Chapter 114

Acute myeloid leukemia in adults: mast cell leukemia and other mast cell neoplasms

Richard M. Stone, MD ■ Charles A. Schiffer, MD

Overview

Acute myeloid leukemia (AML) is the most common variant of acute leukemia occurring in adults, comprising approximately 80% of acute leukemia cases diagnosed in individuals of age >20 years. Remarkable advances in transfusion medicine, treatment of infections, development of potent antiemetics, improved chemotherapeutic approaches, and increased use of safer allogeneic transplantation have led to an improved outcome at least in younger patients. Moreover, a more sophisticated understanding of pathophysiology, particularly in the area of genomics, may soon lead to less toxic, patient-specific, and more effective therapies. At present, approximately 80% of younger (age <60 years) adults and 30%–50% of all older patients achieve complete remission (CR) defined as a morphologically normal bone marrow with reasonable neutrophil and platelet counts and no evidence of extramedullary disease. Varying with patient age and other biologic factors, 10–70% of these complete responders can be expected to achieve long-term survival with the likelihood that most of these individuals are cured of their disease. However, AML is largely an intrinsically chemoresistant disease, the outcome in older adults has changed little, and the chemotherapeutic approach has remained stagnant.

Introduction

Acute myeloid leukemia (AML) affects adults of all ages, but is particularly common in older adults. The median age of patients with AML is approximately 70 years ([Figure 1](#)). AML can present as either a de novo leukemia without an apparent antecedent illness or an evolution from marrow disorders such as myelodysplasia, myeloproliferative neoplasms, aplastic anemia, and Fanconi anemia, or after the administration of therapy for other types of cancers or nonmalignant disorders.^{1–4} AML presenting without prior marrow disease or anti-neoplastic therapy is termed de novo, whereas other types are considered secondary. Such terms may be less important predictors of response to therapy and long-term outcome than the mutational profile reflecting the biological heterogeneity of this condition.⁵ Proper care of patients with AML is a multidisciplinary effort, benefiting from a team approach. Expertise in transfusion medicine, infectious disease, placement and care of indwelling catheters, nutrition, and antineoplastic drug pharmacology are required, as well as sophisticated diagnostic laboratory facilities and psychosocial counseling for both patients and their families are needed. Optimally, allogeneic stem cell transplant, currently used in patients up to age 75, should be available. These disciplines are described elsewhere in this book, but their critical importance in the care of the leukemia patient cannot be overestimated.

(a)

Induction treatment	Total	Deaths	Censored	Median survival
Standard dose (45 mg/m ² /day)	330	199	131	15.7 mo
High dose (90 mg/m ² /day)	327	168	159	23.7 mo

(b)

Induction treatment	Total	Deaths	Censored	Median survival
Standard dose (45 mg/m ² /day)	180	95	85	20.7 mo
High dose (90 mg/m ² /day)	178	71	107	34.3 mo

(c)

Induction treatment	Total	Deaths	Censored	Median survival
Standard dose (45 mg/m ² /day)	59	46	13	10.2 mo
High dose (90 mg/m ² /day)	63	45	18	10.4 mo

Figure 1 Data from ECOG demonstrating that overall survival in AML patients less than age 60 is approximately 40% and varies according to the cytogenetic risk and daunorubicin dose.

Pathogenesis and etiology

Pathophysiology

The pathophysiology of AML can be partially explained by the acquisition of genetic changes in hematopoietic stem cells that both promote self-renewal and impair normal hematopoietic differentiation, resulting in an accumulation of immature cells. The genetic landscape of de novo AML has been recently characterized.⁶ An average of five mutations are found in an individual's leukemia cells and “only” 30 mutations are recurrent (observed in more than 3% of patients). Of the 30 recurrent mutations, several are relatively common, including gain-of-function mutations, which are targets for therapy in active development. FLT3 is a transmembrane tyrosine kinase, which is mutated in approximately 30% of patients with AML.⁷ Approximately three-quarters of these mutations are length or internal tandem duplication (ITD) mutations, in which the protein is elongated in the juxtamembrane region by three to more than 100 amino acids. This type of mutation is associated with an adverse prognosis because of a high relapse rate. Both the ITD mutation and the less common tyrosine kinase domain point mutation (usually D835Y) cause ligand-independent constitutive activation of the receptor. There are several FLT3 inhibitors in active development, both as single agents and in combination with chemotherapy in mutant FLT3 patients. A second common mutation is a point mutation in the NPM1 shuttle protein.⁸ Such mutations, particularly if occurring in patients with a normal karyotype without an associated FLT3 mutation, confer a favorable prognosis.⁹ Mutations in the Ras guanine nucleotide-binding protein occur in approximately 20% of patients with AML and are associated with increased proliferation.¹⁰ Attempts to inhibit posttranslational modification, a required step for activation of Ras, have been largely unsuccessful in AML.¹¹ Ras pathway interruption, such as with MEK inhibitors (useful in melanoma and other solid tumors), shows promise.¹² Mutations in the isocitrate dehydrogenase genes IDH1 and IDH2 occur in approximately 20% of patients with AML (~10% for each case).¹³ While the prognostic significance of these mutations is unclear, they cause the neomorphic production of 2-hydroxyglutarate (2HG) rather than the usual reaction product, alpha-ketoglutarate. 2HG levels may correlate with disease activity.¹⁴ Inhibition of IDH1 or IDH2 with small molecules may prove to be a fertile therapeutic intervention. Mutations in transcriptional machinery and mutations in enzymes, which are epigenetically active (posttranslational modification of the DNA) potentially leading to profound effects on gene expression, are common in AML.⁶ DNMT3, mutations occurring in approximately 20% of patients with AML,¹⁵ confer an adverse prognosis, although may be associated with a response to dose-intensified daunorubicin during induction.¹⁶ The presence of some of these so-called epigenetic modifying enzymes such as ASXL1, EZH2, and TET2 is often associated with AMLs that have arisen from a myelodysplastic syndrome (MDS) prodrome. TP53 mutation confers a bleak prognosis.¹⁷ On the contrary, CEBP α (biallelic) mutations are favorable.¹⁸

Genetic complexity of AML is an important feature of disordered molecular pathophysiology. The epigenetic profiles¹⁹ of AML can differ widely and perhaps suggest a specific therapy. Specific epigenetic profiles are found in distinct cytogenetic subsets of AML. Moreover, because of either mutations or altered patterns of genome regulation, messenger RNA²⁰ and indeed microRNA expression

patterns offer both pathophysiological insights and prognostic information. For example, microRNA expression patterns, particularly with moieties that control immunological regulation, have been found to play an important role in AML.²¹ Integration of the vast potential array of data including genomic lesions, epigenomic changes, and RNA and microRNA expression patterns yield an enormous amount of information and will be the subject of intense research in the future. The overexpression of many specific genes such as BAALC²² or WT1²³ has been shown to confer an adverse prognosis, but their independent significance remains to be confirmed.

Genetic changes in AML were first recognized by the identification of genes at cytogenetic break points involved in balanced translocations. Many of these chromosomal abnormalities, for example, t(8;21), t(15;17), and inv(16), are associated with specific AML subtypes and are of prognostic importance. The fusion proteins generated by the translocation generally result in disruption of transcription factors, which is believed to be critical in myeloid differentiation.^{24–27} Murine experiments indicate that transfection of mutated genes that primarily alter cell differentiation, such as AML1/ETO resulting from the t(8;21) translocation, produces abnormal hematopoiesis, but is not sufficient to generate frank AML.²⁷ Initial murine experiments suggested a “two-hit” hypothesis, in which mutations affecting both differentiation and proliferative signaling pathways are needed to result in AML.²⁸ The mechanisms that account for poor prognosis in patients with complex cytogenetics remain to be elucidated. Findings in 5q-MDS suggest a mechanism by which haploinsufficiency can lead to a myeloid malignancy.²⁹ Many patients with the so-called monosomal karyotype (two monosomes or one monosomal plus one stromal abnormality) have p53 mutations, and this abnormality likely accounts for the dismal prognosis in this disease subset.¹⁷

Exposure and risk

Although more acquired genetic lesions that lead to leukemia are being defined, DNA damage from a known cause comprises only a small fraction of patients with AML. Leukemia occurs with increased frequency after exposure to nuclear bomb³⁰ or therapeutic radiation,³¹ after certain types of chemotherapy,^{32, 33} and with heavy and continuous occupational exposures to benzene or petrochemicals.^{34, 35} There are two types of chemotherapy-related leukemias: (1) the classic alkylating agent-induced type, in which the leukemia is usually preceded by a myelodysplastic prodrome and is characterized by clonal abnormalities, often with loss of chromosome 5 and/or 7³² and (2) an epipodophyllotoxin/topoisomerase II inhibitor-associated type with a shorter (median 2 years vs 5 years) incubation period, often with myelomonocytic or monocytic differentiation and abnormalities at the 11q23 region.³³ Recent studies have challenged preconceived notions about the origin of therapy-related leukemia: (1) some patients who have been exposed to chemotherapy have genetic⁵ or cytogenetic lesions³⁶ and clinical behavior indistinguishable from de novo AML; (2) preexisting p53 mutant hematopoietic clones due to the “normal” stochastic accumulation of mutations may be selected for survival after genotoxic therapy and thus predispose to the development of AML.³⁷

Familial AML

AML is not usually a familial or inherited disorder, which is a fact worth noting to concerned families. There appears to be an increased incidence of acute leukemia in the first 6 months after diagnosis in the identical twin of an affected child.³⁸ Familial syndromes have been described in which the incidence of leukemia was increased.^{39–41} In some of these families, different types of leukemias and other cancers have been found, whereas in other potentially more informative families, such as a large family in which more than or equal to seven cases of erythroleukemia or myelodysplasia developed in three successive

generations,⁴¹ the morphologic or clinical characteristics of the leukemia have been similar, suggesting a common, heritable genetic mutation. A family has been described in which three patients with AML had identical inherited mutations in *CEBPA*,⁴² a gene involved in granulocytic differentiation, while another large kindred with a familial platelet disorder with a predisposition toward AML had been shown to be associated with mutations in the gene encoding *CBF- α* (formerly *AML1*).⁴³ Finally, there seems to be a predisposition toward evolution to AML in individuals with inherited polymorphisms in the receptor for granulocyte colony-stimulating factor (G-CSF).⁴⁴ AML is also more common in certain inherited conditions identified by an inability to repair DNA damage (e.g., Fanconi anemia)⁴⁵ or with defective telomerase machinery.⁴⁶

Prognosis

As noted, AML is a genetic and biological heterogeneous disease; thus, it is not surprising that a patient's prognosis at the time of diagnosis can vary widely from a cure rate of 80–90% in acute promyelocytic leukemia (APL) to virtually zero in those patients with monosomal karyotype and/or p53 mutations in their malignant cells. A reasonably accurate prognosis can be derived from the knowledge of three factors (in addition to the obvious importance of comorbid disease and frailty in the elderly) to estimate the likelihood of long-term favorable outcome in patients with AML: (1) age; (2) cytogenetics; and (3) genetics. In general, the likelihood of remission, the chance of getting through standard remission induction without treatment-related mortality, and the likelihood of not relapsing vary inversely with age.⁴⁷ For practical reasons, patients above 55–65 years of age are considered older adults with AML; however, the ability to withstand cytotoxic chemotherapy varies between individuals. The Eastern Cooperative Oncology Group (ECOG) Performance Status scale offers some help in this regard, but there is a trend toward using a more detailed and comprehensive geriatric assessment to determine a patient's ability to withstand chemotherapy.⁴⁸ In addition to the increased likelihood of occurrence of comorbid diseases with aging, other considerations are the more limited stem cell reserve in the older population⁴⁹ and the inevitable decline in hepatic and renal function. Moreover, the fact that leukemia in older adults tends to be more biologically aggressive with an increased ratio of adverse chromosomal abnormalities to favorable abnormalities⁵⁰ and the increased likelihoods of the so-called myelodysplasia-related genetic abnormalities and an antecedent clinical marrow stem cell disorder are associated with a relatively poor outcome. The prognosis is sufficiently adverse that a different treatment approach is generally employed in older adults with AML.

For the last 40 years, we have relied upon chromosomal findings at diagnosis to establish prognosis and in some cases to guide therapy. Numerous studies have divided newly diagnosed younger adults with AML into three prognostic categories.^{51, 52} Approximately 15% were found to have more favorable prognostic abnormalities (not including APL) including core-binding factor translocations such as t(8;21) and pericentric inversion of chromosome 16. Such patients have a high complete remission (CR) rate and relatively low relapse rate, although at least two-thirds are destined to relapse with an increased likelihood of an adverse outcome in those with an associated mutation in the c-KIT tyrosine kinase gene.⁵³ Approximately 15% had unfavorable chromosomal abnormalities,⁵⁰ including complex karyotypes (generally greater than three, although in some classifications five distinct chromosomal abnormalities) or the so-called monosomal karyotype (two monosomies or one monosomy plus one structural abnormality).⁵⁴ Patients in this adverse prognostic category taken together have a 15% likelihood of long-term disease-free survival, but those with monosomal karyotype are destined to fare even worse.⁵⁵ This is partially explained by high incidence of TP53 gene mutations in this subgroup.¹⁷ About 70% of patients

are considered to have an intermediate prognosis with an approximate long-term survival chance of 40%. Some of these patients have well-characterized abnormalities such as trisomy 8 or translocations involving the 11q23 region (the MLL gene) from chromosome 11.

However, the vast majority of the intermediate prognostic group comprised those with a normal karyotype. Significant effort has been made in the last 10–20 years to divide patients with normal karyotypes into prognostic subgroups. At present, the following three genes have been generally used to provide information required for such a classification: CEBP α , NPM1, and FLT3. Patients with biallelic CEBP α mutations in the leukemia cells tend to exhibit a high expected disease-free survival of 80%; however, only a small number of patients have such an abnormality.¹⁸ The presence of FLT3 ITD (ITD) mutation producing variations in the length of this transmembrane tyrosine kinase is considered adverse, while a mutation in the NPM1 nuclear shuttle protein is considered favorable. When considering the possible combinations of these two mutations, only the subgroup of patients with an NPM1 mutation without a concomitant FLT3 ITD mutation are destined to exhibit high survival rates.⁹ This is the only patient group within the intermediate chromosomal prognostic category that is recommended to undergo a postremission approach based on chemotherapy only.⁹ A recent study suggests that only those with NPM1 mutant and FLT3 ITD wild-type genetic patterns as well as an IDH1/IDH2 mutation had a high overall survival¹⁶ but this remains to be confirmed by other studies. DNMTA3 mutations also imply an adverse prognosis,^{15, 56} similarly to those who have MDS-associated abnormalities such as EZH2 and ASXL1 mutations.⁵⁷

In older adults, there is a higher incidence of complex or adverse cytogenetic findings. However, a small number of older adults have favorable karyotypes and should be treated with conventional induction and consolidation regimens if their other medical conditions permit.⁵⁰ In addition, a large minority of older patients with a normal karyotype at the time of diagnosis who have an NPM1 mutation without an associated FLT3 ITD mutation can be expected to exhibit a higher survival rate than older adults who lack this genetic/chromosomal pattern.⁵⁸

[Table 1](#) depicts a modified European LeukemiaNet (ELN) classification scheme⁵⁹ showing the frequency and general prognosis of those younger adults with various combinations of cytogenetic and genetic findings. This list will likely change over time as other genetic abnormalities are introduced into the equation.

Table 1 Cytogenetics- and genetics-based risk

Risk group	Features	Approximate 4-year survival (%)	Approximate prevalence (%)
Very high	Monosomal karyotype (two monsomies or one monosomy plus balanced translocation)	10	6
High	Complex (>3 abnormalities) or unfavorable (-7, 7q-, -5, 5q-, 3q, or t(6;9)) cytogenetics	20	12
Intermediate	Normal cytogenetics (with <i>FLT3</i> mutation or <i>FLT3</i> -ITD not present/ <i>NPM1</i> wild type/ <i>CEBPα</i> wild type) or other karyotype	35	25
	Inversion 16 or t(8;21) with <i>c-KIT</i> mutation	40	5
	Normal cytogenetics (with <i>FLT3</i> -ITD not present/ <i>NPM1</i> mutation)	50	25
Favorable	Normal cytogenetics (with <i>CEBPα</i> biallelic mutation)	60	5
	t(8;21) or inversion 16 (with <i>c-KIT</i> wild type)	65	10
Very favorable	t(15;17)	85	12

Morphologic classification and clinical and laboratory correlates

The diagnosis of AML depends on the examination of well-prepared specimens of peripheral blood and bone marrow. Both bone marrow aspirates and biopsies should be evaluated. Although the biopsy is usually not helpful in identifying individual cells, it provides the best assessment of cellularity, can occasionally identify aggregates of leukemic cells that are not seen on aspirate, and is necessary to evaluate marrow fibrosis. In 1976, a group of morphologists from France, the United States, and Great Britain suggested a classification system designed to standardize definitions of the sometimes clinically and biologically distinct subtypes of AML and acute lymphoblastic leukemia (ALL).⁶⁰ This French, American, and British (FAB) classification has been serially modified, initially in 2002,⁶¹ and in 2016⁶² by a World Health Organization (WHO)-sponsored undertaking, which represented efforts to improve concordance among different observers and incorporate new findings from immunologic, cytogenetic, and molecular studies.

The diagnosis of AML requires that myeloblasts constitute 20% or more of bone marrow cells or circulating white blood cells (WBC), generally evaluated on Wright or Wright–Giemsa stained smears. The FAB classification required >30% blasts to distinguish AML from myelodysplasia. Although this change was based on a study which showed that the outcome could be based solely on the blast count,⁶³ it is unclear that this is biologically well founded. The difference in eligibility criteria should be considered when comparing older AML trials with more recent studies. Neoplastic promyelocytes, monoblasts or promonocytes, and megakaryoblasts are included in this percentage, and their presence defines the various morphologic subtypes described below. An assortment of histochemical stains may be used to aid

in subclassification and distinguish AML from ALL. Monoclonal antibodies directed against antigen groups [termed cluster designations (CD)] considered to be restricted to cells committed to myeloid differentiation are also helpful in making this diagnostic distinction. Antibodies against CD11b, CD13, CD14, CD33, and C117 are used most commonly.⁶⁴ These antigens are found on normal hematopoietic elements, are not leukemia-specific, or unique to different AML FAB subtypes. In general, they do not correlate with prognosis, with the possible exception of CD34 antigen,⁶⁵ which is detected on undifferentiated hematopoietic progenitors and can be found on the blasts of patients with either AML or ALL. It is suggested that patients with AML whose blasts strongly express CD34 have an inferior outcome because of chemotherapy-resistant leukemia, particularly in patients with less morphologically differentiated leukemias in which other myeloid-associated antigens are less strongly expressed.⁶⁶

The FAB and WHO nomenclatures classify the subtypes of AML according to the normal marrow elements that the blasts most closely resemble. This does not indicate, however, that the leukemic event exclusively involves the cell lineage that is most prominently represented morphologically. Until recently, the involvement of other hematopoietic lineages could be inferred only by the presence of prominent morphologic abnormalities in these other cell lines. In patients with myelodysplasia or erythroleukemia, there is usually morphologic evidence of trilineage dysplasia with the inference that the initial cell that was malignantly transformed was a hematopoietic precursor with capability of multilineage maturation.⁶⁷ Fialkow and colleagues,⁶⁸ on their study of female patients with X chromosome-linked polymorphisms of glucose-6-phosphate dehydrogenase, were able to demonstrate involvement of myeloid, but not erythroid or megakaryocytic progenitors in some patients with AML. This first observation was proved prescient; however, at present, we believe that most hematopoietic elements emanate from a disordered stem cell, with multilineage involvement being quite common. Moreover, AML should be considered oligoclonal, rather than monoclonal; clonal heterogeneity exists at diagnosis; and the predominant clone can change with time, given the selective pressure exerted by chemotherapy. For example, there is evidence for persistence of certain subclones at remission as well as the emergence at relapse of clones, which have acquired “progression” mutations (or these mutations were present in very small subclones at diagnosis)⁵ and that a small clone at diagnosis could be the one to lead to relapse.

Representative examples of different subtypes of AML are shown in [Figures 2–11](#). The immunologic, cytogenetic, and (where they exist) clinical correlates of these morphologic subtypes are reviewed in [Table 2](#).

Figure 2 M0. Marrow blasts from patients with this undifferentiated type of acute myelogenous leukemia can have variable amounts of agranular cytoplasm. Cells are peroxidase- and Sudan Black-negative and can be confused with FAB M7 or FAB L2. Myeloid commitment of these blasts can be confirmed by immunophenotyping with antibodies against myeloid antigens and/or demonstration of ultrastructural peroxidase-positive granules using transmission electron microscopy.

Figure 3 One of the blasts from a patient with M1 acute myeloid leukemia contains a prominent Auer rod.

Figure 4 M2. Leukemia is characterized by evidence of continued myeloid differentiation with myelocytes and more mature myeloid elements present.

Figure 5 M3. Promyelocytic leukemic cells usually have spherical nuclei with heavily granulated cytoplasm. Extracellular granules are often noted, and blasts with multiple Auer rods (not shown) are common. This leukemia has typical 15;17 translocation and a characteristic clinical picture of disseminated intravascular coagulation.

Figure 6 M4. Myelomonocytic leukemia has blasts with both myeloid and monocytoid appearance.

Figure 7 M5. Monocytic leukemia. Prominent nuclei filled with nucleoli in some cells, light granulation, and large amounts of lightly basophilic cytoplasm give these cells the appearance of promonocytes.

Figure 8 M5. Gingival hypertrophy due to infiltration by leukemic cells in acute monocytic leukemia.

Figure 9 M6. Erythroleukemia is characterized by the presence of bizarre megaloblastic and often multinucleated erythroid precursors. Karyorrhexis is seen in some cells. The somewhat arbitrary distinction between FAB M6 and myelodysplastic syndrome with excess blasts in transformation is made by quantification of the fraction of myeloid blasts.

Figure 10 M7. Megakaryocytic leukemia. Blasts in this category are often morphologically undifferentiated. The presence of multinucleated cells, dysplastic micromegakaryocytes, and cytoplasmic budding can be useful diagnostic clues. The diagnosis is confirmed by immunophenotyping or ultrastructural studies.

Figure 11 Typical granular staining with Sudan Black B of a blast and a neutrophil from a patient with FAB M1 acute myeloid leukemia.

Table 2 Recurring karyotypic and molecular abnormalities in AML

Cytogenetic abnormality	FAB morphology	Affected genes	Median age	Approximate incidence in <i>de novo</i> AML	Prognostic effects	Comments
t(8;21)	M2	<i>AML1/ETO</i>	30 years	5–7%	Favorable	Auer rods usually present
t(15;17)	M3	<i>PML-RARα</i>	40	5–8%	Favorable-high cure rate with ATRA-based therapy	DIC
t(11;17)	Similar to M3	<i>PLZF/RARα</i>	?	<1%	Poor response to ATRA-based therapy	
abn 16q22	M4 with eosinophilia	<i>CBFA/MYH11</i>	35–40	5%	Favorable	High reinduction rate post relapse
abn11q23	M5	<i>MLL</i> + many partners	>50	3%	Poor except t(9;11)	Hyperleukocytosis extra medullary disease
+8	Varied		>60	5–10%	Poor	
del 5, del 7, 5q-, 7q-, or combinations	Varied; common in FAB M6		>60	15–20%	Poor	Common in patients with secondary AML, prior MDS
Inv 3	Abnormal megakaryocytes	Ribophorin/ <i>EVI1</i>	?	<1%	Poor	Increased platelet count; other abnormalities

						common (del 5, c7)
+13	Varied; sometimes undifferentiated		Probably >60	~1–2%	Poor	Higher frequency hybrid features
t(6;9) (p2;q34)	M2/M4 with basophilia	<i>DEK/CAN</i>	?	<1%	Poor	Prominent basophilia
t(9;22)	Usually M1	<i>BCR/ABL</i>	Probably >50	~1%	Poor	Splenomegaly
t(1;22)	Often M7	<i>MOZ/CBP</i>	Infants	<1%	Poor	Organomegaly
t(8;16)	M4,5	KAT6A/CREBP	?	<1%	Poor	Erythrophagocytosis often threap-related
<i>Molecular abnormality</i>						
Fms-related tyrosine kinase gene mutations	Varied—most common in CN-AML; can be found with (6;9); t(15;17)	Internal tandem repeat or point mutation of	?	~30% in CN-AML	Adverse	
Nucleophosmin (<i>NPM1</i>)—(5q35) mutation	Varied	Nucleophosmin (<i>NPM1</i>); often found with other mutations	?	~35% of AML, ~50% of CN-AML	Favorable DFS except when associated with mutation	
<i>CEBPα</i> gene	Varied	Mutation results in decreasing levels of <i>CEBPα</i> (CCAAT enhancer binding protein)	?	~15% of CN-AML	Favorable when biallelic with FLT3 ITD mutation	
Overexpression of BAALC (brain and acute leukemia cytoplasmic) protein	Varied	Overexpression of BAALC	?	Studied most extensively in CN-AML	Adverse—further studies needed	
Partial tandem duplication of MLL (mixed lineage leukemia) gene	Varied	Affects <i>HOX</i> gene function	?	~8% of CN-AML	Unclear—further studies needed	
IDH1, IDH2	varied	isocitrate	?	IDH1 in	variable	specific inhibitors

		dehydrogenase		10%, IDH2 in 18%		clinical trials
TET2	varied (common in MDS)	DNA methylation	>60	15%	adverse	increased with o age
DNMT3A	varied	DNA methylation	>60	20%	adverse	increased with o age
ASXL1	varied	epigenetic regulation	?	6%	adverse	associated with other mutations

Abbreviations: AML, acute myelogenous leukemia; ATRA, all *trans* retinoic acid; DIC, disseminated intravascular coagulation; FAB, French, American, and British; MDS, myelodysplastic syndrome.

Peripheral blood

Most patients with AML present with anemia (median hemoglobin 8 g%), thrombocytopenia (median platelet count 40,000–50,000/μL), and leukocytosis (median WBC count 10,000–20,000/μL). The red blood cell morphology is usually relatively normal. Large, sometimes hypogranular, platelets can be observed, and functional defects can contribute to hemorrhagic manifestations. Most patients are neutropenic, and morphologic abnormalities (nuclear hyperlobulation, hypogranulation, Pelger–Huet anomaly) are often noted in the remaining neutrophils. Careful examination can detect blasts in most patients, although it can be difficult to distinguish among leukemia subtypes (or occasionally even to be confident of the diagnosis of acute leukemia) in patients with a low number of circulating blasts. In occasional patients, marked leukopenia at presentation (the so-called aleukemic leukemia) may obscure the diagnosis until a marrow examination is performed.

AML with recurrent genetic abnormalities

Clinical findings associated with t(8;21), inv(16), and t(15;17) have been appreciated for decades and are described in the sections on M2, M4 with eosinophilia, and M3 (APL) later. AML with t(8;21) and inv(16) are referred to as “core binding factor” (CBF) leukemias because of the molecular abnormalities in transcription produced by these translocations. Mutations of the C-KIT tyrosine kinase receptor, which result in a constitutive proliferative signal, are found in approximately 25% of patients with CBF AML with data suggesting a poorer outcome in patients with this additional mutation as well as in whom the protein is overexpressed.⁵³

The 2008 WHO classification added inv3(q21;q26.2), t(3;3)(q21; 26.2), and t(1;22) (p13;q13) [RBM15-MLK1] usually found in infants (see M7 later) as well as t(6;9) (p23;q23)[DEK-NUP214] to this group. The translocation t(6;9) is very uncommon, may occur more frequently in younger patients, and can be found in association with a variety of AML morphologies, often with prominent basophilia.⁶⁹ FLT3 *ITD* mutations are found in approximately two-thirds of patients with t(6;9).⁷⁰ The outcome with chemotherapy only is poor, and allogeneic transplantation should be performed if possible.

AML with MDS-related changes

Addition of this category shows that a substantial fraction of AML, particularly in older patients, evolves from a prior myelodysplastic disorder. This group includes patients with a prior history of MDS, those

with >50% dysplasia in at least two cell lines and patients with the so-called “MDS cytogenetics,” including, -5, -7, i(17)/t(17p), -13, del 11q, del (12p), del 9q and those with complex karyotypes, which may include these changes as well as the presence of marker chromosomes.⁶⁷ These leukemias seem to arise in a very early hematopoietic stem cell and tend to have low response rates with short durations of response. It seems likely that those patients in this category, only based on morphological abnormalities, may exhibit a variety of oncogenic pathways based on mutational profile and thus may not have a uniformly poor prognosis.⁵

Therapy-related AML

This category includes patients whose AML followed treatment with chemotherapy and/or radiation therapy for other disorders. Morphology and karyotypes are often similar to those observed in MDS with the addition of a group of patients with abnormalities of 11q23 associated with prior treatment with topoisomerase II inhibitors and often with a short interval until the development of AML.^{32, 33} Therapy-related AML tends to be more resistant to chemotherapy, and allogeneic transplant should be considered in patients who achieve remission. It is important to note that some patients with therapy-related AML can have inv(16), t(8;21), and t(15;17) (APL) or genetics typical of de novo AML and respond well to standard approaches for these subtypes, although perhaps not as well as those with these karyotypes with de novo disease.^{5, 36}

Extramedullary AML (aka myeloid sarcoma)

Occasionally patients will present for medical attention because of lesions identified to be composed of myeloblasts by histochemical staining, but without apparent bone marrow involvement. Masses can involve the skin, gastrointestinal tract, ovaries, the central nervous system (CNS), and virtually every body organ. There have been only few systematic studies on the management of such patients, although there is a risk of high eventual systemic relapse rate without treatment.⁷¹ Most clinicians consider induction and consolidation in medically fit patients after diagnosis. Despite such “early” treatment, the recurrence rate is high; the role of stem cell transplant is unclear, but it is reasonable to consider transplantation to maintain the remission. Some of these patients have a t(8;21) chromosomal translocation, but in this setting, may not have the same favorable prognostic input as found in more typical t(8;21) AMLs.⁷²

AML not otherwise specified

This category includes the large group of patients whose AML does not fall into the previously listed groups.

FAB classification

Although the “old” FAB classification is not used currently, clinical–pathological correlates can be discussed. Wright–Giemsa stained peripheral blood or bone marrow aspirate smears can prefer AML to ALL. In general, the blasts from patients with AML are larger, with more abundant cytoplasm and more prominent, often multiple, nucleoli. The definitive diagnosis depends, however, on the presence of Auer rods, which are linear bundles of myeloid-containing granules. Cytochemical stains, such as myeloperoxidase, which is present in 73% of blasts, can diagnose AML.

M0: Minimally differentiated AML

As shown in [Figure 2](#), some patients have blasts that resemble myeloid blasts, but are negative at the light microscopic level when examined with myeloperoxidase, Sudan Black B, or other histochemical stains. The myeloid nature of these leukemias can be detected, however, by immunologic means or by electron microscopy of peroxidase-stained preparations. Electron micrographs reveal ultrastructural peroxidase-positive granules, whereas immunologic phenotyping shows reactivity with antibodies directed against myeloid antigens and nonreactivity with antibodies that characterize lymphoid differentiation.^{73, 74} The cells are often reactive with antibodies directed against CD34. In general, terminal deoxynucleotidyl transferase (TdT) is absent, but can sometimes be detected in a minority of blasts.

Approximately 7% of patients with untreated AML have minimally differentiated AML (M0 AML), which is relatively resistant to treatment.⁷⁵ This undifferentiated leukemia can easily be confused with ALL, and it is therefore critically important to obtain data of immunophenotyping of blasts from patients with morphologically undifferentiated leukemias. Other than resistance to chemotherapy, this M0 variant does not appear to be associated with specific clinical findings. Many M0 patients have complex karyotypic abnormalities.⁷⁵ No distinctive cytogenetic pattern has been noted, except trisomy 13, which has been reported to occur in some patients with morphologically less differentiated leukemias.⁷⁶

M1: Myeloid leukemia without maturation

The blasts from patients with M1 morphology have round nuclei with moderate amounts of sometimes lightly granulated cytoplasm, which can contain Auer rods ([Figure 3](#)). In contrast to M2, there is little evidence of myeloid maturation, with <10% of cells beyond the level of the promyelocyte. There is no particular age, gender, clinical feature, or characteristic cytogenetic abnormality associated with this morphologic variant.

M2: Myeloid leukemia with maturation

In contrast to M1, there is obvious continued maturation in the myeloid series with the presence of promyelocytes, myelocytes, and often more mature myeloid elements. Granulation is generally more obvious; Auer rods are often prominent ([Figure 4](#)). Approximately 20–25% of patients with M2 AML have a characteristic translocation between chromosomes 8 and 21 [t(8;21)(q22;22)]; this translocation is seen almost exclusively in patients with M2 and Auer rods. Such patients have a lower median age (~30 years), very high initial complete response rate (>85% in most series), lower relapse rate, and increased long-term disease-free survival, particularly when treated with high-dose cytarabine-based consolidation therapy,⁷⁷ except for a subset with an activating mutation of *KIT* or adverse gene signature.⁷⁸ The incidence of extramedullary granulocytic sarcomas, often in unusual sites, may be increased in patients with t(8;21) M2 AML, whose blasts express the adhesion molecule CD56 on their surface. These can present as discrete tumor masses, sometimes in paraspinal locations, confer a poor prognosis, and are distinct from the gingival and cutaneous involvement found in monocytic leukemia.⁷¹

M3: Acute promyelocytic leukemia

APL is one of the most distinctive subtypes of AML with regard to morphologic, clinical, cytogenetic features, and response to differentiating agent therapies, such as all-trans retinoic acid (ATRA) and arsenic.⁷⁹ In most patients, the morphologic diagnosis is straightforward, with the marrow being replaced by blasts that resemble unusually heavily granulated progranulocytes. The nuclei are spherical, with obvious nucleoli, and the cytoplasm is filled with multiple, large, and often coalesced azurophilic granules ([Figure 5](#)). Auer rods are usually observed, and multiple Auer rods (the so-called faggot cells) are frequently noted. In a minority of patients, the blasts are hypogranular, and sometimes granules can

only be visualized by an electron microscope.⁸⁰ This hypogranular variant often has cells with bilobed or lobulated nuclei, which can sometimes be confused with monocytic variants of AML. In contrast to the typical leukopenic presentation of APL, patients with the hypogranular variant tend to have higher white cell counts. In both types of APL, staining with either Sudan Black B or myeloperoxidase is strongly positive. Class II human leukocyte antigens (HLA DR), which are found on all hematopoietic precursors, are not usually detected on the surface of the malignant progranulocytes. The explanation for and biologic implications of this finding are not known. By contrast, CD33 is consistently strongly expressed.⁸¹

Patients with APL tend to be somewhat younger, with a median age of 30–40 years, although it is observed in patients of all ages. APL accounts for approximately 10% of AML and may be more prevalent in Latinos⁸² and obese people.⁸³ It is almost uniformly characterized by hypofibrinogenemia, variable depletion of other coagulation factors, elevated levels of fibrin degradation products, and increased consumption of endogenous and transfused platelets. The granules contain potent procoagulants, and the rate of disseminated intravascular coagulation (DIC) is generally increased following lysis of blasts by chemotherapy,⁸⁴ often with increased bleeding, although the problem can be rapidly ameliorated with the use of ATRA.⁸⁵ In some patients, there is evidence that accelerated fibrinolysis may be the primary event triggering coagulopathy.⁸⁶ APL is associated with the highest frequency of hemorrhagic morbidity and mortality, the latter usually related to intracranial hemorrhage, emphasizing the need to initiate ATRA at the first thought of APL.⁸⁷ Before DIC is controlled with ATRA, severe hypofibrinogenemia (<100 mg/dL) may require supplementation with cryoprecipitate, and thrombocytopenia should be managed with the aggressive use of platelet transfusions.

Almost all patients with APL have a characteristic translocation involving chromosomes 15 and 17 [t(15;17) (q22;q12)],⁸⁸ which may be accompanied by additional cytogenetic abnormalities, such as trisomy 8.⁸⁹ Reverse transcription polymerase chain reaction (RT-PCR) can be used to detect the fusion transcript, is useful for assessing minimal residual disease (MRD),⁹⁰ and permits the proper classification of a patient with clinically and morphologically typical APL and an apparently normal karyotype. The break point on chromosome 17 is in an intron of the retinoic acid receptor alpha gene. A gene that has been termed *PML*, also with DNA-binding capability, is translocated from chromosome 15, resulting in the formation of a fusion protein that functions in a dominant manner to block transcription of genes controlled by *RAR-α*, probably by nuclear corepressor activity. Retinoic acid treatment relieves the corepressor activity,^{91, 92} allowing transcription of genes involved in differentiation.⁹³ There is also interest in the use of histone deacetylase inhibitors in patients with APL as another means of enhancing gene expression.⁹⁴ FLT3 *ITD* mutations can be detected in approximately one-third of patients with APL, are associated with higher WBC counts and M3 variant morphology, but unlike the case for non-APL AML, does not always seem to be associated with inferior outcome.^{95, 96} A group of patients with a leukemia similar in morphology to APL, but with alternate translocations such as t(11;17)(q23;q21) have been described. Although *RAR-α* is rearranged, these patients fail to respond to ATRA. A novel zinc-finger gene termed PZLF from chromosome 11 is translocated to *RAR-α*, rather than the *PML* gene from chromosome 15, creating a fusion protein that does not allow the ATRA-mediated release of transcriptional corepressor activity.⁹⁷

Historically, the remission rate in patients with APL treated with anthracycline-based chemotherapy was quite high. Initial drug resistance was very unusual, and most treatment failures were related to hemorrhagic or infectious deaths. APL is uniquely sensitive to single agent anthracycline therapy, which can produce CR rates >80%.⁹⁸ In contrast to other types of AML, remission can be attained with chemotherapy in APL without producing bone marrow aplasia.⁹⁹ Posttreatment bone marrows frequently

remain cellular with abnormal progranulocytes, with follow-up marrows demonstrating disappearance of these cells and return of normal hematopoiesis without additional chemotherapy. DIC does not reappear despite the persistence of morphologically abnormal cells. Undoubtedly, this unique feature of APL is related sensitivity to agents that have a differentiating and noncytotoxic mechanism of action (see section titled “Therapy of Acute Promyelocytic Leukemia (APL)”), and is now cured in at least 80% of patients with minimal or no chemotherapy with the use of ATRA and arsenic trioxide in combination.¹⁰⁰

M4: Myelomonocytic leukemia

Myelomonocytic leukemia is characterized morphologically by a mixture of myeloid and monocytic elements and represents approximately 15–20% of newly diagnosed patients with AML. According to the FAB criteria, >20% of the leukemic cells must be monocytic in morphology to distinguish this variant from FAB M1 and particularly from FAB M2. The monocytic elements often resemble partially differentiated monocytes with lightly granulated, grayish cytoplasmic, and folded nuclei, which are frequently seen in the peripheral blood ([Figure 6](#)). Monocytic derivation can be confirmed by staining with nonspecific esterases such as α -naphthyl acetate and α -naphthyl butyrate.

There is no distinct clinical picture associated with this variant, perhaps because this classification encompasses a wide spectrum of patients owing to the generous morphologic criteria for inclusion. The median age tends to be somewhat higher, and there may be an increased incidence of hyperleukocytosis and extramedullary leukemic involvement, as can be seen with monocytic leukemia. There is no particular cytogenetic clustering, and it is impossible to accurately predict short- or long-term outcome in patients with M4.

M4EO: Myelomonocytic leukemia with eosinophilia

Approximately 5% of patients with de novo AML have typical morphologic features of myelomonocytic leukemia in the presence of variable numbers of dysplastic eosinophils at various stages of maturation. The distinctive eosinophils usually represent only 5–10% of the cells of the marrow.¹⁰¹ In general, these cells contain large basophilic granules in addition to typical eosinophilic counterparts. Occasional patients with M2 morphology with eosinophilia have also been described.

M4Eo tends to occur in patients of younger age (median 35–40 years) and is associated with an excellent prognosis.¹⁰² CR rates are high (generally >85%), and failure because of initial drug resistance is unusual. In some series, this variant represents the subtype with the most favorable long-term prognosis. Mutations of the *C-KIT* tyrosine kinase receptor have recently been described in some patients with CBF AML, with data indicating a poorer outcome in this subset.^{53, 78} In addition to long initial CRs, second remissions, which are often quite sustained, are generally easier to accomplish in patients with FAB M4Eo.¹⁰³ Older series indicated the possibility of achieving a high rate of CNS relapse in patients with bone marrow eosinophilia. With more intensive regimens using higher doses of cytosine arabinoside (ara-C), CNS relapse in AML is unusual, and patients with FAB M4Eo do not require prophylactic CNS therapy.

All patients with FAB M4Eo exhibit a cytogenetic abnormality, involving chromosome 16 at band q22. In most patients, the cytogenetic changes involve a pericentric inversion (inv16), although translocations between the two chromosomes 16 with homologous deletions at 16q22 have also been noted.¹⁰⁴ This break point involves a fusion between the CBF- β chain and the gene encoding the smooth muscle myosin heavy chain. The fusion protein thus generated may use nuclear corepressor activity (in the form of histone deacetylase), which prevents transcription of genes required for myeloid differentiation in a

manner analogous to the CBF- α ETO fusion in t(8;21) M2 AML.¹⁰⁵ Although it is evident that patients with inv(16) leukemia respond very well to intensive chemotherapy [3-year DFS rate of >60–70% in those receiving high-dose ara-C (HIDAC)],¹⁰² the reason for this is unclear.

M5: Monocytic leukemia

Two variants of monocytic leukemia have been described; in both, >80% of the blasts are of monocytic derivation. Less common is the so-called M5a, in which the monocytic blasts have spherical nuclei and small amounts of sometimes deeply basophilic cytoplasm without evidence of morphologic differentiation. In monocytic leukemia with differentiation (M5b), at least 20% of the blasts resemble promonocytes with folded nuclei and abundant, lightly granulated cytoplasm, generally without Auer rods. The nuclear folding can often be quite marked with rarification of the nuclear chromatin ([Figure 7](#)). Phagocytosis of other hematopoietic elements by these cells is frequently noted in bone marrow preparations. These monocytic elements stain prominently with nonspecific esterase that is inhibited by fluoride.

Although observed in patients of all ages, monocytic leukemias are somewhat more common in older adults. Patients with FAB M5 have higher blast counts at diagnosis, and problems with hyperleukocytosis are most common in this morphologic variant (see section titled “Complications”).¹⁰⁶ In addition, the incidence of extramedullary leukemia is highest in M5, particularly in those with evidence of morphologic differentiation.¹⁰⁷ For example, it is common for patients to present to the dentist with gingival hypertrophy ([Figure 8](#)). Skin infiltration is common at both diagnosis and relapse, and it generally represents the initial site of recurrence, sometimes while the bone marrow is still morphologically normal. Other less common areas of extramedullary involvement include the gastrointestinal tract, conjunctiva, and the CNS. It is likely that extramedullary infiltration is related to active migration of the leukemic promonocytes to these sites. These partially differentiated cells are capable of migration to skin windows in vivo as well as phagocytosis of microorganisms and adherence to nylon fibers in vitro.¹⁰⁸

Serum levels of lysozyme are elevated in most patients with AML, but are generally much higher in patients with monocytic leukemia.¹⁰⁹ Lysozyme can affect renal tubular function, and severe, symptomatic hypokalemia can occur in patients with FAB M4 and M5 leukemia. This problem generally resolves with cytoreduction, but can also produce hypokalemic side effects of vomiting and diarrhea.

In addition to the initial problems presented by complications of hyperleukocytosis, patients with monocytic leukemia tend to have lower complete response rates related to drug-resistant disease. Although previous studies indicated that CR durations tend to be shorter with very low rates of long-term disease-free survival, an analysis of a large number of patients treated by the ECOG suggested similar outcomes to other morphologic subtypes of AML when other risk factors are taken into account.¹¹⁰ A variety of cytogenetic abnormalities can be detected, although the most common findings involve abnormalities of chromosome 11 at band q23. This break point, at what has been termed the mixed lineage leukemia (*MLL*) gene, can be involved in leukemias of myeloid or lymphoid origin as well as in those following therapy with epipodophyllotoxins and other drugs directed at topoisomerase II.¹¹¹ The *MLL* gene, also called *All-1* or *HRX*, may combine with at least 16 different genes in balanced translocation.¹¹² *MLL* is homologous to a gene important in the development of *Drosophila* and includes DNA-binding elements. The t(9;11) translocation is relatively common, involving the *MLL* gene, which may in fact confer a better prognosis than formerly thought, with high initial CR rates.^{113, 114} There is an association between M5b with extensive erythrophagocytosis and the t(8;16)(p11;p13), a translocation involving the

M6: Erythroleukemia

Erythroleukemia, often called Di Guglielmo syndrome previously, is a variant of AML, in which morphologic abnormalities of erythropoiesis are most prominent.¹¹⁶ Cases of pure erythroleukemia, in which the predominant malignant cell is clearly identified as a pronormoblast, are rare. Rather, this is a disease of the myeloid stem cell with marked dysplastic changes in all three hematopoietic lines. Together with the increase in myeloid-appearing blasts, there is persistence of morphologic abnormalities in the erythroid series with profound megablastosis, multinuclearity, karyorrhexis, increased number of mitoses, and staining with periodic acid–Schiff (PAS), often in a block pattern ([Figure 9](#)). Increased iron stores are usually observed, often with ringed sideroblasts. These changes are morphologically identical to those observed in patients with myelodysplasia, and many observers feel that most cases of erythroleukemia are biologically similar, if not identical, to patients with refractory anemia with excess blasts. This contention is supported by the very poor response to therapy in both groups, the tendency for the disease to occur in patients of older age, and the presence of similar cytogenetic abnormalities (complex karyotypic abnormalities, loss of part, or all of chromosomes 5, and/or 7, and marker chromosomes).¹¹⁶ Nonetheless, in order to be consistent in terms of protocol entry and reports of clinical trials, the FAB and WHO groups, somewhat arbitrarily distinguished among M6, myelodysplasia (RAEB), and other FAB subtypes with significant numbers of erythroblasts by quantification of the number of erythroblasts and myeloblasts. Most of these patients will now be placed in the “AML with MDS-related Changes” in the most recent WHO iteration. M6 is defined by the presence of >30% blasts among nonerythroid cells when >50% of the marrow nucleated elements are erythroid. Antibodies against glycophorin A are lineage-specific for erythroblasts, but immunologic phenotyping is rarely needed to identify these morphologic subtypes.

M7: Megakaryocytic leukemia

Morphologic abnormalities of megakaryocytopoiesis, usually characterized by the presence of mono- or binucleated micromegakaryocytes, are common in many variants of AML and can be particularly prominent in patients with M6 or myelodysplasia. A minority of these patients have thrombocytosis and abnormalities of chromosome 3 [inv(3) (q21;q26)]. This cytogenetic abnormality is often found in association with other chromosomal deletions, with a variety of primary morphologies (M1, M2, M4), and in patients with a prior background of MDS.¹¹⁷ These patients have a poor response to initial treatment and low overall survival (OS). Thrombocytosis is present not only in patients with the inv(3) karyotype, but also in those with AML at the time of diagnosis.¹¹⁸ The gene at the chromosome 3q21 break point is associated with the activation of EVI1 transcription factor.¹¹⁹

Diagnosis of FAB M7 is reserved for patients in whom the predominant leukemic cell is of megakaryocytic lineage.¹²⁰ In some patients, there is evidence of megakaryocytic dysplasia or multinucleated cells that strongly point toward principal involvement of the megakaryocyte ([Figure 10](#)), whereas in others, the leukemia is undifferentiated morphologically, with variable amounts of agranular cytoplasm, and it is sometimes confused with M1 or ALL. Sudan Black B ([Figure 11](#)), myeloperoxidase, and α -naphthyl butyrate stains are negative, whereas PAS and acid phosphatase may be positive, usually in a diffuse, speckled pattern. However, histochemical staining is nondiagnostic and the definitive diagnosis depends on the detection of platelet-specific peroxidase by either ultrastructural techniques or the demonstration of a variety of platelet antigens (usually glycoprotein IIb/IIIa [CD41] or von Willebrand factor) on the surface of the blasts.¹²¹ At times, the diagnosis can be quite difficult to confirm, particularly because of the increased marrow reticulin in most patients, rendering the marrow fibrotic and inaspirable.

Careful evaluation of peripheral blood blasts is necessary in such patients. It is likely that most patients with acute myelosclerosis in fact have acute megakaryocytic leukemia, which should not be confused with the late stages of primary myelofibrosis, and, indeed, prominent splenomegaly is not a clinical feature of M7. Although it is an uncommon variant of AML, most series suggest that this subtype is associated with a very poor prognosis. Prolonged aplasia is common following induction chemotherapy, and, because of the marrow fibrosis, it is often difficult to follow the results of therapy with repeated marrow aspirations. There have been relatively few cytogenetic evaluations of this variant, and except for the inv(3) karyotype and cases of t(1;22) (p13;q13) [RBM15/MKL1 gene fusion] found in infants,¹²² no consistent abnormality has been identified.

Acute panmyelosis with myelofibrosis

This is a very rare variant of AML felt to derive from the hematopoietic stem cell, in which the marrow demonstrates a marked increase in reticulin fibers with evidence of morphologically abnormal trilineage hematopoiesis and a variable number of blasts with an immature myeloid immunophenotype.^{123, 124} Patients usually present with pancytopenia and constitutional symptoms. It can sometimes be difficult to distinguish acute panmyelosis with myelofibrosis (APMF) from acute megakaryocytic leukemia or MDSs with myelofibrosis. APMF responds poorly to standard chemotherapy.

Mixed phenotypic leukemia

There are certain cases of acute leukemia that defy easy categorization, because the cells may have features of both lymphoid and myeloid derivation. The WHO 2008 monograph on classification of hematopoietic and lymphoid tissues uses the term “mixed phenotype acute leukemia” (MPAL) to encompass these heterogeneous groups of neoplasms. MPALs are defined by immature cells which display cytochemical or immunophenotypic features of both myeloid and lymphoid lineages (biphenotypic), or there are two different populations of leukemia cells: myeloid and lymphoid (bilineal). The difference between bilineal and biphenotypic cells generally does not alter the diagnostic therapeutic approach. Although prior systems such as the EGIL (European Group for Immunological Characterization of Acute Leukemias) were used,¹²⁵ the most recent algorithm is based on the 2008 WHO monograph.¹²⁶ Such entities tend to have features of either B-ALL and AML or T-ALL and AML and are called B-myeloid or T-myeloid diseases, respectively. Entities with evidence of derivation from both lineages are specified if there is a known recurrent genetic lesion such as Philadelphia chromosome-positive leukemia, MLL-rearranged leukemia, or AML-defining balanced translocation such as t(8;21). Technically, MPALs also exclude secondary leukemias, leukemias with FGFR1, mutations, and CML in blast crisis.¹²⁷

The essential features of an MPAL is the specific expression of certain lineage-defining markers in two categories. Although the algorithm is slightly complex, CD3 expression is evidence of T-lymphoid derivation, and CD19 together with one or two other markers indicate B-lymphoid origin. Myeloid origin can be determined by a set of monocytic immunophenotypic markers or most commonly by myeloperoxidase expression. TdT is characteristically seen in ALL; however, because 25% of AML patients express TdT, this is not considered a lineage defining abnormality. It is also important to indicate that many AMLs may have lymphoid antigens detectable by flow cytometry, but do not meet the criteria for biphenotypic leukemia. Such cases should be considered in the AML prognostic and therapeutic rubric.¹²⁷

The literature does not yield clear guidelines for the treatment of MPALs. In particular, patients with BCR/ABL-positive disease should be treated by chemotherapy together with a tyrosine kinase inhibitor.

Most other MPALs should be treated with an ALL regimen, although controversy certainly exists particularly if there is prominent expression of myeloperoxidase or even Auer rods. A regimen that combines AML- and ALL-type chemotherapy is also possible, but may be more toxic than a more typical ALL regimen. Given the relatively resistant nature of MPALs, it is reasonable to consolidate any remissions achieved with an allogeneic stem cell transplant.

Presenting signs and symptoms

Patients with AML generally present with symptoms related to complications of pancytopenia, including combinations of weakness, easy fatigability, infections of variable severity, or hemorrhagic findings such as gingival bleeding, ecchymoses, epistaxis, or menorrhagia. Occasionally patients present with prominent extramedullary sites of leukemia usually related to either cutaneous or gingival infiltration by leukemia cells. Bone pain is infrequent in adults with AML, although some individuals describe sternal discomfort or tenderness, occasionally with aching in the long bones, particularly of the lower extremities. In general, it is difficult to determine the time of onset of AML precisely, at least in part because individuals have different symptomatic thresholds for choosing to seek medical attention. It is likely that most patients have had more subtle evidence of leukemia for weeks, to perhaps months, before diagnosis.

The findings on physical examination are variable and generally nonspecific. If fever is present, an infectious site must be vigorously sought and treated empirically with broad-spectrum antibiotics. A large number of patients have fever related solely to the underlying leukemia, which abates with appropriate chemotherapy. Examination of the skin can reveal pallor, infiltrative lesions suggestive of leukemic involvement, cutaneous sites of infection, which may be either primary or embolic, or, most commonly, petechiae or ecchymoses related to thrombocytopenia and/or coagulopathy. Examination of the fundus reveals hemorrhages and/or exudates in the majority of patients (see section titled “Ophthalmic Complications”). The conjunctivae may be pale, according to the magnitude of the anemia. Careful examination of the oropharynx and teeth is important because of the infrequency of leukemic involvement. Palpable adenopathy is uncommon in patients with AML, and significant lymph node enlargement is rare. Similarly, hepatomegaly and splenomegaly are uncommon and, if found, may suggest the possibility of ALL or chronic myeloid leukemia in blast crisis. None of these findings is a diagnostic of acute leukemia, and the final diagnosis and categorization depends on appropriate evaluation of the peripheral blood and bone marrow.

Because of the rigorous nature of the chemotherapy required for the successful treatment of AML, particular attention should be paid to other medical problems that could complicate management of the patient. A history of congestive heart failure or other heart disease may preclude therapy with anthracyclines and mandates careful monitoring of the large amounts of intravenous fluids, including antibiotics, blood and platelet transfusions, hydration for nephrotoxic antimicrobial agents, and sometimes parenteral nutrition, given during the 3–4 weeks of chemotherapy-induced pancytopenia. Prior transfusion for other disorders or multiple previous pregnancies may presage difficulties with platelet transfusions or herald the occurrence of transfusion reactions after red blood cell or platelet administration. Careful appraisal for possible drug allergies is critical, because virtually every patient will require antibiotic therapy. A history of prior herpes simplex infections (or the presence of an elevated antibody titer) provides justification for prophylactic administration of acyclovir.¹²⁸ In premenopausal women, menses should be suppressed with a GNRH agonist or estrogens and/or progestational compounds until thrombocytopenia is resolved. Considerations of fertility preservation should be discussed with selected patients. Sperm-banking in males wishing to have a family should be considered, although many patients

are either oligo- or azospermic at the time of diagnosis. GNRH antiagonist therapy, by shutting down the pituitary–ovarian axis during chemotherapy, may preserve fertility in females with childbearing potential.¹²⁹

Once the diagnosis ([Table 3](#)) is established, the physician and staff must present the goals of therapy and the side effects of treatment to the patient and his/her family. For almost all patients, this discussion can rightfully emphasize the potential benefits of treatment with regard to both the short- and long-term outcomes. It is appropriate and necessary to repeat this discussion and counsel later during the patient's course of hospital stay. In general, for younger patients, induction therapy followed by postremission treatment with intensive chemotherapy and/or allogeneic transplant is appropriate. For older patients (>60–65 years), there may be merit to the standard, more aggressive approach, but hypomethylating agent therapy should be discussed.

Table 3 Initial diagnostic evaluation

History and physical examination—In addition to an overall comprehensive evaluation, emphasis should be placed on the following: <ul style="list-style-type: none">• Duration of symptoms• Menstrual history• Prior pregnancies, transfusions, history of transfusion reactions• Drug allergies (antibiotics)• Sites of infection: rectum, vagina, oropharynx, gingiva, skin• Signs of hemorrhage• Signs of extramedullary leukemia—skin, gingiva• Dentition status
Bone marrow aspirate and biopsy <ul style="list-style-type: none">• Morphologic classification• Cytochemistry• Immunophenotyping• Cytogenetics• Terminal deoxynucleotidyl transferase• Genomic studies
Blood chemistries <ul style="list-style-type: none">• Blood urea nitrogen, creatinine, electrolytes, uric acid• Transaminases, alkaline phosphatase, bilirubin, lactate dehydrogenase, calcium, phosphorus
Coagulation studies <ul style="list-style-type: none">• Prothrombin time, activated partial thromboplastin time, fibrinogen, fibrin split products
Chest radiograph, electrocardiogram, left ventricular ejection fraction if clinically indicated
HLA typing (patient and family); lymphocytotoxic (anti-HLA) antibody screen
Herpes simplex and cytomegalovirus serology
Lumbar puncture (only if symptomatic)

Abbreviation: HLA, human leukocyte antigen.

Therapy: general overview

The therapy of AML has traditionally been divided into stages: induction, postremission therapy of varying intensity and duration, and postrelapse therapy. In newly diagnosed patients with AML, the goal of induction therapy is to achieve CR, which then permits the administration of subsequent therapy that for

most patients is designed to maximize the rate of disease-free survival and cure. CR is defined primarily on morphologic grounds and includes the development of a bone marrow containing less than 5% blast elements, no signs of extramedullary leukemia, and return of normal neutrophil ($>1500/\mu\text{L}$) and platelet ($>150,000/\mu\text{L}$) counts. Even if the bone marrow contains $<5\%$ blasts, patients are not considered to be in remission if distinctive morphologic signs of leukemia, such as Auer rods, are noted. Low hemoglobin levels and the presence of symptoms unrelated to leukemia no longer exclude CR, as they are often treatment-related and slow to normalize.

It has been assumed that CR is accomplished because the cytotoxic chemotherapy markedly decreases the number of cells in the leukemic clone, thereby allowing repopulation of the bone marrow by residual normal progenitors, whose proliferation had been suppressed. This explanation is supported by observations that cytogenetic abnormalities present in the original leukemia cells cannot be detected in patients in remission. However, in some patients, intensive chemotherapy appears to eliminate the block in differentiation such that the apparently normal cells seen in the bone marrow and peripheral blood during a CR are actually progeny of the leukemic clone.^{130, 131} as determined by X chromosome-linked polymorphisms (glucose-6-phosphate dehydrogenase isoenzyme or restriction fragment-length polymorphisms) or the presence of disease-specific mutations in apparent normal cells at the time of CR.¹³² The frequency of such “clonal CRs,” the possible association with particular subtypes of AML or remission duration, the mechanism by which this important biologic phenomenon occurs, and a number of important technical issues need to be further defined.

Induction therapy: general principles

Induction therapy is designed to produce rapid clearing of leukemic cells from the peripheral blood with subsequent marrow aplasia. The only exception to this principle occurs in patients with APL (FAB M3), in whom remission can be achieved despite the persistence 2–3 weeks later of what appear morphologically to be viable leukemia cells,¹³³ although, especially given the use of ATRA/arsenic-based therapies, multiple marrows in APL need not be done. Approximately 1 week after standard induction therapy (the so-called “3 + 7”; 3 days of anthracycline, usually daunorubicin and 7 days of continuous infusion cytarabine) is completed (generally 2 weeks after the initiation of treatment), bone marrow aspirates and biopsies are done to evaluate the magnitude of cytoreduction. If the marrow is profoundly hypoplastic, one waits for count recovery. If the marrow is not hypoplastic and only leukemia cells are noted on the day 14 marrow, then a second course of therapy is generally administered. If high-dose cytarabine-based therapy was used as induction chemotherapy, multiple marrow examinations are not recommended.

At times, particularly if the “day 14” marrow is hypocellular, it can be difficult to distinguish between residual leukemia cells and normal undifferentiated hematopoietic progenitors. In this instance, it is advisable to delay retreatment and perform another marrow aspirate in a few days. If there is no evidence of further maturation, then a second course of treatment is indicated. The presence of erythroid precursors, juvenile megakaryocytes, or increased peripheral blood platelet or neutrophil counts serve as indicators to delay a second course of treatment as normal regeneration is occurring. With standard regimens, approximately 30% of patients with AML require two courses of treatment to enter remission. Despite these guidelines, there remains considerable variability and imprecision as to when a second course of therapy is indicated.

Most trials report results as complete response or no response. It is beneficial, however, to more rigorously classify the causes of failure in investigations of prognostic factors or assessment of the

cytotoxic activity of different regimens, to achieve remission. One such classification divides nonresponders into those with apparent chemotherapy-resistant leukemia, those who die with aplastic bone marrows in whom the response to chemotherapy cannot be determined, and those in whom either early death or failure to obtain adequate bone marrow studies before death preclude determination of whether persistent leukemia was present. Patients with drug-resistant leukemia include those who survive treatment and those who die but have morphologic evidence of leukemia in the bone marrow or blood. The criteria for CR are generally reached a median of 30–35 days after treatment has begun, although patients achieve adequate levels of circulating neutrophils ($>500/\mu\text{L}$) and no longer require platelet transfusion (at counts of $\sim 10\text{--}20,000/\mu\text{L}$), at least 7–10 days earlier, which may be beneficial in sorting out activity of novel and/or noncytotoxic agents. Other types of responses include PR (50% reduction in marrow blast with adequate count recovery), CRp (same as CR, but platelets are not fully recovered), CRi (same as CR, but with low neutrophil counts), and morphological leukemia-free state ($<5\%$ marrow blasts, without mention of normal cell counts). This categorization is relatively simple to perform in most patients and can be beneficial in distinguishing between failures due to drug resistance and inadequacy of supportive care.^{2, 133}

The overall rate of CR with standard chemotherapy in large cooperative group studies is approximately 65%. Patient age and cytogenetics are the most critical clinical variables, with CR rates of 75–80% in younger patients and approximately 50% in patients >60 years of age. The reasons for treatment failure vary according to patient age. With improved supportive care, it is uncommon for patients <50 years of age to die from complications of treatment, and most of the approximately 25% induction failure rate is a consequence of drug-resistant leukemia. By contrast, in patients >60 years of age, failures are due to drug-resistant leukemia and deaths occurring during marrow aplasia as a consequence of reduced end organ tolerance, occurring at overall frequencies of 40% and 10%, respectively.

