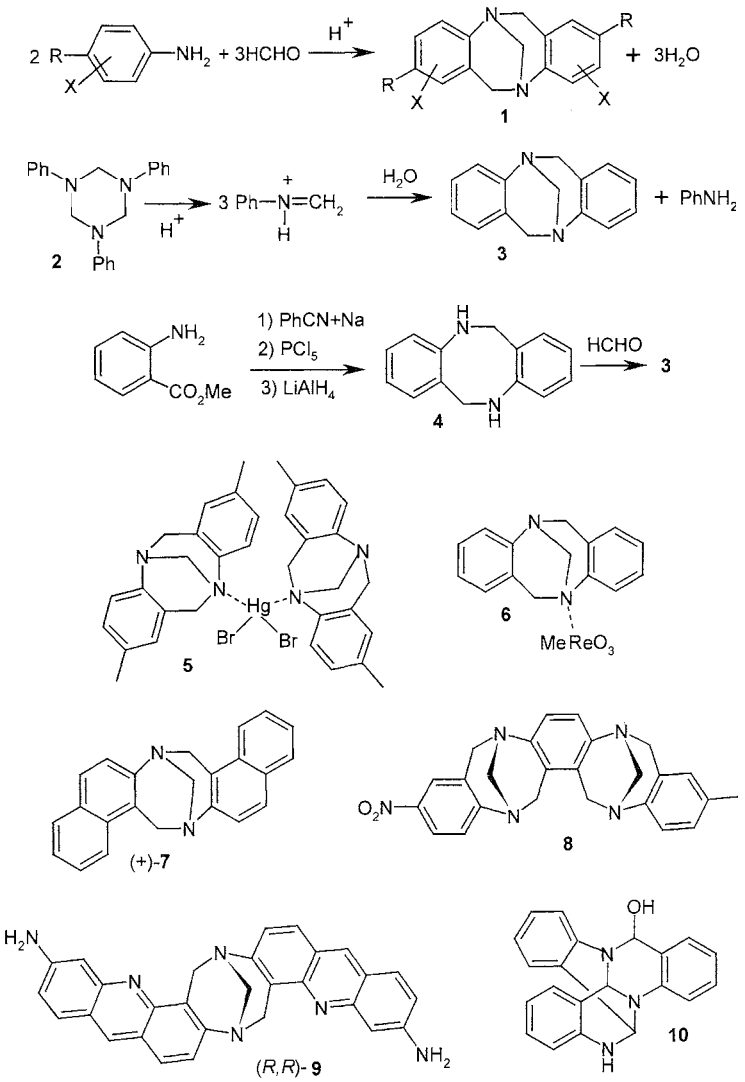

Fig. 1 Syntheses schemes for Troger's bases and some varied structures.

from 1:0.5 to 1:1.25. In all cases, water is also included and is capable of being the sole guest (1:2.25).[16]

Open-chain alcohols, cyclohexane, and p-cymene are not included. The inclusion capacity of **12** is slightly higher than that of **13a** (Fig. 2). The 1:1-competition experiments showed that p-xylene is selectively included by 12 from mixtures with benzene or toluene. whereas **13a** (*X*=*I*) selectively included benzene from these mixtures. Furthennore, 1,4-dioxane is selectively included by **13a** from mixtures with benzene or toluene.[17] The chain length of the alkyl group in the salts **13a–d** influences the stoichiometry of the inclusion, for example, with p-xylene (1:0.5, 1:1. 1:1.25, 1:0.75 host–guest ratio, respectively).[16] The quaternary salts **13a–e**, 14, and **15** (Fig. 2) exhibit a remarkable preference for aromatic guest solvents. Compound **13f** prefers less voluminous guests, including acetone, *n*-BuOH, and EtOH (not MeOH) for 1:1 incorporation into the crystal lattice.[17] Host 15 compares closely with 13f in its inclusion selectivity. Furthermore, compound **14a** corresponds to **13a** (*X*=CH_3OSO_3): phenylmethanol, 1-phenylethanol, acetophenone, mesitylene, cyclohexanone. benzaldehyde, *o*-xylene, chlorobenzene, ethylbenzene are additionally included. Structure 14b resembles **13f** in its inclusion behavior.[17] The reason for the increased enclosure capabilities of the alkylated Tröger's base cations was not investigated further. According to DFT ab initio calculations at the B3LYP/6-31G* level, the dihedral angle between the planes of the benzene rings of the cation **13a** is predicted to be 109°, smaller than for **I**

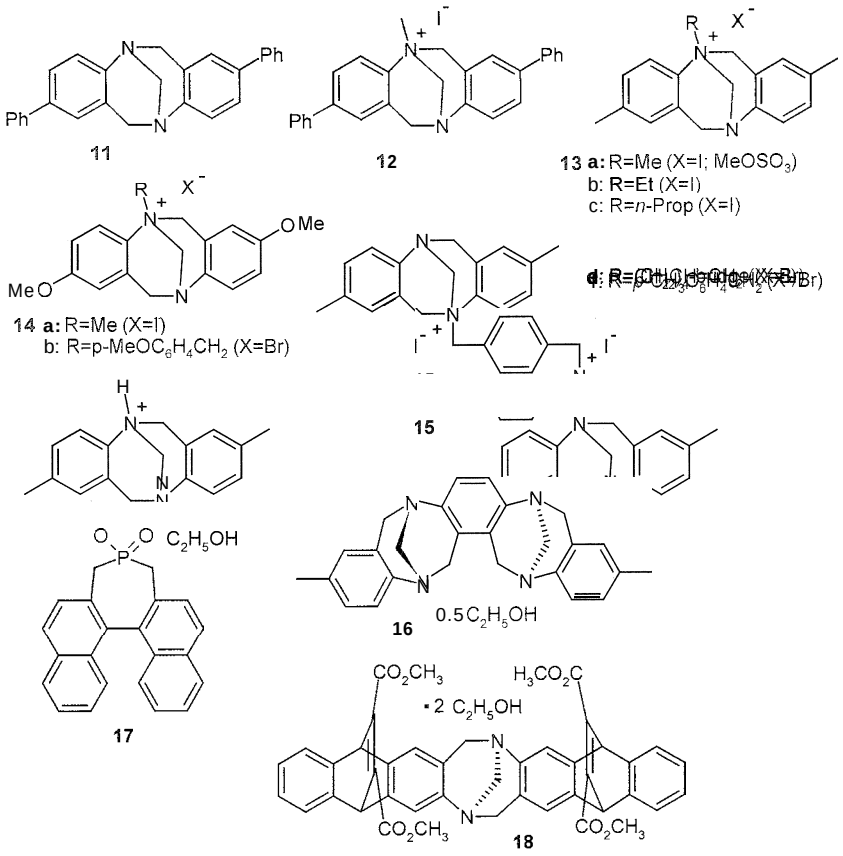

Fig. 2 Troger's base inclusion compounds

(R=CH_3, X=H), with 112°. The angles at the methano bridges are found to be 110" and 111.5°, respectively. Obviously, the inclusion lattices are further improved by alkylation. X-ray crystal analysis of **13a** (X=I)·0.5 1,4-dioxane established an enclathration-type inclusion.[17] An investigation of the molecular packing of the published structure reveals that the dioxane does not immerse into the cleft of the V-shaped host molecules **13a**. It is surrounded by two of them with their cleft open to it and two of them facing the outside of their cleft. Apparently, the V-shape may provide inclusion lattices that accommodate the guest, but the cleft is not the site where the guest resides. This important question was addressed further. The resolved *exo-endo*-bis-Tröger's base inclusion compound 16 (Fig. 2) packs in such a way that both of the U-shaped clefts go in the clefts of the next molecules: every two molecules are intercalated with each other.[15] The ethanol molecules are situated between the rows according to the published crystal structure. The salt 17 (Fig. 2) (inclusion of EtOH) has the counteranion out of ihe cleft, a peripheral aryl ring of the bisnaphthyl moiety covers the cleft of the protonated Troger's base, and ethanol is hydrogen-bonded to the anion at the backside of the cleft, according to the reported crystal structure.[18] A much larger U-shaped cleft (8–9 Å wide. 5–7 Å deep) is formed in the inclusion compound 18 (Fig. 2).[19] Two ethanol molecules are located within the cleft defined by the esters, with the Troger's base moiety at the bottom. The guest molecules are relatively disordered. They are held by hydrogen bonds to the ester groups and are clathrated in a molecular chamber, the fourth side of which is defined by the next molecule in the stack.

The V-motif is certainly used in the herringbone stacking of the crystalline Troger's base (1, R=CH_3, X=H) at a distance of ca. 5.5 Å.[20] Further Tröger's base derivatives use the same stacking motif (for example, **11**).[16] An U-inside-inverted-U-packing requires the much larger U-shaped cleft in the *endo-endo*-bis-Tröger's base **8**.

It could not be shown that the Troger's base cleft is used by included guest molecules. Rather, the clefted molecules are able to create lattices that can accomodate guest molecules, in particular. when they are protonated or alkylated.

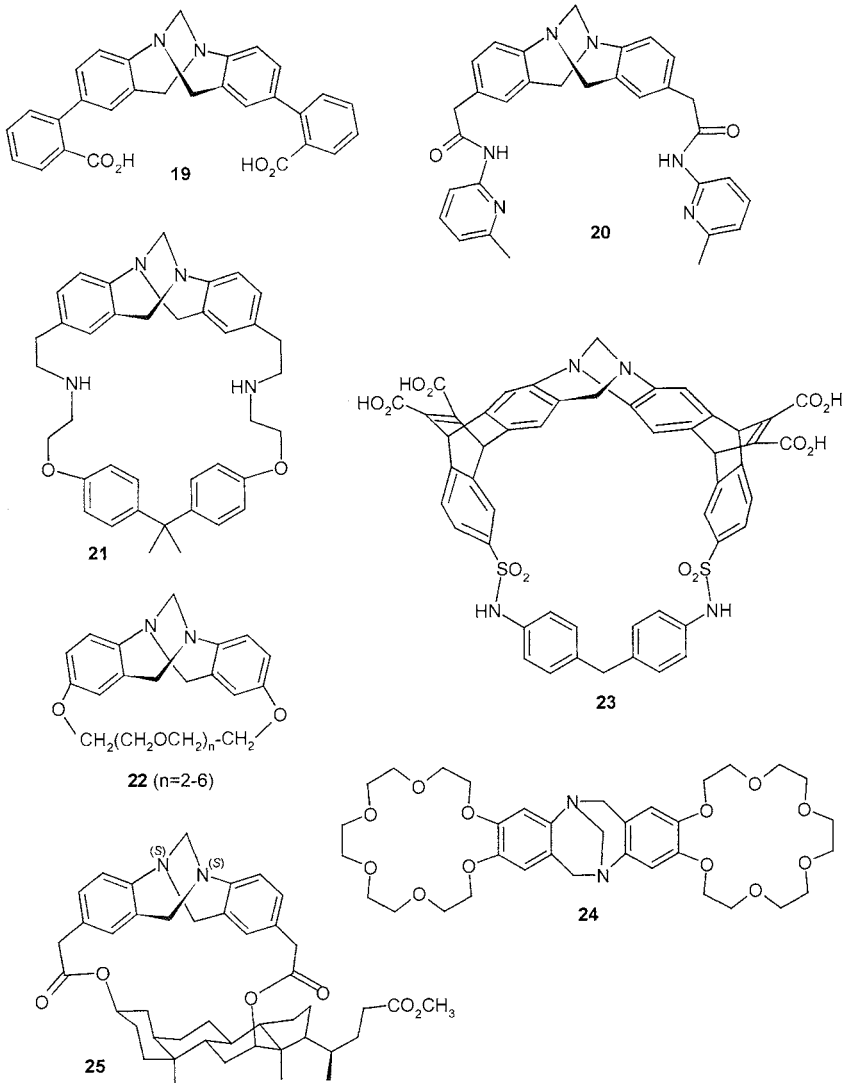

Fig. 3 Troger's base as an armature for systems with molecular recognition.

MOLECULAR RECOGNITION IN SELF-ASSEMBLING SYSTEMS

The cleft of Troger's bases provides only limited success in supramolecular applications, however, their well-defined structures were used as armatures for aligning further functionality in order to provide receptors for molecular and chiral recognition. That goal was achieved with scaffold-type derivatives 19, 20, 24 (cf. 18) and by embedding Troger's bases in macrocycles that were called trogerophanes (21–23, 25) (Fig. 3).

Scaffold 19 with two carboxyl groups intersecting at an angle of 120" forms hydrogen-bonded complexes by host–guest interaction with weak bases and exhibits large association constants (K).[21,22] Thus. 2-aminopyrimidine (K=2600 M^{-1}), dimethyleneurea (K=44,000 M^{-1}), trimethyleneurea (K=33,000 M^{-1}), 2-imidazolidone (K= 21.000 M^{-1}), biotin methyl ester (K=17,000 M^{-1}), and 9-ethyladenine (K=45,000 M^{-1}) are all bound in $CDCl_3$, as determined by ^{1}H-NMR titration. Scaffold 20 is an artificial receptor for dicarboxylic acids by virtue of selective binding.[23]

The trogerophane **21** forms association complexes with various phenols and p-toluenesulfonic acid.[3] It forms complexes with benzenoid substrates in acidic aqueous solutions. The crown ether trogerophanes 22 do not include solvent molecules for n=1–3. The complexation of LiSCN (not NaSCN, KSCN) with 22 (n=3) is weak. However, the larger rings in 22 (n=4–6) exhibit supramolecular cation-binding properties, as was shown for

NH_4^+, K^+, Na^+, Cs^+, Li^+ using Cram's picrate extraction method.[24]

The large trogerophane 23 is particularly versatile for molecular recognition.[21,22] It complexes *trans-tert*-butylcyclohexanol (K=8600 M^{-1}) and much more efficiently *cis-tert*-butylcyclohexanol (K=41,000 M^{-1}) from aqueous (D_2O) phosphate buffer. The enantiopure receptor 23 (tetraammonium salt in D_2O) binds cyclohexanoid and alicyclic alkanes, stereoisomeric menthols, diastereomeric cyclohexane derivatives, and steroids. Furthermore. it is a chiral shift reagent. The differentiation of (−)-menthol (K=2500 M^{-1}) and (+)-menthol (K=2000 M^{-1}) is not pronounced. but (+)-isomenthol (K=1000 M^{-1}) is disfavored. The axial substituent is less welcome in the pocket.[25] Two crown-6 moieties in 24 recognize primary bisammoniuin salts, and the enantiopure Troger's base 24 discriminates *D*- and *L*-lysine.[26] Even larger and more rigid clefts were constructed with Troger's base by [*a*,*b*]- and [*e*,*b*]-condensation to two pyrazino[*b*,*a*]porphyrins. Thus, a templated assembly by superstructure encapsulation is known.[27] The dendrimer *N*,*N*,*N*′,*N*′-tetra-(3-aminopropyl)-1,4-diaminobutane coordinates with all four of its primary amino groups to two clefted Troger's base molecular receptors with two pyrazino[*b*,*a*]-tetra-(3,5-di-*tert*-butylphenyl)-zincporphyrin moieties each condensed to them. The binding sites are at the zinc atoms of the four assembled porphyrins. and a spherical supramolecular capsule results.

The trogerophane based on the deoxycholic acid chiral template in 25 [and in its (*R*,*R*)-epimer] was used for an asymmetric synthesis of the enantiopure Tröger's base analogues after hydrolysis.[28,29] As the two hydroxyl groups of deoxycholic acid have different reactivities for esterification, unsymmetric Troger's bases could be asymmetrically synthesized as well.

OPTICAL INDUCTION BY TRÖGER'S BASES

Resolved Troger's base (**1**) interacts with chiral alcohols as a chiral NMR shift reagent.[21,22] It is also possible to use enantiopure Troger's bases for chiral resolution and chiral induction. When **1** (*R*=CH_3, *X*=H) was imprinted in methacrylic acid–ethylene glycol dimethylacrylate copolymers; enantioselectivity of the synthetic receptors was observed in high-performance liquid chromatography (HPEC) experiments with the polymer as stationary phase.[30] A (+)-Tröger's base. when used as preadsorbed chiral modifier of a Pt/alumina catalyst; provided enantioselective hydrogenation of ethyl pyruvate (65% ee in AcOH).[31] The application of (+)-(*S*,*S*)-Tröger's base (**1**) as ligand in 1,4-additions of lithium aryls to α,β-unsaturated tert-butyl esters provided ee-values up to 57% that compare to those obtained with (−)-sparteine (**37**, below).[32] The (+)-(*S*,*S*)-Tröger's base (**1**) (*R*=CH_3, *X*=H) is a relatively poor chiral ligand in the asymmetric addition of diethylzinc to benzaldehydes.[33] However, the enantiomeric excesses were as high as 86% if 5% of 5*S*.11*S*-6-exomethylene-**1** was applied.

BIOLOGICAL AND PHARMACEUTICAL APPLICATIONS OF TRÖGER'S BASE DERIVATIVES

Troger's base moieties are attractive pharmacological groups. The interaction of drugs with living materials is of a supramolecular nature, and interactions with DNA are particularly important. Thus; compound (−)-**9**, which contains two proflavine units, binds in enantio- and sequence-specific fashions to DNase I. Conversely, (+)-**9** interacts poorly with DNA in a nonsequence-selective fashion.[14] The (−)-enantiomer preferentially recognizes certain DNA sequences containing both A·T and G·C base pairs, such as the motifs 5′-GTT·AAC and 5′-ATGA·TCAT. Similarly, the asymmetrical compound 26 (Fig. 4) containing a proflavine unit and a phenanthroline unit intercalates DNA topoisomerase I, as indicated by linear and circular dichroism experiments and biochemical assay.[34] The data are compatible with a model in which the proflavine moiety intercalates between DNA base pairs, and the phenanthroline moiety occupies the DNA groove. Cleavage experiments revealed the sequence preference of the hybrid ligand, and a well-resolved footprint was detected at a site encoinpassing two adjacent 5'-GTC.5-GAC triplets. The chiral *bis*-(1,10-phenanthroline) Troger's base copper(I) complex **27** (Fig. 4) interacts with DNA and causes strand scission as determined by the almost complete conversion of the covalently closed circular pVC18 plasmid to open circular DNA.[35]

Compound 28 (Fig. 4) is an effective inhibitor of the enzyme thromboxane A_2 (T x A_2) synthase, with an ED_{50} of 30 ng ml^{-1} in a specified in vitro assay.[36]

The trogerophane 29 (Fig. 4) was synthesized for treatment of malignant tumors. It restores c-fos expression disorder in neuroblastoma cells.[37]

The known data indicate that further applications of Troger's bases in pharmacology and medicine are to be expected. However. this prediction is also valid for related clefted systems.

RELATED SYSTEMS WITH CLEFT STRUCTURE

The 5,6,11,12-tetrahydrodibenzo[*b*,*f*][1,5]diazocines such as 4 become Troger's-base-like if they are complexed

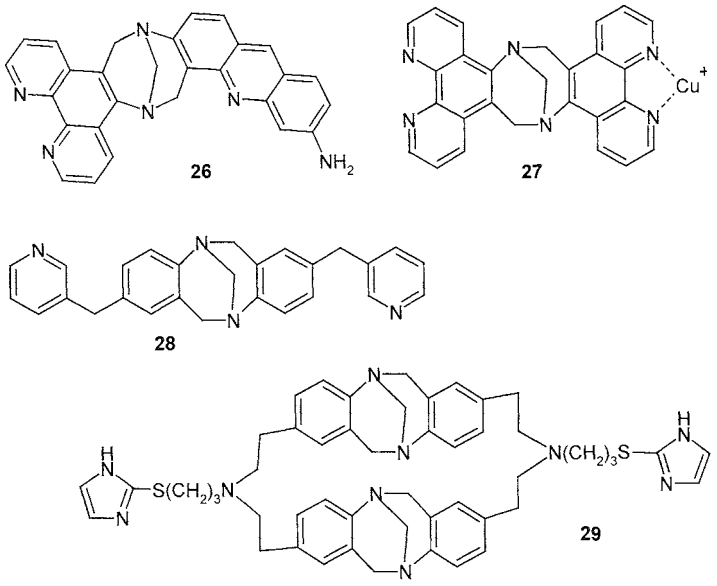

Fig. 4 Tröger's bases with biological and pharmacological action (see also 9).

with heavy-metal salts. The inclusion compound 30 (Fig. 5) is a well-studied example.[38] The methano bridge is formally replaced by the metal salt.

In the *pseudo*-Tröger's bases **31**[39] and ***32*** (Fig. 5),[40] the methano or imino bridge connects the carbons instead of the niirogens of the dibenzo[*b*,*f*][1,5]diazocine. According to DFT B3LYP/6-31G* calculations, the molecular skeleton of 31 (totally unsubstituted) is more stable than compound **3** by 13.6 kcal mol^{-1}. Seven derivatives of 31 were prepared from p-methylamino-benzaldehyde, $POCl_3$, and diethylmalonate or other reagents with two α-H atoms next to an activating heterocycle. The cleft

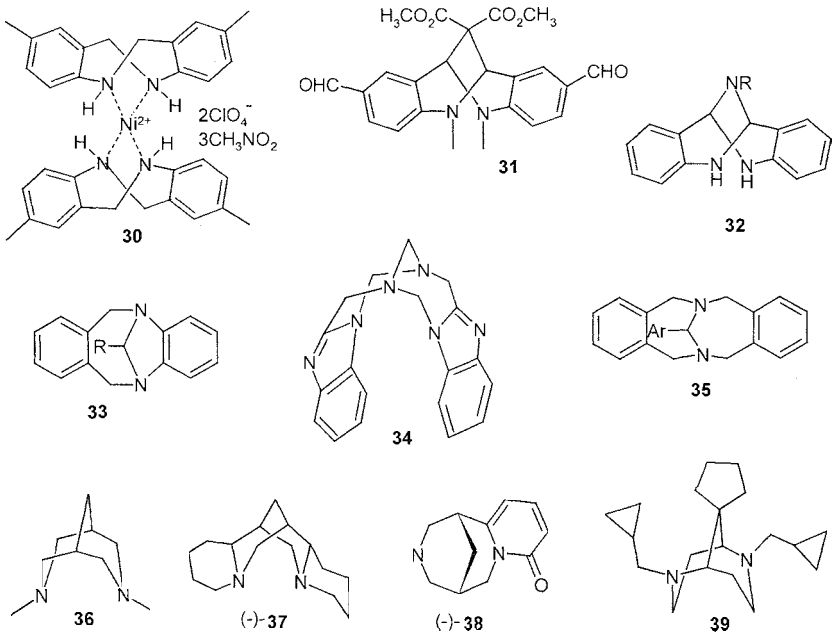

Fig. 5 Clefted molecular systems related to Tröger's base

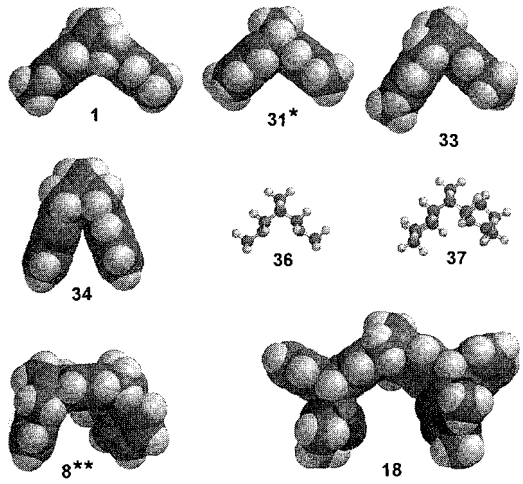

Fig. 6 Visualization of clefts in Troger's base and related systems. (* CH_3 instead of *CHO*, CH_3, and CO_2CH_3 replaced by H; ** NO_2 and CH_3 replaced by *H*.)

shapes (calculated angle between the aryl rings: 109°) do not considerably change with respect to Troger's base. and inclusion of water or acetonitrile occurs.

Compound 32 has an imino bridge instead of the methano bridge and is synthesized by reacting a primary aromatic or benzylic amine with o-(triphenylphosphoranylidene) aminobenzaldehyde. Isomers 33 (Fig. 5) of Troger's bases have long been known.[''] They are prepared from 5,6,11,12-tetrahydrodibenzo[*b*,*f*][1,4] diazocine and formaldehyde. Compound 33 (*R*=H) is 10.1 kcal mol^{-1} less stable than *nor*-Tröger's base (3), according to ab initio DFT calculations at the B3LYP/6-31G* level. The reactions of compounds 33 proved "comparable" to those of 3. even though the calculated cleft angle between the aromatic rings is considerably smaller (81° versus 112°), which leads to a considerably sharper cleft (see Fig. 6).

The homologous Troger's base analogue 34 (Fig. 5) is selectively available in a one-pot synthesis from 2-chloromethylbenzimidazole and hexamethylenetetramine with a 56% yield.[42] The isomeric products of the multimethenylation in the absence of template catalysts are not formed under these conditions.[42] The clefted conformer of the bridged tetrazecine 34 is the most stable (endo-endo-34 is 5.4 or 14.2 kcal mol^{-1} better than exo-rndo- or *exo-exo*-34. respectively) according to ab initio DFT calculations at the B3LYP/6-31G* level. The cleft is very narrow in this case (40°), and more detailed investigations of the supramolecular properties of 34 are clearly indicated. Two related benzo derivatives 35 (Fig. 5) were reported.[43] They were synthesized from 5,6,7,12,13,14-hexahydrodibenzo[*c*,*h*][1,6]diazecine and aromatic aldehydes.

Finally. the saturated bispidines 36 and (−)-sparteine 34 (Fig. 5) exhibit interesting clefts for supramolecular use. Bispidines form metal salt complexes. The *N,N'*-dimethylbispidine (36) has as its most stable conformer the twin-chair V-shape, according to ab initio DFT calculations at the B3LYP/6-31G* level (5.7 or 8.4 kcal mol^{-1} better than boat-chair or twin-boat conformers, respectively).

This preference is not overridden by slight differences in the aqueous solvation energy. The bispidine moiety was combined with crown-ether functionality to form a molecular cavity (19 ring members, including the cleft of bispidine, two *N* and four *O*).[44] Sparteine (37) is less stable than its 11β-diastereomer genisteine (by 9.3 kcal mol^{-1} according to B3LYP/6-31G* calculations). The (−)-sparteine is V-shaped (Fig. 6) and forms versatile chiral bases with lithium alkyls for enantioselective syntheses.[45] These reactions are usually formulated via double coordination of the Li in the cleft of the (−)-sparteine conformer 37. Similarly, bidentate metal salt complexes of (−)-sparteine form readily. The complexing nitrogens in the clefts of the pharmaceuticals (−)-cytisine (38) and tedisamil **(39)** (Fig. 5) (with an isomeric ring system) are certainly involved in the blocking and release of calcium and potassium cations. The (−)-cytisin (38) is a neuronal nicotinic acetylcholine receptor. It activates $\alpha 3\beta 4$ receptors and blocks $\alpha 3\beta 2$ receptors.[46] Tedisamil (39) is a new bradycardic agent that exerts antiischemic and antiarrythmic effects by blockading the different cardiac and vascular K^+ currents.['']

CONCLUSION

The unifying structural motif in this article is the molecular cleft. Clefts may be wide or sharp. If they are formed by (nearly) planar groups in molecules of C2 symmetry, they are most easily characterized by the dihedral angle between the planes. Space-filling models indicate the amount of free space. Space-filling models of ab initio DFT B3LYP/6-31G* calculations are contained in Fig. 6, as experimental values are only available for some of them. Both cleft arms are exactly vertical on the image plane in Tröger's base **(I,** *R*=CH_3, *X*=**H)**, pseudo-Troger's base (31. but CH_3 instead of CHO: CH_3 and CO_2CH_3 replaced by H). iso-Trogers base (33, *R*=H), and the 10-ring compound 34. The alicyclic clefts of dimethylbispidine (36) and (−)-sparteine (34) are better depicted in ball-and-spoke representation. In the *bis*-Troger's base 8 (NO_2 and CH_3 replaced by H). two of the aromatic rings are vertical on the image plane, and the five-clefts compound 18 (semiempirical PM3 calculation)

has the aryl rings for one dibenzo[2.2.2]cyclooctatriene moiety and both olefinic bridges vertical.

A wide cleft (112°; isolated molecule) is present in **I**. It is not much different from the upper dibenzobicyclo[2.2.2]octatriene clefts in **18** (DFT angle for the main cleft of dibenzobicyclo[2.2.2]octatriene: 118°). The cleft shape does not change much in **31** (109°). However. 33 has a considerably sharper cleft (81°), and 34 is very sharp (40°). The clefts of 36 and **37** are of different character, because their nitrogens (distances 2.958 and 3.054 Å, respectively) are not inaccessibly shielded. The nitrogen shielding in Troger-type clefts leads to outside protonation. alkylation. and heavy-metal salt complexation (5, 6, 17). The cleft angles determine the size, but included organic guest molecules profit only from the crystal lattices. Inclusions in 8 profit from a large double cleft. The huge cleft of 18 is created by substitution, and the Tröger's base moiety serves primarily as armature. as in the trogerophanes (21–23 and **25**), with their large rings and pockets. Only these or similar elaborate systems are suitable for molecular and chiral recognition. The supramolecular properties of bispidine and sparteine are of different character. The field is far from being exhausted.

Unimolecular Electronics and Unimolecular Rectifiers

Robert M. Metzger
The University of Alabama, Tuscaloosa, Alabama, U.S.A.

INTRODUCTION

"Molecular electronics" (ME) (*sensu stricto*), or "molecular-scale electronics" or "unimolecular electronics" (UE) is the study of electrical and electronic processes measured or controlled on a molecular scale or on the nanometer scale.[1,2] A wider definition of molecular electronics (*sensu lato*), or "molecule-based electronics" encompasses electronic p ocesses by molecular assemblies of any scale, including macroscopic crystals and conducting polymers.[1,3] This article deals with UE and focuses on electrical conduction (asymmetric or not), through single molecules or through a monolayer of molecules measured in parallel.

In the 1950s, ME was discussed in the U.S. Defense Department and was presaged by Richard P. Feynman's visionary comment "there is plenty of room at the bottom."[4]

THE AVIRAM–RATNER ANSATZ, THE FIRST UE PROPOSAL

The first concrete proposal for UE was the 1974 Ansatz by Ari Aviram and Mark A. Ratner that a rectifier of electrical current could be achieved with a single molecule.[5] A rectifier is an electronic device through which electrical current is conducted asymmetrically, i.e., preferentially from left to right. rather than vice versa: the IV curve is asymmetrical with voltage.

Since the late 1940s, the solid-state inorganic rectifier has consisted of a pn junction, where the p region is a semiconducting Si or Ge crystal "doped" with a small excess of substitutional impurities (electron-poor group-3 elements such as Al, Ga, In) that create a small excess of mobile "holes" (lack of electrons). The n region is a Si or Ge crystal doped with a small percentage of electron-rich group-5 atoms (N. P. As, etc.), creating a small excess of mobile electrons. Such *pn* rectifiers. where electrons flow preferentially from the *n* region to the p region, are used in electrical circuits and in integrated circuits.

Aviram and Ratner proposed that a unimolecular rectifier be a single D-σ-A molecule, where D is a good one-electron donor with relatively first low ionization potential, σ is some saturated covalent "sigma" bridge, and A is a good one-electron acceptor with relatively high electron affinity. when this molecule is placed between two appropriate metal contacts M_1 and M_2.[5] The bridge σ decouples the donor moiety D from the acceptor moiety A. If the decoupling between D and A is complete, then intramolecular electron transfer becomes impossible. The molecular ground state of D-o-A has a low dipole moment and can be written as D^0-σ-A^0, while the first excited state is much more polar, and is the zwitterionic state D^+-σ-A^-.

The Aviram–Ratner mechanism consists of two resonant electron transfers across metal–organic interfaces:

$$M_1 + D^0\text{-}\sigma\text{-}A^0 + M_2 \rightarrow M_1^- + D^+\text{-}\sigma\text{-}A^0 + M_2 \quad (1)$$

$$M_1^- + D^+\text{-}\sigma\text{-}A^0 + M_2 \rightarrow M_1^- + D^+\text{-}\sigma\text{-}A^- + M_2^+ \quad (2)$$

followed by an inelastic downhill intramolecular electron transfer:

$$M_1^- + D^+\text{-}\sigma\text{-}A^- + M_2^+ \rightarrow M_1^- + D^0\text{-}\sigma\text{-}A^0 + M_2^+ \quad (3)$$

which moves one electron from M_2 to M_1.[5] This electron transfer is possible if the molecule has reasonable oscillator strength in an intramolecular optical intervalence transfer (IVT) band.

The Aviram–Ratner proposal involves an electronic transition.[5] which is inherently fast (*ps* to ns), compared with translations, conformational transitions, or molecular rearrangements.

PHYSISORPTION (LANGMUIR–BLODGETT, LB) VERSUS CHEMISORPTION (""SELF-ASSEMBLY")

Aviram and Ratner did not specify how such a device could be interrogated electrically. There are two choices. The Langmuir–Blodgett (LB) technique allows for the assembly of one-molecule-thick ("monolayer") films or of several-molecule-thick films (multilayers):[6,7] the assembly onto surfaces by physisorption has the advantage that the transfer of ainphiphilic molecules from the

Encyclopedia of Supramolecular Chemistry
DOI 10.1081/E.ESMC.120012788

air–water interface to suitable solid substrate could be quantitative: the disadvantage is the weakness of the binding of these layers to the substrate. (The transfer ratio is the area covered by the LB monolayer on the solid substrate, divided by the area lost from the monolayer at the air–water interface.)

A competing technique is the formation of chemisorptive monolayers that are covalently bonded to the substrate:"' this is now called "self-assembly."[9] Self-assembly has the advantage of strong binding, but its disadvantage is that the surface coverage by a self-assembled rnonolayer (SAM) is rarely quantitative and is difficult to measure.

EARLY INTEREST IN ME AND UE

ME was launched with some fanfare,[10–12] then languished for several years. Recently. UE registered significant results, thanks to advances in how to place electrodes above LB monolayers of organic molecules without "frying them." and to studies of SAMs (thiols covalently bonded to gold) by either a scanning tunneling microscopy (STM) tip. by conducting-tip atomic force microscopy (AFM), or by gold "brealc junctions."[13] The interest in UE is due to projections that the technological progress in ultraminiaturization of Si-based integrated circuits. which makes computers faster as the distance ("design rule") between individual components shrinks (Gordon E. Moore's law[14]). may not reach nanoscopic dimensions. At design rules of 3 nm, one-molecule electronic devices (resistors. capacitors. rectifiers, and amplifiers) may present a significant technological alternative.

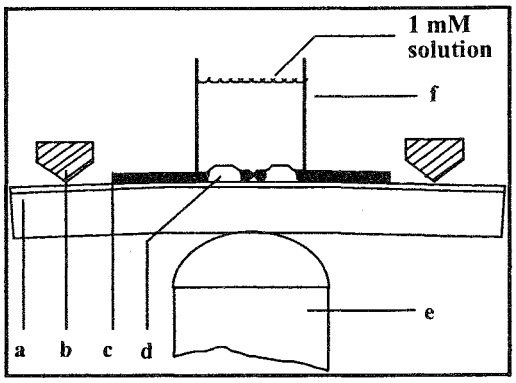

Fig. 2 Lever (b). piston (e). and beaker (f) with 1.4-benzenedithiol solution (From Ref [13])

THE EIGHT MILESTONES OF UE

Here is a subjective list of eight milestones. i.e., recent significant advances in UE:

1. Henry Taube showed that electron transfer between two different metal ions bridged by a shared ligand in solution was faster if the ligand was conjugated than if it was saturated, i.e., nonconjugated.[15] In *Milestone*

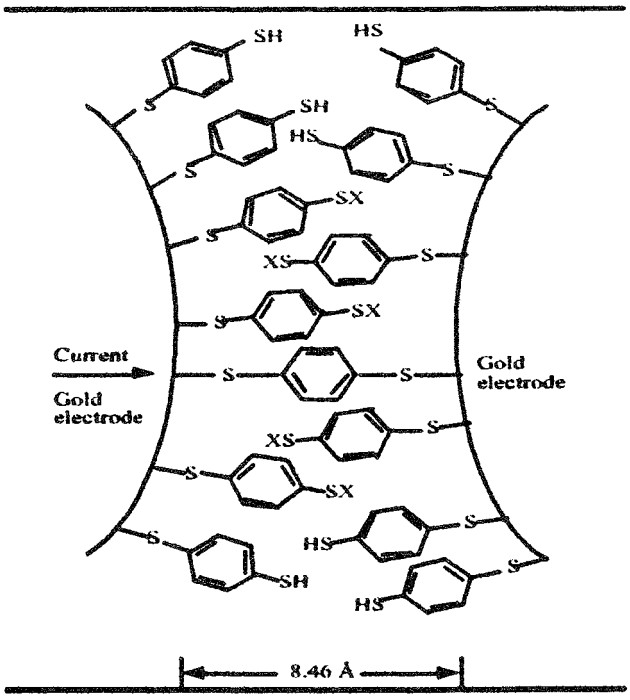

Fig. 3 Depiction of Au shards. and of 14-benzenedithiol molecules attaching themselves to one electrode. the other. or both electrodes. (From Ref. [13].)

One, a STM was used by Paul S. Weiss, David L. Allara, James M. Tour, and coworkers and confirmed Taube's result directly. by measuring the electrical current through individual ''molecular wires.''[16] The current through an aromatic 4,4-di(phenylene-ethynylene)-benzenethiolate bonded to an Au(111) surface is larger than that through an aliphatic *n*-dodecanethiolate bonded to the same substrate[ii6, (Fig. 1).

2. Rolf Landauer proved that the minimum resistance of any single-channel wire (composed of atoms or molecules or polymers), measured between any two macroscopic electrodes. is the quantum of resistance $R = (h/2e^2) = 12.91$ kΩ, where h is Planck's constant, and e is the electronic charge.[17] In *Milestone Two*, this Landauer quantum of resistance was measured by Walt de Heer and coworkers at room temperature between a multiple-walled carbon nanotube (MWCNT), glued to a conducting AFM tip, and a pool of liquid Hg.[18]
3. *Milestone Three* occurred when a break junction was fabricated by Mark A. Reed and coworkers, by evaporating a thin Au wire onto a Si wafer, then compressing this wafer between two static levers and a movable piezoelectric piston. When the Si wafer cracked, the Au wire sepa ated, creating two Au shards. with a mutual separation that could be controlled to ±0.01 nm by the voltage on the piston (Fig. 2).[13] When a benzene solution of 1,4-benzene-dithiol was put into the gap (Fig. 2), some 1.4-benzenedithiol molecules bonded covalently, either to one electrode or to the other or to both (Fig. *3)*. When the latter happened. a one-molecule bridge was created, with a resistance of 22 MΩ (Fig. 4a),[13] which was three orders of magnitude larger than the Landauer resistance quantum, because the lowest unoccupied molecular orbital (LUMO) of the benzene-dithiolate was not in resonance with the work function of Au. The resistances were reproducible (Fig. 4b). If two molecules bonded to both Au shards (two one-molecule bridges). 13 MΩ was measured (Fig. 4c).[13]
4. *Milestone Four* took place when Mark A. Weed developed a "nanopore" technique. Into a thinned-out region of a Si wafer, Au was evaporated to form a 50-nm-wide, few-nm-deep "bowl" of Au{*11*1}, onto which thiols were self-assembled (Fig. 5). The nanopore was then covered with Ti (and its oxide), then Au. Thus. sandwiches ''Au |thiolate|Ti/TiO_2| Au'' could be studied, with maybe a thousand SAM molecules of area 2 nm^2 each. in parallel. A SAM of 4-ethynyl-phenyl-4′-ethynylphenyl-benzene-1-thiolate was a Schottky barrier rectifier."'' In contrast, a SAM of 2'-amino-4-ethynylphenyl-4'-ethy nylphenyl-5′-nitro-benzene-1-thiolate gave a surprise. a negative differential resistance (NDR) peak, useful if this molecule could replace a tunnel diode in a device (Fig. 6).[20] STM suggests that the molecule changes its orientation on Au{111} and thus its conductivity.[21]
5. *Milestone Five* is as follows. When a single-walled carbon nanotube (SWCWT) was deposited by Louis Pasteur's method onto a Si substrate with a 70-nm-wide Au source and drain electrodes, and was studied by STM (Fig. 7), with the STM tip acting as a gate electrode. the nanotube acted as a semiconductor,

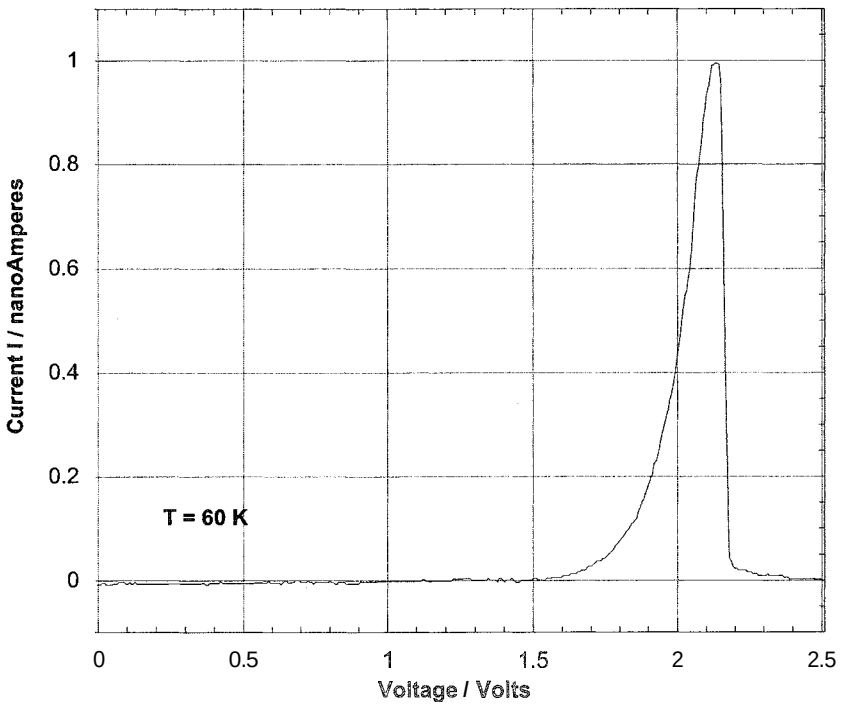

Fig. 6 Current-voltage (IV) curve for Au ¦ 2′-amino-4-ethynylphenyl-4′-ethynylphenyl-5′-nitro-1-benzenethiolate ¦ Au at 60 K, exhibiting NDR. to wit, $(dI/dV) = R < 0$ for $V > 2.1$ Volts. (Redrawn from Ref. [20].)

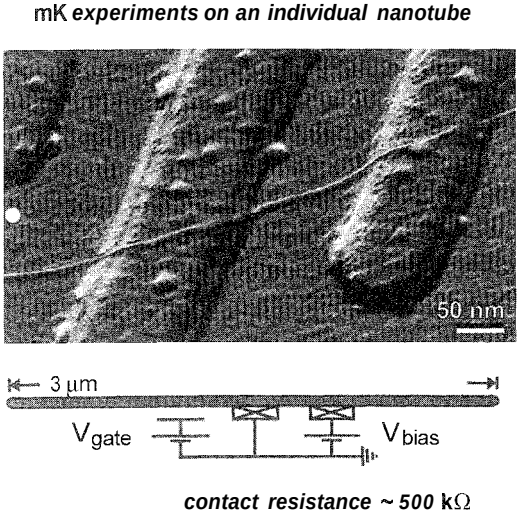

Fig. 7 A SWCNT acting as the semiconductor in a FET measured by STM. (From Ref. [22].)

and field-effect transistor (FET) behavior was observed.[22] FETs are a major source of power amplification in Si-based integrated circuits. They are three-electrode devices, where the current from the source electrode to the drain electrode traverses an electrical semiconductor region, with an effective width (and therefore electrical conductivity) controlled by the electric field between the gate electrode and source and drain electrodes. Thus, a FET requires only that a semiconductor of any dimension be placed between the three electrodes. Its efficiency is due to the sizes and placements of the three electrodes. The gain in the SWCNT FET was only 0.33,[22] but later improvements showed much higher gain.[23,24]

FET behavior in LB physisorbed multilayers of conducting polymers were seen,[25] as was FET behavior in thin-film organic semiconductors, e.g., sexithiophene.[26,27] The assembly of SWCNT in the FET[22-24] is limited to "Pasteur's method" of studying the one SWCNT that fortuitously landed across the "right" Au electrodes. This is a major shortcoming of all carbon nanotube-based devices.

6. In *Milestone Six*, a change in electrical conductivity, presumably tied to a molecular translation, was reported. A cyclic bistable [2]catenane, with two different electron donor moieties (the closed "track") and a cyclic acceptor traveling on the catenane (the "train" on the closed track) (Fig. 8) was measured as a LB monolayer between polysilicon and Ti electrodes. The two donor moieties are naphthalene, a weak donor, and tetrathiafulvalene, a much stronger donor (in the sense that it is more easily oxidized. The electron acceptor is a paraquat salt. The current–voltage plot was asymmetric (Fig. 9), as the train moves from the lower-conductivity station to the higher-conductivity station, although it is not clear which signal is due to which station.[28] The device speed is low, because it depends on a fast electronic transition followed by a slow molecular translation.
7. *Milestone Seven* is as follows. The metal–organic equivalent of a single-electron transistor (SET), which is a Coulomb blockade device with no gain. was recently reported.[29] A Coulomb blockade occurs in a nanodevice (quantum dot, or small metal particle) if adding an extra charge to a finite set of charges on that nanodevice is hindered by Coulomb repulsion, and extra energy is required to add that charge in spite of the Coulomb repulsion. A hexacoordinate Co(II) complex, shown in Fig. 10, was attached at many points to a prefabricated Au wire with a narrow kink in it atop an oxide-covered n-type degenerate Si wafer.[29] The attachment to Au was through one or two thiols.[29] When current was passed through the Au wire at 4.2 K, at some point, the device melted at the kink, and the bithiol then bonded between the two

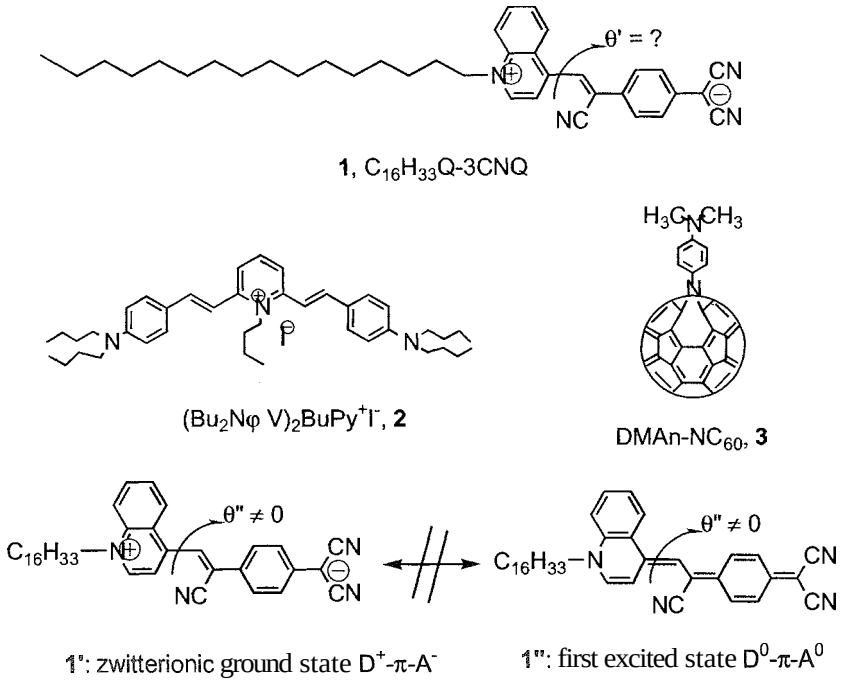

Fig. 11 Three unimolecular rectifies (**1**, **2**. and **3)**

Au shards, with a success rate of a few percent.[29] When a potential was applied to the Si gate electrode. the conductivity through the complex at 0.1 K changed. This change was ascribed to oxidation from Co(II) to Co(III).[29]

8. In *Milestone* Eight, unimolecular rectification was confirmed by Robert M. Metzger and coworkers for an LB monolayer of hexadecylquinolinium tricyanoquinodimethanide. C_{16} H_{33} Q-3CNQ, **1** (Fig. 11) sandwiched at first between oxide-bearing Al electrodes (Fig. 12),[30–32] and later across oxide-free Au electrodes (Fig. 13).[33,34]

The next two rectifiers were dimethylanilinoazafullerene, DMAn-NC_{60} (**2**), a D-σ-A molecule,[35] and 2,6-di[dibutylamino-phenylvinyl]-1-butylpyridinium iodide, $(Bu_2N\varphi V)_2BuPy^+$ I^- (**3**), a charge-transfer salt or interionic rectifier.[36] Details and recent reviews are given elsewhere.[37–40]

RECTIFICATION BY A SINGLE MOLECULE

The electrical conduction through macroscopic matter follows Ohm's law, $\mathbf{I} = V/R$, where **I** is the current, V is the applied potential or bias or voltage, and R is the resistance. Ohm's law is obeyed if the conduction is limited by scattering from impurities or lattice defects.

On the nanoscopic level, the current **I** is limited by quantum-mechanical tunneling in some form and depends exponentially on some power c of V: $\mathbf{I} = A \exp(b V^c)$ (the prefactor A also depends on some power of V). For $V < 0$, **I** is also negative: $\mathbf{I} = -A \exp(b|V|^c)$, so the current–voltage is sigmoidal, or symmetrical with V: $\mathbf{I}(-V) = -I(V)$.

In contrast, electrical rectification, or asymmetrical conduction implies the following:

$$I(V) \neq -I(-V) \tag{4}$$

This asymmetrical conduction, or rectification. for a single molecule or for a monolayer of molecules measured in parallel, can have three causes:

1. A Schottky barrier (dipole layer) at the metal–molecule interface: due to differences in Gibbs free energies of the metal and the molecule or the formation of a dipolar layer of charges on the two sides of the interface. This is ''S'' (for Schottky) rectification.[41]
2. The asymmetric placement between two electrodes of the "chromophore," or electron-rich region of the molecule. This is ''A'' (for asymmetric) rectification.[42]
3. The asymmetric placement between the electrodes of the significant molecular orbital coefficients of the energy levels relevant for electron transfer. This is ''U'' (for unimolecular) rectification.

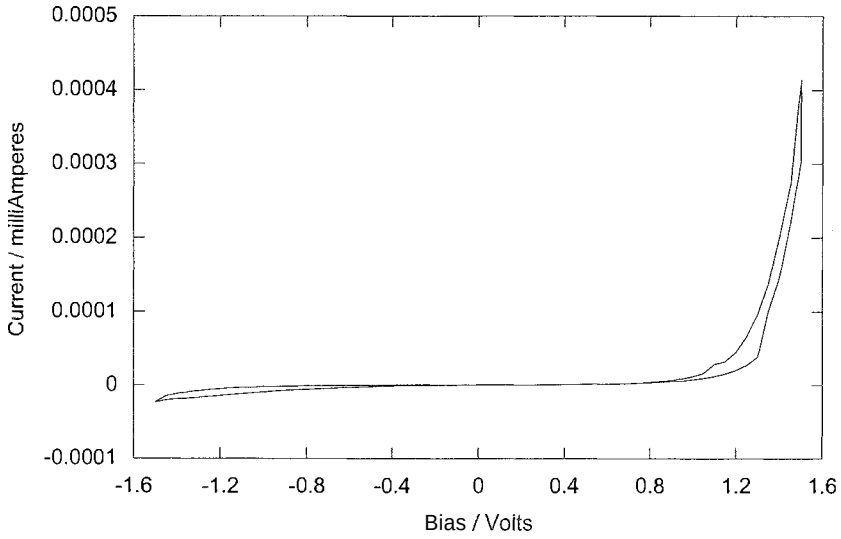

Fig. 12 I–V plot for a monolayer of 1 sandwiched between Al electrodes. (From Ref [30])

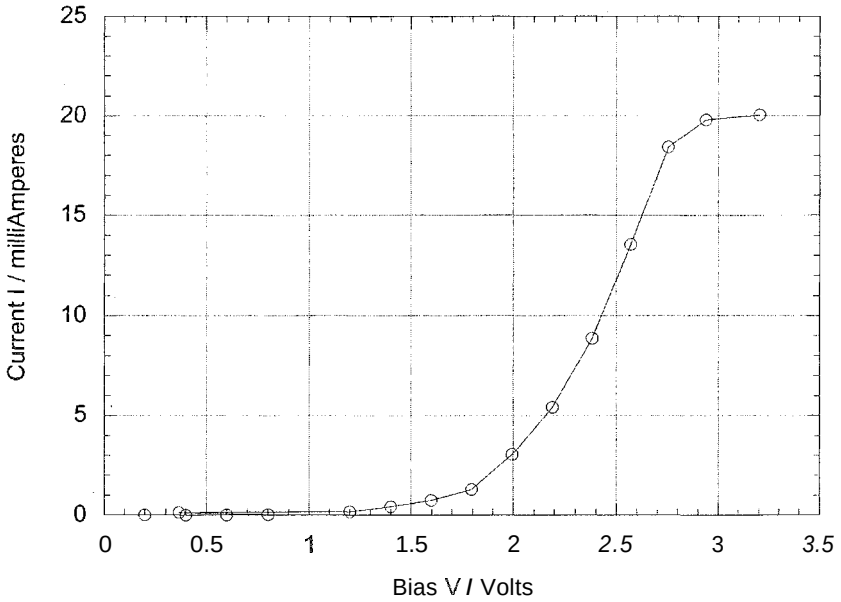
For example. molecule 1 is an "A" rectifier (because of the long hexadecyl ''tail'' needed for LB assembly) and. most importantly. a ''U'' rectifier.

Rectification by Molecule 1

The rectification for 1 was first detected by J. Roy Sambles and coworkers between Mg and Pt electrodes.[43,44] A monolayer of 1 was placed by Metzger and coworkers between two electrodes of the same metal [at first Al,[30–32] then Au[33,34] (Fig. 14)]. Also, Molecule 1 was thoroughly characterized.[45,46] The ground-state static electric dipole moment of 1 is $\mu_{GS} = 43 \pm 8$ Debyes.[30] There is a strong and narrow absorption band peaked between 600 and 900 nm. which is strongly hypsochromic; this IVT[30,45] fluoresces in the near-IR region.[45] The excited-state dipole moment is estimated to be $\mu_{ES} = 3$–9 Debyes:[45] 1 is zwitterionic in the ground state



Fig, 13 I–V plot for a monolayer of 1 sandwiched between Au electrodes. with saturation in the forward current. (From Ref. [34].)

$(D^+\text{-}\pi\text{-}A^-, \mathbf{1}')$, and less dissociated $(D^0\text{-}\pi\text{-}A^0, \mathbf{1}'')$ in the first excited state. Molecule 1 forms amphiphilic Pockels–Langmuir monolayers at the air–water interface, with a collapse pressure of 34 mN m^{-1} and a collapse area of 50 $Å^2$ at 20°C.[30] It transfers well on the upstroke, with transfer ratios around 100% onto hydrophilic glass, quartz, or aluminum,[30] or fresh hydrophilic Au.[33,34] The LB monolayer thickness of **1** was determined as 2.3 nm[30] or 2.9 nm[34] (x-ray diffraction), 2.3 nm (spectroscopic ellipsometry),[34] 2.2 nm (surface plasmon resonance),[30,46] and 2.5 nm (x-ray photoelectron spectrometry, XPS).[46] The molecule in the monolayer is estimated to lie at 46° from the surface normal.[30] To perform rectification measurements, LB monolayers and multilayers of **I** were sandwiched between macroscopic Al electrodes[30] and then between Au electrodes.[33,34] For Au deposition, the sample holder is cryo-cooled to 77 K, and 10^{-3} torr of Ar gas is added to the evaporation chamber. Also. the substrate is shielded from direct thermal radiance from the heated Au source.[34]

When a monolayer of **1** is placed between Al electrodes (with their patchy and defect-ridden Al_2O_3 coating), then a dramatically asymmetric current is seen (Fig. 12).

The rectification ratio (RR) at potential V is the current at a positive bias V divided by the absolute value of the current at the corresponding negative bias −V:

$$RR(V) = |I(V)|/I(-V) \tag{5}$$

For **1**, RR = 26 at 1.5 Volts; this corresponds to a current of 0.33 electrons molecule $^{-1}s^{-1}$.[30] This same asymmetry is seen also for multilayers of **1**, for a sample covered

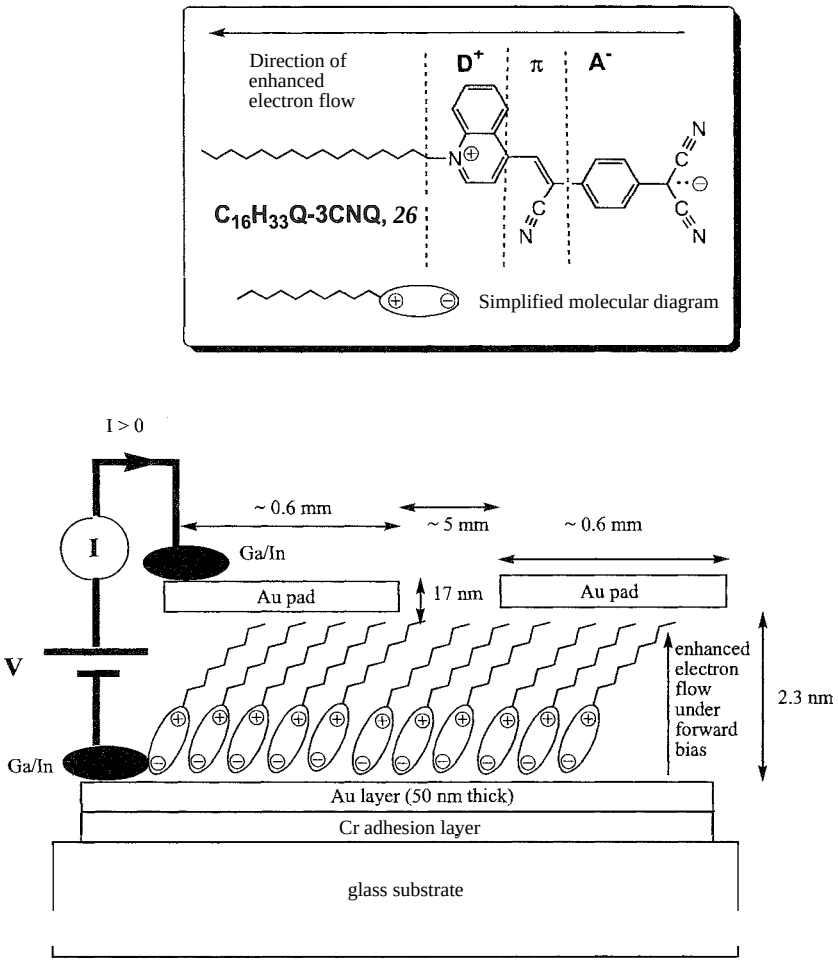


Fig. 14 Molecular structure and geometry of LB monolayer of **1** sandwiched between Au electrodes with direction of enhanced electron flow. The substrate was glass. 50 mm x 50 mm *x* 0.4mm, covered either by a Cr adhesion layer or by a hydrophobic xylene covering, followed by an evaporated Au film 50 mm x *50* mm *x 50* nm. then the LB monolayer or multilayer, then by 48 cylindrical Au pads. 17 nm thick and with an area of *0.283* mm^2. (From Ref. [34].)

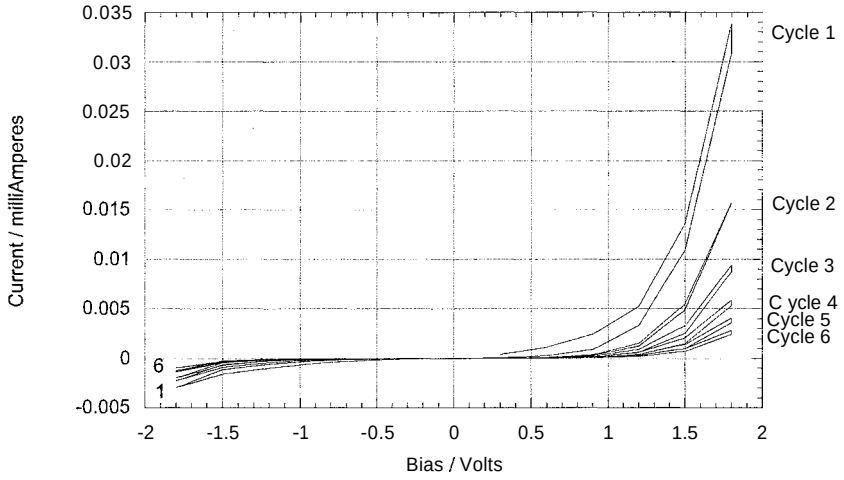

Fig. 15 I–V plots for 2 measured in an ''Au | LB monolayer of 2 | Au'' cell. for six successive cycles of measurement. RR = 12.7. 5.4. 3. 3. for cycles 1 through 6, respectively. (From Ref. [35].)

by Mg pads topped by Al pads,[30,43,44] for monolayers and multilayers of 1 on graphite studied by scanning tunneling spectroscopy,[30] and even for a solution of 1 in dimethylsulfoxide placed in the STM.[30] The RR varies from pad to pad because it is obtained in two-probe measurements. It was suggested that any molecule with RR<2 at maximum V should not be considered a rectifier.'''] As high potentials are scanned, RR decreases gradually, presumably because in an electric field of (1.5 Volts/2.3 nm) = 0.65 GV m^{-1}, molecules in the monolayer may turn around, end over end. to minimize the total energy.[30] Measurements in the temperature range 105 K < T < 390 K established that the asymmetry is not temperature dependent.[32]

When the ''cold gold'' evaporation technique[42] was used, the current through the Au pads increased dramatically.[33,34] The best rectification ratio was 27.5 at 2.2 Volts.[34] The maximum current was 90,400 electrons $molecule^{1}s^{-1}$.[34] Some cells exhibited. as in Fig. 13, the saturation in the forward current[34] predicted by the Aviram–Ratner model.[5]

These results confirm experimentally the Aviram–Ratner Ansatz.[5] but the low-polarity and high-polarity states are interchanged.[45]

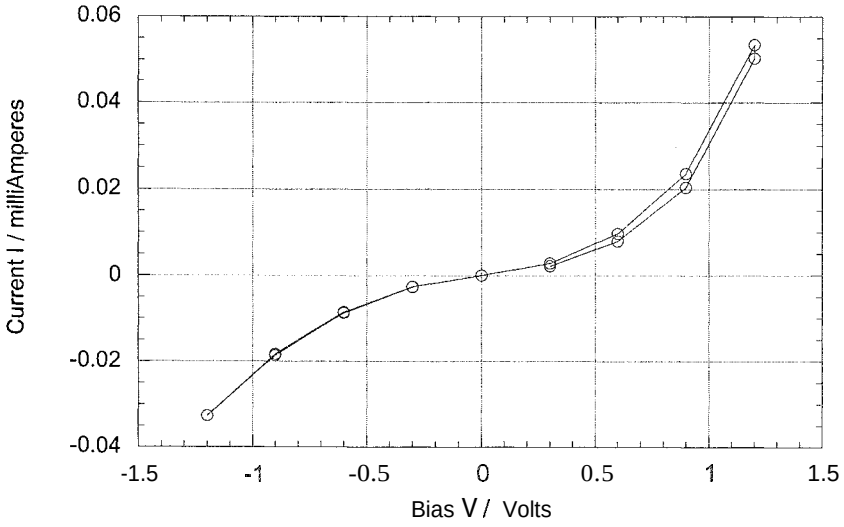

Fig. 16 Current–voltage plots for **3** measured in an ''Au LB monolayer of **3** | Au'' cell. (From Ref. [36].)

Rectification by Molecule 2

The $(Bu_2N\varphi V)_2$ $BuPy^+I^-$, *Molecule 2 forms a* Pockels–Langmuir *film at the air–water interface and transfers to hydrophilic substrates as a Z type* LB multilayer[35] (*"Z-type" means that all dipoles are in the* same *direction). The* monolayer *thickness values were* 0.7 *nm* (ellipsometry) *and 1.15 nm (surface* plasmon *resonance) and 1.3* nm *(x-ray* diffraction).[35] *The films exhibit an absorption* maximum *at* 490 *nm (slightly hypsochromic in solution, attributable to iodide-to-pyridiniuln back-charge transfer). and a second-harmonic signal* $\chi^{(2)}=50$ *pm* V^{-1}.[35] The *rectification in Fig.* 15 *shows a decrease of rectification upon successive cycles. Some cells have* initial RRs *as high as 60. The favored direction of electron* flow *is from the gegenion to the* pyridinium *ion.* i.e., *in the direction of "back-charge transfer," and the rectification in* $(Bu_2N\varphi V)_2$ $BuPy^+I^-$, *2* is *attributed to an interionic process rather than to an intramolecular* process.[36]

Rectification by Molecule 3

The azafullerene DMAn-NC_{60}, **3** *is a weak electron donor* (dimethylaniline) *bonded to a moderate electron acceptor (N-capped* C_{60}), *with a significant* IVT *peak at* 720 nm.[36] *The molecular areas in the monolayer at the air–water interface are only* 70 $Å^2$ at *extrapolated zero pressure.* and 50 $Å^2$ *at 22* mN m^{-1}, *whereas the molecular area of* C_{60} is *close to* 100 $Å^2$. *The* molecules **3** *are probably transferred in a slightly staggered* mode.[36] *The* XPS *film* thickness *is* 2.2 nm.[36] The *monolayer* is *covered, as* previously,[34,45] *by Au* pads.[36] *The current–voltage plot in Fig.* 16 *shows* a *"marginally" rectifying current"'] in the forward direction, with RR of about* 2.[36]

CONCLUSION

Although unimolecular *rectification has been confirmed. there are* still *questions:*

1. *How fast* is *the rectification process?*
2. Can *inelastic electron tunneling spectroscopy* confirm *that the electron really goes through the molecule (instead of tunneling through space)?*
3. Can *the device be made* more *sturdy.* e.g., *by anchoring the molecules covalently to both* metal *electrodes?*
4. Can *one investigate optically what occurs during the electrical* measurements?
5. Can *rectifiers and strands of conducting polymers be grafted together to form a molecular amplifier with power gain?*

Urea Inclusion Compounds

Kenneth D. M. Harris
Cardiff University, Cardiff, Wales

INTRODUCTION

Urea inclusion coinpounds were first discovered in the 1940s with the serendipitous preparation by Bengen[1] of an adduct between I-octanol and urea. Many different families of guest molecules based on long alkane chains are now known to form inclusion compounds with urea, and x-ray diffraction studies[2,3] have been that the host structure in these crystalline solids contains linear. parallel tunnels that are constructed from an extensively hydrogen-bonded arrangement of urea molecules. The guest molecules are densely packed along these tunnels. A remarkable fact is that the vast majority of different urea inclusion compounds (containing different types of guest molecules) have essentially the same urea host structure at ambient temperature, and we refer to such cases as "conventional" urea inclusion compounds (guest molecules that represent exceptions are discussed later in this article). The conventional urea inclusion compounds are characterized at ambient temperature by: a hexagonal host tunnel structure (Fig. 1: space group $P6_122$ or $P6_522$; $a = b \approx 8.2$ Å; $c \approx 11.0$ Å; effective tunnel "diameter" ranging between 5.5 Å and 5.8 Å on moving along the tunnel): an incommensurate relationship (see below) between the periodicities of the host and guest substructures along the tunnel axis; and substantial dynamic disorder (reorientation about the tunnel axis) of the guest inolecules (see below). In the conventional urea inclusion compounds, the urea inolecules form hydrogen bonds only to other urea molecules. and there is no hydrogen bonding between urea molecules and guest molecules. The host structure comprises a spiral arrangement of urea molecules, and a given single crystal contains only right-handed spirals ($P6_122$) or only left-handed spirals ($P6_522$). Thus. the host tunnel is a chiral structure.

Structural compatibility between host and guest components is fundamental to most inclusion phenomena. and the conventional urea tunnel structure is formed only with guest molecules that are based on a sufficiently long alkane chain and with only a limited degree of substitution of this chain allowed. Examples of appropriate guest molecules are *n*-alkanes and derivatives such as α,ω-dihalogenoalkanes, diacyl peroxides, carboxylic acids, alkanones, carboxylic acid anhydrides, and α,ω-alkane dicarboxylic acids. In general. rnolecules containing benzene or cyclohexane rings do not form inclusion compounds with urea. presumably because these structural components are too wide to fit comfortably inside the tunnel. Several empirical generalizations have been made[4,5] concerning the geometric and steric features of guest molecules that form inclusion compounds with urea. The requirement for size and shape compatibility between host and guest components leads to the possibility of using urea inclusion compounds in applications based on molecular separation. such as the separation of mixtures of linear and branched alkanes. Such applications provided the motivation for much early research (particularly within the petrochemicals industry) on urea inclusion compounds. before it was found that zeolites and related materials offer several advantages in such applications. Nevertheless, the formation of urea inclusion compoiinds is still used on the laboratory scale as a method for isolating linear molecules.

The empty urea tunnel structure is unstable, and it has been shown by experiment and computer simulation that the tunnel collapses if the guest molecules are removed from the inclusion compound. leading to the ''pure'' crystalline phase of urea, which does not contain empty tunnels. The instability of the "empty" urea tunnel structure clearly limits the potential for developing certain applications of urea inclusion compounds.

In addition to forming tunnel inclusion compounds, urea can also form specific complexes with a variety of organic and inorganic nlolecules and ions. Discussion of these complexes is beyond the scope of this article. which is focused on tunnel inclusion compounds of urea.

In this article, an overview of structural aspects of urea inclusion compounds is provided, and some of the interesting properties of these materials. such as the dynamic and conformational properties of the guest molecules. chemical reactions, and applied aspects, are elaborated upon. Also highlighted are the types of techniques used to investigate these properties. Several review articles have been published on urea inclusion compounds,[5–10] and they contain comprehensive lists of references to the original literature in this field. The reader is encouraged to consult these review articles. and the original papers cited therein, in order to obtain more information.

Guest molecules have been inserted into the tunnels. illustrating orientational disorder. The positions of the guest molecules are not actually determined from X-ray diffraction data at ambient temperature. (View *this art* in color *at www.dekker.com.*)

STRUCTURAL PROPERTIES

Periodic Structural Properties

As discussed above, the conventional urea inclusion compounds are characterized by the hexagonal urea tunnel structure shown in Fig. I at ambient tempcrature, and by an incommensurate relationship between the host and guest substructures along the tunnel axis (Fig. 2). The periodic repeat distance of the guest molecules along the tunnel (c,) depends directly on the length of the guest molecule in the linear type of conformation required to fit inside the tunnel, and the periodic repeat distance of the urea molecules along the tunnel (c_h) is fixed by the host structure (c_h is essentially invariant at ca. 11 A for urea inclusion compounds containing different guest molecules). The incommensurate relationship between c_g and c_h in conventional urea inclusion compounds is readily evident from x-ray diffraction photographs (see Fig. 2 of article on "Incommensurate and Cornmcnsurate Structures").

Although the focus in this article is on the conventional urea inclusion compounds, we note that the inclusion compounds formed between urea and certain specific gucst molecules arc commensurate tunnel structures. For such commensurate systems, the host structure is usually distorted from the hexagonal tunnel structure shown in Fig. 1. Examples are the inclusion compounds formed between urea and the guest molecules 1,6-dibromohexane,[11] sebaconitrile[12] and (a + 1),(ω - 1)-alkanediones.[13] The inclusion compounds of urea and (a + 1),(ω - 1)-alkanediones exhibit an interesting diversity of commensurate superstructures in which there is direct hydrogen bonding between urea molecules and the guest molecules. Furthermore, a number of tunnel inclusion compounds of urea containing polymeric guests have been found to exhibit host structures that differ from the conventional urea tunnel structure.[14-16]

Many conventional urea inclusion compounds exhibit three-dimensional (3-D) ordering of the guest molecules, and thus there are well-defined structural relationships between guest molecules both within each tunnel and between adjacent tunnels. The mode of intertunnel ordering (characterized by the intertunnel offset A_n, defined in Fig. 2) is found to depend on the functional groups present on the guest molecule, and different homologous families of guest molecules exhibit characteristic modes of intertunnel ordering. Results for selected families at ambient temperature are: alkanelurea, $A_n = 0$ A; diacyl peroxide/urea, $A_n = 4.6$ Å;[17] α,ω-dibromoalkane/urea, A_g and c_g are related by the exact relationship $\Delta_g = c_g/3$;[18] and carboxylic acid anhydride/urea, $A_n = 0$ Å, with the exception of heptanoic anhydride/urea, for which $A_n = 2.3$ Å.[19] The complete 3-D arrangement of guest molecules is understood by extending the Δ_g concept into three dimensions, leading to monoclinic, rhombohedral, and hexagonal guest structures for diacyl peroxide/urea, α,ω-dibromoalkane/urea, and alkane/urea inclusion compounds, respectively. For the alkanelurea and α,ω-dibromoalkane/urea inclusion compounds, these average symmetries require disorder of the guest molecules with respect to reorientation about the tunnel axis. In many cases, a given single crystal contains

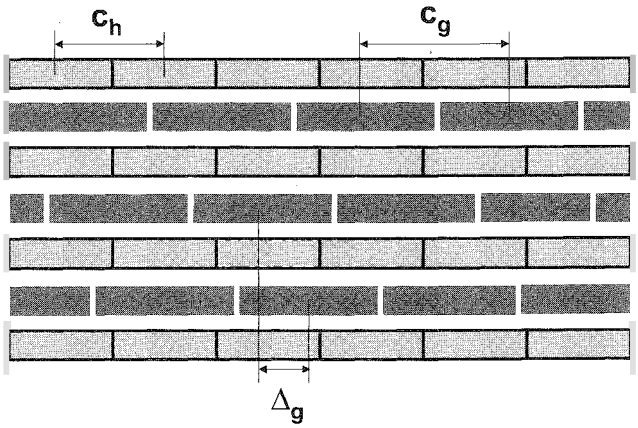

Fig. 2 Schematic two-dimensional representation of a urea inclusion compound viewed perpendicular to the tunnel axis and indicating the definitions of c_g, c_h and A_n. (View *this art in color at* www.deklcer.com.)

different domains of the guest substructure: each domain has an identical packing of guest molecules but has a different (although equivalent) orientation relative to the host structure. Although, as discussed above, diffraction data allow the average periodicity and symmetry of the basic guest structure to be determined, dynamic disorder of the guest molecules in conventional urea inclusion compounds can limit the ability to obtain detailed information on the guest structure. One consequence of the dynamic disorder of the guest molecules is the appearance of different forms of diffuse scattering in diffraction patterns of urea inclusion compounds.

As a consequence of the incommensurate nature of urea inclusion compounds, the symmetry of the composite inclusion compound (i.e., considering host and guest components implicitly together) cannot be described by a 3-D space group, and instead. a four-dimensional (4-D) superspace group is required. Descriptions of the symmetry properties of urea inclusion compounds in superspace groups have been developed,[20] and attempts to determine the incommensurate modulations in the host and guest substructures by solving the structure of the composite inclusion compound in a superspace group have been reported.[21,22] Much research[3,23–27] has been devoted to the study of all aspects of the diffraction patterns from incommensurate urea inclusion compounds (particularly alkanelurea inclusion compounds), including measurement of incommensurate satellite reflections and detailed characterization of different forms of diffuse scattering. The diffraction patterns of incommensurate urea inclusion compounds contain a rich variety of features: which promise to yield important fundamental inforination on the disorder properties and the incommensurate structural nature of these solids. A related aspect concerns the vibrational properties of the inclusion compound, and much attention has focused on the existence and observation of an extra acoustic vibrational mode (the "sliding mode") that may be expected to be observed for incommensurate systems.

Phase Transitions and Structural Properties at Low Temperature

At sufficiently low temperatu es, most conventional urea inclusion compounds undergo phase transitions associated with changes in the symmetry of the host structure and changes in the dynamic properties of the guest molecules. For alkanelurea and α,ω-dibromoalkane/urea inclusion compounds, structural[28–32] and dynamic[33–41] aspects of these phase transitions have been investigated extensively using a variety of techniques. Qualitatively, the alkane/urea and α,ω-dibromoalkane/urea inclusion compounds behave in a siinilar way with respect to these transitions. In both cases. the host structure in the low-temperature phase is orthorhombic and is based on a small distortion from the orthohexagonal description of the high-temperature structure. The structural relationship between the host and guest substructures along the tunnel remains incommensurate. Other urea inclusion compounds, such as 1,10-decanedicarboxylic acid/urea[42] exhibit more complicated structural behavior in the low-temperature phase, with the formation of large superstructures in directions perpendicular to the tunnel axis. Thus. the exact nature of the distortion of the host structure in the low-temperature phase depends critically on the type of guest molecule.

There have been various attempts to rationalize the phase transitions observed in urea inclusion compounds. One of these approaches[43] draws an analogy between the phase transition in alkane/urea inclusion compounds and the order–disorder phase transitions in alkali cyanide crystals and proposes that coupling between transverse acoustic phonons of the host structure and the orientational order of the guest molecules provides an indirect mechanism for orientational ordering of the guest molecules in the low-temperature phase.

The phase transitions for alkane/urea and α,ω-dibromoalkane/urea inclusion compounds are not associated with changes in the mode of 3-D ordering of the guest molecules. However, the behavior of other urea inclusion compounds is different in this regard. For example. heptanoic anhydride/urea exhibits two phase transitions below ambient temperature.[44] The first transition (at 179 K on cooling) is associated only with a change in the mode of 3-D ordering of the guest molecules (A, = 2.3 A above 179 K: A, = 1.5 Å below 179 K), whereas the second transition (at 122 K on cooling) is associated with a distortion of the host structure as well as a further change in the mode of 3-D ordering of the guest molecules (A, = 0 A below 122 K).

Conformational Properties and Local Interactions of Guest Molecules

The structure of a crystalline solid determined from diffraction studies represents a space-averaged and time-averaged representation of the true structure. and in cases for which there is disorder (static or dynamic), structure determination from diffraction data cannot readily provide a complete description of the distribution of local (spatial or temporal) structural features about this averaged representation. As discussed below. there is substantial dynamic disorder of the guest inolecules in conventional\urea inclusion compounds, and although information on the average periodicity of the guest molecules can be established from diffraction data (as discussed above), eiucidating a detailed description of the structural

properties of the guest molecules from such data is far from straightforward. Nevertheless, other experimental and computational techniques can be used to obtain direct information on local structural properties, such as the conformational properties of the guest molecules, the interactions between guest molecules within the tunnel, and the orientational distributions of the guest molecules. Illustrative examples from such studies are now highlighted.

Raman spectroscopy has been used[45] to probe conformational properties of α,ω-dihalogenoalkane guest molecules [$X(CH_2)_nX$; $n = 8$ for $X = Cl$; $n = 7$–11 for $X = Br$: $n = 8$ for X = I] in urea inclusion compounds. In particular. the C–X stretching vibrations were used to assess the relative amounts of *trans* and *gauche* end groups as a function of the length (n) of the guest molecule. the identity of the terminal substituent X, temperature, and pressure. These investigations suggest that there is no well-defined relationship between the proportion of end groups in the *gauche* conformation and the length of the $Br(CH_2)_nBr$ guest molecules. The proportion of *gauche* end groups decreases significantly as the size of the terminal substituent is increased—at ambient temperature, the proportion of *gauche* end groups is 51% for $Cl(CH_2)_8Cl$, 7% for $Br(CH_2)_8Br$, and 1% for $I(CH_2)_8I$. For $Br(CH_2)_nBr$/urea inclusion compounds. the proportion of *gauche* end groups increases slightly as temperature is increased and increases markedly [for $Br(CH_2)_{11}Br$/urea] as the applied pressure is increased.

To directly probe the interaction between adjacent guest molecules in a urea inclusion compound, high-resolution solid-state ^{19}F-NMR spectroscopy (with high-power ^1H decoupling) was employed.[46] For the urea inclusion compound containing 1,10-difluorodecane [$F(CH_2)_{10}F$] guest molecules, the close proximity of the fluorine end groups of neighboring guest molecules gives rise to essentially isolated $^{19}F\cdots{}^{19}F$ spin pairs. Measurement of the $^{19}F\cdots{}^{19}F$ dipole–dipole interaction provides an opportunity to estimate the $^{19}F\cdots{}^{19}F$ distance. although such analysis is complicated by conformational disorder (the ^{19}F nucleus may be in *gauche* or *trans* positions with respect to the alkane chain. leading to the possibility of *trans–trans*, *tmrzs–gauche,* and *gauche–gauche* end group situations between adjacent end groups) and by reorientation of the guest molecules about the tunnel axis. Different ^{19}F-NMR techniques are in agreement that the average $^{19}F\cdots{}^{19}F$ dipole–dipole interaction is about 1 kHz at ambient temperature. This value is consistent with a random distribution over all mutual orientations for the *trans–gauche* and *gauche–guuche* situations. with little or no population of the *trans–trans* situation.

Bromine M-edge extended x-ray absorption fine structure (EXAFS) experiments were carried out[47] to investigate a variety of local structural properties of urea inclusion cornpounds containing α,ω-dibromoalkane guest molecules [$Br(CH_2)_nBr$; $n = 7$–11], and has led to unambiguous information on the intramolecular geometry around the bromine atom based on the Br C distances for the three intramolecular carbon atoms closest to the bromine atom. The value of the $Br\cdots C(3)$ distance indicates that the bromine end groups exist predominantly in the *trans* conformation, in agreement with results from Raman spectroscopy.

Recently,[27] information on the guest–guest interactions in urea inclusion compounds containing α,ω-diiodoalkane [$I(CH_2)_nI$] guest molecules has been established directly from analysis of the intensity distribution of diffuse sheets in their x-ray diffraction patterns. These diffuse sheets are often observed in x-ray diffraction patterns of urea inclusion compounds and correspond to 1-D ordering of the guest molecules along the tunnel axis. Thus, analysis of the intensities of the diffuse sheets provides information on the structural properties of the periodic linear array of guest molecules along an individual tunnel. Experimental measurements were made of the intensity distribution $I(l_g)$ obtained from 1-D scans of reciprocal space perpendicular to the diffuse sheets (where each diffuse sheet is specified by integer l_g). The 1-D Patterson maps constructed from the $I(l_g)$ data have a dominant peak at ca. 3.94 Å. which is interpreted as the projection: onto the tunnel axis, of the intermolecular $I\cdots I$ distance. This value is consistent with a model in which the iodine end groups are in van der Waals contact. with the $I\rightarrow I$ vector lying essentially parallel to the tunnel axis.

Guest molecules in solid host structures are often constrained to exhibit uncharacteristic conformational properties, which can be exploited as a means of carrying out spectroscopic characterization of such conformations. For example. guest molecules in the 1,6-dibromohexane/urea inclusion compound (a commensurate system) exist exclusively with both bromine end groups in the *gauche* conformation: allowing a definitive characterization of the vibrational properties of this conformation.[48]

Studies of End-Group Interactions for Unsymmetric Guest Molecules

For unsymmetric guest molecules of the type $X(CH_2)_nY$ in urea inclusion compounds, three different types of end-group interactions are possible within the tunnel (Fig. 3): $X\cdots X$ (head–head). $X\cdots Y$ (head–tail), and $Y\cdots Y$ (tail–tail). Thus. as proposed by Hollingsworth,[49] experimental measurements of the relative numbers of the different types of end-group interaction may yield fundamental information on the relative preferences for interactions between different types of functional groups. An advantage of this strategy for deriving fundamental information on functional group interactions is that, in a host tunnel

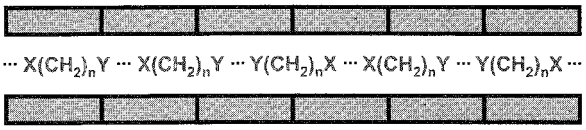

Fig. *3* Schematic illustration of the $X\cdots X$, $X\cdots Y$ and $Y\cdots Y$ intermolecular interactions for unsymmetric guest molecules of the type $X(CH_2)_nY$ inside the urea tunnel structure. (*View this art in color at www.dekker.com.*)

structure. the functional groups are constrained to approach each other in a well-defined and controlled geometry, allowing interactions between different types of fiinctional groups to be compared on a consistent geometric basis. Here we use $N_{X\cdots X}$, $N_{X\cdots Y}$, and $N_{Y\cdots Y}$ to represent the numbers of each type of end-group interaction in a given inclusion compound. For a random distribution of guest orientations, $N_{X\cdots X} + N_{Y\cdots Y} - 2N_{X\cdots Y}$, and any deviations from this relationship indicate the preferential formation of certain end-group interactions.

For many different types of unsymmetric guest molecules $X(CH_2)_nY$ in the urea tunnel structure, the ratio $N_{X\cdots X}/N_{X\cdots Y}$ and the ratio $N_{Y\cdots Y}/N_{X\cdots Y}$ can be determined from high-resolution solid-state ^{13}C-NMR spectroscopy, as many types of end groups show significant chemical shift differences in the presence of different neighboring end groups.[7,49] Examples include the ^{13}C resonances of methyl. aldehyde, nitrile, formate ester. formamide, methyl ester, alkene, alkyne. $-CH_2Cl$, $-CH_2I$, and thiocyanate end groups, the ^{29}Si resonances of SiH_3 end groups, the ^{19}F resonances of $-CH_2F$ and trifluoroacetyl end groups, and the ^{15}N resonances of nitrile end groups. Triple-resonance solid-state NMR techniques may also be exploited in the characterization of different types of end-group interactions.[50]

For a 1-D inclusion compound containing only $X(CH_2)_nY$ guest molecules. $N_{X\cdots X}$ and $N_{Y\cdots Y}$ are equal, and the ratios $N_{X\cdots X}/N_{X\cdots Y}$ and $N_{Y\cdots Y}/N_{X\cdots Y}$ are, therefore, also equal. Knowledge of this ratio from experimental measurements allows assessment of the preference for two $X\cdots Y$ interactions in comparison with one $X\cdots X$ interaction plus one $Y\cdots Y$ interaction, but it provides no information on the relative preferences of $X\cdots X$ interactions versus $Y\cdots Y$ interactions. It has been shown[51] that this limitation can be overcome by considering 1-D inclusion compounds containing two (or more) different types of guest molecules containing the end groups X and Y [for example, $X(CH_2)_nX$ and $X(CH_2)_nY$], and by studying a set of these inclusion compounds for which each member of the set has a different (known) molar ratio of the two types of guest molecules. Provided the molar ratio of the two types of guests in each member of the set is known from independent measurements (such as chemical analysis, elemental analysis, or spectroscopic measurements), the intrinsic relative preferences for all the $X\cdots X$, $X\cdots Y$, and $Y\cdots Y$ interactions can be extracted from the experimentally measured ratios $N_{X\cdots X}/N_{X\cdots Y}$ and $N_{Y\cdots Y}/N_{X\cdots Y}$.

DYNAMIC PROPERTIES

Several techniques have been used to investigate dynamic properties of urea inclusion compounds. including solid-state NMR, incoherent quasielastic neutron scattering; ESR, molecular dynamics simulation, Raman, infrared, dielectric loss, and x-ray diffraction. In addition to investigations of the dynamics of the guest molecules, the dynamic properties of the urea molecules have also been studied.

Early studies of guest motion in urea inclusion compounds focused on solid-state ^{1}H-NMR,[52] with measurements of line widths. second moments, and spin lattice relaxation times. Subsequent NMR work has mainly involved ^{2}H-NMR of urea inclusion compounds containing fully deuterated or selectively deuterated guest molecules.[33–35,38,39,53] These experiments probe the ^{2}H quadrupole interaction parameters, and line shape analysis of the ^{2}H-NMR spectra can provide detailed inechanistic information for motions with characteristic timescales between about 10^{-3} s and 10^{-8} s. ^{2}H-NMR provides information on reorientational motions of the guest molecules but does not yield direct information on translational motions. Progress in understanding translational motions (in addition to reorientational motions) has been made using incoherent quasielastic neutron scattering (IQNS),[36,37] which probes motions on characteristic timescales between about 10^{-10} s and 10^{-12} s. The ^{1}H isotope has a large incoherent neutron scattering cross-section and generally dominates the incoherent neutron scattering from organic solids. For urea inclusion compounds containing urea-d_4 and guest inolecules containing natural isotopic abundances, the incoherent neutron scattering arises predominantly from the guest molecules. BQNS studies of such materials selectively probe the dynamics of the guest molecules. By studying semioriented polycrystalline samples in which the tunnel axes of all crystals are aligned parallel to each other, and measuring the IQNS spectra either with the neutron momentum transfer vector parallel ($Q_\parallel$ spectra) or perpendicular ($Q_\perp$ spectra) to the tunnel axes. the translational motions of the guest molecules along the tunnel ($Q_\parallel$ spectra) can be investigated separately from the reorientational motions of the guest molecules about the tunnel ($Q_\perp$ spectra).

For alkane/urea and α,ω-dibromoalkane/urea inclusion compounds, ^{2}H-NMR studies have provided valuable

insights into the reorientational motions of the guest molecules about the tunnel axis in the high-temperature phase, although the timescale of the dynamics in the high-temperature phase is generally short in comparison with the timescale of the ^{2}H-NMR technique. IQNS spectroscopy has provided a more complete description of the translational as well as the reorientational dynamics of the guest molecules. and detailed studies of alkane/urea[36] and α,ω-dibromoalkane/urea[37] inclusion compounds have been carried out. In both cases, there is quasielastic broadening in the $Q_\perp$ spectra in the high-temperature phase, implying rapid reorientation of the guest molecules about the tunnel axis. This motion is diffusive (rather than discrete jumps) and can be modeled as uniaxial rotational diffusion in a onefold cosine potential. Rotational diffusion coefficients (0.3×10^{-12} s^{-1} for nonadecane/urea-d_4 at 306 K) and other parameters relating to this dynamic process have been determined as a function of temperature. The Q spectra indicate that there is also rapid translation of the guest molecules along the tunnel. This motion can be modeled as translational diffusion between impermeable boundaries, and the diffusion coefficient and translation length have been determined as a function of temperature. For nonadecane/urea-d_4, the translation length is 2.7 Å at 306 K and 1.1 Å at 160 K (just above the phase transition), and the translational diffusion coefficient at ambient temperature is 1.5×10^{-5} cm^{2}s^{-1}. Given the extent of motion of the guest molecules, it is remarkable that x-ray diffraction patterns at ambient temperature indicate both long-range intratunnel and intertunnel ordering of the guest molecules, and there is presumably a high degree of correlation between the translations of neighboring guest molecules both within a given tunnel and between adjacent tunnels.

The dynamics of the guest molecules in nonadecane/urea have also been probed in detail by molecular dynamics simulations.[54] The results indicate, inter alia, that the interaction between adjacent guest molecules in the tunnel exerts an important influence on their translational and reorientational motions and demonstrates that the reorientation of the guest molecules about the tunnel axis is coupled with movements of the host structure. Importantly, this work established links between the results from the molecular dynamics simulations and experimental results from IQNS spectroscopy.

Although the alkanelurea and α,ω-dibromoalkane/urea inclusion compounds exhibit similar dynamic behavior, the dynamic properties of other urea inclusion compounds can differ substantially. The dynamic properties of dioctanoyl peroxide guest molecules have been investigated[53] by a combined approach employing IQNS and ^{2}H-NMR. Both techniques indicate that the reorientation of the guest molecules about the tunnel axis can be described by a model of uniaxial rotational diffusion in a twofold potential, with two preferred orientations separated by 116". The orientational distribution of the dioctanoyl peroxide guest molecules is substantially more restricted than that for the guest molecules in alkanelurea and α,ω-dibromoalkane/urea inclusion compounds, and a mechanism involving conformational interconversion of the dioctanoyl peroxide molecules is consistent with the observed dynamic model. The translation of the guest molecules along the tunnel can be interpreted by a model involving jumps between sites with unequal probabilities of occupation, in contrast with the more continuous description of translational diffusion for alkanelurea and α,ω-dibromoalkane/urea inclusion compounds. There is agreement between the IQNS and ^{2}H-NMR techniques in describing the reorientational dynamics of the guest molecules in this system, and the combination of these techniques represents a powerful strategy for probing motions across a range of different timescales.

The dynamic properties of the urea molecules have also received attention. Thus, ^{2}H-NMR studies of the alkane/urea-d_4[55] and α,ω-dibromoalkane/urea-d_4[56] inclusion compounds have shown that, at sufficiently high temperatures, the urea molecules undergo 180° jumps about their C=O axes. For 1,10-dibromodecane/urea-d_4 at 293 K, the jump frequency is 5×10^6 s^{-1}, and there is no evidence for reorientation of the NH_2 groups about the C–N bond (on the ^{2}H-NMR timescale). The timescale of the 180" jumps of the urea molecules is substantially longer (at a given temperature) than the timescale of the guest motions described above, suggesting that the 180° jumps of the urea molecules are not correlated with the translational and reorientational motions of the guest molecules.

FUNDAMENTAL AND APPLIED ASPECTS

Practical Applications in Industrial, Commercial, and Laboratory Contexts

Many studies of urea inclusion compounds have focused on practical applications, such as inclusion polymerization. stabilization of liquids or unstable solids in an isolated form, and molecular separation and chromatography. Chemists studying fatty acids, for example. routinely use urea inclusion compounds to carry out molecular separations. Among industrial examples, urea inclusion compound formation has been used by the petroleum industry in the dewaxing of certain oil fractions. although zeolites are now routinely used in such applications. Other applications include stabilization of diacyl peroxides and peroxy acids in laundry products, and the use of urea inclusion compounds as solid supports in gas–liquid chromatography.

Chemical Reactions of Guest Molecules

Much early work relating to chemical reactions in urea inclusion compounds focused on studies,[57] primarily using ESR spectroscopy, of radicals generated from the guest molecules by x-ray irradiation. and provided fundamental information about the spin density and its anisotropy in a variety of radical species. Subsequently, a number of other workers have used ESR spectroscopy to identify radicals formed by x-ray or γ-ray irradiation and to study the dynamic, chemical. and electronic properties of these radicals.[''' Details of these studies were reviewed elsewhere.[7]

Detailed studies of the photodecomposition of diacyl peroxide guest molecules within the urea tunnel structure have been carried out. [7] and have provided interesting contrasts to the photodecomposition behavior of the same molecules in their ''pure.' crystalline phases, which have been investigated in considerable depth by McBride, Hollingsworth, and coworkers.

The photolysis processes of alkanone guest molecules in urea inclusion compounds have also been studied[59] and have been shown to involve Norrish Type II reactions. For 5-nonanonelurea and 6-undecanone/urea. the reactions show an almost complete diastereoselective preference for the *Z*-cyclobutanol product.

Papers concerning the physical properties of polymers as the guest components in urea inclusion compounds and polymerization reactions of guest monomer molecules within the urea tunnel structure have been reviewed elsewhere.[7,60] The polymers studied included poly(ethylene), poly(acrylonitrile), poly(1,3-butadiene), poly(ethylene oxide), poly(tetrahydrofuran), poly(acrolein), poly(vinyl chloride), poly(ethyl acrylate), poly(lactide), poly(lactic acid), poly(ethylene adipate). poly(ethylene succinate). acrylonitrile-ethyl acrylate copolymer. and poly(hexanediol diacrylate).

Host–Guest Chiral Recognition

The host structure in the conventional urea inclusion compounds is a spiral hydrogen-bonded arrangement of urea molecules. A given single crystal contains only right-handed spirals (space group $P6_122$) or only left-handed spirals (space group $P6_522$), and the host structure in a given single crystal is therefore chiral. This chirality is generated spontaneously during crystal growth of the inclusion compound. Clearly. the chiral nature of the host structure has the potential to influence the structural and chemical properties of chiral guest molecules. As the *R*-guest/($P6_122$)–host and *S*-guest/($P6_122$)–host systems have a diastereoisomeric relationship, a given crystal of the inclusion compound should have a preference to incorporate one particular enantiorner of a chiral guest species. and extensive experimental investigations by Schlenk[61,62] independently showed that the formation of urea inclusion compounds containing chiral guest molecules can be associated with significant chiral recognition. Recent computational investigations[63] have provided insights into the characteristics of host–guest interaction that underlie the chiral recognition. focusing on urea inclusion compounds containing chiral 2-bromoalkane [CH_3.C(Br)H.-$(CH_2)_nCH_3$] guest molecules. These studies have shown, inter alia, that there is a clear energetic preference for the R-enantiomer of the 2-brornoalkane guest molecules within the $P6_122$ urea tunnel. In assessing enantiomeric excesses for incommensurate systems. such as 2-bromoalkanelurea inclusion compounds, it is necessary to explore the host–guest interaction as a function of the position of the guest molecule along the tunnel. For example, for the lowest-energy conformation (Br *trans*/CH_3 *gauche*) of the 2-bromotridecane guest within the tunnel, the same enantiomer (*R*) is preferred at all positions along the $P6_122$ tunnel (for other conformations, such as Br *gauche*/CH_3 *trans*. the R enantiomer is preferred at some positions, and the S enantiomer is preferred at other positions). The assignment of the lowest-energy conformation (Br *trans*/CH_3 *gauche*) from these computational studies is in agreement with a direct experimental measurement of this property using bromine K-edge x-ray absorption spectroscopy.[64]

Orientation of Molecules for Spectroscopic Research

In general, confinement of guest molecules within the urea tunnel structure can be exploited as a means of isolating and orienting these molecules, or selecting a specific conformational state. in order that detailed spectroscopic studies can be carried out. One example concerns characterization of the spectroscopic properties of linear conjugated polyenes. An important property relating to the use of conjugated poiyenes in nonlinear optoelectronics and other applications is the orientation of the electronic transition dipole moment relative to the long-axis of the molecule. Experimental investigations are rendered difficult by the requirement to prepare perfectly oriented samples of the polyenes. This problem has been addressed[i6''' by constraining such molecules within the urea tunnel structure. ensuring that the molecular axes of all guest molecules are parallel and orientationally well-defined with respect to the crystal morphology. In these studies, octadeca-9,11,13,15-tetraenoic acid was considered as a dilute guest within the hexadecane/urea inclusion compound. and polarized fluorescence excitation spectra showed that the transition dipole lies at an angle of ca. 20 ± 1" with respect to the molecular axis of the guest. On

taking into account the effects of the surrounding medium, this value becomes modified to ca. 15 ± 1° for the isolated molecule. This result has important implications with regard to applications of these materials. There are clearly important prospects for exploiting the urea tunnel structure in such studies that require unidirectional alignment of molecules (guests) for measurement of electronic or other properties.

Control of Crystal Morphology

To explore several properties of crystalline solids and to exploit some of their applications, it is often crucial to obtain single crystals with a specific desired shape (morphology). However, the crystal morphology produced spontaneously by normal crystal growth procedures is often not the required morphology, and in such cases. experimental strategies must be devised to bias the crystal growth toward the desired morphology. Crystal growth is generally governed by kinetic factors, and to alter the crystal morphology requires control of the relative rates of crystal growth in different directions. A general strategy for controlling the crystal morphology of tunnel inclusion compounds (ranging from long-needle crystals to flat-plate crystals) has been developed and demonstrated for alkane/urea inclusion compounds. Spontaneous crystal growth of alkane/urea inclusion cornpounds produces a long hexagonal needle morphology as the rate of growth parallel to the tunnel ($k_{\|}$) is substantially greater than the rate of growth perpendicular to the tunnel ($k_{\perp}$). It has been shown that crystals of alkane/urea inclusion compounds can be induced to grow instead as hexagonal flat plates by using a selective crystal growth inhibitor (5-octadecyloxyisophthalic acid; 5-ODOIPA) that reduces the rate of crystal growth along the tunnel direction, such that $k \ll k_{\perp}$. Furthermore, by altering the concentration (c_{inh}) of inhibitor in the crystaflization solution. crystals with any desired morphology between the two extreme situations [long-needle crystals ($c_{inh} = 0$: $k_{\|} \gg k_{\perp}$) and flat-plate crystals (c_{inh} sufficiently large; $k_{\|} \ll k_{\perp}$)] can be grown, including (for intermediate values of c_{inh}) the growth of crystals that have comparable dimensions parallel and perpendicular to the tunnel axis (arising from $k_{\|} \approx k_{\perp}$).

Guest Exchange Processes

The ability to separate different types of molecules based on their structural characteristics is an important objective in many aspects of chemistry. Solid host structures can play an important role in such applications. as the host structure can display selectivity with regard to incorporation of guest molecules of differing size, shape. and in some cases also chirality. Many families of solid inclusion compounds (forexample. zeolites) are widely used in such applications. However, the fact that the "empty" urea tunnel structure is unstable limits much of the scope for using urea inclusion compounds in this regard. Thus, applications involving diffusion of guest molecules into, within, and out of the "empty" host structure are not feasible. However. it is, nevertheless, feasible to carry out exchange of guest molecules within urea inclusion compounds, provided that full occupation of the tunnel by guest molecules is maintained at all stages during the exchange process (with the actual identity of the guest molecules changing with time due to the exchange process). A general design strategy for achieving such exchange processes in urea inclusion compounds has been demonstrated.[68] Net transport of guest molecules in one direction along the tunnel can be achieved by inserting new (thermodynamically more favorable) guest molecules at one end of the crystal (e.g., by dipping it into the liquid phase of the new guest). with the original guest molecules expelled from the other end of the crystal. Such phenomena have considerable potential as the basis of highly selective microscale separation techniques. based on discrimination of molecular size, shape, and chirality.

Experimental Assessment of Host–Guest Interaction Energies

In order to derive a fundamental rationalization of the structural properties of molecular solids. it is essential to understand the intermolecular interactions that govern the observed molecular packing arrangement. However, while chemists have considerable intuitive understanding of preferred intermolecular interaction motifs, derived from observing common motifs in known crystal structures and from conducting computational studies of intermolecular interaction strengths, there is a paucity of direct quantitative experimental information on intermolecular interaction energies in molecular solids. A method has been developed[69] for estimating interaction energies in tunnel inclusion compounds directly from experimental investigations. The method focuses on the competitive coinclusion of two different types of guest molecules $X(S)_{ni}X$ and $X(S)_{nj}X$ within the same host tunnel structure. For each pair of guest molecule types [i, j), the inclusion compound is prepared for several different values of the proportion of $X(S)_{ni}X$ molecules in the crystallization solution (denoted by γ_i), and in each case. the proportion of $X(S)_{ni}X$ guest molecules in the inclusion cornpound (denoted by m_i) is measured. Thus. the experimental data comprise several values of (γ_i, m_i) for each pair of guest molecule types [i. j). The values of (γ_i, m_i) indicate the

relative extent of uptake of the two different types of guest molecules within the host tunnel structure, which in turn. depends on the interaction energies within the inclusion compound. A mathematical method has been developed for determining interaction energy terms for the tunnel inclusion compound directly from experimental measurements of (γ_i, m_i), and this method has been applied[70] to real experimental data for urea inclusion compounds containing binary mixtures of α.ω-dibromoalkane [$Br(CH_2)_nBr$] guest molecules. The interaction energy terms derived from the experiinental data are found to be in agreement with the corresponding interaction energy terms computed using a standard potential energy parameterization.

Analyzer Crystals for X-Ray Polarization Analysis

Studies of polarization of visible light are dominated by the use of dichroic filters (e.g., the Polaroid sheet), for which radiation with polarization parallel to a certain axis in the material is preferentially attenuated over radiation with polarization perpendicular to this axis. In principle, materials analogous to the Polaroid sheet may be developed as dichroic filters for polarized x-ray radiation and would have considerable potential in a range of applications (for example, in the field of magnetic x-ray scattering), although the development of a dichroic filter material for x-ray polarization analysis was demonstrated for the first time only recently.[71] The material studied was the 1.10-dibromodecanelurea inclusion compound, and the successful application of this material as a dichroic filter was demonstrated in a study of magnetic diffraction from antiferromagnetic holmium. In spite of this success, however. the efficiency of 1.10-dibromodecane/urea as a dichroic filter is limited by the fact that the C–Br bonds undergo reorientation around the tunnel axis at ambient temperature and are oriented at about 35° to this axis. Theoretical considerations suggest that a tunnel inclusion compound in which all C–Br bonds are aligned parallel to the tunnel would be a more effective material, and this situation has been realized subsequently for the 1-bromoadamantane/thiourea inclusion compound.