Although there have been gradual improvements in the CR rates worldwide in younger adults with AML during the past 25 years, much of this can be attributed to better supportive care and not to changes in therapy. With the exception of the use of ATRA and arsenic for patients with APL (see below), relatively few changes in therapy have been made since the introduction of combined therapy with daunorubicin and ara-C, the so-called “7 and 3” regimen.¹³⁴ This two-drug combination was derived from observations of single-agent activity of either compounds. Daunorubicin is generally administered by intravenous push at doses of $45\text{--}90\text{ mg/m}^2/\text{day}$ for 3 days; ara-C is administered at doses of $100\text{--}200\text{ mg/m}^2/\text{day}$ by continuous infusion for 7 days ([Table 4](#)). A series of randomized studies^{134–140} by the Cancer and Leukemia Group B (CALGB) showed that:

1. Results were superior using the 7 and 3 regimen to 5 days of ara-C and two doses of daunorubicin.
2. The addition of oral 6-thioguanine (DAT regimen) to the 7 and 3 regimen did not increase the CR rate.
3. Continuous infusions of ara-C produced a slightly better outcome than twice-daily short intravenous infusions when combined with daunorubicin.
4. Results were not improved when ara-C was administered by continuous infusion for 10 days compared with 7 days.
5. Substitution of doxorubicin for daunorubicin produced almost identical CR rates, although mucosal toxicity was higher with doxorubicin.
6. There was no overall benefit from doubling the dose of ara-C from 100 to $200\text{ mg/m}^2/\text{day}$.

Table 4 Representative chemotherapy regimens for acute myeloid leukemia

	Dose	Route	Days
<i>Induction</i>			
Cytarabine+	100–200 mg/m ²	Continuous IV infusion	1–7
Daunorubicin	45–60 mg/m ²	IV	1–3
or			
Idarubicin	12 mg/m ²	IV	1–3
or			
Mitoxantrone	12 mg/m ²	IV	1–3
<i>Postremission</i>			
Cytarabine	3 g/m ² q12h (over 3 h)	IV (6 doses)	1, 3, 5
or			
Cytarabine	1.5–2 g/m ² q12h (over 1 h)	IV (8 doses)	1–4 (12 doses)
or			
Cytarabine	100 mg/m ²	Continuous IV infusion	1–5

See text for details about number of courses and patient selection for different regimens.

Other modifications of the 7 and 3 regimen

Most attempts to improve the 7 and 3 induction regimen have not led to increase in OS. Alternative anthracyclines or other agents such as mitoxantrone, rubidazone, aclacinomycin, amsacrine, mitoxantrone, and idarubicin have been used in several trials.^{141–145} None of these studies showed a survival or disease-free survival advantage with these different agents, perhaps because most are relatively similar in structure and mechanism of action and hence, become susceptible to the same mechanisms of resistance. The largest reported experience has been with idarubicin, where three initial trials showed that induction results are at least equivalent to results achieved with daunorubicin and ara-C.^{142, 144} An important randomized trial did not show an advantage for idarubicin compared with daunorubicin, in older patients.¹⁴⁶ In addition, the duration of myelosuppression was longer in the idarubicin cohorts, calling into question the equitoxicity of the arms. Therefore, the substitution of these compounds did not have a major impact on the long-term disease-free survival rate of patients with AML.

An Australian trial added etoposide to the 7 and 3 regimen.¹⁴⁷ The CR rate was similar in older patients when compared with daunorubicin and ara-C only with a possibly modest prolongation of CR duration in younger patients receiving etoposide. This was a relatively small study and the overall disease-free survival in the group receiving etoposide during both remission induction and postremission therapy was similar to other larger studies using daunorubicin and ara-C only. Large phase I studies from the CALGB, in which etoposide was added to the 7 and 3 regimen, had outcomes similar to the past experience with only the two drugs.¹⁴⁸

Because HIDAC is a beneficial postremission therapy (see below), several groups have tested the use of this approach during induction in younger patients. Studies have compared standard 7 and 3 to daunorubicin plus intermediate- or high-dose ara-C (2–3 g/m² for 8–12 doses).^{149–151} These studies failed

to show an increased CR rate for the recipients of HIDAC, although one study documented a more prolonged duration of CR (but no change in OS) in the patients randomized to HIDAC.¹⁴⁹ The addition of HIDAC to standard daunorubicin/ara-C during induction has also been studied. Although a small trial showed an 87% remission rate in patients <60 years old,¹⁵² a cooperative group trial failed to confirm those positive results.¹⁵³ Results seem to be equivalent if HIDAC is used either as part of induction or only as postremission therapy.¹⁵⁴

New induction strategies

Although it is evident that 3 + 7-based strategies remain the standard of care, new data suggest that many patients (perhaps all of those up to age 65) should be treated with daunorubicin at a dose exceeding the originally used 45 mg/m². The ECOG 1900 study randomized patients to 45 mg/m² per day of daunorubicin for 3 days versus 90 mg/m² for 3 days and found for most subgroups (and even those with high white counts or FLT3 ITD with longer follow-up)¹⁵⁵ that the higher dose resulted in prolonged survival. A study in older adults in Europe with a similar design also suggested that a dose of 90 mg/m² per day was better than 45 mg/m² at least in those between 60 and 65 years of age.¹⁵⁶ A report from a study conducted in the United Kingdom suggested that 60 mg was equally efficient as 90 mg/m².¹⁵⁷ As noted, most studies that have added drugs to the 3 + 7 backbone or substitute HIDAC for standard continuous infusion ara-C in 3 + 7 have not led to an increased OS. However, the Polish Acute Leukemia Study Group showed that the addition of cladribine to anthracycline/cytarabine was superior to 3 + 7¹⁵⁸; however, the CR rate in the control group in these younger adults was lower than expected and these results need to be confirmed by additional studies. Continuous infusion of HIDAC and idarubicin has led to favorable results in nonrandomized phase 2 studies at the MD Anderson Cancer Center.¹⁵⁹ Addition of CCNU to the 3 + 7 regimen benefited older adults in a French trial.¹⁶⁰ The FLAG IDA regimen, while quite intensive and toxic, led to a high remission rate and disease-free survival rate.¹⁶¹ Another agent that could potentially be added to a 3 + 7-type backbone is gemtuzumab ozogamicin (GO), an antibody toxin conjugate directed against the CD33 antigen expressed on blasts from most patients with AML and which was initially approved as a single-agent treatment for older adults with relapsed AML¹⁶² and then withdrawn after randomized trials comparing standard initial induction treatment with or without the addition of GO showed marginal benefit and/or equivocal results.¹⁶³ However, trials in France¹⁶⁴ and the United Kingdom¹⁶⁵ have suggested that the addition of relatively small doses of GO to standard chemotherapy may have a benefit in patients up to age 70 with AML. The drug has still not reentered the market until the time of this writing; confirmatory trials in North America will likely be required to show that it is worth using this drug routinely, although results in those with favorable chromosomal abnormalities are encouraging.¹⁶⁶

Approach to the older patient and other poor prognostic subgroups

Is it worth administering cytotoxic chemotherapy with a 3 + 7 induction approach to patients who have little chance for long-term benefit? This is still a subject of major debate and controversy relevant to the care of AML patients older than 60–65 years of age and some selected younger patients whose prognosis is very poor based on monosomal karyotype⁵⁴ or p53 mutations¹⁷ if known at the time of diagnosis. For younger adults with known adverse prognostic features, there seems to be little recourse at the moment to using a 3 + 7 regimen or similar induction approach followed by postremission therapy followed by allogeneic stem cell transplant if possible. If a sibling donor, matched unrelated donor, or “favorable” partially mismatched unrelated donor is not available, then strong consideration should be made for

haploidentical or umbilical cord blood stem cell transplantation (SCT) in these cases. The degree of chemotherapeutic resistance is profound in such cases and the results with allogeneic transplant remain relatively poor, but still may offer a slightly better outcome than¹⁷ a chemotherapy-based postremission approach.

It is possible that some older adults will be better served by using a lower-dose chemotherapy approach to initial therapy than a standard 3 + 7 regimen. For a standard chemotherapy, the daunorubicin dose should be ≥ 60 mg/m² in virtually all patients. On the contrary, particularly when adverse prognostic factors are present, at times it may be reasonable to consider lower-dose chemotherapy with drugs such as the hypomethylating agents, azacitidine or decitabine, or in clinical trials, with the slightly more toxic single agent, clofarabine. Although there are many prognostic algorithms for older adults, features that are generally considered to decrease the likelihood of good outcome with 3 + 7-based chemotherapy are those that were used in the clofarabine phase II¹⁶⁷ trial, including age > 70 years, antecedent hematological abnormality, comorbid diseases, nonfavorable cytogenetics. A phase 2 trial using 30 mg/m² of clofarabine for 5 days produced a 35% CR rate with a 10% rate of toxic death. In part because of difficulties in defining a group of patients “unfit for intensive therapy,” this trial did not result in the Food and Drug Administration (FDA) approval and clofarabine is being evaluated in a large ECOG-led phase III trial comparing clofarabine to 3 + 7 in this age-group.

In Europe, low-dose ara-C is another frequently used option for patients who are deemed not fit or at least “inappropriate” for standard induction chemotherapy. Low-dose ara-C seems to be slightly better than hydrea,¹⁶⁸ but is used little in the United States. Two important trials have compared hypomethylating agent to other therapies for older adults with AML. One such trial compared decitabine to low-dose ara-C or supportive care and yielded a 25% CR rate.¹⁶⁹ Although decitabine is approved for an initial therapy for older AML patients in Europe, it is not approved in the United States, primarily because the pivotal trial did not meet its primary end point of extending OS. A trial reported in preliminary form comparing 5-azacitidine to conventional care regimens for AML patients whose white count was less than 15,000/ μ L again did not meet its primary end point, but certainly suggested that 5-azacitidine was a viable alternative to low-dose ara-C or supportive care.¹⁷⁰ It should be emphasized, however, that the CR rates are much lower with hypomethylating agents and low-dose ara-C than with standard chemotherapy, and that the less-intensive treatments have largely been evaluated only in patients with less-proliferative forms of AML with the likelihood that results would be even poorer than summarized, should these treatments be used in patients with high circulating blast counts or a high marrow blast infiltration; as such induction with a 3 + 7-based regimen ideally in the context of a clinical trial should be the default therapy for the relatively fit older adult under approximately 75 years of age.

Patients to be treated with a hypomethylating agent should probably be managed in the same manner as those with MDS receiving such agents. The patient should continue to receive the hypomethylating agent every 4–6 weeks until toxicity or obvious progression occurs. It certainly seems that prolonged exposure to these agents is an important factor in achieving relatively good long-term results. If a patient does achieve a very good outcome such as a CR rate in response to a hypomethylating agent, then the older adult in question, if under approximately 75 years of age, could yet be considered for a nonmyeloablative allogeneic transplant.¹⁷¹ This usually occurs only in people who elect or are given aggressive chemotherapy, but this is nonetheless a consideration even in those who receive a less-intensive chemotherapy.¹⁷²

Postremission therapy

Morphologic assessments of CR are subjective and relatively insensitive. A better quantitation of malignant cells present at the time of CR (MRD) could segregate patients into prognostic subgroups. It is estimated that as many as 10^9 leukemia cells may still be present in patients with apparent morphologic CR. Only few patients can remain in CR for 1–2 years without further treatment, but it is generally accepted that some form of therapy after CR is required to achieve long-term disease-free survival. In a trial conducted by the German Cooperative Leukemia Group, a subset of 37 patients did not receive postremission therapy for a variety of protocol and medical reasons; all of these individuals relapsed.¹⁷³ The ECOG reported a randomized study in which patients achieving CR were randomized to either no therapy, lower-dose maintenance therapy, or an intensive postremission program.¹⁷⁴ All of the patients in the no-treatment arm relapsed rapidly, with a median CR duration of 4 months, resulting in early termination of this arm of the trial. Similar results were noted in a smaller randomized study reported by Embury and colleagues.¹⁷⁵ Although timed sequential therapy, in which patients receive additional chemotherapy during the early postinduction recovery phase, has been associated with prolonged remissions in the absence of postremission chemotherapy,^{176, 177} this treatment regimen is more analogous to consolidation therapy. Thus, it remains a standard practice to administer chemotherapy with or without subsequent SCT after remission is achieved with conventional regimens.

Younger adults are generally treated with curative intent and should receive postremission chemotherapy that includes intensive (or myelosuppressive) “consolidation” chemotherapy and/or SCT. The term “maintenance” is generally referred to lower-dose outpatient therapy administered on an intermittent basis for months to years, patterned on the model successfully used in childhood ALL, but this approach has not been clearly found to be useful in patients with AML.

A variety of agents have been used for postremission therapy, including the agents successfully administered in initial induction, with a particular focus on HIDAC as consolidation, as well as different classes of compounds, some of which have proved activity in AML, and others of which may have had only limited activity. Because a variety of prognostic factors significantly affect ultimate outcome, independent of the type of therapy administered, good results in small nonrandomized studies may reflect inadvertent patient selection and must ultimately be confirmed by multi-institutional applicability.

Overall, in adults, it can be expected that the administration of some sort of intensive postremission chemotherapy will result in a median CR duration of 12–18 months with approximately 20–25% of complete responders remaining as long-term disease-free survivors ([Figure 10](#)). A large review of CALGB patients who achieved CR showed a relatively constant relapse rate of 4.7% per month during the first 6 months following CR. The failure rate decreased in subsequent 6-month intervals (3.5% per month in months 7–12 and 2.4% per month in months 13–18), with a flattening of the curves after 3+ years of CR.¹⁷⁸ In general, patients relapsing earlier have leukemia that is more drug resistant than those who relapse late.¹⁷⁹ Older randomized trials of postremission therapy conducted by the CALGB failed to demonstrate long-term benefits from: (1) an alternate month compared with a monthly schedule of maintenance therapy; (2) 3 years of relatively low-dose maintenance therapy compared with 8 months of a similar program (indeed, there was a modest survival advantage for patients randomized to stop therapy after 8 months); (3) doubling of the dose of ara-C from 100 to 200 mg/m² during maintenance therapy; and (4) addition of nonspecific immunotherapy in the form of methanol-extractable residue of Bacille Calinette Grain (MER) to maintenance therapy. With regard to the role of maintenance chemotherapy, an older ECOG study demonstrated no benefit from the addition of 2 years of maintenance therapy following two courses of postremission treatment with DAT (daunorubicin, ara-C, thioguanine).¹⁸⁰ Studies from Germany reported by Buchner et al.^{181, 182} suggested a modest prolongation of CR duration when long-term maintenance therapy was administered after a single course of postremission DAT, although with a

questionable effect on long-term survival. There was less effect of maintenance in later studies when more intensive postremission consolidation was used before the maintenance.^{181, 182}

Two important randomized trials have shown that HIDAC in the postremission setting is better than lower doses of the drug in younger patients. In an ECOG study, patients randomized to receive one course of very intensive postremission consolidation with a HIDAC-type regimen had a longer median duration of remission than patients receiving 2 years of lower-dose maintenance therapy.¹⁸³ The CALGB randomized 596 AML patients in CR to receive four courses of ara-C administered at three different dose levels [100 mg/m² by continuous intravenous infusion (CIV) for 5 days, 400 mg/m² CIV for 5 days, and 3 g/m² IV for 3 h q12h on days 1, 3, and 5 (total six doses/course)]. There was no benefit from the higher-dose arms in patients >60 years of age with a median duration of CR of approximately 13 months and with only 10–12% long-term disease-free survival.¹⁸⁴ In addition, there was a substantial incidence of CNS neurotoxicity in older patients, manifested primarily as cerebellar dysfunction. Other studies have also failed to show a benefit for higher doses of ara-C in older patients.¹⁸⁵ By contrast, patients <60 years of age benefited substantially from the HIDAC regimen in terms of both relapse-free and OS. The long-term results in patients <40 years of age were similar to those reported with autologous or allogeneic bone marrow transplant (BMT).

These studies strongly support the use of HIDAC-based consolidation programs in younger patients with AML. It is not known how many courses of such therapy are needed, the optimal dose and schedule of HIDAC, and whether the addition of other active agents will improve on these results. It is likely that ara-C incorporated into DNA is maximal at 1–1.5 g/m² per dose and a recently completed randomized study from the United Kingdom has shown identical OS when doses of 1.5 g/m² were compared with the original CALGB doses of 3 g/m².¹⁸⁶ In another randomized study, the use of other potentially noncross-resistant regimens substituted for HIDAC was not superior to three cycles of HIDAC¹⁸⁷ and studies from the Medical Research Council (MRC) in Britain, which used multiple postremission courses using a variety of different drugs, produced similar overall outcomes.^{188, 189} The CALGB data suggest that the benefit from HIDAC was most pronounced in patients with favorable cytogenetic findings [t(8;21) and inv(16)] with much less effect in patients with unfavorable karyotypes typically associated with drug resistance.⁷⁷ If a chemotherapy-based approach is medically feasible, most clinicians attempt to administer at least three courses of reasonably intensive HIDAC-based therapy postremission regimens. As allogeneic SCT is currently becoming more commonly used, HIDAC-based postremission therapy has been reserved most appropriately for younger patients with inv16, t(8;21) or those with normal cytogenetics with an NPM1 mutation but no FLT3 ITD mutations.⁹

The decision about the type of postremission therapy must consider the patient's medical condition and the possible persistence of infection (particularly with fungal organisms) acquired during induction, as well as the ability to provide adequate platelet transfusion therapy, in an attempt to balance the risk of intensive postremission approaches with the potential benefit. Depending on the intensity of the consolidation program, a 5% mortality rate in CR is to be expected and must be carefully explained to the patient, although the use of myeloid growth factors after consolidation can appreciably shorten the duration of severe neutropenia and potentially make the administration of this therapy safer.^{190, 191}

An alternative way to administer high-dose chemotherapy in AML is autologous SCT. Cryopreserved autologous bone marrow can rapidly reconstitute recipients of ablative regimens, although marrow recovery may be delayed compared with allogeneic BMT.¹⁹² Experience using cytokine-mobilized peripheral blood stem cells (PBSCs) indicates that the durations of neutropenia and particularly thrombocytopenia are shortened compared with the use of bone marrow.¹⁹³ The autologous procedure is

well tolerated and can be readily used in patients up to 65 years of age and perhaps older. The major disadvantages include the absence of a graft-versus-leukemia effect, as well as concern that viable leukemic progenitors will be administered with the autologous stem cells. A number of purging techniques have been used including monoclonal antibodies directed against myeloid blasts, as well as incubation with high concentrations of cytotoxic agents¹⁹² that rather remarkably spare hematopoietic progenitors, although delayed marrow reconstitution is not uncommon.¹⁹³ It is unknown whether these in vitro manipulations are beneficial. When unpurged autologous BMT was harvested after high-dose consolidation therapy, retrospective comparisons did not suggest an increased rate of relapse. A number of centers and groups have reported relapse-free survival rates >40% following autologous SCT in first CR.^{194–196} Historically, syngeneic transplant experience in this situation showed relapse rates of approximately 50%, which is probably the best that can be expected with the autologous approach. Other evidence of the potential of this approach derive from reports of apparent cure rates of 20% in patients transplanted in the second and third remissions of AML.¹⁹²

Allogeneic SCT represents an alternative major therapeutic option for postremission therapy for younger patients, and increasingly, nonmyeloablative SCT is being considered in selected older patients. Syngeneic SCT, using identical twins as donors,¹⁹⁷ and allogeneic SCT using HLA-identical siblings,¹⁹⁸ were first evaluated in patients with advanced, refractory AML. After demonstrating an approximately 10% rate of long-term disease-free survival in this refractory group of patients and a 40–50% disease-free survival in patients in first remission receiving syngeneic transplants, studies of allogeneic transplantation in first remission AML were conducted.¹⁹⁹ Early small series were promising, demonstrating a low rate of relapse with most of the mortality related to complications of acute and chronic graft-versus-host disease (GVHD). With the current advances in supportive care, particularly the use of novel GVHD prophylactic and active therapies, allogeneic SCT is safer and more commonly used.^{200, 201}

In the 1990s several large prospective trials “genetically” assigned patients with histocompatible siblings to allogeneic BMT (usually only in those ≤45 years of age) while randomizing the others to either autologous BMT or chemotherapy.^{188, 202} In the first of these trials which included 422 patients <45 years of age (median 33 years), disease-free survival was similar in patients undergoing allogeneic BMT (55% projected at 4 years) and autologous BMT (48%) and superior to the chemotherapy group (30%), which received a second course of consolidation chemotherapy with intermediate-dose ara-C and m-amsacrine.²⁰² OS was similar, however, because many patients relapsing after chemotherapy could be successfully re-induced and then undergo SCT in second CR. Many patients did not undergo treatment as randomized, and no information was provided about responses to the three treatments in different cytogenetic risk groups.

Another similarly designed trial performed in France failed to show a benefit for either type of BMT compared with patients receiving intensive postremission chemotherapy.²⁰³ A large study conducted in Germany failed to show a benefit from autologous transplantation given as a component of consolidation therapy. The MRC 10 trial conducted in Great Britain¹⁸⁸ showed that autologous BMT was beneficial. Patients who were not assigned to allogeneic BMT received three cycles of post-CR chemotherapy and were then randomized to nonpurged autologous BMT or observation. The *addition* of the autologous transplant prolonged CR duration, but there was no significant difference in OS between the two groups. Allogeneic BMT was not significantly better than autologous BMT; no modality was clearly better than another in different cytogenetic risk groups. The MRC trials were updated with an intent to treat analysis of results in patients with and without matched sibling donors.¹⁸⁹ Again, there was no apparent survival

benefit compared with chemotherapy for patients who had available donors in whom a transplant could have been performed, and no advantage when patients with donors who were and were not transplanted were compared.

The trial conducted by the North American Intergroup²⁰⁴ found that chemotherapy was at least as good as autologous or allogeneic BMT in leading to cure, based on the intent to treat analysis. As in all the other studies, many patients assigned to either modality of BMT did not receive this therapy for a variety of reasons. Some general conclusions can be drawn concerning the role of allogeneic BMT in the management of patients with AML in first CR:

1. Applicability of the technique is somewhat limited by patient age. Mortality from GVHD increases every decade. Improvements in supportive care and the increased use of reduced intensity transplants using nonmyeloablative conditioning regimens and PBSCs allow increased use of transplantation to older individuals. Early side effects are markedly decreased by the nonablative approach, which is medically feasible in most older patients.²⁰⁵ A systematic prospective study showed that because of clinical, administrative, and donor availability issues, only a small fraction of older patients in first CR can in fact proceed to transplantation.²⁰⁶ Nonetheless, because the results are poor with chemotherapy in older adults and are better (at least with those who make it to transplant (35% disease-free survival) with reduced-intensity alloSCT, it is generally accepted as feasible for adults up to age 75.
2. Less than one-third of potential recipients have suitable HLA-matched family donors. Alternatives include the use of matched unrelated donors, partially mismatched family donors, haploidentical donors, or cord blood preparations. Administrative delays in identifying suitable donors remain problematic despite the availability of millions of HLA-type donors worldwide.²⁰⁷ This is particularly true for patients from ethnic minority groups with less common HLA types and also indicates that there is considerable selection bias in reports of unrelated donor transplants, because some higher-risk patients relapse while awaiting for a donor to be identified. Nonetheless, with the use of molecular histocompatibility typing, the results following unrelated allogeneic transplant are equivalent to those with matching sibling transplant extending the use of allogeneic transplant for a much larger group of patients with AML in first remission.^{208, 209} Umbilical cord blood may offer an alternative source of stem cells for those without matched siblings or unrelated donors. The incidence of GVHD is much lower following cord blood transplants despite the fact that many of these transplants use mismatched donors. Engraftment can be delayed, however, and dosage considerations represent an issue for many adult recipients, although the use of double cord transplants has helped to address this problem.^{210, 211} At present, haploidentical transplantation from partially matched siblings, parents, or children is also available, and hence donors are available for almost all recipients, although the relapse rate may be higher than that with matched donor.²¹²
3. Although allogeneic SCT can cure some patients with chemotherapy-resistant disease, there remains an appreciable relapse rate and at least some of the factors predictive of drug resistance and relapse after chemotherapy also apply to SCT recipients.^{213, 214}
4. The antileukemic effect following BMT correlates with the occurrence and severity of GVHD, presumably as a result of a graft-versus-leukemia effect. Attempts to attenuate GVHD with a variety of immunosuppressive approaches are associated with a decrease in GVHD, but also an increase in the relapse rate.²¹⁵ Selective T-cell depletion approaches and other immunologic manipulations of the graft are being evaluated in an attempt to make allogeneic SCT safer without an increased relapse risk.^{216, 217}

5. As many as 10–20% of surviving patients may have significant symptoms and impairment of performance status because of chronic GVHD. There is also a small increase in the frequency of secondary tumors in long-term survivors.²¹⁸

There seems little controversy about the advisability of using a HIDAC-based postremission approach for those with CBF cytogenetic abnormalities and in using an allogeneic transplantation-based approach for those with adverse prognosis based on molecular or karyotypic findings at diagnosis. However, there still remains controversy about handling intermediate-risk patients, particularly those with normal chromosomes. Meta-analysis have suggested that in general, all patients with nonfavorable cytogenetics should fare slightly better with an SCT approach.^{219–221} The only subgroup in the intermediate prognosis group for whom this is not clear-cut is those with normal cytogenetics and an NPM1 mutation but without a FLT3 ITD mutation. Survival rates of patients treated by a chemotherapy-based approach are higher, and it would be reasonable to reserve SCT for second remission for such patients as well as for those with favorable translocations.

Therapy of relapsed and refractory AML

A number of agents with clear-cut activity when used alone or in combination in patients with relapsed or refractory AML are available, including amsacrine, mitoxantrone, diaziquone, idarubicin, fludarabine, 2-chlorodeoxy-adenosine, etoposide, homoharringtonine, topotecan, carboplatin, and clofarabine. There is considerable heterogeneity among relapsed patients, and a number of factors in addition to the specific drugs used influence the outcome of treatment.^{222–224} Some consistent trends are evident: (1) Response rates are uniformly low in patients with primary refractory leukemia, in those with short initial CR durations, or in those who relapsed while receiving postremission chemotherapy; (2) leukemias that evolved from a prior hematologic disorder, and patients with poor-risk cytogenetics are particularly resistant to further therapy; and (3) patients in second and subsequent relapses have a poorer prognosis than patients in their first relapse, and the durations of subsequent remissions tend to decrease progressively.

Results from the MRC in Great Britain, which prospectively followed all patients entered on an induction AML trial, are supportive of these conclusions.²²⁴ In another study, patients whose initial remission was more than 18 months had a reinduction rate of 64% (37 of 58) compared with a 29% CR rate in 278 patients with shorter initial remissions. Furthermore, the duration of second CR was longer in the former group (8 months vs 3 months). Patient age and cytogenetic findings are also important prognostic factors, emphasizing the higher effect of patient selection on the results of reported phase II trials. In the absence of comparative trials, differing results may very well be the consequence of patient selection rather than the superiority of a particular regimen.

The type and timing of therapy for relapsed patients should be individualized. Patients with other medical problems who have had poor responses to initial therapy have a small likelihood of sustained benefit from reinduction therapy and, indeed, may have their life shortened by intensive therapy. Some of these patients can be supported for many months, with maintenance of a reasonable quality of life, with a more conservative approach using red blood cell and platelet transfusions and oral hydroxyurea to control elevated WBC counts or symptoms such as bone pain. However, there is no potential for long-term benefit. Conversely, younger patients with longer initial responses may derive prolonged benefit from intensive reinduction therapy, if a remission or at least a good response can be followed by allogeneic stem cell transplant.

Recurrence of leukemia is often detected when the patient is asymptomatic, blood counts are normal, and there is modest marrow infiltration by blasts. Although it is logical to begin reinduction therapy at the earliest sign of relapse, when tumor burden is presumably the lowest, there are no data to demonstrate the validity of this approach except possibly as preparation for subsequent SCT. The drawback of early treatment is that reinduction therapy is often unsuccessful and may result in excessive early morbidity and premature patient death, but if long-term survival is the goal (e.g., an allogeneic stem cell transplant), there is no reason to delay.

There are essentially no comparative trials providing guidance about the choice of agents to be used. The initial decision is generally between reuse of drugs that have previously been effective in a given patient, compared with the use of new drugs, some of which may be investigational. If a patient has relapsed while receiving chemotherapy, it makes little sense to use these same agents for reinduction. The oft-quoted guidance is to repeat the induction regimen if the disease-free interval is >1 year, otherwise a HIDAC-based approach (2–3 g/m² q12h for 8–12 doses) is reasonable. There is no proven benefit of postremission chemotherapy in patients achieving second or third remissions. The drawback of postremission chemotherapy in this setting is that one is potentially depriving patients of time when they would be asymptomatic and discharged from hospital by the administration of therapy of variable toxicity, but no proven long-term efficacy.

It is unclear whether SCT should be offered at the time of initial relapse or whether patients should be reinduced and transplanted when a second remission is achieved. Unfortunately, most patients do not achieve second remission, and some develop medical problems during reinduction therapy that preclude subsequent transplantation. Enthusiasm for transplantation in relapse derives from reports from Seattle indicating that the results of allogeneic transplantation in early relapse were equivalent to or better than those achieved in patients transplanted in second or subsequent remissions.²²⁵ It is often a practical problem to identify patients during early relapse and to be able to refer such patients for transplantation rapidly. Nonetheless, it would probably be best to consider allogeneic transplantation for patients in early relapse if a suitable donor is available, particularly in younger patients. Similarly, allogeneic BMT can result in long-term survival in some patients with primary refractory leukemia, and it is advisable to HLA-type patients and their families at diagnosis to allow for this possibility. It is more difficult to use nonrelated donors for these purposes because of delays caused by tissue typing, identification of donors, and stem cell procurement. Currently, most transplant centers have recommended that patients in more florid relapse receive induction chemotherapy first because of poor results with SCT as primary therapy in such patients. Because many patients under 75 years of age have an allogeneic transplant in CR1, many relapses to date have occurred after such a procedure. Relapse after allogeneic SCT are particularly ominous, with a 7% chance of 2-year survival.²²⁶ Selected patients who relapse following BMT can derive benefit from donor lymphocyte infusions²²⁶ or a second BMT²²⁷ and, in general, can receive and tolerate further chemotherapy. Targeted therapies, such as sorafenib in FLT3 ITD mutant AML^{228, 229} or immune checkpoint inhibitors,²³⁰ produce better results in the post-SCT relapse setting.

Patients who achieve second remission after a first remission in which only chemotherapy or autologous SCT was used probably have a higher chance of long-term survival if transplanted in second remission. Hence, relapsed patients who are candidates for allogeneic transplantation should have donor searches done while they are undergoing reinduction treatment. Patients who respond to reinduction chemotherapy have also identified themselves as affected with more chemotherapy-sensitive disease with predicted better outcomes from allogeneic transplantation.

Therapy of acute promyelocytic leukemia (APL)

Treatment for APL differs substantially from that for other subtypes of AML in that the use of the so-called “differentiation therapy” is included in the former. In theory, if leukemic progenitors could be forced to undergo terminal differentiation *in vivo*, then the leukemic clone could lose the capacity for self-renewal and be eliminated, with fewer side effects than those occurring with intensive cytotoxic chemotherapy. With the exception of the HL-60 cell line and blasts obtained from patients with APL, it has been difficult to reproducibly induce fresh leukemia cells to differentiate *in vitro*.

Limited clinical trials evaluating “differentiating” therapies, including vitamin D and low-dose ara-C, produced disappointing results except for some patients with APL who derived transient benefit from treatment with *cis*-retinoic acid.²³¹ The differentiation paradigm was verified, however, by dramatic responses in patients with APL reported from China with ATRA administered orally for 30–90 days.²³² CRs were seen in >80% of both relapsed and previously untreated individuals. Marrow aplasia did not occur and serial bone marrows showed maturation of the abnormal, hypergranulated promyelocytes.²³³ ²³⁴ DIC resolved promptly, with a profound reduction in the requirement for platelet transfusions following ATRA treatment. Although the hemorrhagic complications are decreased, approximately 20–30% of patients treated with ATRA only develop significant side effects that can include fever, rapidly evolving pulmonary insufficiency, pericarditis, and pleurisy. This syndrome can occur independently of the leukocytosis frequently observed with ATRA therapy and can be fatal. Optimal management includes the prompt administration of corticosteroids at the first signs of the “ATRA” syndrome.^{235, 236} Resistance to ATRA eventually develops in patients treated in relapse, and virtually all patients treated with ATRA only relapse. Possible pharmacokinetic mechanisms include induction of more rapid metabolism of the ATRA and induction of cytoplasmic retinoic acid-binding protein in normal tissues that bind the ATRA, thereby decreasing the exposure of residual APL cells to the drug.²³⁷

Once the efficacy of ATRA in APL was recognized, much effort was made to determine the optimal way to use this agent. Trials conducted on both sides of the Atlantic showed that combinations of retinoic acid and anthracycline-based chemo are better than either agent alone both during induction and postremission therapy.^{85, 238} A risk score based on platelet and white counts at diagnosis derived from results in these trials, notably from successive Spanish (PETHEMA) trials, indicated that those with the poorest long-term outcome are those with a white count >10,000/ μ L and those with the best long-term outcomes are those with a white count <10,000/ μ L and platelet count >40,000/ μ L at the time of diagnosis.²³⁹ Before the introduction of arsenic trioxide, the standard of care could be summarized as anthracyclines plus ATRA, followed by two to three cycles of retinoic acid plus anthracycline as consolidation. Maintenance therapy with oral antimetabolites and ATRA for approximately 1 year after completion of intensive chemotherapy was thought to add an event-free and OS benefit²³⁸ and higher doses of ara-C were felt to be beneficial in those with high-risk disease based on a white count >10,000/ μ L at diagnosis.²⁴⁰ Further, disease recurrence could be predicted by development of molecular evidence of disease (PML-RAR α) transcripts by PCR measurement ahead of morphologic relapse.⁹⁰ Patients who could be rendered molecularly negative with additional therapy could then be salvaged with an autologous transplant,²⁴¹ whereas those who remained molecularly positive would be better served by an allogeneic transplant. Some of the late relapses were in the CNS,²⁴² prompting calls for routine use of prophylactic intrathecal therapy at least in those with high white count at diagnosis and in all patients in relapse after control of the coagulopathy and thrombocytopenia. There was also some question such as whether this intensive chemotherapy could lead to MDS and/or secondary leukemias.²⁴³

The demonstration, again in China, that intravenous arsenic trioxide produces a high rate of CR even in patients with advanced, multiply relapsed disease,²⁴⁴ spurred a major change in our approach to APL. Although the precise mechanism of action and the explanation for its relative specificity for APL remain to be elucidated, arsenic trioxide serves to accelerate apoptotic cell death in APL.²⁴⁵ Recently, tetra-arsenic tetra-sulfide has been shown to be very active in both newly diagnosed and relapsed APL patients with the advantage of oral administration.²⁴⁶ While arsenic trioxide first became the standard therapy for relapsed APL, it is currently routinely used during induction and/or postremission treatment of APL. Investigators from China showed high response rates using ATRA and arsenic as initial treatment,²⁴⁷ while other studies from India²⁴⁸ and Iran²⁴⁹ reported high molecular CR rates, which were durable using arsenic only. Using only ATRA and arsenic in patients not deemed to be candidates for anthracycline-based therapy, with GO added for patients with high WBC or insufficient response, the MD Anderson Group demonstrated a leukemia-free survival (LFS) rate as high as that observed in cooperative trials using more standard therapy.^{250, 251} The North American Intergroup evaluated the addition of two courses of arsenic as consolidation therapy post remission and showed a survival benefit compared with the standard treatment without arsenic.²⁵² Patients with high-risk disease (WBC > 10K) fared very well with this approach. Australian investigators also showed the value of a combined chemo/ATRA/arsenic approach.²⁵³

One of the most dramatic changes in the way we treat APL derived from a Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto (GIMEMA)-led trial which compared a chemotherapy-free based approach (ATRA and arsenic trioxide given together as both induction and post remission therapy) to the aforementioned PETHEMA approach using anthracyclines and retinoic acid ([Figure 12](#))¹⁰⁰ The trial was designed as a noninferiority effort and was restricted to patients <70 years of age whose white count was <10,000/ μ L at diagnosis. Patients assigned to the ATRA/arsenic arm had a 93% event-free and 95% OS, which was statistically superior to the outcome in patients assigned to the chemotherapy-containing arm. As such, the new standard of care for those with white count <10,000/ μ L at diagnosis is the regimen of ATRA and arsenic as used in the GIMEMA trial. The standard of care for those patients whose white count >10,000/ μ L has not yet emerged, but it is reasonable to use CALGB 9710²⁵² or the EORTC trial²⁴⁰ approach in such patients as favorable results have been obtained with these regimens in this subgroup. The future of APL therapy certainly involves the minimal use of cytotoxic chemotherapy. It may soon be possible to cure a large majority of patients with this disease by pills, as oral formulations of arsenic trioxide may be able to replace the frequent and relatively cumbersome IV arsenic infusions.

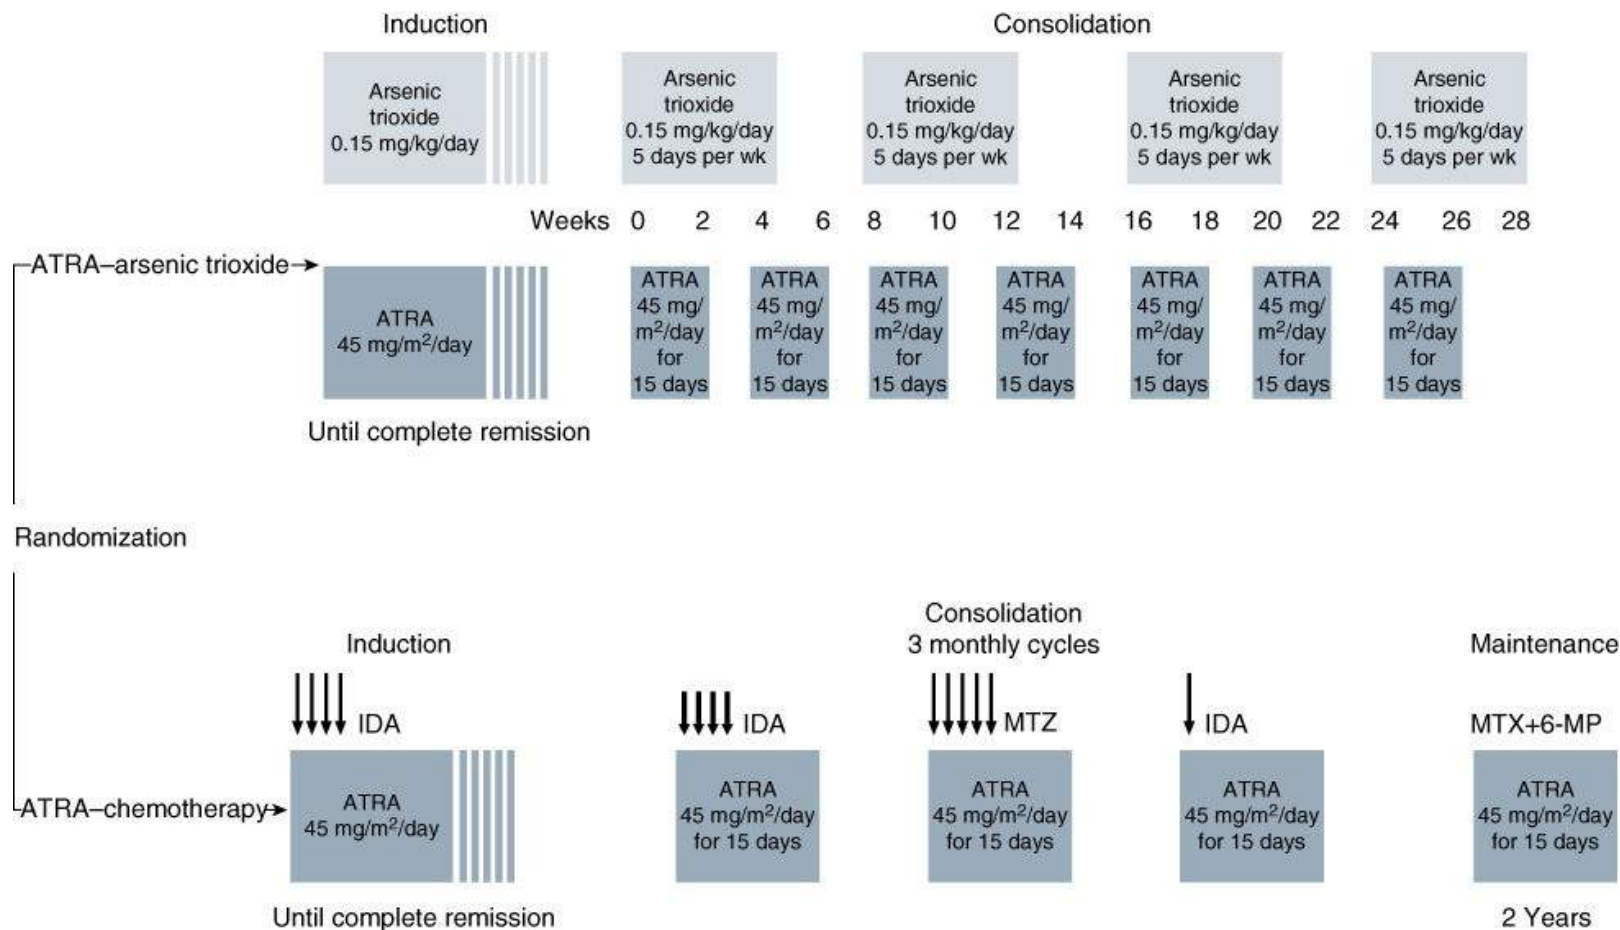

Figure 12 Treatment Groups. In the all-trans retinoic acid (ATRA)–chemotherapy group, the chemotherapy regimen was as follows: idarubicin (IDA) at a dose of 12 mg/m² of body surface area per day on days 2, 4, 6, and 8 of the induction phase; IDA at a dose of 5 mg/m²/day on days 1–4 of the first cycle of consolidation therapy; mitoxantrone (MTZ) at a dose of 10 mg/m²/day on days 1–5 of the second cycle of consolidation therapy; IDA at a dose of 12 mg/m²/day on day 1 of the third cycle of consolidation therapy; and intramuscular or oral methotrexate (MTX) at a dose of 15 mg/m²/week and oral 6-mercaptopurine (6-MP) at a dose of 50 mg/m²/day, alternating with ATRA at a dose of 45 mg/m²/day, for 15 days every 3 months for 2 years. The vertical lines in the induction therapy boxes indicate variability in the duration of remission induction therapy. The arrows indicate the approximate timing and doses of the different chemotherapeutic agents.

The major remaining problem in the treatment of APL is the prevention of hemorrhagic death, often the consequence of delays in diagnosis and the initiation of therapy with ATRA. APL should be suspected in patients presenting with hemorrhagic symptoms in association with abnormalities of coagulation including hypofibrinogenemia, accompanied by seemingly modest elevations of the prothrombin time and evidence of accelerated fibrinolysis. ATRA should be initiated empirically in such patients and then discontinued when cytogenetic or molecular studies fail to confirm the diagnosis of APL.

Other supportive care and therapeutic approaches

Hematopoietic growth factors

Because of the higher myelosuppression-associated toxicity and mortality, particularly in older adults with AML, the development of hematopoietic growth factors (HGFs) ameliorated such side effects.

Granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, and interleukin (IL)-3 as well as the thrombopoietic factors, megakaryocyte growth and development factor (MGDF), IL-11, and the newer thrombopoietic agents (romiplostim and eltrombopag) were evaluated. The use of these agents in AML lagged behind that in solid tumors, because of the concern that pharmacologic doses would lead to blast proliferation and a poor clinical outcome. Although adverse effects of this clinical problem have not been proved, the HGFs have not lived up to their promise for other reasons.

Multiple randomized studies have been completed in which older patients received an HGF or placebo following the completion of initial induction therapy, with the goal of increasing CR rate by reducing infectious complications as a consequence of shortened durations of severe myelosuppression.^{254–259} All trials noted a decrease in the order of 2–5 days in the number of days of neutropenia $<500/\mu\text{L}$, sometimes in association with a smaller 1- to 2-day reduction in the duration of hospital stay, but with the exception of a smaller trial reported by the ECOG,²⁵⁴ there was no significant difference in the incidence of severe infection, deaths from infections, CR rate, or survival. One randomized trial using G-CSF after induction therapy for older patients with AML showed an increased CR rate for the G-CSF recipients.²⁵⁸ Unexpectedly, the infectious mortality was similar in the two groups of patients, and the reason for the increased CR rate is unclear. There was no difference in OS.

In conclusion, the benefits of growth factors administered after the completion of induction therapy are modest at best.²⁶⁰ By contrast, G-CSF following intensive consolidation therapy has appreciably shortened the duration of neutropenia, albeit without improvement in CR duration or survival.¹⁹⁰ Because of the potential for eliminating the need for hospitalization, the use of HGF can be recommended following consolidation therapy. Smaller studies with pegylated thrombopoietin failed to show reduced needs for platelet transfusions during the induction or consolidation treatment of AML.²⁶¹ The thrombopoietin agonists romiplostim and eltrombopag, each approved in steroid-refractory ITP, have been used in clinical trials in MDS,^{262, 263} but evidence suggesting leukemia cell stimulation has precluded use in AML and MDS.

Although in vitro evidence suggests that HGFs can increase the cytotoxic effects of ara-C, at least in part by increasing the fraction of cells in S-phase,^{264, 265} clinical results with the priming strategy have been disappointing. An early study from the MD Anderson Group suggested that GM-CSF administered before and during chemotherapy produced lower response rates and survival than those observed in a historical control group treated with chemotherapy only.²⁶⁶ Most subsequent studies that randomized patients to receive GM-CSF/G-CSF or no marrow stimulants, before, during, and/or after induction chemotherapy^{267–269} also failed to show an advantage for patients primed with growth factor. Some of these studies used HIDAC, whereas others evaluated more conventional continuous infusion schedules. One of the studies purporting to show an advantage²⁷⁰ could not be confirmed in a follow-up investigation.

Immune modulation

A critical component of the therapeutic benefit associated with allogeneic SCT is related to the graft-versus-leukemia effect. Although this is a complex, multifactorial set of events, further studies may enable the rational application of lymphokines to stimulate the appropriate cells in patients treated with chemotherapy only. Circulating natural killer (NK) cells that can be cytotoxic to leukemia cell lines, and autologous leukemia cells in vitro, can be detected after both autologous and allogeneic transplantation, but not after chemotherapy.²⁷¹ The numbers of NK cells can be expanded by the posttransplant administration of IL-2,²⁷² although low-dose IL-2 can ameliorate GVHD by expanding T-reg cells.²⁷³

Standard or high IL-2 has some antileukemic effect in patients with AML in relapse.^{274, 275} Pilot trials have documented the feasibility of administering IL-2 in the postchemotherapy setting, but unfortunately, a large randomized trial failed to demonstrate any benefit from the administration of IL-2 after completion of consolidation chemotherapy in older patients with AML.²⁷⁶ A similar trial in younger adults documented a trend toward improved LFS and OS in patients randomized to IL-2, but many patients refused randomization or IL-2 if they are randomized to receive it.²⁷⁷ Another randomized trial showed that a combination of histamine plus IL-2 was beneficial in the late postremission setting,²⁷⁸ but has been criticized because of the heterogeneity of the prerandomization chemotherapy. Vaccine-based approaches using dendritic cell fusions to present leukemia-associated antigens, such as WT1 and PR1, engineered T cells, or transducing AML cells to express proteins capable of stimulating immune response, are under development.^{279–282}

Circumvention of drug resistance

Drug resistance is conferred by properties of a small fraction of leukemia cells, presumably the fraction capable of efficient self-renewal.^{283, 284} Investigations of these leukemia “stem cells” have been hampered by difficulties in reliably and repeatedly cloning leukemic cells from individual patients to allow serial studies to be performed. In addition, a potential sampling bias exists in that the in vitro results are a reflection only of the characteristics of cells obtained at a single point in time that can grow in an artificial environment. Nonetheless, there is considerable interest in the development of drugs, which may preferentially target these cells.²⁸⁵

The multidrug resistance (MDR) phenotype is associated in most cases with increased amounts of a membrane glycoprotein (p-170), which serves as a pump accelerating the efflux of a wide variety of agents, including the anthracycline antibiotics, vincristine, taxanes, and mitoxantrone.²⁸⁶ Levels of p-170 can be assessed by flow cytometric studies of individual AML cells, Western blots of cell preparations, and indirectly by mRNA levels and gene expression, and are increased in patients refractory to chemotherapy.^{287, 288} The MDR phenotype is most common in patients with relapsed or refractory disease, older patients, and those with other adverse prognostic factors.^{289, 290}

Incubation with a variety of compounds in vitro, including the calcium channel blockers verapamil, quinine, and cyclosporine A, can reverse the effect of p-170.²⁹⁰ Cardiotoxicity occurs at the doses of verapamil required to produce this effect. Cyclosporine can reverse the MDR phenotype in vitro at drug levels that are likely to be clinically acceptable in terms of toxicity. A randomized trial of the addition of cyclosporin A to an ara-C plus continuous infusion daunorubicin regimen for patients with relapsed AML suggested an OS benefit for adults in the experimental arm.²⁹¹ PSC-833 is a more potent nonimmunosuppressive cyclosporine analogue, which has been evaluated in randomized trials as an adjunct to standard therapy. Unfortunately, no improvement in CR rates was observed, with some trials showing increased toxicity in the PSC833 recipients.^{292, 293} Because of their effects on normal tissues such as the liver and kidney, these modulators also affect the pharmacokinetics of antineoplastic agents, such that the dosage of anthracyclines or etoposide usually has to be attenuated if given with an MDR modulator.²⁹⁴ Other MDR modulators have been similarly disappointing.²⁹⁵

Minimal residual disease (MRD)

A number of techniques can detect residual leukemia cells in patients with morphologic CR, including (in approximate descending order of sensitivity) conventional cytogenetics,²⁹⁶ Southern blotting for known

gene rearrangements, fluorescent in situ hybridization (FISH), multiparameter flow cytometry, and RT-PCR.^{297, 298} Serial measurement of MRD is an important component of the management of APL, chronic myelogenous leukemia, and childhood ALL, but is not sufficiently standardized to be used routinely in patients with AML.²⁹⁹ Technical problems abound, including the requirement for a known and already cloned abnormality when applying molecular techniques and the potential for changes in antigen expression over time when using immunologic monitoring. Only few large prospective studies have been conducted on this topic. Although preliminary data are compatible with the logical premise that persistence of detectable disease presages eventual relapse, false-positive and false-negative rates may be appreciable and could result in incorrect decisions about further treatment. Serial monitoring is cumbersome, and it is hoped that future studies will determine specific time points after completion of therapy when detection of MRD is prognostically significant. It is also likely that different sampling strategies will be needed for different AML subtypes. The key clinical question is whether intervention with further therapy or allogeneic SCT is valuable if applied earlier, before gross relapse. There are no prospective data addressing this issue, but retrospective studies have shown much higher-than-expected relapse rates in allogeneic transplant recipients with detectable MRD. Because of the presence of residual disease, autologous collection and high-dose therapy may be predicted to be of less value in this circumstance.

Small-molecule inhibitors and other novel approaches

While there has not been any newly approved drug in non-APL/AML for many years (not counting GO, which was approved and then withdrawn), many agents are under development. A comprehensive discussion of all such agents is beyond the scope of this chapter; however, it is worth highlighting progress in tyrosine kinase inhibitor therapy as well as a few other interesting agents in developments.

The success of imatinib and other BCR-ABL inhibitors in CML prompted a search for similar gain-of-function mutations in AML, whose inhibition could lead to therapeutic benefit. Gain-of-function mutations in the FLT3 transmembrane tyrosine kinase occur in approximately 30% of patients with de novo AML, consisting most commonly of an ITD mutation, which elongates the juxtamembrane region by between 3 and 100 amino acids; a smaller number of patients have an activating point mutation in the tyrosine kinase domain.⁷ Both types of mutations can cause ligand-independent activation³⁰⁰ and a myeloproliferative disease in murine models.³⁰¹ Several so-called FLT3 inhibitors are under development, although none as of yet has been approved by the FDA. Single-agent trials with midostaurin,³⁰² lestaurtinib,³⁰³ and sorafenib³⁰⁴ each showed responses in patients with advanced, mutant FLT3 AML. Sorafenib is approved as a vascular endothelial growth factor receptor inhibitor in patients with advanced renal and hepatocellular carcinomas. Midostaurin can inhibit the growth of cells with a tyrosine kinase domain mutation, while most other agents (except for crenolanib)³⁰⁵ cannot and are only being developed in the FLT3 population that has the ITD mutation. Quizartinib, a potent and relatively specific FLT3 ITD inhibitor, has shown a relatively high response rate as a single agent³⁰⁶ and is being compared with chemotherapy in mutant FLT3 ITD patients with AML in relapse; however, an important mechanism of resistance is the outgrowth of clones with an FLT3 TKD mutation.³⁰⁷

Given the relatively rare CR and brief duration of response with single-agent FLT3 inhibitor therapy, there has been a major thrust to develop these agents in combination with chemotherapy. A trial testing the addition of lestaurtinib to chemotherapy in relapsed mutant FLT3 ITD patients was negative,³⁰⁸ but several other clinical trials comparing chemotherapy with or without an FLT3 inhibitor are underway. Moreover, FLT3 inhibitors, particularly sorafenib, seem to be effective in some patients with mutant FLT3

Given that a sizable minority of patients with favorable chromosome (the so-called CBF translocations) AML have either over of c-kit and/or mutations in the c-kit tyrosine kinase, the c-kit inhibitor dasatinib has been added to chemotherapy in this cytogenetic subset of patients with AML. Preliminary results are encouraging and a randomized trial is ongoing.³⁰⁹ Another gain-of-function mutation noted in approximately 20% of AML patients occur in the IDH1 or IDH2 genes whose products catalyze the neomorphic production of 2-hydroxyglutamate, which epigenetically affects gene expression in a pro-leukemic manner.³¹⁰ Preliminary results with IDH1 and IDH2 inhibitors have been encouraging.³¹¹ MEK pathway inhibitors in patients with activating mutation of the RAS oncogene¹² have also led to responses.

In addition to these genomically based therapies, there are a host of other agents under development, which take advantage of potential biologic differences between AML cells and normal stem cells. AML cells in the marrow niche have their survival promoted by factors elaborated by endothelial and other cells in the marrow stroma.³¹² Drugs such as the CXCR4 inhibitor, plerixafor, may disrupt the survival signals making AML cells more amenable to killing via cytotoxic agents.³¹³ ABT199 is a BCL2 inhibitor with significant advantage in CLL,³¹⁴ and it may be used alone or in combination with chemotherapy to promote apoptosis in AML cells. Another agent in development is KPT330, a nuclear export protein inhibitor, which works primarily by preventing expulsion of tumor suppressor genes from the nucleus of cancer cells in general, and in AML cells in particular.³¹⁵ There are several antibodies and immunoconjugates targeting CD123,³¹⁶ believed to be specifically expressed on leukemic stem cells. The developmental pathway for any agent in AML is slightly daunting as it has to be determined if it is going to be useful as a single agent in advanced patients and whether it needs to be added in chemotherapy in patients in earlier stages of the disease. In the latter case, given the relatively high initial response rate to chemotherapy in patients, large trials or trials with a novel design are needed.

Complications

Hyperleukocytosis

Leukemic blasts are considerably less deformable than mature myeloid cells³¹⁷ and are “stickier” than lymphoblasts because of the expression of cell surface adhesion molecules. With increasing blast counts, usually at levels $>100,000/\mu\text{L}$ in the myeloid leukemias, blood flow in the microcirculation can be impeded by plugs of these more rigid cells. Local hypoxemia may be exacerbated by the high metabolic activity of the dividing blasts, with endothelial damage and hemorrhage. Red blood cell transfusions can potentially further increase the blood viscosity and make the situation worse and should be either withheld or administered slowly, until the WBC decreases. Coagulation abnormalities, including DIC, further increase the risk of local hemorrhage. Liberal use of platelet transfusions is recommended, particularly because the platelet count is frequently overestimated because of the presence of fragments of blasts on blood smears, which can be mistakenly counted as platelets by automated blood cell counters.³¹⁸

Although pathologic evidence of leukostasis can be found in most organs in patients with extremely high blast cell counts, clinical symptomatology is usually related to CNS and pulmonary involvement.^{319, 320} Occasionally, dyspnea with worsening hypoxemia can occur following therapy and lysis of trapped leukemic cells. Spurious elevation of serum potassium can occur because of the release from WBCs during clotting, and it is sometimes necessary to measure potassium levels on heparinized plasma. Similarly, pO_2 can appear falsely decreased because of the enhanced metabolic activity of the WBCs,

even when the specimen is appropriately placed on ice during transport to the laboratory. Pulse oximetry provides an accurate assessment of O₂ saturation in such circumstances. Hyperleukocytosis is more common in patients with myelomonocytic or monocytic leukemia, and it is possible that the clinical manifestations are exacerbated by the migration of leukemic promonocytes into tissue where further proliferation occurs.

The initial mortality rate for patients with AML and symptomatic hyperleukocytosis is high.³²⁰ If patients survive the initial period, they tend to have somewhat lower remission rates and shorter CR durations. Symptomatic hyperleukocytosis in AML (and rarely in ALL) constitutes a medical emergency, and effort should be made to lower the WBC count rapidly. In most patients, rapid cytoreduction can be achieved by chemotherapy, with either standard induction agents or high doses of hydroxyurea (3 g/m²/day). Some centers also advocate low-dose cranial irradiation, including the retina, to prevent further proliferation of leukemic cells in CNS sites, where drug delivery may theoretically be compromised. This treatment is well tolerated, although there are no comparative studies to determine whether the results are superior to chemotherapy only.

In some patients, it is impossible to initiate chemotherapy immediately because of renal insufficiency, metabolic problems, delays in initiating allopurinol therapy to prevent hyperuricemia, or similar considerations. In such patients, emergency leukapheresis has been used to lower or stabilize the white count.^{321, 322} Although intensive leukapheresis, with procedure times often lasting many hours, can improve pulmonary and CNS symptomatology, there are theoretic and practical limitations to its benefits. It is difficult, for example, for leukapheresis to affect already established vascular plugs, particularly if vascular invasion has taken place. In such cases, chemotherapy is the primary modality, although theoretically, leukapheresis could decrease further accumulation of leukocytes at these sites. Furthermore, it is precisely the patient in whom leukostasis is most likely to occur, that is, the patient with high and rapidly rising blasts counts, in whom the technical limitations of leukapheresis are apparent, in that it is often difficult, even with highly efficient cell separators, to reduce the rising count. In such patients with a high proliferative thrust, cycle-specific chemotherapeutic agents are more likely to be most immediately effective. Leukapheresis is also of modest benefit to patients who develop pulmonary problems during cytotoxic treatment, because in some such patients, the symptoms are related at least in part to a local inflammatory response following leukocyte lysis.³²³

Central nervous system leukemia

Involvement of the CNS is considerably less common in patients with AML than in both adults and children with ALL. Most clinicians imply that the incidence has decreased even further in recent years, perhaps because of the use of higher doses of ara-C, which can penetrate into the CNS. The incidence of CNS leukemia has been <5% in large AML clinical trials in recent years.³²⁴ Therefore, diagnostic lumbar punctures are not routinely indicated in the absence of CNS symptoms, and chemotherapy regimens do not include CNS prophylaxis. Symptoms are consequences of increased intracranial pressure and usually consist of a constant headache, sometimes associated with lethargy or other mental changes. Cranial nerve signs (most commonly cranial nerves III or VI) and, occasionally, peripheral nerve manifestations are secondary to nerve root involvement and can be accompanied by headaches or occur alone.³²⁵

The diagnosis is usually suspected clinically and/or by meningeal enhancement on MRI with gadolinium and confirmed by examination of cytocentrifuge preparations of cerebrospinal fluid (CSF) after lumbar puncture. Cell counts can vary from as few as 5 to >1000/μL. Most patients have moderate elevations in CSF protein with a moderate decrease in glucose. Treatment consists of the administration of intrathecal

chemotherapy, with the addition of cranial radiation (usually 2400 cGy), to patients who do not respond fully to chemotherapy or in whom cranial nerve involvement is present.³²⁵ Either methotrexate (15 mg/dose when administered by lumbar puncture) or ara-C (50 mg/dose) can be used as initial therapy, with a crossover to the other agent in the event of refractoriness or relapse. A typical schedule includes treatment twice to thrice a week until the CSF has cleared, generally occurring after a few injections. Treatment is then given at weekly intervals for two more doses to be followed by monthly administration for 1 year. An Ommaya reservoir to permit intraventricular drug administration is frequently needed because of either difficulties in performing repeated lumbar punctures or concern that in some individuals, the CSF flow does not deliver sufficient amounts of the drug from the lumbar space to the entire CNS.³²⁶ Successful therapies with systemically administered agents that penetrate the CNS, such as diaziquone (AZQ), high-dose methotrexate, or HIDAC, have also been reported.³²⁷ Slow-release (depo) preparations of ara-C may be an alternative.³²⁸ Unfortunately, the relapse rate is high, either concomitantly with bone marrow relapse or independently, even after initial successful therapy.

It has been suggested that the incidence of CNS leukemia is higher in patients with FAB M4 E0 morphology and possibly in patients with monocytic leukemia and high circulating blast counts.³²⁹ This may no longer be the case using more contemporary treatment regimens, and prophylactic therapy is not indicated in such individuals. As noted, CNS involvement can occur in patients with APL with high white blood count.

Ophthalmic complications

Essentially every ocular structure can be involved in the leukemias, sometimes dominating the clinical picture in the prechemotherapy era.³³⁰ Leukemia cells can infiltrate the conjunctiva and lacrimal glands, producing obvious masses that may require treatment with radiation therapy. Involvement of the choroid and retina is most common, however. A prospective study of 53 newly diagnosed adults with AML documented retinal or optic nerve abnormalities in 64% of patients.³³¹ Hemorrhage and cotton wool spots (a consequence of nerve fiber ischemia) were most frequent, and the occurrence of these findings was unrelated to patient age, FAB type, WBC count, or hematocrit. Initial platelet counts were lower in patients with retinopathy. A total of 10 patients had decreased visual acuity, including five with macular hemorrhages. It was felt that many of the cotton wool spots were either a consequence of or exacerbated by ischemia due to anemia. Definite leukemic infiltrate of the retina could not be confirmed. All patients received aggressive chemotherapy and platelet transfusion support; no patient received cranial or ocular irradiation. All ocular findings resolved in patients achieving CR and there was no residual visual deficit in any patient. Infectious ocular problems were not noted and seem to be uncommon, perhaps because the prompt empiric use of antibacterial and antifungal antibiotics has decreased the possibility of hematogenous spread of infections to the eye.

Pregnancy

AML is occasionally diagnosed in pregnancy, either because of clinical manifestations or as an incidental finding during blood count checks. If detected during the first trimester, termination of pregnancy followed by treatment of the leukemia is advisable. The management of patients diagnosed later in pregnancy, such as late in the second trimester or during the third trimester, is more problematic. If the leukemia is relatively indolent, it is sometimes possible to manage patients conservatively with leukapheresis and/or transfusion with induction of labor and delivery of the fetus as soon as possible.³³² There have also been many reports of patients treated with chemotherapy later in their pregnancy.^{333, 334} The majority of these women have not aborted, and there has been no report of leukemia occurring in children or an increased

incidence of abnormalities in infants.

Metabolic abnormalities

Patients receiving therapy for AML can experience a wide range of metabolic problems such as vomiting, diarrhea, impaired nutrition, or renal dysfunction, usually because of side effects from antibiotics, particularly amphotericin B. Some metabolic disorders are related to the leukemic process itself. Hyperuricemia, occasionally accompanied by urate nephropathy with renal insufficiency, is the most frequent metabolic accompaniment of AML. All patients should receive allopurinol (≥ 300 mg/day) as soon as the acute leukemia is diagnosed, so that chemotherapy can be administered once it is medically appropriate. In most patients, urate nephropathy can be avoided or ameliorated with vigorous hydration and urinary alkalization with systemic or oral administration of sodium bicarbonate. Allopurinol can usually be discontinued within 1 or 2 days after chemotherapy is completed. In occasional patients with markedly elevated levels of uric acid, the use of recombinant urate oxidase, which can rapidly lower levels within a few hours, may be advisable.³³⁵ A single dose is almost always sufficient, and the decision about subsequent doses depends on serial monitoring of uric acid.³³⁶

Tumor lysis syndrome occurs more frequently in patients with ALL, although some AML patients experience hyperphosphatemia, hypocalcemia, hyperkalemia, and renal insufficiency because of massive leukemic cell death. The inciting cause seems to be the release of large amounts of phosphate from lysed blasts, which coprecipitates with calcium in the kidneys, leading to hypocalcemia and sometimes to oliguric renal failure. Hyperuricemia further contributes to this problem, which is usually self-limited and responds to judicious hydration.

Despite markedly hypercellular marrows, hypercalcemia is extremely unusual in patients with AML. Severe, occasionally symptomatic, hypokalemia is frequent, particularly in patients with monocytic leukemias. The mechanism appears to be renal potassium loss because of tubular damage induced by the high levels of lysozyme often noted in these patients. Aggressive replacement with parenteral potassium is required; the syndrome usually abates after cytoreduction by chemotherapy. Finally, rare patients have been described in whom lactic acidosis has been a constant metabolic accompaniment of the leukemia both at the time of presentation and relapse.³³⁷ The mechanism is unclear, although anaerobic metabolism by the leukemia cells at sites of leukostasis has been postulated.

Summary

Largely because of improvements in supportive care and the anticipatory management of complications of the treatment and underlying disease, the overall outlook for adults <60 years of age with AML has improved worldwide. It is equally clear, however, that results have leveled off and that new approaches are needed to increase the fraction of patients cured. Dramatic advances in molecular genetics offer promise both because of increased understanding of leukemia biology and the production of small molecules, monoclonal antibodies, cytokines, and HGF with potential clinical utility. Further clarification of mechanisms of drug resistance with the possibility of enhancement of the effectiveness of currently available drugs is also an exciting and achievable prospect. These strategies, as well as clinical trials designed to assess the appropriate use of SCT and newer more specifically targeted drugs, determine that therapy for AML will be both more successful and less empiric in the future.

Mast cell leukemia and other mast cell neoplasms

Mast cell disorders are classified among the myeloproliferative diseases and produce a wide spectrum of clinical findings, ranging from reactive benign syndromes with cutaneous involvement to malignant variants with mast cell infiltration of multiple organs, including the bone marrow.^{338, 339}

Reactive mast cell hyperplasia

Mast cell hyperplasia frequently occurs in tissues involved in immediate or delayed-type hypersensitivity reactions, such as in the nasal mucosa during allergic rhinitis. Increased numbers of mast cells in the bone marrow have been noted in association with a wide range of malignant disorders, including lymphoproliferative disorders,³⁴⁰ hairy cell leukemia,³⁴¹ and myeloid neoplasms.^{342, 343} The mast cells in such patients appear to be reactive rather than derived from the malignant clone.

Neoplastic mast cell disease

Urticaria pigmentosa is by far the most common manifestation of neoplastic mast cell proliferation.³⁴⁴ The typical eruption of urticaria pigmentosa consists of multiple discrete hyperpigmented nodulopapular lesions and portends a benign clinical course, particularly in children. Cutaneous symptoms may include the classic urticarial wheals that result from mast cell degranulation due to mechanical insult (Darier's sign), pruritus, or episodic flushing. A blurred distinction exists between cutaneous mastocytosis (CM)³⁴⁵ and systemic mast cell disease (SMCD), an indolent disorder in which mast cells may also be found in extracutaneous sites. The level of serum tryptase is higher in SMCD than in CM.³⁴⁶ Systemic mastocytosis may present with a variety of constitutional and/or gastrointestinal symptoms, each of which can be attributed to excessive elaboration of mast cell mediators. Such symptoms, which may also present to a lesser degree in patients with urticaria pigmentosa, include rhinitis, asthma, nausea, vomiting, diarrhea, syncope, chest pain, bone pain, and rectal discomfort.³⁴⁷ The bony skeleton, the gastrointestinal tract, and the spleen can also be sites of mast cell infiltration.

Malignant mastocytosis is a more aggressive subset of SCMD characterized by a much less favorable clinical course.³⁴⁷ Unlike indolent systemic mastocytosis, in which an affected patient has a normal life expectancy, survival beyond 1–2 years after diagnosis of malignant mastocytosis is uncommon. The bone marrow is always involved, eosinophilia and cytopenias are common, and adenopathy and/or organomegaly are frequently noted.³⁴⁸ In the early 1990s, it was recognized that mast cells from patients with systemic mastocytosis are capable of growing independent of stimulation with C-KIT ligand, the critical mast cell growth factor.³⁴⁹ Cell lines and patient samples demonstrated that the basis for this growth independence was constitutive activation of C-KIT,^{350, 351} most often associated with a mutation at codon 816 in the kinase domain, although mutations of the juxtamembrane region have also been described.³⁵² The ASP-816 VAL mutation has been detected in both B cells and monocytes from patients, suggesting that systemic mastocytosis is a clonal disorder evolving from an early hematopoietic stem cell.³⁵² By contrast, blasts from patients with mast cell leukemia do not have this mutation, suggesting an alternative derivation of the leukemia.³⁵³

Mast cell leukemia represents a rare and aggressive subtype of malignant mastocytosis characterized by the presence of large numbers of atypical mast cells in the peripheral blood.^{354–356} Patients with mast cell leukemia have a median survival of <6 months, in contrast to those with the nonleukemic type of malignant mastocytosis, who tend to survive for a longer time. The majority of reported cases of mast cell leukemia arise in patients with preexisting malignant mast cell disease. Criteria required for the diagnosis of mast

cell leukemia are: (1) the percentage of mast cells in the peripheral WBC differential must be $\geq 10\%$; (2) the leukemic mast cells should display features of morphologic atypia; and (3) cytochemical properties of the leukemic cells must be typical of mast cell derivation (the presence of metachromatic granules staining with chloroacetate esterase, but not with peroxidase).³⁵⁵

Although bone marrow infiltration with atypical mast cells is always present in mast cell leukemia, hematologic findings at the time of diagnosis can vary widely. A mild to moderate degree of anemia is always present; initial leukocyte count can range from normal to $>50,000/\mu\text{L}$.³⁵⁵ The percentage of atypical mast cells (hypogranulated metachromatically staining cells with fragmentation, cytoplasmic tails, and multiple nuclei) may be relatively low (but $>10\%$), but almost always increases substantially with time. Karyotypic studies in several patients with mast cell leukemia have been normal, although the lack of dividing cells for metaphase analysis frequently precludes cytogenetic evaluation. Bone marrow cells from patients with systemic mastocytosis often display cytogenetic abnormalities, such as trisomy 8 and monosomy 7/7q-, 20q-, typical of those with myeloproliferative disorders.^{355, 356} Particularly in patients with concomitant eosinophilia, it is important to exclude cytogenetic abnormalities affecting platelet-derived growth factor receptor (PDGFR, involving chromosome 5q31-32), because such patients can benefit from treatment with imatinib.

Treatment

Treatment of mast cell neoplasms is based on the disease subtype and clinical manifestations. Patients with CM usually require no treatment. SMCD, however, has protean clinical manifestations. For example, those with hematological abnormalities may require supportive care, which could include transfusions or the empiric use of HGFs. Avoidance of mast cell stimulants such as anesthesia, alcohol, aspirin, and morphine may diminish flushing, pruritus, diarrhea, and symptoms that may be histamine-related.^{357–359} H1 and H2 antihistamines or disodium cromoglycolate may offer palliative benefit. Radiation therapy may control localized disease without causing histamine release.³⁶⁰

Unfortunately, the typical ASP-816 VAL mutation is insensitive to the C-KIT inhibitors imatinib mesylate,^{351, 361, 362} and nilotinib,³⁶³ although in vitro studies suggest that this mutated C-KIT may be sensitive to dasatinib.³⁶⁴ Preclinical data suggest that the multitargeted kinase inhibitor, PKC412 (midostaurin), may also inhibit the product of this activating mutation, and early reports suggest potential clinical activity.^{365, 366} Cladribine and alpha interferon exhibit cytoreductive activity in systemic mastocytosis and should be considered in patients with active systemic symptoms.^{367, 368} Responses are usually transient however, and subsequent therapy for those with malignant mastocytosis or frank mast cell leukemia (activating mutations of c-kit are not believed to occur in this entity) is not at all standardized, although induction therapy with an anthracycline in combination with cytarabine for patients with leukemia could be followed by consolidation with HIDAC. Allogeneic hematopoietic SCT could be considered in specific patients, although there is limited experience with this approach.

Chapter 115

Chronic myeloid leukemia

Jorge Cortes, MD ■ Richard T. Silver, MD ■ Hagop M. Kantarjian, MD

Overview

Chronic myeloid leukemia (CML) was the first malignancy where a unique chromosomal abnormality, the Philadelphia chromosome, was directly linked to it. The further unraveling of the molecular and physiologic consequences of this abnormality, with a fusion gene (BCR-ABL) translating into a chimeric protein with increased tyrosine kinase activity, led to the development of specific tyrosine kinase inhibitors. The use of such agents as initial therapy has resulted in a dramatic change in the natural history of the disease where patients properly managed are expected to have a life expectancy similar to that of the general population. Several treatment options are also available for patients who may not have optimal response to their initial therapy. Current research is focusing on approaches that may increase the probability of successful treatment discontinuation for more patients.

Chronic myeloid leukemia (CML) is a myoproliferative neoplasm affecting a pluripotent progenitor and involving myeloid, erythroid, megakaryocytic, B, and sometimes T, lymphoid cells, but not marrow fibroblasts. It is characterized by the presence of a unique chromosomal abnormality, the Philadelphia chromosome (Ph).

Historical perspective

In 1960, a minute chromosome was identified in patients with CML, an abnormality later identified as a balanced translocation between chromosomes 9 and 22.^{1, 2} Later studies demonstrated that this translocation resulted in the creation of a chimeric gene, BCR-ABL, that when transfected into mice can induce CML.³ Translation of this chimeric gene results in a fusion protein with constitutive tyrosine kinase activity.⁴ Interferon-alpha was the first therapy to induce the disappearance of the Philadelphia chromosome, establishing complete cytogenetic responses (CCyRs) as the gold standard of response to therapy.⁵ The knowledge of the activation of a tyrosine kinase led to the development of tyrosine kinase inhibitors (TKIs), initially imatinib⁶ and later second- and third-generation drugs that radically changed the natural history of the disease ([Figure 1](#)).⁷ Today, patients diagnosed with CML, if properly managed, have a life expectancy similar to that of the general population.

Incidence and epidemiology

CML accounts for 15% of all leukemias.^{1, 2} The median age of onset of CML is 55–65 years, and the incidence increases with age with a slight male preponderance (ratio 1.8:1).⁸ It is estimated that 5980 new cases of CML will be diagnosed in the United States in 2014 with 810 patients dying from their disease.⁹ The incidence in the United States has remained constant at about 1.81:100,000. With modern therapy, the annual mortality has decreased from 15–20% to 2%, and the estimated median survival may exceed 20 years. Thus, the prevalence of CML in the United States in the next three decades may exceed 200,000 cases.¹⁰

Risk factors

In most patients with CML, a causative factor cannot be identified. Although ionizing radiation is leukemogenic, the most common leukemia following radiation is acute myeloid leukemia. CML has been reported following the atomic bomb catastrophe in Japan in 1945, and in earlier studies in radiologists and in patients with ankylosing spondylitis treated with radiation therapy.^{3, 4, 11, 12} No other known risk factors have been recognized.

Pathology

CML typically follows a biphasic or triphasic course with a chronic phase, followed by an intermediate accelerated phase, and eventually a frequently terminal blastic phase.¹³ Leukocytosis is common with white cell counts frequently greater than $100 \times 10^9/L$. Historically, the median survival for patients in chronic phase was 3–6 years, with an estimated annual risk of transformation to the blastic phase of 5–10% in the first 2 years and 15–20% subsequently. Accelerated phase is characterized by increasing maturation arrest. Different criteria have been used to define accelerated phase. One common classification defines accelerated phase as the presence of any of the following: $\geq 15\%$ blasts, $\geq 30\%$ blasts plus promyelocytes, $\geq 20\%$ basophils, platelets $< 100 \times 10^9/L$ unrelated to therapy, or cytogenetic clonal evolution.¹⁴ Other criteria have been proposed, such as the World Health Organization (WHO) proposal, but some of these classifications^{7, 15} have not been clinically validated.¹⁶ The median survival for patients in accelerated phase was 1–2 years,^{8, 17} but has greatly improved with the use of TKI.¹⁸ The blastic phase is defined by the presence of $\geq 30\%$ blasts in the peripheral blood or bone marrow or by the presence of extramedullary disease with immature cells.¹⁹ The WHO proposed this to be changed to $\geq 20\%$ blasts, but this change is not justified based on clinical data.^{10, 16} The blastic phase can be classified according to the immunophenotype as myeloid, lymphoid, biphenotypic, or mixed lineage (lymphoblastic–myeloblastic). Lymphoid blastic phase occurs in 20–30% of patients, myeloid in 50%, and undifferentiated in 25%.^{11, 20} The median survival in blastic phase is 3–6 months. Patients with lymphoid blastic phase have a better prognosis, with a response rate of $\geq 90\%$ and median survival of > 18 months with TKI combined with chemotherapy.²¹

Laboratory features in the chronic phase include leukocytosis with left maturation shift and frequently basophilia and eosinophilia ([Figure 2](#)). Thrombocytosis is common but thrombotic phenomena are unusual. Some degree of anemia is common. There is a reduction in leukocyte alkaline phosphatase (LAP) activity and a marked elevation of serum B12 levels.

Figure 2 Chronic myeloid leukemia. Leukocytosis with myelocytes, metamyelocytes, band cells, and polymorphonuclear leukocytes are characteristics of the peripheral blood in the chronic phase of this disease.

The bone marrow is hypercellular. In chronic phase, all stages of differentiation are present, but the myelocytes predominate, whereas myeloblasts and promyelocytes account for $< 10\%$ of cells ([Figures 3](#) and [4](#)). Megakaryocytes may be increased, and there might be increased reticulin fibrosis, which may

worsen with disease progression, and is reversed with TKI.²²

Figure 3 Chronic myeloid leukemia, myeloid blast crisis. The marrow aspiration shows predominance of blast forms, which have a myeloid appearance.

Figure 4 Chronic myeloid leukemia, blast phase. This bone marrow biopsy shows “blasts” with prominent nucleoli comprising about 75% of the marrow cells.

In the blastic phase, lymphoid blasts contain terminal deoxynucleotidyl transferase (TdT). Lymphoblasts usually express CD10, CD19, and CD22 or other B-cell markers²⁰; T-cell blastic phase is less common. The myeloid blastic phase may mimic acute myeloid leukemia. The myeloblasts stain with myeloperoxidase and express myeloid markers including CD13, CD33, and CD117.

Rarely, patients may be present in lymphoid or myeloid blastic phase without a recognized antecedent chronic phase. The differentiation between this presentation and Ph-positive acute lymphoblastic (ALL) or myeloid (AML) leukemias may be impossible, but the distinction is semantic as the treatment and prognosis are the same. Megakaryoblastic, erythroblastic, and basophilic transformations are uncommon.

Prognostic classification

Prognosis in CML is variable. Risk classifications have been proposed to stratify patients and assist in treatment decisions. The Sokal model is most frequently used²³ and defines three risk groups: low (about 40–50% of all patients), intermediate (about 30%), and high risk (10–20%), with median survivals of 4.5, 3.5, and 2.5 years, respectively, with busulfan or hydroxyurea. The model still predicts response to therapy and progression-free survival with imatinib therapy, although outcomes for all risk groups are significantly better than in the past. Other classifications have been proposed such as the Harford score (more applicable to interferon-treated patients),²⁴ the simpler but not universally validated EUTOS score (based only on percentage of basophils and size of spleen),^{25–27} or the Gratwohl score for SCT (stem cell transplant).^{20, 28} With TKI therapy, the significance of several prognostic factors (older age, marrow fibrosis, deletion of derivative 9q, complex Ph chromosome) has been reduced or eliminated.^{21–23, 29–32} Interestingly, adolescents and young adults may have a worse outcome, arguably because of poor adherence to therapy.³³

Pathogenesis

The primary biologic defect in CML is unregulated proliferation with discordant maturation, reduced apoptosis, and defective adherence to the bone marrow stroma.^{34–36}

Cytogenetics

The hallmark of CML is the Ph chromosome. This results from a reciprocal translocation between chromosome 9 and chromosome 22, t(9;22)(q34.1;q11.21) that transposes the 3' segment of the *ABL* gene to the 5' segment of the *BCR* gene.² This abnormality creates the chimeric BCR-ABL oncogene ([Figure 5](#)).

Figure 5 Schematic of 9;22 chromosome translocation.

The Ph chromosome is found in ~95% of patients with CML. It is also observed in 5% of children and 15–30% of adults with acute lymphoblastic leukemia and in 2% of patients with newly diagnosed acute myeloid leukemia.³⁷ Some patients have variant translocations, which may be simple (involving chromosome 22 and one additional chromosome other than chromosome 9) or complex (involving chromosomes 22, 9, and at least one other chromosome).³⁸ These patients historically had an inferior outcome, but with imatinib therapy they have a similar prognosis to patients with the classic Ph chromosome.^{31, 32}

Progression of CML is frequently accompanied by additional cytogenetic abnormalities. The most common abnormalities include a second Ph chromosome, isochromosome 17, trisomy 8, trisomy 19, and deletion 20q.³⁹ The molecular consequences of these abnormalities are not known. Mutations or deletions of tumor suppressor genes, such as p16 and TP53, and methylation of ABL, BCR, p15, and cadherin-13 may contribute to transformation.^{40–44} Activation of JAK–STAT pathway might be responsible for the survival of the leukemic stem cell.^{45, 46} In blast phase, granulocyte-macrophage progenitors are the candidate stem cells, and the activation of β -catenin may enhance the self-renewal activity of these cells.⁴⁷

Figure 6 Summary of the cytogenetic and molecular effects of the Ph chromosome.

After successful treatment with TKI, chromosomal abnormalities are found in the Ph-negative cells in 10–15% of patients, most frequently trisomy 8, monosomy 7 or 5, and deletion 20q.⁴⁸ These may regress spontaneously in some cases, but in rare instances (<1%) may lead to the development of a myelodysplastic syndrome or AML.^{40–42, 49–51}

Molecular biology

The reciprocal 9;22 translocation results in a chimeric oncogene, BCR-ABL, that codes for a Bcr-Abl oncoprotein with constitutional tyrosine kinase activity.^{46, 52}

There is some heterogeneity in the breakpoints on chromosomes 9 and 22. On chromosome 9, breaks may occur in a region 200 kb or more in length, resulting in most of the c-*abl* gene being translocated.⁴⁶ The breakpoints within the ABL gene occur either upstream of exon Ib, downstream of exon Ia, or, more

frequently, between exons 1b and 1a. Breakpoints in BCR occur most frequently in the major breakpoint cluster region that includes exons e12–e16 (formerly b1–b5), resulting in either b2a2 (e13a2) or b3a2 (e14b2) fusion transcripts, both of them generating a 210-kDa protein (p210^{BCR-ABL1}). In few patients with CML (but more frequently in Ph-positive ALL), the breakpoint may occur in the minor breakpoint cluster region, resulting in an e1a2 fusion (translated into a 190-kDa protein).⁵³ Less frequently, the breakpoint may occur in a different, more distal, breakpoint region μ -bcr.

Transcription of the fusion BCR-ABL oncogene results in a chimeric BCR-ABL mRNA that is translated into three fusion proteins of varying sizes p190^{Bcr-Abl}, p210^{Bcr-Abl}, and p230^{Bcr-Abl}, according to the breakpoint on *BCR* ([Figure 6](#)). In all instances, the fusion protein has unregulated constitutive tyrosine kinase activity that triggers intracellular signaling pathways such as STAT, RAS, RAF, JUN kinase, MYC, AKT, and BCL-2, which confer the malignant phenotype.⁵²

Most patients with typical chronic phase CML express either the b2a2 (e13a2) or b3a2 (e14a2) rearrangements. The clinical features, response to treatment, and prognosis are similar in both groups. Patients with Ph-positive acute lymphoblastic leukemia may express either p210^{Bcr-Abl} (30–50%) or p190^{Bcr-Abl} (50–70%). Rare patients with CML in chronic phase express e1a2 (p190^{Bcr-Abl}) and have a worse prognosis.^{53, 54} The p230^{Bcr-Abl} is associated with a more indolent disease and a phenotype similar to chronic neutrophilic leukemia.

In approximately 5–10% of morphologically typical cases of CML, the Ph chromosome cannot be identified. In one-third of these, the BCR-ABL rearrangement is present. These patients have similar characteristics, response to treatment, and prognosis as Ph-positive CML.^{16, 55} The other two-thirds lack the BCR-ABL rearrangement (called “atypical CML” in the WHO classification) with different clinical and hematologic features, including lower initial white cell and platelet counts, with progression characterized by progressive cytopenias and organomegaly rather than blastic transformation and a median survival of 18–24 months.^{17, 56, 57} This type of leukemia is not discussed further in this chapter. Reverse transcriptase polymerase chain reaction (RT-PCR) can detect the BCR-ABL transcript with a sensitivity of 10^{-5} .^{48, 58} BCR-ABL rearrangement has been identified in up to 25–30% of normal adults using RT-PCR approximately 3-log more sensitive (sensitivity $\sim 10^{-8}$) than the one used clinically.⁵⁹ This suggests that clonal disease requires escape from immune surveillance and/or a second oncogenic event to become clinically relevant.

A subset of patients treated with TKI develop resistance. Several mechanisms of resistance have been identified; the most common are mutations in the BCR-ABL kinase domain (KD). More than 50 different mutations have been reported and involve many of the domains in the BCR-ABL structure, including the P-loop (the domain where ATP binds), the activation loop, and the catalytic domain, as well as the amino acids where imatinib makes contact with BCR-ABL.⁶⁰ Different mutations vary in their sensitivity to different TKI. Some mutations are inhibited by slightly higher concentrations of TKI than that is required to inhibit the wild-type form; others are completely insensitive.^{61, 62} Mutational analysis is useful in patients with resistance to TKI to identify the TKI predicted to inhibit a given mutation as determined by the IC₅₀ for particular agents. For example, F317L and V299L are insensitive to dasatinib, V299L is insensitive to bosutinib, and F359V and E255K/V are insensitive to nilotinib, while T315I is sensitive only to ponatinib (a third-generation TKI effective against all mutations).^{63–65}

Diagnosis

Approximately 90% of patients are diagnosed in the chronic phase, which is usually asymptomatic.¹³ Symptoms usually develop insidiously and are usually due to splenomegaly (pain, abdominal fullness, early satiety) or anemia (fatigue). Less commonly, patients may be present with gout, anorexia, weight loss, unexplained fever, or signs of platelet dysfunction (e.g., ecchymoses or hemorrhage). Patients with very high WBC may have signs of hyperviscosity (priapism, cerebrovascular accidents, tinnitus, confusion, retinal hemorrhage). Symptoms associated with the accelerated phase may include fever, night sweats, weight loss, or bleeding associated with thrombocytopenia. Occasionally, blood and bone marrow features of accelerated phase occur in patients who are asymptomatic and identified only during routine follow-up. The blastic phase of CML is commonly associated with constitutional symptoms (night sweats, weight loss, fever, bone pain), anemia, an increased risk of infections, and/or bleeding.

When the diagnosis of CML is suspected, a bone marrow aspiration is mandatory. Although the diagnosis of CML can be made in peripheral blood, proper staging and recognition of all features of the disease can only be made with the evaluation of the bone marrow and peripheral blood. The bone marrow aspiration should include the following: (1) cell differential for proper staging; (2) assessment of fibrosis and other characteristics; and (3) cytogenetic analysis by G-banding to confirm the presence of the Ph chromosome and possibly additional chromosomal abnormalities; at least 20 metaphases are required for a proper interpretation of the karyotype and assessment of response. In addition, RT-PCR is recommended at the time of diagnosis. Although the number of BCR-ABL transcripts has no bearing on the prognosis (and is not reliable at baseline when using ABL as the control gene), it permits investigation of unusual transcripts (e.g., e19a2, b2a3, b3a3) not detected by standard PCR.

During the course of treatment, a bone marrow aspiration with cytogenetic analysis should be performed every 6 months until a CCyR is confirmed. Thus, a bone marrow is needed less frequently or perhaps not at all in most patients. It may be appropriate to continue doing karyotype analysis in patients with recognized chromosomal abnormalities in Ph-negative metaphases. FISH can be used to assess achievement of a cytogenetic response, and it can be done in peripheral blood, but it does not provide information on the presence of additional chromosomal abnormalities whether in Ph-positive cells (i.e., clonal evolution) or in Ph-chromosome-negative cells. A bone marrow aspiration should be performed in all patients with unexplained changes in peripheral blood counts or in those with loss of major molecular response (MMR) (and definitely if levels are close to 1% using the international scale). During treatment, patients should also be monitored with RT-PCR at 3, 6, and 12 months after the start of therapy and every 6 months after that.

Assessment for mutations is unnecessary at the time of diagnosis in patients in the chronic phase as mutations have not been found in this setting with the standard methodology. A search for mutations should be done when there is loss of CCyR. Patients who do not meet the recommended response criteria at the given times as per the European Leukemia Net (ELN) recommendations may have a mutation analysis performed, but mutations are more commonly found among patients with secondary resistance (i.e., loss of cytogenetic response) compared to those with primary resistance (i.e., not achieving optimal response).

Staging and prognostic factors

CML has three stages: chronic, accelerated, and blast phases. The features that define each phase are described earlier in the section titled “Pathology”. For patients in the chronic phase, risk classifications have been proposed. These include the Sokal,²³ Hasford (Euro),²⁴ and EUTOS²⁵ classifications. These classifications are used mostly for prognostic purposes; treatment recommendations generally apply equally to all risk groups. The Sokal score is the most commonly used and is obtained through the

formula: $\exp(0.0116 \times (\text{age} [\text{years}] - 43.4)) + (0.0345 \times (\text{spleen size} [\text{cm}] - 7.51) + (0.188 \times ((\text{platelets} [10^9/\text{L}]/700)^2 - 0.563)) + (0.0887 \times (\text{blasts} [\%] - 2.10))$. Based on the score, three risk groups are identified: low (score < 0.8), intermediate (score 0.8–1.2), and high risk (>1.2). In the United States, only 10–15% of patients have a high-risk score at the time of diagnosis, whereas in other areas of the world, these can represent up to one-third of all patients.

Treatment

Initial treatment for all patients with CML is with TKI. Imatinib mesylate, a selective Bcr-Abl TKI introduced in the 1990s, has changed the natural history of CML.^{6, 66–70} Patients in the chronic phase at the time of diagnosis treated with TKI have a life expectancy that matches that of the general population.⁷¹

Imatinib mesylate

Imatinib is a potent inhibitor of Bcr-Abl and few other tyrosine kinases such as c-kit and PDGFR.^{6, 72} It was first used in CML after failure or intolerance to interferon-alpha.^{73, 74} Imatinib 400 mg taken orally daily, given to 454 patients, resulted in a CCyR of 57%. The estimated 5-year survival rate was 76%.⁷³

The efficacy of imatinib in previously untreated patients was demonstrated in a multicenter randomized trial comparing imatinib to the combination of interferon-alpha and low-dose cytarabine [IRIS (Insulin Resistance Intervention after Stroke) trial].^{75, 76} With 8 years of follow-up, a CCyR was achieved by 83% of all patients, resulting in an event-free survival of 81%, transformation-free survival of 92%, and overall survival of 85%.⁷⁷ The standard starting dose of imatinib in the chronic phase is 400 mg daily. Higher doses of imatinib (600–800 mg daily) may result in improved response rates that are achieved earlier.^{78, 79} It is controversial whether higher doses result in improved long-term outcome of patients.^{65, 80–82} To date, 400 mg daily remains the standard initial dose. Among patients in chronic phase who progress on imatinib 400 mg daily therapy, dose escalation to 600 or 800 mg daily recaptured some CCyRs.^{83, 84}

Second-generation tyrosine kinase inhibitors

Dasatinib and nilotinib are second-generation TKI that are approximately 300-fold⁸⁵ and 30-fold⁸⁶ more potent than imatinib, respectively. They were first investigated and approved for treatment of patients who have experienced resistance or intolerance to imatinib. Subsequently, trials demonstrated that both of these agents resulted in more, deeper and faster responses than those seen with imatinib.^{87–89} This translated in a lower rate of transformation to accelerated and blast phase compared to imatinib. Thus, both agents are approved and considered standard for the initial treatment of patients with chronic phase CML.

In the randomized trial of dasatinib versus imatinib, the rate of confirmed CCyR by 12 months was 77% with dasatinib versus 66% with imatinib, and the cumulative rate of MMR by 36 months was 69% versus 55%, respectively. At 3 months, 84% of patients treated with dasatinib achieved BCR-ABL/ABL transcript <10% compared to 64% with imatinib. Transformation to accelerated and blast phase occurred in 3% and 5%, respectively. No difference in event-free or overall survival has been reported up to 4 years of minimum follow-up.^{90, 91} The standard starting dose of dasatinib for patients with newly diagnosed CML in chronic phase is 100 mg once daily.

A similar randomized trial investigated two different dose schedules of nilotinib (300 mg twice daily and

400 mg twice daily) compared to imatinib. By 12 months, the rate of CCyR was 80% with nilotinib 300 mg twice daily and 78% with 400 mg twice daily compared to 65% with imatinib. By 3 years, the rates of MMR were 73%, 70%, and 53%, respectively. BCR-ABL/ABL levels of <10% were achieved by 91% treated with nilotinib 300 mg twice daily, 89% with nilotinib 400 mg twice daily, and 67% with imatinib; the rates of freedom from progression to accelerated or blast phase at 4 years were 96.7%, 97.8%, and 93.1%, respectively. The 4-year estimated progression-free survivals were 92.7%, 96.3%, and 92%, and overall survivals were 94.3%, 96.7%, and 93.3%.^{92, 93} Nilotinib 300 mg twice daily is the standard therapy for newly diagnosed CML in chronic phase.

Bosutinib has also been investigated as an initial therapy for CML. There is an increase rate of responses, with deeper and faster responses resulting in fewer transformations to the accelerated and blast phases. However, bosutinib is not currently approved as an initial therapy for CML.⁹⁴

Treatment algorithm

Achievement of a CCyR is associated with near eradication of the risk of transformation to accelerated and blast phases and a significant survival benefit, with a 10-year survival probability of 70–80% equivalent to that of the general population. Achieving molecular responses increases the probability of long-term durable responses although such responses have not resulted in improved survival among patients with CCyR. The 7-year probability of event-free survival for patients that achieve MMR is 95% compared to 86% among those with CCyR but no MMR. There is no difference in survival free from transformation to accelerated or blast phase or in overall survival. Deeper responses may offer the possibility of considering treatment discontinuation, something that today should be considered only through clinical trials.

In addition to the depth of response, the time to response is important to improve long-term outcomes. Patients with BCR-ABL/ABL transcripts <10% at 3 months from the start of therapy have significantly better probability of EFS (approximately 95%) compared to those with >10% transcripts (approximately 80%).^{95–98} There is also a significant but smaller difference in the overall survival. This has resulted in recommendations of what is considered optimal response to therapy that include BCR-ABL/ABL <10% by RT-PCR and/or Ph <35% by standard karyotype at 3 months, BCR-ABL/ABL <1% and/or Ph 0% at 6 months, and BCR-ABL/ABL <0.1% at 12 months. Levels above these are defined as warning or failure ([Table 1](#)).⁹⁹

Table 1 Suggested management of most common adverse events associated with imatinib

Adverse events	Management
Nausea/vomiting	Take with food, fluids
	Antiemetics
Diarrhea	Loperamide
	Diphenoxylate atropine
Peripheral edema	Diuretics
Periorbital edema	Steroid-containing cream
Skin rash	Avoid sun exposure
	Topical steroids
	Systemic steroids (early intervention important)
Muscle cramps	Tonic water or quinine
	Electrolyte replacement as needed
	Calcium gluconate
Arthralgia, bone pain	Nonsteroidal anti-inflammatory agents
Elevated transaminases (uncommon)	Hold therapy and monitor closely
	Dose reduction upon resolution
Myelosuppression	
Anemia	Treatment interruption/dose reduction usually not indicated
	Consider erythropoietin or darbepoietin ^a
Neutropenia	Hold therapy if grade ≥ 3 (i.e., ANC $< 1 \times 10^9/L$)
	Consider filgrastim if recurrent/persistent, or sepsis
Thrombocytopenia	Hold therapy if grade ≥ 3 (i.e., platelets $< 50 \times 10^9/L$)
	Consider IL 11 ^a 10 mcg/kg 3–7 days/week

^a The use of erythropoietin, darbepoietin, filgrastim, and interleukin-11 (IL-11) in this setting is not standard and should be considered investigational.

Patients who achieve an optimal therapy can continue therapy unchanged. The current algorithm involves therapy to continue indefinitely although studies are ongoing to determine whether treatment may be discontinued in some patients. Those who meet the definition of warning can continue therapy but adherence should be assessed, therapy optimized, and patients monitored rigorously every 3 months with treatment change considered if failure is identified. Once the definition of failure is met, treatment changes should be implemented.⁹⁹

Intolerance is another reason why treatment change may be needed. Despite the excellent overall tolerability of TKI, they all have adverse events that need monitoring and adequate management. With proper management¹⁰⁰ that may include transient treatment interruptions, dose adjustments, medical management of adverse events, and supportive care, most patients can continue therapy as an experience and adequate response. In general, patients should not be changed to a different TKI based on the first occurrence of an adverse event unless this is life threatening (e.g., Stevens–Johnson's, myocardial

infarction, stroke). True intolerance to TKI occurs in only approximately 5% of all patients. Suggestions for the management of the most common adverse events are presented in [Table 2](#).

Table 2 Response criteria according to the European Leukemia Net.

Time (mo)	Response		
	Failure	Warning	Optimal
3	No CHR, and/or Ph+ >95%	BCR-ABL >10%, and/or Ph+ 36–95%	BCR-ABL ≤10%, and/or Ph+ ≤35%
6	BCR-ABL >10% and/or Ph+ >35%	BCR-ABL 1–10%, and/or Ph+ 1–35%	BCR-ABL <1%, and/or Ph+ 0%

Treatment options after failure of prior TKI

Several TKI are available for the management of patients with resistance (as defined by the ELN⁹⁹) or intolerance to prior TKI. These include dasatinib, nilotinib, bosutinib, and ponatinib. In addition, omacetaxine, a protein-synthesis inhibitor (not a TKI), is also approved for patients who have received at least two prior TKI.

Among patients who have received imatinib as their only prior TKI and experienced resistance or intolerance, dasatinib at a dose of 100 mg once daily induced a CCyR in 44% of patients with resistance and 67% of those with intolerance. A MMR occurred in 37% of patients with resistance or intolerance, with a 6-year probability of progression-free survival of 49% and overall survival of 71%.^{101, 102} Similarly, nilotinib, at a dose of 400 mg twice daily (the standard dose for second-line therapy), induced CCyR in 41% of patients with resistance to imatinib and 51% of those with intolerance for a 4-year progression-free survival of 57% and overall survival of 78%.¹⁰³ Bosutinib is also a second-generation TKI with an activity against Src and Abl, 30–50 times more potent than imatinib against Abl but, in contrast to other TKI used for CML, with minimal inhibitory activity against c-kit or PDGF-R. Bosutinib has also been effective in this patient population inducing a CCyR in 48% of patients with resistance and 52% of those with intolerance to imatinib with MMR in 64% and 65% of those achieving CCyR, respectively. This resulted in a progression-free survival of 73% and 95%, respectively.¹⁰⁴ None of these agents is active in patients with the T315I mutation.

Bosutinib and ponatinib have been investigated among patients who have received two or more TKI. With bosutinib 500 mg once daily, a major cytogenetic response was achieved in 30–35% of 118 patients who had received imatinib and were then resistant or intolerant to dasatinib, or resistant to nilotinib. The corresponding rates of CCyR were 14%, 28%, and 27%, respectively, and 2-year estimates of progression-free survival 65%, 81%, and 77%.¹⁰⁵ Ponatinib is a potent inhibitor of Abl tyrosine kinase activity as well as other kinases including c-kit, FLT3 and VEGFR. Importantly, it has potent inhibitory activity against unmutated BCR-ABL or in the presence of any of the KD mutations tested, including the multiresistant T315I.¹⁰⁶ With ponatinib at a dose of 45 mg daily, among 267 patients of which 93% had received at least two prior TKI (60% had received at least three), a major cytogenetic response was achieved in 56% (complete in 46%) and a MMR in 34%. Major cytogenetic response was sustained for at least 12 months in 91%, and the overall survival was 94% at 12 months. For patients with T315I, the response rates were 70%, 66%, and 56%, respectively, with similar durability of response and overall survival.^{107, 108} With omacetaxine, 20% of patients treated in chronic phase after resistance to at least two prior TKI achieved a major cytogenetic response, with a median overall survival of 33.9 months.¹⁰⁹ Responses can be seen regardless of mutation status including patients with T315I.¹¹⁰ Allogeneic SCT should also be considered in patients who have experienced resistance to TKI.

Stem cell transplantation

Allogeneic SCT may be curative in 40–80% of patients who receive a transplant from an HLA-identical sibling or an unrelated donor.¹¹¹ Among patients transplanted in first chronic phase, 3514 from a match-related sibling and 1052 from an unrelated donor, the 5-year survival probability was 63% and 55%, respectively, and the leukemia-free survival was 55% and 50%, respectively. The 5-year cumulative incidence of relapse is 12–14%.¹¹¹ However, for patients who have been alive and in continuous complete remission for ≥5 years, the survival rate at 15 years was 88% for those receiving sibling donor cells and 87% from those with unrelated donors, with cumulative incidence of relapse of 8% and 2%, respectively, with relapses documented as late as 18 years after transplant.¹¹² Patients who were treated with stem cell transplant had a higher probability of death for the first 14 years after transplant compared to individuals in the general population of similar age, sex, and race.¹¹² The availability of donors has improved in recent years because of the increasingly successful results with transplant using cord blood or haploidentical donors, and the reach has extended to higher age groups with the use of non-myeloablative conditioning regimens. In addition, early mortality rates have decreased with improved supportive care and GVHD (graft-versus-host disease) prophylaxis and management. However, with the availability of TKI, the role of SCT has changed significantly. Several reports have confirmed that previous exposure to TKI does not adversely affect the outcome after SCT although time from diagnosis to SCT remains an important prognostic factor for the outcome after transplant.^{113, 114} Similarly, patients transplanted in chronic phase have a significantly better outcome than those transplanted in advanced phase.¹¹¹ Until the advent of ponatinib and omacetaxine, SCT was the only available therapy for patients with T315I mutation, with 2-year survival probability of 59% for patients transplanted in chronic phase.^{115, 116}

Patients transplanted in accelerated or blastic phase have significantly worse outcomes, with 5-year survival probabilities of 40% accelerated phase and 10–15% blastic phase. Patients in blastic phase transplanted after achievement of a second chronic phase may have long-term outcomes similar to that of the accelerated phase.^{28, 117, 118}

Treatment recommendations in CML in 2015

The results with imatinib to date have been excellent and durable, and with shorter follow-up, the results with dasatinib and nilotinib appear superior with earlier and deeper responses and with lower rate of transformation, although these outcomes have not translated into a significant difference in event-free or overall survival. The life expectancy of patients treated with TKI is similar to that of the general population, particularly for those patients achieving a CCyR. Based on this, TKIs are standard initial therapy for all patients with CML in chronic phase. Because of the improved outcome with dasatinib or nilotinib in randomized trials compared to imatinib,^{90–93} these agents are preferred in many instances. However, imatinib is likely to remain the treatment of choice for a large percentage (perhaps the majority) of patients throughout the world. It should be emphasized that imatinib is also adequate treatment. The most important aspect to offer a patient the best possible long-term outcome is the proper management of the patient. This includes a close follow-up to recognize and manage adverse events. All TKI have adverse events associated with them, but most of these are manageable through transient treatment interruptions, dose adjustments, and/or medical interventions. Very few patients (around 5%) are truly intolerant to a given drug. Until ongoing studies demonstrate a long-term benefit of early change in therapy, patients not having a major cytogenetic response (or not having BCR-ABL/ABL transcripts <10%) at 3 months may continue therapy unchanged but they need to be checked again at 6 months.⁹⁹ For patients still not achieving a major cytogenetic response (or still with BCR-ABL/ABL transcripts >10%) after 6 months of therapy treatment change may be considered, although there are also no studies that have shown that change of therapy in this setting alters long-term outcome. Patients need to continue with monitoring at least every 6 months as detailed earlier. A change of therapy is clearly indicated when the criteria for failure is met (as defined by the ELN). In these instances (i.e., failure), randomized trials have demonstrated that a change of therapy from imatinib to a second-generation TKI improves the outcome compared to an increase in the dose of imatinib.¹¹⁹ A mutation analysis is always indicated when the criteria of failure are met, and a bone marrow aspiration is also needed to determine the cytogenetics and stage of the patient before change. If a mutation is identified, this can guide which TKI is expected to induce a response (e.g., if F317L or V299L identified, consider nilotinib or ponatinib; if F359V, consider bosutinib, dasatinib, or ponatinib; for T315I, ponatinib or omacetaxine may be considered).^{61, 62} If there is no mutation, or there is a mutation for which there is no available information or no meaningful difference between the various TKI, then other considerations may help in the decision of what drug to use, such as comorbidities that might expose the patient more to adverse events associated with one drug or another, the adverse event profile that might be more acceptable for a given patient, and the dose schedule that a patient might find more convenient or acceptable to optimize adherence. Patients with resistance to at least two TKI can be considered for SCT. SCT may also be considered in other settings where long-term therapy might not be optimal or feasible (e.g., for cost considerations).

Patients with accelerated phase features at the time of diagnosis can be treated with a TKI, particularly dasatinib or nilotinib, as their prognosis in this setting is nearly identical to that of patients in chronic phase.¹²⁰ SCT for these patients is not required unless not responding adequately. Patients who progress to accelerated phase while on treatment with TKI for chronic phase should receive a different TKI and considered for SCT.¹²¹ Patients with blast phase CML should receive TKI, usually in combination with chemotherapy,^{21, 122, 123} and SCT should be strongly considered. Although results for SCT in this setting are best with the least residual disease, once the patient achieves a hematologic complete remission transplant can proceed as further chemotherapy may cause comorbidities that may make SCT impossible or of greater risk, and response may not improve further.

Suvivorship and follow-up

Patients with CML should continue therapy and have close follow-up indefinitely. This includes not only monitoring of the status of the disease (with PCR in peripheral blood every 6 months) but also attention to co-morbidities and possible side effects. There is increased awareness of adverse events that will need continued assessment. These include arteriothrombotic events such as ischemic heart disease (including angina and myocardial infarction), ischemic heart disease (including transient ischemic attacks and strokes), and peripheral arterial occlusive disease, particularly with ponatinib and nilotinib. Attention should be paid to monitoring and managing risk factors such as hypertension (frequently caused or aggravated by ponatinib), diabetes (frequently caused or aggravated by nilotinib), hyperlipidemia (also associated with TKI therapy), and others. Recent analyses also suggest there might be an impairment of renal function with TKI, particularly with imatinib. Patients on dasatinib with respiratory symptoms should be evaluated for pleural effusion or pulmonary hypertension. Although most adverse events occur early during the course of the disease, for some (such as pleural effusion or arteriothrombotic events) the incidence is constant and a first event may occur after several years of treatment.

Research is ongoing to explore treatment discontinuation in suitable patients.^{124, 125} Among patients with sustained undetectable transcripts (with PCR sensitivity of at least 4.5 logs) for at least 2 years, treatment discontinuation yielded a sustained remission in approximately 40% of patients after 3–4 years of follow-up. This approach at the moment should be considered only in clinical trials and patients should continue with close monitoring, at least monthly for the first 6 months, then every 2–3 months for 2 years, and then every 6 months indefinitely.

Conclusion

The outcome of patients with CML has improved significantly since the introduction of TKI. It is expected that a patient with CML diagnosed today may have a life expectancy similar to that of the general population. For a patient to have such favorable outcome, adequate management is important including adequate dose optimization, proper management of adverse events, continued periodic monitoring of disease response, timely intervention when indicated, and continued support throughout the life of the patient. With this approach, transformation to advanced stages is uncommon and few patients will die of CML.

Summary

Chronic myeloid leukemia (CML) is characterized by the presence of the Philadelphia chromosome. This results in the creation of the BCR-ABL fusion gene, which is in turn translated into a tyrosine kinase with constitutive kinase activity. The disease evolves in three stages: chronic, accelerated, and blast phases. Most patients are diagnosed in the chronic phase and are asymptomatic at the time of diagnosis. Treatment with TKIs has changed the natural history of the disease with a life expectancy that is similar to that of the general population. Imatinib was the first TKI to be used and is still a standard and an effective therapy for frontline therapy. Most patients will achieve a complete cytogenetic response (CCyR) making transformation to accelerated and blast phases very rarely. Higher doses of imatinib have been suggested to provide higher rates of response including deeper molecular responses. Dasatinib and nilotinib are also the approved treatment options for frontline therapy and may improve the rate of complete cytogenetic and major molecular (as well as

deeper molecular) responses, with fewer instances of transformation to the accelerated and blast phases, but have not resulted in improved event-free or overall survival compared to imatinib in randomized trials. For patients who experience resistance or intolerance to one TKIs, alternative inhibitors can be used. In this setting, bosutinib and ponatinib are additional options. Overall, approximately 40% of patients with resistance or intolerance to initial therapy might achieve a CCyR with a subsequent TKI. The most common mechanism of resistance is the emergence of mutations of the KD. Different mutations may have differing sensitivities to the various inhibitors, and the presence of such mutations, when present, may allow selection of the most appropriate therapy. Although generally well-tolerated TKIs may have caused adverse events, some of them are potentially serious, which require proper identification and management; this may include the change of therapy in some instances. SCT remains a useful and potentially curative treatment modality for patients who have not experienced adequate response to various lines of therapy. With adequate access to treatment and proper management, patients diagnosed with CML should be able to have a normal life expectancy.

Chapter 116

Acute lymphoblastic leukemia

Nitin Jain, MD, MSPH ■ Stefan Faderl, MD ■ Hagop M. Kantarjian, MD ■ Susan O'Brien, MD

Overview

In adults, acute lymphoblastic leukemia (ALL) is a disease with poor prognosis. In the last several years, there have been significant advances in understanding the disease biology, prognostication, and in the development of novel therapies. These include development of monoclonal antibodies, antibody–drug conjugates, tyrosine kinase inhibitors, and more recently, chimeric antigen receptor T-cell therapy. These therapies are beginning to result in improvements in survival of patients with ALL.

Introduction

Acute lymphoblastic leukemia (ALL) is a heterogeneous disease. Identification of cytogenetic-molecular features in ALL has translated into more accurate classification of disease subtypes, institution of risk-adapted therapies, and identification of new drugs. Most impressively, advances in ALL therapy over only a few decades have led to cures for most children with ALL. Adaptation of successful pediatric ALL treatment strategies into therapeutic algorithms for adult ALL have also resulted in significant improvement, although long-term disease-free survival (DFS) rates of around 40% are still inferior. Nonetheless, ongoing molecular dissection of ALL subtypes, refinements of multidrug chemotherapy in combination with the development of new and targeted drugs, comprehension of the kinetics of residual disease, and an increasing grasp of the impact of pharmacogenomic features and drug resistance is expected to contribute to further improvement in the prognosis for adult patients with ALL.

Epidemiology and etiology

ALL is predominantly a disease of children where it constitutes about 80% of all childhood leukemias and 25% of all childhood cancers, peaks between ages 2–5, and is diagnosed at an incidence of 3.5–4/100,000. In contrast, it makes up less than 1% of malignancies in adult patients. The age-adjusted overall incidence of ALL in the United States is about 1.7/100,000, and it is diagnosed annually in approximately 6000 patients in the United States.¹

ALL is more frequent among Caucasians. Geographic variations in its frequency have been described with higher rates among Hispanic populations in Spain and Latin America.² Although there is a slightly higher incidence rate in males than in females among childhood ALL, the rate is much more predominant in males among patients older than 20 years (1.3:1). A higher incidence of ALL has also been observed in industrialized and urban areas giving rise to speculation about socioeconomic factors in the etiology of ALL.³

In most cases, no etiology can be established. Among children, only a few cases (<5%) are associated with inherited, predisposing genetic disorders (e.g., Down's syndrome, Bloom's syndrome, ataxia-

telangiectasia, Nijmegen breakage syndrome).⁴ There is an extensive list of conflicting or isolated papers reporting an increased risk of childhood ALL, based on parental occupation, maternal reproductive history, parental tobacco or alcohol use, maternal diet, prenatal vitamin use, exposure to pesticide or solvents, and exposure to the highest levels (>0.3 or $0.4 \mu\text{T}$) of residential, power-line associated magnetic fields.^{5, 6} Studies have also focused on genetic variability in drug metabolism, DNA repair, and cell cycle checkpoints that might interact with environmental, dietary, maternal, and other external factors to affect leukemogenesis. Genome-wide association studies have identified several genes (such as *ARID5B*, *IKZF1*, *CDKN2A*, *TP63*, *GATA3*) that are associated with increased risk of developing ALL.^{7–12}

The peak age for developing childhood ALL of 2–5 years, an association of ALL with industrialized and affluent societies, and the occasional clustering of childhood ALL cases (especially in new towns) have fueled two hypotheses: (1) population-mixing and (2) delayed infection.^{13–15} The first hypothesis suggests that clusters of childhood cases result from exposure of susceptible (nonimmune) individuals to a common, fairly nonpathologic infection after mixing naïve hosts with carriers.^{13, 14} The second hypothesis is based on a two-hit model where susceptible individuals with a prenatally acquired preleukemic clone have had low or no exposure to common infections early in life because of their affluent hygienic environment.¹⁵ Insulation from infection predisposes the immune system of these individuals to aberrant or pathological responses to common infections at an age commensurate with when they encounter pathogens at an age with increased lymphoid proliferation. Indeed, retrospective studies of archived neonatal blood spots and monozygotic twin pairs have identified preleukemic clones and support the notion that additional postnatal transforming events are needed for full leukemic transformation.^{16–19}

Clinical presentation

The clinical signs and symptoms of ALL are quite variable. Disease can develop insidiously and persist for months prior to diagnosis, but symptoms occur suddenly in most cases and relate to the expansion of leukemic cells in the marrow, and the involvement of peripheral blood and extramedullary sites such as lymph nodes, liver, spleen, and the central nervous system (CNS). Common symptoms include fatigue, lack of energy, constitutional symptoms (fevers, night sweats, weight loss), easy bruising or bleeding, and dyspnea. Extremity and joint pain may be the only presenting symptoms in children, especially when very young. T-lineage ALL can present with a mediastinal mass, causing stridor, wheezing, pericardial effusions, and superior vena cava syndrome. Testicular involvement occurs with a low frequency predominantly in infant and adolescent boys. Less than 10% of patients have overt CNS involvement at diagnosis, although CNS disease occurs more often in patients with mature B-cell ALL (Burkitt's leukemia/lymphoma). Cranial nerve palsy (especially cranial nerves III, IV, VI, and VII) can lead to double vision, abnormal ocular movements, facial dysesthesias, and facial droop. Nausea and vomiting, headaches, or papilledema may point toward meningeal infiltration and increased intracranial pressure. Chin numbness due to mental nerve involvement may be subtle and can be easily missed unless sought. Diagnosis of CNS involvement is made from cytospin slides from the cerebrospinal fluid (CSF). Although previous guidelines required the presence of >5 WBC/ μL of CSF plus identifiable blasts, controversy arose around cases with <5 WBC/ μL , with blasts.²⁰ A more recent approach has been to define three diagnostic scenarios: (1) no detectable blast cells in CSF (CNS 1), (2) <5 WBC/ μL and blasts (CNS 2), and (3) ≥ 5 WBC/ μL and blasts or cranial nerve palsies (CNS 3).²¹ On physical examination, pallor, ecchymoses, petechiae, generalized lymphadenopathy, and hepatosplenomegaly can be observed. Tumor lysis syndrome is common in patients with mature B-cell ALL, but can also occur in any other subtypes of ALL. Disseminated intravascular coagulation (DIC) is a frequent laboratory finding,

but rarely produces clinically significant DIC. [Table 1](#) summarizes the clinical and laboratory characteristics of patients with adult ALL receiving hyper-CVAD chemotherapy as initial treatment presenting to a tertiary referral center.²²

Diagnosis of ALL

The diagnosis of ALL requires identification of blast cells either in the blood, marrow, or tissue section. A thorough morphologic, cytochemical, and immunologic assessment of ALL blasts remains essential in each patient's work up. Identification of distinct cytogenetic-molecular abnormalities has contributed to a more precise classification of the leukemic blasts and thus has enabled a more accurate assessment of the prognosis. Ongoing efforts are focused on genomic profiling leading to a new definition of ALL subtypes and, through it, to the identification of subgroups of patients requiring different treatments and with different prognoses that are only partially distinguished by currently available diagnostic tools.^{23, 24}

Morphology and cytochemistry

ALL blasts are heterogeneous in size and shape and one of the first attempts to classify ALL was based on this observation. The French American British (FAB) Cooperative Group thus distinguished three subgroups of lymphoblasts: L1 blasts are smaller, have a high nuclear-to-cytoplasmic ratio and inconspicuous nucleoli. The cytoplasm is sparse and variably basophilic. L2 blasts are larger and more pleomorphic, have moderately abundant cytoplasm, a lower nuclear-to-cytoplasmic ratio, and more prominent nucleoli. L1 morphology is more common in children than in adults, whereas L2 morphology is more common in adults. L3 blasts are more homogenous, medium in size, with dispersed chromatin, prominent nucleoli, typically deep blue cytoplasmic basophilia, and sharply demarcated vacuoles. L3 morphology is mostly associated with mature B-cell ALL or Burkitt's lymphoma. Mature B-cell ALL is characterized by a high rate of cell turnover, which is reflected morphologically by the so-called starry sky appearance in marrow biopsy specimens. The distinction into L1, L2, and L3 morphologies has been largely abandoned as with the exception of L3 and its association with mature B-cell ALL, it is no longer prognostically or therapeutically relevant.

Although no cytochemical stain is diagnostic for ALL, the key diagnostic cytochemical feature of ALL is lack of myeloperoxidase (MPO) and nonspecific esterase (NSE) activity. Low-level MPO positivity (3–5%) can occur in patients with lymphoid blast phase of chronic myeloid leukemia and other rare cases.^{25, 26} Sudan black B staining closely resembles that of MPO itself, but lack of specificity and the ease with which MPO stains can be applied has limited its use. Terminal deoxynucleotidyl transferase (TdT) is a useful marker to distinguish between reactive versus malignant lymphocytosis and is usually positive in $\geq 40\%$ of ALL blasts. L3 ALL is characteristically TdT-negative.²⁷

Immunophenotyping

Immunophenotyping by flow cytometry is an essential step to accurately diagnose ALL, resolve difficult differential diagnoses, and define subtypes further. Although there is no uniformly accepted panel, commonly used markers as listed in [Figure 1](#) are usually sufficient to establish the diagnosis and confirm lineage affiliation in $>95\%$ of the cases.

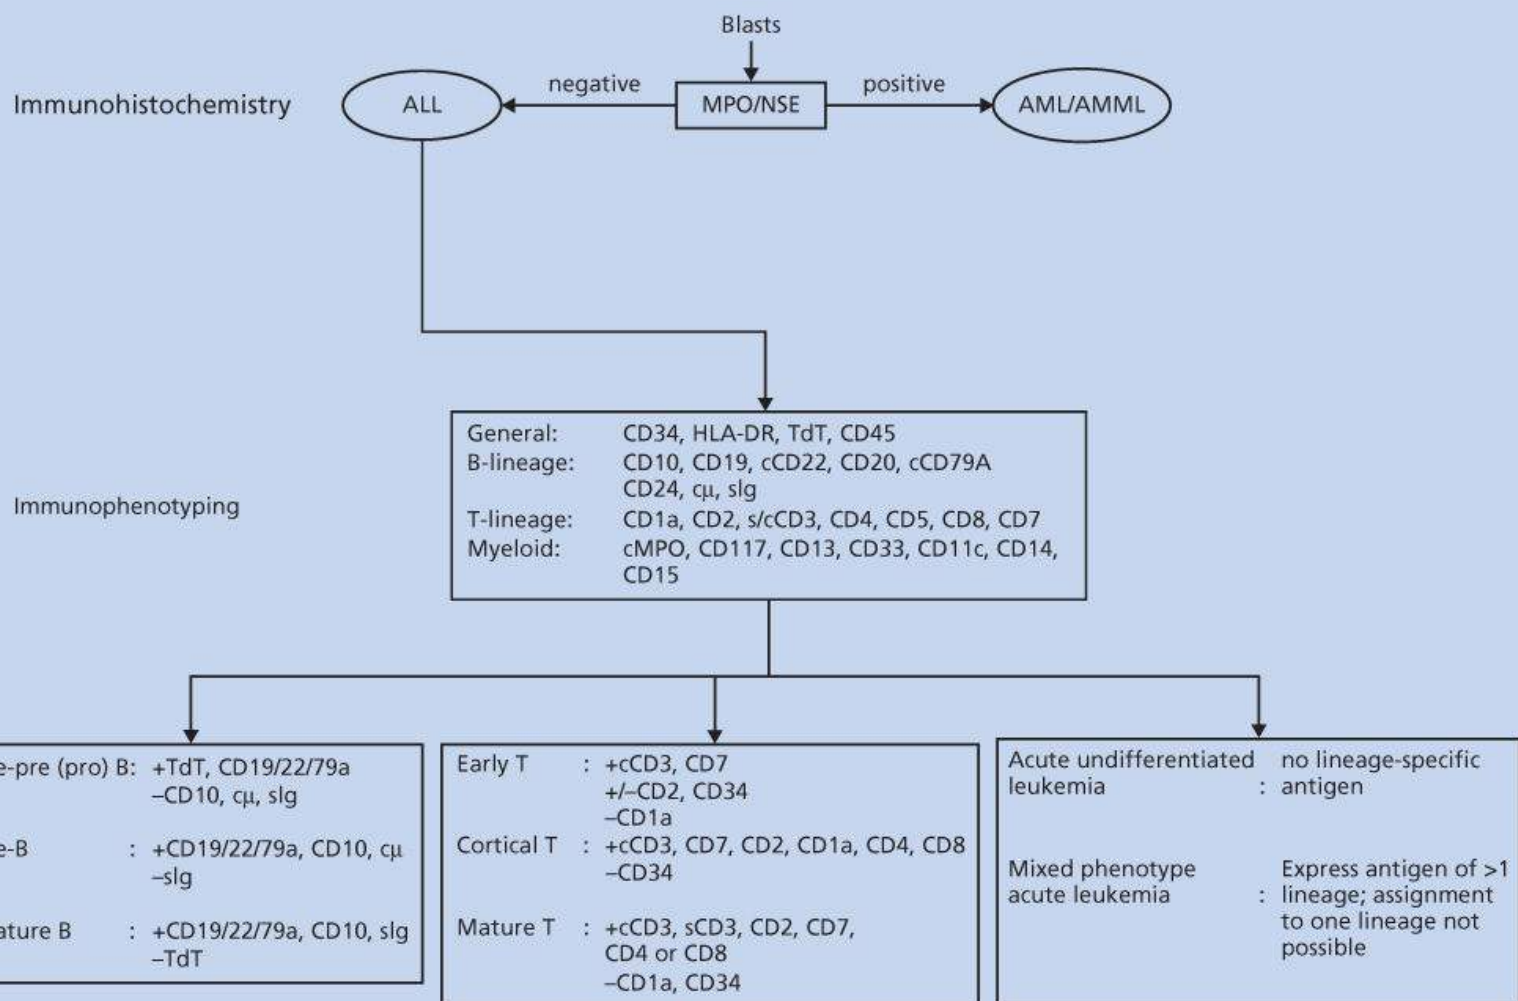

Figure 1 Diagnostic approach to ALL. *Abbreviations:* MPO, myeloperoxidase; NSE, nonspecific esterase; c, cytoplasmic; s, surface.