Properties of Commensurate Systems

While the focus of the majority of this article has been on the conventional (incommensurate) urea inclusion compounds. studies by Hollingsworth and coworkers have revealed a wide range of interesting physical properties of commensurate tunnel inclusion compounds of urea containing alkanone and $(\alpha + 1),(\omega - 1)$-alkanedione guest molecules. These studies have led to a profound level of understanding of the interactions within these materials and the ways in which these interactions control properties such as ferroelastic behavior (i.e., domain reorientation under the application of external anisotropic stresses)[72] and crystal growth mechanisms.[''' As an illustration, we highlight a study of stress-induced domain reorientation in the 2,10-undecanedione/urea inclusion compound, which is a commensurate system ($2\,c_g = 3\,c_h$) with a well-defined stoichiometric guestlurea ratio (1/9) and a well-defined positioning of the guest molecules with respect to the host structure. One out of every three urea molecules is oriented such that its two *syn* N–H groups form N–H···O hydrogen bonds with C=O groups of guest molecules in different tunnels. All C=O groups of the guest molecules are involved in host–guest hydrogen bonding in this way. producing an extended hydrogen-bonded network connecting the host and guest components throughout the structure and providing a direct mechanism for guest molecules in different tunnels to communicate with each other. Not surprisingly, the structure is distorted from the hexagonal structure of the conventional urea inclusion compounds and is orthorhombic. Crystals of this inclusion compound consist of domains; within a given domain, the planes of all guest molecules are oriented in the same direction, with different domains related to each other by rotation of the guest molecules by a multiple of ca. 60° about the tunnel axis. These domains are birefringent, allowing the different domain orientations to be observed directly by optical microscopy (striking optical micrographs illustrating the well-defined sectoring of crystals of this inclusion compound have been published[72]). A remarkable property of these inclusion compounds is that compressive stresses applied to the crystal can bring about reorientation of the domains. Reorientation of the guest molecules associated with this domain reorientation requires breakage and formation of hydrogen bonds (guest–host and host–host), and the requirement to reconstruct the guest–host hydrogen-bonding network underlies the large-scale cooperativity of this process. Interestingly, by incorporating 2-undecanone guest impurities (ca. 20%), the domain reorientation is spontaneously reversible, with the daughter phase reverting to the mother phase when the applied stress is removed. The 2-undecanone impurities disrupt the guest–host hydrogen-bonding scheme. influencing the energetic properties of the mother and daughter phases and the interface between them.

Among studies of other commensurate inclusion compounds of urea. it has been shown[''' that structural changes in the 1,6-dibromohexane/urea inclusion compound as a function of temperature (the metric symmetry

moves progressively toward hexagonal as temperature is increased) can be rationalized on the basis of motions of the guest molecules that occur as a mechanism for relaxation of strain within the inclusion compound.

CONCLUSION

As highlighted above, it is clear that urea inclusion compounds exhibit a diverse range of interesting and important physicochemical phenomena, including incommensurate structural properties, order–disorder phase transitions, molecular motion, properties relating to 1-D confinement, chemical reactivity, and ferroelastic properties. In spite of the apparent simplicity of the 1-D tunnel system in urea inclusion compounds, the quest to develop a fundamental understanding of the intricate details of the structural and dynamic properties of these materials, and the interrelationships between these properties, present many challenges that will continue to captivate the attention of chemists and physicists for many years to come. Furthermore, with continued progress in deepening the level of fundamental understanding of the properties of urea inclusion compounds, it may be expected that future advances in the design and development of applications based upon these materials will be forthcoming.

van der Waals Forces

Hans-Jörg Schneider
Universitat des Saarlandes, Saarbrucken, Germany

INTRODUCTION

Van der Waals forces play a decisive role in many supramolecular complexes, and in many other fields, such as in structure and function of proteins,[1] nucleic acids,[2,3] in adhesion phenomena including cell recognition, in membrane formation and transport, in self-assembly: in new materials from aromatic systems. in dendrimers, etc. A major problem is to distinguish van der Waals effects from hydrophobic interactions, also in supramolecular complexes: such as with cyclodextrins.[4] Van der Waals interactions belong to the most often invoked binding mechanisms in supramolecular systems, but they are the most difficult to quantitatively predict, and even pose serious problems in definition. These high-order interactions are treated in classical textbooks,[5–7] mostly in the context of intermolecular forces between simple "inert" molecules. such as noble gases.

Traditionally, one summarizes under van der Waals interactions high-order noncovalent binding mechanisms that do not rely solely on permanent charges but on polarization of electron clouds. Hydrogen bonds are not generally viewed this way, although one often uses here in force field description a Buckingham or Lennard-Jones potential (see below) in addition to the Coulombic interactions that prevail in hydrogen bonds of weaker or medium strength. The van der Waals attraction, e.g., between a permanent dipole and another dipole generated by polarization of the second is, finally. also based on interactions between permanent charges. Even the classical description of dispersive interactions in the form of the London–Eisenschitz forces involves a Coulomb-type attraction. only that in this case, it is considered to exist between fluctuating dipoles, some of which at a given time will have opposing, and hence attractive charge distributions.

COMPUTATIONAL DESCRIPTIONS

The only gradual distinction between low- and high-order effects in noncovalent binding is reflected by the classical potentials, as they are used in force fields. Noticeably, Coulombic attractions with, e.g., the benzene quadrupole (see below) already fall off with the power of three with the distance r, in contrast to the "soft" long-range potentials for interactions between point charges, which depend on r^{-1}. High-order effects. based on polarization of electron clouds, show increasingly steep dependencies on the distance r between the host and the guest site, and are usually described by simplified Lennard–Jones or Buckingham potentials:

$$\mathrm{EV} = a \cdot \mathrm{r}^{-12} - b \cdot \mathrm{r}^{-6} \quad (\textit{Lennard} - \textit{Jones} - \textit{potential}) \tag{1}$$

$$\mathrm{EV} = \underset{\textit{repulsive}}{10^4 \cdot \mathrm{e}^{-4\,6\mathrm{r}}} - \underset{\textit{attractive term}}{50 \cdot \mathrm{r}^{-6}} \quad (\textit{Buckirzgham} - \textit{potential})$$

The dependence of dispersive attractions on the polarizibilities α of the two interacting atom, or groups i and j is described by the Slates–Kirkwood Eq. 3. e.g., quantifying the factor b in Eq. 1. In Eq. 3, e and m refer to the electron charge and mass, n to the number of electrons in the valence shell, and $\hbar$ to the Planck–Dirac constant. The polarizibility increases with the size of the electron shell of atoms: typical values for α can be found in the literature and in parameters of force fields.[8]

$$b = [1.5\ \mathrm{e}\ (\hbar/m^{1/2})\ \alpha_i\alpha_j]/[(\alpha_i/n_i)^{1/2} + (\alpha_j/n_j)^{1/2}] \tag{3}$$

Force field calculations of such interactions in principle require explicit consideration of polarizibility even of lone pairs, with an appropriate treatment of electron correlation.[9] Several approaches were taken to describe polarizibilities and induced dipole moments within force fields, e.g., on the basis of the MM3 field.[10] Mutual polarizations can be included in the term for electrostatic interactions by describing Coulomb interactions with fluctuating atomic charges.[11–13] Multipole molecular mechanical models using a restrained electrostatic potential approach were shown to accurately reproduce aqueous solution-free energies of methanol and N-methyl acetamide. nucleic acid base, amide hydrogen bonding, and several chloroform and water partition coefficients.[14]

In quantum chemical descriptions,[9] *van der Waals* interactions correspond largely to electron correlation and

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012665

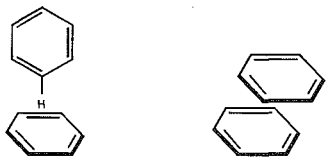
necessarily need to include polarization. For this reason. density functional (DFT) calculations, which describe Coulomb. exchange, and correlation energy altogether as functional of electron densities in three dimensions, need at least the use of the MP2 (second order Mϕller–Plesset) method.[16–18] Still. the problem is that even for gas-phase modeling and with the fast DFT approach, the computational time is long. and it increases, e.g., with the MP2 method by a power of five with the molecular size of a given complex.

STACKING INTERACTIONS

Many well-known supramolecular complexes with aromatic components'[19–21] rely on coulombic-type attractions between electron-poor and electron-rich parts. and are for this reason often called donor–acceptor (D–A) interactions. An important clue to the dominating mechanism. also of practical significance. is that donor–acceptor and electrostatic interactions can be strong in organic solvents of lower polarity, whereas van der Waals forces relying on polarization effects reach their maximum in water due the extremely low polarizibility of this medium. The problem then is to distinguish the corresponding dispersive from hydrophobic interactions.

BENZENE–BENZENE INTERACTIONS: STACKING AND C—H—π BONDS

The classical example for stacking interactions seems to be the benzene dimer.[22] However, MD and ab initio MO calculations indicate a predominance of edge-to-face complexes over the stacked sandwich awangement by 3 kJ/mol in the gas phase and by 6 kJ/mol in water.[23–25] In contrast, the calculations predict for toluene in the gas phase, but not in water, a preference for stacking. Obviously. the permanent negative charges of π-electron clouds must lead to repulsion in parallel face-to-face complexes. In displaced stacks (Scheme 1). the repulsion between the π-moieties can be counteracted by electrostatic attraction between the positively charged aryl protons and the next π system. Such considerations lead to semiquantitative structure and energy predictions of stacked aromatic systems.[26,27] This treatment was criiicized also because ab initio molecular orbital calculations describe stacking between aromatic systems to a large degree by electron correlation.'''' which stands for dispersive interactions of fluctuating dipoles. The high polarizibility of the n-cloud enhances such forces also in less-displaced orientations. In the solid state. one



edge-to-face face-to-face

Scheme 1 Stacking and edge-to-face structures of benzene dimers

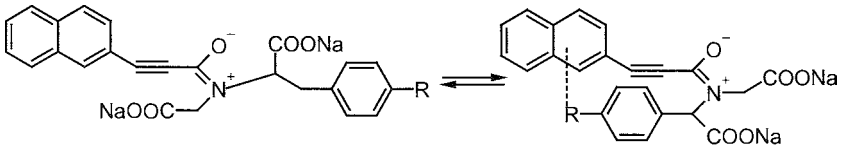
observes for larger. fused aromatic hydrocarbons a packing based most often on displaced stacking and on edge-to-face interactions. with typical herringbone structures'[29–31]

Experimental data on benzene association constants[iz1] show only values around 1 M^{-1} in water but they vary considerably. Magnetic field alignment NMR studies with benzene in water speak for an edge-to-face preference of up to 3 kJ/mol.[32] Significant pattern changes are observed with different substituents at phenyl rings.[33] In 1.8-diarylnaphthalenes. an increase of rotational barriers with the number of fluorine groups in one of phenyl rings was observed: the decreased electron density by the substituents leads to less unfavorable orientation in the enforced parallel stacks in the ground state. The quadrupoles of benzene rings with fluorine or hydrogen atoms have similar magnitudes but opposite signs with an inversion of the C—X bond polarity, which favors parallel stacks.[33,34]

Edge-to-face orientations are frequent motifs also in proteins,[35] and they can be viewed as hydrogen bonds between weakly acidic aromatic C—H bonds and π-moieties,[36] and will therefore noi be discussed in detail here. Due to small polarity. the strengths of such bonds are so small that they are mostly observable only in solid-state structures or with intramolecular balances set up to reflect particular interactions by changes in conformational equilibria.[37] However. it was concluded on the basis of force field calculations, including a solvation model, that van der Waals and solvation forces play a decisive role in the conformational equilibrium involving C—H—π bonds.[38]

INTERACTION OF CATIONS WITH π-MOIETIES AND WITH ELECTRON LONE PAIRS

Cation-π effects.[39,40] result largely from coulombic attraction. as long as metal cations interact with n-moieties: these effects are discussed in other chapters of this *Encyclopedia* and will therefore only be mentioned here



E **Z**

Scheme 2 Aryl–aryl interactions in an intramolecular balance, (see the text for further discussion)

with respect to van der Waals binding contributions. The MO calculations at the MP2 level speak for significant contributions of electron correlation effects in complexes between ammonium cations and aromatic systems.[41,42] Complexation of anions by aromatic clefts also indicates polarization as a dominant factor.[''] Even crown-ether complexes with metal ions are stabilized significantly by polarization effects on the oxygen electron lone pairs.[44]

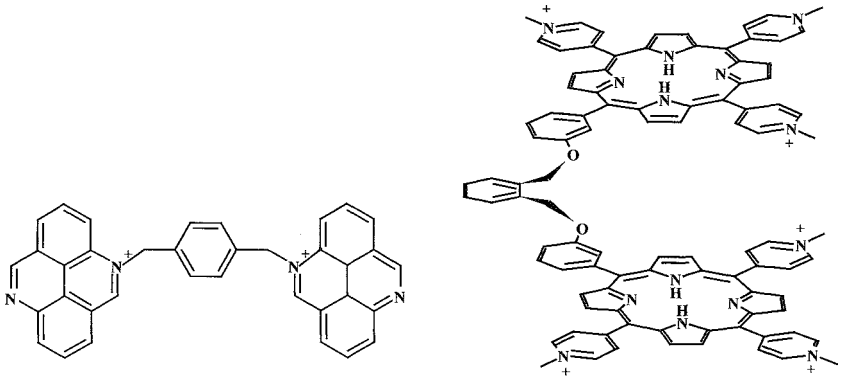
STACKING DOMINATED BY DISPERSIVE INTERACTIONS

The dispersive interactions in stacking aggregations is expected to increase with the size of the interacting π-moieties. A similar increase would be predicted if hydrophobic forces dominate (see *Hydrophobic* Effects in this *Encyclopedia*). That dispersive interactions play a major role is, however, obvious by the fact that such a size-dependence is also seen in solvents such as chloroform: in a classical study with ethyladenine as guest and a series of hosts offering hydrogen bonds as the primary binding force and methyl, phenyl, naphthyl, and anthryl residues for stacking. the association free energies AG show a systematic increase of $\Delta\Delta G = 1.85 \pm 0.15$ kJ/mol for each additional benzene moiety interacting with the nucleobase.[45,46] Measurements of the EIZ equilibrium around the amide bond in the "balance" molecules in Scheme 2 show a preference for the *E* conformer, which for $R = H$ has the same small $\Delta G_{E/Z}$ difference to the *cis*-conformer in water (D_2O) as in chloroform. Only substituents *R* in the pam-position of the phenyl can in the *E* conformer reach the naphthyl moiety, and in water leads to an increase of $\Delta G_{E/Z}$, which is larger for R = phenyl than for R = cyclohexyl. This is in contrasi to expectations on the ground of the much higher hydrophobicity of cylohexane compared to benzene, and clearly speaks for dominant dispersive interactions. Noticeably, in chloroform. the ΔG_{EZ} values remain constant for the different substituents *R*.[47] The same evidence for dispersive instead of hydrophobic interactions between aromatic systems is seen if the aryl groups in the balance bear nitrogen atoms. Thus, with R = pyridyl, pyrimidyl, or quinolyl residues. one observes larger $\Delta G_{E/Z}$ differences, with a stronger preference for stacking with heterocycles than with arenes in spite of their smaller hydrophobicities.[48] The results emphasize the propensity of heteroaromatic systems for stacking, e.g., in nucleic acids, although the observed variations are small, with, e.g., $-\Delta G_{E/Z} = 0.43$ versus 0.79 kJ/mol for R = phenyl or R = pyrimidyl, respectively.

Stacking interactions can become so strong that other possible binding contributions cannot materialize, because optimal geometric disposition for all intermolecular forces is no longer possible. Thus, the observation of the same association energy between positively charged host compounds and either nucleotides or electroneutral nucleosides provides evidence for dispersive interaction mechanisms. *Bis*(phenanthridinium) receptors like **1** (Scheme 3) form equally strong complexes in aqueous media (lg K = 5–6) with both nucleotides and nucleosides. In spite of the positively charged nitrogen centers in the flat aromatic receptors, there is also no dependence on the ligand charges.[49]

PORPHYRIN COMPLEXES: DERIVING A SCALE FOR DISPERSIVE INTERACTIONS

Porphyrins are ideally suited for dispersive interactions due to their extended π-moiety, coupled with a relatively high flexibility that imposes small steric constraints on complexation with a variety of substrates. A porphyrin host has a surface often several times larger than the guest compound, and then it acts as receptor, with, e.g., twice as many binding sites, with a concomitant increase in binding strength. This effect can be further increased by doubling those interactions with a suitable porphyrin dimer **2** (Scheme 3, Fig. 1).[50] Measurements of porphyrin complexes with many ligands in water allowed the discrimination of hydrophobic from other binding mechanisms and the inference of free-energy increments of van der Waals interactions for many substituents.[51,52] The affinities of. e.g., benzoic acids to positively charged porphyrin derivatives, does not change significantly by alkyl substituents; in line with this, the binding constant



1 2

Scheme 3 *Bis*(phenanthridinium) 1 and porphyrin 2 as stacking units.

of cyclohexane carboxylic acid shows only the value expected for ion pairing. In contrast, the phenyl ring in benzoic acid has a similar surface as a cyclohexane ring, which leads to a value higher by about 8 kJ/mol.[53] Affinities of other aromatic compounds exhibit an increase of up to 18.5 kJ/mol for, e.g., acridine; a plot of the complexation free energies against the number of n-electrons is linear and gives an increment of about 2 kJ/mol per electron pair. That saturated systems show smaller interactions in spite of their larger lipophilicity is in line with the above-mentioned conclusions reached with the "balance" in Scheme 2. This emphasizes that dispersive and not hydrophobic mechanisms are the major driving force for intermolecular interactions of unsaturated systems in water, noticeably including cyclopropane (see Table 1).

Measurements of over 50 complexes with positively or negatively charged porphyrins showed additive substituent increments $\Delta\Delta G$ (Table 2), which describe the observed free energies accurately. Because electron-withdrawing and electron-pushing substituents on benzene rings increase the affinity the same way with all porphyrins, and there is a general increase of ΔG with the polarizibility of the groups, other mechanisms except for dispersive interactions can be excluded. The $\Delta\Delta G$ values in Table 2 have to be taken as relative numbers, much like substituent constants in, e.g., the Hammett equation. Their absolute magnitude will depend on the size of the acceptor molecule, which in the case of porphyrins is several times larger than, e.g., a single benzene unit, and also change with the reaction medium.

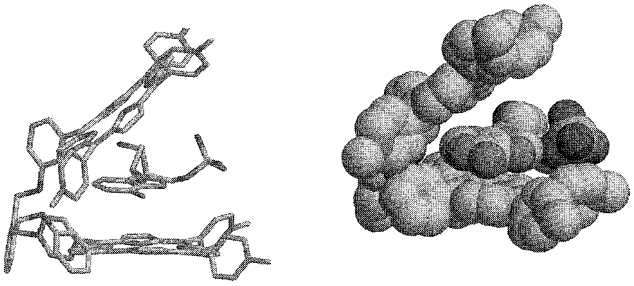


Fig. 1 Dispersive interactions between adenine in AMP and a porphyrin dimer. (For an interactive model, see http://www.uni-sb.de/matfak/fbll/schneider.) *(View this art in color at www.dekker.com.)*

Note: $\Delta\Delta G$ is derived from averaged association constants aith porphyrin derivatives (in water. 298 K. pH 7.00. phosphate buffer I=0.05 M); n: number of underlying systems for $\Delta\Delta G$ calculation: deviations of $\Delta\Delta G$ from different comnplexes: +/−0.25 kJ/mol; (+/−0.35 kJ/mol, R=I, $COCH_3$).

CYCLODEXTRIN COMPLEXES

Inclusion of guests in the cavity of cycloamyloses can have its origin in solvophobic effects as well as in a number of direct host–guest interactions. An empirical equation based on a iarge number cyclodextrin complexation constant K in water describes lgK as a function of solvent–solute and host–guest interaction energies resulting from hydrogen bond or electrostatic interactions. plus an additional term containing the change in accessible nonpolar surface area of the host upon complexation.[4] Calorimetric measurements can show if complex formation is dominated by a favorable entropy AS against an enthalpic disadvantage, as expected with the hydrophobic Frank–Evans effect as the major driving force. Unfortunately, the results are usually not as clear-cut, and often one observes entropy–enthalpy compensation.[54] Calorimetric studies of cyclodextrin complexes with guests of either low or higher polarizibility show systematically more favorable ΔH values for those with larger polarizibility, as long as the cavity size allows the tight fit necessary for dispersive interactions. If the polarizibility is smaller. like in nitrophenol instead of nitrophenolate, or in adamantanes, the ΔH contribution decreases, with more favorable entropy if the complex is not too tight (Table 2).

CHARGE-TRANSFER COMPLEXES

Associations between electron-rich and electron-poor molecules can be accompanied by an electron transfer from high-energy occupied molecular orbitals of the donor D to unoccupied acceptor A orbitals of lower energy: they can be described with linear cornbinations of wave functions corresponding to structures like A–D and A^+D^-.[55–57] Such orbital mixing leads to characteristic CT bands in the low-frequency part of UV/Vis spectra. which, however, do not correlate with the strength of the binding. The interaction free energy ΔG between the soft Lewis acid iodine I_2 as acceptor and a range of hydroxy-, thio-, and aminocompounds correlates linearly with the basicity of these donors, in line with significant polar contribution from the A^+D^- state.[58] The CT complexes are not to be confused with those between hard Lewis acids and bases, which usually are termed donor–acceptor complexes and were mentioned above. The CT complexes in solution are usually weak, with, e.g., ΔG = 4.6 kJ/mol in CCl_4 for the strong acceptor trinitrobenzene with the donor hexamethylbenzene. With toluene. the association constant is already lower than I. Nevertheless. CT complexes can. in contrast to those due to hydrophobic or dispersive interactions, also form in organic solvents and are. therefore. important for applications where solubility problems prohibit the use of aqueous media. Interesting complexations were observed with calixarenes and eiectron-deficient fullerene derivatives;[59] iodine substituents at the calixarene rim increase association constants with C_{60} from K = 460 M^{-1} for the unsubstituted host in benzene as solvent to K = 1840 M^{-1}.[60]

CONCLUSION

The few examples given in this article should illustrate the significance of van der Waals interactions in supramolecular systems. Space does not allow a detailed discussion of the results and views on stacking forces in and with nucleic acids. Only recently has it become clear that the major factor for the formation of the double helix is base stacking.[61] Investigations with a iarge number of heterocycles implemented instead of a natural nucleobase show only a rough correlation of duplex stability with the surface size of the base: a similar dependence holds for intercalators.[2,3,62] Based. i.e., on solvent effects, it was suggested that hydrophobic forces rule the duplex stability.[61,63] However, dispersive interactions would lead to similar solvent effects. and are. e.g., on the basis of calculations,[15] believed to be the major stacking factor. Obviously. much needs to be done to further clarify the

mechanisms of these chemically and biologically significant interactions.

Vibrational Spectroscopy

Carolyn A. Koh
King's College London, London, United Kingdom

INTRODUCTION

Vibrational spectroscopy is an important complementary tool to x-ray diffraction for structural characterization of materials. including supramolecular compounds. Unlike x-ray diffraction. where all the data must be collected to give the structure of the molecule. vibrational spectroscopy can be used to zero-in on part of the structure of interest. Furthermore, information on guest–host interactions of inclusion compounds can be readily determined from infrared (IR) and Raman spectra. whereas this information is not readily accessible from x-ray diffraction. Therefore, IR spectroscopy and more recently Raman spectroscopy are used to study the structure and dynamics of inclusion compounds. IR spectroscopy is also widely and routinely used to characterize supramolecular compounds containing macrocyclic molecules. The structures and dynamics of these compounds can also be studied using resonance Raman spectroscopy.

This article provides a brief overview of the theory of IR spectroscopy and Raman spectroscopy (for more in-depth descriptions of these methods see Refs. [1–3]). This is followed by a review of vibrational spectroscopic studies performed on clathrate hydrates (a class of inclusion compound) and macrocyclic suprainolecular compounds. Clathrate hydrates were highlighted in this article because of all the clathrate compounds. they are particularly amenable to vibrational spectroscopy and are of great industrial significance. Similar IR/Raman methods can be applied to other well-known clathrate compounds. including quinol[4] and urea[in] clathrates. Finally, future directions on the use of vibrational spectroscopy in supramolecular compounds will be given.

THEORETICAL BACKGROUND OF VIBRATIONAL SPECTROSCOPY

Atoms in a molecule vibrate within the wave number range $\sim 10-\sim 10^5$ cm^{-1}. with IR and Raman spectroscopic measurements of supramolecular compounds usually being performed within the region 10–3000 cm^{-1} The vibrational spectrum of a molecule reflects the properties of the molecule as a whole and characteristic features of separate chemical bonds. The compression and extension of a real bond of a diatomic molecule can be represented by an anharmonic oscillator model. The selection rules for an anharmonic oscillator are that the allowed vibrational energy transitions $\Delta v = \pm 1, a2, \pm 3$ (lines beyond this have very low intensities and therefore are not easily observed). Vibrational modes involving transitions of $\Delta v = \pm 1$ are the fundamental (or normal) modes. while those of $\Delta v \geq a2$ are the overtone modes.

Because a polyatomic molecule has more than one vibrational degree of freedom, a linear molecule containing N atoms will have *3M–5* normal modes of vibration (*3N*–6 for a nonlinear molecule). Each vibrational motion of a molecule is considered as a superposition of these normal modes of vibration. Therefore, a particular compound will have several characteristic frequencies that can be assigned to specific vibrational motions. Although a normal vibration in general involves all the atoms in a molecule, some vibrational modes such as O—H bond stretching, C—C—C bond angle bending. or C—N bond stretching always appear at approximately the same wave number region in spectra of different compounds. These characteristic vibrational modes are therefore used to identify specific functional groups present in a molecule. as well as to determine any changes in the bonding or environment of these groups. The symmetry of a molecule changes upon transition from the gas phase to condensed phases and can be detected from the vibrational spectrum. In solids, the situation is complicated by the occurrence of lattice vibrations, however. these are only observed if equivalent atoms in each unit cell vibrate in-phase.

Theoretical calculations and computer simulations can be used to predict the IR/Raman spectra of various molecules and can aid in the interpretation of vibrational spectral data. For example. calculating Raman spectra using molecular dynamics (MD) simulations[iii] involves expressing the energy of a vibrating molecule in a solvent as the sum of the inter- and intramolecular interactions (both contributions are expandable in terms of the normal coordinates). Intramolecular interactions consist of a harmonic part and an anharmonic part. Transitions between perturbed energy levels can be calculated by taking the intramolecular (anharmonic pari) and intermolecular interactions as perturbations to the energy levels of the anharmonic oscillator. Therefore. one can

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012810

calculate the Raman shift that occurs due to intermolecular interactions.

Infrared Spectroscopy

The selection rule for a vibration to be infrared active is that the molecule must undergo a vibrational motion that changes the dipole moment of that vibrational mode. Hence. IR light of a frequency matching that of an IR-active vibrational motion will be directly absorbed by the molecule. This quantum of light will then promote the molecule to a higher vibrational energy state.

The development of Fourier Transform IR (FTIR) spectrometers led to the ability to measure vibrational spectra of supramolecular coinpounds with increased speed and sensitivity. The main feature of an FTIR instrument is the interferometer, which modulates the IR input waves by a moving mirror, M_M, moving back and forth toward and away from the beam splitter. Depending on the position of M_M, recombination of waves from M_M and the stationary mirror, M_S, at the beam splitter creates constructive or destructive interference that results in an output wave of varying intensity, i.e. the interferograin (see Fig. I).

Therefore. the interferograin is the sum of all the frequencies (plotted as intensity versus time). By performing a Fast Fourier Transform algorithm using a computer, the infrared spectrum is obtained in which intensity is now plotted versus frequency (usually given in cm^{-1}). Therefore, by means of the interferometer, an FTIR instrument can analyze all frequencies simultaneously. unlike a dispersive instrument that examines the frequencies one at a time.

Sampling methods used for IR analysis of clathrate hydrate compounds, which are largely composed of highly absorbing water molecules, were limited to mulls, thin films prepared by vapor co-deposition methods (the resulting amorphous deposit is warmed in a vacuum to the crystallization temperature[7]), or adamantane pellets (for samples to be analyzed below 125 cm^{-1}). These mulls, thin films, and pellets need to be prepared at cryogenic temperatures to maintain stability of the clathrate hydrate at atmospheric pressure. Conversely, macrocyclic supramolecular compounds are generally stable at ambient temperatures and pressures. Therefore, IR analysis of these compounds does not require cryogenic temperatures, and sampling methods include KBr disks and pellets and mulls.

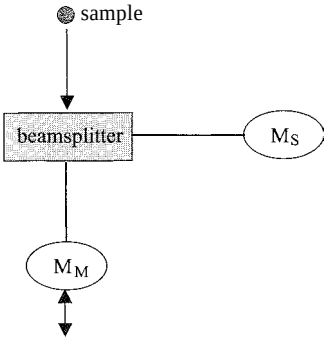

Fig. 1 *The Michaelson interferometer.*

Raman Spectroscopy

The selection rule for a vibration to be Raman active is that the molecule must undergo a vibrational motion that changes the polarizability of that vibrational mode. When a sample is irradiated with light (of visible, ultraviolet; or near-IR frequency), the molecule is excited to a virtual state of higher energy. Relaxation of the molecule to the original or a different vibrational energy state results in Rayleigh scatter or Raman scatter, respectively (see Fig. 2).

The Raman effect can be explained as follows. When a molecule is placed in a static electric field, it experiences some distortion that causes an induced dipole moment, μ, to be set up in the molecule. The molecule is then said to be polarized. The size of the induced dipole depends on the magnitude of the applied electric field, E, and the ease with which the molecule can be distorted, i.e.. its polarizability. α. If the field is supplied by electromagnetic radiation of frequency, ν_o, and the vibrational frequency, ν_{vib}, changes periodically, Eq. 1 is obtained:

$$\mu = \alpha_o E_o \cos(2\pi\nu_o t) + \frac{1}{2}(\delta\alpha/\delta q)_o \times E_o\, q_o \cos 2\pi t[(\nu_o + \nu_{vib}) + (\nu_o - \nu_{vib})] \quad (1)$$

where a, is the equilibrium polarizability, E_o is the maximum field strength, $(\delta\alpha/\delta q)_o$ is the rate of change of polarizability with distortion around the equilibrium position. and q, is the maximum distortion. Therefore. scattered radiation at frequencies ν_o, $(\nu_o+\nu_{vib})$, and $(\nu_o-\nu_{vib})$, are Rayleigh. anti-Stokes Raman. and Stokes Raman scatter, respectively.

Similar to the infrared instruments, there are two general types of Raman instruments: the dispersive and FT Raman spectrometers. The FT Raman instrument incorporates an interferometer that provides similar advantages to those given by the interferometer of an FTIR spectrometer (for further details. see Ref. [3]), although modern dispersive instruments with CCD detectors can measure a range of frequencies simultaneously.

Raman spectroscopy was recently used to study the structures of gas hydrates. It offers the advantage over IR analysis in that the sampling methods are significantly

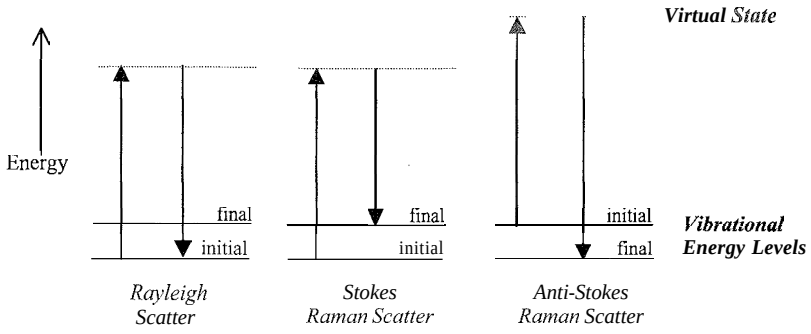

Fig. 2 Energy transitions of Rayleigh and Raman scatter.

simpler, i.e., glass cells and high-pressure cells can be used. Therefore, in situ measurements can be performed on clathrate hydrates at real conditions, which was not possible with previous IR studies.

Resonance Raman spectroscopy is a particularly powerful probe for studying the structures and dynamics of macrocyclic supramolecular compounds, e.g., metalloporphyrins. These compounds have strongly allowed electronic transitions in the visible or UV regions that can enhance the intensity of some Raman-active vibrations by a factor of 10^2–10^4, i.e., resonance enhancement or resonance Raman effect.

CLATHRATE HYDRATES

Clathrate hydrates are crystalline inclusion compounds composed of host water cages that trap guest molecule~.[~.The three most common types of clathrate hydrates are known as structure I, II, and H, which differ in the type of water cage they contain. The type of clathrate hydrate structure formed depends mainly on the size of the guest molecules present (for further details, see the article *Clathrate Hydrates* and Refs. [8,9]). The structures of these compounds were first determined from x-ray diffraction studies,[8] however, as mentioned previously, vibrational spectroscopy can provide important complementary information on the structures and dynamics of these compounds and can also detect the presence of any guest molecule–host lattice interactions.

Evidence of Guest–Host interactions

Far-IR transmission spectra were recorded of Structure I [ethylene oxide (EtO) hydrate][10] and Structure II [cyclopropane, trimethylene oxide (TMO), 1,3-dioxolane, tetrahydrofuran (THF), and cyclobutanone hydrates][11] hydrates. The slight water lattice stretching due to the large size of cyclobutanone was indicated by the most intense peak within the 120–200 cm ' region shifting by 2.5 cm ' lower than the corresponding peak for cyclopropane or 1,3-dioxolane deuterate guests. Guest vibrations were not found to significantly affect the water vibrational spectrum at 4.3 K at frequencies the guest does not absorb. This suggested that the interaction between guest–host vibrations is weak. particularly for THF. Further mid-IR spectral studies on EtO hydrate[1''' showed that only the water-network torsional modes couple with those of EtO molecules (the ring deformation modes of EtO at around 870 cm^{-1}). A later study by Fleyfel and Devlin[13] suggested that the large guest–host interaction of TMO hydrate caused disproportionate lengthening of the weaker H-bonds of the hose lattice.

IR studies on acetylene hydrate also suggested that guest rotation is significantly hindered in the water lattice.[''] This was concluded from the fact that the librational spectra of the hydrate showed no evidence of *P-R* band contours at any temperature, although the bandwidths showed pronounced temperature dependence. Free rotation of guest molecules in the cages would have led to its inertial constant providing a rotational band contour for ν_3 with P and *R* wings. The temperature dependence of the bandwidth was attributed to librational movement of the guest around some fixed orientation in the cage.

The above examples clearly demonstrate the importance of host–guest interactions in clathrate hydrate compounds. These interactions, together with the hydrogen-bonded water network, are important in stabilizing the hydrate system.

Differentiating Between Structure I and II Hydrates and Ice

From IR studies. absorptions by water molecules in EtO hydrate were found to be similar to those in ice.[12] This was expected. because the water lattice of the hydrate is similar to that of ice. with water molecules in EtO hydrate at 100 K being orientationally disordered and reorienting

extremeiy slowly (in contrast to the reorientation rate of EtO of about 10^{10} s^{-1}). However, preparing EtO hydrate from H_2O/D_2O dilutions, the O-H and 0-D stretching modes of isolated HOD rnolecules [ν_{OH}(HDO) and ν_{OD}(HDO), respectively] were found to be different for hydrate and ice materials. The frequency and half-width of ν_{OH}(HDO) and ν_{OD}(HDO) in Structure I hydrate are 2427 ± 3 cm^{-1} and 80 ± 10 cm^{-1}, respectively, compared to 2413 cm^{-1} and about 65 cm^{-1} for the corresponding values for hydrate containing ice. These differences in half-widths were explained in terms of the narrower range of O—O bond distances in ice compared to the hydrate. This was also confirmed later by FTIR studies on Structure I and Structure 11 hydrates.[15] The half-width of the ν_{OD} band of isolated HOD molecules was found to be sensitive to the distribution of O—O distances of the water lattice in ice, Structure I, and Structure II hydrates. Therefore, the ν_{OD} half-width is a useful test for confirming the structure of the hydrate and for detecting any ice impurities in hydrate samples.

Guest Occupancy

The guest IR spectra of EtO and H_2S hydrates indicated that EtO and H_2S occupy small and large water cages.[15] The spectra of Structure II mixed hydrates were used to identify the frequencies of these bands for guest molecules in small and large cages. H_2S molecules in the small cages of Structure I were found to absorb near 2610 cm^{-1}, while in the larger cages. they absorb near 2550 cm^{-1}. This finding'''' suggested that H_2S molecules are not more gas-like in larger cages, as one would intuitively expect. but rather the lower stretching frequency of the large cage reflects the theoretical prediction that small molecules occupy energy minima offset from the large cage centers.'''' This clearly demonstrates that vibrational spectroscopy offers an advancement on information obtained from x-ray diffraction, which only gives a vague picture of the position of a guest molecule in a hydrate cage.

Similarly, splitting of the ν_7 mode of ethane (a single peak in the gas phase) into components at 2982 and 2972 cm^{-1} on enclathration was interpreted as being due to the preferred molecular orientation of ethane in the large hydrate cage. resulting in a nonsymmetric interaction with the cage wall.[15] This will then eliminate the threefold molecular symmetry axis and split the degenerate vibrational states. A later study on EtO, H_2S, TMO, MeCl. and CO_2 hydrates also showed that the frequency of the stretching-mode bands for guest molecules in a small cage is usually greater than that in a large cage.[13] Similarly. FTIR studies of acetylene hydrates showed that the C-D stretching frequency of C_2D_2 guest molecules in large and small cages is at 2319 and 2431 cm^{-1}, respectively.[14] The integrated intensities ratio of these bands was found to be the same as the ratio of the number of large to small cages in Structure I hydrate (3:1).

In agreement with the above IR studies, Raman studies (performed at high pressure) show that the generai trend in vibrational frequencies of guest molecules in hydrate cages is that a guest in a larger cavity gives a lower vibrational frequency.[17] This was attributed to the qualitative ''loose cage–tight cage'' model of Pimentel and Charles. By monitoring the ratio of the vibrations of guest molecules in large and small cages, Raman spectroscopy[18] can be used to determine the relative occupancies of the large and small cavities and the hydration number for single and double gas hydrates (containing one and two types of guest molecules, respectively).

Recent Raman studies[17] also show that contrary to previous reports. ethane can be trapped in the small cage of Structure II hydrate at higher pressures ($\sim$70 MPa). Similarly. Raman microprobe studies of ethylene hydrate at 95 MPa and 303.9 K show that despite ethylene's large van der Waals radius; it can occupy the small cage of Structure I hydrate.[19]

It is assumed that only one guest molecule can be accommodated within each clathrate hydrate cage. However, recent measured[20] and calculated (using MD computer calculations[''']) Raman spectra showed that nitrogen can doubly occupy the large cage of Structure II nitrogen hydrate at higher pressures. The frequency of N_2 doubly occupying large cages (around 2332.5 cm^{-1}) is lower than that in singly occupied small cages (around 2335 cm^{-1}) but higher than that in singly occupied large cages (around 2330 cm^{-1}).

In Situ Studies of Hydrates

Raman spectroscopy provides a rapid and convenient tool for structure analysis without having to use diffraction techniques. Subsequently. Raman spectroscopy was used to study the structures. phase equilibria, and kinetics of gas hydrates at high pressure and close to ambient temperatures.[9] By monitoring the Rarnan spectra of guest molecules. the phase transition from Structure I to II hydrate for an ethane–methane gas mixture was identified for the first time. This was an unexpected result. because both methane and ethane form Structure I hydrate.[21]

Because in situ Raman spectra can be recorded, this provides a particularly convenient and useful tool for following the kinetics of gas hydrate formation and decomposition. For example, such studies we e performed during methane hydrate formation.[9,22–24] The evolution of two peaks at 2905 and 2915 cm^{-1} on hydrate formation from a single peak (at 2911 cm^{-1} for methane dissolved in water) can be monitored as a function of time/temperature/pressure. The effect of adding various chemicals that retard the hydrate formation process was also studied (Refs. [22–24]; see Fig. 3).

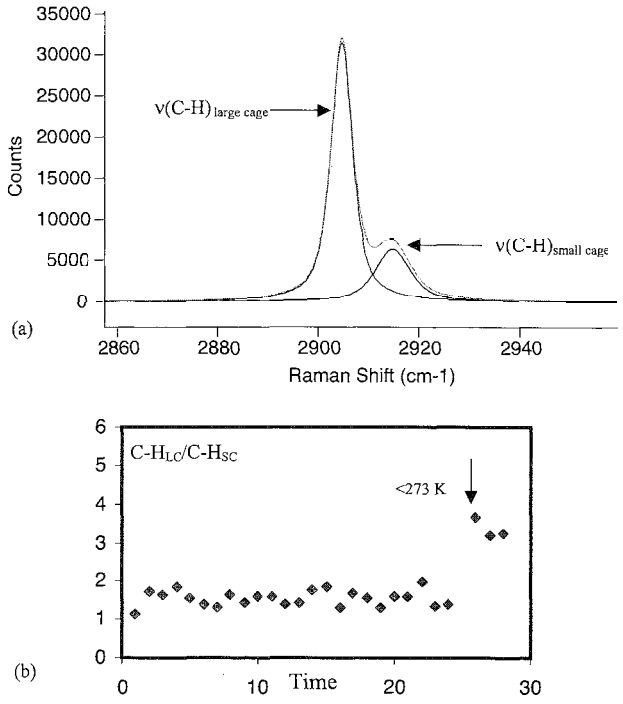

Fig. 3 (a) In situ Raman spectrum of the ν(C-H) symmetric mode of methane in methane hydrate:[23,24] and (b) intensity ratio of $\nu(C\text{-}H)_{large\ cage}/\nu(C\text{-}H)_{small\ cage}$ plotted as a function of time (in arbitrary units) for methane hydrate formation in the presence of a chemical inhibitor. Until the temperature is reduced, the intensity ratio is less than the usual 3:1 ratio. (From Refs. [23,24].) (View *this art in color at www.dekker.com.*)

SUPRAMOLECULAR COMPOUNDS CONTAINING MACROCYCLIC MOLECULES

IR and Raman spectroscopies were used to study the structures of a wide range of supramolecular compounds containing macrocyclic molecules. Some examples of the use of vibrational spectroscopy in structural studies of these compounds will now be given.[25–28]

Iron (IV, V) porphyrins were studied by resonance Raman spectroscopy.[25] These compounds have biological significance. because oxoferryl posphyrins {O=Fe (IV)(por)} are involved in enzymatic reactions of cytochrome P450, horseradish peroxidase (HRP). and related heme proteins. The mechanism of formation of the oxoferryl porphyrin π-cation radical was determined from resonance Raman measurements. The former radical is considered to be a model compound of HRP-I.

Resonance Raman spectroscopy was also used as a probe for detecting aggregation in porphyrin–DNA complexes.[26] For example. *t-bis*(*N*-methylpyridinium-4-yl)diphenylporphine (t_2-H_2-P_{agg})-DNA aggregation is indicated by intensity enhancements of bands due to bending motions of the pyridinium or phenyl groups. Microstructural changes occurring upon aggregation can also be detected from the resonance Raman spectrum.[26]

The study of time-dependent changes in protein structure is important in connecting their structures and functions. A recent Raman study of the heme macrocycle, myoglobin, revealed that a small absorption band, known as Band III. at 762 nm is allowed by means of vibronic coupling rather than the previously proposed Frank–Condon mechanism.[27] Band 111 was found to show an enhancement of non-totally-symmetric vibrational modes. Vibronic coupling involves the non-totally-symmetric modes that promote or enhance an electronic transition by lowering the symmetry of the molecule. Conversely, Frank–Condon active modes involve totally symmetric modes showing displacements of equilibrium positions upon excitation. It was suggested that these results change the interpretation of a large number of studies on myoglobin and will impact models connecting structure and dynamics in myoglobin.[27]

Structural trends in sandwich-type compounds [A-(*crown*)]$_2$[UO_2X_4] (where A=Li, Na, K; X=Cl, Br; crown=18-crown-6, 15-crown-5, 12-crown-4) were studied using IR and Raman spectroscopy in combination with x-ray diffraction and elemental analysis.[28] Understanding uranium coordination chemistry is crucial to the reprocessing and separation of uranium from nuclear energy and weapons industry waste streams. Separation and extraction of actinides in the waste stream by complexation with crown ethers to form coordination compounds is particularly attractive. This is because of the high chelating ability of the crown ethers and the tendency of actinides to adopt high coordination numbers. IR and Raman spectroscopy were used to characterize the structure of these compounds via the asymmetric ν(U-O) and symmetric ν_1(U-O) bands, respectively. In addition. Raman studies show that the coordination trends within this series of compounds are consistent with the principles of hard-soft-acid-base theory and Pearson's principle. i.e., "hard acids prefer to bind to hard bases and soft acids prefer to bind to soft bases." This is likely to be important for predicting binding. e.g., to remove actinide halides in a waste stream by coordination to form these sandwich-type compounds.

CONCLUSION

Vibrational spectroscopy is clearly a valuable tool for studying the structures and dynamics of supramolecular compounds, including inclusion compounds and macrocyclic compounds. In addition, resonance Raman mearurements were shown to be useful in studying the structure and function of biological molecules (containing macrocyclic moieties).

In terms of future directions, Raman spectroscopy will be important in further phase equilibria and kinetic rtudies

of clathate hydrates. These results coupled with macroscopic and x-ray and neutron diffraction measurements will aid in understanding how to control hydrate formation/dissociation in subsea pipelines and during energy exploitation. Finally, further advances are needed in theoretical calculations for interpreting measured vibrational spectra.

Viruses as Host Assemblies

INTRODUCTION

Viruses have long been recognized as being remarkable for their abilities to package. transport. and deliver their genornes using small well–defined containers: viral capsids. These viral containers span a wide range of size and shape, yet they are all essentially molecular assemblies with homogeneous properties.[1] These aspects of their biological functions have been recognized by chemists and materials scientists and are currently being exploited as a platform for the synthesis of inorganic nanomaterials, the attachment of biologically active ligands, the discovery of novel peptides, and the assembly of functionalized viral particles into well-ordered two- and three-dimensional arrays.

VIRUSES AS PROTEIN CAGES

The protein shell of a virus is assembled from multiple copies of virally encoded protein subunits.[2] The interaction among subunits is designed to provide maximum contact through non-covalent bonding.[3,4] Not surprisingly, the repetition of such interactions among a limited number of subunits results in regular structures with symmetry that describes the spatial interaction between protein building blocks. The protein shells of almost all virions are based on icosahedral or helical symmetry. Icosahedral symmetry is the largest closed structure that can be built from a repeating subunit in which the interactions between all subunits are chemically identical.[3] The T number (triangulation number) is a measure of the allowed arrangement of subunits to maintain icosahedral symmetry of the virus particle.

An icosahedron is defined by 20 triangular faces and 12 vertices related by two-, three-, and fivefold axes of rotational symmetry (Fig. 1). *A* spherical virion based on true icosahedral symmetry can be built from 60 copies of an identical coat protein subunit. However. a virion based on true icosahedral symmetry severely restricts the size of the genome that can be packaged. In nature. most spherical viruses are based on quasi-icosahedral symmetry that allows assembly of larger shells necessary to accommodate typical viral genomes (3–500 Kb). The basis for quasi-icosahedral symmetry is that the bonding properties of subunits in different structural environments are similar but not identical.[5] For example. a particle comprised of 180 copies of a single subunit (T = 3) arranges its subunits so that it retains the 12 vertices, but additional subunits arranged with sixfold symmetry are interposed between the fivefold symmetric clusters. In this type of arrangement, each subunit will be present in one of three slightly different chemical environments (designated A. B. and C). Even larger particles can be formed following the quasi-equivalent positions that allow the assembly of protein shells with diameters that typically range from 18–500 nm.

ICOSAHEDRAL VIRUS PARTICLES

Three icosahedral viruses emerged as useful templates with cage-like architectures for nanotechnology: cowpea chlorotic mottle virus (CCMV) and cowpea mosaic virus (CPMV) and Norwalk virus (NV) (Fig. *2)*. CCMV and *CPMV* are both plant viruses. while NV is an animal virus.

The CCMV is an RNA-containing plant virus. These 28 nm diameter virions contain 180 identical coat protein subunits (19.8 kDa each) arranged on an icosahedral lattice (T=3), which self-assemble to form a protein cage 2–4 nm thick and define a central cavity in which the viral *RWA* is packaged. The *N*-terminal 25 amino acid residues are basic, and negatively charged RNA is thought to interact electrostatically with this region of positive charge. In vivo. removal of this region of the protein prevents encapsulation of RNA but does not disrupt formation of empty virus particles in vitro.

The CPMV is also an RNA-containing plane virus. The icosahedral virus particle is formed from 60 copies of two different types of protein subunits (large *37* kDa and small *23* kDa). These proteins assemble into a pseudo (T = I) particle approximately 30 nm in diameter.[6] Very high

yields of virus can be obtained through a straightforward virus purification of infected plants. A kilogram of infected plant tissue can yield 1–2 g of virus. Unlike CCMV, this virus is not easily reconstituted into an empty protcin cage, but these particles are thermostable (up to 60°C) and noninfectious to animal cells.

The NV is a human calicivirus and contains a single-stranded RNA genome.[7] Particles of NV have T = 3 icosahedral symmetry with an approximate outer diameter of 38 nm and an average inner diameter of the central cavity that ranges from 20–29 nm. These virions contain 180 molecules of identical capsid protcin (56.6 kDa each), which has two principle domains, *S* and **P**. linked by a flexible hinge.[7] These viruses arc difficult to cultivate in tissue culture systems or animals,[8] making them difficult to study, and this factor limits their use as nanosynthctic reaction vessels.

Structural Transitions

The CCMV undergoes a reversible pH and metal-ion-dcpcndcnt swelling that results in a 10% increase in virus dimension."" This transition is the result of an expansion at the pseudo threefold axis of the virus particle,[10] which causes the formation of 60 separate 2 nm diameter openings in the protein shell (Fig. 2D). Under swollen conditions (pH>6.5), these openings allow free molecular exchange between the virus cavity and the bulk medium. In contrast, in the non-swollen form (pH < 6.5), there is no apparent exchange of large molecules between the cavity and the bulk medium. This transition can be viewed as analogous to reversible gating in molecular host–guest chemistry,[11,12] with the potential for selective entrapment and release of large molecules from the central cavity of the virion.

MINERALIZATION OF VIRAL CAPSIDS

Molecules can be packaged within the virion of CCMV and NV as crystalline solids that have a very high packing density. For example, it was shown that crystals of an ammonium salt of $H_2W_{12}O_{42}^{10-}$ can be packaged as a nanosizc crystalline solid within the CCMV protein cage,[13,14] and that modified viral cages will accommodate $Fe_2O_3{\cdot}nH_2O$.[15] The size and shape of the encapsulated nanomaterial is determined by the size and shape of the cavity created by the CCMV (or NV) protein cage. Therefore, the viral protein cage acts as a constrained reaction vessel to limit nanoparticle growth and morphology.

The crystallization of guest molecules can be achieved and controlled because the virion provides a charged protein interface (on the interior) that facilitates the aggregation and crystallization of ions. The plant virus CCMV has been a good model system for nanophase crystal growth, and a range of polyoxometalate species (vanadate, molybdatc, tungstate) can be crystallized within the CCMV protein cage. The same type of mineralization reaction (with tungstatc) is possible using NV. Thcse mineralization reactions are accomplished by providing an interface for molecular aggregation, based on complementary electrostatic interactions between the protcin and

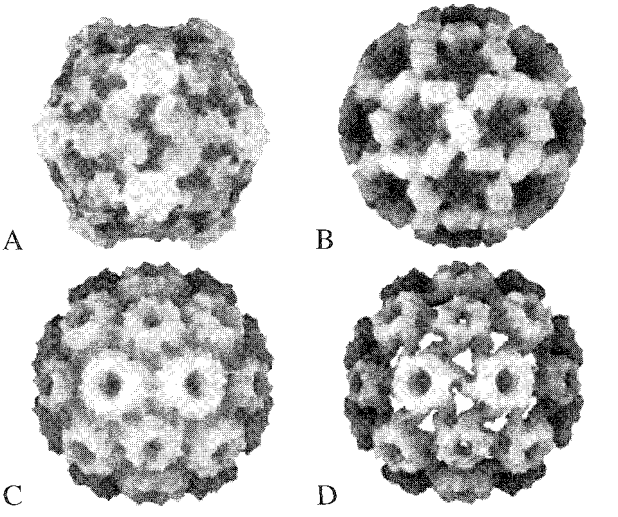

Fig. 2 Cryo electron microscopy and image reconstructions of (A) Cowpea Mosaic Virus (CPMV); (B) Norwalk Virus (NV); (C) Cowpea Chlorotic Mottle Virus (CCMV) unswollen; and (D) CCMV swollen.[1] (Used with permission from http://mmtsb.scripps.edu/viper/viper.htm) (*View this art in color at www.dekker.com.*)

the metal species, which creates a locally high concentration at the protein interface. Briefly outlined, the empty virions were incubated with the precursor ions (WO_4^{2-}, VO_3 , MoO_4^{2-}) at approximately neutral pH. Under these conditions, the virus exists in its open (swollen) form and allows all ions access to the cavity. The pH of the virus solution was then lowered to approximately pH 5.0. This induced two important complementary effects. The inorganic species underwent a pH-dependent oligomerization to form large polyoxometalate species such as $H_2W_{12}O_{42}^{10-}$, which were readily crystallized as ammonium salts. In addition, the viral capsid particle underwent a structural transition in which the pores in the protein shell closed, trapping crystallized mineral or mineral nuclei within the virus. Crystal growth of the polyoxometalate salt continued until the virion container was filled. Thus, the material synthesized was constrained by the size and shape of the interior of the viral protein cage. The resulting product could be easily purified (by centrifugation on sucrose gradients or size exclusion chromatography) and was visualized by transmission electron microscopy (TEM).

To test the dominance of electrostatic effects in the mineralization model, a mutant of CCMV was constructed (subE) in which all the basic residues on the N-terminus of the coat protein were substituted for glutamic acid (E), thus dramatically altering the electrostatic character of the interior of the assembled protein cage.[11] This mutant was able to catalyze the oxidative hydrolysis of Fe(II) to form an iron oxide nanoparticle encapsulated within the protein cage of the modified virus. High-resolution spectral imaging allowed the elemental composition of a protein–mineral composite material to be resolved (1 nm spatial resolution, Fig. 3). This clearly showed that the mineral nanoparticle was completely encapsulated within the protein cage structure. This mutant is able to bind Fe(II), facilitate its autoxidation to Fe(III), and engage in subsequent hydrolysis to form a ferric oxide mineral within the virion. The nanomaterial within the cage is size and shape constrained by the internal dimensions of the particle. Wild-type CCMV showed none of this spatially defined catalytic activity, and when incubated in the presence of Fe(II), bulk autoxidation and hydrolysis was observed, and no virion-encapsulated mineral was detected. Thus, selective engineering of the virion is possible, illustrating the synthetic plasticity of these architectures as biotemplates.

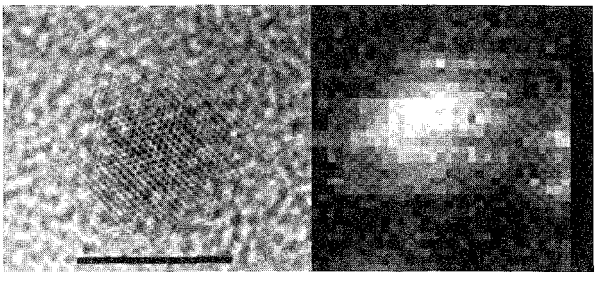

Fig. 3 Iron oxide nanoparticle cores synthesized within the mutant form of CCMV (subE). High-resolution TEM (left) of a single core (scale bar 30 nm) and (right) energy loss spectral imaging of a single particle showing N (dark pixels) and Fe (light pixels). (*View this art in* color *at www.dekker.com.*)

Encapsulation Based on Structural Transitions

Reversible virus gating (swelling) appears to play a role in the selective entrapment and release of materials from the protein cage.[13,14] The selective entrapment of the large anionic organic polymer poly(anetholsulfonic acid) (average molecular weight of 10,000 kDa) was used as a test of the role of gating. Empty virions were incubated under swollen conditions (pH 7.0) in a low concentration of poly(anetholsulfonic acid). When the virion is swollen, the polymer has free access to the interior through the 2 nm holes opened at the quasi-threefold axes and binds strongly to the highly cationic protein inner surface. When the pH of the solution was lowered, closing the holes, the polymer remained trapped inside and could be isolated as an organic composite, as demonstrated by TEM analysis and sedimentation on sucrose gradients. The poly (anetholsulfonic acid) loaded particles isolated from the gradients were subsequently dialyzed at pH 7 in buffer lacking the polymer, whereupon the poly(anetholsulfonic acid) was released from the particles. The release of the polymer was indicated by reanalysis of the particles on sucrose gradients that showed the sedimentation velocity of an empty particle (50S) and the loss of the unique poly(anetholsulfonic acid) absorbance at 315 nm. When the virion was incubated with polymer under nonswollen conditions, no uptake was observed. The same result was achieved with other polyanions such as poly(dextran sulfate). These results suggest that gating can be manipulated to play a central role in the selective entrapment and release of large molecules.

SURFACE MODIFICATION OF VIRUS PROTEIN CAGES

A recent series of articles illustrated the potential of using viruses as addressable nanoblocks having a variety of chemical and physical properties. These icosahedral virus particles can be derivatized using fluorescent organic labels[16,17] or particles of nanogold.[18] This is an illustration of the use of chemical functionality in a

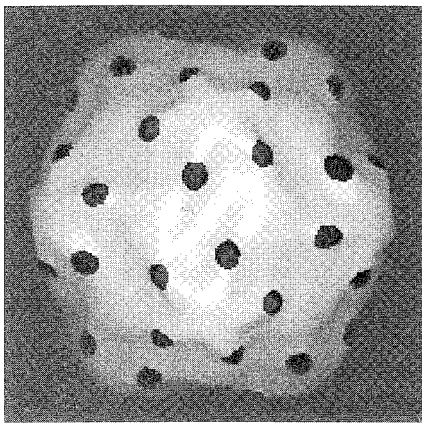

Fig. 4 Cryro electron micrograph and image reconstruction of Au-labeled CPMV. This illustrates the spatial selective labeling of engineered Cys residucs on the outer surface of CPMV. Adapted from Ref. [18] with permission. (*View this art in color at www.dekker.com.*)

biotemplate. Spatial selectivity of the derivatization process could be achieved using specific functionality enginecred into the virion structure.

The native CPMV virion could be reacted with the thiol reactive 5-maleimidofluoroscein, and it was found that 60 cysteine residues on the inside of each icosahedral particle could be derivatized.[16] A mutant form of CPMV was constructed with an exposed sulfhydryl on the exterior surface of the large subunit,[17] and the resulting two cysteine residucs could be differentially labeled, the exterior thiols reacting more rapidly than those on the interior. Qerivatization of thiol groups on the virus with a stilbene derivative for which antibodies wcre available showed the spatial differences between the location of thiols in the wild type and the mutant forms of the virus. The mutant, with thiols on the exterior of the virion, when derivatized with the stilbene, showed conjugate formation when reacted with the antibody. In contrast, attachment of the stilbene to the wild-type thiol on the interior of the virion showed no rcactivity with the antibody.

The surface-exposed thiols on the mutant virus wcre additionally reacted with monomalcimido-nanogold, and a three-dimensional image reconstruction was computed from cryo-electron microscopy.[18] As shown in Fig. 4, the gold particles are clearly visible at the positions of the inserted cysteine residues.

Derivatization of exposed lysine groups ($-NH_2$) on CPMV using rcactivity with *N*-hydroxysuccinimide esters or isothiocyanates provides additional flexibility for the use of viruses as biotemplates. Attachment of biotin to CPMV by this route, followed by reaction with avidin, resulted in c oss-linking of the virus particles to form a gel.[16] This is an initial step toward the programmed assembly of virus nanoblocks to form hierarchical structures with many levels of order.

Similarly, the wild type of CCMV could be chemically derivatized using amine-reactive fluorescent anhydrides or via activation of surface-exposed carboxylates and subsequent reaction with fluorophores bearing nucleophilic amine groups. In addition, genetically engineered CCMV with surface-exposed cysteine residues could be used for additional thiol selective attachment of fluorophores and peptides.

PHAGE DISPLAY

Phage display libraries arc "living" libraries of infectious *Escherichia coli* bacteriophage that were genetically engineered to express a library of small peptides on their exterior surface. A simplified overview of the phage display technique is illustrated in Fig. 5. The M13 filamentous phage (a virus) naturally infects and multiplies in the bacterium E. *coli,* and the genome of this phagc was completely sequenced. By inserting a library of peptide sequences into a "tail-like" protein of the phagc (three to five copies of which are located at one terminus of the assembled virion),[''] the living library is generated. The engineered phage present the corresponding novel peptides on their exterior surfaces and can then be used to test interactions with various targets, including inorganic and organic substrates. The first round of phage display involves introduction of the phagc library to the target and subsequently washing away those phage that do not interact with the target. The bound phage can then be eluted off the target by adding various compounds that

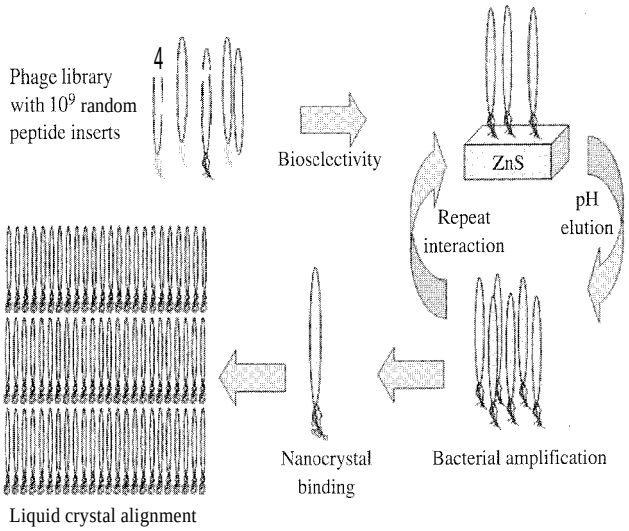

Fig. 5 The process used to generate nanocrystal alignment by the phage display method. (From Ref. [27].)

disturb the peptide–target interaction, without denaturing the remarkably resilient phage.[20] The eluted phage are amplified by re-infection of bacteria and then isolated and re-exposed to the same target (stringencies can be varied, if desired: in order to isolate peptides that interact with the target under certain experimentally relevant conditions). Typically. three to five rounds of phage–target exposure, unbound phage removal, elution (collectively referred to as "biopanning"), and amplification are performed. After the final amplification step, phage are isolated from infected bacteria, and their genetic inserts, corresponding to the novel peptides they each expressed, are sequenced. and the corresponding amino acid sequence of each peptide insert can be deduced. The biopanning results in the identification of several peptide sequences corresponding to those that interact strongly with their targets.

The use of phage display for the identification of proteins that specifically interacted with iron oxide targets was initiated[21,22] using slightly more complex systems than those depicted in Fig. 5. Similar peptide sequences were identified containing an RSK sequence domain. which correlates previous work that employed a bacterial display system.[21] Another sequence, identified by phage display, contained an RRSRHH sequence domain, again consistent with sequences identified in earlier work.[22]

The use of phage display was applied to the identification of a number of different peptides showing affinity for such materials as GaAs,[23] InP,[23] Si,[23] Ag,[24] SiO_2,[25] $CaCO_3$,[26] and ZnS.[27] In addition, the binding to different crystallographic faces of GaAs was probed. and peptide sequences were isolated that bound selectively to GaAS{100} faces but not GaAs{111} faces.[23] Interestingly. those peptides identified as having strong interactions with SiO_2 surfaces showed high sequence similarity to proteins isolated from the diatom *Cylindrotheca fusiformis*, which biomineralizes SiO_2.[28] The peptides identified by phage display were effective in inducing the mineralization of SiO_2 in synthetic reactions using silicic acid.

Recently. the isolation of a phage expressing a seven amino acid long peptide sequence that specifically bound to the surface of ZnS (Asn-Asn-Pro-Met-His-Gln-Asn) was reported.[27] When whole phage expressing this peptide were placed in precursor solutions of Zn^{2+} and S^{2-}, they induced the nucleation of nanoparticles of ZnS that remained bound to the phage. This concentrated solution of phage led to self-assembly of smectic. cholesteric. and nematic liquid crystal-like arrays comprising the filamentous phage bound to five ZnS crystals (2.66 ± 0.22 nm; Fig. 5*)*. The resulting ordered arrays of ZnS with phage showed periodicity of 895 nm corresponding to a separation of the nanocrystal domains (2.66 nm crystals in about a 20 nm cluster) by the dimensions of the phage (880 nm in length, 6.6 nm in diameter) stacking end to end giving a continuous lamellar morphology. This structure extended beyond the nanometer size regime to 72 μm domains that eventually form a film of cm dimensions (Fig. 5*)* but still have quantum dot properties. The value in this quantum dot function lies in an approach to computing based on a binary code that uses the semiconductor properties of ZnS nanocrystals.

In a similar set of experiments, phage display was used to identify peptides with high affinity for Ag.[24] These peptides were active toward the formation of Ag nanoparticles. and when the phage displaying these peptides were placed into a solution of silver ions (0.1 mM $AgNO_3$) for 16–48 h, they formed silver nanoparticles 60–150 nm in diameter. As in the case of the ZnS phage, it was possible to assemble these Ag nucleated phage into liquid crystal-like arrays in which layers of silver particles were separated by 680 nm, the dimensions of the phage.

The phage display technique was shown to have two important implications. For the first time, peptide sequences with high affinity for specific crystallographic mineral interfaces can be identified and were shown in some cases to influence the nucleation of specific minerals from solution. In addition, the ability to use self-assembly of the highly anisotropic and mineralized phage particles opened a new realm of supramolecular host–guest chemistry that combines high selectivity and long-range order.

CONCLUSION

The use of viruses and viral proteins for materials synthesis, encapsulation. and patterning, provides a number of unique advantages. The protein cages are biological in origin and, as such, are amenable to large-scale production (fermentation. farming, etc.) and are also inherently biodegradable. The icosahedral structures can be routinely modified using a genetic approach to impart specific chemical or structural functionality. The presentation of functionalizable reactive groups also allows a chemical approach to be taken to the attachment and presentation of organic and inorganic ligands. This structural and functional plasticity allows many of the protein cage systems described here to be engineered and redesigned for specific applications in materials science, homogeneous and heterogeneous catalysis. and biomedicine. The phage display technique provides a unique coinbinatorial approach to determining specific protein–mineral interactions, which can then be used to selectively synthesize mineral nanoparticles. In addition, the ability of the isotropic and anisotropic viral particles to make self-assembled superlattices and arrays in two and three

dimensions has the potential to make a significant impact in nanoelectronics. This chemistry is fundamentally biomimetic, and the lessons learned from how biological systems deal with issues of spatial control and assembly can now be applied to purely or partially synthetic systems.

Vitamin B_{12} and Heme Models

V

Sabine Van Doorslaer
University of Antwerp, Wilrijk, Belgium

INTRODUCTION

Heme proteins, like the globins *and the cytochromes, fulfill important functions. They share the common structural feature of having a* heme *group,* i.e., *an iron posphyrin complex, embedded in the protein (Fig.* 1A). *Four types of* globin, *differing in structure, tissue distribution, and likely function, were discovered in man and in other vertebrates: hemoglobin (Hb), myoglobin (Mb), neuroglobin (Ngb), and cytoglobin* (Cgb).[1] Tetrameric *Hb, located in the red blood cells, serves to transport* O_2 *in the circulatory system. The* monomeric *Mb, present mainly in the cardiac and striated muscle, acts as an* O_2 *buffer, facilitates* O_2 *diffusion, and plays a role in NO removal. Ngb, predominantly expressed in nerve cells, and Cgb, expressed in* many *tissues, are two recently discovered members of the vertebrate* globin *family exhibiting a hexacoordinated heme. They are of ancient evolutionary origin, and their physiological roles are still not fully* understood.[1] *Besides the* globins, *the cytochromes. which are electron-transfer proteins, form an important class of heme proteins. Several cytochromes have* a *hexacoordinated heme. The most intriguing characteristics of the* cytochrome *family of electron-transfer proteins is the broad range of* redox *potentials featured by the* Fe^{III}/Fe^{II} *couple at the* electro-*active* heme *core.'''* *Cytochrome* P450 *proteins form a separate class of heme proteins, where a cysteine residue coordinates to the proximal site of the heme group. This membrane protein is ubiquitous, occurring in life forms ranging* from *bacteria to man. All cytochrome* P450 *proteins catalyze the oxidation of organic substrates by oxygen, performing essential roles in biosynthesis,* metab-*olism, and the detoxification of* harmful substances.[3]

The versatile functions of the heme proteins challenge chemists in various ways. In the past decades, a lot of effort was put into the synthesis of heme models. The goal of these syntheses is twofold. On the one hand, the models *can help to unravel* stepwise *the chemical process connected to biological* function. *On the other hand, the chemical knowledge attained in this way can be exploited to design new products aimed at* fulfilling *tasks like reversible* O_2 *binding or catalyzing specific electron-transfer reactions or atom-transfer reactions.* In *this article, we will give a brief overview of models put forward to mimic the biological functions of heme proteins and illustrate how modern spectroscopy is used to unravel and* understand *the active site mechanisms.*

The B_{12} *coenzyme (Fig.* 1B) *is highly intriguing. The* B_{12}-cofactors *play a role in enzymatic methyl group transfer. in enzymatic ribonucleotide reduction, and in the enzymatic* 1,2-rearrangements *of a hydrogen atom with heavy atom centers.''' The specific structure of the cofactor gives rise to several interesting questions. First, why did nature chose cobalt, a transition metal that is not very abundant on earth? Second, what is the origin of the corrin ligand? What can this ligand offer that a posphyrin ligand cannot? What is the nature of metal–ligand interactions, and how does the protein use these interactions in its enzymatic role? In order to unravel these points and to try to mimic the biological functions of the* B_{12}-dependent *proteins, several synthetic models were put forward. A brief overview will be given.*

In Fig. 1, *it is shown that the porphyrin and con-in ligand are related. They share a similar biosynthesis path as the one that leads from 6-Ala to uroposphyrinogen* III.[4] *The organic synthesis of vitamin* B_{12} *turned out to be a gigantic effort that took Eschenmoser and coworkers over 11 years and could only be obtained in a more than 90-step* synthesis.[5] *This also shows that nature must have had a clear reason to synthesize this extraordinary* corrinoid. *Therefore,* Co(II) *porphyrin complexes are often studied in* B_{12}-*related analyses, in order to pin down the specific advantage of the corrin ligand. Thus, some of the models mimicking heme proteins are also addressed in the* B_{12} *research domain.*

HEME MODELS

A wide variety of approaches was derived to synthesize model systems for heme proteins. In the following, we will summarize some of these designs. Although I *distinguish here three subsections, depending on the specific heme function that is aimed at, it should be noted that most synthetic strategies presented are of a general nature and are applicable to other subsections.*

Heme Models for Oxygen Transport

In order to mimic the biological functions *of heme proteins, one of* the *challenging targets is to realize*

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012698

reversible O_2 binding. In globins, the heme is held in place by a coordination to the "proximal histidine" at the F8 site and by several noncovalent interactions with the surrounding protein residues. Heme hexacoordination, where the distal HisE7 residue directly coordinates to the heme iron atom is uncommon in Hb of vertebrates. In mammalian Mb and Hb, the protein superstructure shields the iron(II) heme cofactor against irreversible oxidation and μ-oxo dirner formation.[6] The peptide shell is also thought to play a determinant role in the affinity of the heme iron(II) for different diatomic molecules.[7] In the oxy forms of Hb and Mb, the distal histidine is thought to interact with the terminal O-atom of the dioxygen via H-bonding. Although the strength of the H-bond is still disputed; the interaction seems to play an important role in the discrimination of the heme proteins between O_2 and CO binding. The relative binding affinity of CO versus O_2, referred to as the M value, is a useful measure of a complex's susceptibility to poisoning by CO [$M = P_{1/2}(O_2)/P_{1/2}(CO)$, whereby $P_{1/2}$ is the partial pressure of O_2 or CO at half-saturation].

The basic requirements for synthetic heme models are, therefore, a five-coordinate iron(II) porphyrin in a high-spin state, with a proximal nitrogen base and a vacant site for dioxygen. Futhermore, the formation of chemochromes by axial coordinaton of two N-bases to the iron(II) prophyrin should be prevented.[8] Several approaches were put forward. It is found that a sterically hindered axial base, such as 1,2-dimethylimidazole, favors formation of a five-coordinate high-spin complex. Furthermore, covalent attachment of the axial ligand or steric hindrance of one of the two faces of the heme can also be used to prevent axial ligation of two bases. Finally, rapid decomposition of the O_2 adducts via μ-oxo-dimer formation has to be prevented. This can be achieved by attaching bulky substituents onto the iron(II) posphyrin or by bridging the macrocycle.[8]

The above requirements form a sort of blueprint for the synthesis of heme models for reversible oxygenation. The earliest structurally and functionally sound iron porphyrin model of the Hb and Mb active sites was the "picket fence" porphyrin[9] ((Fig. 2A). The CO affinity of the picket fence porphyrin turned out to be more than 30 times that of human Hb. If mammalian Hb or Mb would have the same M value as the picket fence porphyrins, mammals would suffocate in their own heme catabolism.[10] On the basis of this. Collman et al. proposed that the distal histidine plays a dual role of providing an H-bond to facilitate O_2 coordination and of decreasing CO affinity by steric hindrance of the CO binding in a linear manner.[8] In order to investigate this hypothesis further. Collman and coworkers synthesized "pocket" porphyrins, "hybrid" porphyrins. and "capped" posphyrins (for a review, see Ref. [8]). All of these models try to mimic the presence of the protein heme pocket in the natural proteins [see Fig. 2B as an example of a "pocket" porphyrin].[11] Collrnan and coworkers reported a versatile general method, the congruent multiple Michael addition, for attaching macrocycles over a posphyrin ring in a single high-yielding step, which opened interesting synthetic possibilities.[12] Finally, Collman and coworkers developed picnic basket porphyrins (Fig. 2C), a family of porphyrins consisting of a distal binding cavity with variable dimensions and an external bulky axial ligand on

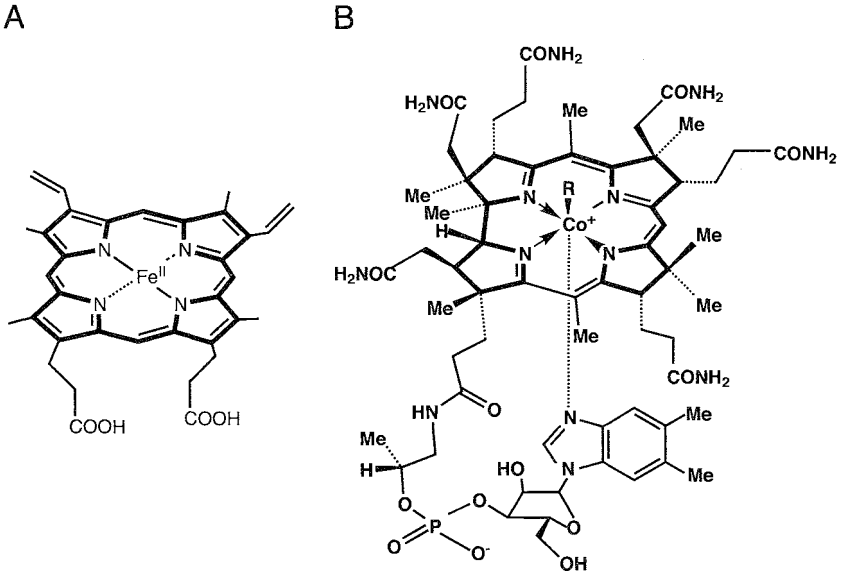

Fig. 1 (A) Heme group [iron(II) protoporphyrin IX]. (B) Vitamin B_{12} (R=CN) or coenzyme B_{12} (R=5′-deoxy-5′-adenosyl).

the proximal side.[13] The ^{1}H-NMR and O_2 affinity measurements show that the iron(II) and cobalt(II) picnic basket porphyrins both bind O_2 reversibly at room temperature with high affinities. The O_2 affinity decreases when the size of the basket increases. This was attributed to a dipole–dipole interaction between the terminally bound O_2 and the amide protons. The O_2 affinities of the cobalt picnic basket porphyrins are more sensitive to changes in basket sizes than those of the corresponding iron posphyrin, consistent with the proposal that $Co—O_2$ adducts have more electron density on the oxygen ligand than do the $Fe—O_2$ adducts. Substitution of iron(II) by cobalt(II) in the porphyrin is, therefore, often used to get additional information on the influence of the surroundings of the dioxygen.

Over the past 5 years, the combination of metalloporphyrin with dendrirner chemistry led to a fascinating new class of Hb and Mb models,''''.''' with the dendritic superstructure mimicking the encapsulation of the heme in the natural protein environment. Modification of the dendritic shell around the iron(II) porphyrin core modulates the shape, density, and polarity of these model systems. thereby profoundly affecting the thermodynamics and kinetics of the complexes formed with O_2 and CO. Diederich and coworkers developed two classes of water-soluble dendritic iron(II) porphyrins with amide dendrons capable of H-bond donation and with ester dendrons lacking H-bond donor centers in the dendritic shell[15] (Fig. 3). Through UV/Vis titrations. it was revealed that the dendritic iron(II) porphyrins containing secondary amide groups in the dendritic branching undergo stable: reversible O_2 and CO complexation in dry toluene, whereby the O_2 affinity largely surpasses that of T-state Hb or Mb. The oxygenated complexes are stable for several hours due to the protection against μ-oxo dimer formation provided by the dendritic shell. The oxygenated Fe(II) complexes were found to be less stable in the presence of water. This suggested that in dry toluene, the dendritic cage is closely packed, and an H-bond is formed between the amide NH group and dioxygen. In water: the cage opens. and the H-bond is weakened, hence the reduced stability of the oxygenated complex. This seemed to be corroborated by the studies of the posphyrin with ester dendrons lacking H-bond donor centers. The UV/Vis analyses revealed that this receptor undergoes reversible stable CO binding in dry toluene, but that the oxygenated complexes are unstable and undergo facile oxidative decomposition. However, our recent pulse EPR (electron

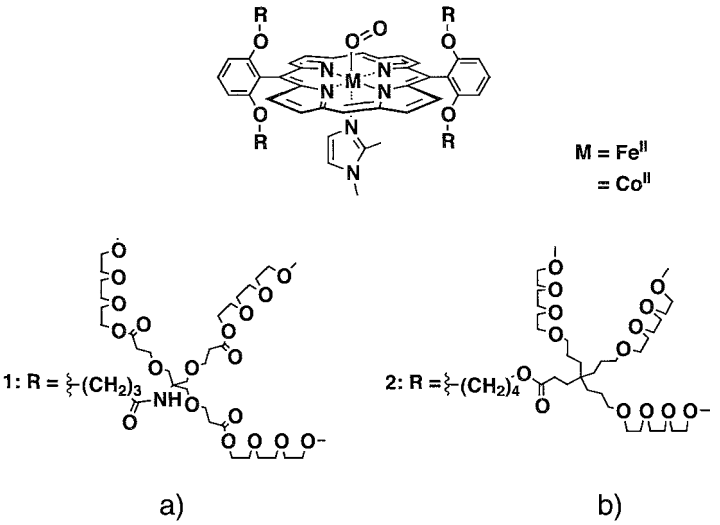

Fig. *3* Example of dendritic porphyrin complexes mimicking hemoglobin as proposed by Diederich and coworkers:[15] (a) amide dendrons; (b) ester dendrons.

paramagnetic resonance) studies of the corresponding Co(II) dendritic porphyrins shed a slightly different light on the subject.[16] Although the low hydrodynamic volume of the dendrimers in dry toluene could be experimentally confirmed, it was found that the difference in O_2 affinities between the amide-dendritic and ester-dendritic metalloporphyrins lies in the different packing and polarity of the dendritic branches. Our results clearly showed that observation of high O_2 affinity and the presence of functional groups capable of H-bond donation are no guarantee of the stabilization of dioxygen by an H-bond.

Heme Models Mimicking Cytochromes

The electron-transfer capacity of the cytochrome family of electron-transfer proteins is interesting, because the Fe^{III}/Fe^{II} couple of the heme core features a broad range of redox potentials.[2] In order to understand and mimic this behavior, several model systems were developed. The fact that the axial ligands of the heme groups in the different cytochrornes varies (the heme iron in Eukaryotic cytochrome c ligates to a histidine and a methionine, whereas cytochrome b_5 contains heme coordinated to two histidines): already shows that axial ligation to the iron center must be an important factor.[2] A variety of model studies indicated that the redox potential also depends on the nature of substituents in the porphyrin ring, H-binding to the axial ligands, and ruffling of the porphyrin macrocycle (see references within Ref. [17]). In the following, three recent models will be discussed that were developed to mimic the properties of cytochrornes.

One strategy to mimic the heme proteins is to embed the iron(II) porphyrins in a polymer. Bell et al. incorporated iron-5,10,15,20-tetraphenylporphyrin into films of a hydrogel polymer support medium, poly(γ-ethyl-L-glutamate) functionalized with imidazole pendent arms (PEG-Im) and studied the model in situ on silver electrodes using resonance Raman spectroscopy.[17] They found striking similarities between the properties of this model system, which contains multiple randomly oriented iron porphyrins bis-axially coordinated by imidazoles, and those of cytochrome c_3, which is a tetracheme protein of low molecular weight. In cytochrome c_3, the Fe^{III} hemes, which are *bis*-coordinated by histidine residues. lie close to each other (heme–heme distances ca. 1–1.5 pm), and they show efficient interheme electron transfer. The structure of the heme environment in the synthetic porphyrin-doped PEG-Im film model appears to be surprisingly close in structure and behavior to the

Another way of mimicking the electron-transfer properties of cytochromes is to use nature's own building blocks, e.g., by designing de novo polypeptides, where the porphyrin can be noncovalently introduced or covalently incorporated into a side chain of an amino acid residue in the peptide.[19]

Because observed environmental effects on the redox potential, such as heme solvation, polarity of the heme microenvironment, and nature of the surrounding protein shell are not well understood, it is important to design model systems with a unique local microenvironment around the electroactive core. Recently, dendritic iron porphyrins with tethered axial ligands were designed in which the dendritic branches guarantee a controlled microenvironment around the heme core.[17] The complexes are soluble in solvents of widely differing polarities, and the redox potential of the complexes was found to be solvent-independent.

Heme Models Mimicking Cytochrome P450 Activity

Cytochrome P450 is one of nature's oxidative workhorses. and it is involved in a wide variety of biological reactions, one of the most important being the detoxification of foreign bodies within the liver. A wide variety of approaches was developed to design and construct synthetic model systems of the cytochrome P450 family.[3] They vary from the earlier mentioned "capped" and "picnic basket" porphyrins, over supramolecular cytochrome P450 models, to dendritic porphyrins.[3]

B_{12} MODELS

Adenosylcobalamin or coenzyme B_{12} attracted great attention because of its interesting activity for selectively transforming organic substrates via homolytic (enzymatic ribonucleotide reduction and enzymatic 1,2-rearrangements) or heterolytic (methyl-group transfer) dissociation of carbon–metal bonds.[4] Structural aspects of the natural holoenzymes suggest a possible contribution of the protein matrix around the active site to the high selectivity of the transformation. In order to unravel the details of B12 functions, several Co^{III}, Co^{II}, and Co^{I} complexes have been synthesized. They can be divided in three groups depending on the equatorial ligand used: corrin, porphyrin, and other ligands.

Cobalt Corrins as B_{12} Models

Intuitively, one would think that one of the prerequisites of a good B_{12} model is a cobalt corrin complex. Cobalamin, however, is only soluble in polar solvents and oxidizes immediately to its Co^{III} form in the presence of O_2. This forms a drawback when one thinks in terms of a wide synthetic applicability, but it can also hamper mechanistic analyses. A change of the ligand substituents can solve this problem. Heptamethyl cobyrinate perchlorate (Fig. 4A), also named cobester, is soluble in polar and apolar solvents.[20] Our recent EPR studies showed that the Co(II) complex is stable at room temperature under air for months.[21] The temperature dependence of the oxygenation reaction of cobester could be monitored, and the complex was found to be in the deoxy form at room temperature. The addition of a nitrogen base was found to shift the oxygenation equilibrium in the direction of the oxygenated complex. Based on the cobester complex, several systems were synthesized that can model the methylmalonyl-succinyl rearrangement.[22,23]

In order to monitor the role of the nucleotide moiety in controlling radical reactions, different analogues of adenosylcobalamin were synthesized with modified α-D-ribose moiety and modified base moiety.[24] In diol dehydrase, it was found that the bulky base of the nucleotide moiety plays a pivotal role in stabilizing the highly reactive radical intermediates, and that it is, therefore. obligatory for catalytic turnovers. The upward distortion of the corrin ring induced by a bulky base to the

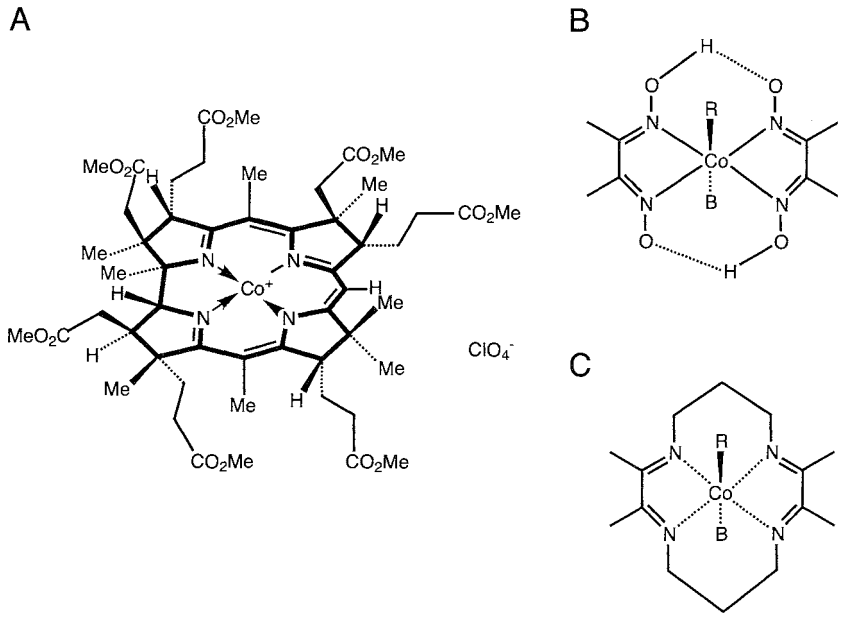

Fig. 4 B_{12} analogues. (A) Heptamethyl cobyrinate perchlorate.[20] (B) Cobaloxime as proposed by Schrauzer.[27] (C) The Costa complex as proposed by Costa et al.[29] (*B*=nitrogen base; *R*=alkyl group).

cobalt seems to be essential to prevent reactive radical intermediates from undesirable side reactions or from escaping out of the active sites during catalysis.[24]

Cobalt Porphyrins as B_{12} Models

One of the central questions in B_{12} research is why complex corrinoids are needed in B_{12} proteins. Cobalt porphyrins occur in nature, and an associated enzymatic reaction was discovered,[''] so why did nature not make use of these cobalt complexes? Can cobalt porphyrins nevertheless mimic some properties of B_{12}? Because porphyrin complexes are more easily synthetized than corrin complexes, this would broaden commercial applicability. In order to seek answers for these questions. cobalt porphyrins were studied in detail. Some of the heme models we discussed in the first section were also considered B_{12} models by replacing the central iron atom with cobalt.[8] Besides this, a lot of effort was put into fine-tuning cobalt porphyrins to perform specific chemical tasks. Recently, Uyemura and Aida successfully designed a novel model of coenzyme B_{12}, having a cobalt(II) porphyrin functionality encapsulated within a radical-tolerant, large poly(aryl ester) dendrimer cage. It was found to have a high potential for the steric control of 2,2′-azo*bis*(isobutyronitrile)-initiated transformation of alkynes.[26]

Other B_{12} Models

The synthetic importance of B_{12}-catalyzed reactions on the one hand and the reduced solubility and large autooxidation rate of cobalamin on the other hand, prompted chemists to design synthetic model systems that can overcome the drawbacks of cobalamin. In the 1970s. Schrauzer[27] recognized that cobaloxime (Fig. 4B) forms a good model for B_{12} systems. In cobaloxime, the two ligands are twofold H-bonded to form a quasi-macrocyclic chelate ring. Based on this early model, several bridged intramolecularly alkylated cobaloximes were synthesized to model the diol dehydratase reaction.[28] The Costa complex (Fig. 4C) is found to be an even better B_{12} mimic. because it exhibits a redox potential closer to the one of cobalamin.[29] An additional advantage of the relative simplicity of the model complexes is that they are of a size that is manageable in modern-day theoretical computations.[30] However, all of these synthetic model systems (and also the cobalt porphyrin systems) have a major disadvantage in that the supranucleophilic Co(I)-form is under physiological circumstances far less stable as in cobalt-corrin systems. Therefore, cobalt-corrin compounds are favored when methyl-transfer reactions are the goal.

CONCLUSION

In this overview, it is shown that the development of heme and B_{12} models has two goals: to gain a deeper understanding of the proteins' inner workings and the mimicking of specific enzymatic or transport functions of the heme and B_{12} proteins. Heme models have an iron porphyrin complex as base. The protein environment around the iron center can be modeled by means of targeted substituents of the porphyrin ring, like in picket-fence porphyrin, by dendritic branches. by a polymer, or by designing de novo polypeptides.

In order to model the extraordinary functions of B_{12} proteins: cobalt complexes with varying equatorial ligands were proposed. Besides cobalt-corrin complexes, cobalt porphyrin models and other cobalt complexes were suggested. The comparison between cobalt-corrin and porphyrin complexes is essential to unraveling nature's choice of the complex corronoid in coenzyme B_{12}.

ACKNOWLEDGMENT

I would like to thank Prof. Dr. B. Kraütler (University of Innsbruck, Austria), who introduced me to the wonders of B_{12} chemistry. I also would like to acknowledge Prof. Dr. L. Moens (University of Antwerp, Belgium). who, in the course of fruitful collaborations; taught me about heme proteins.

Weak Hydrogen Bonds

Motorhiro Nishio
The CHPI Institute, Tokyo, Japan

INTRODUCTION

Properties of organic compounds are described as the consequence of various kinds of chemical forces. Strong covalent bonds bind the atoms together into an organic molecule or group. Weak interactions are important in deciding the three-dimensional (3D) shape of the molecule and play vital roles in supramolecular chemistry and in regulating biochemical processes. Among weak molecular forces, the hydrogen bond is one of the most abundant. The enthalpy of the ordinary hydrogen bond between OH or NH and electronegative atoms such as O or N is within the range of 3—7 kcal mol^{-1}. Pauling termed the above attractive force the hydrogen bond. In the conventional hydrogen bond, contribution from the Coulomb energy is the most important, because this is an interaction between a hard acid and a hard base in the context of the Pearson hard and soft acids and bases (HSAB) principle.

In the second half of the last century, evidence accumulated to show that weaker hydrogen bonds (2∼4 kcal mol^{-1}) are ubiquitous,[1] including XH/π and CH/*n* interactions (*n:* lone pair electrons, as contrasted to n). The former is hydrogen bonds between hard acids (HA) and soft bases (SB), while the latter is hydrogen bonds between soft acids (SA) and hard bases (FIB). More recently. a still weaker attractive force, the CH/π interaction (0.5∼2 kcal mol^{-1}), was shown to play a substantial role in a variety of chemical and biological phenomena. This is the hydrogen bond occurring between SA and SB. Stabilization of this bond, accordingly. comes essentially from the dispersion force and charge-transfer interaction. while contribution from the electrostatic energy is relatively unimportant. The HA/SB and SA/HB interactions fall between these two extremes. That the above interactions are all true hydrogen bonds was demonstrated by a number of spectral, crystallographic, and theoretical studies. Compared in Table 1 are characteristics of the four hydrogen bonds.

The characteristic of a hydrogen bond resides in its attractive nature and orientation dependence. This is shown in Fig. 1 for CH/π interactions as a typical example.[2] Notice that the directionality and H/π-plane distance correlate and depend on the strength of the proton donor. Analogous plots are also reported for other hydrogen bonds.

Shown in Fig. 2 are interaction energies as a function of intermolecular separation. An interesting point is that the stabilization by the weak CH/O hydrogen bond decreases more slowly than the ordinary hydrogen bond.[3]

Readers are referred to the following two monographs aimed at these nonconventional weak hydrogen bonds: *The Weak Hydrogen Bond in Structural Chemistry and Biology* by Desiraju and Steiner[4] and *The CH/π Interaction. Evidence, Nature, and Consequences* by Nishio. Hirota, and Umezawa.[5] The former is a thorough and in-depth treatise on the weak hydrogen bond, dealing largely with crystallographic evidence and consequences. The latter is aimed to a particular interaction, the CH/π hydrogen bond. dealing with various methods and aspects of this molecular force in chemistry and structural biology. Recently, Steiner wrote a review to give a survey of the hydrogen bonds, with a focus on the structure in the solid, on the ground of the modern theory and technology.[6]

Another source of information is a list of literature at the author's Web site (http://www.hi-ho.ne.jp/dionisio). The list is focused on the CH/π hydrogen bond and is updated regularly. The topics are categorized into several parts. such as crystal packing: clathrates, database analyses, structural biology, theoretical calculations, etc. The list also includes literature regarding XH/π and CH/*n* hydrogen bonds, though they are not intended to be complete. In this article, for space reasons, historically important papers are mentioned but not cited in the references. Citations are limited to the most relevant and informative. The interested reader is referred to information appearing in these books, articles, or web sites.

DETECTION OF WEAK HYDROGEN BONDS

The weak hydrogen bonds are studied by various methods. Experimentally. spectroscopy and crystallography are most often used. Formation constants or thermal properties of an interacting system also provide useful information. Conformational analyses of appropriate molecules may provide information, though indirect. for the weak

SA/SB (CH/π, CHIS. CH/Se, etc.)	CH_4/C_6H_6	Unimportant	Unimportant	Moderate[a]	Important

ES: electrostatic; ER: exchange-repulsion: CT: charge-transfer: and CORR: London dispersion (correlation) term.
[a]A matter of current controversy.

hydrogen bonds operating between the interacting group.[5] Theoretically, ab initio calculations at high levels of approximation are used.

Spectroscopy

The IR spectroscopy, among others, is the most useful. The frequency shift of the X—H stretching band on complex formation ($\Delta\nu$) is known as the hydrogen-bond shift. The lower-frequency shift Av of ordinary hydrogen bonds varies from ca. 100–500 cm^{-1}, but the shifts are considerably smaller for weak hydrogen bonds. The NMR spectroscopy also provides information, especially if the electronic substituent effect is analyzed.

Crystallography

The x-ray diffraction method is most often employed.[4,6] Neutron diffraction provides information about the location of hydrogen atoms. Distance and angle parameters of the putative hydrogen-bonded atoms are used in evaluating the nature and strength of the interaction.

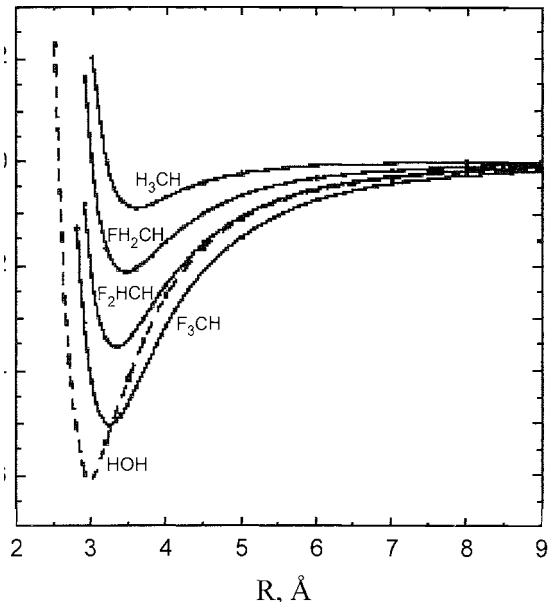

Fig. 2 Interaction energies as a function of intermolecular separation C···O in the *CWO* hydrogen bond. (From Ref. [3], Fig. 3.)

Database Analyses

The Cambridge Structural Database (CSD), Protein Data Bank (PDB). and Nucleic Acid Database (NDB) are used.[4,6] The CSD (http://www.ccdc.cam.ac.uk/) is equipped with programs QUEST3D for data retrieval and VISTA for statistical analyses. The January 2003 release includes more than 270,000 crystal structures of organic. organometallic, and coordination compounds. The PDB (http://www.rcsb.org.pdb/) and NDB (http://ndbserver.rutgers.edu/) are free for use through the Internet and contain more than 7000 protein and 2000 nucieic acid coordinates, respectively, from crystallographic and NMR determinations.

Theoretical Calculation

Ab initio MO calculations are used.[7,8] Correction to BSSE (basis set superposition error) is necessary for supramolecules. An MP2 or higher level of approximations should be employed. This is especially true for softer hydrogen bonds such as CH/π or CH/N. because contribution from the correlation energy is important. The density functional theory (DFT) method is used in calculating relatively large complexes. To analyze the contribution of energetic components. Morokuma partitioning or alternatives such as intermolecular perturbation theory method is used. The Bader's AIM (atoms in molecules) method is used to investigate the nature of the interaction.

HYDROGEN BONDS BETWEEN HARD ACIDS AND SOFT BASES

These bonds between hard acids and soft bases include the OH/π, NH/π. and XH/π (*X*=halogen) hydrogen bonds."."" These kinds of interactions were actively studied from the mid-1950s to the 1960s, by IR spectroscopy. For typical OH/π and NH/π interactions, the hydrogen-bond shift Δν falls between 20 and 100 cm^{-1}. The importance of the OH/π and NH/π hydrogen bonds in organic[9,10] and organometallic[11] crystals was reported.

Perutz suggested,[12] on the ground of vapor phase and crystallographic evidence, the role of aromatic rings as hydrogen-bond acceptors in molecular recognition. Recent MO calculations support this.[13–15] Novoa and Mota compared, by the AIM analysis. characteristics of the OH/π, CH/O, and CH/π interactions and concluded that they are all true hydrogen bonds.[16] Tsuzuki and coworkers examined the strength and directionality of the OH/π and NH/π interactions[17] and compared the results with the CH/π bond (Table 2). Notice that the electrostatic contribution decreases abruptly from an ordinary hydrogen bond to OH/π, NH/π, and then to CH/π hydrogen

bond. The correlation energy, on the other hand, does not change appreciably.

Steiner and Koellner discussed the role of NH/π and OH/π hydrogen bonds in 592 high-resolution protein structures.[18] A brief review emphasizing the importance of NH/π, CH/O, and CH/π hydrogen bonds appeared.[19] The NH/π interactions are more frequently found than OH/π interactions,[20,21] presumably because NH is softer as an acid than OH. The OH/π bond is stronger than the NH/π and CH/π interactions, however, it is not common in proteins. It is likely that OH is harder as an acid and seeks a hard base as the partner in the physiological environment. More information on XH/π interactions in biology is available in Ref. [18] and in Chapter 5 of Ref. [4].

HYDROGEN BONDS BETWEEN SOFT ACIDS AND HARD BASES

Hydrogen bonds between soft acids and hard bases include the CH/*n* interaction. Thermochemical studies and measurements of CH stretching bands of the CH/O and CH/N complexed species suggested the capability of CH groups as hydrogen donors. The lower-frequency shifts Δν are of the order $10 \sim 100\ cm^{-1}$ depending on the system examined. The C—H absorption bands often shift to higher frequencies in CH/O and CH/π hydrogen bonds.[3,5]

In 1962, Sutor proposed the hydrogen-bond nature of the CH/O interaction on the ground of her crystallographic data. In 1982, Taylor and Kennard presented a monumental work in this field by surveying crystal structures in the CSD.[22] Thus, retrieval of neutron diffraction data and statistical analyses of the distance and angle parameters established, unequivocally, the hydrogen-bond nature of the CH/O, CH/N, and CH/halogen interactions. Desiraju, Steiner, and coworkers extensively studied CH/O interactions in crystals, and the results appear in several review articles.[23–27] In Table 3, the H···C distance in CH/X hydrogen bonds, examined by a CSD study is compared. Notice that the distance depends on the strength of the CH donor and the acceptor in the interacting system.

Stoddart and coworkers reported the role of CH/O interactions as a control element in supramolecular complexes.[28] Database studies demonstrated the importance of CH/O hydrogen bonds in the protein structure.[29–31] This topic is dealt with in great detail in Ref. [4].

Compared in Table 4 are the strengths of the CH/O hydrogen bonds calculated for methane and its fluorinated derivatives in complex with water or formaldehyde.[3] It is noted that the proportion of the electrostatic term is comparable to the ordinary hydrogen bond, whereas contribution from the correlation energy is unimportant. Acetylene, ethylene, and ethane were shown to interact favorably with H_2O and NH_3.[32] The interaction of CHs

with N or halogen is important[4,33] but is less common than the CH/O hydrogen bond.

HYDROGEN BONDS BETWEEN SOFT ACIDS AND SOFT BASES

Interactions such as SH/π,[4] CH/S,[34] or CH/Se[35] may belong to this category but are not dealt with here. The most important is the CH/π hydrogen bond.[5]

In 1952, Tamres showed that benzene and analogues dissolve in chloroform exothermically. Huggins and Pimentel found, by measurement of IR spectra, that the interaction of chloroform with benzene showed behavior consistent with the criteria for hydrogen-bond systems. Many workers since demonstrated that the interaction of CH with π-bases was attractive. Argon matrix IR experiments provide good evidence.[6–9] Nuclear Overhauser effects of a series of simple organic compounds provided evidence for the hydrogen-bond nature of the CH/π interaction.[37] Crystallographic database analyses of organic[38,39] and transition metal compounds[40] support the conclusion. A number of theoretical studies supporting the concept appeared.[2,14,16,36,38,41–44]

Compared in Table 5 are the energies of CH/π bonds estimated by high-level ab initio calculations.[41] Notice that the electrostatic contribution is less than 20% when a nonpolar CH group is involved. A proportion of the electrostatic energy increases when going from sp3-CH to sp2-CH and then to sp-CH. A similar trend is obtained by substituting the hydrogens with an halogen atom. Interactions involving aromatic CHs are stronger than the aliphatic ones. The former is termed the aromatic CH/π interaction, but this is often referred to as the T-shape or edge-to-face π/π interaction.[45,46] A considerable part of the interactions between aromatic side chains in protein[47] may trace its origin in the aromatic CH/π interaction.

A unique feature of the CH/π bond is that a number of CH groups may simultaneously participate in the interaction with a π-base. This type of interaction is favorable, in view of entropy, because an assorted arrangement of CH groups is common in organic molecules. Every π-group has at least a plane of symmetry. The total Gibbs energy of the interaction thus increases; this point is

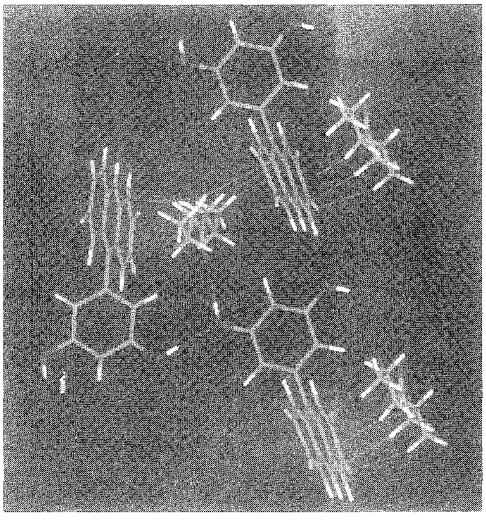

Fig. 3 Crystal structure of 9-(3,5-dihydroxyphenyl)anthracene heptane-4-one clathrate (CSD refcode REKMAV). Dotted lines and Dashed lines indicate CH/π and hydrogens bonds, respectively. (From Ref. [67], Fig. 2.)

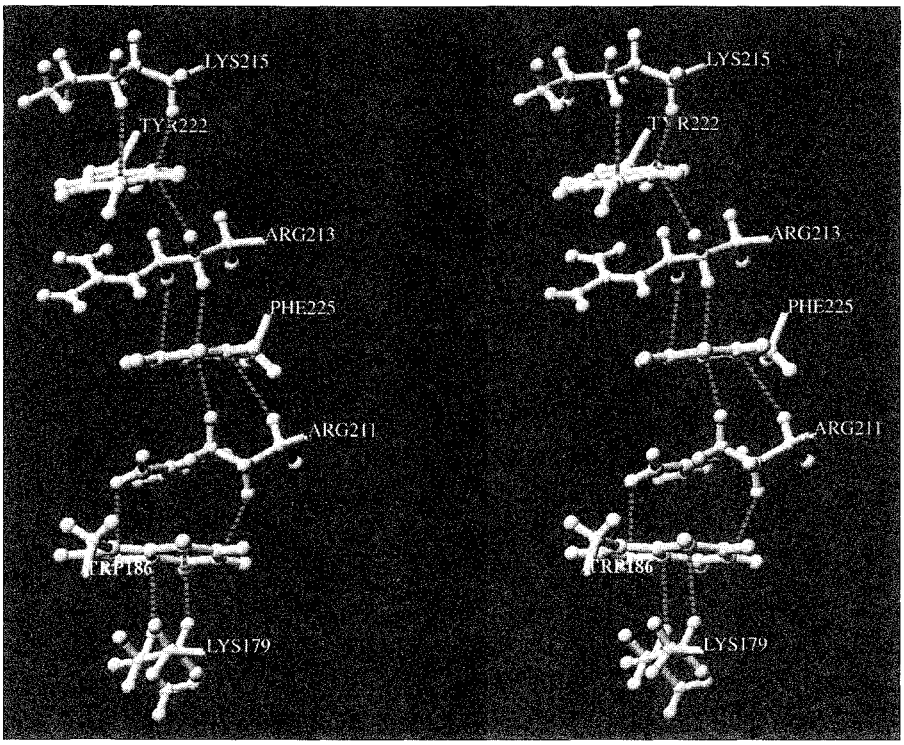

Fig. 4 CH/π interactions observed in human growth hormone-binding protein (PDB code 3HHR) Lys215/Tyr222/Arg213/Phe225/Arg211/Trp186/Lys179 (From Ref [68], Fig 10.)

crucial in understanding the role of CH/π interaction. Another characteristic, which is of supreme importance when considering biochemical processes, is that the CH/π interaction plays its role in protic media, such as water, as well as in nonpolar solvents. This is because most of its energy originates from the dispersion interaction. The specificity in supramolecules comes from weak forces of enthalpic origin, including van der Waals force and weak hydrogen bonds. The so-called "hydrophobic effect" is not the cause[48] of the specific interactions in molecular recognitions, including those of proteins.