The majority of cases of ALL (75–80%) are of B lineage. Based on their stage of maturation, they can be divided into: (1) pre-pre-B-ALL (pro-B-ALL); (2) early pre-B (common ALL); (3) pre-B-ALL; and (4) mature B-ALL. In their earliest identifiable stage, pre-pre-B-ALL blasts are positive for CD19, CD79a, or CD22, but no other B-cell differentiation antigens. CD19-positive, CD10-negative, cytoplasmic immunoglobulin-negative B-lineage ALL with myeloid marker coexpression is common among infants with ALL, is typically associated with translocation t(4;11) and *MLL* gene rearrangements, and has a poor prognosis. Common ALL (cALL, early pre-B-ALL) represents an intermediate stage in blast development and is the most common immunophenotype in adults and children. It is characterized by expression of CD10 (common ALL antigen, CALLA) and is a frequent immunophenotype with Philadelphia chromosome (Ph)-positive ALL. In their more mature stages, pre-B-ALL blasts express TdT, HLA-DR, CD19, CD79a, and cytoplasmic immunoglobulins. A high fraction of pre-B-ALL cases have the translocation t(1;19). Mature B-cell ALL (Burkitt's leukemia) blasts express surface immunoglobulins (sIg, usually IgM), are clonal for κ or λ light chains, and lack expression of TdT. Expression of CD20 is almost ubiquitous in mature B-cell ALL, where as it occurs in only about 40–50% of other ALL subtypes. T-cell ALL accounts for only 20–25% of cases and similar to B-cell ALL can be further stratified into subtypes based on different stages of intrathymic differentiation. T-cell ALL expresses various levels of CD1a, CD2, CD3, CD4, CD5, CD7, and CD8. CD7 is the most sensitive T-cell marker but lacks specificity because cases of AML or NK-cell leukemia are sometimes CD7-positive. Expression of

cytoplasmic CD3 (cCD3) is the most lineage-specific marker for T-cell differentiation. Mature T-ALL expresses both surface CD3 (sCD3) and cCD3, CD2, and either CD4 or CD8 but not both. T-cell ALL of the earlier stages of differentiation expresses cCD3 but not sCD3. Cortical (thymic) T-cell ALL are characterized by expression of CD1a and are double positive for both CD4 and CD8, and are thought to have a favorable outcome.²⁸ A high-risk subtype of T-cell ALL called early T-cell precursor ALL (ETP ALL) was recently identified and characterized by CD1a negativity, CD8 negativity, weak/absent expression of CD5, and presence of one or more myeloid markers (CD117, CD34, HLA-DR, CD13, CD33, CD11b, CD65).²⁹

Coexpression of myeloid-associated markers is common (15–50% in adult ALL; 5–35% in children), but does not automatically indicate bilineage potential.³⁰ Myeloid-associated marker expression is more frequent in ALL with translocation t(9;22), t(4;11), and t(12;21), and is generally absent in mature B-cell ALL. Myeloid-associated marker expression has no prognostic significance,³¹ but it can be used to distinguish leukemic cells from normal progenitor cells, thereby enabling detection of minimal residual leukemia.

Cytogenetic and molecular abnormalities

Cytogenetic-molecular abnormalities are common in ALL ([Table 2](#)).^{4, 32} Their identification is important as they provide pathobiological insights, serve as targets for drug development, and furnish prognostic information, which has been translated into risk-adapted therapies.³² Conventional karyotype analysis remains a cornerstone for the detection of chromosome abnormalities. In addition, fluorescence *in situ* hybridization (FISH) and real-time reverse transcriptase polymerase chain reaction (RT-PCR) assays of mRNA are applied to detect minimal residual disease and to monitor patients after therapy.

Table 2 Cytogenetic and molecular abnormalities in ALL

Cytogenetics	Gene involved	Frequency (%)	
		Adult	Child
t(1;14)(p32;q11)	<i>TAL-1</i>	10–15	5–10

Hyperdiploidy	—	2–15	10–26
Hypodiploidy	—	5–10	5–10

^a As determined by loss of heterozygosity.

^b As determined by polymerase chain reaction.

^c In T-ALL, overall incidence < 10%.

Abbreviations: IgM, immunoglobulin M; Igκ, immunoglobulin κ; Igλ, immunoglobulin λ; TdT, terminal deoxynucleotidyl transferase.

Numerical abnormalities

Numerical karyotypic abnormalities have an important prognostic impact in ALL. Hypodiploidy defines a karyotype with less than 44 chromosomes, is seen in <5% of patients, and is associated with a poor outcome.^{33–36} In a recent study of genomic profiling of >120 hypodiploid ALL identified two subtypes: (1) near-haploid ALL with 24–31 chromosomes harboring alterations targeting receptor tyrosine kinase signaling and *RAS* signaling in majority of the cases and (2) low-hypodiploid ALL with 32–39 chromosomes characterized by alterations in *TP53* in >90% of the cases.³⁶

Hyperdiploidy is defined by chromosome numbers of more than 46. It is detected more commonly in

children than in adults (~25% vs 5%). The range of added chromosomes is not random. Most commonly increased chromosomes are 4, 8, 10, and 21 followed by chromosomes 5, 6, 14, and 17. Gene expression profiles in pediatric patients demonstrated that 70% of the genes that defined this group belonged to either chromosomes X or 21 irrespective of whether or not these chromosomes were increased in the leukemic blasts.²³ Hyperdiploid blasts from patients with ALL have been shown to accumulate more methotrexate and methotrexate polyglutamate, and to be more sensitive to other drugs such as mercaptopurine, thioguanine, cytarabine, and L-asparaginase.^{37, 38}

Structural abnormalities

Translocation t(9;22)

The translocation between the long arms of chromosome 9 and 22, t(9;22)(q34;q11) Ph is the most common abnormality in adult ALL (15–30%), but is rare in children (<5%).³⁹ Although *p210^{BCR-ABL}* is the most frequent oncoprotein in CML, *p190^{BCR-ABL}* occurs in the majority of patients with Ph-positive ALL. ALL with t(9;22) typically affects older patients, presents with higher white blood cell (WBC) and blast counts at diagnosis, is of a pre-B-cell immunophenotype, and often demonstrates coexpression of myeloid markers.⁴⁰ Ph-positive ALL used to be one of the subtypes with the worst long-term DFS, but use of tyrosine kinase inhibitors (TKI; reviewed below) in combination with multiagent chemotherapy is now achieving better outcomes.

Translocation t(12;21) and del(12p)

Abnormalities of the short arm of chromosome 12 involve *ETV6 (TEL)* a transcription regulating gene of the Ets family of transcription factors. In translocation t(12;21), *ETV6* is fused to *RUNX1 (AML1, CBFA2)* on chromosome 21q22.⁴¹ The fusion protein recruits histone deacetylases, induces closure of the chromatin structure, and inhibits transcription, thereby altering both self-renewal and differentiation capacity. The cryptic translocation can be identified in up to 30% of children with ALL using molecular assays making it the most frequent recurring cytogenetic-molecular abnormality in pediatric pre-B-ALL; it is, however, rare in adults.⁴² *ETV6-RUNX1*-positive ALL has been associated with an excellent outcome in children, although late relapses may occur.⁴ *ETV6-RUNX1*-positive blasts were shown to have suppressed expression of the multidrug resistance-1 (MDR-1) gene have decreased *de novo* purine synthesis and to have suppressed genes involved in purine metabolism.⁴³

del(9p21)

Abnormalities of 9p21 occur in up to 15% of patients with ALL.⁴⁴ Prognosis in these patients is generally unfavorable, and characterized by higher rates of relapse and shorter survival. The prognostic associations are stronger in childhood ALL and are less well defined in adult ALL.^{45, 46} Commonly involved genes with del(9p21) include the cyclin-dependent kinase inhibitor genes *CDKN2A (MTS1, p16INK4a)* and *CDKN2B (MTS2, p15INK4b)*. Using FISH or PCR, heterozygous and/or homozygous deletions of *CDKN2A* have been described in up to 80% of children with T-ALL and 20% of pre-B-ALL.

MLL rearrangements (11q23)

The common denominator of 11q23 abnormalities is involvement of the mixed lineage leukemia gene *MLL (ALL-1, HRX, HTRX1)*. *MLL* encodes a nuclear protein that maintains the expression of particular members of the *HOX* family and is frequently involved in reciprocal rearrangements with other genes located on chromosomes 4q21, 9p22, 19p13, 1p32, and many others.⁴⁷ The fusion of *MLL* with *AF4* on

chromosome 4q21 is a frequent abnormality in infant ALL, accounting for up to 85% of the cases, but is detected in only 3–8% of adults.⁴⁸ Adults with this translocation tend to be older, have higher WBC counts and organomegaly; sanctuary sites such as the CNS are involved more frequently. CD10-negative, cytoplasmic immunoglobulin-positive pre-B-ALL has a high *MLL* rearrangement rate.⁴⁹ Myeloid antigen coexpression is common. Prognosis of *MLL* leukemia is poor in infants and adults but is intermediate in children over 1 year of age.⁵⁰

***E2A* rearrangements (19p13)**

The two known translocations with *E2A* rearrangements on chromosome 19p13 are t(1;19)(q23;p13) and t(17;19)(q21;p13). Translocation t(1;19) is strongly associated with the pre-B-ALL phenotype expressing cytoplasmic immunoglobulin. The translocation juxtaposes *E2A* with the homeobox-containing gene *PBX1*. *E2A-PBX1* functions as a potent transcriptional activator and transforms *in vitro* a variety of cell types including fibroblasts, myeloid progenitors, and lymphoblasts. *E2A-PBX1*-positive ALL rearrangements have a worse prognosis to standard or less aggressive therapy, but does better with more aggressive approaches.⁵¹

8q24 rearrangements

The *c-MYC* gene, located on 8q24, is involved in one of the three translocations with κ or λ immunoglobulin (Ig) light chain locus in mature B-ALL: (1) the t(8;14)(q24;q32), with a frequency of 80%, is the most common translocation.⁵² In this translocation, *c-MYC* is juxtaposed to the immunoglobulin heavy chain (IgH) gene locus on 14q32; (2) the t(8;22)(q24;q11), occurs in about 15% of B-ALL patients and involves the Ig λ gene locus on 22q11; and (3) the t(2;8)(p12;q24)] is the least frequent of translocation and involves the Ig κ gene locus on 2p12.

Other molecular abnormalities

More than 60% of cases of T-cell ALL have activating mutations that involve *NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development.⁵³ In fact, activating mutations of *NOTCH1* could be the instigating event in most T-cell leukemias. This genetic abnormality is associated with a favorable prognosis.^{54, 55} About 2% of childhood ALL cases have intrachromosomal amplification of chromosome 21, which is associated with a B-cell precursor immunophenotype, older age, low leukocyte count and more importantly, an increased risk of relapse.⁵⁶

Gene expression microarrays

Microarray technology is used to establish gene expression profiles that further distinguish subtypes of ALL, stratify patients according to risk and response, and identify genetic markers associated with drug sensitivity and resistance pathways, and yield useful insights into pathogenesis and biology of ALL. Based on gene expression profiling, a new high-risk subtype of B-cell ALL, called Ph-like ALL, has been identified (reviewed in detail below).^{57, 58}

The therapy of ALL

Combination chemotherapy has been the mainstay of management of both pediatric and adult ALL.⁵⁹ The design was based on a combination of all available antileukemia drugs that were delivered in a sequence of extended courses of therapy. The goal was to prevent emergence of resistant leukemic subclones and to

rapidly restore normal hematopoiesis. Therapeutic strategies in adult ALL have been patterned after the pediatric regimens, and although various combinations with differences in treatment sequence and choice of agents are being used, the same basic principles apply: induction therapy followed by early intensification and consolidation, specific CNS treatment, and a prolonged maintenance phase.^{60, 61} Given the high remission rates with these regimens, the focus of current ALL programs is concentrated on improvement of remission duration and survival of adult patients and to improve quality of life of pediatric patients. With this goal in mind, validation of subtype-specific prognostic models and development of risk-adapted and targeted therapy designs have become the major objectives of the clinical trials.

Treatment of newly diagnosed patients

As complex as ALL treatment programs are and as much variations are found in many of its details, an easily recognizable framework is common to all of them and is presented in [Figure 2](#). Because therapy is becoming increasingly subset-specific and depends on proper risk-stratification, the section on prognostic factors is discussed first prior to proceeding to therapy programs in more detail.

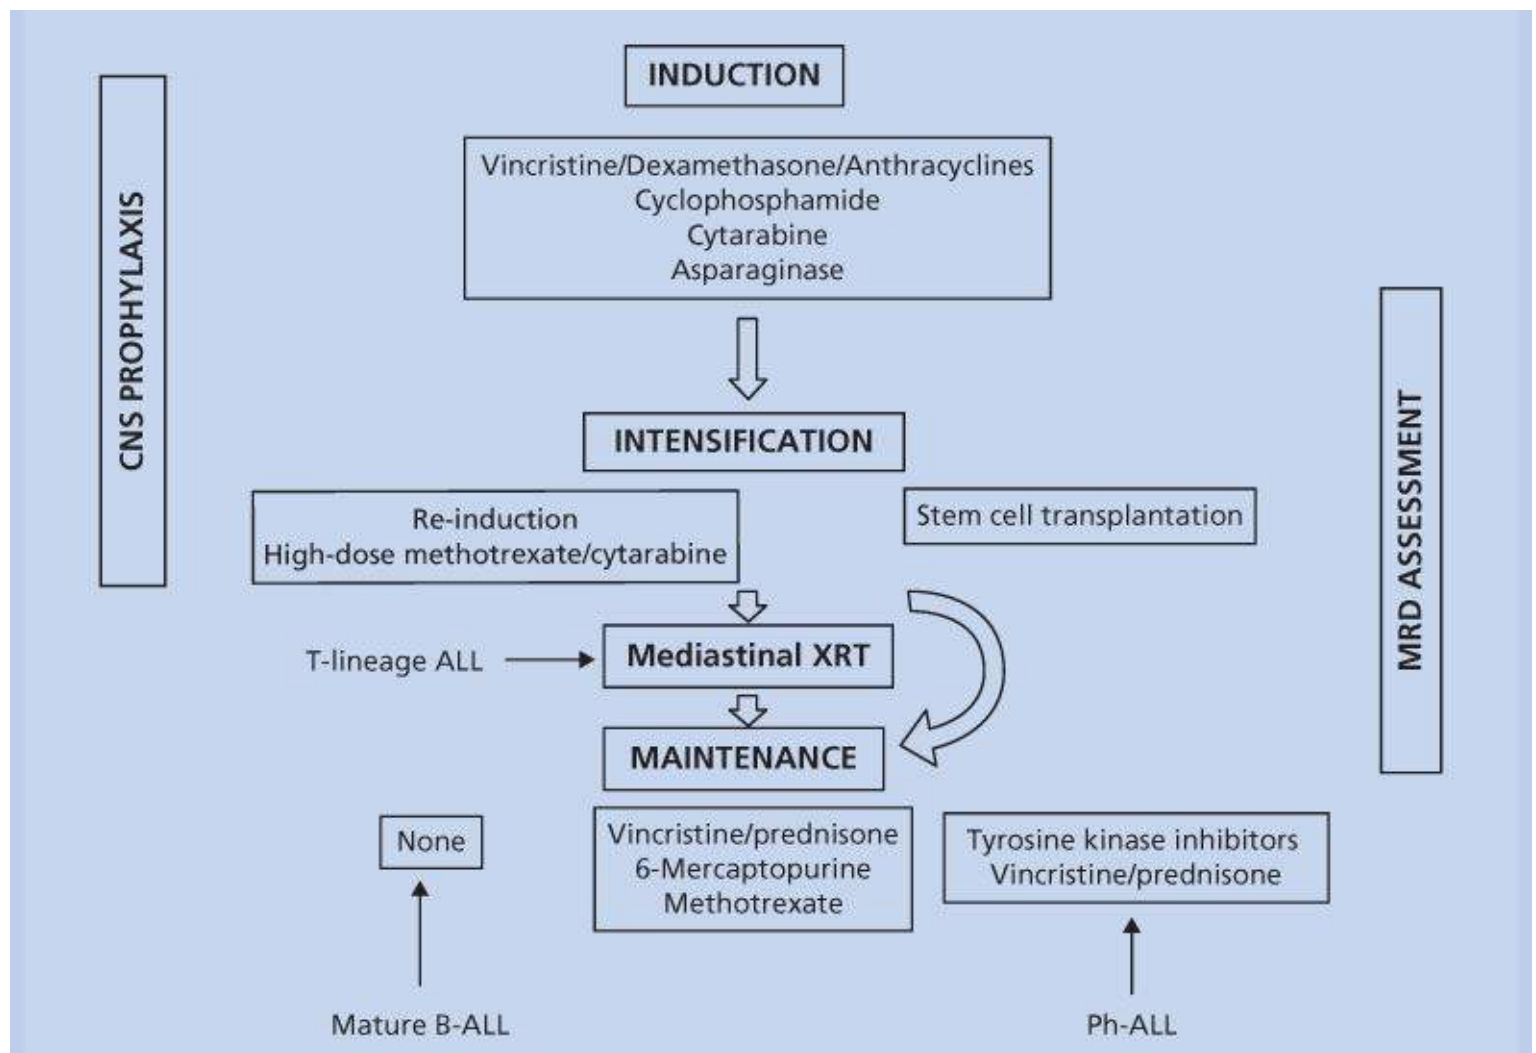

Figure 2 Schematic outline of ALL therapy programs.

Prognostic factors

Efforts to describe risk models for ALL date back to the 1980s and have since experienced continued improvements as a result of the accumulating experience from a sequence of clinical trials. Although remission rates are high with current induction regimens, prognostic models are still useful for risk-

directed postremission therapy to improve the DFS rates in adults and children with high-risk ALL and to avoid overtreatment of those with favorable disease. It should be noted that improved treatment has abolished the prognostic impact of many clinical, laboratory, or biological variables. For example, once associated with poor prognosis, T-cell ALL has long-term DFS of over 50% in adults and 80% in children with current therapies including cyclophosphamide and cytarabine, and mature B-cell ALL have complete response (CR) rates of 90% and DFS rates >50% in adults and >80% in children with short-term dose-intense treatment regimens.⁵⁹ Information from morphological assessment, immunophenotyping, karyotype analysis, molecular genetics, and, increasingly, measurements of minimal residual disease (MRD) has contributed to a more comprehensive risk stratification of patients. Established adverse risk factors include age >60 years, elevated WBC count at diagnosis [$>30,000/\mu\text{L}$ (B-cell ALL), $>100,000/\mu\text{L}$ (T-cell ALL)], pro-B-cell or early T-cell immunophenotype, the presence of $t(4;11)(q21;q23)$ and other MLL rearrangements, and hypodiploidy or complex karyotype.³⁹

Monitoring of MRD after induction and during consolidation has emerged as one of the most powerful predictors of relapse and has been most helpful to further stratify standard-risk patients.⁶² The German Multicenter Study Group for Adult ALL (GMALL) prospectively monitored 196 standard-risk ALL patients at up to nine time points in the first year of therapy with quantitative PCR.⁶³ MRD was predictive for relapse and according to the rapidity of eradication of MRD or persistence of MRD over time, three risk groups could be defined with the 3-year relapse risk varying between 0% (low-risk group) and 94% (high-risk group).

Induction therapy

Vincristine, corticosteroids, and a third agent (anthracyclines in adults and asparaginase in children) have long been the backbone of ALL induction therapy.⁴ No difference in outcome has been established based on the use of different anthracyclines. Dose intensification of anthracycline during induction has not been shown to definitely improve already high CR rates or to result in significant benefits in DFS.^{64, 65}

Additional drugs have become part of ALL induction and intensification cycles. These include cytarabine, methotrexate, cyclophosphamide, L-asparaginase, and less frequently etoposide, tenoside, M-amsacrine, or other agents. With CR rates at around 90%, it will be difficult to demonstrate further improvement. Yet, intensification of induction have shown a positive impact on remission duration and survival, and this effect has been most obvious for specific subtypes. Cytarabine and cyclophosphamide have increased response rates and DFS in T-cell ALL.³⁹ Another important drug has been L-asparaginase. Large randomized pediatric ALL trials have demonstrated improved survival rates where L-asparaginase was given throughout the remission and/or postremission phase.^{66–68} L-Asparaginase is a bacterial enzyme, which efficiently depletes serum asparagine. ALL cells require asparagine for protein production, but, in contrast to normal cells, are unable to produce it themselves so that they depend on sufficiently high serum levels for their survival. The most commonly used form of asparaginase is derived from *Escherichia coli*, whose major limitation is development of hypersensitivity and worse tolerability in adults than in children. Pegasparaginase is a modified form of *E. coli* asparaginase with longer serum half-life and reduced risk of hypersensitivity reactions and several studies have been reported in adults.^{68, 69}

Monoclonal antibodies have been included in adult ALL induction programs. Most experience exists with the anti-CD20 chimeric antibody rituximab [other monoclonal antibodies, including antibody–drug conjugates (ADCs) are reviewed below]. Expression of CD20 has been associated with a higher relapse rate in adult patients with pre-B-ALL.⁷⁰ Several studies have shown improvement in prognosis with chemotherapy plus rituximab combinations especially in mature B-cell ALL.^{70, 71} A recent update of the

modified hyper-cyclophosphamide, vincristine, adriamycin, dexamethasone (hyper-CVAD) regimen from the group at MD Anderson Cancer Center showed that incorporation of rituximab led to very significant improvement in 3-year overall survival (OS) of 75% compared to 47% in the historical controls ($p = 0.003$) in younger patients (<60 years old) with ALL.⁷⁰

Steroids are a standard part of ALL induction and prednisone or prednisolone is the most commonly used steroid, particularly during the maintenance phase. Compared to prednisone and prednisolone, dexamethasone has shown better *in vitro* antileukemic activity and achievement of higher drug levels in the CSF. Using a dose of 6 or 6.5 mg/m² throughout therapy, the Children Oncology Group and UK Medical Research Council randomized trials demonstrated a significant reduction in isolated CNS relapse and a significant improvement of event-free survival.^{72, 73} On the other hand, a smaller study from the Tokyo Children's Cancer Study Group including 231 children with standard- and intermediate-risk ALL showed no difference between dexamethasone (8 mg/m² during induction and 6 mg/m² during intensifications) and prednisolone (60 and 40 mg/m², respectively).⁷⁴

Given the intensity of induction combinations, supportive care has become an important part of ALL therapy. The rationale for hematopoietic growth factors includes shortening of the duration of myelosuppression and therefore associated infectious complications. In addition, a rapid recovery of the marrow function following chemotherapy allows timely administration of dose-intense treatment regimens. Randomized trials have demonstrated advantages of using hematopoietic growth factors such as granulocyte-colony stimulating factor (G-CSF).^{75–77} In the double-blinded, randomized Cancer and Leukemia Group B (CALGB) trial 9111, compared to the 102 patients receiving supportive care alone, the G-CSF treated group ($n = 96$) had faster neutrophil recovery to $>1 \times 10^9/L$ (16 vs 22 days, $p < 0.001$), platelet recovery (16 vs 19 days, $p = 0.003$), shorter duration of hospital stays ($p = 0.02$), higher CR rates (87% vs 71%, $p = 0.01$), and less mortality (5% vs 11%, $p = 0.04$).⁷⁷

Prophylactic antibiotics including antibacterials (e.g., levofloxacin, ciprofloxacin, trimethoprim-sulfamethoxazole), antifungals (e.g., fluconazole, voriconazole, posaconazole), and antivirals (e.g., acyclovir) should accompany induction therapy until recovery of the neutrophil count to at least 1000/ μL in adults. Tumor lysis and, in some cases, DIC should be anticipated in patients with significant leukocytosis and be treated appropriately. Organ involvement and dysfunction may respond to high-dose steroids (e.g., hyperbilirubinemia related to ALL).

Postremission therapy

Postremission therapy consists of an intensified consolidation followed by maintenance therapy and stem cell transplantation (SCT) for some patients. Following the experience from children with ALL, an intensification of postremission therapy has improved outcome, particularly in patients with high-risk disease. There is no consensus, however, on the optimal type or duration of consolidation. Consolidation programs typically consist of a repetition of the induction sequence or rotational programs including additional agents, which may benefit particular ALL subtypes. As dose, schedule, and combinations of cytostatic drugs vary considerably between studies, it remains difficult to assess the value of the individual components of various programs.

[Table 3](#) details the hyper-CVAD program as one example. During hyper-CVAD, hyperfractionated cyclophosphamide alternates with high doses of cytarabine and methotrexate for eight courses, which equals about 6 months of intensified postremission therapy.²² Compared to the earlier and less intense VAD program, there has been a significantly better CR rate (91% vs 75%) and survival. In CALGB study 8811, patients underwent early and late intensification courses with eight drugs following a five-drug

induction regimen.⁶⁰ Maintenance therapy was given until 2 years after diagnosis. The median remission duration was 29 months and the median survival was 36 months, considerably better than the outcome observed with earlier less intense trials.

Table 3 The hyper-CVAD program in ALL

Component	Drug	Subtype

^a During cycles 1 to 4.

- ^b If CD20-positive.
- ^c On days 1–14 of the first course; once daily continuously starting cycle 2.
- ^d Number of intrathecal therapies depending on risk for CNS disease (4 for low risk, 8 for intermediate risk, 16 for high risk including mature B cell). Two intrathecal are given with each induction/intensified consolidation course).
- ^e Dose of intrathecal methotrexate should be reduced by 50% if administered via Ommaya reservoir.
- ^f If bulky mediastinal adenopathy (≥ 7 cm).
- ^g Two cycles of 28–35 days each.
- ^h Total duration 30 months.
- ⁱ Total duration 24 months.
- ^j Continuous administration beyond maintenance.

Most maintenance schedules include 6-mercaptopurine, methotrexate, and monthly pulses of vincristine and prednisone, and extend over 2–3 years. Further intensifications during maintenance are being studied, but remain investigational. Maintenance therapy has become subset-specific. It is of little value in mature B-cell ALL as these patients relapse within the first year of remission and rarely later; TKIs have become an integral component in Ph-positive ALL. Other more T-cell specific drugs such as nelarabine are studied in T-lineage ALL.

SCT has improved outcome for patients with high-risk ALL in first CR.^{78–83} Although there has been resistance to apply SCT for standard-risk patients in CR1, recent reports suggest that the benefit of SCT extends also to some standard-risk patients, in some cases possibly based on MRD levels or other features not captured by traditional prognostic markers.^{79–81} Studies have also compared the results of allogeneic versus autologous SCT or chemotherapy in patients with ALL in first CR. Unbiased comparisons between treatments remain difficult for several reasons. Most patients lack a matched related sibling and cannot be allocated to allogeneic SCT in the first place. Furthermore, significant heterogeneity exists with regard to transplant preparative regimens, source of stem cells (peripheral blood, marrow), the role of T-cell depletion, and uniform application of prognostic markers.^{82, 83}

In a French multicenter trial (LALA 87), patients with a matched sibling donor were allocated to receive allogeneic SCT if they were in CR and younger than 40 years ($n = 116$), or were randomized to chemotherapy ($n = 96$) or autologous SCT ($n = 95$) if they were older or had no sibling donor.⁸⁴ The 5-year survival rates were not significantly different (48% vs 35%, $p = 0.08$), except for patients with high-risk ALL (Ph-positive ALL, undifferentiated ALL, age > 35 years, leukocyte count $> 30 \times 10^9/L$, time to CR > 4 weeks), where allogeneic SCT achieved better 5-year survival (44% vs 20%, $p = 0.03$) and DFS (39% vs 14%, $p = 0.01$). In an update of the LALA 87 study, OS rates at 10 years were 44% in the allogeneic SCT arm versus 11% with chemotherapy ($p = 0.009$) in the high-risk group, and 49% and 39%, respectively ($p = 0.6$), for standard-risk patients.⁸⁵

The LALA-94 study focused on a more risk-adapted postremission strategy and the role of allogeneic SCT in ALL.⁸⁶ A total of 922 patients were divided into standard-risk, high-risk, Ph-positive, and CNS-positive. All patients received a standard 4-week induction and then divided either postremission chemotherapy (standard-risk group) or allogeneic SCT (all other risk groups) if an HLA-identical sibling was identified. Autologous SCT was offered to patients without donor, or they were randomized between autologous SCT and chemotherapy in the absence of Ph or CNS disease. The study confirmed better DFS for high-risk ALL patients in first CR. On the other hand, autologous transplant did not confer a significant benefit over chemotherapy.

The Groupe Ouest-Est des Leucémies Aiguës et Maladies du Sang (GOELAMS) has evaluated the impact of allogeneic SCT for high-risk patients in first CR versus delayed autologous SCT for patients without matched donors and those older than 50 years.⁸⁷ On an intent-to-treat analysis for patients younger than 50 years, 6-year OS was significantly improved with allogeneic SCT compared to autologous stem cell transplant (75% vs 40%, $p = 0.0027$).

The MRC UKALL XII/ECOG E2993 trial was a collaborative effort to address if allogeneic SCT could be beneficial for all suitable adult patients; and if a single autologous SCT could be as effective as postremission chemotherapy.⁷⁹ The study enrolled 1929 patients between 15 and 59 years of age. All patients who had an HLA-matched sibling donor were assigned to receive an allogeneic SCT, whereas those who did not or were over age 55 were randomized to receive an autologous SCT versus chemotherapy. Any randomization was preceded by induction chemotherapy and intensification with high-dose methotrexate. High risk was defined as age > 35 years, leukocytosis ($\geq 30 \times 10^9/L$ for B-lineage and $100 \times 10^9/L$ for T-lineage), and Ph-ALL. CR rate was 90% and 5-year survival was 43% for all patients. The following results emerged: (1) survival at 5 years was 53% for Ph-negative patients with a donor versus 45% for those without a donor ($p = 0.02$); (2) 5-year survival for Ph-negative standard-risk patients was superior for patients with a donor compared to those without (62% vs 52%, $p = 0.02$); (3) 5-year survival for high-risk patients was not significantly different whether patients had a donor or not (41% vs 35%, $p = 0.2$). In this group, transplant-related toxicity prevented a better outcome and abrogated the effect of a reduction in relapse rate; and (4) postremission chemotherapy resulted in superior event-free and OS when compared to autologous SCT ($p = 0.02$ and 0.03 , respectively).

Although a broader role of allogeneic SCT for patients with ALL in first CR is now emerging, optimal timing remains challenging. Novel therapies (e.g., TKIs for Ph-ALL) may affect outcome requiring a redefinition of SCT in some of the risk groups. Nonmyeloablative SCT has been successfully used in older patients.^{83, 88, 89} The major impediment for SCT remains the fact that less than 30% of patients have a matched sibling donor. Much work is, therefore, invested in improving transplants from partially matched related donors, matched unrelated donors, and umbilical cord blood.^{82, 83, 90, 91}

CNS prophylaxis

CNS involvement is rare at diagnosis (<5% in children and <10% in adults).^{60, 92–94} Nonetheless, in the absence of CNS prophylaxis, CNS disease occurs in 40–50% of the patients and has been a major obstacle to cure.⁹⁵ CNS relapse can occur as isolated CNS disease, follow marrow recurrence, or occur concomitantly with a marrow or testicular relapse or both. As CNS relapse confers a poor prognosis, effective CNS prophylaxis is extremely important.²¹ CNS prophylaxis should start early and extend through the induction and intensified consolidation phase as delayed CNS prophylaxis has been associated with an increased incidence of CNS disease.

Risk factors for CNS involvement include younger age, T-lineage and mature B-cell ALL immunophenotype, a high WBC count, and the presence of blasts in CSF at diagnosis.²¹ Expression of CD7, CD56, and interleukin-15 was found to have prognostic implications with regard to extramedullary manifestations of ALL.^{96, 97} Elevated serum LDH levels and a high proliferative index ($S + G2M > 14\%$) proved to be sensitive predictors of the risk of CNS disease.⁹⁸

Therapeutic modalities for CNS prophylaxis include intrathecal (IT) chemotherapy (methotrexate, cytarabine, steroids), high-dose systemic chemotherapy (methotrexate, cytarabine, L-asparaginase, dexamethasone, 6-thioguanine), and craniospinal irradiation (XRT). Combined triple-modality IT therapy is more effective for CNS control than IT methotrexate alone, but it carries a higher risk of treatment-

related CNS morbidity and unexpectedly was associated with an increased risk of bone marrow and testicular relapse in one randomized trial.⁹⁹ One explanation for this paradoxical finding is that an “isolated” CNS relapse may in fact be an early manifestation of systemic relapse, and that better CNS control favors leukemic relapse in other sites at a later time. Several studies in children and in adults have demonstrated that IT therapy is equivalent to craniospinal XRT, so that the role of cranial XRT has become controversial.²¹ Adverse effects of XRT can be severe and disabling leading to seizures, dementia, and intellectual dysfunction, as well as other complications such as multiple endocrinopathies and growth retardation in children. Patients with cranial nerve root involvement may benefit from selective irradiation to the base of the skull.

Minimal residual disease (MRD)

In children and adults, relapse is thought to result from residual leukemia cells, which persist following achievement of a morphologic and cytogenetic remission, but remain undetectable by conventional methods such as microscopy and cytochemical stains. A number of sensitive techniques have been developed including multicolor flow cytometry and PCR assays. Whatever the assay, detection of residual leukemia cells depends on identification of unique leukemia cell markers. For flow cytometry, aberrant expression of surface marker combinations can be followed, whereas for PCR, leukemia-specific fusion genes (e.g., *BCR-ABL*, *MLL-AF4*, *ETV6-RUNX1*) or patient-specific junctional regions of rearranged immunoglobulin and T-cell receptor genes constitute appropriate markers.⁶²

A plethora of studies in both children and adults has provided convincing evidence for the usefulness of MRD monitoring to assess relapse risk.^{62, 100–105} There is general consensus from pediatric studies that high levels of MRD at the end of induction therapy, persistently high levels during consolidation and maintenance, and continuous increases of MRD levels at any point, are associated with a high risk of relapse.¹⁰⁶ Although more adults have higher levels of MRD at the completion of induction, and the relapse risk is higher even with low levels of MRD compared to children, continuous MRD assessment along several time points has proved predictive for relapse in adult patients as well.^{101, 102}

Assessment of MRD status has been included in a number of current studies to decide about intensification of postremission therapy. Several questions, however, still remain: (1) what is a clinically relevant threshold of residual disease upon which clinical decisions should be based? (2) which are the most appropriate time points to measure MRD following induction, and how do they change in the context of the specific treatment administered? (3) does intervention based on a molecular relapse improve outcome, and if so, do response criteria upfront need to be modified to include molecular responses? (4) how reproducible are MRD assays across a multitude of laboratories and how reliably can MRD data from different institutions be compared? Beyond being a helpful tool for risk-adapted treatment stratifications, the study of residual disease will hopefully also reveal more about the biology of ALL itself.

Adolescent and young adults (AYA) with ALL

Patients who are in the adolescent and young adult age group (variably defined in clinical studies from 16 years to up to 39 years) could be treated with pediatric-inspired regimens or with adult ALL regimens. Pediatric regimens in general have more intensive treatment with nonmyelosuppressive drugs such as steroids, vincristine, asparaginase, and typically more intensive CNS prophylaxis. Several retrospective and prospective studies have shown better outcomes of this patient population when treated with pediatric regimens versus adult regimens.¹⁰⁷ The group at MD Anderson Cancer recently reported similar outcomes

in AYA patients treated with a pediatric regimen (augmented BFM regimen) compared to a historical cohort of patients treated with hyper-CVAD regimen.¹⁰⁸ Recent identification of Ph-like gene signature (see below) in AYA patients with ALL, and its association with poor prognosis, and increase in incidence of Ph-like signature with age adds further complexity to the management of AYA patient population.^{24, 109}

Salvage therapy

Prognosis of adult patients with relapsed or refractory ALL remains poor. Postrelapse therapies will lead to a second CR in only 30–40% of patients with a 5-year OS of only around 10%. In the MRC UKALL12/ECOG 2993 study, OS at 5 years after relapse was only 7%.¹¹⁰ Factors predicting for better outcome (indicating 5-year survival rates of 11–12%) included age younger than 20 years and remission durations of more than 2 years. Although there is no standard approach to salvage therapy, there is general consensus, that allogeneic SCT should be first choice in this situation. For most patients, SCT is not an option for lack of a suitable donor, other ongoing comorbid conditions (e.g., infections, poor performance status), or simply uncontrollable disease. Most nontransplant salvage attempts are modeled after patterns familiar from frontline therapy and include: (1) combinations of vincristine, steroids, and anthracyclines; (2) asparaginase and methotrexate combinations; or (3) high-dose cytarabine. Direct comparisons of various regimens are difficult because of differences in patient characteristics, prior drug exposure and sensitivity, number of salvage attempts, variations in dose and schedule of agents, the use of SCT as consolidation in some patients, and not least because of the overall poor outcome. This underscores the need for development of novel therapies for patients with ALL.

Disease subtypes

Ph-positive ALL

Historically, Ph-positive ALL has had the worst survival rates with standard chemotherapy and, being much more frequent in adults than children, was attributed to some degree with the overall worst prognosis for adult patients.¹¹¹

Since the discovery of imatinib and several newer generation TKIs, an array of new treatment possibilities in Ph-positive ALL have become available. Imatinib competitively binds to the ATP binding site of BCR-ABL and inhibits autoactivation of the oncoprotein as well as phosphorylation of downstream intracellular proteins. Imatinib has single-agent activity in Ph-positive ALL with hematologic response rates in the range of 20–30%, but response durations are not maintained and short.¹¹² Single-agent kinase inhibitor therapy possibly combined with low-intensity therapy (vincristine, steroids) is of particular benefit in elderly and frail patients not considered candidates for more aggressive therapy.¹¹³

Several studies have successfully combined imatinib with intensive chemotherapy programs.^{114–116} The group at MDACC combined imatinib with hyper-CVAD.¹¹⁴ Imatinib 600 mg was given daily for 14 days with the induction cycle and then continuously thereafter until the dose was again increased to 800 mg for indefinite maintenance therapy. Of the 54 patients with a median age of 51 years (range 17–84 years) treated, 93% achieved a complete remission with a median time to response of 21 days. The molecular response rate based on nested PCR was 52%. Sixteen patients proceeded to allogeneic SCT within a median of 5 months from start of therapy, though survival at 3 years did not seem improved whether or not patients received a SCT (63% vs 56%). Outcome is superior to hyper-CVAD alone: 3-year OS rates were 55% versus 15% ($p < 0.001$). There is a general consensus that imatinib is more effective when started

early during induction and when given concurrently with and subsequent to induction and consolidation rather than alternating with chemotherapy.¹¹⁷

Dasatinib and nilotinib are two second-generation TKIs, which are many times more potent than imatinib in *in vitro* models, which includes activity against most imatinib-resistant kinase domain mutations. Both have shown activity in imatinib-resistant Ph-positive ALL. The investigators at MD Anderson Cancer Center treated 63 patients with newly diagnosed Ph + ALL with dasatinib in combination with hyper-CVAD chemotherapy.^{118, 119} A total of 93% patients achieved a major molecular remission and 65% achieved complete molecular remission. The median DFS and OS were 31 and 44 months, respectively. Several studies have confirmed these findings and early TKI therapy is now the standard treatment of Ph + ALL.^{39, 120–124} Nilotinib has also been combined with multiagent chemotherapy for patients with Ph + ALL.¹²⁵ Ponatinib, a third-generation TKI, is currently being investigated in combination with hyper-CVAD chemotherapy as frontline therapy for patients with ALL.¹²⁶

Mature B-ALL (Burkitt's leukemia)

Mature B-cell ALL is a rare entity of ALL and predominates in children. The genetic basis of the disease is the underlying MYC translocation at band 8q24 to either the immunoglobulin heavy chain region on chromosome 14 or less commonly at the λ (22q11) or κ (2p12) loci. Prompt diagnosis and recognition of this entity are essential for optimal treatment outcomes. These patients are at high risk for the development of tumor lysis syndrome. Aggressive hydration and administration of allopurinol and/or rasburicase are important. Intensive chemoimmunotherapy is the standard treatment for these patients.^{71, 127} Thomas et al. combined hyper-CVAD with rituximab to treat 31 newly diagnosed patients with mature B-ALL or lymphoma and median age of 46 years (29% older than 60 years).¹²⁷ The overall CR rate was 86%. The 3-year OS and DFS rates were 89% and 88%, respectively, which was similar in the elderly patients. Younger age and treatment with rituximab were identified as independent favorable factors. Recently, the German ALL study group reported impressive results on 363 patients with Burkitt's leukemia/lymphoma treated prospectively on a chemoimmunotherapy regimen in combination with rituximab.⁷¹ The rate CR, 5-year PFS, and 5-year OS were 88%, 71%, and 80%, respectively.

Ph-like ALL

In 2009, a subgroup of B-cell ALL was identified in children with ALL that had a gene expression profile similar to that of Ph-positive ALL, but these patients lack the Ph.^{57, 58} These patients, referred as “Ph-like ALL,” comprise up to 15% of pediatric B-cell ALL and 20–25% in adolescents and young adults.^{24, 128} Patients with Ph-like ALL have a very high rate of disease relapse and short overall survival.^{24, 128–131}

About 50% of Ph-like ALL cases harbor a rearrangement of *CRLF2* located at the pseudoautosomal region of Xp22.3/Yp11.3, either as a translocation to the immunoglobulin heavy chain enhancer region at 14q32.33 (*IGH-CRLF2*), or a focal deletion proximal to *CRLF2* resulting in the expression of a *P2RY8-CRLF2* fusion transcript.^{109, 129, 132–135}

About 50% of patients with *CRLF2* rearrangement have *JAK* mutations (*JAK2*, most commonly *JAK2R683*, and *JAK1*).²⁴ Non-*CRLF2* rearranged cases have been reported to have fusions of several genes including *ABL1*, *ABL2*, *JAK2*, *EPOR*, and *PDGFRB*. These diverse genetic alterations activate signaling pathways, notably *ABL1* and *PDGFRB* (both of which may be inhibited with the TKI such as dasatinib) and JAK-STAT signaling, which may be inhibited by *JAK* inhibitor such as ruxolitinib.^{109, 136}

Harvey et al. evaluated 207 children with “high-risk” B-cell ALL and found that 14% had *CRLF2*

overexpression.¹²⁹ Interestingly, patients with Hispanic ethnicity were more like to have CRLF2 overexpression (35% vs 7% in others, $p < 0.001$).

Early precursor T-cell ALL (ETP ALL)

A subgroup of high-risk T-cell has been identified based on a myeloid gene expression signature.²⁹ This ALL subset is derived from ETP, cells that recently arrived in the thymus from the bone marrow and retain multilineage differentiation potential. Approximately 10–15% of childhood cases of T-cell ALL and 7–10% of adult cases of T-cell ALL have the ETP phenotype.^{29, 137} A specific immunophenotype of ETP ALL has been described: (1) CD1a negative; (2) CD8 negative; (3) weak or absent CD5; and (4) presence of one or more of myeloid/stem cell marker such as CD117, CD34, HLA-DR, CD13, CD33, CD11b, and CD65.²⁹ Patients with ETP ALL have significantly worse outcomes than those with non-ETP T-cell ALL (St Jude's pediatric data—10-year OS, 19% for ETP ALL vs 84% for non-ETP T-cell ALL, $p = <0.0001$; 10-year relapse rate, 72% for ETP ALL vs 10% for non-ETP T-cell ALL, $p = <0.0001$).^{29, 138} The German ALL study group reported that ETP ALL comprised 7.4% of adult T-cell ALL cases.^{137, 139, 140} They reported a 35% incidence of FLT-3 mutation and a 14% incidence of DNMT3A mutation in patients with ETP ALL.

Novel therapies

A better understanding of the disease biology has led to several novel therapies for patients with ALL ([Table 4](#)). A continuous source of active drugs in leukemias is the vast group of nucleoside analogs. Clofarabine is a new generation purine nucleoside modeled after fludarabine and cladribine, but with different mechanisms of action and spectrum of activity.¹⁴¹ In a phase II trial of clofarabine in 61 pediatric patients with relapsed or refractory ALL, 30% responded.¹⁴² Clofarabine has been approved by the Food and Drug Administration (FDA) for children with R/R ALL. Kantarjian et al.¹⁴³ reported 17% response rate with single-agent clofarabine in adults with relapsed/refractory ALL. The Southwest Oncology Group Study conducted a phase II trial of combination of clofarabine and cytarabine for R/R ALL with a modest response rate of 17%.¹⁴⁴ Nelarabine is a soluble prodrug of 9- β -D-arabinofuranosylguanine (ara-G) with activity predominantly in relapsed T-lineage lymphoid malignancies and is approved by the FDA for this indication.^{145–149} Response rates of 33% and up to 41% have been achieved in a group of 121 children and 39 adults with relapsed T-lineage leukemia/lymphoma, respectively.^{145, 146} Neurotoxicity is the major adverse event of nelarabine, which is both dose and schedule dependent. The MD Anderson group reported 40 patients with newly diagnosed T-cell ALL or T-cell lymphoblastic lymphoma treated with nelarabine in combination with hyper-CVAD chemotherapy.¹⁴⁹ Patients received two cycles of nelarabine at a dose of 650 mg/m² intravenous daily for 5 days both early (after cycles 4 and 5 of hyper-CVAD) and later during the maintenance (replacing cycles 6 and 7 of the maintenance). The overall response rate (ORR) was 97% with 91% patients in CR. The DFS at 3 years was 61% and 3-year probability for OS was 63%. Vincristine is an important component of ALL treatment. Liposomal vincristine facilitates vincristine dose intensification plus enhances target tissue delivery. O'Brien et al. evaluated liposomal vincristine monotherapy in adult patients with Ph-negative ALL in second or greater relapse.¹⁵⁰ Sixty-five patients were treated with a CR/CRi rate of 20% and an ORR rate of 35%. Based on this study, liposomal vincristine has been approved by the FDA for this patient population.

Table 4 New agents in ALL

Class	Examples
Nucleoside analogs	Clofarabine Nelarabine
Liposomal and pegylated compounds	Liposomal vincristine (Marqibo) Liposomal doxorubicin Pegasparaginase
Monoclonal antibodies	
Unconjugated	Rituximab (CD20) Ofatumumab (CD20) Epratuzumab (CD22) Alemtuzumab (CD52)
Antibody drug/toxin conjugates	Inotuzumab ozogamicin (CD22/calicheamicin) SAR3419 (CD19/maytansine) Moxetumomab (CD22/Pseudomonas toxin)
Bi-specific antibodies	Blinatumomab (CD19/CD3)
Tyrosine kinase inhibitors	Imatinib Dasatinib Nilotinib Ponatinib Ruxolitinib
T-cell immunotherapy	Chimeric antigen receptor T cells

Targeting cell surface receptors

Rituximab, a chimeric monoclonal antibody against the cell surface protein CD20, has a well-established role in B-cell ALL (see above).⁷⁰ Ofatumumab targets a different epitope of CD20 and has been found to be more potent than rituximab in promoting complement-dependent cytotoxicity *in vitro* and is currently being studied for patients with ALL.^{151, 152}

CD19 is expressed uniformly in B-cell ALL. Blinatumomab is a novel antibody (bispecific T-cell engager antibody) designed to target patient's T cells to CD19-expressing tumor cells resulting in a cytotoxic T-cell response.¹⁵³ Blinatumomab has been shown to eradicate MRD in a majority of patients with ALL.^{154, 155} The German ALL study group conducted a phase II trial of blinatumomab in patients with relapsed/refractory B-cell ALL.¹⁵⁶ Blinatumomab was administered by continuous intravenous infusion for 28 days followed by a 14-day treatment-free interval. Responding patients could receive three additional cycles of treatment or proceed to bone marrow transplantation. Of the 36 patients treated, 25 patients (69%) achieved a CR/CRi. The median OS was 9.8 months, and the median relapse-free survival was 7.6 months. In a multicenter international phase II study, 189 patients with R/R ALL were treated with blinatumomab.¹⁵⁷ This study included particularly high-risk patient population [primary refractory or relapsed (first relapse within 12 months of first remission, relapse within 12 months after allogeneic SCT, or no response to or relapse after first salvage therapy or beyond)]. Forty-three percent of patients achieved CR/CRi within two cycles of treatment with blinatumomab. The median overall survival was 6.1 months. Based on these data, blinatumomab is now approved in the United States for treatment of

patients with R/R B-cell ALL.

SAR3419 is an ADC that targets CD19. The ADC is created by conjugation of the IgG1 antibody huB4 to the maytansinoid DM4, a potent inhibitor of tubulin polymerization and microtubule assembly. In a phase I study, SAR3419 was administered every 3 weeks in patients with relapsed B-cell lymphoma.¹⁵⁸ The most common drug-related toxicity was ocular toxicity, which was noted in 44% of patients. Of 35 patients evaluable for efficacy, 26 (74%) patients demonstrated a reduction in their tumor size. A second phase I study was conducted to evaluate a once weekly schedule of SAR3419.¹⁵⁹ There was a lower incidence of ocular side effects and 55% of patients noticed tumor shrinkage.

CD22 expression occurs in >90% of patients with ALL. Inotuzumab ozogamicin is a CD22 monoclonal antibody bound to a toxin, calecheamicin, and has shown single-agent activity in relapsed/refractory ALL.¹⁶⁰ In a phase II study, patients were given inotuzumab ozogamicin (1.8 mg/m²) intravenously every 3–4 weeks. Forty-nine patients were treated. The overall response rate was 57% (CR 18%, marrow CR 39%). Based on higher *in vitro* efficacy with more frequent exposure, a weekly schedule (0.8 mg/m² on day 1, and 0.5 mg/m² on days 8 and 15, every 3–4 weeks) has been developed.¹⁶¹ With the weekly schedule, the overall response rate was 53% with an improved toxicity profile. Inotuzumab ozogamicin in combination with rituximab has been evaluated in patients with R/R NHL.¹⁶² The MTD of inotuzumab ozogamicin in combination with rituximab was 1.8 mg/m² every 4 weeks. The most common grade 3–4 adverse events were thrombocytopenia (31%) and neutropenia (22%). At the MTD, the objective response rates were 87% and 74% in patients with relapsed follicular lymphoma (FL) and diffuse large B cell lymphoma (DLBCL), respectively.

Epratuzumab, an unconjugated monoclonal antibody targeting CD22, has also been studied in ALL. Advani et al.¹⁶³ added epratuzumab to the combination of clofarabine and cytarabine in adults with R/R B-cell ALL (Southwestern Oncology Group study S0910). The CR/CRi rate was reported as 52%, significantly higher than their previous trial with clofarabine/cytarabine alone, where the response rate was only 17%.¹⁴⁴ Epratuzumab in combination with vincristine and steroids has also been tested in older patients with R/R ALL with a 20% CR/CRi rate.¹⁶⁴

Moxetumomab is a recombinant immunotoxin composed of the Fv fragment of an anti-CD22 monoclonal antibody fused to the pseudomonas toxin.¹⁶⁵ In a phase I study in pediatric patients with relapsed/refractory CD22+ B-cell ALL, moxetumomab was administered at doses of ranging from 5 to 40 mcg/kg, every other day for 6 doses.¹⁶⁶ Twenty-one patients were treated. The most common treatment-related adverse events were increased weight, increased transaminases, and hypoalbuminemia. The ORR was 29%. A phase I/II trial of moxetumomab in adult patients with R/R ALL is currently enrolling patients (NCT01891981).

CD52 is expressed on nearly all normal and malignant B lymphocytes and T lymphocytes, monocytes, and macrophages.¹⁶⁷ Alemtuzumab is an unconjugated monoclonal antibody directed against CD52. In a phase I/II CALGB study, alemtuzumab was administered to 24 patients with ALL in CR1 with an intent to eradicate the MRD.¹⁶⁸ Serial assessment of MRD was possible in 11 patients of which 8 patients had a median 1-log decrease in MRD. Alemtuzumab, as a single-agent, has limited activity in relapsed/refractory pediatric and adult patients with ALL.^{169, 170}

Chimeric antigen receptor (CAR) therapy

Immunotherapy with chimeric antigen receptors (CARs) is an active field of research. CARs are synthetic receptors composed of an antigen-binding domain fused to a transmembrane domain followed by one or

more cytoplasmic signaling domains. The resultant receptor is then expressed on autologous or allogeneic T cells. CD19 CARs have shown remarkable activity in B-cell ALL patients with >80% CR rate in a relapsed/refractory patient population.^{171–174} Davila et al.¹⁷¹ reported on 16 patients with relapsed/refractory B-cell ALL who were treated with CD19-directed CAR T cells. The CR rate was 88%. Maude et al. reported on 30 pediatric and adult patients with R/R ALL treated with CD19-directed CAR T cells.¹⁷⁴ CR was achieved in 27 patients (90%). Six-month event-free survival (EFS) rate was 67% and OS was 78%. Cytokine release syndrome is common after CAR T-cell infusion. Targeting CD19 also leads to B-cell aplasia and these patients require regular immunoglobulin replacement.

T-cell ALL

Unlike B-cell ALL where several therapeutic targets are being investigated, only a limited number of drugs/targets are currently being investigated in T-cell ALL.

Notch inhibition in T-cell ALL

Notch signaling is highly conserved evolutionary pathway and is required for commitment of stem cells to T-cell fate.^{175, 176} Ellisen et al. first reported Notch involvement in T-cell ALL when they described a translocation t(7;9)(q34;q34.3).¹⁷⁷ Weng et al. reported activating *NOTCH1* mutations in 56% of patients with T-cell ALL.⁵³ Asnafi et al. reported a 72% incidence of *NOTCH1* and *FBXW7* mutations in adult patients with T-cell ALL.⁵⁵ Presence of *NOTCH1*/*FBXW7* mutations is associated with better clinical outcomes.^{55, 178} A phase I trial of an oral γ -secretase inhibitor MK-0752 in patients with R/R T-cell ALL showed modest clinical activity but with significant gastrointestinal toxicities.¹⁷⁹ Gastrointestinal toxicity is an on-target effect where small bowel epithelial cells are skewed to goblet cell fate instead of enterocytes.¹⁸⁰ A phase I trial with a γ -secretase inhibitor, BMS-906024, given weekly, is currently underway (NCT01363817).

Summary

Progress in the understanding of the biology of ALL and refinements of prognostic systems have led to increasing sophistication of therapy. Patients with mature B-cell ALL do best with short-term dose-intensive therapies, whereas outcome in T-cell ALL has improved with the addition of cyclophosphamide and cytarabine. It is now well established that treatment for Ph-positive ALL should include TKIs, ideally from the start and probably best maintained for many years thereafter. The role of transplantation is modified according to better and more predictable risk stratification. Transplantation should be considered in first remission in any high-risk patients without prohibitively serious comorbidities, or any patients beyond a first remission. Its expansion into standard-risk groups is being discussed, but not a standard approach. As for any other malignancy, the key to improving prognosis of ALL, especially for adult patients, lies in continuously better definitions of the many subtypes of ALL. Ph-like ALL and ETP ALL represent two recently defined high-risk subtypes of ALL and may be targetable with TKIs. Treatment programs in ALL are complex and will continue to be. Development of new drugs such as ADCs and CAR T-cell therapy is very promising. Incorporation of these new agents with the currently established treatment programs remains an ongoing challenge.

Chapter 117

Chronic lymphocytic leukemia

Kanti R. Rai, MD ■ Jacqueline C. Barrientos, MD

Overview

Chronic lymphocytic leukemia (CLL) is an indolent B-cell neoplasia characterized by a progressive accumulation of small functionally incompetent lymphocytes in the blood, marrow, and lymphoid tissues. Given its indolent presentation, initiation of therapy is deferred until patients become symptomatic. CLL primarily affects the elderly population who generally has clinically significant coexisting conditions. The use of traditional chemoimmunotherapy regimens has been historically limited to fit patients able to tolerate the known toxicities from such regimens. A major shift in the management of CLL is currently taking place with the approval of several new targeted agents with unprecedented clinical activity in patients with poor prognostic markers and high-risk disease. New drug combinations are being evaluated with the goal to optimize treatment approaches based on the clinical and biological profile of the CLL patient.

Chronic lymphocytic leukemia

CLL biology: Historical perspective

CLL is a monoclonal CD5⁺ B-cell lymphoproliferative disorder derived from antigen-experienced B lymphocytes that differ in their level of immunoglobulin heavy chain variable region (IGHV) gene mutations.¹ [Table 1](#) summarizes some of the important differences between the way CLL is defined now and in the past. The pace of research in CLL received a major boost over the past decade with the finding of chromosomal abnormalities and genetic mutations that contribute to the heterogeneity of the clinical presentation and help predict the disease course. Equally important has been the discovery of the role of the microenvironment and of the signaling factors that are necessary to CLL pathogenesis.^{2–5} This greater understanding has led to the development of agents that specifically target dysregulated pathways that allow the proliferation and survival of the malignant clone. The recent introduction of therapies with excellent clinical activity in patients previously refractory to chemotherapy is changing the natural history of the disease with long-term survival expectations substantially improved. Despite these rapid advances, the majority of CLL patients who initially achieve a remission eventually relapse. Presently, research is focused on elucidating mechanisms of resistance to the novel targeted agents.

Table 1 B-cell chronic lymphocytic leukemia as viewed then and now

Previously	Currently
<ul style="list-style-type: none">• A clinically heterogeneous disease with a homogeneous cellular origin• A disease derived from naive B lymphocytes• Leukemic cell accumulation occurs because of an inherent apoptotic defect involving the entire mass of leukemic cells• A disease of accumulation• Prognostic markers identify patients at low/intermediate/high (Rai) or A/B/C (Binet) risk with an acknowledged heterogeneity (vis-à-vis clinical outcomes) among patients in the low/A and intermediate/B risk categories• Therapy based largely on clinical observations and trial-and-error methods	<ul style="list-style-type: none">• A clinically heterogeneous disease originating from B lymphocytes that may differ in activation and maturation state or cellular subset• A disease derived from antigen-experienced B lymphocytes that differ in the level of immunoglobulin V gene mutations• An inherent apoptotic defect involving the entire mass of leukemic cells is unlikely to exist initially. Cell accumulation occurs because of survival signals delivered to a subset of leukemic cells from the external environment through a variety of receptors (e.g., <i>BCR</i>, chemokine, and cytokine receptors) and their cell-bound and soluble ligands• A disease of accumulation with an associated level of proliferation that exceeds that previously appreciated• Newer molecular and protein markers separate patients within the low/A and intermediate/B risk categories that follow different clinical courses• Above-noted newer findings provide clues to discover discrete targets for developing hypothesis-driven and effective therapeutic agents

Incidence and epidemiology

CLL is the most prevalent adult leukemia in the Western world accounting for approximately 30% of all leukemias diagnosed in the United States. Approximately 15,720 new cases of CLL and 4600 deaths are expected in the United States in 2014.⁶ For the most part, CLL is a disease of the elderly, with a median age of 71 years at diagnosis. The male : female incidence ratio of CLL is approximately 1.5 : 1.^{6, 7} CLL is more common in Europe, Australia, and North America than in Asia, Africa, or other less developed countries.⁸

Diagnosis of CLL

The World Health Organization (WHO) classification of hematopoietic tumors describes CLL as a leukemic, lymphocytic lymphoma, distinguishable from small lymphocytic lymphoma (SLL) only by its leukemic presentation.⁹ In this classification, CLL is always a disease of neoplastic B cells, while the entity formerly known as T-CLL is now called T-cell prolymphocytic leukemia (T-PLL).¹⁰ The International Workshop on CLL (IWCLL) established the diagnosis of CLL as requiring the presence of at least 5×10^9 clonal B lymphocytes/L (5000/ μ L) in the peripheral blood confirmed by flow cytometry.¹¹ Peripheral blood smear review reveals small, mature lymphocytes with a narrow border of cytoplasm (Figure 1). Gumprecht nuclear shadows, also known as “smudge cells,” can be found as debris. The

nuclear chromatin is clumped and exhibits partially aggregated chromatin with up to 55% larger or atypical cells, cleaved cells, or prolymphocytes.¹²

Figure 1 Chronic lymphocytic leukemia morphology in peripheral blood smear. Leukocyte count: $100 \times 10^9/\text{L}$. Most of the lymphocytes are mature appearing. One smudge cell is present. Platelets are absent in this thrombocytopenic patient (Wright-Giemsa stain; $\times 100$ original magnification).