The number of papers reporting the role of CH/π interaction is rapidly increasing. Only recent key papers are cited here. Chloroform interacts favorably with an arene π-cloud of fullerene complexes of calixarenes[49] and cyclotriveratrylene.[50] Evidence for the role of CH/π interaction in self-assembly was presented.[51,52] The significance in molecular capsules[53,54] and lattice-[55,56] and cavity-inclusion type clathrates[57,58] is well documented. Possibilities in designing useful drug[59] and liquid crystal[60] or agents for enantiomer separation[61] and enantioselective catalysts[62] were suggested. Houk and coworkers attributed the origin of a remarkable *endo*-stereoselectivity in Diels–Alder reactions to the CH/π and π/π interactions.[63] Importance in the efficiency and stereoselectivity in the photocycloaddition[64,65] and topochemical polymerization reactions[66] was demonstrated.

Illustrated in Fig. 3 is an example.[67] Notice that the nonpolar CH/π interactions dominate over the ordinary hydrogen bonds.

Significance in the structure of proteins, such as GTP-binding proteins, SH2 motif,[68] MHC antigens, and TATA-box binding protein/DNA complex[69] was reported. A stacked arrangement of carbohydrates with aromatic residues was interpreted as being a consequence of the CH/π interaction.[70] An inhibitor with a polyethylene glycol moiety was shown to effectively bind the substrate-binding cleft, lined with many aromatic residues, of acetylcholine esterase. The result was attributed to the CH/π interaction.[71]

An example is given in Fig. 4 for a sequence of CH/π bonds observed in human growth hormone-binding protein. Notice that the methylene hydrogens in Lys and Arg are involved in a stacked manner with aromatic residues, Phe, Tyr, and Trp.

By analyzing 19 adenine-cofactor specific enzymes, Chakrabarti and Samanta found CH/π interactions to play

an essential role in the binding of substrates.[72] Weiss and coworkers analyzed 1154 PDB entries and found that CH/π interactions are ubiquitously present in the protein structure.[73] Further information is available in several reviews[18,19,70,74] and in Chapter 11 of Ref. [5] CH/π interactions in DNA structure were also reported.[75]

CONCLUSION

The characteristics of the weak hydrogen bonds may be summarized as follows. The stronger the protoll-donating ability of XH, the stronger the attractive nature of the hydrogen bond. Thus, the following order obtains OH>NH>CH. Among carbon acids, sp-CH≫sp2-CH>sp3-CH. The H/acceptor distance decreases in the above order. As for the proton acceptor, O is stronger than N, S. and κ-bases. Among the κ-bases, the electron density of the acceptor (π-donor) is important. Directionality is a requisite for the hydrogen bonding, distinguishing it from the van der Waals force. This also follows the above order of strength: the stronger the hydrogen bond. the stronger the trend for linearity.

The implication of weak hydrogen bonds in supramolecular chemistry is immense, as shown in this and other articles in the *Encyclopedia.* A century has just begun where the interaction between molecules is becoming the most fascinating target in chemistry and biology; the weak hydrogen bonds undoubtedly play the central part.

X-Ray Crystallography

Kari Rissanen
University of Jyväskylä, Jyväskylä, Finland

INTRODUCTION

X-ray crystallography is the most powerful tool in the structural analysis of crystalline solids. The extremely fast development of computers had a direct impact on the speed of x-ray diffraction analysis. Modern area detector-based diffractometers allow fast and accurate data collection and processing, giving the possibility of collecting and processing several. even very large, data sets in a day. Fast computers also speed structure solution and refinement. so that even complicated problems can be tackled within reasonable time frames. Supramolecular systems impose a demanding task on x-ray crystallography. The size of the structures to be solved are comparable to small proteins (up to MW 10000), yet protein crystallographic techniques cannot be applied to supramolecular systems. The methods developed for small molecule crystallography have to be adapted to large supramolecular systems, thus inaking the analysis of such structures demanding and, when successful, rewarding.

APPLICATION AREAS

This article is written for nonspecialists to give practical hints and advice to those supramolecular chemists designing and synthesizing systems they would like to study by x-ray crystallography with the help of an x-ray diffraction service or a collaborator. To learn the theoretical basis of x-ray crystallography, the reader is encouraged to read some of the recent x-ray crystallography textbooks to become acquainted with the principles [at introductory,"' intermediate[L2]' or advanced"'] levels]. Modem single-crystal x-ray crystallography has two major application areas. Small-molecule crystallography focuses on target structures with weights of the asymmetric unit, W_{au},[a] between 100–700, resulting in precise and accurate bond distances and angles with low crystallographic R-value (normally <0.07) due to good-quality crystals with no disorder and a high (usually >10) ratio of the number of observed reflections to the number of refined parameters. The R-value is a measure of the level of disagreement between the properly scaled observed structure factors (F_{obs}) and calculated structure factors (F_{calc}). It is usually given as %, i.e., an R-value of 0.07 is reported as 7%.

The other, technically quite different application area, is protein crystallography, which deals with very large structures, even virus structures, up to W_{au} of 10^6. However, these structures cannot be considered to be crystallographically accurate. Often, the resolution is not high enough to determine individual atom positions, and instead. amino acid residues are located. Protein R-values are seldom less than 0.15. and the ratio of the number of observed reflections and number of refined parameters is low (<5). However, protein x-ray structures are considered reliable structural information about the conformation and overall structure of the protein in the crystalline state.

Determination of the accurate structures of molecular inclusion complexes and molecular assemblies gained a lot of importance in supramolecular chemistry.

Since its birth, supramolecular chemistry was defined as "chemistry beyond-the molecule, bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces.''[4] Detailed information about the nature of these weak intermolecular interactions is crucial in order to understand and further develop supramolecular systems. Particularly accurate structural inforination can be gained in the solid state by single-crystal x-ray crystallography.

THE CRYSTAL

By far the most important piece of the puzzle in structure determination by x-ray crystallography is the crystal. Without a good enough single crystal, nothing can be done. The first step in x-ray diffraction structural analysis is to produce crystalline material that contains at least one single crystal with certain properties. The most important property is good periodicity of the crystal lattice, viz..

[a] W_{au} is defined as the sum of the molecular weight of all atoms in the asymmetric unit. W_{au} of the system studied can be much higher than the MW of the (supra)molecule. For example, three molecules of MW 250 + four solvent molecules of MW 78 in the asymmetric unit will give W_{au} as high as 1062 (3 x 250 + 4 x 78 = 1062).

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012825

packing of the molecules and solvent molecules (if present), to gain enough diffraction power. The periodicity is induced by crystal growth, a subtle and more or less spontaneous orderingldesolvation process of molecules, ions, and solvent molecules. No matter what technique is used to obtain the crystal. the only goal is to induce the best possible periodicity of the entities to be studied. The reader is encouraged to read some key articles on crystal growing[5,6] or search the World Wide Web for information, using the search term "crystal growth." With modern area detector diffractometers. the size of the crystal is not as important as it was earlier (well-diffracting crystals as small as 0.05 x 0.05 x 0.05 mm can give good data sets).

The periodicity of the crystal lattice is not the only item affecting the diffraction quality of the crystal. In addition, the types of the ordered atoms have a significant influence on the diffraction power of the crystal. Heavier and well-ordered atoms in the crystal lattice will produce the best diffraction power. In supramolecular systems, the crystal lattice consists mainly of light elements like carbon, hydrogen, oxygen, and nitrogen. and only when metallo-supramolecular systems are studied can heavier elements. such as transition metals, bromide. and iodine, be present. A rough but practical estimate for the intrinsic diffraction power of the compound can be simply calculated by dividing its molecular weight by the number of atoms in the molecule/assembly (N). viz. $dp = MW/N^b$, e.g., benzene $dp = 6.5$, hexaiodobenzene $dp = 49.5$. Therefore: the quality of the crystal. viz. perfect periodicity of the crystal lattice, is crucial for light-atom structures with high W_{au} (>1000) values. as frequently encountered in supramolecular systems.

The third important point about the crystal is its stability. The first two points related to diffraction quality of the crystal may be fine. but the crystal might be unstable under normal laboratory conditions. Large supramolecular assemblies are held together with weak intermolecular interactions. and crystals consisting of such entities are often fragile and sensitive to the environment. Solvent often plays a crucial role in the crystal growth of supramolecular systems and is needed in the construction of the crystal lattice. Due to this fact, many supramoleculer crystals are only stable in the solvent from which they were crystallized. It is not usually practical to change laboratory conditions to eehance crystal stability, and crystals can be easily handled inside the mother solvent and protected against decomposition. When no information about the stablity of the crystals exists, all crystals must be treated as extremely unstable. This starts immediately at the crystal growing phase. When and if crystals form in solution. the crystallization vessel must be closed to ensure that the mother solvent does not evaporate and that the crystals remain in solution. Also, mailing or transporting crystals must be done accordingly, in well-packed, sealed tubes, flasks, or ampoules.

For mounting sensitive and unstable crystals, two practical methods exist. The selected crystal is ''fished'' under a microscopy from the mother solvent by a "loop" crystal holder (see Fig. 1), dipped into perfluorinated polyether (so-called "Magic Oil"). This "oil" is viscous, oxygen free, and unreactive. and it forms a film around the crystal. protecting it from the hostile environment. During data collection. the crystal must not move inside the loop. This is best achieved when the crystal is cooled (with cooling devices available from x-ray diffractometer manufacturers) below 193 K (−80°C). This procedure has an additional advantage in that the low temperature maintained during data collection reduces the thermal movement of the atoms in the crystal. thus improving the quality of the data set.

If the crystal does not survive cooling (cracks appear or intensity of the reflections is lost) or it cannot be iransferred intact into the loop (or seems to react or decompose inside the oil, as happens occasionally). the crystal can be sealed into a capillary crystal holder (see Fig. 1). The advantages of this procedure are that the crystal is in contact only with the mother solvent (actually surrounded by it all the time) and that the data collection can be performed at room temperature. Disadvantages are the extreme care needed to seal and manipulate the fragile capillary crystal holder, which is unique for each crystal, and the possible movement of the crystal inside the capillary tube during data collection.

If the periodicity of the molecules. ions, and solvent molecules in the crystal lattice is good (no disorder, see below) and the structure contains some heavier atoms (sulfur or heavier) and data collection can be performed without decomposition of the crystal. all should be fine for the next phase of the x-ray analysis: data collection and structu e solution.

DATA COLLECTION AND STRUCTURE SOLUTION

Modern diffactometers have automated data collection routines after the crystal is placed into the center of the x-ray beam. With area-detector (e.g., CCD or image plate systems) diffractometers. it is advisable to take one image to check the diffraction quality of the

[b] More precisely dp should be calculated as $dp = W_{au}/N$, where N = number of atoms in the asymmetric unit. This. however, can be done only after the completed x-ray analysis, when the total contents of the asymmetric unit are known.

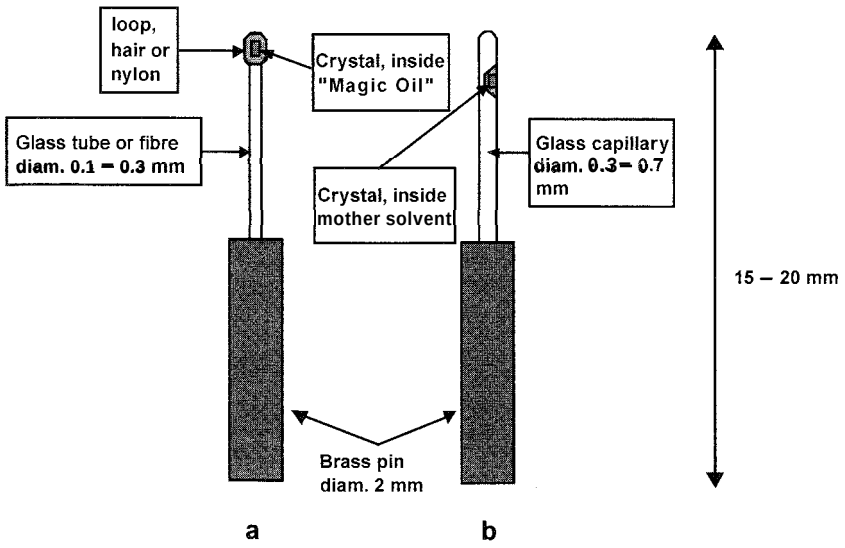

Fig. 1 "Loop" *(a)* and *capillary crystal holder (b)*

crystal. Single-reflection-detector diffractometers proceed directly to the unit-cell determination by randomly collecting reflections that are then used for unit-cell calculations. Before the actual data collection, the diffraction pattern image obtained should be carefully evaluated for two factors: Does the diffraction pattern indicate twinning of the crystal ("twin peaks" or two reflections systematically too close to each other)? Mow high a resolution does the crystal diffract to (visible reflections near the edge of the image. Fig. 2).

If either of these two factors is not acceptable, viz. crystal is clearly twinned or does not diffract well enough or not at all. select a new crystal. Only with persistent selection of a best possible crystal can success be reached. Do not give up with the first five crystals, test at least 15–20 crystals until you find a well-diffracting single crystal. Remember that even bad-looking (under the microscope) crystals can diffract well and give excellent results and, vice versa, good-looking samples might not diffract at all. If the batch of crystals you have does not have any good crystals, then recrystallize the whole batch. Working with a bad or defected data set obtained from poor-quality crystals will result in frustration and loss of time. It is advisable to start from the beginning and focus on getting good crystals rather than forcing data collection on a bad crystal. If you collected or obtained a bad data set (with a structure that cannot be solved), then return to the crystals and redo the crystallization or select a new crystal. The authors' laboratory has many examples of where only a persistent crystal selection procedure produced acceptable results. With a bad data set, you might be able to solve the skeleton of the structure. but you will not be able to refine or publish it.

Even though modern area detector diffractometers are able to collect a data set without first determining the unit cell, it is advisable to determine the unit cell first. The unit cell will tell you something about the constitution of the crystal. When starting the data collection, you do not know the W_{au} of your crystal. However, knowing W_{au} gives you an estimate of possible difficulties you may encounter when obtaining the structure solution. The unit-cell determination will give unit-cell volume (V), which is needed while evaluating W,. A simple equation holds:

$$d = \frac{Z \cdot W_{au}}{0.6023 \cdot V}$$

where d=density of the crystal (Mg m^{-3}), V=unit cell volume (A'), and Z=number of equivalent positions in a given space group. Reorganizing, we get:

$$W_{au} = \frac{(0.6023 \cdot d \cdot V)}{Z}$$

Because Z must be an integer [symmetry fixed. see Refs. [1–3]], we can only have values of 1, 2, 3, 4, 6, 8, 9, 12, 16, 24, 32, 48, 96. The density of the crystal can be measured using a flotation technique. but a plain intelligent guess (''light'' organic d=1.0 – 1.25, metal complex d=1.3 – 1.6) is enough. In the following imaginary example, crystallizing G-ethylresorcarene from pyridine produces nicely diffracting crystals. and the unit-cell determination gives a monoclinic crystal system (see Refs. [1–3]) with V=4952 Å^3. The MW of C-ethylresorcarene is 600.72 and that of pyridine 79.10. Z must

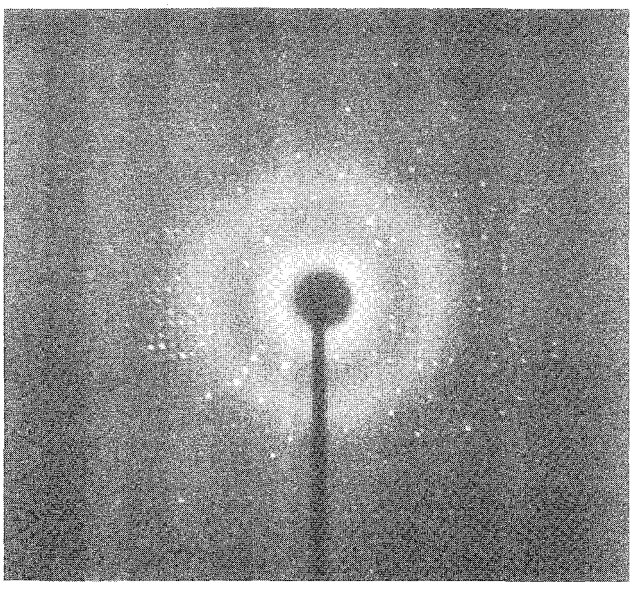

Fig. 2 *CCD* image *from* a *well-diffractingsingle crystal with large* W_{au} *(= 3293).*

have a value of 1, *2, 4, or 8 (in a monoclinic system). So, with d=1.2 (intelligent guess), Z=*1, *we get* W_{au}= *(0.6023 x 1.2 x* 4952)/1=3579.11. *In a* monoclinic *crystal system, Z=*1 *is rare, so calculate the same with Z=2 and Z=*4. *We get Z=2=>*W_{au}= *1789.55 or Z=*4*=>*W_{au}= 894.78. *The* W_{au} *of 1789.55 fits with asymmetric unit* contents *of two rcsorcarenes and seven pyridines* (W_{au}=1755.14) *and* W_{au} *of 894.78 fits with the sum of one resorcarene and four pyridines* (W_{au}=*917.12). So,* here, W_{au} *tells us that we have two resorcarenes and* seven *pyridines or one resorcarene and four pyridines in the asymmetric unit. This is not crucial at this moment, because after data* collection, *the space group (see* Refs. *11–31) will be determined, and Z will be fixed. In this example,* the *space group would be* $P2_1/c$ *and Z=*4, *and the* real *calculated d=1.23, and in the structure, the rcsorcarene would* be *solvated with four pyridines.*

The structure solution (see Refs. [1–3]) *is done using sophisticated* (semi)automatic *computer programs that* convert *the measured intensities (the data set) into* so-*called-structure factors and then use different techniques to solve "the phase problem" (again, see Refs.* [1–3]). *Modern structure solution programs [themost used* being SHELXS/SHELXD[7] *and* SIR97/SIR2000,[8] *others exist* too] need as *input only the* W_{au}, *in a form of reasonable chemical composition, and the collected data set. The success of the structurc solution depends mainly on two factors: the quality of the data collected (which, in turn, depends on the quality of the crystal) and how much of the data is observed over a certain threshold value (normally used criteria* for *an* observed *reflection is intensity, I* >2σ*I). Generally speaking, it can be said (fornontwinned structures) that the higher the percentage of the observed reflections, the better* the *data (severe* systematic *errors in the data can* overrule *this), and it is more* likely *that the structurc solution programs can produce a feasible model for the experimental electron density, viz. the program prints out three-dimentional coordinates for the best structure solution. Frequently, with smaller and* well-diffracting *structures* (W_{au} <700 *and dp* >10), all *atoms of the structure are output as the initial model by the program, and they just have to be named correctly and refined (see Refs. [I–31).* The *refinement process uses incremental movement of the atom coordinates and atomic displacement parameters (commonly called "thermal parametcrs") of the structure solution model, fits this model (the calculated structurc factors) against the data collected (the observcd structure factors), and calculates the R-value. However, with large supramolecular structures, all the atoms are* rarely *obtained directly from the structurc solution program, this is particularly true for the included guests and solvent molecules. The missing atoms (some of which will occur as atoms only at this stage of structural analysis) are located when the partial model and observcd data arc subjected* to *difference Fourier analysis (see Refs.* [1–3]), *which subtracts the electron density of the partial model from the observed electron density, revealing the missing atoms contributing to the observed electron* density. *The cycle,* refinement→diffrence *Fourier* analysis→refinement, *is repeated until the residual* elec-*tron density does* not *show any more peaks* (non-H *atom cut-offlevel is ca. 1.0* $e\text{Å}^{-3}$) *and the atomic parameters no longer shift during the refinement.*

The above applies to structures with good quality and well-behaved data. Unfortunately, this is not true in most cases for supramolecular structures due to the poor-quality crystals often used. Large supramolccules do not form *well-ordered crystal lattices (periodicity), the dps are low* (<10), *the* W_{au} *are* large (>1000), *and the crystal lattice can contain substantial amounts of (different) solvent molecules, which quite* often *are severely disordcrcd, further decreasing* the *periodicity.*

When you have ensured that you have the *best possible data set from your* supramolecular *crystal, proceed to the structure solution* phase. *Remember that the higher* W_{au} *you* have, the *greater difficulties the structure* solution *programs will havc in producing a good model for your structure.* Here, *the* same *principle applies as with crystals, do not* give *up* if *the first try with rhe default parameters of the structure solution program does not produce results.* The *programs have many other sets of parametcrs that will affect the structure solution procedure. A rule of thumb as to what set of values will actually produce success with your crystal cannot* be *given. Each crystal structure determination is unique,*

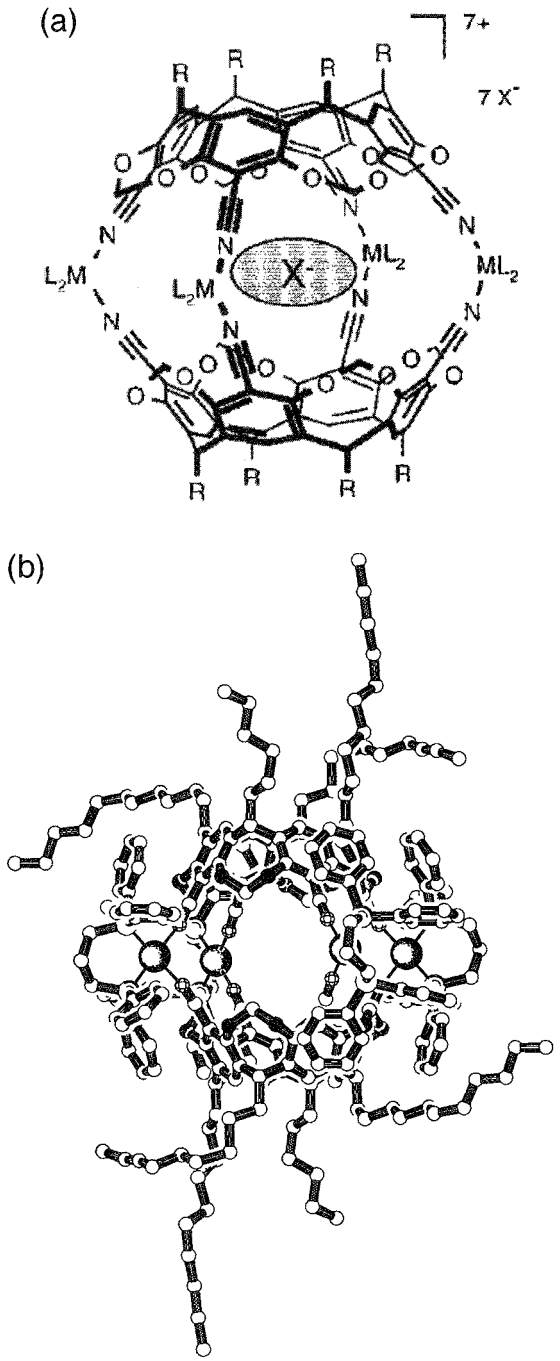

Fig. **3** Schematic (a) and x-ray (b) structure of a cavitand cage.[9] The H-atoms and the included disordered triflate anion are excluded for clarity

and it might be that you have to try various settings and even different structure solution programs in order to get a proper solution. If you tried your best with varying the set of parameters and still do not get a solution, you have to consider that your space group or crystal system may be incorrect (carefully check the data for systematic extinctions, and redetermine the crystal system). Sometimes a change to lower symmetry might help to solve the structure (e.g., going from monoclinic to triclinic). This, however, will double. triple: or quadruple. your W_{au}, thus making structure solution more difficult (if W_{au} grows large, this simplification will make structure solution impossible).

If the space group and the crystal system are correct, and you cannot find an alternative, then you must accept the fact that the quality of your data is not good enough for the structure solution and return to recrystallization of your compound.

DISORDER

Even if structure solution was successful. the task of completing the structure is not yet over. Supramolecular structures. almost by definition, contain included guest or solvent molecules inside the host coinpound or in the crystal lattice. This is, as such. not a problem. but quite often, these molecules are crystallographically disordered. This means that the electron density resulting from the guest or the solvent molecule cannot be clearly determined, and in severe cases, the guest or solvent cannot be located. This unwanted disorder is most prominent when the guest or solvent molecule has weak or nonexistent interactions with the host, e.g., inside molecular capsules and carcerands. Also. if the host compound contains long aliphatic chains, these are often seriously disordered, and it can be particularly difficult to solve and refine the structure to an acceptable level. However, careful control of the crystal growing process or change of the recrystallization solvent can reduce the disorder and thus improve the quality of the crystal. One example of such is a work from the authors' laboratory, where a large cavitand cage compound, $[(C_{268}H_{320}N_8O_{16}P_8Pt_4) @ CF_3SO_3]^{7+} \times 7\ CF_3SO_3^- \times 12.5\ C_6H_6$ was studied.[9] The first data collections produced a result where the core of the cage was clearly determined. but all together, 88 carbon atoms from the eight $C_{11}H_{23}$ alkyl chains could not be located. After 6 months of repeated recrystallizations and after 20 data coilections from 20 different crystals. an acceptable data set was obtained from which the structure with all atoms was obtained (Fig. 3).

CONCLUSION

The x-ray crystallography of supramolecular systems is a difficult but rewarding task. The success of an x-ray study of a supramolecular system requires a well-diffracting single crystal. Obtaining it is often the most difficult and

time-consuming part of the work. Being persistent with the diffraction quality of the crystals, viz. best possible periodicity of the crystal lattice with no twinning, is the key to success. Do not collect data on a bad crystal, test several different crystals and do data collection only for the best possible crystal. Repeat the crystal growing process and change the solvent system if needed. Do not worry which solvent you use, aim for a well-ordered and nicely diffracting single crystal. Only good data can bring you a structure solution. Even though the modern structure solution programs are powerful, do not underestimate the role of the crystal. Even good data does not necessarily produce instant structure solution. Be as persistent with the structure solution programs as you should be with the crystal quality. The larger the W_{au} of your system under study, the more difficulties you will face, but successful x-ray analysis of an interesting supramolecular system is always worth the time you put into it.

X-Ray and Neutron **Powder** Diffraction

John S. O. Evans
University of Durham, Durham, United Kingdom

INTRODUCTION

Powder x-ray and neutron diffraction are extremely powerful tools for probing the structural chemistry of materials in the solid state. Both techniques can be used to gain information about the composition of a bulk material, the degree of crystallinity of its components, information about its unit cell size and symmetry, and, in favorable cases, full three-dimensional (3-D) structural information comparable to that obtained from single-crystal methods. Powder diffraction experiments can be readily performed under the influence of external factors such as temperature, pressure, or applied magnetic field; under laser illumination of a sample; and even as a function of time or chemical environment during the synthesis of materials, giving valuable kinetic and mechanistic insight into their formation. In this article, an overview of the technique will be given along with guidelines on the collection of high-quality diffraction data and an indication of some of the information that can be derived from powder diffraction studies.

BACKGROUND

The techniques and information yielded by single crystal x-ray diffraction and single crystal neutron diffraction methods (see entries by Rissanen and Wilson) are well known and widely utilized by supramolecular chemists. The interaction of x-rays or neutron beams with wavelengths comparable to interatomic distances with an oriented crystal leads to interference effects that give rise to diffracted beams in certain specific directions and with characteristic intensities.[1] From their directions, information about the size and shape of the unit cell can be determined: from their intensities, information on the atomic positions within the unit cell can be determined. Thanks to improvements in single-crystal diffractometer design and the huge software advances of recent years, at the time of writing, there are some 281,000 crystal structure entries in the Cambridge Structural Database,[2] with approximately 30,000 being added annually. The majority of these were determined by single-crystal methods.

While single-crystal techniques will probably remain the primary tool for structural analyses of supramolecular materials in the solid state: the opportunities offered by powder diffraction methods should not be overlooked. In many cases, single crystals of interesting materials of sufficient size and quality for single-crystal methods simply cannot be prepared (though increasingly small microcrystals can now be studied at a synchrotron source). For such materials, structural information comparable to that from single-crystal studies may still be obtained using powder techniques. In other cases, powder diffraction may provide complementary information (such as bulk sample composition) to single-crystal techniques. Non-ambient studies (under extremes of temperature, pressure, magnetic field, or optical irradiation) are often simpler to perform on powdered samples than on single crystals, allowing for the potential to study functional materials under "real" operating conditions; powder studies become essential when phenomena such as phase transitions cause single crystals to shatter under working conditions. Recent advances in the speeds of powder diffraction studies (whole patterns being collected in a matter of minutes, seconds: or less) using advanced sources and detectors mean that phenomena such as host–guest inclusion reactions, chemical transformations in the solid state, and crystallization can now be followed in real time, allowing valuable kinetic and mechanistic insight into the process of chemical transformations. Despite powder diffraction being seen as a "poor cousin" to single-crystal techniques by many, it is a key member of the family of analytical methods that can be brought to bear on understanding structural problems. This article highlights areas of potential interest to supramolecular chemists. For more in-depth and mathematical descriptions of powder diffraction, the reader is referred elsewhere.[3–6]

POWDER DIFFRACTION

In a conventional single-crystal experiment, a beam of monochromatic x-rays/neutrons is incident on a suitably mounted and oriented single crystal. The phenomenon of diffraction leads to diffracted beams being produced in

Encyclopedia of Supramolecular Chemistry
DOI 10.1081/E-ESMC 120012724

certain directions in space.'" In a single-crystal diffraction experiment. the positions and intensities of these beams are recorded by film. point detector, or (most commonly nowadays) area detector methods.

In a powder experiment (Fig. I), instead of a single crystal. one has a collection of randomly oriented polycrystallites exposed to the beam. Each of these polycrystallites can be thought of as giving rise to its own diffraction pattern, and individual "spots" on a film become spread into rings of diffracted intensity (these rings are the intersections of cones of diffracted intensity with the film). The intensities of these rings can be recorded using film and area detector methods, but they are most commonly measured by scanning a point or one-dimensional (1-D) area detector across a narrow strip of the rings. In either case. one can represent the diffraction data as a plot of total diffracted intensity against the diffracted angle 28.

To understand at which values of 28 one may see peaks in a diffraction pattern, it is often convenient to treat the phenomenon of diffraction from a polycrystalline sample in terms of the interference of x-rays reflected from different planes within the unit cell of a crystal. In this way, Bragg's law, which reiates the 2θ angle at which diffraction peaks occur to distances between planes in the unit cell (d_{hkl}), can be readily understood (see Fig. 2). Planes are described by Miller indices, *hkl*. which are related reciprocally to the point at which the plane intercepts the cell edges, *a*. *b*, and c.

The information contained in Figs. 1 and 2 immediately shows one of the inherent problems of powder diffi-action. The 3-D intensity distribution of a single-crystal experiment is compressed onto the I-D of 28 space leading to a vast loss of information due to peak overlap. In a metrically cubic crystal, for example, the 221 and 300

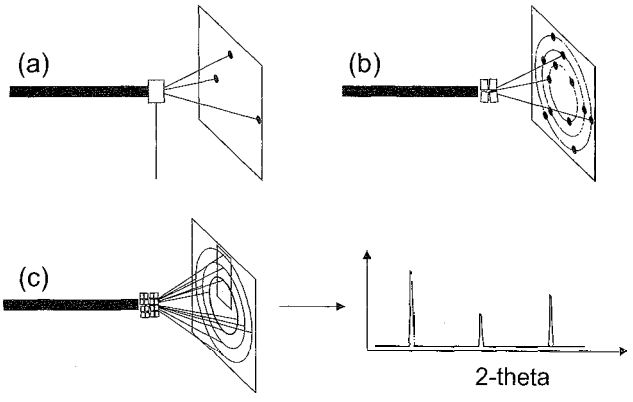

Fig. I (a) Diffraction from an oriented single crystal. (b) from a collection of four crystals at different orientations with respect to the incident beam. and (c) from a polycrystalline material. 2θ increases from the film center to the edge.

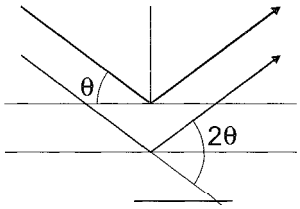

$$n\lambda = 2d_{hkl}\sin\theta$$

Fig. 2 Bragg's law. Constructive interference occurs when the path length difference, $2d_{hkl}\sin\theta$ between two beams is an integral multiple of ?. For cubic systems ($a=b=c$, $\alpha=\beta=\gamma=90°$), interplanar spacings are given by $d_{hkl}=a/(h^2+k^2+l^2)^{1/2}$, and the more complex relationships for noncubic systems are given elsewhere (see Ref. [1].).

reflections (which will generally be of different intensities) will occur at identical values of 28, and only information on their summed intensities is available from a powder diffraction experiment. For a triclinic cell of the complexity that would be routine for modern single-crystal methods (3400 Å^3) using a typical laboratory powder diffractoixeter, there would be —5500 reflections predicted between 0 and 90° 28 (d_{min}=1.09 A). Even for a highly crystalline material, this will lead to a considerable degree of peak overlap.[7,8] There are a number of methods that attempt to alleviate overlap problems. In one approach (see below), some separate information regarding overlapping peaks can be retrieved from intensity variations around the Debye–Scherrer rings of deliberately textured samples;[9] in another. one can make use of anisotropic thermal expansion to try and resolve different families of reflections at different temperatures. In the absence of such methods, overlap can only be reduced by recording the highest resolution data attainable for a given sample.

EXPERIMENTAL METHODS

There are a host of experimental methods available for recording powder diffraction data. each with inherent advantages and disadvantages. Those most commonly encountered in chemistry laboratories, and therefore most likely to be available to supramolecular chemists, are outlined here.

The two most commonly used geometries for obtaining x-ray diffraction data in home laboratories are shown in Fig. 3. In the simplest "reflection" or Bragg–Brentano setup (Fig. 3a), one has an x-ray line source at 3. A flat plate sample is mounted at 4 and a point detector at 6. The sample is scanned through θ degrees as the detector is moved through 20. The most common laboratory x-ray source is a sealed Cu tube. To produce monochromatic

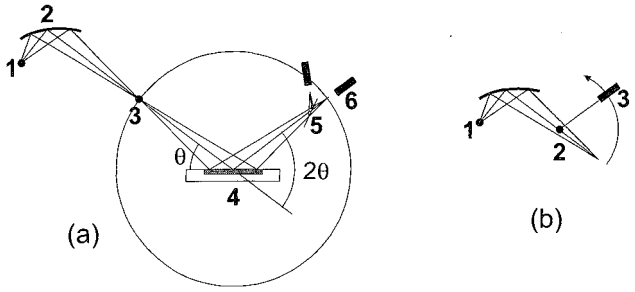

Fig. *3* Typical laboratory powder diffraction setups (see text for details). Diagrams are not to scale, typical distances 1–3. 3 4 . and 4–6 would be ~200 mm; a sample area of ~100 mm^2 would be illuminated.

radiation (Cu $K\alpha_1$ (λ=1.540596 Å), one can place the line source of the tube at Position 1 and a curved Johannsen monochromator (e.g., Ge 111) at Position 2 to produce an effective line source at Position 3. Either a scintillation counter or linear position-sensitive detector is commonly placed at Position 6. This arrangement gives high resolution but can suffer from high backgrounds for samples that fluoresce under Cu irradiation. Fluorescence effects can be reduced by placing a monochromator between the sample and detector. Perhaps the most common laboratory setup is a post-sample pyrolytic graphite monochromator placed at 5 giving an approximate 2:1 mixture of Cu $K\alpha_1$ (*h*=1.540596) and $K\alpha_2$ (h=1.544493) radiation.

Flat-plate samples can be prepared in a number of ways: as bulk powders pressed into a recessed holder or sprinkled onto an amorphous surface, such as glass. or (preferably) a "zero background" sample holder. such as a 511 cut Si wafer. Flat-plate methods are. however. prone to problems due to preferred orientation, whereby a non-random arrangement of crystallites is presented to the beam. This can severely skew diffraction intensities—in extreme cases. making experimental patterns appear completely different to calculated data or database standards. Several methods for reducing preferred orientation are described in the literature[3,10] The positions and intensities of reflections are also influenced by factors such as the sample surface roughness and sample absorption properties. For organic samples, low absorption can lead to a significant portion of diffracted intensity occurring from below the ideal sample surface, leading to peak shifts and broadening. This method of data collection is, therefore. perhaps best suited to relatively absorbing samples or "quick'' qualitative measurements.

The transmission setup of Fig. 3b is particularly well suited for studies on low-absorbing organic/molecular materials. Here, the sample is placed at Position 2. usually mounted in a thin-walled glass capillary of 0.2–1.0 mm internal diameter and spun in the plane of the page, though samples can also be mounted on thin mylar sheets. The use of capillaries significantly reduces preferred orientation effects, though sample mounting is slightly more time consuming.

As with any piece of scientific equipment. the performance of a powder diffractometer should be regularly checked. Various standard materials are available[11] to check the alignment and intensities of the system. There are several commercial suppliers of powder diffractometers. with many of the modern designs allowing for a number of different experimental configurations on the same basic instrument. The introduction of new optical devices such as x-ray mirrors to replace monochromators gives further flexibility in experimental design. A typical "quick" scan from 5–90° 28 on a conventional laboratory instrument might take 30 min, a higher-quality scan for Rietveld refinement may take 12 h or more. depending on instrument configuration.

Significantly higher fluxes and higher resolution are available at a synchrotron source. These also offer the possibility to select a precise wavelength for a specific experiment (allowing absorption edge studies. etc.) or to perform white beam diffraction. Synchrotron-based diffractometers such as ID31 at the ESRF receive a useful flux several orders of magnitude greater than a typical laboratory source and can give very high resolution data.

Powder neutron diffraction offers significant potential advantages over x-ray methods in some situations. In particular. because scattering occurs from the nucleus rather than electrons, one can detect light atoms in the presence of heavy atoms (e.g., O/H in the presence of metals). The penetrating nature of neutrons also gives more confidence that one is studying the bulk of a sample rather than a thin surface layer and allows the use of relatively complex sample environment equipment. Neutrons are also scattered by magnetic moments in a material. giving the possibility of magnetic structure determination. Neutron diffraction can be performed at a reactor (usually using constant λ neutrons) or at a spallation source (usually by the time-of-flight method). Perhaps the major drawback of this technique for the supramolecular chemist is the fact that H scatters neutrons incoherently. To avoid unreasonably high backgrounds. it is. therefore. nearly always necessary to deuterate samples.

INFORMATION IN A POWDER DIFFRACTION PATTERN

Any experimental powder diffraction pattern contains a wealth of information of potential use to the supramolecular chemist. The most important of these (arranged approximately in order of increasing complexity of analysis) are described below.

Phase Identification

Each (crystalline) phase present in a bulk sample will give rise to a characteristic set of peaks in a powder diffraction pattern. These can be compared to a database of known diffraction patterns or compared against patterns calculated from single-crystal diffraction data. Many powder diffractoineter manufacturers supply automatic search and match software to compare experimental data sets against the powder diffraction file (PDF), a collection of around 157.000 data sets maintained by the International Centre for Diffraction Data.[12] Many single-crystal refinement packages provide a facility for simulating a diffraction pattern from a refined structural model or directly from experimental single-crystal data. Recently, a large percentage of the Cambridge Structural Database (approximately 200.000 entries by November 2003) were made commercially available as calculated powder patterns in a format suitable for automated search and match algorithms. Many other resources for calculating powder patterns are available via the Web.

Perhaps the most important application of phase identification to the supramolecular chemist is in confirming whether the powder pattern of a bulk sample corresponds to a structure determined from a single crystal obtained during the same synthesis — there are innumerable examples where the few single crystals produced in a synthesis are due to minor products from side reactions or impurities. The presence of crystalline coproducts (e.g., KCl from a salt elimination reaction) can also be readily identified. A relatively quick powder diffraction experiment can often shed considerable light on otherwise conflicting pieces of analytical data.

Quantitative Analysis

it is also possible to obtain quantitative information about the composition of a multiphase sample from powder diffraction data. Various techniques have been developed based on the analyses of intensities of individual peaks due to different phases contributing to the pattern. on whole pattern intensity analysis. or multiphase Rietveld refinement (see below). Specific details are beyond the scope of this article. and the reader is referred elsewhere.[13] It is worth noting that extreme care should be taken when determining and interpreting quantitative composition. Results can be severely influenced by methods of sample preparation (see above), data collection. and analysis. Careful calibration experiments on the system of interest are recommended. It is also worth noting that it is possible to estimate the quantity of ainorphous material in a sample by powder diffraction measurements (amorphous materials generally give rise to a gradualiy oscillating contribution to the background of the diffraction pattern), by careful quantitative dilution of a powdered sample with an additional crystalline phase.

Peak Shape Information

While the position and intensity of peaks in a powder pattern are determined by the unit cell size and contents. their shapes and widths are determined by instrumental effects (which can be corrected for or modeled) and sample properties. such as the sizes and strains of crystallites and stacking faults.[3] The simplest expression for peak broadening due to sample size (the Scherrer formula) predicts that peak width and particle size are related by $fwhm = K*\lambda/size*\cos\theta$, where K is a shape factor (often 0.9), *fwhm* the peak full width at half maximum. and λ the wavelength: absolute numbers from this expression should be treated with caution. A sample strain leads to a peak width dependence on $\tan\theta$. In more sophisticated treatments. hkl-dependent peak widths can be used to obtain information on the anisotropies of size and strain in a sample. More details on the interpretation of peak shapes are given elsewhere.[14,15]

Rietveld Refinement

One of the main factors that has driven the explosion of powder diffraction methods in recent years is the popularization of the Rietveld method.[16–18] In this method, a powder pattern is expressed in terms of y_{obs}, the intensity observed at a given value of 20. One can use a structural model (equivalent to that used in a single-crystal refinement) and a mathematical model to describe how experimental peak widths vary as a function of 2θ to deterinine the calculated intensity. y_{calc}, at each experimental value of 2θ. The most commonly used function for describing powder peaks is a psuedo-Voigt (a mixture of Gaussian and Lorentzian contributions). though more sophisticated approaches can model peak shape contributions from the experimental setup and sample size and strain directly. One then typically uses a least-squares method to adjust structural parameters. such as unit cell size, fractional atomic coordinates, and temperature factors. to minimize the difference between y_{obs} and y_{calc} over the whole experimental pattern. The quality of a refinement can be monitored in terms of agreement factors R_{wp} or R_{Bragg} ($R_{wp} = [(\Sigma w_i[y_i(obs) - y_i(calc)]^2)/(\Sigma w_i[y_i(obs)]^2)]^{1/2}$; $R_{Bragg} = [(\Sigma|I_{hkl}(calc) - I_{hkl}(obs)|)/(\Sigma|I_{hkl}(obs)|)]$), though the best indication of the quality of a structural refinement is often a visual inspection of the agreement of observed and calculated patterns. An example of a Rietveld refinement of an inclusion compound is given in Fig. 4.[19] A number of commercial and academic software packages are available for Rietveld refinement. The most widely used are GSAS. Fullprof.

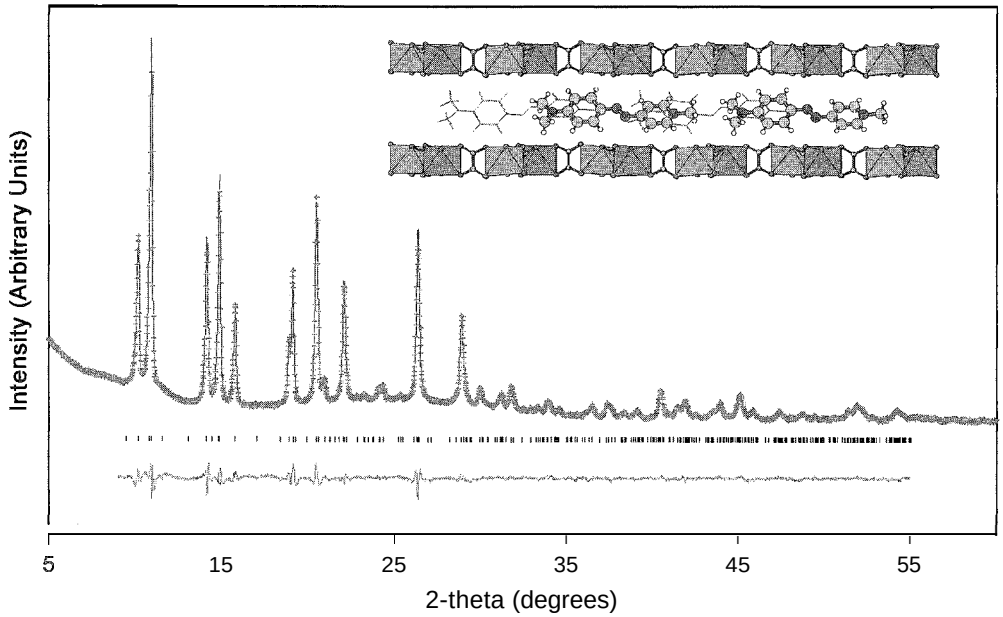

Fig. 4 A Rietveld refinement of an NLO-active-layered inclusion compound DAZOP[MnCr(ox)$_3$]0.6CH$_3$CN [DAZOP = 4-(4-dimethylamino-phenylazo)-1-methyl-pyridinium]. (*View* this *art in color at www.dekker.com.*)

descendants of the DBWS code and Topas.[20–23] Many of these packages offer the opportunity to simultaneously refine a model against x-ray and neutron data. allowing one to utilize the often complementary information from the two techniques.

Structure Solution from Powder Diffraction Data

It should be emphasized that the Rietveld technique is a refinement method—one needs an approximate set of coordinates from which to refine a model. Until the late 1990s. this meant that Rietveld refinement was largely confined to extended metal oxides and chalcogenides. where starting models could be inferred from other known materials. In recent years, there have. however, been dramatic breakthroughs in solving structures ab initio from powder data; these will have considerable impact on the supramolecular community.[24.25]

The process of structure solution of an unknown material from powder data can be divided into several steps. First; one must record the highest-quality data possible on a (ideally) pure sample. One must then determine the unit cell parameters from observed peak positions (several software packages exist to tackle this nontrivial step). The space group symmetry must then be determined from systematic absences. At this stage. one of a number of different routes can be followed. One possibility is to extract integrated peak intensities from the pattern and use techniques similar to those employed in single-crystal studies, such as direct methods or Patterson synthesis, to solve the structure. Various software packages exist for this. some dedicated to overcoming the inherent uncertainties in intensities due to peak overlap and the inherent data shortage from a powder pattern. Structure completion can then be performed via a series of Fourier difference maps and Rietveld refinement.

Alternatively (and perhaps more powerfully for supramolecular chemistry). one can utilize information about the cell contents in the form of known molecular fragments and their geometric degrees of freedom and attempt direct space structure solution. From the molecular cell contents. one generates a trial structural model and compares its calculated diffraction pattern to the experimental data. Using a Monte Carlo or simulated annealing approach, the structural model can then be adjusted in a random fashion, and the agreement between the observed and calculated patterns can be examined again. The move is then accepted or rejected based on user-definable criteria, and the process is repeated until the best agreeinent between model and experiment is obtained. With efficient algorithms. many hundreds of thousands of trial structures can be generated and tested relatively rapidly, even on desktop computers, to produce a structural model that can be improved by Rietveld methods. Many variations on this general methodology

and alternative genetic and differential evolution algorithms have been developed. Materials of remarkable complexity have been solved by this method. The structure of the NLO-active-inclusion compound of Fig. 4. for which single crystals could not be grown. was solved by a related technique.[19]

It should, however, be noted that each stage of the structure solution pathway from indexing to refinement is complex and potentially insoluble. The range of techniques for overcoming each barrier is. however, expanding rapidly in what is a fast-moving area of research.

NONAMBIENT STUDIES

Experiments beyond a simple room-temperature diffraction pattern can yield considerable insight into the properties of materials. One of the most readily accessible thermodynamic variables experimentally is temperature. Commercial attachments are available for most diffractometers to cool and heat samples from liquid He temperatures to ~1600°C. Of particular relevance to supramolecular chemistry are cryofurnaces. which operate over the ''chemically interesting'' temperature range of 100–600 K, and gas-flow systems that typically operate from 77–373 K. Shown in Fig. 5. for example, is how a low-spin to high-spin phase transition in $[FeL_2](BF_4)_2$ [L = 2,6-di(pyrazol-1-yl)pyridine] is revealed by a marked discontinuity in unit cell parameter as a function of temperature at 260 M: structural information above and below T_C can be obtained directly from the experimental data.[26] Many single crystals of framework inaterials produced by crystal engineering studies are prepared in a solvated form. Structural changes on desolvation can be readily followed by powder methods, alleviating problems due to crystal degradation in single-crystal studies. Polymorphic phase transitions and the evolution of solvate and hydrate pseudopolymorphs, of particular relevance to the pharmaceutical industry, car! also be followed readily in simple sample stages.

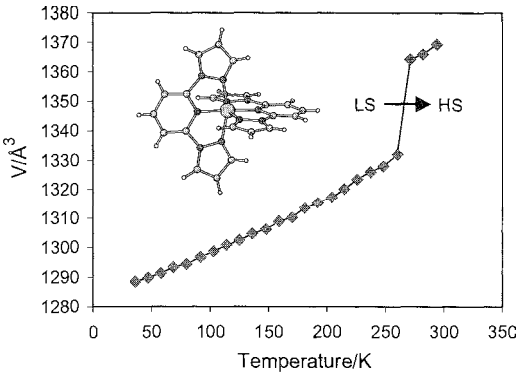

Fig. 5 The unit cell parameter of a powdered sample of $[FeL_2](BF_4)_2$ [L=2,6-di(pyrazol-1-yl)pyridine] determined from laboratory powder diffraction data. Structural changes at the low- to high-spin phase transition are readily visible. (*View this art in color at www.dekker.com.*)

The behaviors of materials under applied pressure are also readily studied by powder methods. Using small-volume diamond anvil cells most suitable for x-ray work, pressures of several hundred GPa at temperatures up to several thousand K can be achieved.[27] Larger volumes of samples can be studied by neutron techniques using gas-pressure cells (up to ~1 GPa on several cm^3 of sample) or more sophisticated designs such as the Paris–Edinburgh design cell (up to ~30 GPa/370 K on 30 mm^3). Such studies have revealed a wealth of important structural chemistry in a variety of molecular systems.

Finally, the possibility of perforining a powder diffraction experiment during a chemical reaction should not be overlooked. Various workers have shown that by using high-energy (and therefore highly penetrating) x-ray beams at synchrotrons, one can literally monitor reactions occurring in test tubes (or more sophisticated reactors) in real time by powder diffraction methods.[28,29] By way of an example. O'Hare and coworkers showed that diffraction patterns of ~100 mg of a suspension of solid SnS_2 in toluene can be recorded in as little as 5 sec. One can then introduce a molecule such as cobaltocene and monitor in real time the structural changes and kinetics of the host–guest intercalation reaction. The opportunities afforded by such a methodology to other areas of supramolecular chemistry must be considerable.

CONCLUSION

Powder diffraction studies can provide a wealth of structural and nonstructural information. Powder diffraction studies can provide quantitative information on multiphasic samples, atoinic coordinates similar to those from single-crystal studies. and give microstructural information on the properties of individual crystallites. The ease with which nonambient experiments can be performed makes powder diffraction one of the more powerful characterization tools available to the supramolecular chemist.

Zeolites in the Petroleum Industry

Christian Marcilly *(Retired)*
French Institute of Petroleum (IFP), Rueil Malmaison, France

INTRODUCTION

Since the first synthesis of a zeolite. the A zeolite, developed by Milton[1,2] in 1949. there has been constant development in the work on these special microporous solids and their applications. During the second half of the twentieth century, zeolite properties were chiefly exploited by the oil refining industry. but from the 1970s onwards. they gradually came to be used by the major intermediate petrocheinical industry and also by the end of the 1980s[3] by the promising field of fine chemicals. This article on the principal applications of zeolites will deal only with the refining and petrochemical industries. Nowadays, these applications concern two major categories of petroleum cut processing: the physical types of processing that belong to the field of adsorption and chemical types of processing by catalysis. These forms of processing produce petroleum cuts with characteristics that comply with the specifications laid down by government authorities. Shown in Table 1 are the chief characteristics that allow us to judge the qualities of four major petroleum fractions: liquefied petroleum gases (LPG), gasoline, gas oil, and lube oils. It also shows how the different types of hydrocarbon contribute to these characteristics and indicates the quality of the fractions produced by three typical refining processes.