Pathogenesis and causation

Monoclonal B-cell lymphocytosis and familial CLL

The absence of cytopenias, lymphadenopathy, organomegaly, or disease-related symptoms (B symptoms) in the presence of fewer than 5×10^9 clonal B lymphocytes/L in the peripheral blood is defined as “monoclonal B-lymphocytosis” (MBL).¹³ Rawstron and colleagues¹⁴ found MBL among 13.5% of normal first-degree relatives of people known to have CLL. That incidence is much higher than the 3.5% that Rawstron and colleagues discovered among adults with normal blood counts without a first-degree relative with CLL.¹⁵ Furthermore, there is an increased incidence of CLL or related disorders among the family members of people known to have CLL.^{17, 16} Further research is needed to elucidate a putative CLL predisposition gene or a possible CLL carrier state. Similar to Kyle's MGUS data in multiple myeloma,¹⁸ the rate of progression to CLL that requires treatment is 1.1% per year.¹⁹

Immunobiology and immunophenotype of CLL cells

Morphologically, CLL cells resemble mature lymphocytes in the normal peripheral blood and coexpress the T-cell antigen CD5 with the B-cell surface antigens CD19, CD20, and CD23. The levels of surface immunoglobulin, CD20, and CD79b are characteristically low compared with those found on normal B cells,²⁰ with the clones restricted to expression of either kappa or lambda immunoglobulin light chains. Several other malignancies of mature-appearing lymphocytes ([Table 2](#)) present with clinical features overlapping those of CLL; hence, flow cytometry is extremely helpful in distinguishing CLL from other diseases ([Table 3](#)).^{21–23}

Table 2 Malignancies of morphologically mature-appearing B lymphocytes

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL)
B-prolymphocytic leukemia (B-PLL)
Hairy cell leukemia (HCL)
Follicular lymphoma in leukemic phase (FL-L)
Mantle cell lymphoma in leukemic phase (MCL-L)
Splenic lymphoma with villous lymphocytes (SLVL)
Lymphoplasmacytoid lymphoma

Table 3 Phenotypes of lymphoproliferative disorders

Disease	Typical phenotypes
CLL	CD20 (d), CD19 ⁺ , CD22 (d), sIg (d), CD23 ⁺ , FMC-7 ⁻ , CD5 ⁺ , CD10 ⁻ , CD38 ^{+/-}
Mantle cell lymphoma	CD20 (i), sIg (i), CD23 ^{+/-} , FMC-7 ^{+/-} , CD5 ⁺ , CD10 ⁻ , cyclin-D1 ⁺
B-prolymphocytic leukemia	CD20 (+i), sIg (+i), FMC-7 ^{+/-} , CD5 ^{+/-} , CD10 ⁻
Marginal zone B-cell lymphoma	CD23 ⁻ , CD11c ^{+/-} , CD103 ^{+/-} , CD5 ^{+/-} , CD10 ⁻ , CD138 (b)
Lymphoplasmacytic lymphoma	CD23(-/d), sIg ^{+/-} , cIg ⁺ , CD5 ^{+/-}
Follicular lymphoma	CD20 (+i), CD5 ⁻ , CD10 ⁺ , bcl-2 ⁺ , CD43 ⁻
Diffuse large B-cell lymphoma	CD20 (+i), CD5 ⁻ , CD10 ⁺ , bcl-2 ^{+/-} , CD43 ^{+/-} , CD5 ^{+/-}
Burkitt's lymphoma	Bcl-2 ⁻ , CD10 (+b), CD43 ⁺ , CD5 ⁻
Hairy cell leukemia	CD20 (b), CD22 (b), CD11c (b), CD25 ⁺ , CD103 ⁺ , sIg (i), CD123 ⁺ , CD5 ⁻

Abbreviations: +, usually positive; -, usually negative; +/-, may be positive or negative; d, dim; i, intermediate; b, bright; sIg, surface immunoglobulin; cIg, cytoplasmic immunoglobulin.

Clinical aspects

Patients infrequently present with constitutional symptoms. The classic symptoms are known as “B symptoms”: unintentional weight loss of 10% or more, fevers higher than 100.5°F (38°C), or night sweats for more than 1 month without evidence of infection. Fatigue may also be reported.

Absolute lymphocytosis in blood

By IWCLL criteria, the presence of at least 5×10^9 B clonal lymphocytes per liter (5000/ μ L) with the phenotypes CD19⁺, CD20⁺, CD23⁺, and CD5⁺ is required to diagnose CLL, as lymphocytosis may occur with infections or in other neoplastic conditions (e.g., leukemic phase of lymphomas, hairy cell leukemia (HCL), PLL—[Figure 2](#), and large granular cell leukemia).

Figure 2 Prolymphocytic leukemia. Peripheral blood smear shows cells with prominent nucleoli and abundant cytoplasm (Wright-Giemsa stain; $\times 1000$ original magnification).

Clinical presentation

Upon physical examination, a CLL patient may have enlarged nodes that are firm, rounded, discrete, nontender, and freely mobile upon palpation. The most consistent abnormal finding on physical examination is lymphadenopathy, but splenomegaly or hepatomegaly may also be present. Enlargement may be generalized or localized, and degree can vary widely leading to obstruction of adjacent organs. In addition to palpably enlarged peripheral lymph nodes, liver, and spleen, virtually any other lymphoid tissue in the body—for example, Waldeyer's ring or the tonsils—may be enlarged at diagnosis. In addition, infiltration with CLL cells may occur in any organ or tissue. In contrast to lymphoma, gastrointestinal mucosal involvement is rarely seen in CLL. Similarly, meningeal involvement is extremely unusual.

Radiologic findings

Radiologic examinations are neither required nor recommended as part of an evaluation at the time of initial diagnosis or during routine follow-up. Computed tomography (CT) scans or chest films will often reveal adenopathy not detected on examination, but these findings do not change the clinical Rai or Binet stage. Unless there is a specific clinical question brought up by a new symptom or complaint, we recommend not doing these procedures. The American Society of Hematology embarked on the “Choosing Wisely” campaign to advocate clinical staging and blood monitoring in asymptomatic patients with early-stage CLL rather than performing CT scans. In the setting of a therapeutic research protocol, imaging may be obtained for specific protocol-related purposes.

Laboratory abnormalities

Although the absolute blood lymphocyte threshold for diagnosing CLL was placed at $5 \times 10^9/\text{L}$, most patients present with considerably higher counts, occasionally even in the hundred-thousand range. Upon examination of a peripheral blood smear, mature-appearing small lymphocytes may be preponderant in the

population of leukocytes, ranging from 50% to as much as 100%.

In addition to an increased ratio of mature-appearing lymphocytes in the smears of aspirated marrows, three patterns of infiltration by lymphocytes are recognized in trephine biopsy specimens of the bone marrow ([Figure 3](#)): nodular, interstitial, and diffuse. It has been observed that patients with diffuse infiltration tend to have advanced disease and worse outlook. For prognostic purposes, nodular and interstitial patterns, which are associated with less-advanced disease and better prognosis, are grouped together and termed “nondiffuse.”^{24–26}

Figure 3 Chronic lymphocytic leukemia (CLL). Marrow biopsy with diffuse infiltration by CLL cells (hematoxylin and eosin stain; ×600 original magnification).

Asymptomatic anemia and thrombocytopenia may be observed at the time of initial diagnosis, but usually these are of a relatively mild degree. A direct antiglobulin (Coombs) test may be positive in ~25% of cases, but overt autoimmune hemolytic anemia occurs less frequently. In the absence of a reliable test to demonstrate antiplatelet antibodies, autoimmune thrombocytopenia is most often diagnosed on the basis of the presence of adequate numbers of megakaryocytes in the bone marrow with abnormally low platelet counts.

Hypogammaglobulinemia may be present at the time of initial diagnosis, but it becomes clinically significant only later in the course of the disease. All three immunoglobulin classes (IgG, IgA, and IgM) are usually decreased, although in some patients only one or two classes may be reduced. Concurrent hypogammaglobulinemia and neutropenia result in increased vulnerability of CLL patients to severe bacterial, viral, and opportunistic infections. As a large proportion of cells are B lymphocytes, the normal lymphocyte T : B ratio (2 : 1) is altered. As patients are not immunocompetent, they should avoid inoculation of any live vaccines (varicella, measles, Bacille Calmette-Guérin, etc.). In this immunocompromised population, replication of the virus after administration can be enhanced and live vaccines can actually induce active infection.^{27, 28}

No abnormalities in blood chemistry are characteristic of CLL, but increased levels of serum lactate dehydrogenase, uric acid, hepatic enzymes [alanine aminotransferase (ALT) or aspartate aminotransferase (AST)], and (rarely) calcium may be observed. Pseudohyperkalemia can occur occasionally in patients with extreme leukocytosis.

Natural history and terminal events

It is a generally held belief that CLL is an indolent disease with a prolonged chronic course and that the eventual cause of death may be comorbidities unrelated to CLL; however, this observation is true for fewer than 30% of all CLL cases. The natural history is heterogeneous in most patients. Many patients live for 5–10 years with an initial course that is relatively benign but that is almost always followed by a terminal phase lasting 1–2 years. During the initial asymptomatic phase, the patients are able to maintain their usual lifestyle, but during the terminal phase, performance status declines rapidly. In patients with progressive disease, the cause(s) of death are directly related to CLL or complications from therapy. Infection is a major cause of mortality in patients with CLL, accounting for 30–50% of all deaths.

Transformations to a high-grade disease are characteristically refractory to usual chemotherapeutic agents.²⁹ In up to ~10% of CLL patients, a transformation to a diffuse large B-cell lymphoma occurs³⁰ (“Richter's transformation” or “Richter's syndrome”; [Figure 4](#)). Richter's syndrome is associated with a rapidly progressive course, refractoriness to all currently known chemotherapy, and poor overall survival (OS).^{31, 32} The diagnosis of Richter's syndrome requires histopathologic examination of a lymph node that shows large B cells with high proliferative rate (high Ki-67). In addition, a small proportion of patients with CLL undergo “prolymphocytoid transformation,” and peripheral blood morphology reveals the presence of a mixture of small mature CLL cells and prolymphocytes in contrast to typical B-PLL (B-prolymphocytic leukemia) where the circulating cells are monomorphic prolymphocytes.³³ Similar to a Richter's transformation, prolymphocytoid transformation has an aggressive clinical course.

Figure 4 Chronic lymphocytic leukemia, Richter's syndrome. Section of lymph node with immunoblastic proliferation consisting of large cells with prominent nucleoli (hematoxylin and eosin stain; ×600 original magnification).

Acute leukemia is observed extremely rarely in the setting of a CLL diagnosis. If it occurs, it is usually myeloid in origin (myelocytic, myelomonocytic, or acute erythroleukemia). Prior therapy with alkylating agents has not been clearly implicated as a cause because a few cases have been observed in treatment-naïve patients. The acute leukemia is treated with an acute leukemia regimen, although almost invariably the outcomes are very poor.

Patients with CLL have been found to have over twice the risk of developing another cancer compared to

the general population.³¹ Skin cancers and other malignancies occur with considerably greater frequency among CLL patients. We recommend that all CLL patients (including treatment-naïve) adhere to age-appropriate cancer screening guidelines.

Clinical staging and other prognostic features

Two staging criteria, the Rai³⁴ system and the Binet³⁸ system, are widely used in clinical practice owing to their simplicity (only a physical examination and a complete blood count are needed) and accuracy in predicting outcomes.

Method of Rai and colleagues

The Rai system is based on the concept that in CLL, a gradual and progressive increase in the tumor burden of leukemic lymphocytes occurs, resulting in sequential clinical manifestations of the disease. The abnormalities start in the blood followed by the lymph nodes, spleen, and liver; to eventually compromise the bone marrow function. The earliest stage is blood lymphocytosis (clinical stage 0). The later stages (anemia and thrombocytopenia—excluding AIHA and ITP) are explained by progressively increasing bone marrow infiltration by CLL cells.

At the time of initial diagnosis of CLL, approximately 25% of patients are in the earliest clinical stage (stage 0), ~25% are in the advanced stages (stages III and IV), with the remaining 50% in the stage I or II categories. [Table 4](#) shows the stage distributions from various series, revealing a consistent pattern. The median survival times from the time of diagnosis in the Rai series were 150 months for stage 0, 101 months for stage I, 71 months for stage II, 19 months for stage III, and 19 months for stage IV.³⁴ Although Rai and colleagues noted in their 1975 paper that only three (and not five) distinct actuarial survival patterns emerged from the data (stage 0, stages I and II combined, and stages III and IV combined), they recommended that the five-stage system be maintained to investigate prospectively whether biologic and clinical differences would emerge between stages I and II and between stages III and IV. In 1987, the Rai staging system was modified to consist of three groups: low (Rai stage 0), intermediate (Rai stages I and II combined), and high (Rai stages III and IV combined) risk categories.³⁹ The modified Rai staging system was used for risk stratifying patients in the landmark study of chlorambucil against fludarabine in the front-line therapy of CLL conducted in the 1990s that established the superiority of fludarabine.⁴⁰ Fludarabine and purine analogs are now part of the combination regimens for frontline therapy in fit patients with no major comorbidities.^{41, 42}

^a The hemoglobin level for stage III in Medical Research Council of Great Britain Chronic Lymphocytic Leukemia Trial I was <110 g/L.

Method of Binet and colleagues

Binet's method classifies all patients with anemia (defined as hemoglobin below 100 g/L) and/or thrombocytopenia (platelets less than $100 \times 10^9/L$), or both, as stage C.³⁸ All of the remaining (non-C) patients are divided into two groups, depending on the presence of fewer than three (stage A) or three or more (stage B) sites of palpable enlargement of lymphoid organs. This staging takes into consideration five sites: cervical, axillary, and inguinal lymph nodes (whether unilateral or bilateral, each area is counted as one), and the spleen and liver. This system has been found to be of great value in dividing patients into three types of survival curves, with A, B, and C corresponding, respectively, to Rai's low-, intermediate-, and high-risk groups.

Criteria predictive of disease course in the low- and intermediate-risk groups

Virtually, all high-risk group patients (stages III and IV) have a relatively rapid clinical course with an expected shorter survival. The course of disease is not uniform in the other categories. Patients in the low- and intermediate-risk groups (stage 0 and stages I and II, respectively) may have a benign clinical course in which the disease remains indolent and is associated with a long OS measurable in years or even decades. On the other hand, the disease in patients in the low-and intermediate-risk groups may also progress rapidly with relatively short survival times. Major prognostic markers of considerable importance to stratify risk in this heterogeneous disease include chromosomal aberrations, *IGHV* mutation status, CD38, and Zap-70 expression (Table 5). Additional prognostic factors that have been tested and found to be useful in predicting the course of disease include age, gender, comorbidities, complex chromosomal karyotype,⁴³ genetic mutations,⁴⁴ and β -2-microglobulin, among others.

Table 5 Molecular and cytogenetic markers of prognosis in CLL

	Markers of	
	Good prognosis	Worse prognosis
<i>IGHV</i> mutation status	Mutated	Unmutated
<i>ZAP-70</i>	Negative	Positive
CD38	Negative	Positive
FISH cytogenetics	13q del	11q del, 17p del

Major prognostic markers

IGHV gene mutation

Two main subgroups of CLL are recognized based on the presence or absence of mutations in the *IGHV* gene that is expressed by leukemic B cells.⁴⁵ Patients with *IGHV*-mutated genes tend to have a milder form of the disease, better progression free, and OS.^{46, 47} This may be explained in part by the fact that B-cell receptors (BCRs) of unmutated CLL cases transduce stimulatory downstream signals with greater capacity than those of mutated cells.^{1, 48} Patients with or without *IGHV* mutations may be further subclassified based on other significant findings, such as the presence or absence of mutations in TP53,⁴⁹ NOTCH1,⁵⁰ SF3B1,⁴⁴ ZAP-70 expression,⁵¹ and CD38,⁴⁶ all of which have been shown to have an

impact on the clinical course of the disease.

Cytogenetics

Cytogenetic analysis of CLL used to be limited because of an inability to induce metaphases in the leukemic cells with conventional banding techniques. Using interphase fluorescence *in situ* hybridization (FISH) technique, chromosomal aberrations can be detected in 82% of cases.⁵² A seminal study by Döhner and colleagues found the following common lesions and frequencies in CLL patients: deletion in 13q14 (55%), deletion in 11q (18%), trisomy of 12q (16%), deletion in 17p (7%), and deletion in 6q in 7%. In the same study, normal karyotypes were present in 18% of patients. Among the abnormalities, del(13q), del(11q), and del(17q) were considered to have the greatest significance. Deletion in 13q correlates with the best median OS at 133 months. Patients with deletion of either 11q or 17p have the poorest prognosis with a median OS of 79 and 32 months, respectively. Loss of 11q and 17p are believed to involve alteration of the gene encoding for the ataxia-telangiectasia mutation, and inactivation of the tumor suppressor gene p53, respectively. These high-risk lesions were found to be associated with aggressive disease and resistance to chemotherapy.^{53, 54} Patients with normal karyotypes and patients with trisomy 12 have similar survival times of 111 and 114 months, respectively.

Zap-70 expression

Zap-70 is an intracellular protein involved in activation signaling normally present in T lymphocytes and natural killer cells (not in normal B lymphocytes).⁵⁵ Although ZAP-70 testing can be obtained by flow cytometry, the methodology and reproducibility of these tests have yet to be standardized across centers. Studies demonstrated that its aberrant expression in leukemic B lymphocytes correlates with U-CLL.^{51, 56} Data show that Zap-70 positivity in CLL as an independent predictor of disease progression and inferior clinical outcome.^{55, 57} ZAP-70 expression is superior to mutation status in predicting time to treatment.^{58, 59}

Molecular genetics

A range of genetic mutations has been found to have prognostic implications in CLL. Somatic mutations in the tumor suppressor gene TP53 are one of the most frequent alterations in several human cancers. This mutation is known to be associated with poor prognosis. The German CLL Study Group (GCLLSG) found that 8.5% of previously untreated CLL patients had the p53 mutation, and some of these even in the absence of a 17p deletion.⁴⁹ Patients with a p53 mutation have a poor prognosis regardless of whether 17p is deleted, and its presence is associated with poor response to therapy, short progression-free survival (PFS) and OS. Moreover, in a multivariate analysis, TP53 mutations analysis provided prognostic value beyond the recognized adverse genetic factors mentioned earlier in this chapter.⁶⁰

Additional mutations with prognostic significance in CLL include those in NOTCH 1⁶¹ and SF3B1⁴⁴ genes. Detailed findings regarding these abnormalities have led some experts to propose the development of a risk algorithm that would incorporate prognostic information regarding gene mutations, chromosomal abnormalities, and changes that take place during clonal evolution in CLL.^{62, 63}

Treatment

Although early intervention is considered crucial in most malignant diseases, this is not the case in CLL. The lack of evidence that CLL can be cured with currently available modalities⁶⁴ has resulted in a “watch

and wait” approach for most patients; that is, follow-up approximately every 3–4 months (sooner if there are indications of aggressive disease) with a history, physical exam, and complete blood counts.

The availability of therapeutic agents with significant activity in CLL—namely, purine analogs, monoclonal antibodies, and the most recent introduction of small molecules that target the BCR signaling pathway into our armamentarium—may change the treatment landscape in the future if ongoing early intervention trials demonstrate improved outcomes in asymptomatic high-risk disease. Currently, this approach is not recommended outside of a clinical trial.

Treatment options available for frontline and salvage therapy in CLL are given in [Tables 6](#) and [7](#), respectively.

WCLL guidelines to initiate therapy

1. Rai stage I or II (Binet stage B) with disease-related symptoms
2. Rai stage III or IV (Binet Stage C)
3. Massive or rapidly enlarging, symptomatic lymphadenopathy, or splenomegaly
4. Lymphocyte doubling time of <6 months
5. AIHA or thrombocytopenia (or both) that is poorly responsive to corticosteroid therapy.

Enlarging lymph nodes and/or rapid lymphocyte doubling should be assessed cautiously given that such events can be transient. No data exist establishing a particular threshold of lymphocyte count that warrants treatment. Anecdotal evidence suggests that hyperleukocytosis may potentially lead to hyperviscosity symptoms in a minority of patients; thus, therapy may be considered in selected patients at risk.

Goals of therapy

Choosing the optimal treatment for an individual patient depends on the age, functional status, and genetic aberrations. Traditionally, treatment of CLL continued until symptoms resolved or troubling lymphadenopathy was controlled. With the advent of the anti-CD20 monoclonal antibody (mAb), rituximab (and its addition to a chemotherapy backbone), came the observation that minimal residual disease-negative (MRD-negative) complete responses improved PFS and OS;⁶⁵ therefore, criteria to define complete remission (CR) and MRD negativity were developed.¹¹

Nevertheless, creating a clear algorithm for CLL treatment is difficult because of the heterogeneity of the disease and the prevalence of comorbidities in the CLL population. Although a CR and MRD negativity may be desirable endpoints, in some cases, these are not appropriate goals owing to toxicities. Clinicians must match the profiles of the patient to one of the available therapies and set a realistic therapeutic goal.

The introduction of small molecules that target BCR signaling and the microenvironment required a recent update of the previously established response criteria in order to incorporate the “redistribution phenomenon” seen with these novel agents.⁶⁶ BCR inhibitors exert their effects by mobilizing CLL cells from the bone marrow and the lymph nodes into the peripheral blood with a resulting lymphocytosis that may be mistaken for progression of disease (PD) or lack of response.

Response criteria to treatment

A CR requires the absence of symptoms attributable to CLL, normal findings on physical examination, a lymphocyte count below $4 \times 10^9/\text{L}$, neutrophils at $1.5 \times 10^9/\text{L}$ or higher, platelets greater than or equal to $100 \times 10^9/\text{L}$, and hemoglobin level of 110 g/L or higher. Normalization of serum immunoglobulin levels is not a requirement for complete response. For patients on clinical trials, bone marrow aspirate and biopsy performed at least 2 months after the last treatment should demonstrate a normocellular marrow with

lymphocytes making up <30% of nucleated cells for classification of CR. Patients with persistent CLL in the bone marrow are defined as having a partial response (PR). Patients with lymphoid nodules found in the marrow following treatment are categorized as nodular PR. The guidelines recommend that these nodules be further characterized by immunohistochemistry staining to determine if these are CLL cells. Those patients without evidence of CLL but persistent cytopenias after treatment should be considered to be in a CR with incomplete bone marrow recovery (CRi).

Other criteria for strict PR were defined as a reduction in previously elevated lymphocyte counts, enlarged nodes, spleen, or liver by 50% or more. Peripheral blood should also show one of the following: a neutrophil count of 1.5×10^9 /or higher, a platelet count of 100×10^9 /L or higher, or a hemoglobin level of 110 g/L or higher (or a 50% or better improvement over pretherapy deficits in these counts). These responses must persist for a minimum period of 2 months.¹¹

The new concept of “partial response with lymphocytosis” (PRL) require that all PR criteria are met except for the blood lymphocyte count. In the absence of other objective evidence of PD, lymphocytosis alone should not be considered an indicator of PD. Patients with lymphocytosis and no other evidence of PD should continue therapy until they develop definitive signs of PD.⁶⁶

MRD eradication refers to the complete eradication of leukemic cells by either four-color flow cytometry or by allele-specific oligonucleotide PCR. This determination must be made at least 3 months after the completion of therapy in the setting of a clinical trial only.¹¹ While absence of MRD may indicate a more favorable prognosis in the setting of chemoimmunotherapy, its value as a therapeutic goal remains unclear at this time.

Chlorambucil monotherapy

Despite evidence that chlorambucil monotherapy is associated with lower response rates and shorter remission durations compared to other available agents, chlorambucil remains a widely used agent in frail and older patients given its ease of use and tolerability. Great variability in the dose and schedule of chlorambucil has been observed.^{67, 68} A CALGB study revealed that chlorambucil is equally effective when given daily or on an intermittent basis.⁶⁹ Chlorambucil is usually administered for a period of several weeks until maximum clinical response is reached. Maintenance therapy is uncommon. Recent data seem to suggest combination with a monoclonal antibody targeting CD20 may obtain better results in terms of efficacy with excellent tolerability. The role of monotherapy may change the next few years.

Corticosteroids

Prednisone had been administered to CLL patients in the past as a single agent, usually in an initial dose of 20–60 mg, with dose reductions occurring in a stepwise manner.^{67, 70} Often, in the first 1–2 months, an increase in the lymphocyte count was followed by a subsequent decline, caused by a shift of lymphocytes from lymph nodes and bone marrow into the blood. Anemia and thrombocytopenia improved in approximately two-thirds of patients. The major side effects were those of chronic corticosteroid therapy and infections. Currently, the major indication for prednisone is for the management of antibody-mediated anemia and thrombocytopenia.

Fludarabine–cyclophosphamide–rituximab (FCR)

FCR remains the standard of care for upfront treatment of medically fit CLL patients. A landmark study done as a single-arm study successfully treated 224 previously untreated patients with fludarabine,

cyclophosphamide, and rituximab (FCR).^{40, 71} The overall response rate (ORR) was 95% with 72% of these patients achieving CR and many achieving MRD negativity. A substantial number of patients remain free of disease more than a decade later. Grades 3–4 neutropenia occurred in over 50%.

A well-designed, phase III trial of 817 previously untreated patients by the GCLLSG evaluated the benefit of adding rituximab to FC establishing FCR's superiority.⁴¹ At a median of 47 months follow-up, a superior PFS was maintained in patients receiving FCR compared with FC (57.9 vs 32.9 months, respectively; $P < 0.001$).⁷² The FCR arm had a greater incidence of neutropenia but not of grade 3 or 4 infections. FCR as well as other purine analog-alkylator-rituximab regimens should all be given with antibiotic prophylaxis against *Pneumocystis*, varicella, and *Candida*. Most recently, FCR was compared with a less toxic regimen (bendamustine and rituximab, BR) but the comparator arm failed to outperform FCR (see section titled “Bendamustine”). A large ongoing US intergroup trial (E1912) is currently accruing patients to evaluate FCR against ibrutinib in combination with rituximab in frontline young CLL patients with no 17p deletion. The primary endpoint of this study is to establish PFS and change in quality of life between the arms.

Bendamustine

The FDA-approved bendamustine in 2008 based on a randomized trial comparing it to chlorambucil in previously untreated CLL patients.⁷³ Bendamustine, given at a dose of 100 mg/m² IV for 2 days every 4 weeks, was found to be superior to chlorambucil in ORR and PFS. Given bendamustine's efficacy and tolerability when combined with rituximab in frontline and relapsed CLL patients,^{74, 75} the regimen emerged as an attractive approach to improve the early and late toxicities observed with FCR.

The phase III CLL10 trial tested frontline BR compared to FCR in fit patients except 17p deletion patients. Although the ORR was identical in both treatment arms (97.8%), CR was greater in FCR-treated patients and correlated with longer PFS. No difference in OS was observed. Patients receiving FCR experienced significantly greater rates of grade 3/4 adverse events including severe neutropenia, myelosuppression, and infections compared with patients receiving BR. Given the milder toxicity profile of BR, this combination may have a role in the upfront treatment of medically unfit CLL patients.⁷⁶

Ofatumumab

Ofatumumab is a fully human IgG1 anti-CD20 mAb created from transgenic mice that binds a different epitope on CD20 compared with rituximab. It is a type I mAb that has demonstrated greater complement-dependent cytotoxicity in CLL cell lines when compared with rituximab and it is approved as monotherapy for relapsed CLL.^{77, 78} Ofatumumab has been recently approved for frontline therapy in combination with chlorambucil.⁷⁹

Obinutuzumab

Obinutuzumab is a humanized mAb targeting CD20 indicated in combination with chlorambucil for the treatment of previously untreated patients with CLL. Previously untreated patients with CLL were randomized to receive chlorambucil against chlorambucil plus rituximab against chlorambucil plus obinutuzumab.⁸⁰ Goede and colleagues found that, in patients with multiple debilitating coexisting conditions (median age, 73 years), the combination of obinutuzumab with chlorambucil was associated with a significant and clinically meaningful prolongation of PFS, increased CR, and an increased rate of MRD negativity, as compared with the results with a combination of rituximab and chlorambucil. Moreover, treatment with obinutuzumab plus chlorambucil resulted in a significant OS benefit as

compared with chlorambucil alone suggesting that the induction of deeper remissions could translate into a survival advantage even in frail patients. Combination studies of this drug with the novel BCR inhibitors are planned.

Ibrutinib

Ibrutinib is an orally bioavailable, small-molecule, irreversible inhibitor of Bruton's tyrosine kinase that has been shown to induce rapid lymph node responses in patients with CLL. As with other kinase inhibitors developed to treat patients with CLL, ibrutinib inhibits several signaling pathways, including BCR, Toll-like receptors, BAFF, and CD40, as well as interfering with the protective effect of stromal cells.³ In an early phase Ib/II clinical trial, treatment with ibrutinib as monotherapy for patients with relapsed/refractory CLL resulted in a high ORR of 71% and durable remissions (estimated PFS at 26 months: 75%) for all groups of patients tested, including elderly patients and those with high-risk disease.⁸¹ Three-year follow-up indicated long-lasting response to ibrutinib.⁸² In the phase III RESONATE trial, ibrutinib was compared with ofatumumab in patients with relapsed/refractory CLL/SLL.⁸³ The ORRs were 4.1% and 42.6% in patients receiving ofatumumab and ibrutinib, respectively. Outcomes were independent of 17p status and were seen even in patients refractory to purine analogues. Minimal toxicities were reported.

In the largest prospective trial dedicated to the study of del (17p), ibrutinib demonstrated marked efficacy in terms of ORR and PFS, with a favorable risk-benefit profile.⁸⁴ At a median follow up of 13 months, 79.3% of patients remained progression-free at 12 months, consistent with efficacy observed in earlier studies.⁸¹ The PFS in this previously treated population compares favorably to that of treatment-naïve del 17p CLL patients receiving FCR⁴² with a median PFS of 11 months. These results support ibrutinib as an effective therapy for patients with deletion 17p CLL/SLL.

Idelalisib

Idelalisib is a targeted, highly selective oral inhibitor of phosphoinositide 3-kinase delta, an isoform with selective leukocyte expression that promotes the survival and proliferation of malignant B cells. A randomized, double-blind, placebo-controlled phase III trial of rituximab with or without idelalisib in patients was stopped early following recommendations by an independent data and safety monitoring committee with ORR of 81% versus 13% in patients receiving idelalisib plus rituximab compared with placebo rituximab, respectively.^{85, 86} Subpopulation analysis indicated idelalisib plus rituximab was effective for patients regardless of the presence of 17p, TP53, or *IGHV* mutational status.⁸⁷ Combination idelalisib and rituximab also has shown clinical activity in frontline therapy in a small cohort of patients that participated in a phase II trial, including patients with 17p deletion.⁸⁸

Venetoclax

Members of the B-cell lymphoma-2 (BCL-2) protein family are important regulators of intrinsic apoptosis. They are usually overexpressed in CLL cells and contribute to tumor cell survival and drug resistance. Venetoclax is the first-in-class selective and potent inhibitor of BCL2. The drug was recently approved by the US FDA as it induces rapid reduction in CLL disease burden in the blood, lymph nodes, and bone marrow, resulting in a high overall response, including CLL patients with relapsed del(17p). Venetoclax (in combination with rituximab) is currently undergoing evaluation for approval in all patients with relapsed or refractory CLL.

Stem cell transplantation

Although hematopoietic stem cell transplantation (HSCT) is the treatment of choice for many aggressive hematologic malignancies, the role of HSCT in CLL has remained controversial. Autologous stem cell transplantation (SCT) has no clear benefit in CLL.⁸⁹ HSCTs should be reserved for very specific cases given the high treatment-related mortality associated with the procedure.

Psychosocial aspects of CLL

A diagnosis of leukemia is a major emotional challenge to patients. Careful explanation of the natural history of the disorder, emphasizing that some patients never need treatment and that early treatment has not been shown to be beneficial, is required at the time of diagnosis. Patients need to be reassured that effective treatments are available when treatment becomes necessary because of progressive disease or symptoms. Knowledge that survival in many early-stage CLL patients is the same as in the age- and gender-matched general population is comforting to patients. Explanation of newer prognostic factors must also be made with care. Favorable markers can reassure that observation is appropriate but many patients have difficulty accepting this initial approach when the markers indicate high risk. Development of a close relationship with patients, particularly those in the early phases of disease, and careful responses to questions raised are important in providing psychological and emotional support to the patient and family. The rapidly increasing range of options for therapy, particularly for younger patients, provides a basis for optimism when treatment becomes necessary.

Unmet needs and future directions

The current goal is to individualize treatment strategies based on the patient's clinical profile when therapy is indicated. As mentioned earlier in this chapter, the exact time to initiate therapy depends on several factors. If the patient has symptoms attributable to CLL, treatment is warranted. The presence of markers of high-risk disease is not an indication for therapy. A gray area exists when no clear symptomatology is present and cytopenias are beginning to manifest. If the patient prefers, it is reasonable to continue observation revisiting the issue before when cytopenias drop to levels of concern.

A purine analog-based regimen such as FCR is still the standard of care in frontline management of young fit CLL patients with no comorbidities. In patients with Coombs positivity or a history of AIHA, avoiding a purine analog may be preferable. For older frail patients with comorbidities who do not carry a 17p deletion, strong consideration should be given to frontline therapy with obinutuzumab plus chlorambucil, BR, ofatumumab and chlorambucil, or ibrutinib; unless a confounding condition exists prohibiting the use of any of these regimens.

There is much expectation that the novel targeted therapies alone or in combination with cytotoxic chemotherapy will impact the clinical outcome of patients with CLL. This is the reason for ongoing large phase III trials comparing frontline chemoimmunotherapy regimens against targeted agents with the potential to change the current standard of care. It is possible that in the future, several patients (including young fit patients) may be treated with relatively nontoxic regimens that do not contain cytotoxic chemotherapy agents. It is also conceivable that the incorporation of the novel targeted agents into chemoimmunotherapy regimens in the frontline may generate deeper responses and longer remissions without increases in toxicity.

The most challenging treatment decision is for patients with symptomatic treatment-naïve CLL patients

with a deletion 17p. There is no clear consensus among experts as to the best therapy for this group of patients. Cytotoxic chemotherapy regimens are much less effective with suboptimal responses in spite of the addition of monoclonal antibodies. There is encouraging phase I–II data in small cohorts of 17p deletion patients treated with ibrutinib as monotherapy or in combination with rituximab,^{90–92} and as such ibrutinib should be definitely considered. Ibrutinib and venetoclax are the only agents approved in the United States for treatment of patients that carry a deletion in chromosome 17. If unable to tolerate ibrutinib or venetoclax, a reasonable choice of therapy would be idelalisib as it has demonstrated clinical activity in 17p deletion patients.^{87, 88} It is important to mention that stem cell transplant evaluation should be discussed with young fit patients with high-risk disease (17p deletion, failure after a novel targeted agent, short PFS after initial therapy).

Nevertheless, the goals and duration of therapy for CLL are poorly defined. High CR rates with chemoimmunotherapy regimens, as well as the attainability of MRD negativity, had been promising advancements a decade ago, but long-term benefit of these successes remains unproven in patients using a BCR inhibitor. Therefore, MRD negativity should be regarded as a treatment goal only in the setting of a clinical trial.

The recent advances achieved over the past few years—that is, the development of inhibitors of B-cell signal transduction, immunomodulators of the CLL microenvironment, and glycoengineered monoclonal antibodies—have been a breakthrough revolution.⁹³ The era of targeted therapy in CLL has categorically arrived and we anticipate that progress will continue. We hope that novel therapies and new treatment paradigms will transform the way we manage CLL today.

Chapter 118

Hodgkin lymphoma

Carol S. Portlock, MD ■ Anita Kumar, MD ■ James Armitage, MD

Overview

This chapter provides a historical perspective on the marked advances in radiotherapy and chemotherapy that have contributed to significant improvements in the curability of Hodgkin lymphoma (HL) over the past several decades. The classic features and new insights into the epidemiology, biology, and pathologic characteristics of HL are described. With emphasis on the modern clinical approach to the staging, imaging, and treatment of HL, the chapter highlights how current management approaches, such as refined risk stratification, use of PET imaging, and the reduction of radiation field and dose, seek to limit long-term toxicities of therapy while maintaining excellent cure rates. Finally, the authors describe how the development of novel, biologically targeted therapies has contributed to significant changes in the therapeutic landscape for patients with relapsed, refractory HL.

Introduction

Classical Hodgkin lymphoma, cHL, is now potentially curable in at least 80% of patients. Well-defined diagnostic criteria, prognostic factors, improved imaging, emphasis on systemic therapy first, and selective limited field radiotherapy consolidation have all contributed to this outcome. An increased appreciation of curability/quality of survivorship has now added the important goal of reducing the intensity of initial treatment when possible, without compromising cure rates; and, such changes in chemotherapy and radiation dose/field have resulted in reduction of long-term toxicities such as infertility, cardiopulmonary toxicity, and secondary malignancy.

History

In his historic paper of 1832, “On Some Morbid Appearances of the Exorbant Glands and Spleen,” Thomas Hodgkin described the clinical history and postmortem findings of massive lymph node and spleen enlargement in patients studied at Guy's Hospital, London.¹ Hodgkin recognized that these patients had suffered from a disease that started in the lymph nodes located along the major vessels in the neck, chest, or abdomen. Sir Samuel Wilks, and later W.S. Greenfield described the microscopic lymph node appearance. Carl Sternberg, in 1898 and Dorothy Reed, in 1902, are credited with the first definitive microscopic descriptions of Hodgkin lymphoma.^{2,3} The early treatment of Hodgkin lymphoma with crude X-rays in 1901 followed the discovery of radiographs by Roentgen, radioactivity by Becquerel, and radium by the Curies at the end of the nineteenth century. Before this time, serum and other biologic preparations, arsenic, iodine, and surgery were ineffective in cHL. These first reports of successful X-ray radiograph treatments produced great excitement and premature predictions for the curability of Hodgkin lymphoma.^{4,5}

Modern radiation therapy (RT) techniques began in the 1920s with the work of Gilbert, who was one of the first to point out the predictable clinical patterns of cHL. He advocated treatment of apparently uninvolved adjacent lymph node chains that might contain suspected microscopic disease in addition to the involved nodal sites.⁶ In 1950, Vera Peters extended this approach, reporting 5- and 10-year survivals of 88% and 79%, respectively, for patients with stage I.⁷ However, the concept that early-stage Hodgkin lymphoma might be curable with RT was slow to be accepted. Henry Kaplan developed the linear accelerator and successfully applied this technology to curing cHL. He defined radiation field sizes and doses, refined and improved diagnostic staging techniques, developed models for translating laboratory findings into clinical practice, and, with Saul Rosenberg, promoted early randomized clinical trials in the United States.^{8–10}

Advanced-stage cHL was uniformly fatal until the development of combination chemotherapy. Mechlorethamine was shown to be an active drug in the 1940s, and in the mid-1960s Vincent DeVita and colleagues first treated patients with an effective four-drug regimen termed MOPP (mechlorethamine, vincristine, procarbazine, and prednisone).¹¹ MOPP provided a high rate of complete remission and prolonged survival, resulting in curative outcomes.¹²

Like radiotherapy, randomized trials were also pivotal to the development of combination chemotherapy. These studies demonstrated no benefit of maintenance chemotherapy, established that treatment durations could be relatively short, and, ultimately, showed that ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) was associated with reduced toxicity and similar efficacy compared to MOPP (or MOPP-containing regimens), thus confirming ABVD as the standard regimen.^{13, 14}

Epidemiology and etiology

In 2014, there were expected to be 9190 new cases of cHL in the United States. The incidence is 2.7 per 100,000 per year and has remained relatively constant for decades. In the United States, the median age for all new cases is 39 years with 31% occurring between the ages of 20 and 34. Somewhat more men than women (3.1 to 2.4 per 100,000) develop HL.¹⁵ Although a bimodal distribution was previously apparent in economically developed countries, the second peak is less apparent but persistent, as better pathology classification has found many of these cases to be non-Hodgkin lymphomas.

The etiology of Hodgkin lymphoma remains unknown. Epidemiologic data suggests both infectious and genetic components.^{16, 17} A viral etiology is suggested by an association between cHL in younger patients and childhood factors that decrease exposure to infectious agents at an early age, including increased maternal education, decreased numbers of siblings and playmates, early birth order, and single-family dwellings in childhood for economically developed countries.^{18, 19} This association has led to the proposal that cHL appears to mimic a viral illness that has an age-related host response to infection (such as seen with polio and infectious mononucleosis). Supporting this theory is the infrequent occurrence of cHL in children younger than 10 years in economically developed countries.

Epstein–Barr virus (EBV) is the leading viral candidate.^{16, 20, 21} EBV is the causative agent in African Burkitt lymphoma, and EBV-associated lymphomas are documented in patients with immune deficiency disorders and following organ transplantation. There is a two- to threefold excess in the incidence of cHL among patients with a prior history of mononucleosis. In addition, there is an altered antibody response pattern to EBV in patients who later develop cHL.

Recent cellular and molecular biology data have provided additional support for the association of EBV and cHL. Through the use of sensitive molecular probes, 30–50% of Hodgkin lymphoma specimens have

been found to contain EBV genome fragments in the diagnostic Reed–Sternberg (R–S) cells.²² EBV genome status appears to be stable over time when studied in initial biopsies and at relapse. EBV genome-positive R–S cells express the so-called type II latency profile, with expression of latent membrane protein (LMP)-1, LMP-2a, EBNA-1, and EBV-encoded ribonucleic acid (EBER). LMP-1 is critical in transformation and acts as an oncogene in transfection studies, whereas EBNA-1 is essential for the replication of the episomal viral genome.

A genetic predisposition is evident with increased incidence among first-degree relatives, in some sibling studies, in monozygotic twins, and among parent–child pairs but not among spouses. In addition, cHL has been linked with certain human leukocyte antigens (HLAs) that are associated with EBV status; and genome-wide association studies have identified, but not proven, non-HLA susceptibility genes.¹⁷

Immunologic abnormalities in patients

cHL is characterized by functional deficits in cellular immunity and in T-cell-mediated immune responses that exist before treatment. These deficits persist in cured patients²³ and include impairment of delayed cutaneous hypersensitivity, depressed proliferative responses to T-cell mitogen stimulation, enhanced immunoglobulin production, and decreased natural killer cell cytotoxicity. These abnormalities suggest an immunosuppression secondary to chronic overstimulation by cytokines. In patients with active cHL, these findings are consistent with increased cytokine secretion by R–S cells. However, it has been difficult to explain the persistence of these abnormalities in patients after successful treatment.

Treatment-induced immunosuppression returns toward normal after treatment, but has its greatest effect over the first few years.²³ For example, there is an excess of herpes zoster infections, and more than 75% of such cases occur within the first year. Few occur after the third year (6%). The risk of H. zoster appears highest as the intensity of therapy increases.²⁴

Unlike the deficits in delayed hypersensitivity, most patients with cHL at diagnosis appear to have relatively normal B-cell number and function which may be adversely affected by treatment.²³ Patients should be encouraged to keep vaccinations up to date.

Pathology

Hodgkin lymphoma is unique among lymphomas for its histologic diversity.²⁵ Involved lymph nodes contain varying degrees of normal reactive and inflammatory cells, fibrosis, and a scattering of the characteristic malignant cHL cells, the R–S cells, and their mononuclear variants. The typical R–S cell has abundant cytoplasm and 2–3 nuclei, each with a single prominent nucleolus. The large size and unusual appearance of the R–S cell sets it apart from the adjacent smaller background cells. The mononuclear variants have nuclear and cytoplasmic features of R–S cells, but have only a single nucleus. Although the diagnosis of cHL should rarely be made in the absence of R–S cells, the presence of these cells alone is not sufficient to make the diagnosis. R–S-like cells have been found in infectious mononucleosis, non-Hodgkin lymphoma, and in some carcinomas and sarcomas. Thus, criteria for a cHL diagnosis include the presence of the R–S cells and the characteristic background of normal lymphocytes, plasma cells, and eosinophils.

The current pathology classification includes cHL: nodular sclerosis (NSHL), mixed cellularity (MCHL), lymphocyte-rich (LRHL), and lymphocyte depletion (LDHL) subtypes; as well as NLPHL, nodular lymphocyte predominance Hodgkin lymphoma. The subtyping of cHL does not affect clinical management,

prognosis, or therapy. Nevertheless, the histologic subtypes are associated with different presentations, distinct natural histories, and variable prognoses. These differences are most evident in NLPHL.

Hodgkin lymphoma subtypes

Two histologic features of NSHL help to differentiate this cHL subtype: a proliferation of collagenous bands dividing the lymph node into circumscribed nodules and these nodules contain a variant R–S cell called the lacunar cell. In formalin-fixed tissue, this cell's abundant pale cytoplasm often retracts and gives the appearance of a cell in space ([Figures 1–3](#)). Molecular profiling studies have shown a close relationship between primary mediastinal large B-cell lymphoma and NSHL, rarely a “gray-zone” neoplasm that combines features of both neoplasms may be identified.^{26–28}

Figure 1 Reed–Sternberg cells and variants in Hodgkin lymphoma of the nodular sclerosis type. Large multinucleated or multilobated cells and a few mononuclear cells with macronucleoli stand apart from cellular background elements.

Figure 2 Hodgkin disease, nodular sclerosis. A fibrous band is present in the left lower part of the field. Neoplastic lacunar cells having abundant, clear cytoplasm stand out against the lymphocytic background.

Figure 3 Immunostain for CD15 in Hodgkin disease, nodular sclerosis type. Neoplastic Reed–Sternberg cells and mononuclear Hodgkin cells show positive immunoreactivity.

NSHL is the only subtype of cHL as common in women as in men. It occurs in adolescents and young adults and is unusual in patients older than 50 years. It has a striking propensity to involve lower cervical, supraclavicular, and mediastinal lymph nodes with an orderly pattern of spread.²⁹ It makes up 60–70% of cHL in economically developed countries, but is less commonly seen in underdeveloped countries.

MCHL has an inflammatory background abundant in normal cells as well as 5–15 R–S cells and variants per high-power field (Figures 4 and 5). These patients are older, more likely to have B symptoms, and often have abdominal involvement or advanced disease. Approximately 25% with cHL in the United States have MCHL, and it is more common in underdeveloped countries. MCHL can be confused with peripheral T-cell lymphoma, and the antigen PAX5 may be particularly helpful, as it is a B-cell marker.

Figure 4 Hodgkin disease, mixed cellularity type. Reed–Sternberg cells in histiocyte-rich cellular background. Inset: Multinucleated Reed–Sternberg cell at higher magnification.

Figure 5 Immunostain for Epstein–Barr virus-latent membrane protein in Hodgkin disease, mixed cellularity type (same biopsy as [Figure 4](#)).

LRHL may resemble other histologic subtypes and may be nodular or diffuse. R–S cells are relatively rare, and the background is dominated by small mature lymphocytes ([Figures 6](#) and [7](#)). Eosinophils and neutrophils are usually restricted to blood vessels.

Figure 6 Lymphocyte-rich classic Hodgkin disease. Reed–Sternberg cells and mononuclear Hodgkin cells are relatively rare within the background proliferation of small lymphocytes and histiocytes.

Figure 7 Lymphocyte-rich classic Hodgkin disease. Binucleated Reed–Sternberg cell in center of field. In same biopsy, Reed–Sternberg cells immunostained positively for CD15 (inset).

LDHL is rarely diagnosed, accounting for less than 1% of cHL in economically advanced countries. Generally, these patients present with advanced disease and B symptoms. R–S cells and “pleomorphic” variant cells are frequent and most cases have only sparse normal lymphocytes.

In NLPHL, the lymph node architecture is usually effaced, although a remnant of normal nodal architecture may remain. Diagnostic R–S cells are not seen, but variant lymphocyte predominance (LP) cells are typical ([Figures 8](#) and [9](#)). These cells often have multilobated nuclei and have been called popcorn cells because of their resemblance to a popped kernel of corn. Fibrosis is not usually seen. The LP or “popcorn” R–S variants occur in a background of polyclonal B lymphocytes ([Figure 9](#)).^{30, 31} LP cells are usually positive for the B-cell marker CD20, but negative for the cHL markers of CD15 and CD 30 ([Figures 10](#) and [11](#)).^{31, 32} EBV is rarely detected in NLPHL.³³ The benign disorder, progressive transformation of germinal centers, is often associated with NLPHL. R–S cells and LP variants are absent

in this entity. Progressive transformation of germinal centers can also be seen in association with NLPHL in the same or an adjacent node.³²

Figure 8 Lymphocyte predominant Hodgkin lymphoma (same biopsy as [Figures 9–11](#)). Immunostain for CD57 reveals a marked increase in immunoreactive cells showing localization around nonimmunoreactive L and H cells within a nodule. The CD3 immunostain showed a similar distribution of immunoreactive cells.

Figure 9 Lymphocyte predominant Hodgkin disease. The vaguely nodular histologic pattern is apparent.

Figure 10 Lymphocyte predominant Hodgkin lymphoma at higher magnification (same biopsy as [Figure 9](#)). Within the background of lymphocytes and histiocytes are scattered large lobated cells having a fine chromatin pattern, relatively small nucleoli, and sparse cytoplasm so-called L and H cells.

Figure 11 Lymphocyte predominant Hodgkin lymphoma (same biopsy as [Figures 9](#) and [10](#)). Immunostain for CD20 demonstrates positive staining of L and H cells as well as a high percentage of lymphocytes within a nodule.

NLPHL makes up 5–10% of all Hodgkin lymphoma in the United States. It is often localized to a single peripheral nodal region (high cervical, submandibular, epitrochlear, inguinal, or femoral nodes) and infrequently involves mediastinal or abdominal sites.

Immunophenotype and biology

The R–S cell is of B-lymphocyte origin.²⁵ These cells may express antigens found on resting or activated lymphocytes, most often B cell: usually positive for PAX5, and infrequently, CD20 or CD79a; and rarely positive for T-cell surface antigens (CD3, CD4, and CD8). The LP cells of NLPHL consistently express B-cell antigens. In cHL, the surface antigens CD30 and CD15 are present on most R–S cells, and nearly

all cases are CD30+, and approximately 80% are CD15+, whereas CD45 (leukocyte common antigen) is usually negative. In contrast, the LP cells of NLPHL are CD15 and CD30 negative and CD45 positive.³³ Microdissection studies of single R–S cells demonstrate clonal immunoglobulin gene rearrangements in the vast majority of cases, confirming the clonality of the cells and establishing their B-cell lineage, despite their aberrant lack of immunoglobulin gene expression.^{34, 35} Moreover, R–S cells possess somatically mutated V genes, implying a germinal center or postgerminal center origin. The mutational pattern suggests that this may account for the lack of immunoglobulin expression. Other possible mechanisms include epigenetic silencing of heavy chain gene transcription or constitutive expression of Notch 1 and STAT 5.²⁵ Normal germinal center B cells that lack functional immunoglobulin receptors are usually eliminated within the germinal center via apoptosis; and therefore, R–S cells appear resistant to this usual apoptotic mechanism. This apoptosis pathway via FAS/CD95 is inhibited by c-FLIP, a gene that is constitutively expressed by R–S cells.³⁶ Several hypotheses have been generated to explain this phenomenon, including activation of the NF-κB pathway, general lineage promiscuity, and Epstein–Barr infection. Evidence favoring the NF-κB pathway includes the observation of constitutive expression of NF-κB in Hodgkin lymphoma-derived cell lines, the finding that suppression of NF-κB impairs tumor growth in severe combined immunodeficient mice and growth of cell lines,³⁷ and an epidemiology study showing that regular aspirin use is associated with a reduced risk of developing Hodgkin lymphoma, presumably through inhibition of NF-κB transcription.³⁸ The cause of the constitutive activation of NF-κB may include amplification of the REL gene, mutations in NF-κB inhibition, and somatic mutations in TNFA1P3.²⁵ LMP-2a expression may substitute for a functional B-cell receptor in EBV-associated cases. Microdissection studies of LP cells also demonstrate clonal immunoglobulin gene rearrangements, again establishing clonality and confirming B-cell lineage.³⁴ In addition to demonstrating somatically mutated V genes, intraclonal sequence diversity can also be detected, providing strong evidence that NLPHL is a germinal center lymphoma. In contrast to cHL, the mutations are compatible with functional antigen receptors.

Cytogenetic abnormalities are common in R–S cells; however, no consistent pattern has been described. Rarely, the t(14 : 18) translocation, common in follicular B-cell lymphomas, may be detected. Comparative genomic hybridization studies demonstrate recurrent gains on chromosomal arms 2p (the site of NF-κB, REL, and BCL1 1a), 9p (the site of JAK2), and 12q (the site of MDM2), and amplifications on chromosomal bands 4p16, 4q23–q24, and 9p23–p24 (associated with high level of PD-L1 protein expression). Recurrent imbalances have been demonstrated in a majority of cHL using genome-wide GeneScan technology.³⁹

The tumor microenvironment has been found to have an important role in the pathogenesis, associated manifestations, and prognosis of Hodgkin lymphoma.^{40, 41} It has been hypothesized that cytokines are responsible for the marked inflammatory component, fibrosis, and diverse histologic patterns of cHL, as well as the associated clinical symptoms of fever, weight loss, and night sweats.^{42–44} Many cases are associated with upregulation of tumor necrosis factor receptor (TNFR) and ligand family members, Th2 and to a lesser extent Th1 cytokines, and other chemokines. Necrosis factor receptor (NFR) members may lead to constitutive activation of NF-κB, an important factor in proliferation and survival of B lymphocytes. Preferential expression of Th2 cytokines and chemokines may explain the frequent presence of eosinophils and fibroblasts, as well as local suppression of the cellular immune response. EBV may contribute to the production of cytokines, for example, via LMP-1-induced activation of NF-κB and stimulation of interleukin (IL)-10, a potent inhibitor of cellular immunity. In some cases, specific cytokines may be associated with specific histologic features. For example, transforming growth factor

(TGF), a known stimulus for fibroblast proliferation and collagen formation, is associated with NSHL,⁴⁵ and TARC (CCL27), a lymphocyte-directed CC chemokine secreted by Hodgkin cells, may be responsible for the infiltration by CD4+ T cells.⁴⁶ Tissue eosinophilia may be due to expression of IL-5, IL-9, CCL11, and CCL28; and IL-13 may play a role in autocrine stimulation of R–S cells.⁴⁷

Staging

Most patients with cHL have a central pattern of lymph node involvement (cervical, mediastinal, and paraaortic) with >80% presenting initially above the diaphragm. In contrast, certain nodal chains (mesenteric, hypogastric, presacral, epitrochlear, and popliteal) are seldom, if ever involved. Spleen involvement is associated with adenopathy below the diaphragm and systemic symptoms. Isolated liver disease is rare; bone and bone marrow involvement is usually focal. Staging has recently been updated with the Lugano classification, incorporating the original Ann Arbor Stage and the later Cotswolds revision ([Table 1](#)).⁴⁸ PET imaging is now recognized as the most accurate means of identifying all sites of cHL involvement, and routine bone marrow biopsy is no longer recommended. See [Table 2](#) for pretreatment evaluation.

Table 1 The Lugano classification.⁴⁸

Stage I	A single lymph node or a group of adjacent nodes. Stage IE: A single extralymphatic site Tonsils, Waldeyer's ring, and spleen are considered nodal tissue
Stage II	Two or more lymph node groups on the same side of the diaphragm Stage IIE: Stage I or II nodal extent and limited contiguous extranodal involvement on the same side of the diaphragm
Stage III	Involvement of nodal tissue on both sides of the diaphragm
Stage IV	Noncontiguous extranodal involvement with or without associated lymph nodes
Designations applicable to any disease stage	
A:	No symptoms
B:	Fever (temperature, >38°C [100.4°F]), drenching night sweats, and unexplained loss of >10% of body weight within the preceding 6 months
X:	Bulky disease (a single nodal mass with a maximal dimension of 10 cm or greater, as measured by CT)

Source: Data from Ref. ⁴⁸.

Table 2 Recommended staging

Adequate biopsy reviewed by an experienced hemopathologist (Surgical excisional biopsy is preferred and core needle biopsy may be sufficient in some cases. Fine needle aspiration is inadequate).
History with attention to the presence or absence of systemic symptoms
Physical examination, emphasizing node chains, size of liver and spleen, and Waldeyer ring inspection
Laboratory tests: complete blood count with differential, erythrocyte sedimentation rate, comprehensive metabolic panel including liver function tests, and HIV, hepatitis B and C serologies.
PET scan Selected CT imaging of neck, chest, abdomen, and pelvis, if required for radiotherapy
No bone marrow biopsy unless PET scan is equivocal and result of biopsy will change treatment Evaluation of ejection fraction for doxorubicin-containing regimens Evaluation of pulmonary function for bleomycin-containing regimens Counseling: fertility preservation

Source: Data from Ref. 48.

Principles of treatment in classical Hodgkin lymphoma

The initial treatment of cHL is determined by stage at presentation and clinical prognostic category. In general, there are three groups with unique treatment considerations: Early stage, favorable risk; Early stage, unfavorable risk; and Advanced stage.

Radiotherapy

In the earliest years, RT alone was used for treatment, and maximal doses/field sizes were applied. Since then, the RT extent has been dramatically reduced. Several randomized studies confirmed that, in the setting of combined modality therapy (CMT, chemotherapy + radiotherapy), replacing the extended radiation fields (mantle/inverted Y) with involved-field radiotherapy was equivalent, with disease control and survival remaining similar.^{49, 50} Consolidative RT could be limited to the initial macroscopically involved volume and radiation doses could be reduced.⁵¹ Such reductions in dose and volume are expected to lessen late RT effects.⁵² Currently, the radiation field can be involved node, INRT (prechemotherapy disease volume with minimal margins requiring excellent prechemotherapy imaging) or involved site, ISRT (initially involved tissue volumes, but requiring more clinical judgment to plan margins, as pretreatment imaging is suboptimal). ISRT has been adopted by many organizations as the standard cHL RT field.⁵³ Both INRT and ISRT are significantly smaller than involved-field RT.

Chemotherapy

The introduction of combination chemotherapy facilitated the reduction of RT dose/field, and chemotherapy is now the cornerstone of cHL therapy. Prior toxic regimens, such as MOPP, which were associated with infertility and secondary acute leukemia, have been supplanted by the equally efficacious,

but less toxic regimen of ABVD.¹³ ABVD is the treatment standard in the United States. Many regimens have been developed to further improve outcomes. Dose intensification with escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) led to improved FFTF, but with increased acute and late toxicities and without overall survival benefit.^{54–56}

Risk-adapted interim PET

In an effort to optimize outcome and minimize toxicity, early response assessment with an interim FDG-PET (PET) scan is often performed. This PET is done before completion of treatment, often after the second or fourth cycle of chemotherapy. After two cycles of ABVD, interim PET has been found to predict treatment response and clinical outcomes,^{57–59} thus leading to the concept of “response-adapted therapy,” whereby treatment intensity may be de-escalated with a good early response, or escalated if early response is inadequate.⁶⁰

The cHL criteria for PET response utilize the “five-point scale” (FPS) or Deauville Criteria: baseline and interim PET scans are scored according to uptake in sites initially involved by lymphoma: (1) no uptake, (2) uptake = mediastinal blood pool, (3) uptake = liver, (4) moderately increased uptake > liver, or (5) markedly increased uptake > liver and/or new lesions.⁶¹ A score of 1–3 is usually interpreted as negative for lymphoma, while a score of 4 or 5 is considered positive. In clinical trials, negativity may be more stringently defined as a score of 1–2 in cases where treatment may be substantially reduced for interim PET-negative patients.

Early stage cHL

In early-stage cHL, favorable and unfavorable risk groups have been defined.^{62–65} Common unfavorable features include: bulky mediastinal mass, B symptoms, elevated ESR, and involvement of multiple lymph node groups. Bulky disease is variably defined: >1/3 of the mediastinal mass ratio (MMR, maximum width of the mass divided by the maximum intrathoracic diameter), >1/3 of the mediastinal thoracic ratio (MTR, maximum width of the mass divided by the intrathoracic diameter at T5–T6), or any mass >10 cm. Three risk systems have been retrospectively analyzed in early-stage cHL following four cycles of ABVD + IFRT, and the common poor prognostic feature was tumor burden (bulky mass or greater number of nodal sites).⁶⁶

Favorable risk

Many studies in early-stage, favorable risk cHL have focused on reducing late effects without compromising cure. The GHSG HD10 study included 1131 patients with stage IA–IIB disease without any risk features.⁶⁷ Four treatment arms were randomized: ABVD × 2 cycles + 30 Gy IFRT, ABVD × 2 cycles + 20 Gy IFRT, ABVD × 4 cycles + 30 Gy IFRT, and ABVD × 4 cycles + 20 Gy IFRT. The 5-year freedom from treatment failure (FFTF) was 91.1% versus 93% for two versus four cycles of ABVD, respectively. Similarly, the 5-year FFTF in the two radiotherapy arms were not significantly different, 92.9% (20 Gy) versus 93.4% (30 Gy). Adverse events and acute toxic effects were more frequent in patients who received ABVD × 4 cycles + 30 Gy of IFRT. The authors recommended two cycles of ABVD followed by 20 Gy IFRT in these favorable patients.