The considerable success of zeolites is partly due to their shape selectivity, which has led to decisive progress in numerous applications in which they are involved: intensive drying and purification, fine separation. and improved catalytic activity. selectivity. and stability. Their shape selectivity is due to the very fine and regular pores present in their structure. Access to the pores is controlled by apertures with size that varies according to the zeolite considered. Zeolite success is also due to the confinement of molecules in the restricted pore space, which results in high molecule concentrations in the pores. This property is involved in adsorption and catalysis. promoting bimolecular reactions as opposed to monomolecular reactions in the latter. Shown in Table 2 are the structural types and pore aperture sizes of the zeolites used in the different processes of the refining and petrochemical industries. It also indicates the nature of the principal molecules capable of penetrating the pores and of some molecules that are too large to diffuse throughout the microporous structure.

APPLICATIONS IN ADSORPTION

Almost all the zeolites used in the field of adsorption are silicoaluminates.[4–8] Their adsorption properties depend on the concentration of intrazeolitic cations, which is governed by the concentration of aluminium in the zeolite framework, by the nature of the cations (valence and size), and by their crystallographic positions. The high degree of confinement of the molecules in the fine pores of the zeolites results in intensive adsorption of the molecules at low partial pressure, and it is significantly more intensive than with the traditional silica. alumina, or activated charcoal adsorbants. The intensive electrostatic field in the immediate vicinity of the zeolitic cations promotes the adsorption of the polar molecules (e.g., water, alcohols, H_2S) or the polarizable molecules (e.g., olefins). The adsorption properties differ greatly from zeolites rich in aluminium (hydrophilic zeolites). which have a strong affinity for polar molecules: and zeolites that contain little aluminium (and, consequently, zeolitic cations) (hydrophobic zeolites), which tend to adsorb preferably nonpolar molecules, such as saturated hydrocarbons. The transition from hydrophilic zeolites to hydrophobic zeolites corresponds to a silicon-to-aluminiin (Si/Al) atomic ratio of around 8–10.

Industrial adsorption applications in the refining and petrochemical industries fall into two main categories: the purification of various fluids, including intensive drying. and the fine separation of molecules within a mixture. These applications mainly involve two zeolite structures: LTA (zeolite A) and FAU (faujasite) (Table 2). Other zeolites are also of interest but to a lesser degree: for example. mordenite (MOR structure) is more resistant and was used in some catalytic reforming installations for drying recycle gas rich in HCl. and silicalite (silica-rich zeolite with the MFI structure) is potentially useful for removing some organic compounds present in refinery wastewater.

The choice of the zeolite structure to be used as adsorbent is based on three criteria: its adsorption capacity, its shape selectivity, and its varying affinity for removing or recovering the molecules. After adsorption. the zeolite has to be regenerated before it is used again. Three main regeneration techniques are used: thermal swing processes (TS). pressure swing adsorption

(PSA), or displacement by a fluid that may be inert or, on the contrary. may compete with the adsorbate.

Raising the temperature is the desorption method most commonly used in cyclic processes. It can be used in the liquid or gas phase and is much more effective when the adsorbate has a strong affinity for the zeoiite (as in the case of polar molecules like water). Reducing the pressure is a faster desorption method but is used preferably in the gas phase with gases that are only weakly adsorbed. Desorption by displacement may be used in liquid or gas phase and is the only method that can be used continuously (with countercurrent processes).

Drying and Purification sf Fluids

The choice of the adsorbent to be used for drying a fluid depends chiefly on the nature of the fluid. which in most cases, is a gas. For drying natural gas that contains only saturated hydrocarbons, the 4A zeolite (Si/Al=1, cation= Na. pore aperture ~0.4 nm) is generally used (Table 2). For drying olefin-rich gases [e.g., cracked gases from the fluid catalytic cracking(FCC) stream], the 3A zeolite (Si/Al=1, cation =M, pore aperture ~0.3 nm) is preferably used, because its pore size excludes hydrocarbons. The various impurities contained in the fluids are generally removed simultaneously with drying. as in the case of the purification of saturated acid hydrocarbon cuts (sour gases) containing sulfur compounds such as H_2S and mercaptans, CO_2, and water. The zeolite used is generally 13X ($1.2<Si/Al\leq 1.5$, cation=Na, pore aperture—0.74 nm), which has an adsorption capacity greater than that of the A zeolite. The affinities of the various impurities for the adsorption sites are in the following decreasing order: $H_2O>H_2S>CO_2$. Apart from drying. which is generally

carried out simultaneously, the sweetening of sour gases only requires the removal of the sulfur compounds (H_2S and mercaptans). so that regeneration of the molecular sieve is only necessary once these molecules, particularly H_2S, have broken through. However, a factor that often has to be taken into account is the forination of COS due to the reaction between CO_2 and H_2S. The formation of COS should be minimized. because only a small amount of the gas is adsorbed on the sieve, and H_2S may then be reformed by hydrolysis in the presence of traces of water. The use of a 10X zeolite (cation=Ca) instead of a 13X zeolite reduces this risk.

Drying and purification operations are almost all carried out in processes using at least two reactors and operating in a cyclic manner. Desorption by temperature switch (TS) is the technique most frequently used.

Separation Applications

The main applications in the field of hydrocarbon separation concern the recovery of *n*-paraffins contained in the light cuts from C_4 to C_6, or in heavier cuts such as kerosene from C_{10} to C_{15} approximately, and that of some isomers contained in the aromatic cuts (e.g., the recovery of paraxylene from C_8 aromatic cuts) (Table 2).

The separation of branched paraffins from a mixture of *n*- and isoparaffins with 4. 5, or 6 carbon atoms is almost always associated with an isomerization operation to maximize the production of isoparaffins for the gasoline pool (Table 1). It is performed on a 5A zeolite with pore apertures in the region of 0.45 nm that allow the passage of n-paraffins but not of other isomers (Table 2). A wide range of techniques for the use of this zeolite were adopted in the various existing industrial processes. Most operate in the gas phase according to a cyclical technique involving vacuum desorption or displacement by a gas. Two of them operate in liquid phase using a desorption technique invoiving chromatographic-type displacement.

Long straight paraffins from C_{10} to C_{15} contained in kerosene find applications in the detergent industry. Although these paraffins are strongly adsorbed on the 5A zeolite, a temperature-switch cyclic desorption process cannot be used, because it would require temperatures of over 350°C, at which coking inevitably occurs. The only possibilities. therefore, are vacuum desorption or displacement with a desorbent. The possible desorbents include hydrogen. *n*-pentane, or ammonia.

It is impossible to remove paraxylene from a mixture of xylenes and ethylbenzene by distillation, because the boiling points of para- and metaxylene are too close to each other. It is difficult and costly to do so by crystallization, mainly because of the existence of an eutectic between these two isomers that restricts the rate of paraxylene recovery to around 65%. The modern separation technique simulates a countercurrent flow between the isomer mixture and the adsorbent bed composed of the cationic form of an FAU structure zeolite (Table 2) and allows a rate of recovery of at least 92% of paraxylene of over 39.7% purity. This technique uses liquid-phase chromatography. and the recovery of paraxylene is realized by means of a desorbent. In order to make the operation continuous, the column in which the fixed adsorbent bed is located is equipped with multiple inlet/outlet connections, allowing liquid to be injected or drawn off. Countercurrent flow is simulated by the passage from one connection to the next in order to displace the level of injection of the mixture of liquid isomers and desorbent and that of the withdrawal of the extract (the paraxylene) and the raffinate, at the same speed as the displacement of the liquid in the fixed zeolite bed. The adsorbent used is an X or Y zeolite containing alkaline-earth ions. mainly Ba^{2+}, and possibly potassium ions, the role of which is to optimize the affinity of the zeolite for paraxylene.

The technique of desorption by simulated countercurrent flow displacement is also applied to other separation operations: the separation of ethylbenzene from a mixture of aromatics and that of olefins from a mixture of olefins and paraffins. The composition of the zeolite adsorbent is adjusted in each case to optimize the effectiveness of the separation: Na-Y or KSr-X zeolites for ethylbenzene and Ca-X or Sr-X for olefins. The nature of the liquid desorbent also depends on the molecule to be separated.

APPLICATIONS IN THE FIELD OF CATALYSIS

Refining

Cracking of heavy feedstocks

Cracking of vacuum gas oil (VCO) is the first catalytic application of zeolites.[9–14] From 1962–1963 onwards, the replacement of the former amorphous silica–alumina-based low-acid catalysts by catalysts containing the Y zeolite (FAU structure) with higher acidity resulted in considerably improved catalytic activity and gasoline yield. Today, cracking catalysts. except in rare cases. contain from 10–40% of Y zeolite dispersed in a more or less active solid matrix and are used in fluidized bed units (FCC or fluid catalytic cracking units). The role of the matrix is to ensure the precracking of the larger molecules in the feed. principally the alkylnaphthenoaromatics and the alkylpolyaromatics that cannot penetrate the micropores of the zeolite. which are limited by a circular

aperture with a diameter of around 0.74 nm (Table 2). The acidity of the zeolite is thus protected from these large coke precursor molecules and from large highly basic nitrogenous molecules, enabling it to effectively convert the smaller, less coking-prone molecules into gasoline with a satisfactory octane number (Table 1).

In an FCC unit, the fluidized catalyst constantly circulates between a reaction section where the temperature is about 500°C and where it is rapidly deactivated by the coke formed, and a regeneration section where the coke is burned in air at around 700–750°C. In the severe conditions prevailing in the regenerator, the framework of the Y zeolite is impaired, and fairly quickly it irrevocably loses its acid sites. The speed of the loss of acidity can be moderated by introducing varying amounts of rare earth (RE) ions into the zeolite. A strong concentration of RE ions maintains a high density of acid sites in the zeolite over a long period of time, which promotes the bimolecular hydrogen transfer (HT) reaction. In the absence of these ions, the density of the acid sites decreases rapidly, and the capacity of the Y zeolite to promote hydrogen transfer (HT) is considerably diminished. These ions are important with respect to the quality of the gasoline produced, because the HT reaction converts a large proportion of the olefins in this cut into paraffins and, at the same time, reduces its octane number.

Even when it does not contain any RE ions, the Y zeolite is always responsible for a drop in octane number compared to the old amorphous silica–alumina-based catalysts. In order to gain a few points in the octane number, many refiners add to the principal catalyst a small percentage of a ZSM-5-based additive that has pores 0.55 nm in diameter that can only be penetrated by linear aliphatic structures and, to a lesser degree, by monobranched aliphatic structures (Tables 1 and 2). These hydrocarbons, which are those with the lowest octane number, are mainly cracked to olefin-rich LPG, obviously at the expense of a few percentage points in gasoline yield.

Since the mid-1990s, the ZSM-5 zeolite has also been increasingly used to maximize light olefin production in fluid catalytic cracking.

Hydrocracking of heavy feedstocks

Cracking heavy feedstocks, such as VGO, at around 370–420°C, under high hydrogen pressure, is a more costly process than the previous one, but it is also more flexible, because it can be oriented toward the production of light products (LPG and gasoline), middle distillates (jet fuel, gas oil), and lube oil base stocks.[15–21] The gasoline produced has a poor octane number, but its high naphthene concentration makes it an excellent feedstock for catalytic reforming. The middle distillates possess good combustion characteristics (Table 1), because they are rich in hydrogen. The lube oil base stocks have excellent lubrication properties, in particular, a high viscosity index (Table 1). A high viscosity index indicates that the viscosity of the lube oil does not change much when the temperature increases. The hydrocracking catalysts are all of the bifunctional type and associate an acid function with a hydrodehydrogenation function (either a combination of nickel and molybdenum or tungsten sulfides, or noble metals such as palladium or platinum). Most of these catalysts contain a small proportion (approximately 5–30%) of Y zeolite, depending on the desired product (Table 2). The first zeolite catalyst, a Mg-Y catalyst containing Pd, was developed by Union Carbide and used industrially by Unocal in the early 1960s.[1] Modern catalysts generally contain a H-USY zeolite. (USY means ultrastable Y and refers to a Y zeolite treated at high temperature in the presence of steam to adjust its acidity and the stability of its structure.)

The first advantage of the Y zeolite compared to amorphous silica–alumina-based catalysts is its higher activity that allows it to operate at lower temperatures (ΔT of around 20–40°C), resulting in better hydrogenation and improved quality of middle distillates and lube oil base stocks. A further advantage is its greater stability over a period of time. Both advantages are mainly due to its higher acidity, which offers better resistance to nitrogen poisons, particularly ammonia, and also partly to its shape selectivity, which does not allow access of the larger and more coking-prone molecules to the acid sites. On the other hand, the limited pore size of the zeolite promotes the consecutive cracking of the larger molecules that are able to penetrate the pores because their diffusion is slower, which leads to a deterioration in both middle distillate selectivity and yield in relation to amorphous catalysts.

Zeolite catalysts are used in two main types of process:

1. Processes involving two reactors without any intermediate separation (one-stage process): the feed is hydrotreated in the first reactor with a conventional catalyst, and almost all the organic sulfur and nitrogen compounds are converted into H_2S and NH_3 gas, which are relatively well tolerated by the zeolite catalyst in the second reactor. The hydrodehydrogenation function added to the zeolite is usually of the metal-sulfide type.
2. Processes involving two reactors with an intermediate separation (two-stage process). The effluent from the reactors of the first stage is fractionated, and only the heaviest fraction, the nonconverted residue, from which all the sulfur and nitrogen compounds have

been removed, is treated by the zeolite catalyst in the second-stage reactor. The hydrodehydrogenation function is usually based on a noble metal.

Dewaxing of gas oils and lube oil base stocks

Some gas oils and lube oil base stocks. particularly those produced by hydrocracking, have cold flow properties that do not comply with specifications. The molecules responsible for these problems are mainly the long straight-chain alkyls, including those linked to a naphthene or aromatic ring (Table I). There are two ways to remove these chains—by selective hydrocracking or by selective hydroisomerization.

Dewaxing of Jet Fuels, Gas Oils, and Lube Oil Base Stocks by Selective Hydrocracking. In 1977, Mobil announced that it developed a selective acid ZSM-5-based catalyst for dewaxing jet fuels and gas oils (Table 2).[20,22] The pores of this zeolite (diameter around 0.55 nm) readily allow the penetration of straight-chain paraffins and long straight-chain alkyls juxtaposed to a ring, and to a lesser degree. alkyl chains that include a branched methyl group. These chains are cracked by the ZSM-5 zeolite at a temperature of between 300–400°C into smaller fragments that are distributed between the LPG and gasoline fractions. At the beginning of the 1980s, this application was extended to lube oil base stocks using the same zeolite.

Cracking all or part of the straight-chain paraffins improves cold-flow characteristics of the hydrocarbon cut processed. but on the other hand, it has the disadvantage of reducing its yield and of slightly deteriorating some important properties of the cut—the jet fuel smoke point, gas oil cetane number. and lube oil viscosity index. The dewaxing operation should therefore offer the best possible compromise between the desired cold-flow characteristics. the yield requirements, and the combustion or viscosity characteristics.

The feed does not require previous hydrotreating before dewaxing, because the organic base nitrogen molecules that it contains are too large to penetrate the pores of the ZSM-5 zeolite and inhibit its acidity. Hydrotreating would lead to the conversion of these bulky nitrogeneous organic molecules into ammonia that would penetrate the pores of the zeolite and inhibit its acidity. In such a case, this would impose the separation of ammonia upstream of the dewaxing reactor.

A large amount of the cracked products is present in the gasoline cut. In the absence of any strong hydrogenation function. the acid ZSM-5 zeolite produces olefinic gasoline with a high octane number as a by-product.

Isodewaxing. The second way of catalytically improving the cold-flow characteristics of a petroleum cut is to isomerize the paraffins while minimizing cracking so as to obtain a very high distillate or lube oil base stock yield.[20,23,24] This is an attractive solution in the case of lube oil base stocks. Their added value is much higher than that of distillates and so provides an incentive to minimize cracking into light by-products of lower value.

With the acid ZSM-5 zeolite used in dewaxing by selective hydrocracking, the cracking of n-paraffins is preceded by their isomerization into branched paraffins. The most branched of them are retained in the pores and are cracked into smaller fragments that may break free. There are two ways of avoiding or restricting the cracking: by using a more open zeolite such as the Beta zeolite (BEA structure), for example, which allows multibranched isomers to escape from the pores before they are cracked, or by finding a zeolite with a pore size and shape that do not allow the formation of multibranched isomers that are easily cracked. The first solution cannot prevent significant cracking, whereas the second solution appears more promising, provided the appropriate zeolite(s) can be found. The first results of removing linear paraffins by selective hydroisoinerization were published around 1987 and concern the treatment of lube oil base stocks by the SAPO-11 zeolite (Table 2). This zeolite has intermediate pore apertures (with a diameter of around 0.5 nm) and the required shape selectivity to inhibit the formation of easily cracked multibranched isomers and to allow the formation. even at a very high rate of conversion, of only slightly branched isomers that are difficult to crack. The catalyst used is bifunctional and possesses a strong hydrogenation function based on a noble metal (Pt or Pd) that requires operating with feeds that have low concentrations of organic sulfur and nitrogen compounds. Other zeolites possess properties comparable to those of the SAPO-11 zeolite: ZSM-22 and 23, and ferrierite, for example.

The first process for dewaxing by hydroisomerization was commercialized in 1993 for lube oil base stock treatment.

Isomerization of C_5–C_6 light paraffins

The most effective zeolite for this industrial application is an acid-modified mordenite (Table 2) associated with a small amount of Pt and has been used since 1970.[25–28] It does not involve the pollution and corrosion problems of conventional superacid catalysts with Pt on highly chlorinated alumina. It has much lower acidity. and therefore requires a high reaction temperature (220–250°C) that is thermodynamically not favorable to isomerization. It could rapidly be superseded by new

solid catalysts that are much more acidic. nonpolluting. and noncorrosive. such as sulfated zirconia.

Aliphatic alkylation

During the 1990s, considerable work was carried out on aliphatic alkylation for the purpose of replacing liquid acid HF and H_2SO_4 catalysts that were considered to be too dangerous for human beings and the environment.[29–33] The potential catalysts identified, including the USY and BEA, have selectivities similar to those of liquid acids, in spite of lower activity. but they are rapidly deactivated, and so a simple and economical procedure for regenerating their activity has to be designed. Several interesting processes were imagined. including suitable hydrogen treatments at low or medium temperature, but none has yet reached the industrial stage, because they do not provide sufficient gains in perforinance or investment and operating costs. At present, these new catalysts inay not make any headway unless substantial incentives are imposed by the authorities.

Aromatization of aliphatic hydrocarbons

Zeolites were used in various processes that convert paraffins or olefins into alkyl monoaromatics containing chiefly from six to nine carbon atoms.[34–37] There are various catalysts, and they involve a base or an acid zeolite. according to the type of process. The first catalyst, identified at the end of the 1970s. is composed of Pt deposited on the L zeolite (Table 2) exchanged with large alkaline ions such as potassium or alkaline earths. such as Ba. which gives it an alkaline nature. This cataiyst is monofunctional and is conceptually different from the conventional bifunctional acid catalysts based on Pt on chlorinated alumina. It selectively dehydrocyclizes the paraffins into aromatics, particularly hexane. which is the least reactive of them. The reaction takes place on the metal, which develops a special selectivity in contact with the alkaline zeolite. This aromatization process has not been successful so far. partly because of the extreme sensitivity of the catalyst to the slightest trace of sulfur compounds.

The other processes developed in the 1980s involve an acid catalyst. The purely acid H-ZSM-5 zeolite, for example. is used at around 500°C for cracking the olefins and paraffins in light FCC gasoline into smaller olefins. some of which are subsequently oligomerized and cyclized into monoaromatics.[22,36,37]

The bifunctional catalyst composed of gallium or zinc or. to a lesser degree, of Pt which are introduced into the ZSM-5 zeolite. is capable of aromaiizing saturated or unsaturated C_2 to C_4 hydrocarbons. particularly LPG, and hydrocarbons with five and six carbon atoms, at around 500°C[36 37] (Table 2)

The environmental constraints prevailing at the beginning of the twenty-first century are not likely to promote the commercial success of these processes. The scheduled reduction in the aromatics content of gasoline is likely to result in a surplus of these hydrocarbons on the market in the coming years.

Skeletal isomerization of linear olefins with four and five carbon atoms

This reaction produces the isobutene and isopentenes necessary for the synthesis of the principal ethers MTBE, ETBE, and TAME used as high-octane-number gasoline blending components.[38–41] On most of the nonzeolite acid solids, the isomei-ization of *n*-butenes takes place via two different mechanisms: the monomolecular one selectively produces isobutene, and the bimolecular one is not selective. Some zeolites of intermediate pore size, especially ferrierite (Table 2), with acidity and shape selectivity that strongly favor the monomolecular mechanism, have a selectivity for isobutene far greater than that of other solids. The situation is somewhat different in the case of pentenes. In this case. the selective monomolecular mechanism is dominant on all the solids and is not particularly favored by any acid zeolite. The superiority of ferrierite for the synthesis of isobutene was proven in a demonstration unit, but very few processes have yet been commercialized, due mainly to the threat that bangs over MTBE. The addition of this ether to gasoline might be permanently prohibited in a number of countries following the contamination of groundwater in California at the end of the 1990s due to leakage from MTBE storage tanks.

Oligomerization of olefins

The dimers and trimers of the light olefins ($C_3^=$ to $C_5^=$) produced with acid catalysts are generally branched and make good gasoline-blending components.[22,42] However. the open zeolites like the Y zeolite are less effective catalysts for this application. because they have a lower stability than amorphous silica-alumina catalysts. On the other hand, the shape selectivity of zeolites with small pore apertures. like the ZSM-5 zeolite (Table 2), only allows the formation of slightly branched oligomers. Around 200°C and a pressure of 2 MPa, the major parts of the hydrocarbons formed are aliphatic, of which the C_{12}–C_{25} fraction can be used, after hydrogenation, as jet fuel and diesel oil.[22] At higher temperatures, the oligomerization is followed by cracking. MT, and aromatization. all reactions that lead to a good-quality aromatic-rich

gasoline as the major product.[42] This type of process, commercialized in the early 1980s, is still far from being widespread, as the product qualities are just at the limit of the specifications imposed. For instance, the motor octane number of gasoline is below 85, and the cetane number of diesel oil is at the best only just above 50.

In another type of process. mordenite ion-exchanged with nickel is used to convert olefins from C_2 to C_5 into gasoline, jet fuel, and gas oil, under pressure and at a temperature between 200–280°C.[42]

Conversion of the aromatics of some petroleum cuts

The acid ZSM-5 zeolite is used to lower the benzene content of reformates to below 1%.[42] For this, the benzene of the light fraction of the reformate is alkylated by the light olefins, ethylene and propylene, present in the FCC fuel gas, into higher monoaromatics. This operation, which is performed in a fluidized fixed-bed reactor with a continuous catalyst regeneration, decreases the total gasoline yield of the reformate due to the cracking of part of the paraffins but slightly increases the octane number.

Conversion of methanol into gasoline

The first industrial unit for gasoline production by conversion of methanol on an acid ZSM-5 zeolite fixed bed (Table 2) came onstream in New Zealand in 1985.[22,43,44] The gasoline produced is rich in isoparaffins and aromatics and has a high octane number (NOR—93). A moving-bed process producing a slightly better gasoline was also developed but never went further than the demonstration stage. The main advantage of the ZSM-5 zeolite is its shape seiectivity that does not allow the formation of heavy aromatic products with over 10 carbon atoms and, hence, prevents the formation of coke. At present, this application is only viable in specific local political and economic situations and only limited success can be expected in the near future.

Petrochemicals

Applications of zeolites in the petrocheinical industry first concern the transformation of aromatics and second. light olefins—on one hand, their production from methanol and, on the other hand, their interconversion.

Isomerization of C_8 aromatics with transformation of ethylbenzene

The catalysts used differ considerably according to the nature of the desired transformation of the ethylbenzene present in the aromatics.[22 45–50]

Mordenite has been used since the second half of the 1970s in industrial xylene and ethylbenzene isomerization processes, chiefly for the production of paraxylene. the isomer for which there is the highest demand (Table 2). First, the isomerization of ethylbenzene into xylenes implies a bifunctional acid catalyst. Second. it requires a temperature of around 400°C and hydrogen pressure in the region of 1–1.5 MPa. The catalyst is. therefore. composed of acid mordenite associated with a strong hydrogenation function, supplied by Pt.

Although mordenite is much more active than the former amorphous silica–alumina-based catalysts. it is not fully selective for this application and should progressively be replaced by other high-performance acid zeolites such as that with a 10-membered ring aperture, which was recently developed[50] (Table 2).

The isomerization of xylenes and the dealkylation of ethylbenzene into benzene are other possibilities that have been industrially exploited on a large scale since the mid 1980s. This requires a catalyst that is more effective than mordenite; which is not very active in dealkylation. The best-suited catalyst is undeniably ZSM-5 (Table 2). If this zeolite is used in its purely acid form. the ethylene produced by dealkylation of ethylbenzene at around 350°C is alkylated on another ethylbenzene molecule mainly to form paradiethylbenzene. some of which is produced industrially by this method. In order to avoid the alkylation reaction in the dealkylation of ethylbenzene, it is necessary to operate under hydrogen pressure (~1.5 MPa) and to associate a small amount of Pi to the ZSM-5 zeolite, which hydrogenates the ethylene into ethane as it is produced.

Disproportionation and transalkylation of aromatics

The industrial disproportionation of toluene into benzene and xylenes on an acid zeolite has been performed since the 1970s.[22,45–47,51] At present. it is generally performed on the ZSM-5 zeolite (Table 2), but the practice is not widespread for economic reasons: the price of xylenes is not high enough above that of toluene. Moreover, the conversion of toluene is restricted to less than 50% by thermodynamics. which entails considerable recycling of the nonconverted reactant.

The acid ZSM-5 zeolite can be modified to selectively convert toluene into benzene and paraxylene. which is the least bulky of the xylenes. This modification requires the following: 1) reducing access to the channels by the two other xylenes through a suitable chemical or coking treatment; 2) passivating the external surface of the zeolite: and 3) limiting conversion to around 30%. When xylenes are produced by transalkylation of toluene and C_{9+} polymethylbenzenes, the ZSM-5 zeolite is unsuitable,

because its pores are too narrow for the latter. The acid zeolite most widely used for this application is mordenite (Table 2). associated with a mild hydrogenating function. sulfided Ni for example, which does not hydrogenate the monoaromatics but considerably improves the stability of the catalyst. especially when the feed to be processed contains a large amount of C_{9+}.

Alkylation of aromatics by olefins

The two most important applications in this field are the synthesis of ethylbenzene and cumene, in which zeolites replaced the former liquid HF and $AlCl_3$ catalysts.[22,52,53] These two applications reached the industrial stage in 1976 and the mid 1990s, respectively.

Shape selectivity is not a decisive parameter in achieving good performance, and consequently, acid zeolites with different apertures are used in the various rival industrial processes. For example, the synthesis of ethylbenzene is performed with ZSM-5 zeolites (pore diameter -0.55 nm) (Table 2), MCM-42, Beta (pore diameter $\sim 0.76 \times 0.64$ nm), and USY (pore diameter ~ 0.74 nm) zeolites (Table 2). Moreover. the small size of the pores is a handicap for the ZSM-5 zeolite with an operating temperature that is much higher than that of the other two zeolites, because the molecules diffuse less easily inside the pores. The most important parameter is zeolite acidity, which should be high enough to allow operation in the liquid phase ($T < 300°C$ approximately), which avoids the rapid deactivation associated with operation in the vapor phase.

For cumene synthesis through alkylation of benzene by propylene, four different zeolites are used industrially (Table 2): MCM-22, mordenite, Beta. and Y zeolites. The ZSM-5 zeolite cannot be used because of its restrictive pore size.

Other alkylaromatics synthesis processes are also of interest. The H–ZSM-5 zeolite is used industrially to selectively alkylate ethylene on toluene into paraethyltoluene, which is an intermediate for production of the monomer paramethylstyrene. The selective synthesis of paracymene was considered by selective alkylation of propylene on toluene with the H–ZSM-5 zeolite. Open zeolites (e.g., Y) are catalysts of potential interest for the alkylation of benzene by C_{10}–C_{15} linear olefins, which produce linear alkylbenzenes (LABs) used in manufacturing detergents. Good selectivities for 2.6-dialkylnaphthalene (alkyl = methyl or isopropyl) can be obtained by alkylation of naphthalene by methanol. propylene. or isopropanol on H-mordenite.

Conversion of methanol into C_2–C_4 olefins

This application was discovered in the mid-1980s but was little exploited until the beginning of the twenty-first century.[22,43,44,54] It could prove highly successful in the future due to the increasing demand for light C_2–C_4 olefins. particularly for ethylene and propylene, by the chemical industry. These two olefins, which are kinetically the first two formed from methanol. are rapidly converted into heavier products. particularly aromatics then coke precursors. if their desorption from the zeolite is too slow. Two properties can help to avoid this problem: 1) small pore size to inhibit the forination of heavy products; and 2) low acidity to enable operation at a sufficiently high temperature and hence rapid desorption of the olefins formed. The two most effective zeolites, silica-rich ZSM-5 and especially SAPO-34. at least partly fulfil these conditions (Table 2).

bight olefins interconversion

Some olefinic petroleum cuts produced in steam-cracking or FCC processes can be upgraded by converting their olefins into lighter ones, especially ethylene and propylene, that are sought by the chemical industry. through a complex set of oligomerization–cracking reactions.[▼▼] Olefin selectivity in the process is slightly deteriorated by a secondary reaction of aromatization. But. this latter reaction is limited, through the use of the acid ZSM-5 zeolite as a catalyst, to the production of a C_{5+} cut that principally contains monoaromatics and few polyaromatics.

CONCLUSION

Since zeolites were first used, in the 1950s for adsorption and in 1960 in catalytic applications in refining, they have made a considerable contribution to economic, technical, and scientific progress.[1,55] Their remarkable properties, due to their acidity confined within a restricted space and the small. regular size of their pores, have been largely instrumental in achieving this progress and will continue to be so in the future. The synthetic zeolite market has developed considerably and stood at 1.3 M tons in 1998, with over I M tons for the A zeolite alone: which has an enormous field of application in the detergent industry. In the field of refining, the largest market is for the Y zeolite, with over 150,000 tons produced in 1998. mainly in FCC. Although the tonnages of the other zeolites used are smaller. they are nevertheless important from the economic point of view. In the space of 50 years, the number of known zeolite structures increased significantly, from less than 30 structures identified at the end of the 1950s to over 125 in 2001.[1,55] Many new materials will probably be discovered in the years to come. with the hope of new industrial applications. However. at present, only a dozen

zeolite structures are used in industrial applications or applications with high industrial potential. This low success rate indicates the great difficulties that have to be overcome for an exciting laboratory discovery to become a genuine industrial success. Any application must satisfy a fundamental economic condition — it must be cost-effective and competitive in order to be viable.

Zeolites: Catalysis

Takashi Tatsumi
Yokohama National University, Yokohama, Japan

INTRODUCTION

Zeolites and related microporous materials offer abundant chemical diversity. Over the past three decades. many new synthetic zeolites have been discovered. The Structure Commission of The International Zeolite Association have approved 145 framework types (November 2003). In addition. there are numerous other zeolites with structures that are not yet known or are only hypothetical. The goals of this article are to briefly mention the main categories and principal industrial uses of zeolites, before providing more detailed discussions of molecular sieving and redox reactions.

CLASSIFICATION

Zeolites are crystalline aluminosilicates with the structural formula $M_{x/n}(AlO_2)_x(SiO_2)_y$, where n is the valence of cation M, $x+y$ is the total number of tetrahedra per unit cell. and y/x is the Si/Al atomic ratio varying from a minimum value of 1 to infinite. Catalytic processes involve diffusion of molecules into the zeolite pores, only pores with a minimum of eight-membered oxygen ring (8-MR) apertures (eight tetrahedral and eight O atoms) are generally considered. Zeolites are usually classified into three categories: smail-pore zeolites with 8-MR apertures having free diameters of 0.30–0.45 nm; medium-pore zeolites with 10-MR apertures, 0.45–0.60 nm in free diameter: and large pore with 12-MR with free diameter 0.60–0.75 nm. The catalytic properties of zeolites can vary considerably by modifying them during or after the actual synthesis. The types of catalysis of zeolites can be roughly classified into four groups:

- Acid catalysis.
- Hydrogenation/acid bifunctional catalysis.
- Base catalysis.
- Redox catalysis.

INDUSTRIAL APPLICATIONS

Although there are I45 confirmed zeolite framework types, only a dozen zeolites and their modifications are used for industrial catalytic processes. Listed in Table 1 are the important industrial processes using zeolites as catalysts.

CATALYSIS

Among the primary tasks of catalysis of zeolites, the most important is shape-selective catalysis, which is the molecular-sieving function in action during a catalytic reaction that distinguishes between the reactants, the products, or the transition state species in terms of the relative sizes of the molecules and the pore space in which the reaction occurs. Over 40 years ago, Weisz and Frilette (1960) of Mobil Research Laboratories coined the term "shape-selective catalysis" to describe the then unexpected catalytic behavior of synthetic crystalline molecular-sieve zeolites. They found that the calcium ion exchanged zeolite A, having pore sizes of 4–5 Å selectively cracked straight-chain *n*-paraffins exclusively to straight-chain products. This is accounted for by the molecular sieving effect; branched-chain paraffins are too large to enter the pores of zeolite A. whereas straight-chain paraffins fit.

Shape Selective Catalysis

Since then, great strides have been made in the understanding and the use of shape-selective catalysis in commercial catalytic processes. Their applications have expanded well beyond the boundaries of traditional petroleum refining to petrochemical and fine chemicals manufacturing. Meanwhile. many new synthetic zeolites have been discovered; of particular importance was the discovery of the synthetic medium-pore zeolites (Table 1), having pore sizes of 5–6 Å (0.5–0.6 nm), which meet the industrial need for selective catalysts. Mobil produced ZSM-5, commercialized new petroleum refining and petrochemical processes. based on this zeolite, and the ZSM-5 catalyzed methanol-to-gasoline (MTG) processes attracted worldwide attention. Since the 1980s shape-selective catalysis has extended from the medium-pore zeolites to several large-pore zeolites, including zeolite L and zeolite β. A titanium-containing zeolite, TS-I. a novel derivative of ZSM-5, was first synthesized by the

Table 1 Industrial processes using zeolite catalysts

Zeolite catalyst (framework code name)	*Process*
Large-pore zeolites (12-membered oxygen ring)	
Ultrastable H–Y and Rare-earth-Y (FAU)	Cracking of vacuum distillates and residues
Pt–Pd–H–Y (FAU)	Hydrocracking of vacuum gas oils
H-mordenite (MOR)	Transalkylation of aromatics: dimethylamine synthesis
Pt–H-mordenite (MOR)	Hydroisomerization of light gasoline: xylene isomerization
H–β (BEA)	Benzene alkylation (C_2, C_3); aromatics acylation
Pt–K–L (LTL)	Hexane aromatization
Medium-pore zeolites (10-membered oxygen ring)	
H-ZSM-5 (MFI)	Methanol to gasoline: toluene disproportionation: dewaxing: xylene isomerization: cyclohexene hydration
Silicalite-1 (MFI)	Beckmann rearrangement
GaMFI (MFI)	LPG to BTX
Pb-ZSM-5 (MFI)	Synthesis of pyridines from aldehydes and NH_3
TS-I (MFI)	Phenol oxidation; oxime synthesis; epoxidation
Fe-ZSM-5 (MFI)	Synthesis of phenol from benzene and N_2O
H-MCM-22 (MWW)	Benzene alkylation (ethylene. propylene)
H-ferrierite (FER)	Light olefins (C_4, C_5) isomerization
Small-pore zeolites (eight-membered oxygen ring)	
Ni-erionite (ERI)	Enhancement of light gasoline Octane No
SAPO-34 (CHA)	Methanol to olefin
H-rho (RHO)	Dimethylamine synthesis

researchers at ENI of Italy through the isomorphous substitution of titanium for silicon in ZSM-5 (Taramasso et al., 1983). A remarkable class of reactions having industrial importance was developed utilizing H_2O_2 as the oxidant.

The phenomenon of shape-selective catalysis is almost limited to the heterogeneously catalyzed reactions over zeolites and zeolite-related microporous solids. In a simplified manner, shape-selective catalysis can be described as the combination of catalysis with the molecular sieve effect. Shape selectivity effects can be produced if the sizes and shape of reactants, of products, of transition states. or of reaction intermediates are similar to the dimensions of pores and cavities of the zeolite. The zeolites contain intracrystalline pores and apertures having dimensions approximately equal to those of many of the molecules converted in catalytic processes, and they are classified according to the sizes of their apertures (Table 1). The number of oxygen atoms in the aperture of each molecular sieve[8,10,12] is shown in the table. There are also ultralarge-pore zeolites with apertures consisting of more than 12 oxygens. The aperture dimension ranges from about 0.4 nm to nearly 1 nm. The size of the aperture is also dependent on the size and number of the nearby cations. which may partially block it. The shape selectivity is also affected by the structure inside apertures: many zeolites have cavities (supercages) with internal dimensions that are larger than those of the apertures. Transition-state shape-selectivity is often governed by the sizes of these cavities. Recently, a variety of mesoporous molecular sieves such as MCM-41 and SBA-15 with apertures in the range of 2–20 nm have been synthesized and thus expected to be useful in converting large molecules such as those contained in heavy fractions of petroleum and fine chemicals intermediates.

Shape-selective catalysis is not limited to the use of the molecular sieve. There are many applications that involve transition metal species that are supported inside or synthesized inside the cages or pores channels of molecular sieves ("ship-in-a-bottle") that can be used for catalyzing many selective reactions, such as hydrogenation and oxidation.

Acid Catalysis

Zeolite catalysts are mainly used for a number of important acid-catalyzed reactions. Synthetic zeolites were developed for fluid catalytic cracking (FCC) in the early 1960s. This reaction occurs via carbonium ion intermediates and is. therefore. catalyzed by Brønsted acids. These sites normally consist of protons attached to bridging framework oxygen atoms and are introduced into the zeolite via ion exchange.

In general: zeolite synthesis yields the form neutralized by sodium ions. Usually, this is also the case if template molecules (structure-directing agents) are used; the

template removal step is followed by removal of Na^+ by ion-exchange techniques. However, many of the crystalline zeolites decompose when treated with strong acids. Therefore. the most effective and gentle methods for converting the sodium forms into the hydrogen forms involve exchange of the cation by ammonium from an aqueous solution of ammonium salt. Subsequent thermal treatment of the ammonium-exchanged zeolites results in the liberation of NH_3 and the formation of the proton (acidic) form of the zeolites (Eq. 1):

$$NH_4^+\{\text{zeolite}\} \rightarrow NH_3(g) + H^+\{\text{zeolite}\} \quad (1)$$

Thus. ideally. the total number of acid sites is equal to the total number of Al atoms on framework tetrahedral (T) sites. Because the acidity of zeolites is adversely affected by a small amount of residual Na^+, Na^+ must be exhaustively removed in order to obtain a highly active solid acid catalyst. Removal of Na^+ from zeolites usually requires repeated ion-exchange steps combined with calcination. in the temperature range of 823–1050 K. Only about 70% of the Na^+ ions are replaced by NH_4 ions during the first exchange. It is assumed that as a result of calcination Na^+ atoms. which were not accessible for ion exchange, are redistributed over the zeolite surface and made accessible. Simultaneously, solid-state reactions occur in the zeolite, and framework aluminum is removed. This phenomenon results in stabilization of the zeolite structure: the acid forms of low-silica zeolites are inherently unstable.

Although the enormous potential of zeolite Y as a cracking catalyst was recognized early. its low stability was a serious drawback to practical use. Therefore, efforts were made to develop techniques to enhance the thermal and hydrothermal stabilities of zeolite Y by increasing the Si/Al of the framework. During the dealumination treatment, pores with a diameter of ca. 20 nm are formed in the zeolite grains. The mesopores emerge when parts of the structure collapse, which is associated with removal of framework Al, leaving extra-framework Si as well as extra-framework Al. The mesoporous structure of the Y zeolites should be advantageous for use as an FCC catalyst; because the diffusivity of the feedstocks in the catalyst will be increased.

Hydrogen forms can be prepared in different ways. In general, zeolites with a Si/Al ratio of 5 or higher are resistant to acids. Direct treatment of high-silica zeolites with strong acids results in the progressive replacement of the cation by the hydronium ion. For mordenite, for example, this reaction is illustrated by the following reaction:

$$Na_8[(AlO_2)_8(SiO_2)_{40}].24H_2O + n\ H_3O^+ \rightarrow Na_{8-n}(H_3O)_n[(AlO_2)_8(SiO_2)_{40}].m\ H_2O + n\ Na^+ + (24 - m)H_2O \quad (2)$$

Replacement of all the original cations by the hydronium ions is possible. However. dealumination, removal of aluminum from the lattice, occurs to a certain extent. which is an unavoidable side effect.

Heating at high temperatures removes water from the Brønsted acid site, exposing a threefold coordinated Al ion, which has Lewis acid character. A reaction scheme for the formation of these sites is shown in Fig. 1,

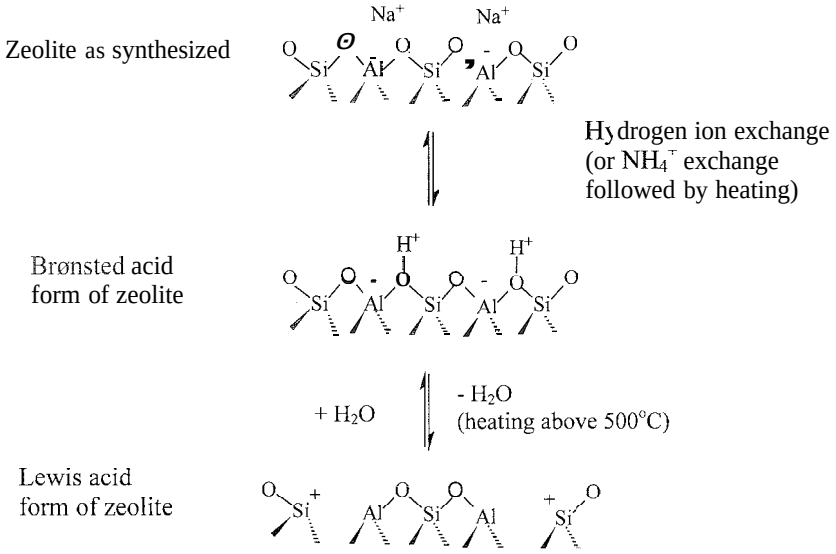

Fig. 1 Generation of Lewis and Brønsted acid sites in zeolites.

Table 2 Acid-form zeolites classified by their Si/Al ratios

Si/Al atomic ratio	*Zeolites*	*Properties*
Low (1–1.5)	*A*, X	Relatively low stability of framework: low stability in acid: high stability in base; and high concentration of acid groups with moderate acid strength
Intermediate (2–5)	Erionite, chabazite, clinoptilolite, mordenite, Y	
High (−10− x)	ZSM-5, erionite," β, MCM-22, mordenite,[a] Y[a]	Relatively high stability of framework: high stability in acid; low stability in base: low concentration of acid groups with high acid strength

"Formed by chemical framework modification (dealurnination): the Al is partially removed by treatment with steam or $SiCl_4$ at high temperatures.

although the structure of the Lewis acid is still a controversial issue.

The surfaces of zeolites can thus display Brønsted or Lewis acid sites or a combination of the two, depending on how the zeolite is prepared. Brønsted acid sites are converted into Lewis acid sites as the temperature is increased above approximately 500°C and water is driven off. The overall catalytic activity of zeolites as solid acids depends on the number and the properties of the acid site. The strength of the acid sites is directly related to the framework composition of the zeolite. Zeolites with low Si/Al ratios can have higher concentrations of catalytic sites. and zeolites with high Si/Al ratios show strong acidity. Their classifications are shown in Table 2. An H-Y or H-ZSM-5 zeolite with a low density of acid groups is like an ideal solution of dispersed noninteracting protons in a solid matrix.

Elements other than hydrogen are introduced into the zeolites by means of ion exchange in order to enhance catalytic activity. By polyvalent ion exchange followed by calcination. the zeolite is changed into the protic form:

$$M(H_2O)^{n+}Z \xrightarrow[(M = Ca\ \text{Rare earth elements, etc})]{} M(OH)^{(n-1)+}Z + H^+Z \quad (3)$$

The first generation of zeolite FCC catalyst involved the use of zeolite Y exchanged with trivalent rare earth ions and was activated by calcination according to Eq. 3.

There are other transitions in properties exemplified by the acid-form zeolites (those incorporating H^+ as the exchangeable ion). The zeolites with high concentrations of H^+ are hydrophilic, having strong affinities for polar molecules small enough to enter the pores. The zeolites with low H^+ concentrations (in the limit, silicalite-I (MFI), for example) are hydrophobic. taking up organic compounds from water–organic mixtures; the transition occurs at a Si/Al ratio near 10. The stability of the crystal framework also increases with increasing Si/Al ratios: decomposition temperatures of the different zeolites range from roughly 700–1300°C. Zeolites with high Si/Al ratios are stable in the presence of concentrated acids, but those with low Si/Al ratios are not; the trend is reversed for basic solutions.

Because of the need to develop new environmentally benign catalytic reaction processes. zeolites will continue to be applied. and their use will further diversify into various branches of chemicals synthesis and hydrocarbon processing. As catalysts, they offer less or no corrosion, little waste, are ready adaptation to continuous processes, exhibit high thermal stability, etc. These properties make zeolites the environmentally friendly catalysts, which could contribute to sustainability of the world. For example, acid zeolite catalysts could be substituted for highly corrosive and polluting acids such as $AlCl_3$, H_2SO_4, H_3PO_4, and HF. There are many reactions that utilize zeoites as a catalyst in clean synthesis processes. such as alkylation, catalytic cracking, aromatization, alcohol dehydration, rearrangements, base-catalyzed reactions, and oxidation, including ammoximation and epoxidation. There are only a few examples of industrial applications of zeolites to the syntheses of fine chemicals. such as pharmaceuticals, fragrances, liquid crystals, etc.: fine chemicals synthesis is mostly carried out in noncatalytic conventional ways through processes with poor atom economy or low E-factor, so often inefficient in reducing wastes. The application of zeolites catalysts to the fine chemicals synthesis is being developed.

Bifunctional Catalysis

Bifunctional (metallic and acidic functions) catalysts are applied to a variety of oil-refining and petrochemical processes. For example, paraffin hydroisomerization involves *n*-paraffins dehydrogenation to a-olefins over metal, skeletal isomerization of *n*-olefins to isoolefins over acidic sites. followed by hydrogenation of isoolefins to isoparaffins over metal. Zeolite-supposted noble metal catalysts are often used for these types of reactions, which

are conveniently prepared by ion exchange using an aqueous solution of a cationic metal complex. For platinum and palladium. $[Pt(NH_3)_4]^{2+}$ and $[Pd(NH_3)_4]^{2+}$ are used, respectively. The ion-exchanged product is then reduced in a stream of hydrogen to produce small metal particles inside the zeolite pores, ideally. This reduction is accompanied by formation of the Brønsted acid sites:

$$[M(NH_3)_4]^{2+}Z + H_2 \rightarrow M + 4NH_3 + (H^+)_2Z(M = Pt \text{ or } Pd) \quad (4)$$

If acidic activity is undesirable, the acid sites thus formed must be neutralized before catalytic use.

Because of the cost of noble metal. the inetal loading should be low. and the inetal must be well dispersed to make the exposed metal surface as high as possible. Each type of metal complex, the conditions for ion exchange, the calcination procedure. and the reduction conditions have profound effects on the dispersion of the metal.

Coordination Chemistry in Zeolites

Research on coordination chemistry in zeolites started in the 1970s. A metal complex of the appropriate dimensions can be encapsulated in a zeolite. being viewed as a bridge between homogeneous and heterogeneous systems. Complexes that are smaller than the free diameters of the channels and windows have access to the cavities. On the other band, complexes that are larger than the diameters of the windows must be synthesized in situ, namely, by adsorption of the ligands into the zeolites containing transition metal ions or by synthesis of the ligands in those zeolites. Herron et al. first referred to such zeolite guest molecules as "ship-in-a-bottle" complexes. Since the first report on the synthesis of a metal phthalocyanine inside zeolite Na^+-Y in 1977. numerous examples of encapsulation of metal phthalocyanine complexes have been discovered. Related porphyrin and N,N′-*bis*-(salicylidene)ethylenediimine (SALEN) complexes have been trapped in a zeolite cavity with restricted apertures. These are typical examples of ship-in-a-bottle complexes and are given names such as zeozymes and inorganic proteins in regard to their biomimetic chemistry, e.g., as a model for dioxygen binding and oxygenase.

Bass Catalysis

In zeolite catalysis. emphasis has been placed on the reactions catalyzed by acids. However. complete ion exchange with alkali metal cations such as K^+, Rb^+, and Cs^+ would allow for the preparation of weakly basic zeolites. Oxide ligands as counteranions of these alkali metal cations act as basic sites. Their basicity depends on the fractional negative charge they bear and, therefore, the composition of the zeolite, which can be quantified by the intermediate Sanderson electronegativity, S_{int}. It is also dependent on structural parameters such as bond length, bond angles, and Al distribution.

Redox Catalysis

For catalyzing redox reactions: one can introduce transition-metal active sites into the framework of zeolites. In current epoxidation processes: chlorine. hydroperoxides, and peracids are most commonly used as oxidants. Organic and inorganic compounds are coproduced in the reaction, which need to be recycled or disposed of. In the chlorohydrin route, generally preferred in the epoxidation of C_3 and higher olefins, stoichiometric amounts of sodium or calcium chlorides are produced by the dehydrohalogenation of intermediate chlorohydrins. Chlorinated organic by-products. such as halogen ethers and dichlorides. are formed as well in the process, further increasing the quantity of waste. A major breakthrough was the discovery that titanium silicate could be used as an efficient epoxidation catalyst with hydrogen peroxide as an oxidant. The reaction with TS-1 may be performed under mild conditions; for example, at room temperature in dilute aqueous or methanolic solution. Direct use of hydrogen peroxide is a more attractive epoxidation route based on ease and cleanliness of the process. The active oxygen content H_2O_2, 47 wt % (16/34), is much higher than that of organic peracids and hydroperoxides: water is the only co-product. Ti-silicalite catalyzes, besides epoxidation reactions, a broad range of oxidation reactions. with hydrogen peroxide as the oxidant, as shown in Table 3.

The most widely accepted mechanism for TS-1 catalyzed epoxidation is the peracid-like mechanism, which

Table 3 Catalytic chemistry with Ti-silicates

Substrate	Product

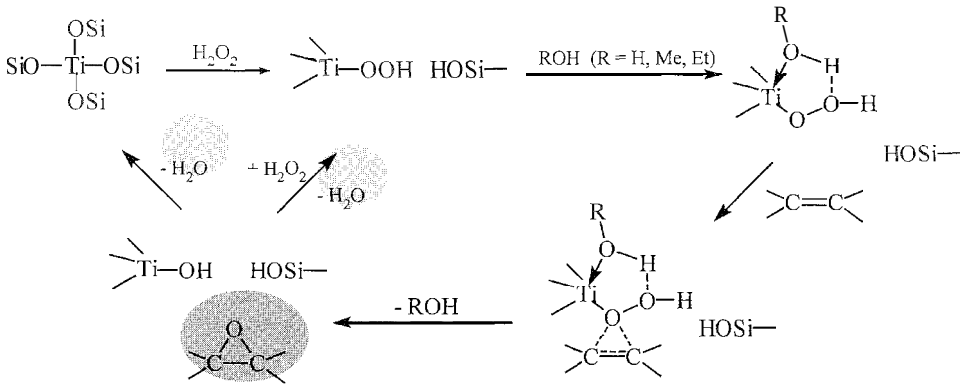
Thioethers	Sulfoxides



Scheme 1. Mechanisms of epoxidation on titanosilicates. (*View this art in color at www.dekker.com.*)

involves a hydroperoxo rather than a peroxo species, and coordination of an alcohol or water molecule to the site (Scheme 1). Ti seems to be isomorphously substituted for Si in the zeolite framework in tetrahedral coordination. This site is much more resistant to hydrolysis compared to titanium species on amorphous silica. A key characteristic of these materials is their relatively high hydrophobicity, resulting in the favorable adsorption of alkanes and other hydrocarbons. Thus. the low concentration of hydrogen peroxide present at all times in the catalyst results in its efficient use. The strong hydrophobicity also enables fast desorption of the product. Therefore. oxidations can occur up to high conversions with high H_2O_2 selectivities and high efficiencies.

The structure of TS-1 prevents all compounds with cross sections larger than ca. 0.55 nm from diffusing inside TS-1 channels and, therefore. from reacting or interfering with reactions occurring at Ti-sites. Although the discovery of TS-1 is a milestone in zeolite catalysis. the smaller pore size of the zeolite-type framework restricts its use, even for small molecules such as simple cyclic alkenes. Thus, new materials with various pore sizes are always sought. Ti-β and Ti-MWW (MCM-22) proved to be promising catalysts for similar oxidation reactions of larger substrates.

It was recently discovered that Sn-β catalyzes the Baeyer–Villiger oxidation of cyclic ketones to lactones without using peracids but using H_2O_2.

Pollution Abatement

The application of zeolite catalysts to pollution abatement is also promising. The main pollutants in gaseous emissions that can be potentially treated by zeolites are volatile organic compounds (VOCs) and NOx.

The treatments of VOCs by zeolite materials consist of adsorption/separation and catalytic oxidation. Although the VOCs adsorbed by zeolite are often recovered, at low VOCs concentrations, adsorption is followed by catalytic oxidation or incineration. Catalytic combustion is an efficient way to remove of VOCs. Zeolite-supported catalysts are favorable for VOC abatement, because they offer high selectivity to deep oxidation to CO_2 resulting from the highly developed microporosity. Both noble metals and base metals supported on zeolite catalysts can be used. Noble metals are preferable to base metals when VOCs do not contain chlorine or bromine atoms. Pd-zeolite such as Y(FAU) is most active for the combustion of hydrocarbons. One of the least combustible hydrocarbons is methane, which is widely used as a fuel, and emission of methane as a greenhouse gas must be controlled.

Zeolite catalysts constitute the best available technologies for reducing NOx and N_2O emissions from industrial activities. Emission levels of N_2O must be regulated. There are two types of N_2O emissions. Zeolites are not suitable for the simple abatement of highly concentrated N_2O (20–40%) gas discharged from adipic acid plants. However. direct oxidation of benzene to phenol was industrialized by using N_2O as an oxidant and Fe-MFI zeolites (AlphOx process). The treatments with N_2O of a low concentration remain challenging. Fe-exchanged zeolites show high activities in the catalytic decomposition of N_2O to N_2 and O_2, and the catalytic reduction of N_2O with reductants such as NH_3, CO, and H_2. Despite intensive work in the catalytic decomposition of NO. even the most promising system. Cu-MFI, is subject to poisoning by O_2, water, and SO_2, is efficient only at low space velocities. and has unsatisfactory catalyst activity. The selective catalytic reduction of NOx with hydrocarbons over zeolite-based catalysts has been widely investigated. This could be the best technology with which to achieve efficient NOx removal from off-gas emitted from power plants, stationary diesel engines, marine vessels; etc.

CONCLUSION

Zeolites are crystalline aluminosilicates and metallosilicates with distinct structures. The relationships between active site properties and chemical composition are more established than for analogous amorphous materials. Moreover. the structural diversity of zeolites is wide and still expanding. Zeolites can be industrially used not only for acid-catalyzed and bifunctional (metal–acid) processes but also for oxidation processes. Zeolite catalysts were mainly developed in the petroleum-refining and petrochemical industries; however. application of zeolite catalysts to fine chemicals synthesis is being developed, leading to the replacement of conventional noncatalytic processes or highly polluting processes with more environmentally friendly systems. To achieve these objectives. rational design of zeolite-based catalysts and methods for tailoring and fine-tuning zeolite catalysts, including control of active site arrangement, crystallite size. provision of mesoporosity. etc., as well as elaborate reaction engineering will be vitally important.

Zeolites: Separation Science

Toshinori Tsuru
Yuko Takata
Hiroshima University, Higashi-Hiroshima, Japan

INTRODUCTION

Zeolites are used as detergent builders, adsorbents, and catalysts. In the past decade, we saw the development of a variety of zeoiite membranes, and a number of investigators reported on the preparation of such membranes and their applications to a variety of separation systems. These research activities are motivated by features common to inorganic membranes. such as thermal resistance and resistance to organic solvents, and features unique to zeolite materials. such as molecular sieving, selective adsorption, and catalytic activity.[1] In this article, the discussion will be restricted to zeolite membranes for use in separation and catalysis. First, an overview is presented on recent progress in zeolite membranes. followed by a discussion of our research activities.

ZEOLITE MEMBRANES—PREPARATION AND APPLICATION FOR SEPARATION AND REACTION

Zeolite membranes, which have been successfully prepared and applied to separations and reactions, are largely MFI, LTA (NaA), and FAU (NaY) membranes, as summarized in Table I. In terms of membrane preparation. a wide variety of preparation methods can be categorized into hydrothermal synthesis with or without seeds[2,3] and the dry-gei conversion method.[4] Sano et al.[2] reported on the successful preparation of MFI zeolite membranes (silicalite) on porous stainless steel supports by in situ hydrothermal synthesis without seeds; zeolite crystals nucleate and grow on the surface of supports. Kita et al.[3] developed NaA zeolite membranes by hydrothermal synthesis using micometer-size seed crystals. On the other hand. Lovallo and Tsapatsis[5] reported on the secondary growth of colloidal silicalite seeds, the size of which was approximately 100 nm, under hydrothermal conditions. and provided an evaluation of their gas permeation properties. The secondary growth of crystalline colloidal zeolites. in which the growth of seed crystals on the order of the seed crystal size would be expected to be sufficient to close the interzeolite pores, represents a potential method for the preparation of thin zeolite membranes rather than the use of microineter-size seed crystals. The secondary growth of seed crystals has an advantage in that nucleation and crystal growth can be independently controlled for the preparation of zeolite membranes. Another advantage in utilizing seed crystals is, the potential for preparing MFII membranes without organic structure-directing agents, that is. templates. such as tetrapropylammonium. Templates: which are required for the formation of MFI structures in hydrothermal synthesis but need to be burned out in order to open the pore structures, often cause microcracks as the result of thermal stress. It was reported that high-quality MFH zeolite membranes can be successfully prepared without a template by utilizing MFI crystal seeds.[6] Finally. in the dry-gel conversion method, a dry aluminosilicate gel is deposited on the support and then transformed to the zeolite layer in the presence of steam and template vapor.

Excellent separation was reported for various types of zeolite membranes. The focus of most articles has been on inorganic and organic gaseous permeation, including CO_2/N_2 separations,[7] C4 (*n*-/*i*-butane),[8] and C6[8] and C8 isomers (*o*-/*m*-/*p*-xylene).[9–12] Moreover, zeolite membranes were used to separate liquid mixtures by pervaporation.[2,3,13] Silicalite membranes, the surface property of which is hydrophobic. permit the preferential permeation of organic components rather than water, which has a smaller molecular size. Separation factors larger than 100 were achieved for ethanol over water by silicalite membranes. On the other hand. NaA zeolite membranes permit the selective permeation of water with the separation factor larger than 1000.[3] The NaY membranes showed high selectivities for the separation of organic liquid mixtures such as benzene/cyclohexane.[13] This excellent separation is based on molecular sieving effects (molecular size and pore size) and selective adsorption.[1] The mechanism by which gas permeates through porous membranes is classified into Knudsen diffusion, surface diffusion. and molecular sieving. Several permeation models were proposed in terms of amorphous silica membranes[14] and zeolite membranes.[15,16] Bakker et al.[15] proposed a permeation model for MFI membranes that combined surface diffusion (transport by adsorbed gaseous molecules) and configurational diffusion (activated diffusion based on molecular sieving). At present.

the mechanism of permeation through microporous membranes (pore size: <1 nm) appears to remain a controversial subject, and for a complete understanding of this process. more experimental data will be required.

On the other hand. little attention was given to the use of zeolite membranes as membrane reactors, in comparison with separation applications. Several types of membrane reactor configurations were proposed. including the packed-bed meinbrane reactor (PBMR), the fluidized-bed membrane reactor (FBMR), and the catalytic membrane reactor (CMR).[17] Catalytic membranes can be categorized into two types. Catalytic membranes. the materials of which are inherently catalytic, represent the first class, while for the other class: catalysts are tightly bound to the separation membranes, that is, catalysts are attached to the membrane surface or on the pore surface.[17,18] As mentioned above, the features of zeolites not only involve separation but also catalytic activity for various types of reactions. and therefore, zeolite membranes have great potential for use as catalytic membranes. Zeolite A membranes were evaluated for use in the esterification of oleic acid with ethanol, resulting in an 100% conversion by the selective removal of water vapor.[19] Silicate membranes were examined for use in dehydration reactions of hydrocarbons.[20] In these cases, zeolite membranes were used as separation membranes and not as catalytic membranes. Catalytic activity would be expected for most zeolite membranes. such as Zeolite Y and ZSM-5. Masuda et al.[21] applied ZSM-5 membranes to the conversion of methanol to olefins (the MTO reaction), which is a consecutive reaction starting from methanol and then progressing through dimethylether and olefin finally to paraffin. They reported that the product composition of olefins could be controlled by appropriate adjustment of the pressure difference across the MFI membrane. Hasegawa et al.[22] applied Pt-impregnated Y-type zeolite membranes for the selective oxidation of CO, which was present at concentrations of several hundred ppm in a stream of hydrogen. The MFI membranes incorporated with vanadium (V-MFI) were found to be effective for the selective oxidation of propane to propene via dehydrogenation reactions.[23] Selectivity of p-xylene by the methylation of toluene with methanol was also reported to be enhanced using ZSM-5 catalytic membrane reactors.[24–26]

EXPERIMENTAL

Silicalite colloidal solutions with approximate diameters of 100 nm were prepared using distilled water, tetrapropylammonium hydroxide (TPAOM), and sodium hydroxide. Cylindrical α-alumina microfiltration membranes (average pore diameter 1 μm, outer diameter 10 mm, inner diameter 8 mmj were used as substrates for the zeolite membranes. A hydrothermal synthesis was carried out in a solution of distilled water, tetrapropylammonium bromide (TPABr), and sodium hydroxide in a molar composition of $TPABr/SiO_2/H_2O/NaOH = 0.1/1/80/0.1$.[2,26] For the case of ZSM-5 membranes, sodium aluminate was added at Si/Al molar ratios of 20 and 50. Seeded substrates were immersed in the solution contained in Teflon test tubes and hydrothermally treated in a stainless-steel vessel for 12 hr at 180°C. After controlled secondary growth, the membranes were rinsed with hot water several times. followed by drying at 75°C. They were then calcined in a muffle furnace at

500°C for 5 hr (heating rate 1°C/min) in an air atmosphere.

Gas permeation experiments were performed in the temperature range of 35–300°C. The feed stream was pressurized, while downstream pressure was maintained at atmospheric pressure; no sweep gas was used. The permeate flow rate was determined by a soap-film meter.

After the ion-exchange of MFI zeolite membranes from Na-type to H-type, the alkylation of toluene with methanol was carried out at temperatures of 450 and 500°C. The reactants, in a molar composition of 2 toluene: 1 methanol, were fed with a syringe pump. The carrier gas used from the outer to the inner side of the cylindrical membranes was He. The composition was analyzed by gas chromatography using a xylene-isomer separation column (Bentone 34, Supelco). The pressure difference across the membrane was controlled at approximately 10 kPa.

RESULTS AND DISCUSSION

Membrane Preparation

Shown in Figs. 1a and b are SEM photos of the synthesized MFI membranes with Si/Al ratios of ∞ and 20, which were prepared under the same conditions (180°C, 12 hr), respectively. The MFI membrane of Si/Al = ∞ showed a continuous and well-intergrown layer, and the zeolite layer, the thickness of which was approximately 15 pm, appeared to have grown from the inside of the α-alumina support to the outer surface. Moreover, the surface was oriented in the (101) plane, which was also confirmed by x-ray diffraction analysis.[26] On the other hand, an MFI zeolite membrane of Si/Al = 20 has a relatively thin thickness of approximately 5 μm and an agglomerate structure of smaller crystals (primary crystal size of 1 pm). The addition of aluminum ion to the synthesis solution appears to retard the secondary growth rate.

Gas Permeation Properly

Shown in Fig. 2a is the temperature dependency for the permeances of inorganic and organic gases through M-1 (Si/Al = ∞). The permeances for H_2 show a temperature dependency similar to Knudsen diffusion; the permeance decreases slightly with an increase in temperature, as shown by the dotted line in the iigure. This is probably because the pore sizes for H_2 permeation are sufficiently large, in comparison with the molecular size. On the other hand, CO_2 shows a decreasing tendency in pcrmeance in a steeper slope than was the case for H_2. The permeation mechanism can be simply described as surface diffusion, because these gases arc thought to be adsorbed to the MFI

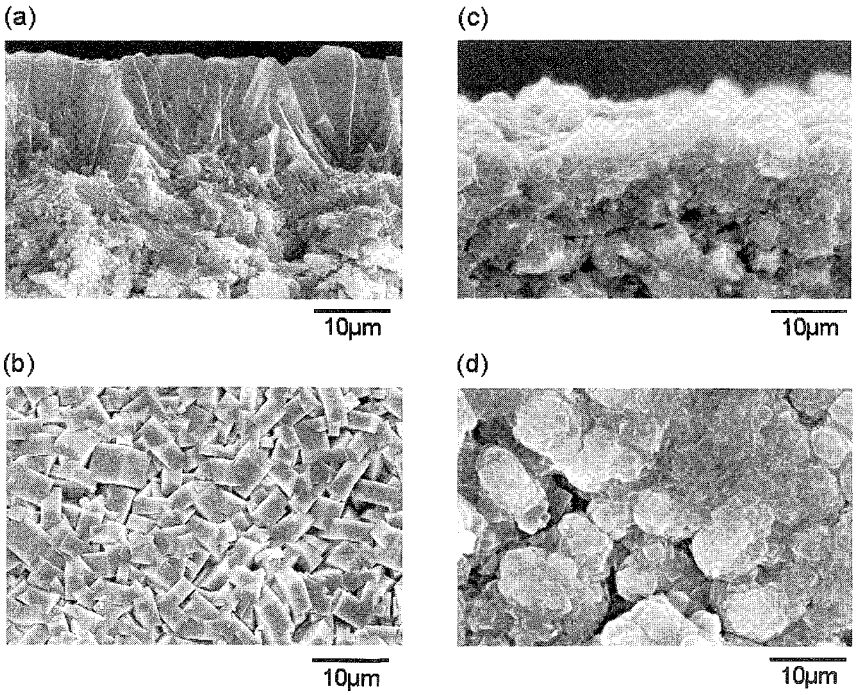

Fig. 1 MFI zeolite membranes: (a) cross-section (Si/Al = ∞); (b) surface (Si/Al = ∞); (c) cross-section (Si/Al = *20);* and (d) surface (Si/Al = *20).*

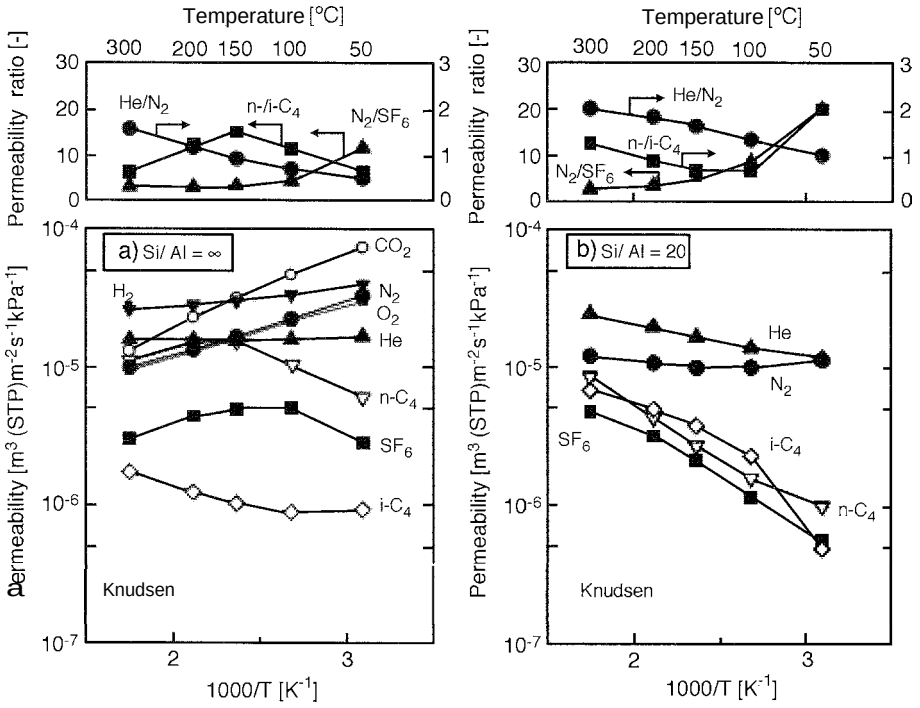

Fig. 2 Permeance and permeability ratio as a function of reciprocal temperature of M-1 (Si/Al = ∞) and M-2 (Si/Al = 20). (*View this art in color at www.dekker.com.*)

zeolite [15] N_2 and O_2, which are assumed to be non-adsorptive gases, also show a decreasing tendency, the slope tor which is intermediate between H_2 (Knudsen diffusion) and CO_2 (surface diffusion) Permeances of n-C_4H_{10} and SF_6 leached a maximum at 150°C and 100°C. respectively The maximal permeance can be explained as follows the number of adsorbed molecules decreases at temperatures higher than the maximum, while adsorption. which is enhanced at lower temperatures, causes a decrease in mobility (liquid-like diffusion of pore-filling molecules). On the other hand, the permeance of *i*-C_4H_{10} increased with temperature. and no peak was evident, which is similar to an activated diffusion mechanism.[14] The permeability ratio of *n*-C_4H_{10} over *i*-C_4H_{10}, based on pure gas permeances, shows a maximum of 15 at a temperature of 150°C, while the permeance of *n*-C_4H_{10} was 1.5 x 10^{-5} $m^3(STP)m^{-2}s^{-1}kPa^{-1}$. The M-1 membrane showed a large permeance and moderate selectivity,

Table 2 Summary of the methylation of toluene with methanol using MFI powders and membranes

Configuration	Si/Al	WHSV [$g_{feed}/(g_{catal}.h)$]	Temperature [°C]	Conversion [%]	Xylene composition [%]			Ref.
					o-	*m*-	*p*-	
Powder		33	400	23.5	21	47	32	[28]
Disc	50	34	450	26.7	3	18	79	[24]
Disc	50	17	450	37.8	3	20	76	[24]
Membrane	∞	9.7	500	4.3	22	22	*56*	[26]
Membrane	50	44	*500*	7 3	*6*	17	77	This work

Thermodynamic equilibrium			427	—	26	51	23	[24]

which might be caused by the formation of a thin zeolite layer by the secondary growth method, the existence of intercrystalline *pores, or the orientation of the* crystalline.[26] *On the other Band, as shown in Fig.* 2b, *M-2* (Si/Al *= 20) shows an increasing ten-iperature dependency for He.* SF_6, *n*-C_4H_{10}, *and i*-C_4H_{10}. *The effect of the* Si/Al *ratio on gaseous permeances is not yet clear. but the existence of* intercrystalline *pores for M-2* (Si/Al = *20) is strongly suggested. because since the permeability ratio of n*-C_4H_{10} *over i*-C_4H_{10} *was approximately 1.*

Methylation of Toluene

The reaction performances are summarized in Table 2, in terms *of* toluene *conversion and composition of o-/m-/p-xylene. Because toluene reacted with* methanol *in the case of an MFI membrane of* Si/Al = ∞, *it is clear that* aluminum *ions must have been incorporated into the MFI zeolite membranes. (The origin of the aluminum ions was probably* the α-alumina *support that was dissolved in strong alkali solutions during the hydrothermal synthesis.) The selectivity* for *p*-xylene *was as high as* 80%, *while the thermodynamic* equilibrium *was reported to have* a *composition of o-/m-/p-*xylene *of 26/51/23 at* 427°C.[24] *The alkylation reaction cakes place inside the ZSM-5 zeolite pores (intracrystalline pores) in the para-position, and the diffusioninside* ZSM-5 *also favors para*-selectivity *based on size selectivity. On the other hand. no para-selectivity would he expected on the external surface of the ZSM-5 crystals. including the intercrystalline pores. Furthermore. the* isomerization of *p-xylene. which is a primary product in the intracrystalline pores, to o- and m-xylene, occurs on the outer surface of the* H-MFI *zeolite. Therefore.* ZSM-5 *membranes, which have limited external surface area in comparison with powders, increased para*-selectivity.[24–26] *The present investigation confirms the possible* application *of MKP zeolite membranes to the alkylation* of *toluene with methanol.*

CONCLUSION

The MFI zeolite membranes containing different Si/Al *ratios were prepared by* the *secondary growth of colloidal* silicalite *on* α-alumina *microfiltration membranes. An* MFI membrane (Si/Al = ×), *the zeolite* layer *of which was oriented* in *the* (101) *plane. showed a n*-C_4H_{10} *permeance of* 1.5 *x* 10^{-} $m^3(STP)m^{-2}s^{-1}kPa^{-}$ *and a n-/i-*C_4H_{10} selectivity *of 15 at 150°C. After ion exchange of the* MFI *zeolite membranes* from *the Na-type to the* H-*type, the alkylation of toluene with methanol was carried out.* A *p*-xylene *selectivity of 80% was attained* using H-MFI *zeolite membranes at 450 ~ 500°C. confirming the possible application of an MFI zeolite* membrane *for use in a catalytic membrane reactor.*

Zeolites: Structures and Inclusion Properties

Jiří Čejka
Academy of Sciences of the Czech Republic, Prague, Czech Republic

INTRODUCTION

Zeolite-based molecular sieves represent one of the most important groups of crystalline inorganic materials, with a great potential for application as adsorbents. ion-exchangers, and heterogeneous catalysts. The first natural zeolite, stilbite. was discovered about 250 years ago by Swedish mineralogist Crønsted, who showed that this mineral released water upon heating. Thus, this mineral was named *zeolite* after Greek *zeo* (to boil) and *lithos* (stone). Since that time, about 50 natural zeolites have been found in different parts of the world.[1]

Several hundreds of synthetic zeolites (crystalline microporous aluminosilicates) and zeotypes (crystalline microporous ferrisilicates, gallosilicates, titanosilicates, isomorphously substituted aluminophosphates, etc.) have been successfully synthesized in recent decades.[2] All these microporous materials have tetrahedral coordination of their central atoms (Si, Al, P, Fe, etc.), which are interconnected with four oxygen bridges to form a three-dimensional crystal structure. These structures exhibit regular micropores with dimensions up to 1.0 nm and cavities. high surface areas, and adsorption capacities, and shape selectivity toward reactants, products, and transition states.''''

In the last decade of the twentieth century, new types of zeolitic materials were synthesized, namely. mesoporous molecular sieves with pore sizes larger than 10 nm,[5] and delaminated or pillared zeolites, which preserve the zeolite structure but allow access of significantly larger molecules.[6,7] These materials attracted remarkable attention, as they enabled scientists to escape from the so-called ''1-nm prison'' imposed by the structures of classical zeolites.

At present, zeolites have found a wide array of applications ranging from ion exchangers, detergents, drying and separation agents. to catalysts. The estimated production of zeolites is to exceed 1,100.000 tons per year. In particular; the application of zeolites. as highly active. selective, and stable catalysts in large-scale technologies steadily increases and includes oil refineries, petrochemistry, and synthesis of fine chemicals and environmental catalysis.[4,8]

STRUCTURES OF ZEOLITES AND ZEOTYPES

Zeolites are crystalline microporous alurninosilicates with a three-dimensional framework consisting of tetrahedral SiO_4 and AlO_4, (Si, Al=T atoms) connected by oxygen bridges. Two neighboring tetrahedra are connected by one oxygen bridge. and no edge connection has yet been described. Tetrahedra SiO_4 and AlO_4 (or PO_4, FeO_4, GaO_4, etc., for various zeotypes) are the primary building units, which in turn. form the so-called secondary building units like 4-, 5-, and 6- membered rings, double 4-, 5-, and 6-membered rings. etc. By combining these secondary building units, a three-dimensional channel structure is formed. Depending on the connections among individual tetrahedra, channels of different shapes and dimensions in the microporous range and cavities can arise. The number of tetrahedra forming these windows controls their diameter. For microporous aluminosilicate and related aluminophosphate molecular sieves, the windows usually consist of 6. 8, 10. 12. 14, 18, and 20 tetrahedra.[2] Only one zeolite with an odd number of tetrahedra forming the windows has been described so far.''' The inne volume of zeolites contains cations (protons) that compensate the negative charge of the zeolite framework due to the presence of AlO_4 tetrahedra and water molecules. Clearly, a straiglztforward relationship exists between the sizes and shapes of zeolite entrance windows to the channel system imposing the molecular sieve effect and their application in catalysis and adsorption. Zeolites and zeotypes with even-membered rings are usually divided into the following four categories (some examples with channel dimensions and dimensionalities are given in Table 1):

1 Small-pore zeolites (eight-membered rings with pore dimensions up to 0 40 nm)—e g . chabazite. Linde type A. $AlPO_4$-34, $AlPO_4$-22
2 Medium-pore zeolites (10-membered rings with pore sizes up to 0 55 nm)—e g . ZSM-5. ZSM-11, ZSM-22, ZSM-23, $AlPO_4$-11. $AlPO_4$-31, and MCM-22 (in addition. they have large cavities defined by 12-membered rings)

3. Large-pore zeolites (12-membered rings up to 0.75 nm)—e.g., zeolites Y and L, EMT, mordenite. Beta, and $AlPO_4$-5.
4. Extra-large-pore zeolites (at least 14-membered rings with pore sizes around 1.0 nm)—e.g., aluminosilicates CIT-5, UTD-1. aluminophosphates (VPI-5, JDF-20, gallophosphate. cloverite).

Typical examples of the individual structures. showing the type of secondary building units and entrance windows to the channel systems of zeolites ZSM-5 (10-membered rings), β (12-membered rings), CIT-5 (14-membered rings), and zeotype aluminophosphate $AlPO_4$-11 (10-membered rings) are shown in Fig 1 Summarized ın Table 1 are the structural characterıstıcs of the most Important zeolites. zeotypes, and mesoporous molecuiar sieves, including a three-letter code for different structure topologiei, based on the assignment of approved zeolite structures by the Structure Commission of the International Zeolite Association.[10]

The type of the individual zeolite structure is related to the chemical composition of the zeolite. The molar ratio of SiO_4 and AlO_4 tetrahedra can reach unity 1:1, which represents the regular periodicity of the $(Si–O–Al–O–Si–O–Al–O)_x$ structural motif. According to Lowenstein's rule, two neighboring Al atoms cannot be connected via one oxygen bridge. This finding implies that zeolites crystallizing with low Si/Al molar ratios are exclusively formed by secondary building units having an even number of T atoms. This is, e.g., the case of zeolites A and X (Si/Al=I) or zeolite Y (Si/Al=2.8). With decreasing concentration of Al in the zeolite framework, secondary building units with an odd number of T atoms are also utilized (ferrierite, Si/Al>8, ZSM-5, Si/Al>10, etc.). A similar rule is also valid in

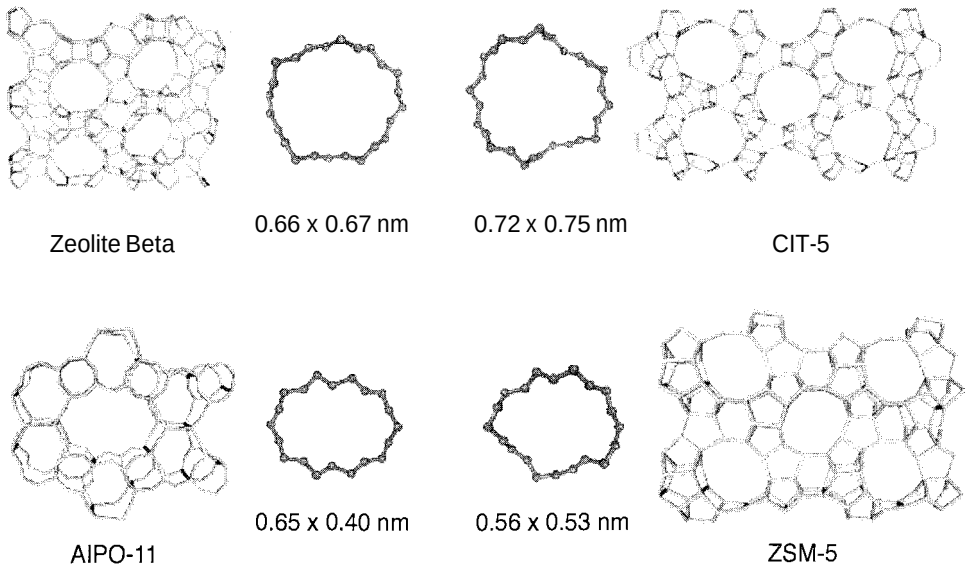

Fig. 1 Structure and entrance windows of zeolites β, CIT-5. ZSM-5. and zeotype $AlPO_4$-11. (*View this art in color at www.dekker.corn.)*

the case of aluminophosphate-based zeotypes, in which all the aluminum atoms are connected via oxygen bridges exclusively to four different phosphorus atoms. Thus, the secondary building units in aluminophosphates are limited to those with an even number of T atoms. Isomorphous substitution of aluminum by divalent metal cations like Co, Ni. Mn, Zn, Mg. or replacement of phosphorus by silicon can take place, resulting in the formation of negatively charged framework zeotypes.[2]

With the increasing concentration of aluminum in the framework (with the Si/Al ratio decreasing to 1), the hydrophilic character of zeolites rises. The same relation exists between the number of exchangeable cations and the affinity for polar molecules. On the other hand. thermal stability, stability in acidic solutions, hydrophobic character of zeolites, and their affinity for nonpolar molecules increases with the decreasing aluminum concentration (increasing Si/Al ratio).

The above-mentioned structural features of zeolite molecular sieves results in the following characteristic properties, which represent important advantages compared to other solid materials:

1. Well-defined inorganic crystalline structures yielding a large variety of structural types differing in the channel diameters, geometry, and dimensionality.
2. Precisely defined inner void volume providing high-surface areas up to 600 m^2/g.
3. Fine tuning of chemical properties through isomorphous substitution or various postsynthesis treatments.
4. Shape-selective properties related to the ratio between kinetic diameters of organic molecules and dimensions of the zeolite channels or cavities.
5. Environmental tolerance.

Based on the IUPAC nomenclature. microporous molecular sieves have pores with dimensions up to 2.0 nm in dimension. The mesopore dimension is between 2.0 and 50 nm, while macropores exhibit pores larger than 50 nm. Shown in Fig. 2 are the pore size and schematic structure of several zeolites. zeotypes, and mesoporous molecular sieves. Evidently, a large number of different zeolite or zeotype structures and mesoporous materials are available from which the optimum one for the given application can be selected.

EXTENSIONS OF ZEOLITE STRUCTURES

Although zeolites and zeotypes attracted attention in many areas of chemistry and its applications, much effort has been devoted in the last decade in particular to the enlargement of the size of their channels in order to allow larger molecules to reach the zeolite active sites. This work could have particular importance in fine chemical and pharmaceutical manufacturing and in petroleum refining. Access of larger organic molecules to the active sites of zeolites will significantly increase the number of reactions catalyzed by zeolites. The maximum size of zeolite channels is about 1.0 nm for

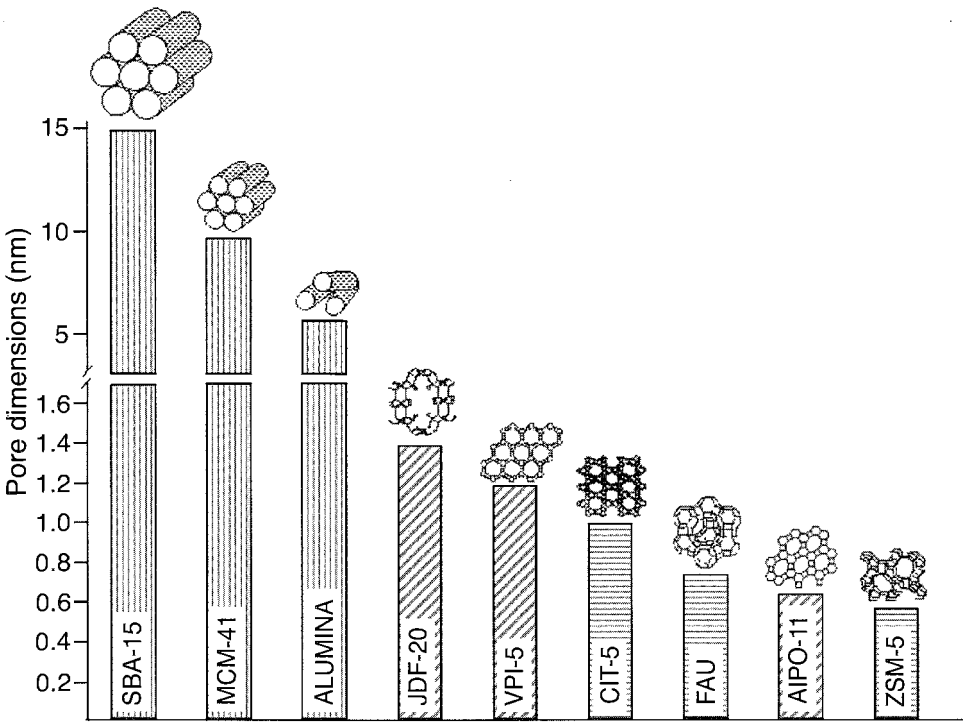

Fig. 2 Several zeolites. zeotypes, and mesoporous molecular sieves with dimensions of their channels

14-membered ring zeolites CIT-5 and UTD-1: while in zeotypes, channel sizes up to 1.4 nm in JDF-20 and cloverite have been achieved. However. further attempts to increase this pore size and at the same time to preserve the zeolite crystal structure unfortunately failed. Therefore, new synthetic approaches have been developed, namely, as follows:

1. Preparation of delaminated zeolites from zeolite precursors.
2. Preparation of pillared layered materials based on zeolite layers.
3. Synthesis of mesoporous molecular sieves with amorphous channel walls of various chemical compositions. different pore sizes, and dimensionalities.
4. Synthesis of mesoporous molecular sieves with crystalline zeolite phases embedded into the channel walls.

Several zeolites (e.g., MCM-22 and ferrierite) can be synthesized in the form of a layered precursor, which can be transformed into the three-dimensional crystalline structure by thermal treatment. These layered solids arouse interest due to their potential to intercalate guest molecules between the individual layers. Using a proper treatment. layered zeolite precursors can be delaminated, but their layered structure with surface areas exceeding 700 m^2/g is preserved. Such delaminated zeolites exhibit strong acidity and stability, which is characteristic for zeolite materials. In addition, they are better accessible for larger organic molecules.[6] Moreover, the layered nature of these materials enables zeolite-based pillared molecular sieves to be synthesized by inserting different inorganic materials (e.g., silica, alumina, heteropoly acids) into the interlayered space, yielding large-pore pillared materials with zeolitic properties.[11]

The invention of mesoporous molecular sieves at Mobil Research and Development Corporation, started a new era in the investigation of molecular sieves.[5] Mesoporous molecular sieves exhibit uniform pores with dimensions ranging from 2.0 to about 30 nm, surface areas often larger than 1000 m^2/g, and long-range ordering. These materials are obtained using supramolecular assemblies of surfactants, which template the inorganic components during the synthesis. Anionic: cationic. and neutral synthetic routes have been reported, defining the type of interaction among the head groups of inorganic and surfactant species in the initial steps of the synthesis of different mesoporous inaterials (MCM-41, MCM-48, SBA-15, mesoporous alumina).[12,13]

In order to overcome the limitations of individual micro- or inesoporous materials and to combine the advantages of these two types of molecular sieves, the synthesis of new molecular sieves incorporating porosity of both types presents a challenge. Several approaches and methods of synthesis of micro/mesoporous materials

have been described. One possible method of obtaining micro/mesoporous composite materials is by secondary teinplated crystallization of zeolites, starling from amorphous mesoporous materials containing structure-directing agents for the synthesis of the required zeolite phase. This approach consists of two steps: preparation of the amorphous mesoporous precursor and transformation of the amorphous mesopore walls into crystalline walls by additional hydrothermal treatment in the presence of a suitable organic template."'' Another approach is to impregnate mesoporous materials such as MCM-41 with tetrapropylarnmonium hydroxide followed by recrystallization at elevated temperatures to obtain a ZSM-5-like phase.[15] The dual-templating method through two-step crystallization represents another way of synthesizing micro/mesoporous molecular sieves.[16] Last but not least, direct assembly of nanoclustered alumosilicate precursors (zeolite seeds) with crystalline zeolite structure can be used under defined drying conditions.[17] Using this method, steam-stable aluminosilicate mesostructures assembled from zeolite Y, zeolite ZSM-5, and zeolite p seeds have been prepared.

A great deal of research effort aimed at enlargement of the zeolite and zeotype structures resulted in numerous papers on the synthesis, properties, and characterization of delaminated and pillared zeolitic materials and mesoporous molecular sieves with amorphous or partially crystalline channel walls. Also, evidence of their potentials for catalytic applications was reported. The individual synthetic approaches are summarized in Fig. 3. Depending on the reaction conditions and on the structure of organic template (structure-directing agent), various molecular sieve materials can be synthesized (zeolites—route A, delaminated zeolites—B. pillared layered zeolites—C, mesoporous molecular sieves—D, and mesoporous molecular sieves with zeolitic walls—E).

INCLUSION PROPERTIES OF ZEOLITES AND MESOPOROUS MATERIALS

The inclusion properties of zeolites and related molecular sieves are strongly controlled by the unique structures of their channel systems and the presence or absence of cavities. Introduction of various inorganic, organic. or organometallic species into the zeolite channels profoundly changes their properties. In addition, properties of guest molecules located in zeolite matrices can significantly differ from their bulk properties due to their nanoscale dimensions and locations in a constrained system. Crystalline structure of zeolites imposes important shape-selective properties, characterized by a negative framework charge and low

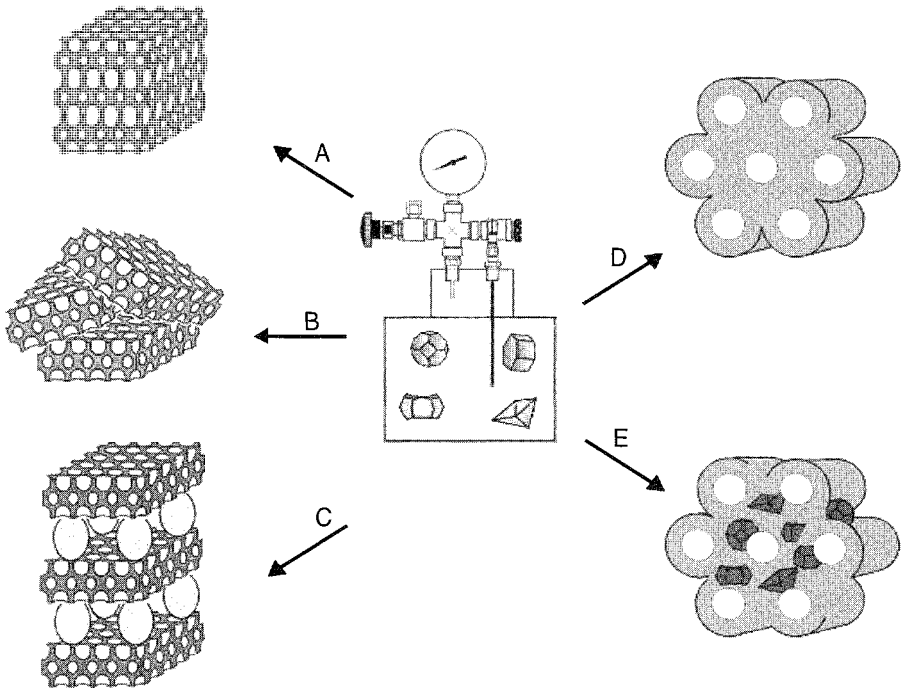

Fig. *3* Routes to zeolites (A), delaminated zeolites (B), pillared layered zeolites (C), mesoporous molecular sieves (D), and mesoporous molecular sieves with zeolitic walls (E).

flexibility of the zeolite structure. Excellent reviews covering this topic were recently published by Bein[18] and de Vos and Jacobs.[19]

Different synthetic approaches have been described for the formation of zeolite inclusion compounds, including direct adsorption. impregnation. ion-exchange from solutions or solid-state ion-exchange. ship-in-the-bottle synthesis. formation of large molecules (e.g., by polymerization reactions). and zeolite synthesis around the metal complex. Some examples of these approaches are given in the next sections.

METAL AND METAL-OXIDE **CLUSTERS**

Incorporation of metals or metal oxides into zeolite cavities leads to the formation of nanosized clusters exhibiting different catalytic properties from the bulk materials. These metal particles are usually introduced into zeolite channels through ion-exchange followed by reduction or oxidation/reduction to get their final dispersions.[20] Metal clusters can also be formed via zeolite impregnation by corresponding azides from methanolic solutions followed by thermal decomposition.[21] Catalytic activities of the bifunctional or basic catalysts prepared using these methods can be successfully combined with shape-selective properties of parent zeolites.

SHIP-IN-THE-BOTTLE SYNTHESIS

The ship-ill-the-bottle synthetic approach represents an elegant method of forming entrapped molecules within the zeolite channel system that are larger than dimensions of the channels of the zeolite. These entrapped molecules cannot be easily removed from the zeolite due to steric reasons. A typical example is the synthesis of Fe-phthalocyanine in the cavities of zeolite Y. Iron is introduced into the zeolite by ion exchange from its water solution followed by complexation with 1,2-dicyanobenzene. A schematic picture of the location of Fe-phthalocyanine in zeolite Y is provided in Fig. 4. This mechanism was examined in order to synthesize active catalysts for, e.g., oxidation and hydrogenation reactions and to mimic natural enzymes. It is expected that the mechanism of oxygen transfer of Fe-phthalocyanine in zeolite Y is analogous to the natural cytochrome P-450.[22] Complexes of other transition metals have been synthesized in zeolites using, e.g., bipyridine and salen ligands with application for epoxidation reactions. The ship-in-the-bottle synthesis was used by Meinershagen and Bein[23] for incorporation of the solvatochromic dye nile red in zeolite Y to test its sensing properties. This dye, located inside the zeolite. was shown to act as an optical sensor with extremely high sensitivity toward different organic compounds.

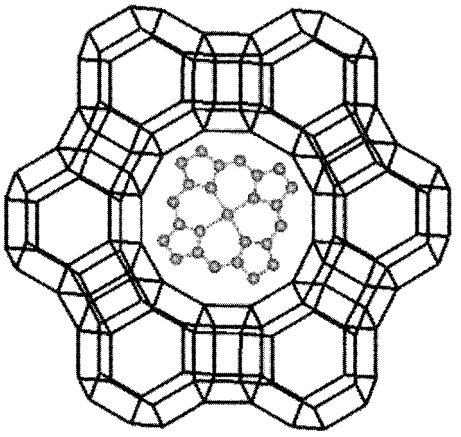

Fig. 4 Location of Fe-phthalocyanine in the cavity of zeolite Y. (*View this art in color at www.dekker.com.*)

FORMATION OF LARGE MOLECULES

The constrained geometry of the inner void volume of zeolites, and particularly of mesoporous materials, provides an important space of nanodimensions for accommodation of large molecules. It is expected that flexible polymers synthesized in the conditions of constrained geometry could exhibit different properties compared to nonconstrained systems. Considerable effort has been exerted to synthesize conducting polymers by polymerization of the respective monomers in the presence of zeolites ion-exchanged with some transition metals.

It has been shown that N-vinylcarbazole and vinyl ethers can be used for the cationic host–guest polymerization in MCM-41 and MCM-48 mesoporous molecular sieves. leading to new polymer/MCM-41 and polymer/MCM-48 host–guest hybrid materials.[24] It seems that the molecular weight and the degree of the loading of the enclosed polymers can be adjusted to a certain degree by modification of the polymerization conditions.

On the other hand. Balcar et al.[25] showed that the immobilization of $[Rh(cod)OCH_3]_2$ on mesoporous MCM-41 provides an inorganic hybrid catalyst, which is effective for polymerization of various substituted phenylacetylenes into substituted polyvinylenes (investigated for their interesting photoelectrical and optical properties) with molecular weight between 50.000 and 180,000 and high *cis-trans*oid structure.

ZEOLITE SYNTHESIS AROUND ORGANIC AND INORGANIC MOLECULES

A completely different approach involves organometallic complexes with a relatively rigid structure that can be used as templates for the synthesis of zeolites. Balkus et al.[26] showed that perrnethylated cobalticinium ion ($CoCp_2^+$) can be employed to synthesize a new zeolite UTD-1, which was the first zeolite with 14-membered ring channels. The ($CoCp_2^+$) complex was also used to synthesize ZSM-51 and AlPO-16. This zeolite and zeotype, respectively, exhibit cages into which this template nicely fits. Another example is the employment of 1-aminoadamantane for the synthesis of chabazite.

CONCLUSION

The continuous effort of numerous laboratories around the world resulted in the last decades in the synthesis of a number of new zeolites, zeotypes, and mesoporous molecular sieves of different chemical compositions. Hand in hand with the success of basic research in this area, zeolites found new industrial applications.

In the case of zeolites and related materials, unfortunately no breakthrough has been achieved in the synthesis of extra-large pore zeolites. UTD-1 and CIT-5 remain the only examples of 14-membered ring zeolites, while cloverite and JDF-20 represent the largest zeotypes with 20-membered rings. Therefore. much effort is exerted to enhance the accessibility of catalytically active sites by delamination and pillaring of zeolite precursors. while preserving the structure and properties of zeolitic layers. Several successful examples of these new types of materials are described in this article. Evidently, synthesis of other types of molecular sieves possessing chemical composition and properties can be expected. These synthetic activities are connected with the effort to increase the number of zeolitic materials applicable in industrial catalysis. Recently. synthesis of polymorph C of zeolite β and ITQ-21 has been reported, confirming the extremely high amount of research activity in this area.[27,28]

As for mesoporous molecular sieves. their synthesis opened a new subfield of molecular sieve chemistry. which has grown rapidly over the last 10 years. New synthetic approaches. different from those known for zeolites, have been applied. The variety of the synthetic procedures described and the differences in the textural properties due to different synthetic procedures, as well as to the high-temperature treatment, give evidence that mesoporous molecular sieves of different chemical compositions are interesting materials, not only for materials science but also for application as heterogeneous catalysts. support for immobilization of homogeneous catalysts, adsorbents, materials for synthesis of new types of inclusion compounds, etc. There is no doubt that research in this field will rapidly grow. and new types of mesoporous molecular sieves will be synthesized. Tailoring of the textural properties and industrial application of these materials in the near future are likely.

The first successful preparation of micro/mesoporous molecular sieves started an intensive search to optimize procedures of their synthesis, to increase their thermal stability, and to tailor their acid, base, and redox properties for possible application in heterogeneous catalysis. Although only a few syntheses of composite molecular sieves have been reported, it is clear that mastering this synthesis represents an important challenge in the area of porous materials. There is no doubt that molecular sieves represent a flourishing and expanding field of chemistry, and further interesting achievements and applications can be expected.

ACKNOWLEDGMENT

The long-term support of my projects focused on the synthesis, characterizations, and applications of zeolites and molecular sieves by the Grant Agency of the Academy of Sciences of the Czech Republic (A4040001) and the Grant Agency of the Czech Republic (104/02/0571 and 203/03/804) is gratefully acknowledged.

Zinc-Containing Enzymes and Their Models

Takashi Hayashi
Kyushu University, Fukuoka, Japan

INTRODUCTION

Zinc is one of the essential and widely used transition metals (Group 12) in biology, because it is the second most abundant transition metal in our body. Recently. the structures of over 300 zinc-containing proteins were determined, where the zinc atom acts as a strong catalyst as well as regulates the physiological process or fixation of the unique structural conformation of bioactive species. Zinc usually exists only in the dication state, Zn^{2+} with a closed d^{10} electronic configuration, indicating that no reduction-oxidation process occurs in physiological systems, whereas it is well known that zinc is the most common Lewis acidic metal cation in bioinorganic chemistry. A zinc-bound water molecule rapidly exchanges, because the ligand–zinc bond is kinetically labile. These features provide an effective hydrolysis function of the zinc complex through the activation of coordinated water. Therefore, it is of particular interest to study the metabolic conversion or degradation of biomolecules catalyzed by zinc enzymes. However, the mechanistic details of the enzyme function in the protein matrix are sometimes complicated, even though the structures of many zinc enzymes can be characterized by several different spectroscopies. On the other hand, a synthetic zinc complex related to the active site sphere will be a good tool with which to understand the role of the zinc ion and the complicated mechanism of catalytic reactions.[5,6] A great deal of interest focused on the design of excellent functional or structural models on zinc enzymes. In this article. several representative zinc enzymes and related functional models with supramolecular components will be discussed.

GENERAL MECHANISM OF HYDROLYSIS CATALYZED BY ZINC ENZYMES

It is known that the hydrolysis of peptides, proteins, or esters is accelerated by zinc-containing enzymes such as peptidases. lactamases, or dehydratases, even at neutral pH (Eq. 1), because a solvent water molecule readily binds to the strong Lewis acidic zinc ion to form $[Zn—OH_2]^{2+}$ (Eq. 2), and then the deprotonation of the coordinated water molecule occurs even at neutral pH (Eq. 3). In fact, a series of model studies demonstrated that the pK_a value of the coordinated water molecule decreases to as low as 7–8. The obtained metal-bound hydroxide species, $[Zn—OH]^+$ can then act as a nucleophile toward a hydrolyzable substrate. It is found that in some zinc-containing enzymes, the coordinated water molecule is not completely deprotonated. In such cases, a proton acceptor such as glutamate assists in the generation of the hydroxide complex (Eq. 4). In the enzymatic systems, the pK_a value of the coordinated water is controlled by the coordination number, ligand property, and amino acid residues near the zinc complex. Another catalytic pathway of the zinc enzyme is the displacement of a coordinated water molecule with a substrate (Eq. 5). For example, an alcohol is a substrate for a zinc complex in alcohol dehydrogenase, where a coordinated water molecule is replaced with an alcohol, and then deprotonation occurs to yield a zinc–alkoxide complex, $[Zn—OR]^+$, in the same manner as depicted by Eq. 3.

$$R—NH—CO—R + H_2O \rightarrow R—NH_2 + HO—CO—R \quad (1)$$

$$Zn^{2+}(\text{in protein}) + H_2O \rightarrow [Zn—OH_2]^{2+} \quad (2)$$

$$[Zn—OH_2]^{2+} \rightarrow [Zn—OH]^{+} + H^{+} \quad (3)$$

$$[Zn—OH_2]^{2+} + B^{-} \rightarrow [Zn—OH\cdots H\cdots B]^{+} \quad (4)$$

$$[Zn—OH_2]^{2+} + \text{Substrate} \rightarrow [Zn—\text{Substrate}]^{2+} + H_2O \quad (5)$$

INTRODUCTION TO REPRESENTATIVE ZINC ENZYMES

Shown in Fig. 1 is the three-dimensional active-site structures of four representative zinc-containing enzymes: carboxypeptidase[7] and β-lactamase[8] belong to the hydrolase family, while carbonic anhydrase[9] is one of

Encyclopedia of Supramolecular Chemistry
DOI: 10.1081/E-ESMC 120012699

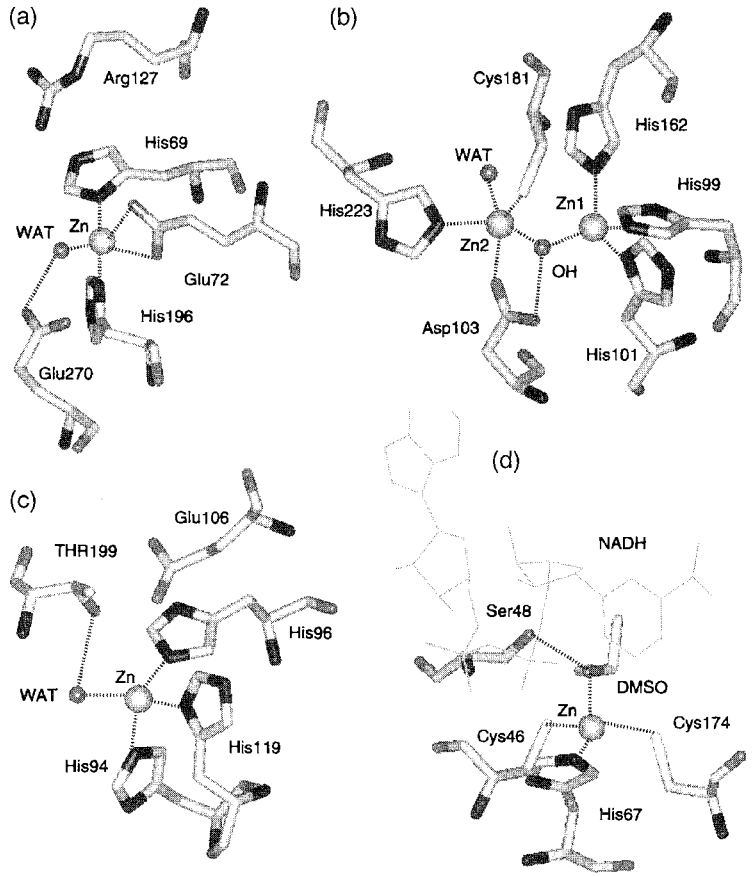

Fig. 1 Active site structures of four zinc-containing enzymes: (a) carboxypeptidase A from bovine pancreas. (b) β-lactamase from *Bacteroides fragilis*, (c) human carbonic anhydrase. and (d) horse liver alcohol dehydrogenase.

the famous lyases, and alcohol dehydrogenase[10] is classified as an oxidoreductase. All of these enzymes except for β-lactamase have four-coordinate zinc complexes with a normal or distorted tetrahedral geometry including a water molecule as the fourth ligand. In the case of some β-lactamases, there are two zinc sites, although the role of the second zinc atom is still not clear.