The elimination of radiotherapy altogether in selected early-stage cHL is emerging as a new standard of care. In 2004, MSKCC reported a study of 152 nonbulky cHL patients with stages I, II A or B, and IIIA randomized to six cycles ABVD + RT versus six cycles ABVD alone.⁶⁸ At 5 years, FFS and OS for ABVD + RT versus ABVD alone were 86% versus 81% ($P = 0.61$) and 97% versus 90% ($P = 0.08$),

respectively. The NCIC and ECOG HD.6 randomized stage IA or IIA nonbulky cHL patients to receive ABVD alone or ABVD + subtotal nodal radiation therapy (sTLI).⁶⁹ Patients in the RT group who had a favorable risk profile received sTLI alone, whereas patients with an unfavorable risk profile (any of the following: age older than 39 years, an ESR ≥ 50 mm/h, mixed cellularity or lymphocyte deplete histology, or ≥ 4 sites of disease) received two cycles ABVD + sTLI. Patients who received ABVD only received four to six cycles, based on interim CT. At 12 years there was a significant survival benefit favoring ABVD, 94% versus 87% for ABVD + sTLI ($P=0.04$), with excess secondary malignancies in the CMT arm. This study has been criticized, given outdated sTLI, nevertheless it demonstrated the value of ABVD alone and emphasized concerns regarding CMT.

ABVD alone is also being studied with interim PET.^{70, 71} The UK RAPID study was a randomized noninferiority study including 602 nonbulky stage IA or IIA cHL patients, favorable, and unfavorable risks. All received three cycles ABVD followed by PET imaging. If negative (Deauville 1 or 2), patients were randomized to no further treatment versus one cycle ABVD + 30 Gy IFRT. If interim PET positive, all received one cycle ABVD + 30 Gy IFRT. With median follow-up of 60 months, the 3-year PFS was 94.6% for CMT versus 90.8% for three cycles of ABVD alone, with an absolute risk difference of 3.8 percentage points. The EORTC/LYSA/FIL H10 trial, a randomized noninferiority study of both favorable and unfavorable risk early-stage cHL patients utilizing ABVD and interim PET after two cycles, concluded after a preplanned interim futility analysis that, when compared to CMT, the chemotherapy alone arms should be discontinued. However, the 1-year PFS in the ABVD arms were excellent, approximately 95%, raising the question of whether conclusions were made prematurely. The long-term results of ongoing PET-adapted studies will further clarify whether ABVD alone is an effective strategy for selected early-stage cHL.

Unfavorable risk

The standard of care for patients with early-stage unfavorable risk cHL is combined modality therapy with a 5-year PFS of 80–85%.^{50, 72} Some with nonbulky unfavorable risk may have good outcome with early-interim PET negativity, and may be candidates for chemotherapy alone.⁷⁰ With bulky disease, however, the addition of RT appears particularly important and PET-adapted studies omitting radiotherapy have generally excluded such patients.⁷³

Several randomized trials have examined dose and schedule of combined modality therapy in early-stage, unfavorable risk cHL.^{50, 72, 74–76} The GHSG HD11 trial compared 4 CMT regimens in 1570 patients: 4 ABVD + 20 Gy IFRT, 4 ABVD + 30 Gy IFRT, 4 BEACOPP + 20 Gy IFRT, versus 4 BEACOPP + 30 Gy IFRT. Stage IIB was considered advanced stage and excluded. Five-year FFS was: 81% (4 ABVD + 20Gy), 85% (4 ABVD + 30Gy), 87% (4 BEACOPP + 20Gy), and 87% (4 BEACOPP+30Gy).⁷² When combined with 20 Gy IFRT, results favored BEACOPP, however, with 30 Gy, ABVD + RT was equivalent with less toxicity. The authors recommended 4 ABVD + 30 Gy IFRT in early unfavorable cHL. The GHSG HD14 trial compared four ABVD + 30 Gy IFRT versus two escalated BEACOPP followed by two cycles of ABVD (2 + 2) + 30 Gy IFRT.⁷⁶ The “2+2” arm had 5-year FFS of 94.8% versus 87.7% with 4 ABVD + IFRT ($p = <0.001$), however, there were significantly increased acute toxicities in the “2+2” arm. At a median follow-up of 43 months, there were no differences in treatment-related mortality or secondary malignancies however.

The Intergroup Trial E2496 compared 6–8 ABVD + 36 Gy IFRT versus Stanford V.⁷⁷ For patients with stage I or II bulky disease (bulk defined as MMR of greater than one third on chest radiography or ≥ 10 cm on CT), the 5-year FFS was 85% for ABVD + IFRT versus 79% for Stanford V (HR, 0.68; 95% CI,

0.37–1.25), with no significant difference between the two treatment approaches. More patients got IFRT (bulk was defined > 5 cm) with Stanford V and more patients on ABVD received long-course chemotherapy.⁷⁵ On the basis of these results, ABVD followed by consolidative RT remains the standard of care for bulky early-stage cHL.

Advanced-stage cHL

The International Prognostic Score (IPS) identifies seven independent prognostic factors associated with inferior progression free and overall survival in advanced cHL: serum albumin less than 4 g/dL; hemoglobin less than 10.5 g/dL; male gender; stage IV disease; age of 45 years or older; white cell count of 15,000/mm³ or more; lymphocyte count less than 600/mm³ or 8% of total white cell count.⁷⁸ The highest risk group (5 or more risk factors) had a 5-year FFP of 42% as compared to 80% for patients without risk factors. The IPS analyzed data before 1990, prompting a new evaluation. This study included 740 patients treated with ABVD or ABVD-like regimens in the British Columbia Cancer Agency (BCCA) database.⁷⁹ The IPS was still found to be prognostically significant, but with a narrower difference between outcomes: 5-year FFP of 70% for patients with > 4 IPS factors compared to 88% with no adverse factors and 5-year OS of 73% and 98%, respectively. These results demonstrate improved outcomes likely due to uniform anthracycline containing chemotherapy (ABVD), growth factor support, improved accuracy of staging, and more accurate pathologic diagnosis.

Treatment

Standard therapy for advanced cHL is six cycles of ABVD. Dose-intensive treatment regimens have been studied. Although phase II trials suggested that Stanford V might have superior efficacy as compared to ABVD, the Intergroup Study for advanced-stage cHL patients found no difference in FFS: 74% for ABVD and 71% for Stanford V at 5 years.^{80–82} Moreover, the Stanford V arm was associated with a higher incidence of lymphopenia and neuropathy.

The GHSG-escalated BEACOPP regimen is widely used in Europe, however it has failed to gain popularity in the United States owing to excess toxicities and no clear survival benefit. Three GHSG phase III trials—HD9, HD12, and HD15—have examined BEACOPP.^{55, 56, 83}

In the HD9 study, 1196 patients were randomized: COPP-ABVD, standard-dose BEACOPP, versus escalated BEACOPP.⁵⁵ All were eight cycles + RT to initial sites ≥5 cm. The 5 and 10-year analyses showed that escBEACOPP was significantly better than BEACOPP or COPP-ABVD with FFTF (82%, 70%, and 64%) and OS (86%, 80%, and 75%). escBEACOPP appeared to have the greatest clinical benefit for IPS scores 4–7, but had greater myelosuppression, infertility and secondary myelodysplasia/acute leukemia.

HD12 compared 8 esc BEACOPP to 4 escBEACOPP + 4 baseline BEACOPP (4+4).⁸³ Patients were then randomized to no further therapy versus 30 Gy RT consolidation. Five-year FFTF was 86.4% escBEACOPP versus 84.8% 4 + 4, and OS 92% versus 90.3%. The FFTF was better in the RT arm, although OS was not significantly improved.

HD15 trial included 2182 patients: 8 escBEACOPP, 6 escBEACOPP, or eight cycles of a time-intensified standard-dose BEACOPP.⁵⁶ RT (30 Gy) was restricted to patients with PET-positive residual sites (2.5 cm or more). Five-year FFTF was 4.4%, 89.3%, and 85.4%; and 5-year OS 91.9%, 95.3%, and 94.5%, respectively. The authors recommended six cycles of escBEACOPP with significantly better outcome, less treatment-related mortality, and fewer secondary cancers.

A subset of cHL is CD20+, with expression of this B-cell antigen on the R–S cell. Phase II studies adding rituximab (anti-CD20 monoclonal antibody) administered weekly for 6 weeks with ABVD in advanced-stage CD20+ cHL have been reported.^{84, 85} In one study, 5-year EFS and overall survival rates of 83% and 96% were reported and appear promising for this histologic subset.⁸⁴

Risk-adapted interim PET imaging is also being applied in advanced-stage cHL. A phase II study from Israel suggests that risk and response-adapted treatment may be effective. In this study, 45 poor-risk (IPS ≥ 3) advanced-stage cHL patients received two cycles of escBEACOPP, followed by a PET scan. If PET was negative, patients were subsequently treated with four cycles of ABVD. For the 31 patients who achieved a negative early-interim PET scan, the 4-year PFS was 87%.⁶⁰ Early results from the SWOG S0816 and UK RATHL studies applying interim PET response-adapted treatment strategies in advanced-stage cHL show promise.⁸⁶

Management of relapsed, refractory Hodgkin lymphoma

The standard treatment approach for relapsed, refractory—r/r—cHL is salvage chemotherapy to achieve remission status, followed by myeloablative chemotherapy and autologous stem-cell transplant (ASCT). Various groups have developed prognostic models to predict the outcome of r/r cHL completing ASCT.^{87–91} Unfavorable risk factors include: presence of extranodal disease, abbreviated remission duration after frontline therapy (generally < 1 year), and presence of B symptoms. In addition, a powerful independent prognostic factor is pretransplant functional imaging status.^{92, 93} In one study with median follow-up of 51 months, patients with a negative PET scan before ASCT had superior outcomes with event-free survival $>80\%$ versus 29% for patients with a positive scan.⁹²

There are many salvage regimens for r/r cHL including ICE (ifosfamide, carboplatin, and etoposide), DHAP (dexamethasone, high-dose cytarabine, and cisplatin), ESHAP (etoposide, methylprednisolone, high-dose cytarabine, and cisplatin), IGEV (ifosfamide, gemcitabine, and vinorelbine), and GVD (gemcitabine, vinorelbine, and pegylated liposomal doxorubicin).^{88, 94–97} These regimens have not been prospectively compared, nevertheless, they do appear to have similar efficacy in phase II studies.

The goal of salvage treatment is to achieve a PET-negative remission before consolidative ASCT, as patients with persistent disease at the time of transplant have poor outcomes. This aim may be achieved by one or more salvage regimens, with or without radiotherapy. The potential curative role and significant survival benefit of ASCT in r/r cHL have been established by two large randomized trials comparing chemotherapy alone to chemotherapy followed by ASCT.^{98, 99}

Novel agents in Hodgkin lymphoma

Approximately 15% of cHL patients will fail both first- and second-line therapy, and require novel therapy. Brentuximab vedotin (BV) was FDA-approved in 2012 for r/r cHL after failure of ASCT or for those not deemed ASCT candidates after failure of at least two multiagent regimens.^{100, 101} Other agents with demonstrated activity include histone deacetylase inhibitors, PI3-kinase/Akt/Mtor pathway inhibitors, lenalidomide, and bendamustine.¹⁰² Most recently, immune checkpoint inhibitors targeting the programmed death-1 (PD1)-PD1-ligand pathway have shown promise in cHL. The PD1-PD1-ligand pathway dampens immune responses, and inhibition of this pathway results in augmentation of host immune response against tumor cells. Preliminary data (2014 American Society of Hematology) has revealed overall response rates ranging from 50% to 89% for two of these agents, pembrolizumab and nivolumab.^{103, 104}

Brentuximab vedotin, BV, is an antibody-drug conjugate (ADC) consisting of the chimeric anti-CD30 monoclonal antibody, cAC10, chemically conjugated to monomethyl auristatin E (MMAE).^{105, 106} MMAE is internalized into the Reed–Sternberg cell, where it is a tubulin inhibitor resulting in cell cycle arrest and apoptosis.¹⁰⁷ The initial phase I study enrolled 45 patients with r/r CD30-positive hematologic malignancies. BV was administered intravenously every 3 weeks at doses ranging from 0.1 to 3.6 mg/kg. Dose-limiting toxicities included grade-4 thrombocytopenia, grade-3 hyperglycemia, and febrile neutropenia. The maximum tolerated dose (MTD) was 1.8 mg/kg every 3 weeks. Promising responses were seen, and a phase 2 study in 102 patients with r/r cHL after ASCT confirmed these results.¹⁰¹ Patients received 1.8 mg/kg BV every 3 weeks for up to 16 cycles. The overall response rate was 75%, with complete remissions in 34 of 102 (33%). The median PFS was 5.6 months and OS 40.5 months. Moreover, 14 patients remained in durable remission after BV and of these, 9 had not started new therapy and 5 had proceeded to consolidative allogeneic SCT.¹⁰⁸

BV is now being studied for initial treatment of cHL in combination with AVD: an international phase III study randomizes BV + AVD versus ABVD for advanced-stage cHL. Similar BV combinations regimens are under investigation for early-stage and elderly cHL. Another strategy is BV before ASCT in place of, or in addition to, standard salvage, such as ICE.¹⁰⁹ Post-ASCT, a phase III study of BV maintenance versus placebo demonstrated a significant improvement in median PFS favoring maintenance BV versus placebo (42.9 months vs 24.1 months) in high-risk cHL.¹¹⁰

Special populations

NLPHL

This rare subset of lymphoma (see pathology discussion) is now recognized to be highly treatable but likely not curable with standard cHL therapy.^{111–113} Management options include excision only, INRT or CMT in early stage; and monitoring, Rituximab alone or with chemotherapy, or palliative INRT for relapsed/advanced-stage disease. Most importantly, survival remains excellent but can be negatively impacted by the late effects of prior therapy. Thus, in this lymphoma, it is important to be mindful of the young age, the intensity of treatment utilized, and the likely good outcome achievable with limited therapy. Like indolent lymphoma, NLPHL is associated with the late development of histologic transformation (T-cell-rich B-cell lymphoma, a subtype of DLBCL, or DLBCL). This may be a life-threatening development and requires a multiagent chemotherapy regimen as in management of DLBCL.

Elderly

In the elderly, the curative aim of cHL treatment remains realistic, although the management approach may be modified for tolerability. ABVD is the standard regimen, although bleomycin may be more lung-toxic, and other regimens are often considered (without adriamycin or bleomycin). Brentuximab vedotin may become a successful substitute for bleomycin in ABVD (see above). Relapsed/refractory cHL may still be approached with salvage chemotherapy/ASCT in selected patients, generally with physiologic age of 70 or less. Without second-line ASCT, most patients do not have a curative option at this time and are managed with phase I–II clinical trials, palliative chemotherapy, and/or RT.

Pregnancy

cHL may occur in young women, and not infrequently, may present during pregnancy. Details of management are discussed elsewhere. Most importantly, cHL is generally a slowly progressive lymphoma

and its treatment can often be delayed until delivery, or ABVD can be safely administered during the second and/or third trimesters. Imaging during pregnancy should be minimized with use of MRI, and no PET should be performed.

HIV

cHL may be seen in association with HIV, and in this context the pathology is more likely mixed cellularity or lymphocyte-depleted histologic subtypes, and the stage more advanced with unusual sites such as skin. Treatment regimens remain the same as non-HIV patients, when the CD4 count exceeds 200 and patients receive concurrent cART therapy and prophylactic antibiotics as indicated. A more selective approach is needed in more immunosuppressed patients where infectious complications may be greater.¹¹⁴

Post-treatment surveillance

The ability to predict sustained remission and curability has increased with PET imaging. This has raised the important question of when, how frequently, and for how long should surveillance imaging be continued postremission. All agree that in the surveillance setting, PET is too sensitive, identifying excess false positives. Selective CT or MRI imaging can be alternatives when needed. As most relapses occur in the first two years post-treatment, routine imaging after this timeframe is not recommended.¹¹⁵

Chapter 119

Non-Hodgkin's lymphoma

Arnold S. Freedman, MD ■ Ann S. LaCasce, MD

Overview

The malignant lymphomas are neoplastic transformations of cells that reside predominantly within lymphoid tissues. Although Hodgkin lymphomas (HLs) and non-Hodgkin lymphomas (NHLs) infiltrate lymphohematopoietic tissues, their biologic and clinical behaviors are distinct. They differ with neoplastic cells of origin, sites of disease, presence of specific symptoms, and response to treatment. Although both are among the most sensitive malignancies to radiation and cytotoxic therapy, their cure rates markedly differ. HLs are cured in nearly 80% of all patients employing both conventional and salvage treatment strategies whereas NHLs are cured in fewer than 50% of patients.

Epidemiology and etiology

Incidence and mortality

In 2014, 70,890 new cases of NHL (non-Hodgkin lymphoma) were diagnosed in the United States¹ with 18,990 deaths predicted. Cases increase steadily with age. There is a slight male predominance and the incidence is higher in Caucasians than in African Americans. Although the rate of increase has slowed since the mid-1990s, the incidence continues to rise by 1.5–2% each year.

The incidence of NHL subtype varies significantly by age. In children, Burkitt's lymphoma (BL), lymphoblastic lymphoma (LBL), and diffuse large B-cell lymphoma (DLBCL) predominate. With increasing age, rates of follicular lymphomas (FLs) and other aggressive lymphomas continue to increase. Small lymphocytic and FLs are most commonly diagnosed in patients over age 60.

Exposures and diseases associated with increased risk of developing NHL

Infectious agents are involved in the pathogenesis of some NHLs ([Table 1](#)). Epstein–Barr virus (EBV) has a strong association with development of BL, natural killer cell lymphoma, and human immunodeficiency virus-related (HIV-1) lymphoma.^{2, 3} About 45–70% of HIV-associated NHLs are EBV related, as are nearly 100% of the primary central nervous system (CNS) lymphomas in HIV-1 positive individuals. Human T-cell lymphotropic virus (HTLV)-1 is responsible for adult T-cell leukemia/lymphoma, endemic to the Caribbean and southern Japan.⁴ Gastric marginal zone lymphoma (MZL) is associated with *Helicobacter pylori* infection.⁵ Splenic MZL is associated with hepatitis C infection.⁶ Chronic hepatitis B infection carries an increased risk of NHL.⁷ In Europe, ocular adnexal MZL is linked with *Chlamydia psittaci* infection⁸ and MZL involving the skin with *Borrelia burgdorferi*. Immunoproliferative small intestinal disease (Mediterranean lymphoma, alpha heavy chain disease) has been associated with *Campylobacter jejuni*.⁹ Kaposi sarcoma-associated herpes virus, also known as HHV-8 (human herpes virus-8), has been isolated from the neoplastic cells in patients with primary effusion lymphomas.^{10, 11}

Table 1 Risk factors for the development of lymphoma

Inherited immunodeficiency states	Acquired immunodeficiency states	Autoimmune and inflammatory disorders	Infectious agents (other than HIV)	Chemicals and drugs
Autoimmune lymphoproliferative disease	HIV-1 infection	Rheumatoid arthritis	Epstein–Barr virus	Herbicides, pesticides, organic solvents
Ataxia telangiectasia	Iatrogenic	Systemic Lupus Erythematosus	HTLV-1	Ionizing radiation
Chediak–Higashi syndrome	Tumor necrosis factor agonists	Sjögren's syndrome	HHV-8	Chemotherapy, radiation therapy
Common variable immunodeficiency		Celiac disease	<i>Helicobacter pylori</i>	
Wiskott–Aldrich syndrome		Hashimoto's thyroiditis	<i>Campylobacter jejuni</i>	
X-linked lymphoproliferative disease		Inflammatory bowel disease	<i>Chlamydia psittaci</i>	
			<i>Borrelia burgdorferi</i>	
			HCV	

HIV-1, human immunodeficiency virus-1; HTLV-1, human T-cell lymphotropic virus-1; HHV-8, human herpes virus-8; HCV, hepatitis C virus.

An increased risk of NHL is associated with a number of exposures and/or disease states. Controversial evidence suggests certain chemical exposures, including the herbicide phenoxyacetic acid, arsenic, pesticides, fungicides, chlorophenols, organic solvents, halomethane, lead, vinyl chloride, or asbestos, increase the risk of NHL.^{12–14} Occupational exposures associated with an increased risk include agricultural work, welding, and work in the lumber industry.^{15, 16}

Diseases of inherited and acquired immunodeficiency and autoimmune diseases are associated with an increased incidence of lymphoma.^{17, 18} The association between immunosuppression and NHLs is compelling given a percentage of lymphomas will regress with the withdrawal of immunosuppression.¹⁹ Patients undergoing organ transplantation necessitating chronic immunosuppression have a nearly 100-fold risk of NHL, which is greatest in the first-year posttransplant. DLBCL is most common NHL in this setting and is frequently associated with EBV.²⁰ The rare inherited immunodeficiency diseases such as X-linked lymphoproliferative syndrome, Wiskott–Aldrich syndrome, Chédiak–Higashi syndrome, ataxia telangiectasia, and common variable immunodeficiency syndrome are complicated by highly aggressive lymphomas. An increased risk of NHL has been observed in first-degree relatives with NHL, CLL, and Hodgkin lymphoma (HL).²¹

Pathology, immunobiology, and natural history of NHL

The World Health Organization (WHO) published a new classification of tumors of the hematopoietic and lymphoid tissues ([Table 2](#))²² that integrate morphology, immunotyping, genetic features, and clinical

syndromes. To provide a context for this classification, the large numbers of entities will be grouped into “indolent,” “aggressive,” and “highly aggressive” categories ([Table 2](#)).

Table 2 World Health Organization Classification of Lymphoid Neoplasms 2008: selected B- and T-cell neoplasms

<i>Precursor B- and T-cell neoplasms</i>		
	Precursor B-lymphoblastic leukemia/lymphoma Precursor T-lymphoblastic leukemia/lymphoma	
<i>Mature B-cell neoplasms</i>		
	Chronic lymphocytic leukemia/small lymphocytic lymphoma	
	B-cell prolymphocytic leukemia	
	Lymphoplasmacytic lymphoma	
	Splenic marginal zone lymphoma	
	Hairy cell leukemia	
	Splenic B-cell lymphoma, unclassifiable	
	Plasma cell neoplasms	
	Extranodal marginal zone lymphoma	
	Nodal marginal zone lymphoma	
	Follicular lymphoma	
	Primary cutaneous follicle center lymphoma	
	Mantle cell lymphoma	
	Diffuse large B-cell lymphoma (DLBCL)	T-cell/histiocyte-rich large B-cell lymphoma Primary DLBCL of the central nervous system Primary cutaneous DLBCL, leg type EBV-positive DLBCL of the elderly
	DLBCL associated with chronic inflammation	
	Lymphomatoid granulomatosis	
	Primary mediastinal large B-cell lymphoma	
	Intravascular large B-cell lymphoma	
	ALK-positive large B-cell lymphoma	
	Plasmablastic lymphoma	
	Burkitt's lymphoma (BL)	
	B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL	

	B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Hodgkin lymphoma	
--	--	--

Mature T-cell neoplasms

	T-cell prolymphocytic leukemia	
	T-cell large granular lymphocytic leukemia	
	Adult T-cell leukemia/lymphoma	
	Extranodal NK/T-cell lymphoma, nasal type	
	Enteropathy-type T-cell lymphoma	
	Hepatosplenic T-cell lymphoma	
	Subcutaneous panniculitis-like T-cell lymphoma	
	Mycosis fungoides	
	Sézary syndrome	
	Primary cutaneous CD30+ T-cell lymphoproliferative disorders	
	Primary cutaneous peripheral T-cell lymphomas, rare subtypes	
	Peripheral T-cell lymphoma, not otherwise specified	
	Angioimmunoblastic T-cell lymphoma	
	Anaplastic large-cell lymphoma, ALK+	
	Anaplastic large-cell lymphoma, ALK-	

MALT, mucosal-associated lymphoid tissue; ALK, anaplastic lymphoma kinase; HHV8, human herpes virus-8; NK, natural killer; EBV, Epstein–Barr virus; HIV, human immunodeficiency virus.

Chromosomal translocations and oncogene rearrangements. Given the mechanism of immunoglobulin (Ig) and T-cell receptor (TCR) gene rearrangements in normal lymphoid cells, lymphomas are frequently found to have chromosomal translocations that involve the activation of an oncogene or inactivation of a tumor suppressor gene. The former is more common, whereby a proto-oncogene is brought under the control of a constitutively active promoter, resulting in overexpression of the oncogenic gene and its protein product. Examples include the (8;14)(q24;q32) translocation in BL, involving the *MYC* proto-oncogene and the IgH gene; the (14;18)(q32;q32) translocation in FL, involving the *BCL2* proto-oncogene and the IgH gene; and the (11;14) (q13;q32) translocation in mantle cell lymphoma (MCL), involving the gene encoding cyclin D1 (*CCDN1*) and the IgH gene. Less commonly, chromosomal translocations produce fusion genes that encode chimeric oncogenic proteins. Examples of this include the (2;5) (p23;q35) translocation involving the *ALK* (anaplastic lymphoma kinase) and *NPM1* genes in anaplastic large-cell lymphoma (ALCL) and the t(11;18)(q21;q21) translocation involving the *API2* and *MLT* genes in MZL lymphoma. These translocations and rearrangements can be detected by polymerase chain reaction (PCR) using probes that span the chromosomal breakpoints, reverse transcriptase polymerase chain reaction (RT-PCR) to detect the RNA product of the fusion gene, or fluorescence *in situ* hybridization (FISH) using probes to specific chromosomal segments. In cases where the translocation results in expression of a protein or portion of a protein that is never expressed in normal lymphocytes (e.g., ALK kinase), immunohistochemistry can be used to detect the protein.

Indolent lymphomas

The indolent NHLs are generally associated with survival measured in years, even if left untreated, but are typically incurable with conventional treatment. Indolent lymphomas represent 35–40% of the NHLs diagnosed in western countries. The most common subtypes are FL, small lymphocytic lymphoma, and MZL, comprising 22%, 6%, and 5% of all NHLs, respectively. In comparison, lymphoplasmacytic lymphoma, mycosis fungoides/Sézary syndrome, and splenic MZL are rare diseases, comprising 1% or less of all NHLs.

FL is the most indolent NHL and morphologically recapitulates normal germinal centers of secondary lymphoid follicles ([Figure 1](#)). The WHO classification includes three grades based on the number of large cells per high power field: grade 1 (0–5) ([Figure 2](#)), grade 2,^{6–15} and grade 3 (>15). Grade 3 is subdivided into grade 3A, in which centrocytes predominate, and grade 3B, in which there are sheets of centroblasts. Grade 1 and 2 and many cases of grade 3A FLs are approached similarly. FL grade 3B is an aggressive disease and is grouped with DLBCL.

[Figure 1](#) Follicular lymphoma grade I (low power).

Figure 2 Follicular lymphoma grade I (high power).

FL and normal follicular center B cells express cell surface antigens including monoclonal immunoglobulin and the B-cell antigens CD19, CD20, CD10, and CD79a, but lack CD5. Cytoplasmic bcl-2 protein is overexpressed in essentially all cases of grade 1–2 disease, whereas nuclear bcl-6 is expressed by at least some of the neoplastic cells. The most common cytogenetic abnormality in FL is t(14;18) that leads to overexpression of the antiapoptotic protein bcl-2 in over 85% of cases (see [Chapter 8](#)). Recent sequencing studies have found that the most common mutations in FL (90% of tumors) involve MLL2, a gene encoding a histone H3 methylase. Other less common recurrent mutations involve other genes involving epigenetic modifying genes, such as EZH2, CREBBP, and EP300.^{23, 24}

FL accounts for about 22% of NHL.²⁵ Uncommon before the fourth decade, the median age at diagnosis is 60 years. FL is less common in Asians and blacks. Patients usually present with painless peripheral adenopathy, which are often longstanding and may wax and wane. Hilar and mediastinal nodes are often involved, but large mediastinal masses are rare. Patients may present with asymptomatic large abdominal masses. Staging studies usually demonstrates widely disseminated disease with involvement of spleen (40%), liver (50%), and bone marrow (70%). Marrow involvement in FL reveals a unique pattern of paratrabeular infiltration. Few patients present with extranodal extramedullary disease, and only 20% present with B symptoms or lactate dehydrogenase (LDH) elevation. Intestinal-only presentation may occur and has a favorable prognosis.²⁶ CNS involvement is uncommon although peripheral nerve compression and epidural tumor masses causing cord compression may develop.

FL grade 3 was previously called follicular large-cell lymphoma. BCL6 rearrangements are present in a high fraction of grade 3B cases. Most studies have included both FL grades 3A and 3B, which affects the interpretation of the outcomes. Clinically grade 3B more closely approximates DLBCL.^{22, 27} In contrast many patients with FL grade 3A have a more indolent disease.

The course of FL is quite variable. Some patients can be observed with waxing and waning disease for 5 years or more without the need for therapy.²⁸ Others present with more disseminated disease and rapid growth and require treatment due to organ enlargement, lymphatic obstruction, or organ obstruction.

Histologic transformation to aggressive lymphoma, usually DLBCL, occurs in up to 60%, approximately

2–3% per year, of patients with FL and is characterized by rapid progression of lymphadenopathy, extranodal disease, B symptoms, elevated LDH, and often a poor prognosis.^{29, 30}

Small lymphocytic lymphoma

Small lymphocytic lymphoma and B-cell chronic lymphocytic leukemia are viewed as the same entity by the WHO classification. Although the major population of cells resembles small normal lymphocytes, larger cells resembling those seen in prolymphocytic leukemia are seen in the nodal tissue in areas known as proliferation centers ([Figure 3](#) and Figures 2, 3 of [Chapter 116](#)). The small lymphocytic lymphomas are phenotypically identical to B-cell chronic lymphocytic leukemias but have fewer than 5000 circulating malignant B cells. They express HLA-DR, B-cell antigens CD19, CD20, CD23, weak surface immunoglobulin, and CD5. Cytogenetic abnormalities include trisomy 12 present in about 40% of cases, 13q in 45–55%, 11q abnormalities in 17–20%, and 17p abnormalities in 7–10% of cases. Cases with 13q deletions have the most favorable prognosis, whereas those with 11q or 17p abnormalities have an unfavorable prognosis.³¹

[Figure 3](#) Small lymphocytic lymphoma.

Recent studies suggest that 30–50% of these diseases have nonmutated immunoglobulin variable region genes and correspond to naïve B cells. These cases often express CD38 and the tyrosine kinase ZAP-70 and have a worse prognosis.³² The remaining 50–70% of cases have mutated immunoglobulin variable region genes, are derived from germinal center or postgerminal center B cells,³³ and have a favorable prognosis.³⁴ Deep sequencing studies of chronic lymphocytic leukemia have revealed a number of recurrent mutations, including NOTCH1, MYD88, and SF3B1 genes.³⁵

Small lymphocytic lymphomas makes up about 6% of all NHLs.²⁵ The clinical presentation is similar to FL. Unlike B-cell chronic lymphocytic leukemia, the peripheral blood may be normal or reveal only a mild lymphocytosis although the bone marrow is positive in 70–90% of cases. A serum paraprotein is found in about 20% of cases and hypogammaglobulinemia is present in about 40%. Small lymphocytic lymphomas and B-cell chronic lymphocytic leukemia can convert to DLBCL or less commonly HL (Richter syndrome, [Figure 4](#)).³⁶

Figure 4 Diffuse large B-cell lymphoma.

Lymphoplasmacytic lymphoma

Lymphoplasmacytic lymphoma is an indolent lymphoma composed of diffuse proliferation of small lymphocytes with evidence of maturation to plasma cells.³⁷ Evidence of immunoglobulin is seen in these cells by special stains or inclusions. These tumors express B-cell antigens, CD19 and CD20, and surface immunoglobulin M isotype, and in general do not express CD5, CD10, or CD23. Deletions of 6q21 have been identified in 40–60% of patients with lymphoplasmacytic lymphoma and the syndrome associated with this is known as Waldenström's macroglobulinemia. Activating mutations in MYD88, a protein involved in signaling pathways downstream of the Ig receptor, are present in close to 100% of cases.³⁸

Lymphoplasmacytic lymphoma represents about 1% of all NHLs. Clinically, this disease is similar to small lymphocytic lymphomas. The median age is early 60s, and virtually all patients have stage IV disease by virtue of bone marrow involvement, and lymph nodes and spleen are commonly involved. B symptoms and elevated serum LDH are rare. A serum M component is common. As with B-CLL, the paraprotein may have autoantibody or cryoglobulin activity. However, most cases with mixed cryoglobulinemia have been shown to be related to concurrent hepatitis C virus (HCV) infection³⁹ and may respond to therapy directed at hepatitis C. In the WHO clinical study, 5-year overall survival (OS) (58%) and failure-free survival (25%) were identical to that of small lymphocytic lymphomas.

Marginal zone lymphomas

MZLs are a group of distinct entities including nodal MZL; extranodal MZL also known as the lymphomas of mucosal-associated lymphoid tissues (MALTs); and the splenic MZL.^{40, 41} In the nodal MZL, the tumor cells cytologically resemble “normal” monocytoid B cells and often involve lymph node sinuses. Phenotypically, tumor cells express surface immunoglobulin M and B-cell antigens (CD19, CD20). Similar to other indolent lymphomas, MZL can transform into a higher grade lymphoma. The nodal MZLs constitute 1% of all NHLs. Over 70% of patients present with stage III/IV disease and the majority are asymptomatic. Bone marrow involvement is less common than in most indolent lymphomas. The 5-year survival for patients with nodal MZL is 55–79%.

The extranodal MZL tumor cells resemble monocytoid B cells, express CD19, CD20, and surface immunoglobulin M, and are thought to arise from memory B cells. Lymphoepithelial lesions may be seen associated with centrocytes. The disease does not form follicles; rather the malignant cells surround reactive follicles. When extranodal MZL spreads to lymph nodes, the neoplastic cells involve the marginal zones. The most common cytogenetic abnormality is trisomy 3, occurring in up to 60% of cases (particularly the gastric extranodal MZL), and t(11;18), occurring in 25–40% of cases.⁴²

Extranodal MZLs constitute about 5% of all NHLs and almost 50% of all gastric lymphomas. B symptoms are uncommon and most patients present with stage I or II disease. There is no age predilection. The gastrointestinal tract (most commonly stomach), lung, dura, lacrimal and salivary glands, skin, thyroid, and breast may be involved. MZL is associated with autoimmune diseases and infections with *H. pylori*, *B. burgdorferi*, *C. psittaci*, *C. jejuni*, and HCV.^{43–46} Fewer than 25% of cases have lymph node or bone marrow involvement. Patients can present with peptic ulcer disease, abdominal pain, and sicca syndrome, or a mass at the site of involvement. These lymphomas can disseminate to other MALT sites or bone marrow in about 30% of cases, typically later in the course of the disease. This is more commonly seen in nongastric MZLs.⁴⁷ Complete remission rates are high, and OS up to 80% at 10 or more years.⁴⁸ Like all indolent NHLs, these can transform to DLBCL.

Splenic MZL constitutes <2% of all NHLs, with a median age of 65, and is uncommon before age 50.²⁵ Histologically, there is expansion of marginal zones in the spleen. Bone marrow and peripheral blood involvement (referred to as splenic lymphoma with villous or nonvillous lymphocytes) can also be present. In splenic MZL, trisomy 3 is present in 39% of cases. The survival of patients is in excess of 70% at 10 years. Sequencing studies demonstrate recurrent somatic mutations in genes involved in the NOTCH, NF- κ B, and B-cell receptor pathways, as well as mutations in TP53.⁴⁹

Aggressive lymphomas

Mantle cell lymphoma

MCL is generally an aggressive disease.^{50, 51} The neoplastic cells are counterparts of naive “mantle zone” B cells and are medium sized with irregular nuclei. The disease may have either diffuse architecture or a vaguely nodular appearance. Some cases of MCL have a predominance of “blastoid” cells with a high mitotic rate. The cells express B-cell antigens, surface immunoglobulin M with or without immunoglobulin D, CD5, and CD43, but lack CD10 and CD23, respectively, and overexpression of cyclin D1. Approximately 70% of MCLs have t(11;14)(q13;q32) that creates rearrangements of the *bcl-1* (cyclin D1) gene. Eight percent of MCL cases are cyclin D1-negative and overexpress cyclin D2 and 4 or cyclin D3, without chromosomal rearrangements⁵² and are clinically similar to cyclin D1-positive cases.⁵³ Deep sequencing⁵⁴ has identified NOTCH1 mutations in a minority of cases, which may be associated with poor prognosis. SOX11 overexpression is also associated with a worse prognosis.^{52, 55}

MCL constitutes about 7% of all NHLs. About 75% of patients are males, with median age of 63. Approximately 70% of patients have stage IV disease, and B symptoms are observed in approximately one-third of patients. Typical sites of involvement are lymph nodes, spleen, liver, Waldeyer's ring, and bone marrow. Peripheral blood involvement is present in 25–50% of patients at presentation. MCL can involve any region of the gastrointestinal tract, occasionally presenting as multiple intestinal polyposis. The median survival of patients with MCL is 3–6 years and patients with the blastic variant at diagnosis have a median survival of 18 months. Blastic transformation occurs in 35% of patients, with a risk of 42% at 4 years; the median survival is 3.8 months.⁵⁶ Mutations and deletions of p53 are also associated

with a worse prognosis.⁵⁷

Diffuse large B-cell lymphoma

DLBCL consists of a diffuse proliferation of large cells with a high mitotic rate. The cells have a moderate amount of cytoplasm with either cleaved or noncleaved nuclei often with multiple nucleoli, although there can be great variability in the morphology ([Figure 4](#)). DLBCL represents many distinct disease entities.²² ([Table 2](#)) Gene expression profiling has been applied to DLBCL.^{58–61} These studies subdivided DLBCL into distinct genetic entities. DLBCLs correspond to germinal center B cells or activated B cells. The tumor cells generally express B-cell antigens (CD19 and CD20), monoclonal surface immunoglobulin M, and occasionally other heavy chain isotypes. CD5-positive cases are uncommon and may have a worse prognosis.⁶² CD10 and bcl-6 support a germinal center origin, whereas expression of MUM1 supports a nongermlinal center origin. Approximately 70% express bcl-6 protein, consistent with a germinal center origin.⁶³

Several chromosomal abnormalities have been observed in DLBCL. Bcl-6 is associated with chromosomal rearrangements involving 3q27.⁶⁴ Rearrangements of the gene occurs in 20–40% of diffuse aggressive lymphomas. t(14;18) has been observed in approximately 30% of patients with DLBCL. Some of these cases may represent histologic transformations of prior FL. By gene expression profile (GEP), the germinal center B-cell (GCB) type is often associated with the t(14;18) and amplifications of the *REL* oncogene on chromosome 2. In contrast, the activated B-cell (ABC) type is associated with loss of 6q21, trisomy 3, gains of 3q and 18q21–22, and mutations of *EZH2*.^{65, 66} ABC cases also have high-level activation of NF- κ B.⁶⁷ MYC is rearranged in 10% of DLBCLs, with the partner gene being one of the Ig genes in 60% of cases and alternative genes in 40% of cases. Approximately 20% of MYC-rearranged cases have concurrent BCL2 or BCL6 rearrangements, a combination referred to as “double-hit lymphoma.”⁶⁸ Amplification and/or overexpression of MYC independent of rearrangements or amplification has also been described and is also associated with a poor prognosis.^{69, 70}

DLBCL constitutes 31% of all NHLs and is the most common histologic subtype. Patients who are generally middle-aged or older (median age 64 years) present with either nodal enlargement or extranodal disease. DLBCL presents in a localized (stage I or IE) manner approximately 20% of the time and 30–40% of patients will have I or II disease. Stage IV disease is seen in approximately 40% of patients. B symptoms occur in 30% of patients, and unlike most NHLs, LDH is elevated in over half the patients. During the course of the disease, the liver, the kidneys, the lung, the bone, and the peripheral nerves may be involved. Bone marrow involvement is initially found in 10–20% of patients. Extranodal diseases, specifically testicular, bone marrow, paranasal sinus, multiple extranodal sites, and elevated LDH, are other risks for CNS dissemination.⁷¹ Rare cases of DLBCL present with a disseminated intravascular proliferation of large lymphoid cells, involving small blood vessels, without an obvious tumor mass^{72–74} most commonly involving the CNS, kidneys, lungs, and skin.

Within the DLBCL group is a distinct clinical entity known as primary mediastinal large B-cell lymphoma (PMLBCL) (7% of all cases of DLBCL).⁷⁵ Histologically, the cellular infiltrate is heterogeneous, and sclerosis is frequently present. The immunophenotype includes B-cell antigens (CD19, CD20), but they are often negative for surface and cytoplasmic immunoglobulin. GEP suggests that this is a distinct entity from germinal center or ABC types of DLBCL. Recent studies suggest that the GEP pattern of PMLBCL closely resembles the Reed–Sternberg cells of HL.^{76, 77} Copy number gains in the region on chromosome 9p containing the genes for JAK2 and programmed cell death ligand 1 and 2 (PDL1 and PDL2) and ligands for the programmed cell death receptor-1 (PD-1), which has a role in suppressing T-cell function,

are common.⁶⁵ PMLBCL resembles classical HD by GEP.⁷⁶ PMLBCL has a female predominance, with a median age of 40. Over 70% of these patients present with stage I/II bulky disease involving the mediastinum. Pleural and pericardial effusions are seen in about one-third of patients. Superior vena cava syndrome is common. Similar to DLBCL, an elevated LDH is present in the majority, whereas bone marrow involvement is infrequent. The prognosis of patients with PMLBCL is similar to patients with DLBCL.

Peripheral T-cell lymphomas

Peripheral T-cell lymphomas (PTCLs) include a large number of entities that constitute 15% of all NHLs in adults.⁷⁸ Among these, in decreasing frequency, are PTCL, not otherwise unspecified (NOS); ALCL; angioimmunoblastic T-cell lymphoma (AITL), extranodal NK/T-cell lymphoma, nasal type; and much rarer entities, panniculitis-like T-cell lymphoma, enteropathy-type T-cell lymphoma, and hepatosplenic γ/δ T-cell lymphoma.

PTCLs can be nodal- or extranodal-based diseases. The diffuse cellular infiltrates range from a mixture of small and large cells; infiltrates of pleomorphic cells, often with a background of epithelioid histiocytes, plasma cells, eosinophils, and Reed–Sternberg-like cells; or predominantly large cells. In contrast to B-cell lymphomas, the pattern of expression of T-cell surface antigens is highly variable. The majority express CD2, CD3, and CD4, with a subset of expressing CD8.⁷⁹ In most cases, one or more “mature” T-cell antigens, such as CD5 or CD7, are lost. Many cases of PTCL express EBV, especially the extranodal NK/T-cell lymphomas, nasal type.⁸⁰ EBV positivity is associated with a poor prognosis.

Abnormal metaphases are seen in 90% of T-cell lymphomas. The most commonly seen translocations in PTCLs are t(7;14), t(11;14), inv(14), and t(14;14). AITL is associated with trisomy 3 and/or 5.⁸¹ These translocations involve genes for the TCR at 14q11, 7q34–35, and 7p15. Young patients with ALCL have t(2;5) and less commonly t(1;2).⁸² ALCL in adults generally lack t(2;5). Hepatosplenic γ/δ T-cell lymphomas are associated with isochromosome 7q and trisomy 8.⁸³

Patients with PTCL have a similar median age as patients with DLBCL. In contrast, 80% of patients with PTCL have stage III/IV disease and more frequently have B symptoms, hepatosplenomegaly, and extranodal disease, such as the skin. PTCL generally has a worse prognosis than DLBCL.^{84, 85} A number of uncommon subtypes of PTCL have unique histologic features. AITL, in addition to a pleomorphic heterogeneous cellular infiltrate, displays increased amounts of high endothelial venules, giving a hypervascular appearance. In this subtype, Ig heavy chains may be rearranged in 10% cases, and EBV genomes are detected in most cases and may be in either T or B cells.⁸⁶ AITL typically affects older adults who present with the acute onset of generalized lymphadenopathy, hepatosplenomegaly, skin rash, and B symptoms.⁸⁶ Immunologic abnormalities are common and include plasmacytosis, polyclonal hypergammaglobulinemia, and a positive Coombs test. The median survival is 30 months. Infection is the most common cause of death, followed by the T-cell lymphoma or development of EBV-positive DLBCL.

ALCL is a T-cell NHL that can present as primary systemic ALCL, ALK-positive; primary systemic ALCL, ALK-negative; and primary cutaneous ALCL. When involving nodes, ALCL characteristically fills the sinusoids of lymph nodes with bizarre large cells. Neoplastic cells derived from patients with ALCL also generally express the phenotype of mature activated T cells (HLA-DR, CD30, CD25). The ALK protein is detected in 40–60% of cases using the ALK1 monoclonal antibody, showing both nuclear and cytoplasmic stainings in cases with the t(2;5).⁸⁷ The resulting fusion gene encodes a chimeric NPM-ALK fusion protein with constitutive tyrosine kinase activity. ALK-positive cases are more common in children and younger adults and have a better prognosis than ALK-negative cases.⁸⁸

ALCL constitutes 2% of all NHLs in adults, but is the second most common T-cell lymphoma. The median age of patients with ALCL is 34 with a male predominance. There is a bimodal distribution of this disease, with peaks in childhood, young adults, and late adulthood. In adults, B symptoms, peripheral adenopathy, and retroperitoneal adenopathy are common. Skin is a frequent site of extranodal disease (about 25% of patients), whereas bone marrow involvement is uncommon. An unusual form of ALCL arises within the breast associated with breast implants.⁸⁹ The prognosis of adult patients with systemic ALK-positive ALCL is similar to patients with DLBCL.⁹⁰ When ALCL, PTCL NOS, and AITL are compared, ALCL has the highest OS, whereas AITL had the lowest.⁹¹

Gray zone lymphoma

The gray zone lymphomas include B-cell lymphoma unclassifiable with features intermediate between BL and DLBCL (B-UNC/BL/DLBCL) and between DLBCL and cHL (B-UNC/cHL/DLBCL).²²

In B-cell lymphoma unclassifiable with features intermediate between BL and DLBCL (B-UNC/BL/DLBCL), the neoplastic cells are intermediate to large size, may have a very high Ki67 index, and are CD10+. Cells are more variable in size than BL cells, often BCL2 positive, may be BCL6 negative, and may have a Ki67 index lower than 100%. GEP has shown these to be heterogeneous.⁹² Between 30% and 45% cases have chromosomal translocations involving c-myc and bcl-2, known as “double-hit” lymphomas.⁶⁸ *B-UNC/BL/DLBCL* often presents with extranodal disease with high IPI and generally has a poor prognosis. Double-hit lymphomas, with this histology, have a very poor prognosis, with a median OS of 4 months.⁹³

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical HL (B-UNC/cHL/DLBCL) has features intermediate between PMBCL and classical HL, or B-UNC/cHL/DLBCL. This rare disease presents commonly in men with a mediastinal mass. Histologically, cells resemble both the Reed–Sternberg cell of classical HL and the large cells of DLBCL or PMLBCL. Fibrous stroma and an inflammatory infiltrate are seen. Malignant cells express CD45, CD20, CD79a, and CD30, but often are CD15(–); other B-cell markers such as PAX5, OCT-2, and BOB1 are often positive. The prognosis of these patients is inferior to both cHL and PMLBCL; the optimal therapy has not been demonstrated.⁹⁴

Highly aggressive lymphomas

Precursor T- or B-lymphoblastic leukemia/lymphoma

LBL and acute lymphoblastic leukemia ALL (see [Chapter 116](#)) represent two presentations of the same disease with LBL defined as having <25% bone marrow involvement. The neoplastic cells have a high nuclear to cytoplasmic ratio, scant cytoplasm, and nuclei with fine chromatin with multiple small nucleoli and have a high mitotic rate. The nuclei can have folds or convolutions. Typically, nodes involved with LBL are effaced by malignant cells ([Figure 5](#)).

Figure 5 T-lymphoblastic lymphoma.

The vast majority of LBLs are of T-cell lineage. Several investigators have noted that most T-cell LBLs correspond to stages of thymocyte differentiation (see [Chapter 116](#)).

Although LBLs represent a major subgroup of childhood NHLs, they are unusual in adults (2% of adult NHLs). Patients are usually males in their 20s or 30s, who present with lymphadenopathy in cervical, supraclavicular, and axillary regions (50%) or with a mediastinal mass (50–75%). This entity may be associated with superior vena cava syndrome, tracheal obstruction, and pericardial effusions. Less commonly, patients present with extranodal disease (e.g., skin, testicular, or bony involvement). More than 80% of patients present with advanced stage disease, almost 50% have B symptoms, and the majority have elevated LDH. Although the bone marrow is frequently normal at presentation, virtually all patients develop bone marrow infiltration and a subsequent leukemic phase. Patients with bone marrow involvement have a very high incidence of CNS infiltration. B-cell LBL is a very rare variant, affecting patients with a median age of 39.⁹⁵ B-cell LBL presents without a mediastinal mass but instead involves lymph nodes and extranodal sites.

Burkitt's lymphoma

BL cells resemble the small noncleaved cells within normal germinal centers of secondary lymphoid follicles. Because of the high mitotic rate, frequent mitotic figures are seen and, analogous to normal germinal centers, tingible body macrophages are seen, giving the classical “starry sky” appearance. It is generally agreed that the fraction of Ki-67 (proliferating cells) in BL should be 99% or greater.²²

BL is a tumor of B-lineage derivation identified by the expression of a variety of B-cell-restricted antigens including CD19, CD20, surface immunoglobulin M, CD10, and nuclear bcl-6 protein.⁹⁶ The endemic BL is EBV positive, whereas the vast majority of nonendemic BL is EBV negative. BL cells lack bcl-2 protein.

BL involves a translocation of chromosome 8q24 in over 95% of the cases with chromosome 14, 2, or 22.²² Pathologically identified Burkitt or histologically atypical Burkitt has a GEP that is associated with overexpression of *myc* target genes, differential expression of normal germinal center genes, and

decreased expression of MHC class I and NF- κ B target genes. These studies will help refine the histologic diagnosis of difficult to classify cases.^{92, 97, 98}

BL, in general, is a pediatric tumor that has three major clinical presentations. The endemic (African) form presents as a jaw or facial bone tumor that spreads to extranodal sites including ovary, testis, kidney, breast, and especially to the bone marrow and meninges. The nonendemic form has an abdominal presentation with massive disease, ascites, renal, testis, and ovarian involvement and, like the endemic form, also spreads to the bone marrow and CNS. Immunodeficiency-related cases more often involve lymph nodes and peripheral blood. BL has a male predominance and is typically seen in patients <35 years of age. These tumors have a high propensity to invade the bone marrow and CNS.

Adult T-cell leukemia/lymphoma

ATLL is a rare disease associated with infection by the HTLV-1 in 100% of cases.^{99–101} ATLL is endemic in southern Japan, the Caribbean basin, Africa, and the southeastern United States. The normal counterparts of the neoplastic cells are activated CD4⁺ T cells expressing CD2, CD3, CD5, and CD25. The median age of patients is 60.¹⁰² The disease can present as four variants: acute (most common and highly aggressive), lymphomatous, chronic, and smoldering. The median survival of these variants is 6, 10, 24 months, and “not reached,” respectively.¹⁰³ Patients present with BM and peripheral blood involvement, high white blood cell count, hypercalcemia (owing to PTH-related protein, TGF- β , and RANK ligand), lytic bone lesions, lymphadenopathy, hepatosplenomegaly, skin lesions, and interstitial pulmonary infiltrates.

Differential diagnosis and sites of disease at presentation

More than two-thirds of patients with NHL present with persistent painless peripheral lymphadenopathy. At the time of presentation, differential diagnosis of generalized lymphadenopathy includes infectious etiologies. A firm lymph node larger than 1.5 \times 1.5 cm not associated with a documented infection, persisting longer than 4–6 weeks, and progressing should be considered for biopsy. However, lymph nodes in indolent NHLs frequently wax and wane. In teenagers and young adults, infectious mononucleosis and HL should be placed high in the differential diagnosis. Involvement of Waldeyer's ring, epitrochlear, and mesenteric nodes are more frequently observed in patients with NHL than HL. 40% of all patients with NHL present with systemic complaints. B symptoms are more common in patients with aggressive subtypes approaching 50%. Less frequent presenting symptoms, occurring in <20% of patients, include fatigue and malaise.

NHLs also present with thoracic, abdominal, and/or extranodal symptoms. Approximately 20% of patients with NHL present with mediastinal adenopathy. These patients most frequently complain of persistent cough and chest discomfort and rarely display superior vena cava syndrome. Differential diagnosis of mediastinal presentation includes infections, sarcoidosis, HL, and other neoplasms. Involvement of retroperitoneal, mesenteric, and pelvic nodes is common in most subtypes of NHL, and the majority of patients are asymptomatic. Aggressive NHLs can present with primary cutaneous lesions, testicular masses, acute spinal cord compression, solitary bone lesions, and rarely lymphomatous meningitis. Symptoms of primary NHL of the CNS include headache, lethargy, focal neurologic symptoms, seizures, and paralysis.

When NHL presents in an extranodal site, the differential diagnosis is more difficult. NHL uncommonly presents in the lung.¹⁰⁴ Between 25% and 50% of patients with NHLs present with hepatic infiltration, although relatively few have large hepatic masses; these are almost always associated with aggressive

lymphoma. Of the advanced stage indolent lymphomas, nearly 75% of patients have microscopic hepatic infiltration at the time of diagnosis. Primary lymphoma of bone occurs in <5% of patients, presenting as a painful bony site, most commonly involving the femur, pelvis, and vertebrae. Approximately 5% of NHLs present as primary gastrointestinal lymphoma. These patients may have hemorrhage, pain, or obstruction as the stomach is most frequently infiltrated followed by the small intestine and the colon, respectively. Most gastrointestinal lymphomas are of the aggressive subtypes, specifically DLBCL, MCL, and the intestinal T-cell lymphoma and may present rarely with bleeding, obstruction, or perforation. The most common site for extranodal MZL is the stomach. A subset of MCLs presents as multiple intestinal polyposis involving any sites in the gastrointestinal tract. Two to fourteen percent of NHL present with renal infiltration, and even less common has localized presentation in the prostate, the testis, or the ovary. The typical histologic subtypes of these sites are DLBCL and BLs. Rare sites of primary lymphoma include the orbit, the heart, the breast, the salivary glands, the thyroid, and the adrenal gland.

Staging and disease detection

The Lugano classification¹⁰⁵ is the currently used staging system. It is derived from the Ann Arbor staging system, which was originally developed for HL in 1971. [Table 3](#) summarizes the essential features of the Ann Arbor system. Because NHLs most frequently disseminate hematogenously, this staging system has proven to be much less useful than for HL. The Lugano modification requires documentation of size of bulk disease.

Table 3 Revised staging system for primary nodal lymphoma

Stage	Involvement	Extranodal (E) status
Limited		
I	One node or a group of adjacent nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
II bulky*	II as above with “bulky” disease	Not applicable
Advanced		
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	Not applicable
IV	Additional noncontiguous extralymphatic involvement	Not applicable

*Whether stage II bulky disease is treated as limited or advanced disease may be determined by histology and a number of prognostic factors

Systemic “B” symptoms (fever, sweats, and weight loss) are no longer included into the staging system for NHL, because these symptoms are not independent prognostic factors for these patients.

The concept of staging has less impact in NHL than in HL. Multiple studies demonstrate that prognosis is more dependent on lymphoma subtype and clinical parameters than stage at presentation. Staging is undertaken in NHLs to identify the small number of patients who can be treated with local therapy or combined modality treatment and to stratify within subtypes to determine prognosis and assess the impact

of treatment.

Diagnosis and initial evaluation

Staging must be undertaken in the context of the histology. After the initial biopsy, blood tests should be obtained, including complete blood count, routine chemistries, renal function, liver function tests, and serum protein electrophoresis to document the presence of circulating monoclonal paraproteins. HIV, hepatitis B (which may reactivate with lymphoma therapy), and hepatitis C serologies should be performed. Serum beta-2 microglobulin can be useful as a surrogate marker of disease burden in indolent NHLs. Serum concentrations of LDH are an important independent predictor of survival. Isolated Waldeyer's ring involvement is associated with intestinal involvement in 20% of cases and endoscopy should be considered. Chest, abdominal, and pelvic computed tomography scan is essential for accurate staging. Unilateral bone marrow biopsies should be performed in most subtypes of lymphoma, as the likelihood of lymphomatous involvement of the marrow is relatively high, especially in most indolent lymphomas. Recently, the role of BM biopsy in DLBCL is being questioned. In a recent analysis of patients with DLBCL undergoing initial staging with PET-CT scanning, the sensitivity and specificity of PET scanning for marrow involvement was 89% and over 99%, respectively. BM biopsy should still be performed in patients with a negative PET scan, but of limited utility in patients with a positive scan showing BM involvement.¹⁰⁶ In patients with aggressive lymphomas with marrow involvement, paranasal sinus involvement, paraspinal masses, testicular, or if clinically indicated, examination of the cerebral spinal fluid (CSF) by lumbar puncture should be performed. Positron emission tomography, PET, using ¹⁸F-fluorodeoxyglucose is a highly sensitive and specific scanning modality for detecting NHL in both nodal and extranodal sites. PET scanning is very useful for DLBCL, MCL, and FL and is now recommended in the initial staging of these entities. PET scanning is not as sensitive in SLL and MZL.¹⁰⁷ The International Harmonization Project has provided consensus recommendations for PET scanning. Among the recommendations are the following: PET should be used for DLBCL and HL; scanning during therapy should still be only part of clinical trials; and the scan after all therapy is completed can be done at least 3 but preferably 6–8 weeks after chemotherapy and 8–12 weeks after radiation or chemoradiotherapy. There is no evidence that long-term follow-up should include PET scanning.¹⁰⁸ Magnetic resonance imaging is most valuable for evaluation of the brain and spinal cord.

Immunologic and molecular studies

Biologic studies including cell surface markers, cytogenetics, and molecular techniques are used in diagnosis, staging, and minimal disease detection. Monoclonal antibodies directed against cell surface antigens expressed on lymphoid cells and molecular techniques to define immunoglobulin and TCR gene rearrangements are sensitive tools with which to assess tumor cell infiltration. Immunophenotypic and cytogenetic studies can help to determine histologic subtypes of lymphomas. For those NHLs with known chromosomal translocations, it is possible to identify unique chromosomal breakpoints that can be studied with FISH, cytogenetics, and PCR. Studies of minimal disease may provide important prognostic information.

Disease parameters that influence prognosis and assessment of disease response

Prognostic factors in NHL

Aggressive NHLs

Clinical prognostic models have been developed for a number of NHL subtypes. The analysis of a large group (2031 patients) with diffuse aggressive NHLs treated with an anthracycline containing regimen led to the establishment of a prognostic model of predicting outcome known as the International Prognostic Index (IPI) (Table 4).¹⁰⁹ Of a large number of factors examined for all patients, age (≤ 60 vs >60), serum LDH (\leq normal vs $>$ normal), performance status (PS) (0 or 1 vs 2–4), stage (I or II vs III or IV), and extranodal involvement (\leq site vs >1 site) were independently prognostic for OS. The 5-year OS rates for patients with scores of 0–1, 2, 3, and 4–5 were 73%, 51%, 43%, and 26%, respectively. The IPI has been adapted following treatment with rituximab and cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) therapy for DLBCL. Within that model, the 4-year progression-free survival (PFS) is 94%, 80%, and 53% for 0 and 1, 2, and 3 or more risk factors, respectively.¹¹⁰

Table 4 International Prognostic Index (IPI)

International Prognostic Index (IPI)				
Age > 60 years				
LDH > upper limit normal				
ECOG performance status ≥ 2				
Ann Arbor stage III or IV				
Number of extranodal disease sites > 1				
# Factors	Risk group	3-year EFS (%)	3-year PFS (%)	3-year OS (%)

Follicular NHL

A predictive model based on over 4000 patients with FL in the prerituximab era, known as the Follicular Lymphoma International Prognostic Index (FLIPI) score, identified the following prognostic factors: age > 60 ; stage III/IV; more than four nodal sites; elevated serum LDH concentration; and hemoglobin (Hgb) < 12 . The 10-year survival rates for patients with 0–1, 2, and 3 or more risk adverse factors averaged 71%, 51%, and 36%, respectively (Table 5).¹¹¹ The FLIPI remains clinically relevant with rituximab-based therapy.¹¹² For other NHLs, prognostic models have been developed from uniformly treated patient populations. The mantle cell lymphoma International Prognostic Index (MIPI) includes age, PS, LDH, and WBC as prognostic factors.¹¹³ The proliferation index alone as well as when incorporated into the MIPI provides additional prognostic utility.¹¹⁴ Several prognostic models for PTCL NOS have been reported, but generally the IPI provides a reasonable stratification of outcome, with low-risk patients having a 55% 2-year OS and high-risk patients a $< 15\%$ 2-year OS.¹¹⁵

Table 5 Follicular Lymphoma International Prognostic Index (FLIPI)

Age > 60 years

Gene expression profiling as prognostic factors

GEP using DNA microarrays has been used to examine DLBCL to identify prognostic subgroups.^{58–60, 116} DLBCLs may be subclassified into GCB or ABC types. Patients with GCB DLBCL had significantly better OS than those with the ABC type. On the basis of the findings from gene expression profiling, immunohistochemistry using tissue microarrays has been used for a limited number of gene products as prognostic markers.¹¹⁶ Germinal center and non-GCB derivation can be determined by expression of CD10 and bcl-6, and MUM1. Using tissue microarrays, 42% of DLBCLs are considered GCB derivation and 58% are non-GCB derivation.

In FL, gene expression profiling has shown that genes associated with the nonmalignant cell infiltrate segregate patients into subgroups with favorable and unfavorable prognoses. Immune response 1 signature (gene associated with certain T-cell and macrophage markers) was favorable, whereas immune response 2 signature (genes highly expressed in macrophages) was unfavorable.¹¹⁷ Gene expression profiling in MCL patients has identified the proliferation signature and high expression of cyclin D1 as being associated with an unfavorable prognosis.¹¹⁴

Therapeutic approaches according to WHO classification

Indolent lymphomas

Therapy of early stage indolent lymphoma

Ten to twenty percent of patients with indolent lymphoma present with stage I/II disease, and patients with all histologic subtypes, should be considered for local radiotherapy (RT) treatment with curative intent. In a study of 177 patients from Stanford (44% stage I and 56% had stage II), the majority of whom were treated with involved or extended field RT¹¹⁸ experienced OS rates at 10, 15, and 20 years of 64%, 44%, and 35%, respectively. The relapse-free survival rates at 10, 15, and 20 years were 44%, 40%, and 37%, respectively. In a recent report of over 6000 patients with stage I or stage II FL, 34% of whom were initially treated with RT, patients who received initial RT had higher rates of disease-specific survival at 5 (90% vs 81%), 10 (79% vs 66%), 15 (68% vs 57%), and 20 (63% vs 51%) years.¹¹⁹ A recent

retrospective analysis suggested an improved PFS outcome with chemoimmunotherapy or systemic therapy plus RT as compared to RT alone, with no impact on OS.¹²⁰ In a small, retrospective study, observation, that is, no immediate treatment, has been reported as an alternative, especially for stage II patients,¹²¹ with a median OS of 19 years. At a median follow-up of 7 years, 63% of patients had not required treatment.

The extranodal MZLs often present with localized disease involving the gastrointestinal tract, salivary glands, thyroid, orbit, conjunctiva, breast, and lung. In patients with *H. pylori*-associated gastric MZL, therapy with antibiotics and a proton pump inhibitor induces disease regression in over 80% of patients with good long-term disease control and OS in a subset.^{122–124} The presence of bcl-10 nuclear expression and/or t(11;18) may be useful to prospectively identify those patients with gastric MZL lymphomas who do not benefit from anti-*H. pylori* treatment.¹²⁵ Antibiotic therapy (doxycycline) against *Chlamydophila* has been reported with variable results in ocular MZLs.⁸ Single-agent rituximab has an overall response rates (RRs) of 87% for treatment naive patients.¹³⁰

For patients with localized disease who progress after antibiotic therapy or are *H. pylori* negative, involved-field RT with or without surgical resection has a 10-year disease-free survival of over 90%.^{126, 127} For other sites of extranodal MZL, surgery remains a highly effective approach, often with adjuvant involved-field RT, as these diseases tend to remain localized for long periods of time before systemic spread. In a retrospective study of patients with stage IE or IIE MZL, most were treated with involved-field radiation therapy alone.¹²⁸ The 5-year disease-free and OS for the entire group was 76% and 96%, respectively. Patients with gastric and thyroid disease had 5-year disease-free survival of 93%, whereas disease-free survival for other sites of involvement was 69% ($p = 0.006$). For MZL, the RR for chemotherapy with alkylating agents, fludarabine or rituximab alone, is high.^{129, 130}

Treatment of advanced stage indolent NHL

Asymptomatic patients with low-volume disease can be monitored closely without active therapy. The long natural history of indolent NHLs and the lack of symptoms in some patients at diagnosis have fostered close observation as the initial approach to many of these patients. In studies from Stanford and the British National Lymphoma Investigation¹³¹ where asymptomatic patients were randomized either to initial therapy or to deferred treatment until the time of symptoms (usually progressive bulky disease), there was no difference in the actuarial survival between the two groups. In the Stanford study, the median time until therapy was needed was 3 years.¹³² “Watchful waiting” versus observation has been studied in the rituximab era. A prospective study compared observation to rituximab alone or rituximab followed by maintenance in previously untreated FL. The median time to next treatment was 34 months in the watch-and-wait patient but was not reached in the rituximab treatment arm. The 3-year PFS was 33%, 80%, and 90% for patients who underwent observation, rituximab alone, and rituximab with maintenance respectively, with 95% OS in all three groups.¹³³

The treatment paradigm for treating advanced stage FL has changed with the use of rituximab. Phase III randomized trials have demonstrated a significant improvement in outcome by combining chemotherapy regimens with rituximab.^{134–138} All of these studies demonstrated improved RRs, and time to progression in the rituximab containing arms, and improvement in OS.

Other regimens have been compared to rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) in an effort to improve efficacy and reduce toxicity. Bendamustine-R (BR) was compared to R-CHOP in a phase III randomized trial that included predominantly FL and also mantle cell

and MZLs.¹³⁹ The median PFS was superior with BR (69.5 months vs 31.2 months) at 45 months without difference in OS. In addition, BR had less toxicity, including lower rates of grade 3/4 neutropenia and leukopenia. Phase II trials employed rituximab alone as initial therapy in patients with indolent lymphoma with overall RRs of 54–73%.^{140–142} At a median follow-up of 30 months, median PFS was 34 months in one of the trials. Moreover, extended treatment with rituximab increased event-free survival (EFS) twofold compared to observation.¹⁴² For patients who were treatment naive, 45% were progression free at 8 years with abbreviated maintenance rituximab.¹⁴³ Radioimmunotherapy was studied in previously untreated patients with FL. ⁹⁰Yttrium-ibritumomab-tiuxetan and ¹³¹I tositumomab (no longer available) yield excellent results in phase II studies, but the benefit compared to rituximab has not been evaluated.^{144,145} In a randomized trial comparing R-CHOP to CHOP followed by ¹³¹I tositumomab, no differences in PFS was seen between the two arms.¹⁴⁶

Maintenance rituximab after chemoimmunotherapy has been studied in a large phase III trial.¹⁴⁷ In the primary rituximab and maintenance (PRIMA) trial, maintenance rituximab as compared to observation improved PFS, but to date no impact of OS was seen with maintenance in previously untreated FL patients who responded to chemoimmunotherapy [R-CVP, R-CHOP or fludarabine, cyclophosphamide, mitoxantrone, and rituximab (FCM-R)]

Treatment for other indolent lymphomas

Patients with other indolent NHLs besides FL, including nodal and extranodal MZL, are generally treated similarly to FL. Patients with SLL are treated with chemoimmunotherapy regimens used for chronic lymphocytic leukemia (see [Chapter 117](#)). In the R-CHOP versus BR study, no difference in PFS was seen for MZLs. For lymphoplasmacytic lymphomas, regimens include dexamethasone, rituximab, cyclophosphamide,¹⁴⁸ BR, bortezomib, and rituximab with or without dexamethasone.¹⁴⁹ For dexamethasone, rituximab, and cyclophosphamide, the overall and complete RRs were 83 and 7%, respectively, and 2-year overall and PFS rates 81% and 67%, respectively. Patients with splenic MZL often benefit from splenectomy with excellent symptom management and improvement in cytopenias.¹⁵⁰ Single-agent rituximab and chemoimmunotherapy have high RRs and 5-year PFS over 90%.¹³⁰

High-dose therapy and autologous stem cell transplantation (ASCT) have been used in first remission for patients with FL^{151–156} with an increased risk of second malignancies including MDS/AML and solid tumors. The majority of the randomized trials preceded use of rituximab and reported a significant improvement in PFS, but no OS benefit.¹⁵⁷

Following relapse, indolent lymphomas continue to be sensitive to single agents including rituximab alone and combination chemotherapy; but the median relapse-free survival with chemoimmunotherapy progressively decreases with each subsequent relapse. A recent update of single-agent rituximab therapy in patients with relapsed FL is from the randomized SAKK trial. Martinelli et al.¹⁴³ found that 35% of responders remain in remission at 8 years. However, it remains uncertain as to whether the response data to single-agent rituximab is as high or durable as in patients who received chemotherapy without rituximab as induction therapy.

A phase II trial of rituximab in patients with relapsed indolent NHL¹⁵⁸ yielded overall RR of 40%, with 11% complete remissions and estimated median time to progression of 18 months. Rituximab has been combined with other agents with reasonable results in patients with relapsed/resistant disease. A phase III study in relapsed FL patients who had not previously received an anthracycline or rituximab¹⁵⁹ randomly assigned patients to CHOP versus R-CHOP. Responding patients underwent a second randomization to

maintenance rituximab (375 mg/m² IV once every 3 months) for a maximum of 2 years or observation. The overall (85% vs 72%) and complete (30% vs 16%) remission rates as well as PFS (33 months vs 20 months) were significantly higher in the R-CHOP. The median PFS from the time of second randomization was longer for those receiving rituximab maintenance (52 months vs 15 months), regardless of induction regimen. Moreover, maintenance rituximab, as compared with observation, also significantly improved 3-year OS (85% vs 77%). A number of phase II trials of other agents plus rituximab associated with high RRs included BR with 90% RR and median PFS of 2 years.^{160, 161}

Radioimmunoconjugates have been FDA-approved therapies for patients with relapsed follicular NHL. 90-yttrium ibritumomab has an 82% RR with 26% complete responses (CRs) and median duration of response >12 months in patients with relapsed disease.¹⁶² In a phase III study of 143 patients with relapsed or refractory low-grade, follicular, or transformed NHL, the overall RRs to rituximab or the rituximab 90-yttrium ibritumomab tiuxetan combination were 56% and 80%, respectively.¹⁶³ As in the upfront setting, the role for radioimmunotherapy in the treatment paradigm of indolent lymphoma remains uncertain. The PI3K delta isoform-specific inhibitor idelalisib was recently approved for use in relapsed follicular and small lymphocytic lymphoma with overall RRs of 57% and median duration of response of 12.5 months.¹⁶⁴

FL is responsive to low-dose radiation therapy (e.g., total dose of 4 Gy, given as 2 consecutive daily 2 Gy fractions) and can be used for the palliation of patients for an isolated disease site, with CR rates of 57% and overall RR of 82% with respectable durability.¹⁶⁵

Autologous stem cell transplantation for relapsed indolent NHL

Long-term follow-up of phase II studies suggest that a subset of patients with relapsed FL, with chemosensitive disease, who undergo high-dose therapy and ASCT are long-term survivors with disease-free survival of 48% at 12 years.^{71, 144, 166} A randomized trial compared conventional chemotherapy to ASCT with purged or unpurged bone marrow, referred to as the European CUP trial.¹⁶⁷ In this study, 89 patients with relapsed or progressive FL received three cycles of CHOP. Those patients who achieved a CR or PR, and had <20% bone marrow involvement with FL, were randomized to three further cycles of CHOP chemotherapy or to high-dose therapy and autologous stem cell support with anti-B-cell antibody purging or high-dose therapy and autologous stem cell support without purging. At a median follow-up of 69 months, the overall 5-year survival for all registered patients was 50%, but the median survival had not yet been reached for the subset of patients treated with high-dose therapy and ASCT (either purged or unpurged). Both PFS and OS favored the transplantation arms, but there was no difference between those patients receiving a purged autograft and those receiving an unmanipulated graft.

Allogeneic stem cell transplantation in relapsed FL

Both myeloablative and reduced intensity conditioning (RIC) approaches have been employed for relapsed FL patients. Myeloablative conditioning has a treatment-related mortality of up to 40%; however, the relapse rate is <20%.¹⁶⁸ In contrast, RIC alloSCT has lower treatment-related mortality,^{169–171} but some reports suggest that the relapse rate may be higher than conventional myeloablative conditioning. The role of alloSCT versus ASCT for FL remains uncertain. A recent NCCN database retrospective analysis found significantly higher 3-year OS for ASCT versus alloSCT (87% vs 61%).¹⁷² For selected patients, alloSCT remains a potentially curative option for relapsed FL.

Histologic transformation

The prognosis for patients following histologic transformation of indolent NHL is generally poor, particularly in previously treated patients.¹⁷³ The median survival of a large series of patients with FL undergoing histologic conversion was 11 months.¹⁷⁴ In a report from Stanford, the median survival for the entire group of patients was only 22 months, except for patients who achieved a CR with treatment who had an actuarial survival of 75% at 5 years.¹⁷⁵ There have been several reports of ASCT in patients after histologic transformation for FL. The DFS is about 40–50%, and patients can relapse with both DLBCL and FL.^{176–179} Aggressive therapy with ASCT is a reasonable treatment option for selected patients who have chemosensitive disease.

Aggressive lymphomas

The aggressive lymphomas within the WHO classification include diffuse large B cell, the PTCLs (nonspecified and the specific subtypes), ALCL, and MCL ([Table 2](#)).

Therapy of early stage aggressive lymphoma

Fewer than 20% of patients with diffuse large-cell lymphoma have truly localized disease. The recommended treatment for localized disease outside of clinical trials is abbreviated chemotherapy plus involved-field RT, or combination chemotherapy alone. A SWOG randomized trial of patients with localized diffuse aggressive lymphoma compared eight cycles of CHOP to three cycles of CHOP plus involved-field RT. Patients treated with three cycles of CHOP plus RT had a significantly better 5-year PFS and OS than patients treated with eight cycles of CHOP (77% vs 64% for PFS, 82% vs 72% for OS).¹⁸⁰ The benefit of attenuated chemotherapy was largely found in patients over the age of 60. Another randomized trial studied eight courses of CHOP with or without involved-field RT in patients with previously untreated bulky or extranodal stage I or II diffuse aggressive NHL. The disease-free survival was greater for CR patients who received RT (73% vs 56%), although 10-year OS was similar in the two treatment arms (68% vs 65%).¹⁸¹ The role of radiation therapy remains uncertain in some patients with stage I or II disease. In patients aged 60 or less with low-risk disease, an aggressive regimen (ACVBP) was superior to CHOP plus RT.¹⁸² Similarly, in patients over age 60, the addition of radiation therapy did not improve disease-free or OS for patients who received four cycles of CHOP alone.¹⁸³ These studies raise the question of the necessity of RT for patients with early stage disease. A phase II trial of patients with early stage DLBCL with at least one risk factor (age >60; increased serum LDH; stage II disease; or performance status ≥ 1) utilized three cycles of R-CHOP followed by involved-field radiation therapy.¹⁸⁴ The PFS and OS at 2 and 4 years were 93% and 88%, and 95% and 92%, respectively. A phase III study in patients age 60 or under with IPI score of 0 or 1 compared six cycles of CHOP to R-CHOP, with all patients with bulky disease (masses >7.5 cm) or extranodal sites receiving involved-field radiation. For the patients with IPI score of 0, with no bulk, and includes early stage patients, the 5-year EFS was approximately 90% with R-CHOP alone, suggesting chemoimmunotherapy alone is an option for early stage disease. However, bulky disease, defined as masses >7.5 cm, was associated with inferior outcome. In the MiNT trial of CHOP versus R-CHOP, all patients (IPI 0 or IPI 1) with masses >7.5 cm received 30–40 Gy of involved-field radiation to those sites. Those patients with IPI of 0 and bulky disease had a 10–15% lower PFS than patients without bulky.¹⁸⁵ In the UNFOLDER trial of a similar patient population, early data suggests a benefit for RT after chemotherapy. Presently the most appropriate management of patients with early-stage DLBCL with bulky disease remains controversial.

PMLBCL patients often present with early stage disease, and historically patients have received combined modality therapy. In the MiNT trial, 87 patients with PMLBCL¹⁸⁶ received six cycles of R-CHOP, 75% of whom also received radiation therapy; only 7% of patients who received radiation

subsequently progressed or relapsed. A recent study of 51 patients treated with dose adjusted EPOCH plus rituximab (DA-EPOCH-R), and no RT, reported an outstanding PFS (93%) and OS (100%).¹⁸⁷ In terms of the needs for radiation, a recent study reported that a negative PET-CT scan at the end of therapy was associated with an excellent outcome in the absence of radiation.¹⁸⁸

Extranodal NK/T-cell lymphomas present with early stage disease in 97% of cases. The 5-year OS and PFS for patients with stage IE disease were 78% and 63%, respectively, and for stage IIE, the OS and PFS were 46% and 40%, respectively, with no difference between combined modality and RT alone.¹⁸⁹ For patients with stage IE/IIE, early use of RT (50–55 Gy) is critical, whereas chemotherapy initially followed by RT yields inferior results. More recent studies suggest that combined modality treatment may yield more favorable results. Phase II trials of concurrent radiation therapy and weekly cisplatin followed by etoposide, ifosfamide, cisplatin, and dexamethasone reported overall RR of 83% and 3-year PFS and OS of 85 and 86%, respectively.^{190, 191}

Therapy of advanced stage aggressive lymphoma

The current recommendation for treatment of advanced stage DLBCL or PTCL, outside a clinical trial, is combination chemotherapy with R-CHOP or CHOP, respectively. Recent clinical trials have evaluated the number of cycles and the interval for those cycles. In patients with DLBCL ages 60–80, the GELA group reported that eight cycles of R-CHOP was superior to CHOP alone in terms of PFS, DFS, and OS.^{192, 193} In a US Intergroup study of CHOP versus R-CHOP in patients over 60,¹⁹⁴ responding patients were randomly assigned to receive either rituximab maintenance therapy or no maintenance. A beneficial impact of rituximab added to CHOP chemotherapy on event-free and OS was observed; however, no benefit was seen for maintenance rituximab following R-CHOP induction. Similarly, in patients <60, R-CHOP with IPI of 0 and 1, the addition of rituximab to CHOP improved time-to-treatment failure and OS. This benefit was greater in the patients with an IPI of 1.¹⁸⁵

In the RICOVER trial, in patients over age 60, R-CHOP was superior to CHOP given for six or eight cycles (70% vs 57%), and there was no benefit of eight cycles of R-CHOP over six cycles.¹⁹⁵ In another study, R-CHOP given every 21 days (R-CHOP 21) for eight cycles was compared to six cycles of R-CHOP given every 14 days with no difference in PFS or OS.¹⁹⁶ This supports R-CHOP 21 for six cycles as the standard of care. Alternatives to R-CHOP have been examined in phase III trials. The aggressive regimen R-ACVBP followed by consolidation with methotrexate and leucovorin.¹⁹⁷ was compared to R-CHOP plus intrathecal methotrexate in patients under age 60 with IPI score of 1. R-ACVBP plus methotrexate and leucovorin led to higher PFS and OS. The benefit was seen in the non-GCB subgroup of patients.¹⁹⁸

Testicular DLBCL

Historically, the long-term results of treatment of primary testicular DLBCL are worse than predicted by the IPI.^{199, 200} Current therapy has been defined by a report of 53 patients with untreated stage I or II primary testicular lymphoma treated with six to eight cycles of R-CHOP 21, four weekly doses of intrathecal methotrexate (12 mg), and radiation therapy to the contralateral testis (30 Gy) for all patients and (30–36 Gy) to regional nodes for patients with stage II disease.¹⁹⁹ With a median follow-up of 65 months, the OS and PFS at 5 years were 85% and 74%, respectively.

Prophylaxis for CNS disease in DLBCL is highly controversial.²⁰¹ In the prerituximab era, the risk of CNS involvement was 2.8%, with intraparenchymal and intraspinal disease occurring in 66%, and isolated leptomeningeal disease in 26%.²⁰² Risk factors include the sites of disease (the testis, the ovary,

the bone marrow, the breast, the epidural space, the kidneys, the adrenals, and the paranasal sinuses); high-intermediate or high IPI score; multiple extranodal sites; and “double-hit” cytogenetics. With the significant number of parenchymal relapses, intrathecal chemotherapy alone may be inadequate prophylaxis, making high-dose methotrexate a potentially more effective therapy. However, there is no strong evidence that high-dose methotrexate is superior to intrathecal.

The treatment of the subtype of the new WHO entity B-UNC/BL/DLBCL is uncertain.^{203, 204} There is retrospective evidence that intensive regimens such as modified Magrath regimen with CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate with ifosfamide, cytarabine, etoposide, and intrathecal methotrexate), HyperCVAD, and DA-EPOCH-R had better outcomes than R-CHOP (ORR 86% vs 57%, 4-year PFS approximately 50–65% vs 0–30%).²⁰⁵ Those cases with c-myc translocations are associated with a particularly poor prognosis. Data of MYC translocation-positive DLBCL treated with DA-EPOCH-R on the National Cancer Institute phase II studies is promising.²⁰⁶ This regimen is currently being explored further in BL and MYC translocation-positive DLBCL in a multicenter trial. The entity B-UNC/BL/DLBCL is heterogeneous, but for double-hit lymphomas, many of which are B-UNC/BL/DLBCL, R-CHOP is insufficient.

For PTCL, similar treatment approaches to DLBCL have been taken for patients with localized and advanced stage disease. When patients are stratified by the IPI, the disease-free survival and OS are generally inferior for patients with PTCL than for patients with DLBCL. There is presently no overwhelming evidence to support superiority of different treatment regimens for PTCL.²⁰⁷ A retrospective subset analysis of a phase III study in PTCL patients of CHOP versus CHOP with etoposide showed a significant improvement in EFS for PTCL patients younger than age 60 with a normal LDH at diagnosis, but there was no difference in OS.¹¹⁵ ALCL has the most favorable prognosis of the T-cell lymphomas.⁹¹ The prognosis for patients who express the ALK protein is particularly favorable with 5-year OS of 79%.⁸⁸ The anti-CD30 monoclonal-drug conjugate, brentuximab, is being examined in the initial treatment of ALCL given its strong activity in relapsed CD30+ ALCL.

Autologous stem cell transplantation for aggressive NHL in first remission

Several studies have not shown clear evidence for a survival benefit for high-dose therapy and ASCT in first CR/PR for patients with aggressive NHL.^{208, 209} A meta-analysis of 3079 patients treated in the prirituximab era on 15 randomized trials with either conventional therapy or ASCT in first CR showed no difference in EFS, OS, or treatment-related mortality.²¹⁰

Given the generally inferior prognosis of patients with PTCL, autologous SCT has been investigated in first remission in several phase II studies with encouraging results.^{211, 212}

Mantle cell lymphomas (MCL)

With the advent of chemoimmunotherapy, the median survival of patients with MCL is now 3–6 years.²¹³ R-CHOP has been historically the regimen of choice for MCL. A randomized trial comparing R-CHOP to bendamustine plus rituximab (BR) reported superior PFS with BR with less toxicity (35 months vs 22 months).¹³⁹ Another study of R-CHOP versus FCR (fludarabine, cyclophosphamide, rituximab)²¹⁴ in patients over age 60 yielded similar CR rates, but R-CHOP had less toxicity; the OS at 4 years was 62% versus 47% in favor of R-CHOP.²¹⁴ A second randomization of maintenance with interferon- α or rituximab was given until progression. For the patients who received R-CHOP, a survival benefit from maintenance rituximab was observed (OS rate at 4 years of 87% vs 63%).

Autologous transplant for patients <65, in first CR or PR, has shown improvement in PFS as compared to interferon- α maintenance and a nonstatistically significant improvement in OS.²¹⁵ Many phase II studies have intensified the induction therapy before ASCT. Incorporation of high-dose cytarabine²¹⁶ has given excellent results, with median OS and response duration longer than 10 years and a median EFS of 7.4 years.

HyperCVAD is an intensive regimen, with escalated doses of cyclophosphamide, high-dose methotrexate, and cytarabine. It is an alternative to ASCT for patients in first remission as a way to prolong remissions in MCL. The MD Anderson reported that a median OS was not reached at 8 years, and a median time to failure was 4.6 years.²¹⁷ Two multi-institution trials of R-HyperCVAD reported excellent disease control but a significant proportion of patients could not complete the proscribed treatment due to toxicity.^{218, 219}

The vast majority of patients are with MCL relapse. Three agents are FDA approved for relapsed MCL; bortezomib, lenalidomide, and ibrutinib. Bortezomib has a 29% overall RR (5% CR) with a median duration of 7 months.²²⁰ Lenalidomide, approved for bortezomib failures, has a 26% RR (7% CR) and median duration of response of 17 months.²²¹ Ibrutinib has a 68% RR (21% CR), with a median duration of 17.5 months.²²² Idelalisib has activity with a 40% RR.²²³ ASCT for relapsed MCL patients is of limited benefit.²²⁴ Nonmyeloablative alloSCT can be considered for select relapsed patients. The 3-year PFS and OS are 30% and 40%, respectively.²²⁴

High-grade lymphomas

Lymphoblastic, Burkitt's lymphomas

The treatment of LBL is detailed in [Chapter 117](#).

BL treated with CODOX-M/IVAC, designed for pediatric populations, yields 2-year OS of 82% for low-risk patients and 70% for high-risk patients.^{225, 226} Similar results have been seen with HyperCVAD.²²⁷ A study of DA-EPOCH-R reported excellent results with freedom from progression of 95% and OS of 100%, at a median follow-up of 86 months.²²⁸ There is presently no evidence that first remission autologous transplant is indicated for adult BL.²²⁹

Adult T-cell leukemia/lymphoma

ATLLs are approached with intensive multiagent chemotherapy regimens.²³⁰ Antiviral therapy with zidovudine and interferon- α should be considered upfront for the smoldering, chronic subtype.^{230, 231} For the acute leukemia lymphoma type, a phase III randomized trial²³² reported that an intensive regimen (VCAP-AMP-VECP) had a 3-year OS of 24% compared to only 13% with CHOP. With the poor results of chemotherapy, both myeloablative and reduced intensity alloSCT have been applied to ATLL, with limited success.^{233, 234}

Treatment of recurrent aggressive NHL

The majority of recurrences from chemoimmunotherapy are within the first 2 years after treatment.²³⁵ Following relapse, about 60% of patients' disease remains sensitive to conventional treatment, but <10% of patients with aggressive NHL experience prolonged disease-free survival with second-line treatment regimens. Following relapse, the current curative approach for patients with relapsed NHL involves high-dose therapy and stem cell transplantation.

Conventional salvage therapy

The vast majority of patients with relapsed or refractory DLBCL have limited benefit from conventional salvage regimens with duration of responses and OS of approximately 6 months. Several combination chemotherapy regimens have been compared in randomized trials with equivalent results. Specifically, rituximab plus ifosfamide, carboplatin, and etoposide yield similar results to rituximab plus dexamethasone, cytarabine, and platinum, which is equivalent to rituximab plus gemcitabine, dexamethasone, and platinum.^{236–239} The goal is to identify patients with chemosensitive disease who have the greatest likelihood of benefiting from high-dose therapy and ASCT.

Recurrent PTCL has a very poor prognosis, with a median OS of 6.7 months.²⁴⁰ Gemcitabine and other conventional chemotherapies have limited benefit.²⁴¹ Newer agents for relapsed PTCL, including the antifolate agent pralatrexate, and HDAC histone deacetylase romidepsin and belinostat, all have a 25–30% RR with median durations of response <18 months.^{242, 243} Nonmyeloablative alloSCT for highly selected patients has a 5-year OS and PFS of 50% and 40%, respectively.²⁴⁴

Autologous stem cell transplantation for relapsed aggressive NHL

Disease sensitivity at the time of ASCT has remained the most significant prognostic variable for predicting treatment outcome. Several large series have shown that patients who undergo ASCT with primary refractory disease have less than a 10% probability of disease-free survival. Those relapsed patients whose disease remains sensitive to chemotherapy have a 30–60% probability of long-term disease-free survival. In contrast, only 10–15% of patients with resistant disease are long-term survivors.

ASCT has been compared to conventional salvage therapy for relapsed aggressive NHL in the PARMA trial.²⁴⁵ Patients with relapsed aggressive NHL (largely DLBCL) received two cycles of cisplatin, cytarabine, and solumedrol and if responsive, were randomized to continued chemotherapy for four additional cycles or high-dose chemotherapy and autologous bone marrow transplantation. With median follow-up in excess of 5 years, patients randomized to the high-dose arm and autologous bone marrow transplantation had superior EFS (46% vs 12%) and OS (53% vs 32%).

Investigators have to date failed to improve on these results with the addition of maintenance therapy post-transplant with rituximab,²⁴⁶ an anti-CD19 immunotoxin, the oral kinase inhibitor enzastaurin, or adding radioimmunotherapy²⁴⁷ to the conditioning regimen. For patients with relapsed or refractory DLBCL, high-dose therapy and ASCT remains the treatment of choice for patients with chemosensitive disease. If the recurrence is localized, adjuvant RT either before or after high-dose therapy and ASCT may be beneficial in terms of disease control but may not impact on OS. For patients with chemorefractory disease, clinical trials or palliative therapy, but not stem cell transplantation, should be considered. Several new agents have shown some promise in patients with relapsed DLBCL, including ibrutinib, particularly in the ABC subtype, as well as lenalidomide, and everolimus.

Allogeneic stem cell transplantation in NHL

Allogeneic stem cell transplantation has been applied to patients with relapsed and refractory NHL. Nearly all patients had relapsed disease, many of whom were resistant to conventional dose therapy. In the European Bone Marrow Transplant registry, the recurrence rate after allogeneic transplantation for aggressive NHL was lower than for autologous transplantation without difference in OS, owing to the associated higher transplant-related mortality. The EFS and OS at 5 years was 43%, with treatment-related mortality 25% at 1 year. Patients with recurrent disease following ASCT who have good performance status and chemosensitive disease are considered for alloSCT usually with RIC. Studies

have reported 40–60% PFS, at several years, but with treatment-related mortality of 20% for RIC alloSCT and up to 40% for myeloablative transplants.^{248, 249}

New therapeutic approaches for NHL

Significant improvements have been made in the treatment of NHL, with the major impact in B-cell malignancies. However, less progress has occurred in therapy of many disease entities, such as PTCLs and relapsed and refractory DLBCL. There are a vast number of new, rational targeted agents under evaluation including antibody drug conjugates, kinases inhibitors, and immunotherapies that enhance T-cell cytotoxicity (chimeric antigen receptor T cells and checkpoint blockade antibodies). The most significant advance is our understanding of the genetic events and aberrant pathways driving lymphomagenesis. This knowledge drives the development of agents directed against novel targets, thereby limiting toxicity to normal cells.

Chapter 120

Mycosis fungoides and Sézary syndrome

Richard T. Hoppe, MD ■ Youn H. Kim, MD ■ Ranjana H. Advani, MD

Overview

Mycosis fungoides/Sézary syndrome (MF/SS) is the most common cutaneous T-cell lymphoma. It originates in the skin and its presentation may range from very limited patch disease to wide-spread cutaneous tumors. When there is peripheral blood involvement, usually in conjunction with erythroderma, it is known as the SS. Although patients with limited patch disease have a very long natural history, respond to a variety of topical therapies, and even enjoy a survival similar to age-matched control populations, patients who present with cutaneous tumors or extracutaneous disease have a relentless progressive course of disease. Treatments for patients with limited disease are primarily topical and include topical chemotherapy (nitrogen mustard), radiation therapy, and phototherapy. When the disease is advanced, topical therapies are still often needed, but systemic treatment becomes essential. Conventional chemotherapy (single agent or combination) is often not effective. However, systemic biologics such as histone deacetylase inhibitors, the interferons, photopheresis, alemtuzumab, and brentuximab vedotin may achieve responses. Most recently, hematopoietic cell transplant, especially with nonablative conditioning regimens, has shown promising results in a cohort of patients with advanced MF or SS.

Historical perspective

Mycosis fungoides (MF) was first described by the French dermatologist Alibert. MF/SS (mycosis fungoides/Sézary syndrome) is the most common cutaneous T-cell lymphoma (CTCL). Sézary syndrome (SS) is an erythrodermic, leukemic variant of MF.¹

Incidence and epidemiology

There are <1000 cases in the United States annually.² The median age is 55–60 years; however, younger patients may be affected.³ There is 2 : 1 male predominance, without racial predilection. The etiology is unknown.⁴ There is no evidence to support an association with chemical exposure or any virus.^{5, 6}

Pathology

Abnormal mononuclear “cerebriform” cells infiltrate the epidermis and upper dermis as single cells or clusters (Pautriermicroabscesses). They have a helper T-cell phenotype (CD4+).⁷ Occasional cases are CD8+ (cytotoxic/suppressor T-cell phenotype). Studies indicate monoclonal rearrangements of the T-cell receptors in the skin, lymph nodes, and peripheral blood.⁸ Lymph nodes are classified as LN-0–LN-4 depending on the degree of infiltration of atypical cells.⁹ Potential involvement with clonal cells may be demonstrated even in lymph nodes with only dermatopathic changes.¹⁰

Pathogenesis and natural history

MF may present first in a premycotic phase with nonspecific, slightly scaling skin lesions. Later, patches, plaques, tumors, or generalized erythroderma may develop. The disease is often in a “bathing trunk” distribution. Pruritus is a common symptom. Infiltrated plaques may eventually develop into ulcerating or fungating tumors. Infected tumors may lead to sepsis and death.

Patients with erythroderma have intense pruritus. The complex of erythroderma, lymphadenopathy, and circulating abnormal cells in the blood is known as SS.¹¹ Other presentations include folliculotropic,¹² pagetoid reticulosis,¹³ granulomatous,¹⁴ and hypopigmented.¹⁵

MF is usually indolent,^{16, 17} but 15–20% develop extracutaneous disease, most commonly those with cutaneous tumors or erythroderma.¹⁸ Regional nodes are the most common site of extracutaneous disease but MF may affect the spleen, liver, lungs, and other organs.¹⁹

Diagnosis

Immunophenotyping supports routine histology. T-cell receptor gene rearrangements can be detected by Southern blot analysis^{20, 21} or by methods utilizing polymerase chain reaction (PCR) amplification.^{8, 22} Flow cytometry studies of the blood may show expansion of the CD4+CD7– population reflective of circulating atypical lymphocytes of Sézary type.²³ PCR methods can be helpful in determination of blood²⁴ or lymph node involvement.¹⁰

Patients with limited disease require a good physical examination, careful mapping of skin lesions, complete blood count, Sézary cell detection, screening chemistries, and a chest radiograph. If these are within normal limits, additional studies are unnecessary. Patients with generalized disease should undergo CT (computed tomography) or PET/CT (positron emission tomography and computed tomography) imaging.²⁵ Enlarged nodes should be biopsied but bone marrow is not routinely sampled.

TNMB staging

The TNMB (tumor, node, metastases, blood) staging system for MF/SS²⁶ is summarized in [Tables 1](#) and [2](#).²⁶

Table 1 Tumor-node-metastasis-blood classification for MF

<i>T (Skin)</i>	
T1	Limited patch, papules, or plaques covering <10% of the skin surface
T2	Patches, papules, and/or plaques covering ≥10% of the skin surface
T3	One or more tumors (>1 cm in diameter)
T4	Confluence of erythema >80% of body surface area
<i>N (Nodes)</i>	
N0	No clinically abnormal peripheral lymph nodes; biopsy not required
N1	Clinically abnormal peripheral lymph nodes; histopathology Dutch Gr 1 or NCI LN0–2
N2	Clinically abnormal peripheral lymph nodes; histopathology Dutch Gr 2 or NCI LN3
N3	Clinically abnormal peripheral lymph nodes; histopathology Dutch Gr 3–4 or NCI LN4
NX	Clinically abnormal peripheral lymph nodes; no histologic confirmation
<i>M (Viscera)</i>	
M0	No visceral organ involvement
M1	Visceral involvement (must have pathology confirmation and organ involved should be specified)
<i>B (Blood)</i>	
B0	Absence of significant blood involvement: <5% of peripheral blood lymphocytes (PBL) are atypical (Sézary) cells
B1	Low blood tumor burden: >5% of PBLs are atypical (Sézary), but does not meet criteria for B2
B2	High blood tumor burden: >1,000/mcL Sézary cells with positive clone

Table 2 Clinical staging system for MF/SS

	T	N	M	B
IA	1	0	0	0, 1
IB	2	0	0	0, 1
II	1–2	1, 2	0	0, 1
IIB	3	0–2	0	0, 1
III	4	0–2	0	0, 1
IIIA	4	0–2	0	0
IIIB	4	0–2	0	1
IVA1	1–4	0–2	0	2
IVA2	1–4	3	0	0–2
IVB	1–4	0–3	1	0–2

Prognostic factors and biomarkers

T-classification and presence of extracutaneous disease are the most important prognostic factors for survival ([Figure 1](#)).¹⁸ Patients with limited patch/plaque (T1; stage IA) disease have an excellent survival, similar to an age-, sex-, and race-matched control population.¹⁶ Median survival is >33 years and <10% progress to a more advanced stage.

Figure 1 Disease-specific survival by initial disease stage for 525 patients with MF treated at Stanford University.

Patients with generalized patch/plaque disease without evidence of extracutaneous involvement (T2; stage IB, IIA) have a median survival >11 years.¹⁷ Twenty-four percent develop progressive disease and ~20% die from MF. Patients with cutaneous tumors (T3; stage IIB) or generalized erythroderma (T4; stage III) without extracutaneous disease have median survivals of 3–5 years and the majority will die of MF.²⁷

Patients with extracutaneous disease in lymph nodes (stage IVA) or viscera (stage IVB) have a median survival of <1.5 years.²⁸ The presence of Sézary cells in the peripheral blood usually correlates with more advanced T-classification (usually T4) and the presence of extracutaneous disease.²⁹

Patients may develop cutaneous tumors with atypical lymphocytes comprising >25% of the dermal infiltrate.^{30, 31} This is referred to as large cell transformation. These cells may express CD30, have a high proliferation rate, and share a clonal origin with the pre-existing MF.^{30, 32} These large cells can exhibit variable loss of one or more T-cell-associated antigens.^{30, 31} These patients may have more rapid disease progression and require more intensive therapy.³³

Multidisciplinary care

The National Comprehensive Cancer Network (NCCN) has established consensus guidelines for the therapy of MF and the SS.³⁴ Common skin therapies include corticosteroids, psoralen plus ultraviolet A (PUVA), topical chemotherapy, retinoids, and irradiation. Some patients (10–20%) will require treatment for systemic disease. Treatment selection is based on clinical stage ([Figure 2](#)).

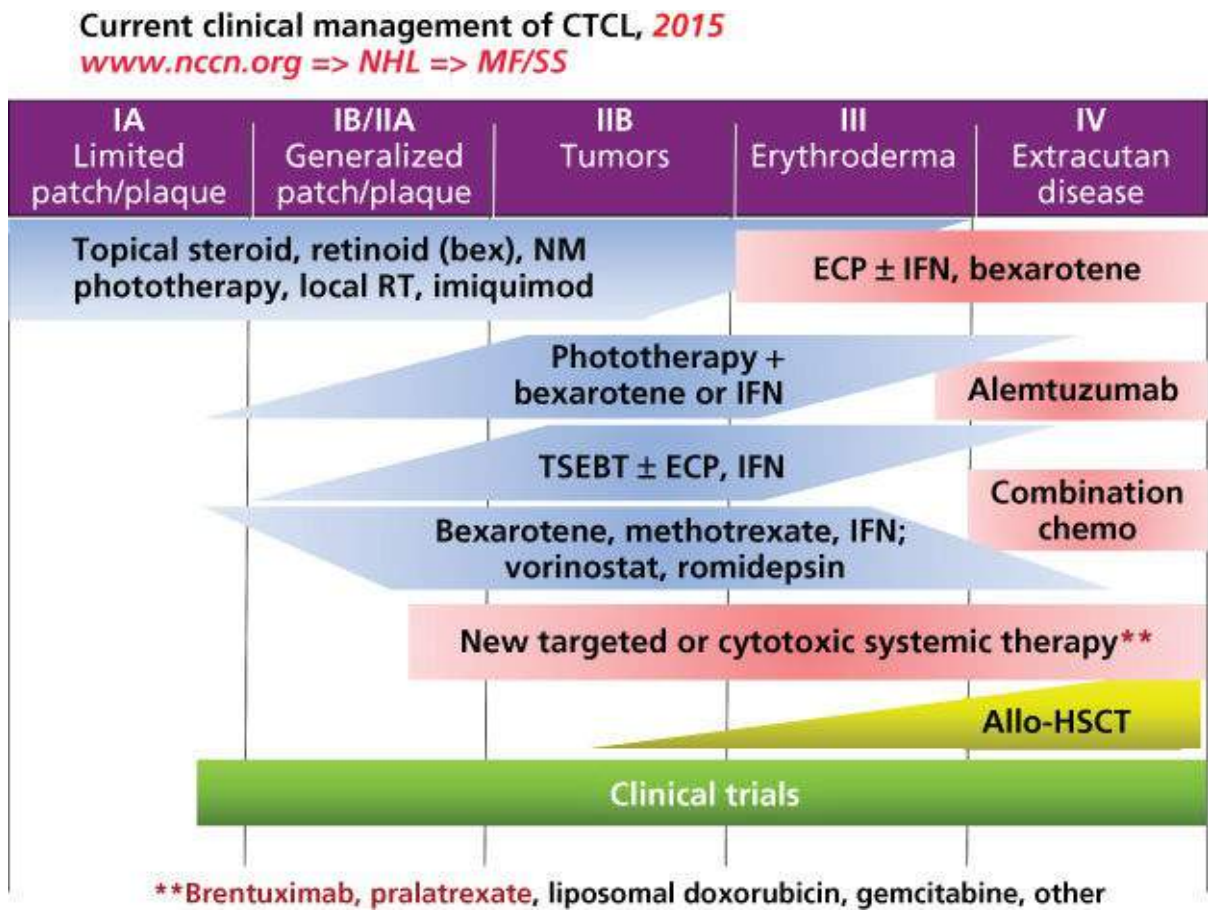

Figure 2 Algorithm for the management of patients with MF/SS.

Topical chemotherapy

Topical nitrogen mustard (mechlorethamine, HN2) is an effective treatment, especially for T1–2 disease.³⁵ The mechanism of action may be its alkylating agent properties together with immune mechanisms/interaction with the epidermal cell–Langerhans cell–T-cell axis. HN2 may be applied locally or to the entire skin. It may be mixed in water, but most often is in a gel or an ointment base. Topical HN2 is applied at least once daily during the clearing phase. Skin clearance may require 6 months or longer and is followed by maintenance. The gel preparation is available commercially in a concentration of 0.02% (Valchlor).³⁶

If response is particularly slow, the concentration of the ointment-based HN2 may be increased or the frequency of application may be increased. The complete response (CR) rate for T1–T2 disease is ~15% and the partial response (PR) rate is ~50%.³⁶ The median time to skin clearance is 6–8 months, and response may be maintained for ≥10 months. Treatment is well tolerated. The primary acute complications include cutaneous hypersensitivity,³⁶ contact dermatitis, skin irritation, and erythema. There is no systemic absorption and it is safe to use even in children.³⁵

Topical retinoids

Bexarotene (Targretin) 1% gel is an RXR-selective synthetic retinoid. It is applied thinly to the patches/plaques twice daily. Owing to its irritant effect, it is used to treat only limited areas. Responses

are seen in the majority of patients with stage IA–IB disease.³⁷ The most common toxicity is local irritation, which occurs in most patients. It may be necessary to withhold therapy a few weeks to assess disease activity. Bexarotene gel is approved for patients with stages IA–IB disease who have refractory or persistent disease after other therapies or who have not tolerated other therapies.

Phototherapy

Phototherapy includes ultraviolet (UV) radiation in the UVA or UVB wavelengths. The long-wave UVA has the advantage over UVB in its greater depth of penetration. For limited disease, UVB alone³⁸ or home UV phototherapy (UVA + UVB)^{38, 39} may be effective. UVB is initiated daily or three times per week with gradual increase in dose. The frequency is gradually reduced during the maintenance period. Narrow-band UVB (nb-UVB) phototherapy is associated with less toxicity than broadband UVB and achieves a CR rate of 68% in stage IA–IIA disease.³⁷ The clinical efficacy of nb-UVB may be superior to broadband UVB.⁴⁰

UVA may be used with a photosensitizing agent, psoralen, as PUVA, referred to as photochemotherapy. In the presence of UVA, psoralen intercalates with DNA, forming monofunctional and bifunctional adducts, which inhibit DNA synthesis. This results in cytotoxic and antiproliferative effects and potential immunomodulatory effects. Patients ingest the psoralen (8-methoxypsoralen) followed by controlled exposure to UVA 1–2 h later. Only the eyes are shielded routinely, but other selected areas can be shielded to minimize undesired photo damage. “Shadowed” areas such as the scalp, perineum, axillae, and other skin folds will not receive adequate exposure.

PUVA treatment is initiated thrice weekly until skin clearance, then the frequency is decreased. Maintenance therapy is discontinued within a year to minimize risks of cutaneous carcinogenesis. The time to skin clearance is 2–6 months. The CR rate is 62% and PR rate 25% in stage IA–IIA disease.³⁷ The duration of response averages ~12 months. PUVA is a primary therapy in stage IA–IIA or a secondary therapy following the failure of other treatments. In patients with SS, PUVA may be supplemented by systemic therapies such as interferon alpha⁴¹ or systemic retinoids.⁴²

The primary acute complication of PUVA is a phototoxic reaction, with erythroderma and blistering, occurring in ~20% of patients.³⁷ Patients should shield their skin and eyes for at least 24 h following psoralen ingestion. The potential long-term complications of PUVA include cataracts and cutaneous malignancies.⁴⁰

Radiation therapy

MF is extremely radiosensitive. Plaques or tumors may be treated with doses of 8 Gy with ~95% likelihood of local control.⁴³ Techniques have been developed to treat the entire skin with electrons (total skin electron beam therapy [TSEBT]).⁴⁴ Patients are treated while standing in multiple positions at an extended distance. Overall response rates (ORR) with doses of 30–36 Gy in 9–10 weeks are nearly 100%, with CR rates of 40–98%, depending on the extent of skin involvement.^{44, 45} TSEBT is most useful for patients with IB–IIB disease. In order to reduce toxicity and duration of therapy and to allow repeat application of TSEBT, low-dose (12 Gy) TSEBT programs have been introduced with an ORR of 88% and CR rate 27%.⁴⁶ The duration of clinical benefit is >16 months.

The complications of high-dose TSEBT include erythema, desquamation, and temporary epilation. Patients also experience temporary loss of their fingernails and toenails and an impaired ability to sweat for up to 12 months. There is an increased risk of secondary skin malignancy. Patients treated with 12 Gy

TSEBT will experience temporary epilation but generally retain their fingernails and toenails, and all other cutaneous effects are much less than with high-dose TSEBT programs.

In patients who have lymph node involvement, traditional megavoltage (4–15 MeV) photon irradiation may be used with doses of 30 Gy in 3–4 weeks to achieve local control.⁴⁴

Systemic chemotherapy

Systemic chemotherapy is appropriate for patients with extracutaneous, advanced, or refractory disease. Virtually, all drugs effective in other lymphomas have been tested in MF/SS. Unfortunately, they often result in only temporary palliative responses. In a retrospective study of 198 patients with MF/SS receiving systemic therapy, the time to next therapy was only 3.9 months, and there were few durable remissions.⁴⁷ Following the NCCN published guidelines, it is expected that only a minority of patients with MF (10–20%) require systemic chemotherapy.⁴⁸

In 526 patients reported in single-agent chemotherapy trials, the response rates were 20–80% and the median duration of responses was 3–22 months.⁴⁹ Single agents include the anti-folates methotrexate^{50–53} and pralatrexate,⁵⁴ chlorambucil,⁵⁵ the purine analogs,^{56–63} pentostatin, 2-CDA, and fludarabine, gemcitabine,^{64–67} pegylated liposomal doxorubicin,^{68–71} temozolamide,^{72, 73} and bortezomib.^{74, 75}

The largest experience with combination chemotherapy is with cyclophosphamide, vincristine, and prednisone with or without doxorubicin.^{76, 77} CR rates are generally about 25% and response duration 3–20 months.⁴⁹ More intensive regimens include etoposide, idarubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (VICOP-B)⁷⁸ and ESHAP (etoposide, high-dose cytarabine, and methylprednisone).⁷⁹

Combined chemotherapy and TSEBT was once considered a preferred treatment.^{80–82} However, a prospective randomized trial at the NCI failed to show an improvement compared to sequential conservative therapies.^{83, 84}

Hematopoietic stem cell transplant (HSCT)

Although autologous transplantation has been used successfully in many lymphomas, this has not been the case for MF/SS.^{85–87} The responses are short lived, with a median time to progression <3 months.⁸⁵ Similar experience has even been shown with T-cell depletion of the apheresis products in an effort to eliminate contaminating lymphoma cells.⁸⁸

Allogeneic transplantation is more appealing, as an allogeneic graft-versus-tumor effect may provide an immune mechanism to control the malignant T-cell process. Eligibility and preparatory regimens have varied. Early reports of patients who received allografts from HLA-matched siblings following myeloablative therapy suggested that complete and sustained remissions could be achieved and that the presence of mild graft versus host disease (GVHD) suggested a possible graft versus lymphoma effect.^{89, 90}

These results for allogeneic transplant are encouraging, but it has limited applicability owing to transplant-related morbidity and mortality, especially in older patients. More recent data using nonmyeloablative approaches with reduced intensity conditioning regimens are effective and less-toxic than myeloablative regimens.⁸⁵ International registries report progression-free survival (PFS) as high as 32% at 5 years and 30% at 7 years.^{91–95}

A novel approach is to combine TSEBT, total lymphoid irradiation, and anti-thymocyte globulin as a

nonablative preparatory regimen.⁹⁶ This regimen has been shown to be associated with a lower risk for GVHD. In a series of 29 patients with stage IIB or IV MF/SS transplanted at Stanford, the incidence of grade II–IV GVHD was 21%.⁹⁷ The 2-year PFS was 50% and OS was 76%.

It appears that allogeneic hematopoietic stem cell transplant (HSCT) (especially with reduced intensity conditioning regimens) may result in durable long-term remissions. Larger prospective studies will be required to identify the optimal timing of transplant and the best conditioning regimen. With numerous biological agents showing promising activity and tolerability, there may also be a role for maintenance therapy.

Extracorporeal photopheresis

Photopheresis [extracorporeal photopheresis (ECP)] is a method of delivering PUVA systemically using an extracorporeal technique.⁹⁸ The patient's white blood cells are collected via leukapheresis, exposed to a photoactivating drug (8-methoxypsoralen, Uvadex), and then irradiated with UVA. The irradiated cells are then returned to the patient intravenously. The mechanism of action of photopheresis remains unclear but it may induce apoptosis of circulating tumor cells (Sézary cells). The released tumor antigen is then processed by the peripheral dendritic cells leading to the augmentation of systemic antitumor responses.⁹⁹ The treatment is most effective for patients with erythroderma (T4).¹⁰⁰ Response rates may be higher when combined with biologic agents such as interferons or retinoids^{101–104} or skin-directed therapies such as topical steroids, topical nitrogen mustard, or TSEBT.^{48, 102} ECP has minimal adverse effects. Some patients may experience nausea, mostly due to the ingested psoralen, and some have a transient low-grade fever or slight malaise after treatment. There are no reports of significant organ damage or bone marrow or immune suppression.¹⁰³

Systemic biologic therapy

IFN- α may be used alone, but more often with other topical or systemic therapies. Reported ORRs when used as monotherapy are 53–74%, with CR rates of 21–35%.^{41, 104, 105} The response rate and duration appear better when combined with phototherapy.⁴¹

Systemic retinoid therapy with bexarotene may be effective.¹⁰⁶ It may be combined with PUVA (Re-PUVA), IFN- α , or TSEBT. The response rate is 45–55% (10–20% CR).^{42, 104–111} The most common complications include photosensitivity, xerosis, myalgia, arthralgia, headaches, hyperlipidemia, and central hypothyroidism, as well as possible teratogenic effects. Most toxicities are reversible after cessation of therapy.

Two histone deacetylase (HDAC) inhibitors are useful, Vorinostat (suberoylanilide hydroxamic acid) and romidepsin. Vorinostat, an oral agent, has an ORR rate of 24–30% but only rare CRs.^{112, 113} The median time to response is 12 weeks, and the median duration of response is 15–26 weeks. Pruritus relief is common. The most common side effects include fatigue, diarrhea, nausea, anorexia, dysgeusia, and thrombocytopenia.

Romidepsin (depsipeptide), an intravenously administered HDAC inhibitor, is associated with an ORR of 34%.^{114, 115} The primary adverse effects include nausea, vomiting, fatigue, thrombocytopenia, and granulocytopenia.

Alemtuzumab (Campath-1H), a humanized monoclonal antibody directed against CD52, achieves complete and PRs in 32% and 23%, respectively, with a median time to treatment failure of 12 months.¹¹⁶ Serious infections are a risk, and these patients require antibiotic and antiviral prophylaxis. Modified

dose schedules have been introduced that have been associated with less severe toxicities.^{117, 118} Alemtuzumab is particularly effective in reducing the peripheral blood Sézary count in patients with SS. Brentuximab vedotin (BV) is an anti-CD30-monomethyl auristatin E anti-tubulin conjugate with potent and selective antitumor activity against CD-30 positive malignancies.¹¹⁹ Its efficacy in MF, which has variable expression of CD30, has been demonstrated.¹²⁰ An objective global response was observed in 73% of patients. The most common adverse events related to BV are peripheral neuropathy, fatigue, nausea, alopecia, and neutropenia. Lenalidomide is an oral immunomodulatory drug.¹²¹ The ORR is 28%. Primary complications included fatigue, infection, and leukopenia.

Conclusions

MF/SS is a challenging disease. It has a variety of clinical presentations and although often pursues an indolent course, in many patients, it has an aggressive behavior. It responds to topical therapies and systemic biologic treatments, but chemotherapy plays only a minor role in its management. Allogeneic stem cell transplantation may be a curative treatment in selected patients.

Chapter 121

Plasma cell tumors

Noopur Raje, MD ■ Teru Hideshima, MD, PhD ■ Andrew J. Yee, MD ■ Kenneth C. Anderson, MD

Overview

Plasma cell disorders have in common a proliferation of monoclonal plasma cells associated with the production of a monoclonal protein. These disorders range from the common, indolent condition of monoclonal gammopathy of undetermined significance to malignancies, such as multiple myeloma, characterized by the presence of hypercalcemia, anemia, renal dysfunction, and/or lytic lesions. Progress in the understanding of the molecular underpinnings of myeloma has led to remarkable advances in its treatment. High-dose melphalan with autologous stem-cell transplant was historically a mainstay of treatment. Now, highly effective and well-tolerated drug classes such as the proteasome inhibitors (e.g., bortezomib and carfilzomib) and immunomodulatory drugs (e.g., lenalidomide and pomalidomide) have rapidly transformed the treatment of myeloma and significantly improved the overall survival. The increasing use of extended treatment strategies such as maintenance therapy and the arrival of newer drug classes such as plasma cell-specific monoclonal antibodies are setting the stage for improving outcomes further.

Multiple myeloma

Multiple myeloma (MM) is a malignant proliferation of plasma cells and plasmacytoid cells in the bone marrow (BM) characterized nearly always by the presence, in the serum and/or urine, of a monoclonal immunoglobulin (Ig) or Ig fragment.¹ This disease has probably been recognized since 1845, when the first patient was noted with bone pain and heat soluble “animal matter” in urine.^{2, 3} The term MM was coined in 1873, reflecting distinct sites of BM involvement. The plasma cell was discovered in 1890 and MM associated with plasmacytosis shortly thereafter, in 1900. The application of electrophoresis in 1939 and immunoelectrophoresis in 1953 allowed for the identification of monotypic Ig characteristic of MM.^{4, 5}

Diagnostic criteria

Active MM is both a clinical and a pathological diagnosis that is defined by the presence of a monoclonal protein in the serum and/or urine, with $\geq 10\%$ plasma cells in the BM, and associated hypercalcemia, renal dysfunction, anemia, and/or bone disease (also known as the “CRAB” criteria, see [Figure 1](#)), related to the MM ([Table 1](#)).^{7, 8} Active MM must be distinguished from other disorders characterized by monoclonal gammopathies, both malignant and otherwise, in particular monoclonal gammopathy of undetermined significance (MGUS) and smoldering MM. Other conditions associated with a monoclonal protein include Waldenström's macroglobulinemia, non-Hodgkin's lymphoma, primary amyloidosis, idiopathic cold agglutinin disease, essential cryoglobulinemia, and heavy chain disease. *Smoldering* MM is defined by the presence of a monoclonal protein ≥ 3 g/dL and/or $\geq 10\%$ plasma cells in the BM and the absence of end organ involvement (i.e., the CRAB criteria of hypercalcemia, renal insufficiency, anemia,

or bone lesions). The International Myeloma Working Group (IMWG) has recently updated the definition of symptomatic myeloma to include any one of the following biomarkers of disease such as $\geq 60\%$ marrow infiltration with plasma cells, an involved : uninvolved serum free light-chain (FLC) ratio of ≥ 100 , or >1 focal lesion on an MRI.⁶

Figure 1 Characteristic lytic bone lesions in multiple myeloma.

Table 1 Classification of monoclonal gammopathies

Monoclonal gammopathy of unknown significance <3 g/dL M spike <i>and</i> <10% clonal plasma cells in bone marrow <i>and</i> Absence of CRAB ^a criteria
Smoldering multiple myeloma ≥ 3 g/dL Monoclonal protein or 10–60% clonal plasma cells in bone marrow Absence of CRAB criteria
Active multiple myeloma $\geq 10\%$ plasma cells or biopsy proven plasmacytoma and Presence of any of the CRAB criteria or <i>in absence of CRAB criteria</i> : >1 focal lesion on MRI, $\geq 60\%$ plasma cells in bone marrow; or an abnormal involved:uninvolved FLC ratio of ≥ 100

^a CRAB criteria is end organ damage due to the plasma-cell disorder: hypercalcemia (>1 mg/dL higher than the upper limit of normal or >11 mg/dL); renal insufficiency (creatinine clearance <40 mL/min or creatinine >2 mg/dL); anemia (hemoglobin >2 g/dL below lower limit of normal or hemoglobin <10 g/dL); or bone lesions (one or more osteolytic lesions on skeletal radiography, CT, or PET CT).

Monoclonal gammopathy of undetermined significance

MGUS is present in 3.2% of persons 50 years of age or older and 5.3% of persons 70 years of age or older.⁹ Patients have <3 g/dL monoclonal Ig, fewer than 10% monoclonal marrow plasma cells, and no bone lesions, anemia, hypercalcemia, or renal dysfunction (CRAB criteria).⁸ In a large experience of

1384 patients diagnosed at the Mayo Clinic, 115 patients progressed to MM, IgM lymphoma, primary amyloidosis, macroglobulinemia, chronic lymphocytic leukemia, or plasmacytoma with relative risk of progression of 25.0, 2.4, 8.4, 46.0, 0.9, and 8.5, respectively.¹⁰ The risk of progression of MGUS to MM or related disorders is about 1% per year, and the initial concentration of serum monoclonal protein was a significant predictor of progression at 20 years. Similar results have been published by Cesana et al.¹¹ Independent prognostic factors associated with MGUS transformation to MM include (1) >5% BM plasmacytosis, (2) Bence Jones proteinuria, (3) decrease in polyclonal serum immunoglobulin, and (4) an elevated erythrocyte sedimentation rate.¹¹ More recently, risk factors for progression include an abnormal serum kappa : lambda FLC ratio, a high serum monoclonal protein level ≥ 1.5 g/dL, and non-IgG type monoclonal protein.¹² The risk of progression from smoldering MM to symptomatic disease is related to the proportion of BM plasma cells and serum monoclonal protein level at diagnosis¹³ as well as abnormal serum FLC ratio.¹⁴ In some cases, MGUS can be associated with symptomatology requiring therapy. For example, plasma exchange appears to be efficacious in neuropathy associated with IgG or IgA MGUS.¹⁵

Epidemiology

In addition to MGUS, a potential risk factor for the development of MM includes exposure to irradiation or petroleum products. Unlike leukemia, there is no increased risk of MM with benzene exposure.¹⁶ Families with two or more affected individuals have been reported, suggesting a possible genetic predisposition.¹⁷ MM has also been found to occur with somewhat greater frequency (but less than twofold) in farmers, paper producers, furniture manufacturers, and wood workers.

There are two major misconceptions regarding MM. The first is that MM is a rare disease. MM is the second most common hematologic malignancy, accounting for 24,050 new cancer cases in the United States in the year 2014 and approximately 2% of cancer-related deaths.¹⁸ The highest incidence rates have been reported for African-Americans and Pacific Islanders; Europeans and North American white people have intermediate rates, while generally low rates have been reported for Asians living in Asia and the United States.¹⁹ Although it has been suggested that the incidence of MM is increasing, data from Olmstead County, Minnesota, demonstrate that the incidence of MM has not changed significantly during the past 46 years.²⁰ A second misunderstanding is that MM is solely a disease of the elderly. In a large Mayo Clinic series, the median age was 66.^{21, 22} Although 98% of MM patients were 40 years of age or older, 30% of patients were <60 years old. The fact that a significant population of affected individuals is younger than age 70 and therefore can tolerate more aggressive therapeutic approaches influences potential treatment strategies.

Clinical features

The presenting features of 1027 cases of newly diagnosed MM evaluated from 1985 to 1998 are summarized in [Table 2](#).²¹ Symptoms of bone pain and anemia remain the most common presenting features.