Carboxypeptidase A

The carboxypeptidase A, mainly isolated from bovine pancreas, is a metalloprotease that hydrolyzes peptide linkages. Particularly, the catalytic cleavage of the peptide in the presence of the enzyme preferably occurs at the C-terminal amide bond with a large hydrophobic amino acid side chain. such as phenylalanine, because the enzyme has a steady binding pocket for an aromatic ring. A proposed mechanism of initial step is shown in Fig. 2.[11] The zinc ion is coordinated by two histidines, one chelating (η^2-)glutamate and one water molecule, as shown in Fig. 1. The coordinated water is converted to the metal-bound hydroxide that is assisted by Glu270 as a general acid catalyst. The hydroxide then acts as the nucleophile to attack the peptide carbonyl carbon that is polarized with the assistance of Arg127. The tetrahedral obtained intermediate is stabilized by several interaction networks. It decomposes by proton donation from Glu270 and affords the final products via C—N bond cleavage.

β-Lactamase

The metallo-β-lactamases hydrolyze a series of β-lactam antibiotics, such as penicillin and cephalosporin derivatives. making them harmless to pathogenetic bacteria.[12] Thus. it is important to study the hydrolysis mechanism and prepare a clinically useful inhibitor. According to the three-dimensional structure of a zinc β-lactamase from *Bacteroides fraglis*, there are two zinc binding sites. where the two zinc ions, Zn1 and Zn2, are 3.5 Å apart and bridged by one hydroxide group; and Zn1 and

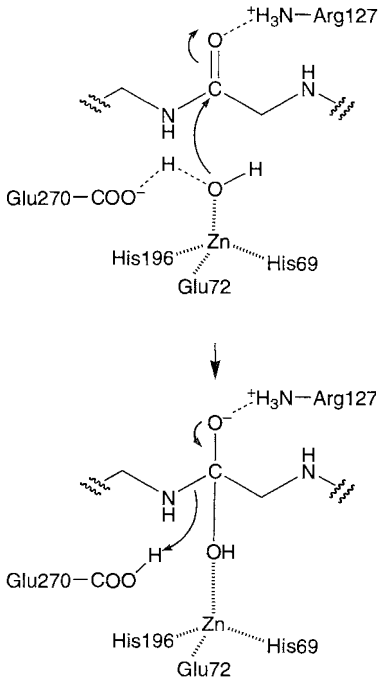

Fig. *2* A proposed mechanism of the nucleophilic attack of zinc-hydroxide to a carobonyl carbon of a peptide linkage.

Zn2 have a tetrahedral and trigonal-bipyramidal coordination geometry. respectively, as shown in Fig. 1. Although the mechanism of the N—C(=O) bond cleavage in the β-lactam is not completely clear, functional model studies suggested that the β-lactam antibiotics could be fixed at the active site by the interaction between a carboxylate of the β-lactam and one of the zinc ions (Zn2), and then the zinc-bound hydroxide acts as a nucleophile to attack the β-lactam. The intermediate species after the cleavage of the four-membered ring of the β-lactam is stabilized by two zinc ions. One zinc ion (Zn1) interacts with the carboxylate anion generated, and the other (Zn2) acts as a receptor of anionic nitrogen. Subsequent protonation of the intermediate species gives the hydrolytic opening product, which is antibiotic inactive.

Carbonic Anhydrase

The role of carbonic anhydrase is to reversibly convert carbon dioxide into bicarbonate. The structure of the active site containing one zinc ion is relatively simple compared to the carboxypeplidase A; however, it is one of the typical examples that demonstrates the nucleophilic attack at carbon by activated zinc-coordinated water.[''''] The catalytic zinc ion of carbonic anhydrase II is bound to three histidines and one water molecule to form a distorted tetrahedral geometry, as shown in Fig. 1. It is known that the pK_a value of the coordinated water molecule is approximately 7, indicating that the metal-bound hydroxide group is easily produced under physiological conditions, because deprotonation of the coordinated water is assisted by the Thr199 and Glu106 hydrogen-bonding network and a proton relay system including several histidines. The generated metal-bound hydroxide acts as a strong nucleophile to attack the carbon dioxide, and then the metal-bound carbonate is produced as an intermediate. The proposed reaction mechanism is summarized in Fig. 3. It is well-known that the hydrolysis equilibrium for CO_2 is fast. by diffusional control with a turnover number of 10^6 s^{-1}, indicating that the reaction is accelerated by a factor of 10^7 compared to that observed for the uncatalyzed reaction under physiological conditions, and hence, carbonic anhydrase represents a highly sophisticated catalyst.

Alcohol Dehydrogenase

Primary alcohols are metabolized to the corresponding aldehyde by mammalian liver alcohol dehydrogenase containing a catalytic site and a structural zinc site.[3,4] This enzyme requires a binding site for the dehydrogenase coenzyme NAD^+/NADH that directly catalyzes the oxidation of an alcohol or reduction of an aldehyde, because the zinc does not have any oxidation or reduction activity. The zinc ion located at the active site is tetrahedral coordinated by two cysteines, one histidine, and one water molecule. The coordinated water molecule must be replaced with the alcohol during the first step of the reaction. After the deprotonation of the alcohol to an alkoxide on the zinc ion, the subsequent proton transfer from the alkoxide to NAD^+ is accelerated to yield the corresponding aldehyde and NADH. For the reverse reaction from the aldehyde, the zinc ion interacts with the carbonyl oxygen of the substrate to polarize the C=O bond and accelerate the hydrogen transfer from NADH. According to the three-dimensional structure of the alcohol dehydrogenase, there is another zinc ion coordinated by four cysteines, and the role of the zinc might be fixation of the enzyme structure.

SEVERAL FUNCTIONAL **MODELS WITH SUPRAMOLECULAR** STRUCTURES FOR ZINC ENZYMES

The development of synthetic models for metalloenzymes is one of the most advanced fields in bioinorganic chemistry, because a well-defined model often gives us

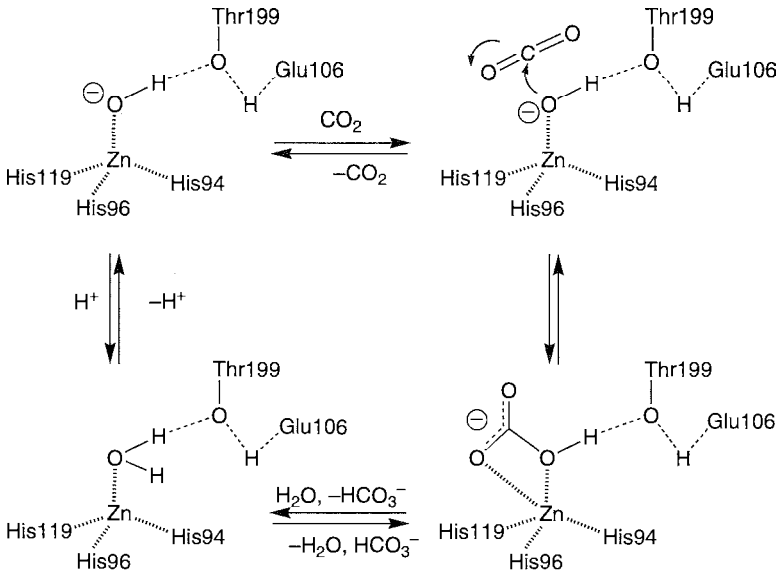

Fig. 3 A proposed catalytic mechanism of carbonic anhydrase.

a good suggestion about structure and function relationship\ and the complicated reaction mechanism of metalloproteins. Much effort on zinc enzyme modeling was devoted to demonstrating the catalytic importance of the Lewis acidity of the zinc atom by mimicking the active site. Reported herein are several representative models *focusing on the reactivity of zinc enzymes.*

Carboxypeptidase A Models

Model studies of carboxypeptidase A are limited. It is found that some zinc complexes can hydrolyze the carboxylic ester, however, there is no suitable functional model that demonstrates *the hydrolysis of normal* carboxamide *by* [Zn—OH]$^+$species.

β-Lactamase Models

It *is* important *to understand the mechanism of the cleavage of the (3-lactam ring catalyzed by* β-lactamase *involving a zinc atom as an active site, because the* zinc-containing *enzyme is a factor in bacterial resistance to the 0-lactam antibiotics such as penicillin, cephalosporin, and so on. The first functional model for* β-lactamase *was reported by* Kimura *and* coworkers.[14] They *demonstrated that the zinc complex involving* 1,4,7,10-tetraazacyclododecane ([12]aneN$_4$) forms *the* [Zn—OH]$^+$ *species under neutral conditions, and it accelerated the hydrolysis of benzylpenicillin in aqueous solution. In contrast, the native* β-lactamase *has two zinc atoms in the active site. From the three-dimensional structure information,* Lippard *and his coworkers recently prepared the unique functional models formed by dinuclear* Zn^{2+} *complexes as shown in Fig.* 4.[15,16] *For example, the observed rate constant for the hydrolysis of nitrocefin catalyzed by* [Zn_2 (BPAN)(μ-OH)(μ-O_2PPh_2)](ClO_4)$_2$, *where BPAN is* 2,7-*bis*[2-(2-pyridylethyl)aminomethyl]-*1.8-naphthyridine, is 2800–fold greater than that observed in the absence of a zinc complex at pH 7, whereas this value is comparable with that obtained by mononuclear zinc complexes. This finding indicates that the second* Zn^{2+} *does not activate the hydroxide as a nucleophile to nitrocefin. Moreover. the intermediate 2 in the (3-lactam hydrolysis based on the dinuclear zinc models* 1. *the* adduct *between dinuclear zinc complex and the opened nitrocefin, was characterized by* UV/Vis, *IR. and NMR spectroscopy, as shown in Fig.* 4.[17] *The structural data of the intermediate species suggest that two zinc* atoms *in the enzyme might play a role in the substrate binding sites, and the bridging hydroxide* intramolecularly *attacks the* β-lactam *antibiotics.*

Carbonic Anhydrase Models

Over the last two decades, a thousand structural and functional models for carbonic anhydrase were reported to address the features of the active site and the mechanism of the catalytic reaction. One of the earliest functional models is *the supramolecular composite of the* *bis*(histamino)cyclodextrin-Zn-imidazole *complex 3 that accelerates* CO_2 *hydration at* pH *7.0. although the catalytic activity is not good compared with the native*

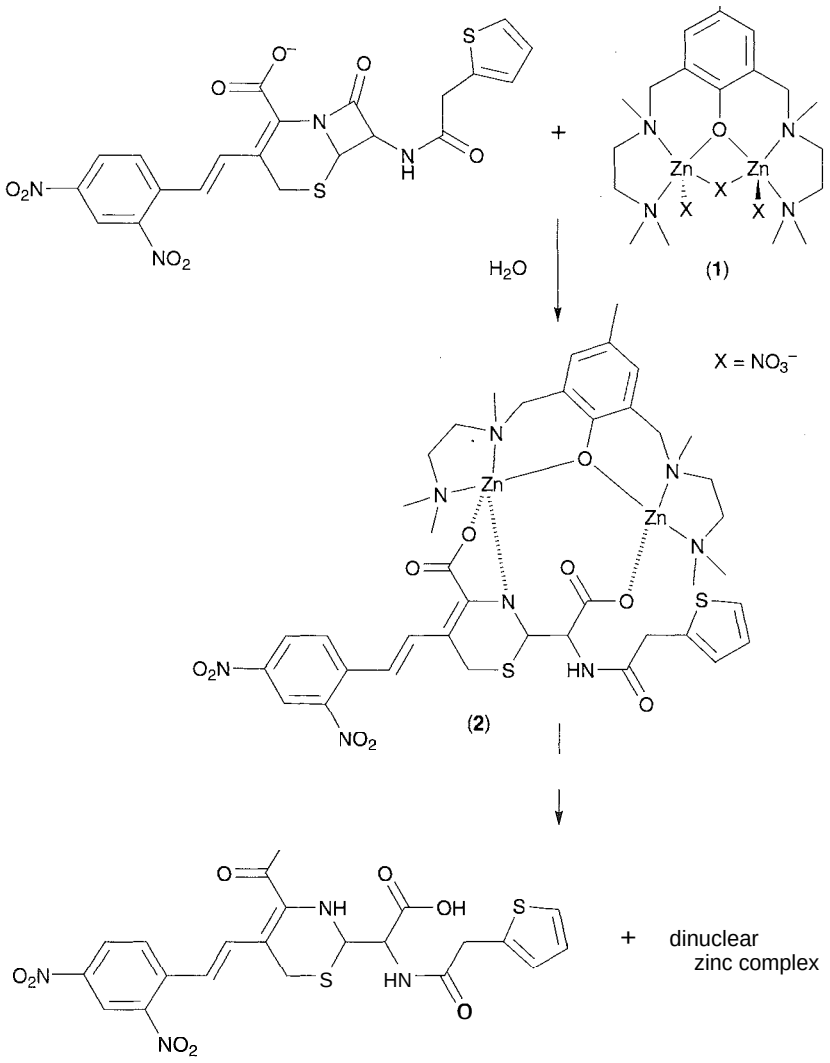

Fig. 4 Nitrocefin hydrolysis catalyzed by a dinuclear zinc(II) complex and its intermediate.

enzyme.[18,19] Kimura and coworkers demonstrated that the zinc(II) complex 4 with 1,5,9-triazacyclododecane, [12]aneN$_3$, as a ligand catalyzes the pH-dependent hydration of CO_2. Based on a titrimetric experiment, the pK_a value of Zn([12]aneN$_3$)·H$_2$O was determined to be 7.4. which is almost the same as that observed in the native carbonic anhydrase. The acceleration of CO_2 hydration was clearly observed in the region higher than pH 7.4. indicating that the zinc hydroxo species smoothly reacts with CO_2 under mild conditions.[20] The rate of the catalytic hydration of CO_2 also increased by 1,4,7,10-tetraazacyclododecane ([12]aneN$_4$) as a ligand. Eldik and coworker detcribed that an inflection point at pH 8.1 obtained in this reaction from the hydration rate by Zn([12]aneN$_4$)·H$_2$O 5 is almost comparable with the pK_a value of the deprotonation of the coordinated water.[21] Furthermore, Zn([12]aneN$_4$)·H$_2$O shows one of the highest catalytic activities of all reported zinc model complexes for the dehydration of HCO_3^- and hydration of CO_2, respectively. In contrast, Brown and coworkers prepared the *tris*(4,5-dialkyl-2-imidazolyl)phosphine-zinc complex 6, which mimics an active-site model for the carbonic anhydrase.[22] Although their models did not dramatically enhance the rate of interconversion between CO_2 and HCO_3^-, it is of interest to evaluate the catalytic mechanism using this system, because the coordination environment of the model zinc complex is an analog to that of the native enzyme, having a tetrahedra1 zinc center composed of three imidazoles and one water. Furthermore, Parkin, Vahrenkamp, and coworkers discussed the

intermediate of the catalytic reaction using *tris*(3,5-dialkylpyrazolyl)hydroboratozinc complex **7**.[23] Particularly. the hydroxide complex can smoothly react with CO_2 to yield a bicarbonate complex characterized by spectroscopy and then form the dimeric zinc complexes via a carbonate ligand bridge. The zinc complex obtained shows a unidentate or chelated bidentate coordination mode (8 or 9. respectively), which depends on the bulkiness of the substituted alkyl groups at the 3-position of the pyrazolyl ring, as shown in Fig. 5. From the ^{17}O-NMR study on the exchange of oxygen between CO_2 and $^{17}0$-labeled water, which is a critical process for the catalytic reaction of the carbonic anhydrase, it is concluded that the formation of a bidentate carbonate intermediate inhibits the displacement of the bicarbonate by water.[26,27] These results also rationalize the fact that the catalytic activity of $Zn[12]aneN_3$ is lower than that of $Zn([12]aneN_4)$, because the former complex may form the bidentate bicarbonate intermediate that decreases the displacement of the bound bicarbonate ligand by H_2O. In addition. Parkin and coworker recently reported the fact that protonation of the zinc hydroxide complex also inhibits the reactivity toward CO_2, indicating that the CO_2 hydration requires deprotonation of the coordinated water.[25] A series of model studies suggests that the catalytic activity of CO_2 hydration requires the deprotonation of the coordinated water and the prevention of the bidentate interaction of the carbonate with the zinc atom at the intermediate state.

Alcohol Dehydrogenase Models

To mimic the zinc-containing alcohol dehydrogenase enzyme, several groups focused on the complexation between an alcohol and the zinc complex and the subsequent hydrogen transfer from the obtained alkoxide complex to NAD^+ to yield the corresponding aldehyde derivatives (Fig. 6). Vahrenkamp and coworkers isolated the zinc alkoxide complex **10** with a *tris*(thioimidazolyl)hydroborate ligand from the reaction between the zinc hydroxide complex and phenols or trifluoroethanols.[26] Furthermore, the hydroxide and ethoxide interconversion in the zinc complex **7** with a *tris*(pyrazolyl)hydroborate as a ligand was also observed by Parkin and coworker.[27] In addition, Berreau and coworkers recently demonstrated that the zinc methoxide **11** with the *N*-2-(ethylthio)ethyl-*N*,*N*-*bis*(6-neopentylamino-2-pyridylmethyl)amine shows a significant hydrolytic stability due to the hydrogen bonding interaction between the methoxide and the N—H proton of the ligand, so the equilibrium is shifted to the zinc alkoxide from the zinc hydroxide, which mimics the native enzyme, where the alkoxide is stabilized by Ser48.[28] In contrast, Kimura and coworker demonstrated a hydride transfer reaction from 2-propanol to hydrogen acceptors such as a NAD^+ model or p-nitrobenzaldehyde by $Zn([12]aneN_3)$ **4**.[29] It is the first functional model for the alcohol dehydrogenase to demonstrate hydride transfer around the zinc coordination sphere.

CONCLUSION

Described in this article are four zinc enzymes and their representative functional models. Although the three-dimensional structures of many zinc enzymes were determined in the last decade, the dynamics and mechanisms of the catalytic process of the zinc enzyme are complicated and still not fully understood. Therefore, to resolve the nature of the active site in enzymes; it is necessary to prepare an appropriate model complex. From a series of studies by functional models, it is found that the pK_a of the coordinated water controlled by the ligand properties and the coordination mode of the substrate are essential to obtain catalytic activity for zinc enzymes. However, no functional models exhibit the activity observed by the native enzyme under physiological conditions. Thus, the goal that remains is to elucidate the significant difference in catalytic activity between the zinc enzymes and these models and then create a supramolecular composite of an artificial zinc enzyme that demonstrates the excellent catalytic function.

Zwitterion Receptors

INTRODUCTION

In a zwitterion, either of the charged functions is a likely site of recognition. Thus. a receptor specifically designed for the efficient recognition of a zwitterion should consist of at least two subunits, strategically arranged in a precise geometrical relationship. each of which is capable per se of binding one functional substructure of the substrate. The simultaneous recognition of additional part-structures of the guest should be performed in order to achieve selectivity and increased stability of the host–guest complex.

Since Pedersen's seminal article[1] published 35 years ago, the amount of research done in the field of molecular recognition of cations is overwhelming.[2] However. for a number of reasons, much less interest was focused for a long time on the molecular recognition of anions, and significant progress in the field has been achieved only recently.[3] Consequently, the entire field of molecular recognition of zwitterions was still in its infancy in the mid-1980s.

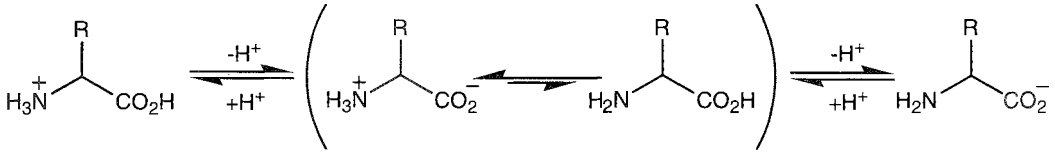
For the purpose of classification, this short article is divided into three sections, in accordance with the strategy used to achieve recognition of the ionic subunits of the zwitterion's guest. The strategy used in the design of receptors belonging to the first category is simply based on charge complementarity, which means that a major driving force for recognition is provided by a pair of antiparallel salt bridges. A second group is formed by receptors in which a neutral multidentate ligand is deputed to provide a recognition site for the cationic end of the zwitterion. Finally, in the third section, the only available example of a betaine receptor is discussed.

Becauce of their biological relevance, most of the work published in this field refers to the recognition, and the closely related problem of transport across liquid membranes. of the zwitterionic form of amino acids, which is the most abundant form in solution at pH values around neutrality (see Eq. I below).

ZWITTERIONIC RECEPTORS

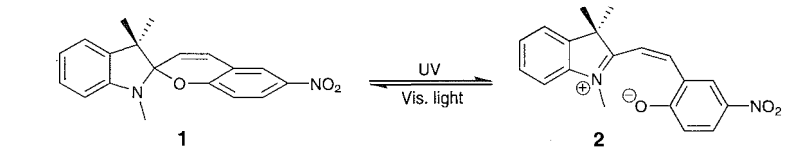
a-Amino acids are mostly in zwitterionic form around neutral conditions. These are highly solvated species that represent a significant challenge for molecular recognition, because the electron densities of the carboxylate and the ammonium functions are greatly affected by their mutual vicinity, causing the binding forces of complementary groups of the receptor to be less effective for complexation. Although receptors based also on positively and negatively charged binding sites (zwitterionic receptors) would in principle be the molecules of choice for recognition, these designs are often of limited interest, because they tend to collapse internally or to aggregate into dimers or oligomers.

The first successful example of amino acid transport under neutral conditions, using a receptor designed in such a way as to provide charge complementarity to the zwitterionic form of the ainino acid (Eq. 2). was reported by Sunamoto and coworkers in 1982.[5] Upon UV irradiation, the photospiran 1 is converted to the purple form 2 bearing a merocyanine dye skeleton. When an aqueous suspension of single-walled liposomes containing the amino acid in the interior and I in the bilayer was

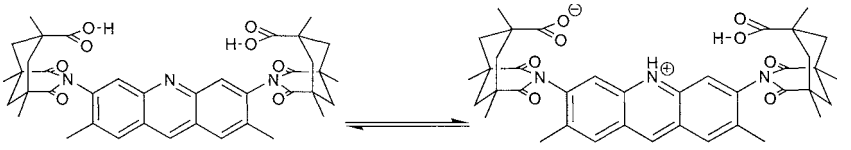


(1)

DOI: 10.1081/E-ESMC 120012722



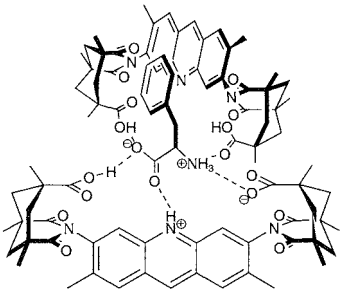
1 2



3 4

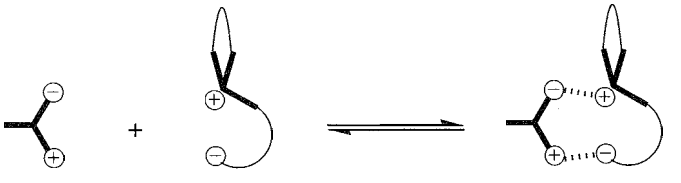
UV irradiated for 20 min. followed by being visible light irradiated for 5 min, a significant transfer of phenylalanine from the liposome to the outer solvent took place. No transport of amino acid was observed in the dark or in the absence of 1. The system suffers from several drawbacks, including the question of the integrity of the membrane under the conditions of the experiment and the photochemical instability of the photospiran **1.** However, in spite of such limitations. Sunamoto's work established for the first time the simple concept of charge complementarity for recognition and transport of the zwitterionic form of amino acids, as schematically depicted in Eq. 2 (see below).

This concept was adopted shortly afterwards by Rebek and coworkers.[6,7] Their acridine-based derivative ***3*** features a molecular cleft endowed with receptor properties toward guests of complementary size, shape, and hydrogen-bonding capacity. The zwiiterionic form 4 indicated by ^{1}H-NMR spectra to be the dominant species was held responsible for the successful extraction of phenylalanine, tryptophan, and tyrosine methyl ether from their aqueous solutions into chloroform with efficiencies of ca. 50%, accounted for by a 2:1 ternary complex. The same system was employed as an artificial carrier for amino acids across bulk liquid membrane. The aryl/aryl stacking interaction clearly revealed by NMR spectra, from which the structure of the intermolecular ternary complex 5 was established, provides a rationale for the finding that amino acids bearing a lipophilic side chain. such as leucine and isoleucine, were not extracted into chloroform.



5

The schematic representation of the proposed structure of the complex between tryptophan and β-cyclodextrin modified with pyrrolidinyl and carboxyl subsiituents at neighboring AB (or BA) rings (6. only one regioisomer is shown) effectively illustrates Tabushi's design[s1] of receptors for amino acids based on triple recognition, namely, a combination of hydrophobic interaction between indolylmethyl and a cyclodextrin cavity, and a pair of complementary electrostatic interactions between ionic groups. Stability constants for complexation of D- and L-tryptophan in aqueous solution were in the range of 36–54 M^{-1} with little preference, if any, for the D-enantiomer. Comparison with a binding constant of 13 M^{-1} obtained with unsubstituited β-cyclodextrin shows that the hydrophobic effect is a major driving force for complexation.

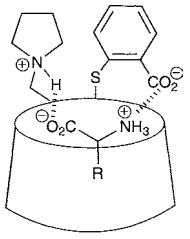


(2)

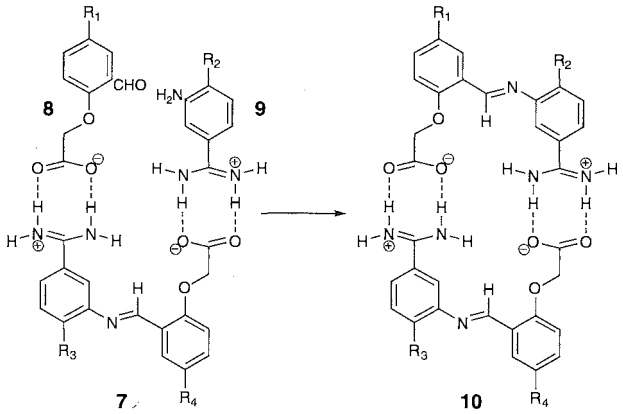
amino acid 2

The high stability of the amidinium-carboxylate salt bridge (K = *350* M^{-1} in Me_2SO at 35°C, based on simple model compounds) provides the basis for the simple self-replicating system described by von Kiedrowsky.[9] Anils of type **7** are not only capable of self-recognition via a pair of identical antiparallel salt bridges with four hydrogen bonds (as shown in duplex **10**), but also of acting as a template for Shiff-base bond formation between formylphenoxyacetate **8** and aminobenzamidinium **9** precursors. In this sense, anils **7** act as receptors of the zwitterionic transition states in the autocatalytic processes leading to self-replication.

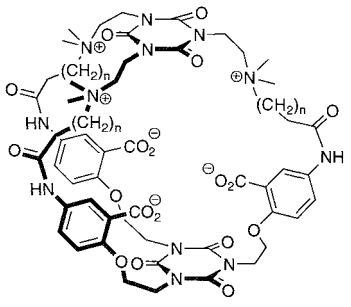
The water-soluble macrobicyclic host **11** synthesized by Askew[10] features three quaternized nitrogens in the molecular backbone and an equal number of convergent

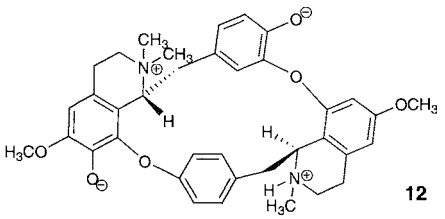


6



7 **10**





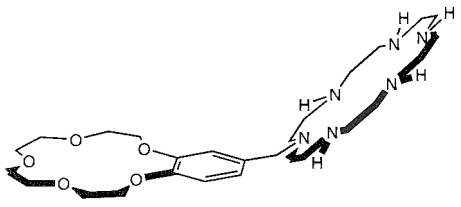
12

carboxylates. NMR evidence indicates that zwitterionic γ-aminobutyric acid (**GABA**), with size that matches that of the host cavity, is strongly complexed with a K value of about *3* x 10^3 M^{-1}. Much lower binding affinities are observed with glycine and 6-aminohexanoic acid, which are too short and too large, respectively, to match the host cavity size. The complexation properties of the zwitterionic form of the macrocyclic alkaloid (+)-tubocurarine **12** were investigated by Uatsimirsky et al.[11] The (+)-tubocurarine shows a moderate affinity toward phenylalanine at pH = 9.0, with a preference for the D-form (K = *30* ± 9 M^{-1}) over the L-form (K = 12 ± 2 M^{-1}).

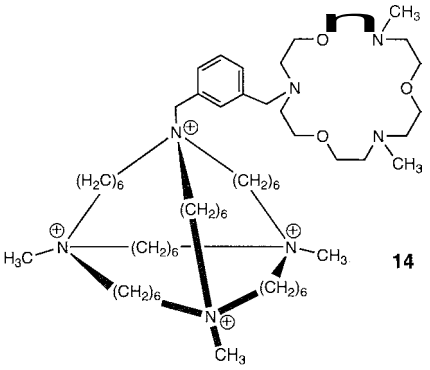
RECEPTORS BASED ON CROWN ETHERS AND RELATED IONOPHORES

The discovery that crown ethers. besides metal ions. complex ammonium ions via hydrogen bonding to the oxygen donors dates to 1967.[1] Thus, the use of crown ethers and related ionophores as docking sites for the $-NH_3^+$ function of amino acids is an obvious choice. It must be borne in mind. however, that the nearby carboxylate considerably diminishes the likelihood that an ammonium will form hydrogen bonds with lone pair donors. This explains why a large number of receptors for amino acids were designed for single-charge substrates and not for zwitterions. Nevertheless, a sizable number of examples are available, where binding of zwitterionic amino acids was obtained by combining a crown ether or related ionophore moiety with a subunit suitable for carboxylate recognition. In addition, the rich variety of side chains of amino acids offers the potential for selective recognition.

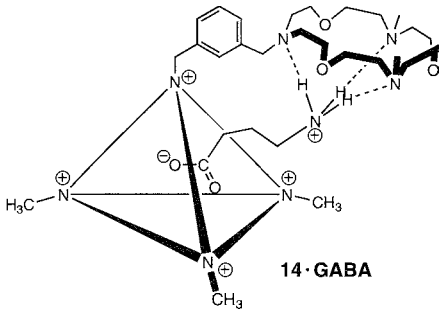
The first attempts at receptors for carboxylate concentrated on protonated polyazamacrocycles.[12,13] These compounds bind their guests via a combination of electrostatic interactions and hydrogen bonds. An early example of a ditopic receptor composed of a macrocyclic polyamine and crown ether subunit was reported by Kimura.[14] The triprotonated form of **13** forms 1:1 complexes with zwitterionic compounds, such as glycine,



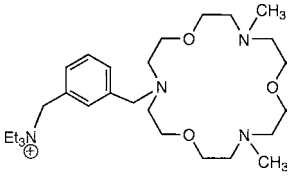
13



14



14·GABA

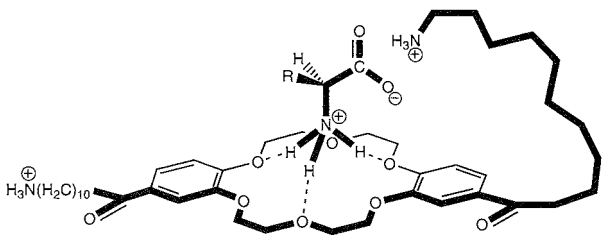


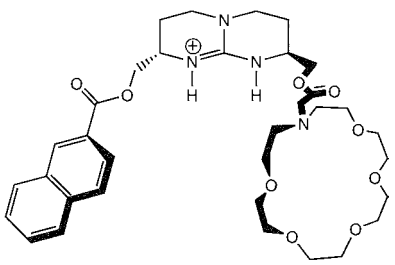
15

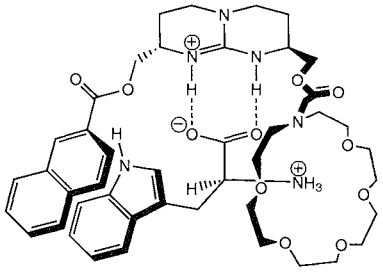
β-alanine, $H_2N(CH_2)_3CO_2H$, $H_2N(CH_2)_5CO_2H$, and diglycine in aqueous solution at pH values close to neutrality, with conditional binding constants of the order of $10^2\ M^{-1}$. Because the monotopic model compounds do not interact with the given amino acids under the same conditions, it was argued that the strong binding to **13** is a concerted action resulting from interaction of the carboxylate with the protonated azacrown moiety and from the primary ammonium function with the benzo-crown counterpart.

In place of a protonated macrocycle polyamine. Schmidtchen's ditopic receptor **14**[15,16] features a macrotricyclic quaternary ammonium unit for complexing carboxylate, and an azacrown macrocycle serving as an anchor group for the $-NH_3^+$ end, as schematically shown in the **14·GABA** complex. However, 14 showed no discrimination between GABA and its higher homologue $H_2N(CH)_6CO_2H$ in MeOH/H_2O 9:1, and the model compound 15 turned out to be a stronger binder than 14. Barboiu and coworkers[17] isolated in the solid state a series of complexes between a large number of L-amino acids and a macrocyclic receptor composed of a dibenzo-18-crown-6 unit endowed with two protonated 10-aminodecylcarbonyl side arms. Elemental analysis and spectroscopic data pointed to the formation of 1:1 complexes 16 in which the ammonium end group of the amino acid is bound to the crown ether, while the carboxylate forms a salt bridge with one of the ammonium end groups of the host.

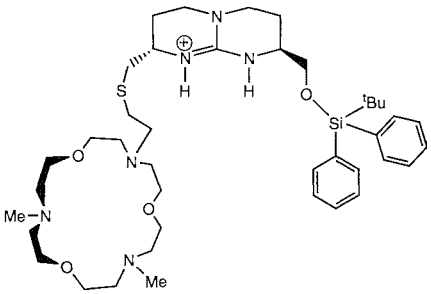
An efficient combination of monotopic receptor subunits characterizes de Mendoza's tritopic receptor **17** [(S,S)-isomer shown] for the enantioselective recognition of α-amino acids.[18] Binding sites for carboxylate and ammonium are provided by nonself-complementary counterparts, such as a guanidinium and crown ether. respectively. Additional structural features are the aromatic surface of naphthalene for a stacking interaction of the side chain of aromatic amino acids and a chiral structure for enantioselective recognition. Thus, in a single extraction experiment, **17** removed about 40% of L-triptophan and L-phenylalanine from saturated aqueous solutions into dichloromethane, whereas the D-forms were extracted to a negligible extent. The high degree of chiral



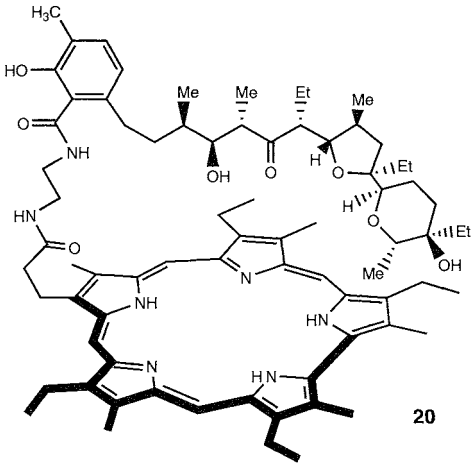




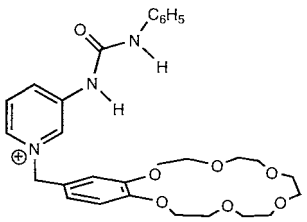
18



19



20

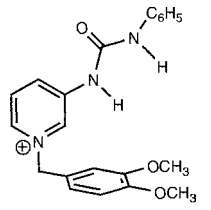


21

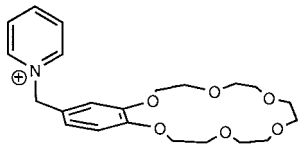
recognition is understood on the basis of three simultaneous interactions of the guest with the binding units of the host, as depicted in the proposed structure 18 of the complex with L-triptophan. Detailed molecular mechanics and dynamic calculations[19] showed that the salt bridge contributes about one half of the total binding, whereas the remaining attractive interactions are provided by the aza-crown ether and, to a minor extent. by the naphthalene moiety. The closely related receptor 19 was synthesized by Schmitdchen et al.[20] Thanks to the strongly hydrophobic silyl ether moiety, receptor 19 turned out to be much more effective than 17 in the extraction of a number of amino acid zwitterions from water to dichloromethane, but only a modest enantioselectivity was observed (40% ee for D,L-phenylalanine).

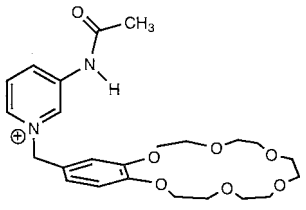
Although the underlying strategy is analogous to that of Kimura's receptor **13,** there are two elements of novelty in Sessier's design[21] of ditopic receptor 28 that features a sapphyrin unit for binding in its protonated form to carboxylate, and the naturally occurring ionophore lasalocid as the ammonium binding group. Receptor 20 acts as an efficient and selective carrier for aromatic n-amino acids, with a preference for phenylalanine > triptophan > tyrosine, and for L-amino acids over the corresponding D-enantiomers.

Instead of positively charged groups, neutral moieties can serve the purpose of providing docking units for carboxylate via hydrogen bonding. Receptor 21, synthesized by Joeng and Park,[22] combines benzo-18-crown-6 and urea functionalities for binding the ammonium and carboxylate groups, respectively, of zwitterionic amino acids. Receptor 21 extracted with high efficiency amino acids with nonpolar side chains. such as phenylalanine, isoleucine, leucine, and triptophan, from their aqueous solution into $CHCl_3$. Unlike 21, none of the model compounds 22 through 24 dissolved phenylalanine and isoleucine in $CHCl_3$. Clearly, the two binding subunits in 21 are cooperatively involved in the hydrogen-bonding

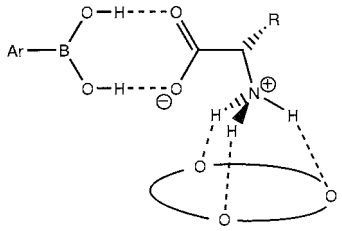


22





24



25

interactions with the ammonium and carboxylate end groups of the amino acids. Reetz's strategy[23] to bind and lipophilize zwitterionic amino acids involves the novel hydrogen-bonding interaction between arylboronic acids and the carboxylate group. in combination with the usual interaction between crown ethers and the ammonium function, as schematically depicted in 25. The transport rate of L-phenylalanine through $CHCl_3$ in the presence of crown-ether-modified arylboronic acids 26. **27a**, **27b** was very low for 26 and increased in the order 26 < 27a < **27b**. However, the transport rate in the presence of **27b** was lower than that observed in the presence of a mixture of phenylboronic acid and 18-crown-6, strongly suggesting that the geometry in **27b** is far from ideal for optimal cooperative binding of the two subunits.

Interaction with a metal ion may provide a suitable docking site for the carboxylate of a zwitterionic amino acid, on condition that the receptor molecule is endowed with a multidentate ligand substructure, in which the metal ion is implanted by a complexation process that leaves the cation coordinatively unsaturated. The above strategy is well illustrated by the ternary complex 28, isolated in the solid state (picrate or BF_4^- counterion) by Barboiu and coworkers.[24] Their bis-macrocyclic ligand is capable of multiple recognition of zwitterionic phenylalanine by combining various noncovalent interactions. The Na^+ cation, preferentially complexed by the benzo-15-crown-5, is anion paired to carboxylate, whereas the benzo-18-crown-6 moiety is hydrogen bonded to the $-NH_3^+$ function, and additional stabilization comes from a $\pi-\pi$ stacking interaction. Besides a benzo-18-crown ether moiety, ligand 29 contains the elements of the tetradentate nitrogen ligand *tris*(2-pyridyl-methyl)amine that forms stable complexes with metal ions such as Zn(II) and Cu(II). Canary et al.[25] measured the equilibrium constants for complexation of $29{\cdot}Cu^{2+}$ with a series of amino acids $^+H_3N(CH_2)_nCO_2^-$ in 50% aqueous acetonitrile at pH = 5.8. The measured K values (M^{-1}) were <40 for n = 2, 100 for n = 3. 91 for n = 4, 131 for n = 5, 57 for n = 6. and 22 for n = 7, to be compared with a K value of 40 for AcONa. Optimal complexation with 6-aminohexanoic acid was taken as an indication of a cleft-like arrangement of binding sites approximately 6.5 Å apart, with coordination of $-CO_2$ to the metal ion and concomitant hydrogen bonding of $-NH_3^+$ to the crown-ether oxygens. In addition to alkali and transition metal ions, lanthanides are used as carboxylate recognition sites in ditopic receptors for zwitterionic amino acids. Liquid–liquid extraction experiments of several amino acids from their aqueous solutions at pH = 5.9–6.2 into dichloromethane using ditopic receptor **30**,[26] showed that only with M = Er was the extraction ability of **30** higher than that obtained with a mixture of monotopic model receptors. This was taken as evidence that zwitterionic amino acids are cooperatively bound to the erbium center and to the crown-ether ring.

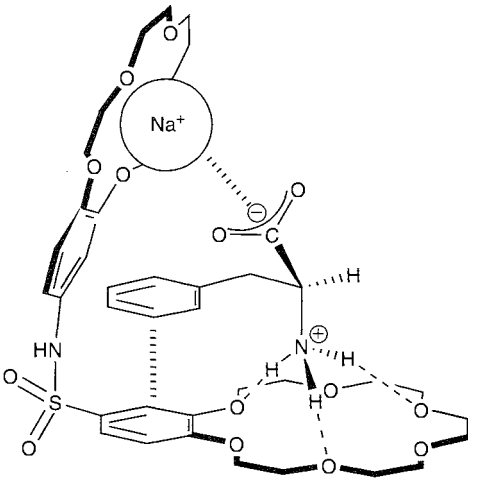
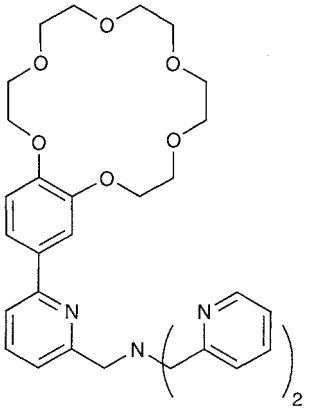
BETAINE RECEPTORS

Designing ditopic receptors for a betaine such as dioctanoyl-L-α-phosphatidylcholine **31** poses a difficult problem, because recognition of the trimethylammonium end group cannot take advantage of hydrogen-bonding interactions with negatively charged or electrically neutral

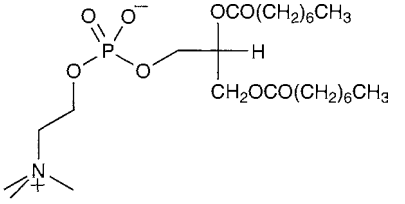


28

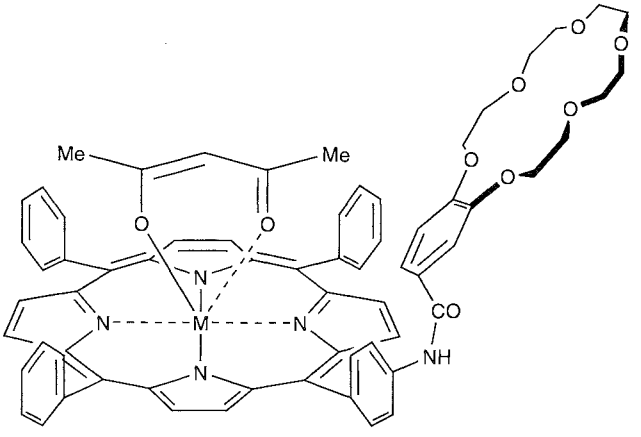
donors that have proved to be effective in the recognition of the primary ammonium function. Inspiration for the design of a suitable receptor for **31** came from the key interactions found in the crystal structure of the Fab domain of the McPC 603 antibody complexed with phosphorylcholine,[27,28] in which the phosphate group is engaged in a salt bridge with Arg 52H, and the quaternary ammonium head establishes a cation–π interaction with the aromatic residues of a number of amino acids. Thus, receptor **32**, designed by de Mendoza et al.,[29] contains a bicyclic guanidinium for the recognition of phosphate monoanion, and a calix[6]arene subunit for the complexation of the trimethylammonium head through cation–π interactions. NMR evidence was reported that upon mixing equimolar amounts of **31** and **32** in CD_2Cl_2 and $CDCl_3$, a stable complex is formed, in which the amide proton and one of the guanidinium protons are strongly hydrogen bonded to the phosphate, and the choline trimethylammonium head is included in the cavity of the

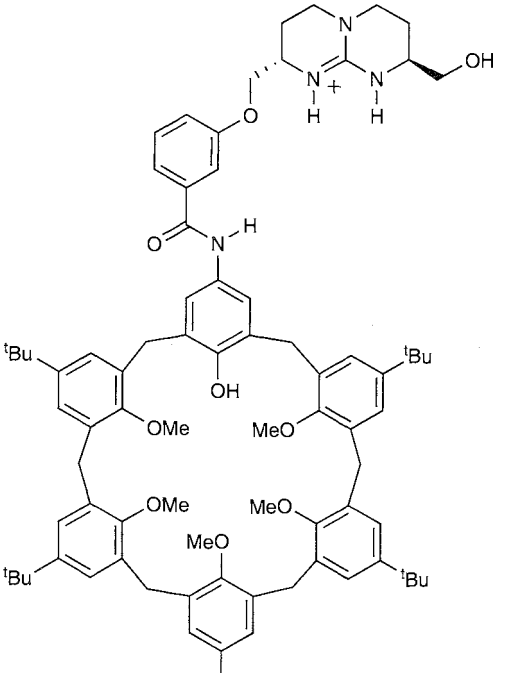


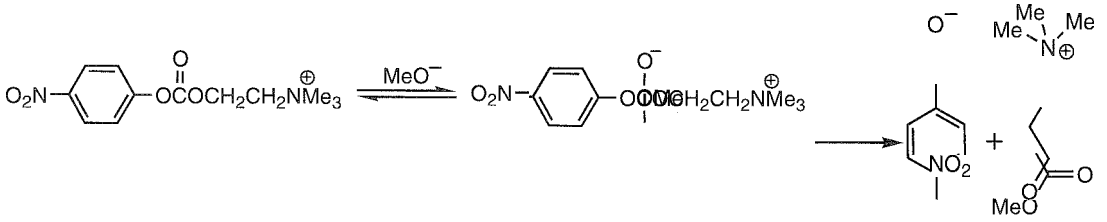
29



31







(3)

calix[6]arene in its cone conformation, as shown in the energy minimized structure 33, resulting from a detailed molecular dynamics study in a box of chloroform. Although binding of 31 by receptor 32 in chloroform ($\Delta G^\circ = -6.7$ kcal/mol) was as strong as binding of phosphorylcholine by McPC 603 in water ($\Delta G^\circ = -6.6$ kcal/mol), the former is enthalpically driven by the electrostatic contribution in the apolar solvent, while the latter has an entropic origin (desolvation of the charged ligand in water).

In view of the strong structural similarities of phosphate diesters with the tetrahedral intermediates involved in the $B_{Ac}2$ hydrolysis of esters, the former are good transition state analogues for the given reaction. This notion suggested that 32 would catalyze the cleavage of choline esters under basic conditions. In fact, it was found[13] that the methanolysis of choline p-nitrophenylcarbonate in $CH_3OH/CHCl_3$ 1:99 (v/v) in the presence of Hünig base buffer (Eq. 3) was catalyzed with high turnover efficiency by receptor 32 ($k_{cat}/k_{uncat} = 600$). Much lower rate enhancements were brought about by equimolar mixtures of monotopic model receptors, showing that the two subunits in 32 bind to the zwitterionic transition state with a high degree of synergism.

CONCLUSION

Despite the above examples, the design of molecular receptors or membrane carriers for zwitterions such as natural amino acids is still a challenging task for the supramolecular community. Strong solvation and nearby opposite charges conspire against complexation or transport by complementary binding sites in synthetic candidates. Zwitterionic receptors are prone to collapse by self-assembly, so the designs have to be carefully drawn so as to use binding sites that are noncomplementary to each other. To achieve selectivity among the various members of the amino acids family is by no means free of difficulties, unless structural differences in the side chains (i.e., aromatic versus aliphatic side chains, presence of functional groups) smooth the way for efficient discrimination. This is closely related to the problem of chiral recognition, as the highest differences in binding constants among the enantiomers are to be expected for similarly weighted three-point contributions of the binding subunits.

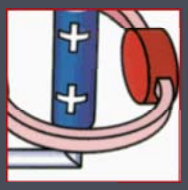
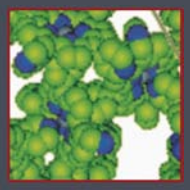
ENCYCLOPEDIA OF SUPRAMOLECULAR CHEMISTRY





EDITED BY

JERRY L. ATWOOD
JONATHAN W. STEED

Pre-publication praise. . .

"...the time is ripe for an Encyclopedia of Supramolecular Chemistry...It will be of great value."—Jean-Marie Lehn, Supramolecular Chemistry Laboratory, Universite Louis *Pasteur, Strasbourg,* France, and Winner, 1987 Nobel Prize in Chemistry

"...the most ambitious undertaking in the field of supramolecular chemistry... well done!"—Jerald *S.* Bradshaw, *Brigham* Young University, Provo, Utah, U.S.A.

"...this Encyclopedia will be of immense use to both experts and those with growing interest in supramolecular science...[a] masterpiece."—Antonio Bianchi, University of Florence, Italy, and International Scientific Committee, International Symposium on Macrocyclic Chemistry

about the encyclopedia . . .

Crystallizing a rapidly expanding interdisciplinary field, this two-volume Encyclopedia of Supramolecular Chemistry offers authoritative, centralized information on the topic. Designed for specialists and students alike, the Encyclopedia simultaneously covers the fundamentals of supramolecular chemistry and sets the standard for relevant future research.

Commencing with a foreword by Jean-Marie Lehn, user-friendly and high-quality articles *parse* the latest supramolecular advancements in the areas of chemistry, biochemistry, biology, environmental and materials science and engineering, physics, computer science, and applied ma*thema*tics.

Guided by editors at the fore of supramolecular research and an elite international editorial advisory board, Atwood and Steed's Encyclopedia encompasses concepts in crystal engineering...DNA as a supramolecular scaffold...energy and electron transfer in supramolecular systems...imprinted polymers...macrocyclic synthesis—templates, high dilution, and high pressure...molecular-level machines...natural strategies for the molecular engineer...self-assembly...soft/smart materials...supramolecular chirality...and much more in the rich expanse of its more than 200 entries.

about the editors. . .

JERRY L. ATWOOD is Curators' Professor and Chair of the Department of Chemistry at the University of Missouri-Columbia. The founder or cofounder of three journals, current editor of The Journal of Supramolecular Chemistry, and an associate editor of Chemical Communications, he has over 550 refereed papers, 20 book chapters, and ten patents to his name. Along with Dr. Steed, he is coauthor of the influential textbook Supramolecular Chemistry (John Wiley & Sons, Inc.). Awarded the Izatt-Christensen International Macrocyclic Chemistry Award (2000) and the University of Missouri President's Award for Research and Creative Activity (2000), Dr. Atwood received the B.S. degree (1964) from Southwest Missouri State University, Springfield, and the Ph.D. degree (1968) from the University of Illinois at Urbana-Champaign.

JONATHAN W. STEED is a Reader in Inorganic Chemistry at the University of Durham, United Kingdom. An associate editor of the New Journal of Chemistry, Dr. Steed is the author of more than 170 research papers and numerous reviews, book chapters, and popular articles. Past collaborations with Dr. Atwood culminated in the development of a new class of supramolecular hosts for anions, as well as the publication of Supramolecular Chemistry (John Wiley & Sons, Inc.). The recipient of the Royal Society of Chemistry Meldola Medal (1998), Dr. Steed received the B.Sc. (1990) and Ph.D. (1993) degrees from University College London, United Kingdom.