Table 2 Presenting features of multiple myeloma

Presenting feature	
Anemia (hemoglobin ≤12 g/dL)	73%
Calcium ≥ 11 mg/dL	13%
Creatinine ≥ 2 g/dL	19%
Radiographic abnormality (on plain film) ^a	79%
Bone pain	58%
Fatigue	32%
Weight loss	24%

^a Lytic lesions present in 67% of patients.

Source: Kyle et al. 2003.²¹ Reproduced with permission of Elsevier.

Laboratory features

Laboratory evaluation identifies roentgenographic abnormalities in bone and monoclonal Ig in serum and/or urine in the majority of cases. In most series, 50–60% of patients with MM have both serum and urinary monoclonal protein; 20–30% of patients have serum without urinary protein; 15–20% of patients have monoclonal protein in urine only; and only 1–2% of patients do not secrete monoclonal protein in blood and/or urine.²³ IgG or IgA monoclonal proteins are most common, and IgD or IgE are rare. A biclonal process is much more common than previously appreciated, often only documented by immunofixation techniques. Thirty-three percent are IgG and IgA; 24% are IgM and IgG. It appears that patients with biclonal and IgD disease have prognoses similar to those patients with monoclonal disease.²⁴ Close observation is an appropriate choice for patients with MGUS or smoldering MM, whereas multiple regimens have been employed for therapy of individuals with overt MM. The natural history of MM is a progressive increase in tumor growth. The M protein doubling time, a measure of the MM growth rate, shortens with each relapse. Eventually, marrow failure develops, with sideroblastic anemia, leukopenia, and thrombocytopenia. The median interval from marrow failure to death is 3 (range 1–9) months.²⁵ Infection and renal failure account for 52% and 21% of deaths, respectively, in patients with MM.²⁶ Acute myeloid leukemia develops in a small fraction of patients but in excess of the anticipated baseline incidence.²⁵

Biology

Cell surface phenotype

B-cell-restricted and associated antigens (Ags) have been utilized to delineate stages of normal and malignant B-cell differentiation.²⁷ Moreover, antigenic profiles are useful not only to identify stages of malignant B-cell differentiation but also to categorize B-cell tumors. MM cells share cell surface expression of some Ags, for example, CD38 and PCA-1 (prostate cancer antigen-1), which are also present on normal plasma cells, suggesting that the normal cellular counterpart of MM is the normal plasma cell. However, a number of other Ags to date have been described on the surface of MM cells, which in some cases react with B cells at stages of differentiation earlier than the plasma cell and also

react with non-B cells.^{28–33} Harada et al.³⁴ have shown that normal plasma cells are CD19+CD56–, whereas no MM cells have this phenotype. The core protein of MUC-1 antigen is expressed on MM cells³⁵ and its inhibition triggers MM cell death.³⁶ The expression and function of adhesion molecules on MM cells is described in the following section. This observed heterogeneity in cell surface phenotype has led to controversy as to the cellular origin of MM.

Cellular origin of MM

As is well known, the cells that accumulate in the BM of patients with MM have plasma cell or plasmablast morphology. However, it has been known since the 1970s, based on studies using anti-idiotypic antibodies, that unique idiotypic determinants can identify clones of peripheral blood lymphocytes in patients with macroglobulinemia, MM, MGUS, and chronic lymphocytic leukemia.³⁷ The presence of idiotypic determinants on cytoplasmic μ -containing pre-B cells in MM BM provided further evidence that the oncogenic event may occur at the pre-B-cell stage. Studies identified B and T cells bearing identical idiotypic determinants, suggesting that target cells for oncogenic transformation could be precursor cells for both B and T cell clones.³⁸ Aneuploid marrow MM cells can express mRNA for cell surface proteins characteristic of myeloid, erythroid, and platelet lineages, also supporting the view that the malignant clone can extend from an early stage of differentiation.³⁹ Moreover, monoclonal B lineage cells in peripheral blood of MM patients, which are late-stage B cells (low CD19 and CD20, moderate CALLA and PCA-1, with strong CD45RO antigen expression) are continuously progressing toward the plasma cell stage.³¹ However, it remains unclear as to which cell within the malignant clone is “clonogenic” and capable of self-renewal. Some evidence suggests that pre-B and naive B cells migrate from the BM to the lymph node (LN) where antigen recognition, selection, and somatic hypermutation occur. The memory B-cell compartment is thought to contain the cytoplasmic μ -positive precursor cell of MM, which then undergoes Ig class switching in the LN.⁴⁰ Ig variable (VH) gene sequence analysis has shown MM tumor cells to be postfollicular, with the mutated homogeneous clonal sequences indicating no continuing exposure to somatic hypermutation mechanism.⁴¹ VH gene analysis of IgM MM indicates an origin from a memory cell undergoing isotype switch events.⁴² Mutated heterogeneous sequences in MGUS suggest that tumor cells remain under the influence of the mutator.⁴³ Abnormalities of 14q (the location of IgH) are most common in MM. As proto-oncogenes are translocated to this region and overexpressed in B-cell malignancies including follicular lymphoma, Burkitt's lymphoma, and chronic lymphocytic leukemia, they may also play a role in the oncogenesis of MM. In addition, translocations involving switch regions indicate that the final oncogenic molecular event in MM occurs late in B-cell ontogeny.⁴³ More recently, CD138– cells with a memory B-cell phenotype are thought to be the clonogenic MM “stem” cells, although this concept needs further validation.⁴⁴

Role of adhesion molecules, cytokines, and BM stromal cells in MM

Adhesion molecules mediate both homotypic and heterotypic adhesion of tumor cells to either extracellular matrix (ECM) proteins or bone marrow stromal cells (BMSCs) ([Figure 2](#)).⁴⁵ Moreover, they play a critical role in pathogenesis of disease progression. After class switching in the LN, adhesion molecules such as CD44, VLA-4 (very late antigen-4), VLA-5, LFA-1 (leukocyte function-associated antigen-1), CD56, syndecan-1 (CD138), and MPC-1 mediate homing of MM cells to the BM.^{45–49} Subsequently, binding of MM cells occurs to BMSCs, for example, via VLA-4 to VCAM-1 (vascular cellular adhesion molecule-1), and to ECM, for example, via syndecan to type I collagen and VLA-4 to fibronectin. Such binding not only localizes tumor cells in the BM microenvironment but also stimulates interleukin-6 (IL-6) transcription and secretion from BMSCs with related paracrine growth of MM

cells.^{50–52} Moreover, triggering via CD40 found on tumor cells induces IL-6 transcription and secretion, with related autocrine MM cell growth ([Figure 3](#)).⁵³ TNF- α upregulates adhesion molecules on MM cells and BMSCs, thereby increasing binding and cell adhesion-mediated drug resistance (CAM-DR).⁵⁴ Syndecan-1 is a multifunctional regulator of MM cell growth and survival as well as of bone cell differentiation, and elevated serum syndecan-1 correlates with increased tumor cell burden, decreased metalloproteinase-9 activity, and poor prognosis.^{55–57} It also mediates decreased osteoclast and increased osteoblast differentiation.⁵⁵ Adhesion also induces matrix metalloproteinase-1, which favors bone resorption and tumor invasion.⁵⁸ As the disease progresses, the development of plasma-cell leukemia (PCL) is characterized by decreased expression of certain adhesion molecules (e.g., CD56, VLA-5, MPC-1, and syndecan-1), which in turn facilitates tumor cell mobilization. Furthermore, the acquisition of other adhesion molecules on PCL cells, such as CD11b, CD44, and RHAMM, assists transit through endothelium during egress from the BM. Extramedullary spread of MM cells is facilitated by the reappearance of CD56, VLA-5, MPC-1, and syndecan-1. As adhesion molecules play a central role in the pathogenesis of MM, therapeutic strategies targeting these molecules have been developed and tested in animal models; for example, anti-ICAM-1 antibodies have been shown to inhibit tumor development in severe combined immunodeficient (SCID) mice.⁵⁹ Moreover, a model of MM in SCID mice bearing human fetal bone grafts (SCID-hu mice) provides for the first time an *in vivo* model for the evaluation of homing of human MM cells to human BM ECM proteins and BMSCs, the biologic sequelae of binding, as well as testing of novel treatments based on interruption of this process.^{60, 61} MM cells resistant to melphalan and doxorubicin typically overexpress VLA-4, and adherence to ECM proteins such as fibronectin induces CAM-DR, with upregulation of p27^{Kip1} in tumor cells.⁶² As we will discuss in the following paragraph, novel agents, including immunomodulatory drugs (IMiDs), such as thalidomide and lenalidomide, and the proteasome inhibitor bortezomib can target both the tumor cell and its BM microenvironment, thereby overcoming CAM-DR.^{63–67}

Figure 2 Role of adhesion molecules in myeloma pathogenesis.

IL-6-induced signal transduction in MM cells

Figure 3 Interleukin-6 signaling cascades.

We have characterized the mechanisms whereby MM cells home to the host BM and adhere to BMSCs and ECM proteins, as well as the functional sequelae of this binding, in order to identify targets for novel therapies. Importantly, our past studies have identified those adhesion molecules mediating MM cell binding to fibronectin and BMSCs, as well as the MM cell growth and survival advantage conferred by this binding.^{45, 52, 68–70}

Our studies show that BMSCs secrete cytokines, such as IL-6,⁷¹ insulin-like growth factor-1 (IGF-1),⁷² vascular endothelial growth factor (VEGF),^{73, 74} stromal cell derived growth factor (SDF-1 α),⁷⁵ and B-cell activating factor (BAFF),^{76, 77} which augment MM cell growth, survival, drug resistance, and migration in the BM milieu (Figure 4). Besides localizing tumor cells in the BM microenvironment, our studies demonstrate that adhesion of MM cells to BMSCs also triggers the paracrine NF- κ B-dependent transcription and secretion of IL-6 in BMSCs, the major cytokine-mediating MM cell growth, survival, and resistance to dexamethasone-induced apoptosis via activation of p42/44 MAPK, JAK2/STAT3, and PI3K/AKT signaling cascades.^{50, 52, 72, 78–89} VEGF is secreted by both MM cells and BMSCs, and its secretion is similarly upregulated by binding of MM cells to BMSCs; it augments MM cell growth and BM neovascularization, although the pathophysiologic significance of angiogenesis is undefined.^{90, 91} VEGF induces migration via PKC signaling.⁷⁴ Although tumor necrosis factor- α (TNF α) does not directly alter MM cell growth and survival, our studies show that it induces NF- κ B-dependent upregulation in cell surface expression of adhesion molecules (ICAM-1 and VCAM-1) on both MM cells and BMSCs, resulting in increased cell adhesion and related induction of IL-6 transcription and secretion in BMSCs.⁵⁴ Recombinant IL-1 β stimulates MM cells to produce IL-6, which consequently augments proliferation of

MM cells.⁹² Transforming growth factor- β (TGF- β) is secreted by MM cells and triggers IL-6 secretion in BMSCs,⁹³ thereby augmenting paracrine IL-6-mediated tumor cell growth. TGF- β secreted by MM cells likely also contributes to the immunodeficiency characteristic of MM by downregulating B cells, T cells, and natural killer cells, without similarly inhibiting the growth of MM cells. IL-10 is a proliferation factor, but not a differentiation factor, for human MM cells.⁹⁴ IGF-1 has been shown to augment MM cell growth, survival, and drug resistance.⁷² Macrophage inflammatory protein-1 α (MIP-1 α) is an osteoclast stimulating factor in MM.^{95, 96} BAFF is produced by the BMSCs, and specifically by osteoclasts. It signals through several receptors including BAFF-R, transmembrane activator, calcium modulator, and cyclophilin ligand interactor (TACI), and B-cell maturation Ag (BCMA).^{76, 77} The level of TACI gene expression in MM cells is associated with microenvironment dependence.⁹⁷ This signaling cascade has a prosurvival effect on MM cells. Autocrine growth mediated by IL-15,⁹⁸ and most recently IL-21,⁹⁹ has been demonstrated in both MM cell lines and patient cells.

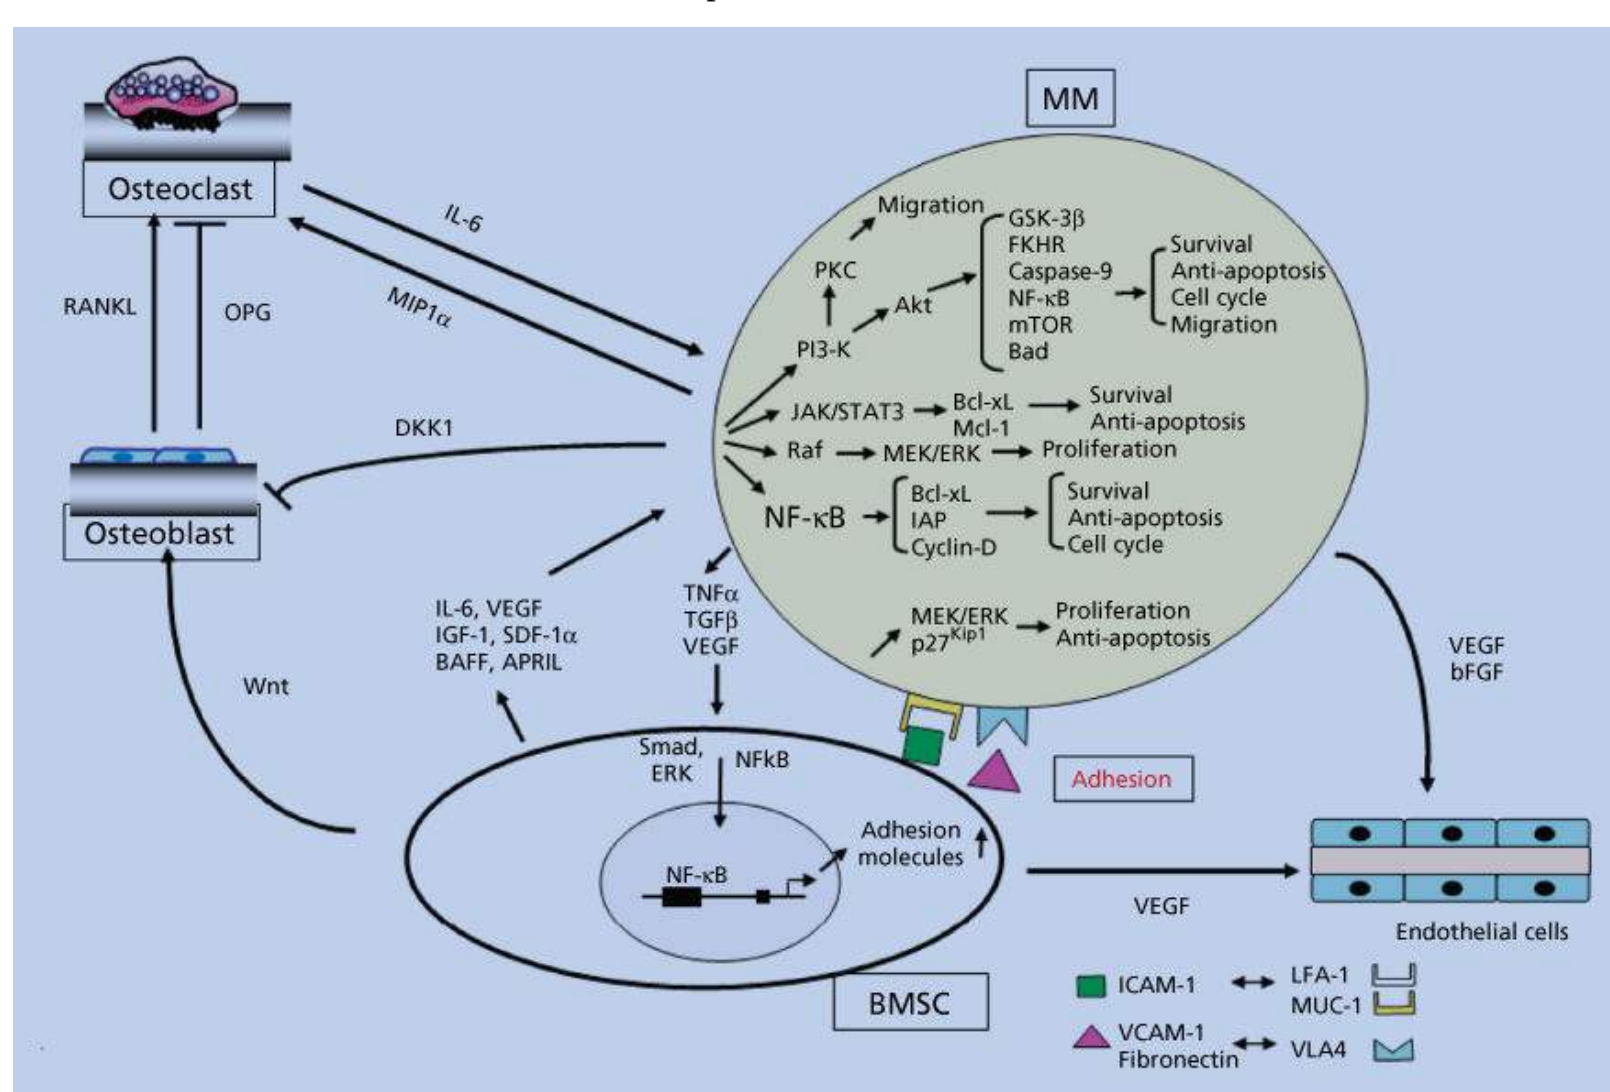

Figure 4 Signaling cascades in the context of the microenvironment.

Wnt signaling regulates various developmental processes and can lead to malignant formation and has been recently studied in the context of MM. Wnts are a family of secreted glycoproteins that bind to frizzled seven-transmembrane span receptors. Intracellularly, the Wnt signaling cascade blocks degradation of β -catenin in proteasomes, thereby leading to accumulation of β -catenin in the cytoplasm. In MM, a canonical Wnt signaling pathway is activated following treatment with Wnt-3a, associated with accumulation of β -catenin. Wnt-3a treatment further led to significant morphological changes in MM cells, accompanied by rearrangement of the actin cytoskeleton.¹⁰⁰ Derksen et al.¹⁰¹ demonstrated that MM cells

overexpress β -catenin, including its N-terminally unphosphorylated form, consistent with active β -catenin/T-cell factor-mediated transcription. Further accumulation and nuclear localization of β -catenin, and/or increased cell proliferation, was achieved by stimulation of Wnt signaling with Wnt-3a, LiCl, or the constitutively active mutant of β -catenin. Wnt signaling has also been shown as an important regulatory pathway in the osteoblast differentiation of mesenchymal stem cells. Interestingly, MM cells in BM-biopsy specimens contained detectable Dickkopf 1 (DKK1), a negative regulator of Wnt signaling cascade and a target of the β -catenin/TCF pathway.¹⁰² Moreover, elevated DKK1 levels in BM plasma and peripheral blood from patients with MM correlated with the DKK1 gene-expression patterns and were associated with the presence of focal bone lesions.¹⁰³

Most importantly, adhesion of MM cells to BMSCs induces changes in gene profile: that is, upregulation of growth, survival, and drug resistance genes in tumor cells; upregulation of adhesions molecules on MM cells and BMSCs; and changes in cytokines in BMSCs both in *in vitro* and *in vivo* models of human MM in mice.^{104–106} Interaction of MM cells with BMSCs activates Notch signaling, which induces melphalan resistance.¹⁰⁷ Induction of proteasome activity when MM cells bind to BMSCs may sensitize them to therapy.

We have shown that IMiDs (e.g., lenalidomide) inhibit VEGF and IL-6, which are known to downregulate antigen-presenting function of dendritic cells in MM.¹⁰⁸ Moreover, lenalidomide directly activates CD28 on T cells, thereby stimulating transcription and secretion of IL-2, with resultant upregulation of T and NK cell anti-MM activity.^{108, 109} Lenalidomide can upregulate antibody-dependent cellular cytotoxicity (ADCC).¹¹⁰ IMiDs also affect the cytokine signaling stimulated by the interaction of effector cells with MM cells and BMSCs, and this is via regulation of *SOCS1*, a member of the suppressor of cytokine signaling (SOCS) genes.¹¹¹

Molecular pathogenesis of MM

The malignant plasma cells in MM are localized to the BM in close association with BMSCs. They are long-lived cells with a very low (1–2%) labeling index (LI) that provides a measure of the proliferative rate of the malignant BMPC predicting survival in patients with newly diagnosed MM. The rearranged Ig genes are extensively somatically hypermutated in a manner compatible with antigen selection, with no evidence that the process of hypermutation is continuing.⁴¹ However, MM cells have a significantly lower rate of Ig secretion than normal plasma cells. Thus, it appears that the critical oncogenic events in MM cells either occur after or do not interfere with most of the normal differentiation process involved in generating a long-lived plasma cell.

Gene expression profiling has recently been utilized to characterize changes associated with the progression from normal plasma cells to MGUS to MM.^{112–114} The mRNA profile of MGUS and MM is similar and distinct from that of normal plasma cells.¹¹⁴ These studies may not only enhance understanding of basic pathophysiology but also identify novel therapeutic targets.

By conventional analyses, karyotypic abnormalities are detected in MM at a frequency of 30–50% in large studies of MM tumors ([Table 3](#)).^{115–117} The frequency and extent of karyotypic abnormalities correlates with the stage, prognosis, and response to therapy. For example, approximately 20% are abnormal in stage I disease, 60% in stage III patients, and >80% for extramedullary tumor. This analysis is dependent on obtaining reliable metaphase preparations and greatly underrepresents the extent of DNA alterations in these infrequently dividing cell populations. By interphase fluorescence *in situ* hybridization (FISH) analysis, two studies report that at least one chromosome is trisomic in 96% or 89%

of MM tumor samples, respectively.^{118, 119} Although conventional karyotypes are not routinely reported for MGUS, it appears that a substantial fraction of MGUS plasma cells are aneuploid as well. By FISH analysis, the incidence of trisomy for at least one chromosome was 43% and 53% in two studies of MGUS cells; in the former, 61% of the cells had an aneuploid DNA content by image analysis.^{118, 120} The characteristic numerical abnormalities are monosomy 13 and trisomies of chromosomes 3, 5, 7, 9, 11, 15, and 19. Nonrandom structural abnormalities most frequently involve chromosome 1 with no apparent locus specificity; 14q32(IgH) locus occurs in 20–40%; 11q13(bcl-1 locus) in about 20%, but mostly translocated to 14q32; 13q14 interstitial deletion in 15%; and 8q24 in about 10%, with about half of these involved in a translocation. Importantly, a recent report documents similar translocations in MGUS and MM, including t(4;14)(p16.3;q32) and t(14;16)(q32;q23), without any obvious clinical or biologic correlation.¹²¹

Table 3 Myeloma chromosomal alterations

Genetic lesion	Incidence (%)
Hyperdiploid	60
t(11;14)	20
t(4;14)	15
MAF translocations	5
Del (13q)/monosomy 13	50–60
Del (1p)	7–40
Chr 1q21 amplification	40
Cyclin D dysregulation	80
RAS mutations	30–50
FAM46C, DIS3	10–21
NF-κB activating mutations and CNVs	15–20
IgH MYC rearrangements	15
UTX deletions and mutations	30
TP53 inactivations (mutations+del(17p))	10–20
p18 and/or Rb inactivation	<5
p14 promoter methylation	<5
PTEN loss	<2

The hallmark genetic lesion in many B-lymphocyte tumors involves dysregulation of an oncogene as a consequence of a translocation involving the IgH locus (14q32.3); less frequently, variant translocations involve one of the IgL loci (2p12, kappa or 22q11, lambda) ([Tables 3](#) and [4](#)). From conventional karyotypic analyses, translocations involving 14q32 appear to occur in about 20–40% of MM with an abnormal karyotype.¹²³ The incidence of these translocations is significantly higher in the extramedullary phase of the disease and in cell lines, perhaps because of a higher number of metaphase spreads that are examined. In about 30% of these translocations, the partner chromosomal locus is 11q13 (bcl-1, cyclin D1), but in most cases, the partner is not identified (14q32+). Transcriptional activation of cyclin D1 has recently been confirmed in some primary tumors, as has cyclin D3 activation associated with t(6;14)

(p21;q32) translocation.^{121, 124, 125} Other recurrent partner loci have been identified infrequently, including 8q24(c-myc) in <5%, 18q21(bcl-2), 11q23(MLL-1), and 6p21.1. By combining conventional karyotypic analysis with a comprehensive Southern blot assay, which detects translocations involving IgH switch regions, it has become apparent that most MM cell lines and one primary tumor fully examined have IgH translocations that mainly involve IgH switch regions.^{43, 126} Recent FISH studies have also shown that IGH gene rearrangements are present in 73% of MM patients.¹²⁷ The apparent oncogene dysregulated by t(4;14) is the fibroblast growth factor receptor 3 (*FGFR3*) gene, and it is possible that dysregulated expression of *FGFR3*, as a result of t(4;14), receives an *FGFR3*-mediated signal from FGF produced by stromal cells in the BM microenvironment.¹²⁸ In addition to *FGFR3*, the t(4;14) translocation in MM regulates a novel gene, *MMSET*, resulting in IgH/MMSET hybrid transcripts.¹²⁹ Ectopic expression of *FGFR3* promotes MM cell proliferation and prevents apoptosis, and its oncogenic potential has been tested in a murine model, confirming its capacity to transform hematopoietic cells.^{130, 131} Finally, there is evidence that elevated expression of c-myc and selective expression of one c-myc allele may occur frequently in MM, even though structural genetic changes near c-myc have been identified in only 10–20% of tumors.

Table 4 Nonimmunoglobulin sites for illegitimate switch recombination

Chromosome	Gene	Function
11q13	Cyclin D1	Induces growth
4p16	<i>FGFR3</i> , <i>MMSET</i>	Growth factor
8q24	<i>MYC</i>	Growth/apoptosis
16q23	c-maf	Transcription factor
6p25	<i>IRF4</i>	Transcription factor

Ras mutations occur in about 39% of newly diagnosed MM patients, and the frequency of ras mutations increase with disease progression. Mutations of N- and K-ras are rarely detected in solitary plasmacytoma and MGUS, but occur more frequently in MM (9–30%) and in the majority of terminal disease or PCL patients (63–70%).^{132, 133} Activating mutations of the ras oncogenes may also result in growth factor independence and suppression of apoptosis in MM.

Although translocation (14;18) occurs at a low frequency (0–15%) in MM, an overexpression of Bcl-2 is seen in the majority of MM patients and in MM cell lines.^{134, 135} High levels of Bcl-2 protein are likely to mediate the resistance of MM cells to apoptosis induced by IL-6 deprivation, staurosporine, or other drugs.¹³⁶ In a murine MM cell line, Bcl-XL showed a predominant role in preventing apoptosis in response to cycloheximide treatment or IL-6 withdrawal.¹³⁷ Similarly, overexpression of Bcl-2 or Bcl-XL could prevent apoptosis induced by IL-6 withdrawal in the B-9 IL-6-dependent cell line.¹³⁸ Mcl-1 is overexpressed in MM cells, upregulated by IL-6, and mediates potent resistance to apoptosis, whereas Mcl-1 downregulation triggers apoptosis ([Figure 5](#)).¹⁴⁰

Chromosome 13 deletions are present in over 50% of MM and are associated with poor prognosis.^{121, 141–143} However, these deletions are also associated with MGUS, and their role in transformation to MM is therefore at present undefined.^{121, 144, 145}

Recent understanding of the molecular pathogenesis of MM has resulted in a new proposed classification of MM.^{146, 147} Majority of MM tumors have chromosomal abnormalities and are broadly classified into hyperdiploid (HRD) or nonhyperdiploid (NHRD) tumors. Nearly half of MM tumors are HRD, the remaining being categorized as NHRD, which includes tumors that are hypodiploid, pseudodiploid, or subtetraploid. These NHRD tumors have been associated with a poorer prognosis. Five recurrent IgH translocations have been seen in MM including MMSET and FGFR3 (15%), cyclin D3 (3%), cyclin D1 (15%), c-maf (5%), and MAFB (2%) accounting for a prevalence of 40%. Recent evidence suggests that three of these five translocations are predominant in the NHRD tumors.

Deletions of chromosome 17p involving the *TP53* locus are rare in newly diagnosed myeloma (5–10%), but more common in relapsed and refractory cases (20–40%), and are associated with a negative prognosis.^{148, 149} Regimens containing bortezomib can however overcome this unfavorable prognosis, as shown by the HOVON-65/GMMG-HD4 trial.¹⁵⁰ 1q21 amplification is detected by FISH in about 40% of newly diagnosed and 70% of relapsed myeloma. It can negatively impact overall survival (OS). Possible downstream target genes include *CKS1B*, a protein that regulates cyclin-dependent protein kinases, *PSMD4*, a proteasome subunit modulating response to bortezomib treatment, *MCL1* and *BCL9*.^{151–153} In addition, deletions of 1p, present in 7–40% of patients, are linked to reduced PFS (progression-free

survival) and OS despite autologous stem-cell transplant.^{154–156} *FAM46C* loss or *FAM46C* mutations (evident in 15% of patients) are especially associated with shortened survival (median OS 25.7 months vs 51.3 months, $P = 0.004$).^{156, 157} The biologic function of *FAM46C* is unknown, but possibly related to mRNA stabilization. Other abnormalities include *MYC* rearrangements involving unbalanced translocations and insertions, small duplications, amplifications, and inversions on chromosome 8p24^{158–161}; homozygous deletions of 11q22 locus resulting in loss of *YAP1*, *BIRC3*, and *BIRC2* genomic region^{162–164}; chromosome 4, 14, and 16 aberrations, disrupting *FGFR3*, *WVOX*, and *CYLD*; and deletions or amplifications of chromosome 6 and homozygous deletions of Xp11.2 locus,^{165, 166} involving *UTX*, a histone H3 lysine 27 (H3K27) demethylase mutated in 10% myeloma.^{157, 167}

With the advent of cDNA microarrays, an expeditious and comprehensive gene expression profiling is possible to better define disease biology, highlight prognostic factors, and identify potential targets for novel therapies.^{124, 168} These studies may also identify mechanisms of sensitivity versus resistance to conventional and novel MM therapies.^{169, 170} Known target antigens likely represent only the tip of the iceberg. Most recently, array comparative genomic hybridization (aCGH) has been correlated with gene profiling to identify chromosomal amplifications and transcript overexpression, respectively.¹⁶⁵ Classical overexpression and knockdown experiments may be done first in cancer models and then in MM models to identify potential novel targets for monoclonal antibody (cell surface) or small molecule inhibitor (intracellular) therapies.

Somatic mutations and interclonal diversity

MM is often preceded by MGUS or smoldering myeloma transforming to overt myeloma,^{171, 172} characterized by accumulation of mutations conferring growth advantage (driver mutations) or functionally irrelevant mutations (passenger mutations). To date, more than 300 myeloma patient DNA samples have been sequenced using whole-genome-sequencing or whole-exome sequencing approaches.^{157, 173, 174} Frequently mutated genes include *KRAS*, *NRAS*, *FAM46C*, *DIS3*, and *TP53*. Other significant genes are *BRAF* (4% of patients), *TRAF3*, *CYLD*, *RB1*, *PRDM1*, and *ACTG1*. *TRAF3* and *CYLD* mutations, together with homozygous deletions in *BIRC2/BIRC3*, *NIK* overexpression, and mutations in other genes (*CARD11* and *MYD88*) contribute to constitutively activating the NF- κ B pathway. Genes involved in protein homeostasis, unfolded protein response, or lymphoid/plasma-cell development, such as *PRDM1* involved in plasmacytic differentiation, and *XBP1*, *IRF4*, *LRRK2*, *SP140*, and *LTB* form a cluster of genes mutated in myeloma. Other recurrent mutated genes are *ROBO1*, a transmembrane receptor involved in β -catenin and MET signaling, *EGR1* transcription factor, *FAT3*, a transmembrane protein belonging to cadherin superfamily, and histone-modifying genes (*MLL*, *MLL2*, *MLL3*, *WHSC1/MMSET*, *WHSC1L1*, and *UTX* among others). -PCL patients tend to have different types of aberrancies, such as p14ARF promoter methylation, *PTEN* loss, *RB1* mutations, and higher rates of *TP53* mutations and deletions.¹⁷⁵

Recent data supports the concept of intratumor heterogeneity in myeloma, where different subclones can emerge and become predominant following different mechanisms of evolution, including linear, branching, parallel, or convergent evolution.^{173, 176} Clonal diversity similar to Darwinian-like selection favors cancer progression and adaptation to therapy. Next-generation sequencing analyses show that most patients have a subclonal structure at diagnosis, with one predominant clone and several others which can reappear at different stages of disease evolution or following treatment.^{173, 177, 178}

Prognostic factors

Multiple attempts have been made to define clinical and laboratory parameters that have prognostic significance.^{7, 179–181} The Durie–Salmon system was historically utilized ([Table 5](#)).⁷ Tumor cell mass for patients in stage I is low at $<0.6 \times 10^{12}$ cells/m², intermediate for patients with stage II disease at 0.6 to 1.2×10^{12} cells/m², and high for patients with stage III disease with $>1.2 \times 10^{12}$ cells/m². In this system, survival duration is 61.2, 54.5, 30.1, and 14.7 months for patients with stage IA, stage IB + IIA + IIB, stage IIIA, and stage IIIB disease, respectively.

Table 5 Durie–Salmon staging system and international staging system

Stage	Durie–Salmon stage	ISS stage	Overall survival by ISS stage
I	All of the following: <ul style="list-style-type: none">• Hemoglobin value >10 g/dL• Serum calcium value normal or ≤12 mg/dL• Bone X-ray, 0–1 lesion or solitary bone plasmacytoma only• Low M-component production rate: IgG value <5 g/dL IgA value <3 g/dL Urine light-chain M-component on electrophoresis < 4 g/24 h	Serum β2 microglobulin <3.5 mg/L and Serum albumin ≥3.5 g/dL	62 months
II	Neither stage I nor stage III	Serum β2-microglobulin <3.5 mg/L, but serum albumin <3.5 g/dL or Serum β2-microglobulin 3.5 to <5.5 mg/L, irrespective of serum albumin	44 months
III	One or more of the following: <ul style="list-style-type: none">• Hemoglobin value <8.5 g/dL• Serum calcium value >12 mg/dL• Advanced lytic bone lesions (≥3 lesions)• High M-component production rate IgG value >7 g/dL IgA value >5 g/dL Urine light-chain M-component >12 g/24 h	Serum β2-microglobulin ≥5.5 mg/L	29 months

Source: Durie and Salmon 1975⁷ and Greipp et al.¹⁸¹

Many additional single parameters have been examined for their value as prognostic features. Higher labeling indices, serum IL-6 receptor levels, more ras mutations, more aggressive disease, and shortened survival have been reported in patients with plasmablast morphology.¹⁸² Serum β₂ microglobulin (β2M) represents the light chain of the major histocompatibility complex of the cell membrane, and increased

serum β 2M results from release by tumors with high growth fraction and cell turnover rates. In patients with MM and normal renal function, rising serum β 2M predicts for progression.¹⁸³ The LI, a measure of DNA synthesis by MM cells, predicts for survival. It is usually low (<1%) at diagnosis, higher at relapse, and lower in MGUS and indolent MM.¹⁸⁴ Chromosome 13 deletions are present in over 50% of MM and are associated with poor prognosis^{141–143}; however, these deletions are also associated with MGUS,^{121, 144, 145} and their role in transformation to MM is therefore at present undefined. HRD MM has improved outcome and distinct clinical features, and chromosome 13 deletion does not have adverse impact.¹⁸⁵ Moreover, it is not prognostic for response to bortezomib, highlighting the importance of prognostic factors for particular therapies.¹⁸⁶ Gene expression profiling will not only define disease pathogenesis but also identify both novel prognostic factors and potential therapeutic targets.^{124, 130} These studies will also identify mechanisms of sensitivity versus resistance to conventional and novel MM therapies.^{169, 170} Cyclin D dysregulation has been identified as an early and unifying event in MM. Using gene expression profiling to identify five recurrent translocations, specific trisomies, and expression of cyclin D2 genes, MM can prognostically be divided into eight TC (translocation/cyclin D) groups.¹⁸⁷ Additional molecular classifications have been proposed,¹⁸⁸ with high-risk myeloma defined by deregulated expression of genes mapping to chromosome 1.¹⁸⁹ Most recently, the first DNA-based classification scheme has been proposed to predict outcome to high-dose therapy (HDT).¹⁶⁵

Serum IL-6 levels in some studies appear to correlate both with stage of disease and survival.^{190, 191} IL-6 stimulates hepatocytes to produce acute phase proteins, such as CRP; CRP therefore may reflect the IL-6 level and proliferative status of BM plasma cells. Indeed, CRP levels are significantly lower in patients with MGUS than in those with MM, and survival can be correlated with serum CRP level.¹⁹² High serum soluble interleukin-6 receptor (sIL-6R),¹⁹³ hepatocyte growth factor,¹⁹⁴ and syndecan-1¹⁹⁵ levels, as well as low serum hyaluronate levels,¹⁹⁶ are independent prognostic factors predicting poor outcome. The percentage of circulating plasma cells in peripheral blood and their labeling indices are independent prognostic factors for survival in MM after both conventional and HDT.^{197, 198} Circulating endothelial cells also correlate with disease course and response to thalidomide.¹⁹⁹ Finally, circulating proteasome levels are an independent prognostic factor for survival.²⁰⁰

Many of these factors are interrelated and, therefore, of limited independent value. Using multivariate analysis, several groups have found that the best combination of variables to predict outcome was serum β 2M, reflecting both the tumor burden and the renal function; and the proliferative activity of plasma cells, evaluated by the LI or number of tumor cells in S-phase. Age and performance status also improves the prognostic assessment.^{201, 202} An international staging system (ISS) based on serum β 2M and albumin has provided a three-stage ISS ([Table 5](#)), which is currently the most commonly used staging system and in reporting for clinical trials.¹⁸¹

Complications

Complications of MM include bone disease and hypercalcemia, hyperviscosity, recurrent infections, renal failure, and cardiac dysfunction.

Bone disease and hypercalcemia

The presence of osteolytic bone lesions, bone pain, increased risk of pathological fractures, or generalized bone loss (or osteoporosis) is a well-defined feature of myeloma.²⁰³ Myeloma bone disease

is characterized by an imbalance between osteoblast and osteoclast activities, with suppression of bone formation by osteoblasts and uncoupled activation of osteoclasts ([Figure 6](#)).^{204, 205} The ligand for receptor activator of NF κ B (RANKL) binds to RANK receptor to stimulate osteoclast differentiation, formation, and survival²⁰⁶; myeloma cells produce RANKL and upregulate RANKL expression in BMSCs and osteoblasts via direct contact, signal induction,^{207–209} or production of IL-7. Moreover, they promote suppression of osteoprotegerin (OPG),^{210–212} a decoy receptor that normally prevents RANK–RANKL interaction²¹³ via soluble factors, integrin $\alpha_4\beta_1$ -VCAM1 interaction,²¹⁴ production of DKK1,²¹⁵ or inactivation by syndecan-mediated internalization into myeloma cells.²¹⁶ Interestingly, OPG levels are decreased in the serum of myeloma patients and correlate with the presence of lytic bone lesions²¹⁷; a high RANKL/OPG ratio is associated with a poor prognosis.²¹⁸ Recombinant OPG constructs, soluble RANK, OPG peptidomimetics,^{211, 213, 219} and, more recently, an anti-RANKL antibody, denosumab,²²⁰ have been developed to modulate RANKL/OPG axis and reduce osteoclast activity in myeloma. MIP-1 α , or chemokine C–C motif ligand, is also produced by myeloma cells and promotes maturation of precursor cells into osteoclasts; MIP-1 α signals via CCR1 and CCR5 on osteoclasts and can further upregulate RANKL in stromal cells.^{96, 221, 222} MIP-1 α levels are elevated in myeloma patients,²²³ while MIP-1 α silencing or blockade of CCR1 reduces bone disease in *in vitro* or animal models.⁹⁶ IL-6,²²⁴ PTHrP,^{225, 226} annexin II,²²⁷ and ephrinB2/EphB4 axis²²⁸ also promote bone resorption. Osteoblast suppression is another major player in myeloma bone disease: WNT signaling antagonists, including DKK1, frizzled related protein-2 (FRP-2),²²⁹ and sclerostin (SOST),²³⁰ interfere with osteoblast maturation. DKK1 is expressed by myeloma cells and can upregulate RANKL levels in osteoblasts, increasing osteoclast activity.^{103, 231} DKK1 levels are increased in the serum of myeloma patients,²³² and anti-DKK1 antibodies have been tested in animal studies^{233–235} and are currently being studied in clinical trials. Finally, high levels of activin A, a member of TGF- β superfamily, IL-3, and IL-7 via RUNX2/CBFA1 blockade can inhibit bone formation and promote bone reabsorption. Furthermore, the bone niche itself supports myeloma cell survival and prevents TNF- α -mediated apoptosis.²³⁶

Figure 6 Osteoclastogenesis.

Treatment

Bisphosphonates play a key role in the supportive management of MM by not only blocking osteoclasts and modulate osteoblasts but also have an effect on tumor burden²³⁷; a similar response is reported with OPG peptidomimetics and RANKL constructs in *in vivo* xenograft models.²³⁸ Bisphosphonates, especially zoledronic acid, are currently used in the clinic to reduce bone disease,^{239, 240} but are also associated with an increase in OS when compared to placebo based on a recent meta-analysis.²⁴¹ Markers of bone resorption and formation correlate with the extent of osteolytic disease.²⁴² Specifically, urine levels of pyridinoline (PYD) and deoxypyridinoline (DPD) cross-links and serum levels of tartrate-resistant acid phosphatase isoform 5b (TRACP-5b), a resorption marker only produced by activated osteoclasts and of collagen degradation products, including the *N*-terminal cross-linking telopeptide of type I collagen (NTX) are elevated in myeloma patients compared with healthy controls and can predict early progression of bone disease in myeloma. Conversely, bone formation markers, such as bone alkaline phosphatase (bALP) and osteocalcin (OC), are reduced.²⁴² Another randomized trial demonstrated that oral clodronate slowed progressive skeletal disease and associated morbidity but achieved no benefit in survival. Pamidronate has been shown in a prospective randomized trial to reduce skeletal-related events, including pathologic fractures, radiation therapy to bone, and spinal cord compression in patients with Durie–Salmon stage III MM and ≥1 lytic bone lesion.²⁴³ This benefit was maintained until 21 months and formed the basis of previous ASCO recommendations, suggesting that MM patients remain on intravenous

bisphosphonates indefinitely to reduce skeletal events and pain, regardless of their response to chemotherapy.^{244, 245} Interestingly, patients in this study who had failed first-line chemotherapy also had improved survival, suggesting that bisphosphonates may have anti-MM activity.²⁴⁶ Recent evidence supports the view that bisphosphonates may downregulate IL-6 production from BMSCs as well as induce apoptosis of both osteoclasts and tumor cells. Pamidronate has been studied in patients with indolent MM. Bone turnover was reduced in treated patients,^{247, 248} but no significant antitumor activity was noted.²⁴⁹ Zoledronate is more potent than pamidronate and has the advantage of a shorter infusion time with similar efficacy compared to pamidronate for preventing skeletal related events.²⁵⁰ More recently, the MRC Myeloma IX trial has demonstrated the superiority of zoledronic acid compared with the oral bisphosphonate clodronate in patients with MM with an OS benefit favoring zoledronic acid.²⁵¹ A word of caution should however be exercised with the use of bisphosphonate therapy because of reported cases of osteonecrosis of the jaw.^{252–254} This newly recognized complication in a small percentage of patients led ASCO to update their guidelines and now recommend discontinuing bisphosphonates after 2 years in patients with very good partial response (VGPR) or better and continuing if response is partial response (PR) or less.²⁵⁵ Other supportive care measures such as vertebroplasty or kyphoplasty can restore supine stability and relieve pain for patients with localized disease.^{256, 257}

The treatment of hypercalcemia consists of treatment of the underlying MM, as well as inhibition of osteoclastic bone resorption with corticosteroids, calcitonin, and/or bisphosphonates. Corticosteroids may impair formation of new osteoclasts. Calcitonin and corticosteroids are almost always effective for the short term and useful even in the setting of renal failure. Bisphosphonates bind to the bone surface and inhibit osteoclast activity, and they constitute a mainstay of treatment. Therapeutic recommendations therefore include initial cytotoxic therapy for MM, saline hydration, and bisphosphonate therapy, with the use of calcitonin for nonresponders to these first-line treatments. In a randomized trial of 287 patients with hypercalcemia of malignancy, zoledronate was found to be superior to pamidronate.²⁵⁸ Hypercalcemia may also be compounded by patient immobility because of bone pain or other reasons.

Hyperviscosity

Hyperviscosity is characterized clinically by spontaneous bleeding with neurologic and ocular disorders. Hyperviscosity occurred in 4.2% of 238 patients with IgG MM and in 22% of 46 patients with serum IgG M components >5.0 g/dL.²⁵⁹ The IgG3 subclass produces hyperviscosity at lower levels than other IgG paraproteins.²⁶⁰ The severity of the syndrome is not directly related to the serum viscosity. Clinical findings improve with plasmapheresis, which reduces both MM protein concentration and serum viscosity.

Recurrent infections

Patients with MM had 15 times more infections than a control group of patients with heart disease.²⁶¹ *Streptococcus pneumoniae* and *Haemophilus* infections usually occur early and typically during response to chemotherapy. Gram-negative infections occur in refractory, advancing disease; in the setting of previous antibiotic therapy; instrumentation; immobilization; colonization with hospital flora; and azotemia. Fatal infections may be hospital-acquired, emphasizing the need to minimize indwelling foreign bodies such as catheters in patients with MM. There is lack of correlation between bacteremia (either gram-negative or -positive) and chemotherapy-induced febrile neutropenia. Fungal, herpes, mycobacterial, and *Pneumocystis* infections are only rarely described in MM patients. Infection is the most common cause of death (20–50% of cases).²⁶

The evidence of increased clinical infections in MM has led to attempts at prophylaxis. Although MM patients have normal-fold rises in antibody titers after pneumococcal vaccination, preimmunization titers are markedly diminished.²⁶² Postimmunization titers are therefore low and considered nonprotective. Nonetheless, because of its low cost and possible benefit to some patients, the use of pneumococcal vaccination has been recommended. In a double-blind randomized trial of gammaglobulin prophylaxis in patients with MM, no benefit of gammaglobulin prophylaxis at reducing infection was noted,²⁶³ although a trial in patients in the plateau phase suggested possible benefit.²⁶⁴ At present, gammaglobulin is reserved for those patients with recurrent or life-threatening infections and hypogammaglobulinemia.

Renal failure

Renal failure in MM can predict for adverse outcome. One series found that 22% of patients had a serum creatinine ≥ 2 mg/dL at diagnosis; renal function normalized with treatment in 48% of those with creatinine < 4 mg/dL.²⁶⁵ The causes of renal failure in MM are often multifactorial and include hypercalcemia; MM kidney, with distal and proximal tubules obstructed by large, laminated casts containing albumin, IgG, and κ and λ light chains surrounded by giant cells; hyperuricemia; toxicity from intravenous contrast; dehydration; plasma-cell infiltration; pyelonephritis; and amyloidosis. The most important predisposing factor is dehydration; aggressive hydration is therefore crucial to avoid irreversible renal dysfunction. Otherwise, treatment is for the underlying disease, along with avoidance of intravenous contrast. The type and quantity of proteinuria can distinguish MM kidney, with larger amounts of light chains and less albuminuria; light-chain deposition disease, characterized by low levels of both light chains and albumin in urine; and amyloidosis, in which large amounts of albuminuria and less light-chain proteinuria occur.²⁶⁶

The renal manifestations associated with the production of monoclonal light chains in MM, light-chain deposition disease, and amyloidosis result from the deposition of certain Bence Jones proteins (BJP) as tubular casts, basement-membrane precipitates, or fibrils, respectively.^{267–269} For unknown reasons, the severity of the renal manifestations varies greatly from patient to patient. BJP from 40 patients were injected into mice and 26 (65%) were deposited in mouse kidneys as tubular casts, basement-membrane precipitates, or crystals in a pattern similar to those noted in patients.²⁶⁹ This experimental model has potential value for the identification and differentiation of nephrotoxic or amyloidogenic light chains. The development of progressive kidney damage and MM kidney has been demonstrated in IL-6 transgenic mice, shedding additional insight into the role of IL-6 in the pathogenesis of MM.²⁷⁰

Cardiac failure

The mean and median age of patients with MM is approximately 60 years, and affected patients are also frequently at risk of cardiovascular disease. However, patients can be uniquely susceptible to cardiac ischemia and/or congestive heart failure (CHF) because of myocardial infiltration with amyloid, causing dilated or restricted cardiomyopathy, hyperviscosity syndrome, and/or anemia. Rarely, MM patients are also susceptible to high output CHF,²⁷¹ mainly in patients with extensive bone disease.²⁷² This has been attributed to arteriovenous shunting in bone lesions.²⁷³

Anemia

Anemia in MM can be due to a number of factors, including tumor infiltration of the BM, renal impairment, the myelosuppressive effects of chemotherapy, and a deficient production of erythropoietin (EPO) relative to the degree of anemia. Pilot studies demonstrated efficacy of exogenous EPO

administration in MM.^{274–276} Osterborg et al.²⁷⁷ have carried out a randomized study of EPO therapy at 10,000 U/d, a titrated dose of EPO starting with 2000 U/d and escalating stepwise until response, or no EPO for 24 weeks; response was defined as an increase in Hb > 2g/dL and elimination of transfusion need. Sixty percent of EPO-treated groups responded, 72% of those with low EPO levels, and only 20% of those with normal EPO levels. 10,000 units SC three times weekly was the optimal starting dosage, although more recently 40,000 units SC once weekly is a commonly used approach. However, erythropoiesis-stimulating agents such as EPO and darbepoietin are restricted under a risk evaluation and mitigation strategy (REMS) program owing to several trials showing increase in thrombotic risk and adverse effects on survival with these drugs (though this risk has not been as well demonstrated in MM compared to solid tumors).^{278, 279}

Neuropathies

A variety of malignant and paraproteinemic disorders can be associated with neuropathies.²⁸⁰ In MM, a symmetric, distal sensory, or sensorimotor neuropathy is most common and is associated with axonal degeneration, with or without amyloid deposition; there is no specific therapy. In some cases, this is associated with monoclonal antibodies directed against peripheral nerve myelin.²⁸¹

Associated diseases

MM has been described in association with both hematologic disorders and solid tumors. Acute leukemia either is induced by leukemogens, such as radiation and alkylating agents, or is part of the natural history of MM. The mean interval from diagnosis of MM to occurrence of acute leukemia is 60 (17–147) months, consistent with either possibility. The occurrence of acute leukemia in untreated MM patients suggests that it may be part of the natural history of the disease.²⁸² Furthermore, acute leukemia has been reported in 6 of 125 (4.8%) MM patients treated with alkylating agents, which is significantly higher than the incidence of acute leukemia in ovarian cancer patients treated with irradiation and alkylators.²⁵ Actuarial risk of leukemia in MM patients treated with melphalan and prednisone (MP) or with melphalan, cyclophosphamide, carmustine, and prednisone has been reported to be as high as 17.4% at 50 months from initiation of therapy.²⁸³ Gonzalez et al.²⁸² described 11 of 476 patients with MM who developed myeloid leukemia or sideroblastic anemia. All had received melphalan–prednisone for a median of 3 years and had major cytogenetic abnormalities. This study suggests that leukemia is predominantly treatment related. Finally, in 628 patients with MM, the incidence and diversity of solid tumors were similar to those observed in otherwise healthy persons of the same age.²⁸⁴

Treatment

While MM is not considered curable, its treatments are very effective and very well tolerated, including in the older patient population. The adoption of high-dose melphalan with autologous stem-cell transplant and the introduction of two new drug classes—IMiDs such as lenalidomide and proteasome inhibitors such as bortezomib—have resulted in dramatic improvements in outcomes. A retrospective study comparing patients diagnosed in 1997 and later to those diagnosed before 1997 found a significant improvement in OS, 44.8 months versus 29.9 months, respectively.²⁸⁵

An area of active investigation is when to initiate treatment for patients with MM. There is uniform consensus recommending treatment for active MM as defined by the presence of one of the CRAB criteria of end organ involvement.⁶ For patients who are asymptomatic, that is, with smoldering MM, the current

paradigm recommends close observation. However, the availability of well-tolerated, effective myeloma therapy has now motivated studies examining treatment earlier in the disease, before the onset of symptoms. Recently, the Spanish myeloma group conducted a randomized study of active treatment with lenalidomide and dexamethasone v. observation in patients with high-risk smoldering MM.²⁸⁶ High risk was defined by the presence of both BM involvement and elevated serum monoclonal protein or flow cytometry criteria and suppressed immunoglobulins (immunoparesis). The study found that 3-year OS was superior in the group undergoing active treatment, 94% versus 80%, and this was the first time this type of benefit was seen in a smoldering MM trial. These results suggest that earlier initiation of therapy may be helpful, and the generalizability of these findings awaits confirmation in further trials as well as identifying the specific patients who are most likely to benefit from early initiation of treatment. Additional strategies in smoldering MM include vaccines, such as with PVX-410, a multi-peptide vaccine designed to elicit an immune response against MM cells. This vaccine targets XBP1, CD138, and CS1, which are proteins highly expressed in MM cells and involved in MM pathogenesis.²⁸⁷ PVX-410 is currently in phase I clinical trials and in combination with lenalidomide in order to enhance of the immune response (NCT01718899).²⁸⁸

Patients undergoing therapy for MM should have clinical and laboratory assessments to assure both safety and efficacy of treatment. Monoclonal protein in the serum and/or urine should be measured by immunoelectrophoresis and more sensitive immunofixation techniques as well as serum FLCs. The serum FLC assay allows for diagnosis and assessment of patients previously thought to have oligosecretory or nonsecretory disease.²⁸⁹ A skeletal survey should be done annually, with BM examination reserved for diagnosis and time of subsequent change in clinical status, monoclonal Ig, or hemogram. It is important to remember that reduction of serum or urine M component as objective evidence of tumor response could reflect increased protein catabolism, decreased protein production, or both. Moreover, non-M protein-secreting MM clones may emerge during treatment, so that even a marked reduction in monoclonal Ig may not correlate with decrease in tumor burden.

The Bladé criteria to assess response post-transplant were developed for the European Group for Blood and Marrow Transplant (EBMT), the International BM Transplant Registry (IBMTR), and the Autologous Blood and Marrow Transplant Registry (ABMTR).²⁹⁰ These criteria include a more sensitive and rigorous definition of complete response (CR), including the absence of paraprotein assayed by immunofixation, and excludes transient responses. More recently, serum free light chain assays have been incorporated into response criteria^{291–293} and the IMWG response criteria are now universally used ([Table 6](#)). Stricter definitions of complete remission resulted in the inclusion of a category of stringent complete remission in which monoclonal plasma cells are not detectable in the marrow by immunohistochemistry or immunofluorescence and the free light-chain ratio is normal. The previously used near complete remission (only positivity by serum monoclonal immunoglobulin immunofixation) is now included in the new category VGPR and the previously used minor response category was eliminated. Limitations of the new criteria are that response calls are determined by monoclonal immunoglobulin and marrow evaluation. Dynamic changes in skeletal events readily identified by modern imaging techniques such as MRI and FDG PET CT are excluded from response assessments.

Table 6 Uniform response criteria from the international myeloma working group

Response subcategory ^a	Response criteria
CR	Negative immunofixation of the serum and urine and disappearance of any soft-tissue plasmacytomas and <5% plasma cells in marrow ^b
sCR	CR as defined above plus Normal FLC ratio and Absence of clonal cells in marrow ^b by immunohistochemistry or immunofluorescence ^c
VGPR	Serum and urine M-protein detectable by immunofixation but not on electrophoresis or 90% or greater reduction in serum M-protein plus urine M-protein <100 mg/24 h
PR	≥50% reduction of serum M-protein and reduction in 24-h urinary M-protein by ≥90% or to <200 mg/24 h If the serum and urine M-protein are unmeasurable, ≥50% decrease in the difference between involved and uninvolved FLC levels is required in place of the M-protein criteria If serum and urine M-protein are unmeasurable, and serum-free light assay is also unmeasurable, ≥50% reduction in plasma cells is required in place of M-protein, provided baseline marrow plasma-cell percentage was ≥30% In addition to the above-listed criteria, if present at baseline, a ≥50% reduction in the size of soft-tissue plasmacytomas is also required
SD	Not meeting criteria for CR, VGPR, PR, or progressive disease

CR, complete response; FLC, free light chain; PR, partial response; sCR, stringent complete response; SD, stable disease; VGPR, very good partial response; M-protein, monoclonal protein.

^a All response categories require two consecutive assessments made any time before the institution of any new therapy; complete and PR and SD categories also require no known evidence of progressive or new bone lesions if radiographic studies were performed. Radiographic studies are not required to satisfy these response requirements.

^b Confirmation with repeat marrow biopsy not needed.

^c Presence/absence of clonal cells is based on the κ/λ of >4 : 1 or <1 : 2. An abnormal κ/λ ratio by immunohistochemistry and/or immunofluorescence requires a minimum of 100 plasma cells for analysis.

Note: SD is not recommended for use as an indicator of response; stability of disease is best described by providing the time-to-progression estimates.

Source: Rajkumar et al. 2011.²⁹⁴

Sequencing-based platforms, quantitative PCR (polymerase chain reaction), and multiparametric flow cytometry are now being employed to detect minimal residual disease (MRD) in patients attaining at least a VGPR after primary therapy that may be of significant prognostic value. Martinez-Lopez et al. recently reported the results of sequencing-based BM evaluations on 133 patients in VGPR or better following primary therapy. In patients achieving a CR, the TTP (time to progression) was 131 months for MRD negative patients versus 35 months for MRD positive patients. When stratified by level of MRD, the respective TTP medians were 27 months for MRD $\geq 10^{-3}$, 48 months for MRD 10^{-3} to 10^{-5} , and 80 months MRD $< 10^{-5}$ ($p = 0.003\text{--}0.0001$).²⁹⁵ Although not currently a standard of care, MRD assessment may play an important role in evaluating disease response in the future.

Initial treatment

Oral administration of MP was historically considered a standard form of therapy that produces objective response in up to 50–60% of patients.^{296, 297} Multiple older studies have examined whether MP is as effective as combination chemotherapy (CCT) (generally with older agents such as vincristine and cyclophosphamide). In an attempt to determine which patients, if any, do better with more aggressive therapy, Gregory et al.²⁹⁸ examined published reports of 18 randomized controlled trials comparing MP with CCT in the primary treatment of 3814 patients. The overall results suggested that there was no difference in efficacy between these treatment modalities. The studies with a high MP 2-year survival rate showed a survival difference in favor of MP, whereas those with a low rate suggested a difference in favor of CCT. These results imply that, rather than there being no difference between MP and CCT, MP is superior for patients with an intrinsically good prognosis and inferior for those patients with a poor prognosis.

Immunomodulatory drugs

The introduction of thalidomide, an IMiD, was the first in a series of improvements over the MP regimen. The incorporation of thalidomide in combination with MP (MPT, melphalan, prednisone, thalidomide) in newly diagnosed patients with myeloma over the age of 65 years²⁹⁹ resulted in a 76% complete or PR rate compared to 47% in the MP arm. This translated into a doubling of the 2-year event-free survival (EFS) to 54% versus 27%. On the basis of these data, MPT was the standard of care for transplantation-ineligible patients. However, all studies showed an increase in adverse events in the MPT arm, including infections, neuropathy, and thromboembolism, suggesting that thromboprophylaxis and antimicrobial prophylaxis are required.³⁰⁰ Melphalan, prednisone, and lenalidomide (MPR) is another effective regimen in this population. Palumbo et al. then went on to evaluate the efficacy and safety of induction therapy with MPR followed by lenalidomide maintenance therapy (MPR-R), as compared with MPR or MP without maintenance therapy, in patients with newly diagnosed MM who were ineligible for transplantation. At a median follow-up of 30 months, the median PFS was 31 months for MPR-R versus 14 months for MPR and 13 months for MP. This benefit was observed in patients 65–75 years of age but not older than 75. Response rates were superior for the lenalidomide-containing regimen 77% for MPR-R and 68% for MPR versus 5% with MP.³⁰¹

Randomized trials with the use of other novel agents such as bortezomib with MP have proven benefits as well. For example, the VISTA trial compared the regimen of bortezomib, melphalan, and prednisone (VMP) MP in patients who were not candidates for autologous stem-cell transplant.³⁰² OS was significantly improved in the VMP group versus MP group, with 3-year OS of 68.5% versus 54%, respectively.³⁰³

Most recently, the FIRST trial, a randomized, phase III trial compared continuous lenalidomide with low-dose dexamethasone (Rd) against lenalidomide with low-dose dexamethasone for 18 cycles (Rd18) and MPT for 12 cycles.³⁰⁴ Median PFS for continuous Rd was 25.5 months versus 20.7 for Rd18 and 21.2 for MPT. The OS at 4 years was 59.4% for Rd versus 55.7% for Rd18 and 51.4% for MPT. In the continuous Rd arm, the ORR was 75.1% (15.1% CR, 28.4% VGPR) versus 73.4 in Rd18 (Cr 14.2%, VGPR 28.5%) and 32.3% MPT (CR 9.3%, VGPR 18.8%). The safety profile with continuous Rd was manageable as hematologic and nonhematologic adverse events were as expected for Rd and MPT. Notably, the incidence of hematological second primary malignancies was lower with continuous Rd than MPT. In newly diagnosed transplant-ineligible patients, the FIRST trial established continuous Rd as the new standard of care. There are ongoing trials looking at three drug combinations including bortezomib,

lenalidomide, and dexamethasone at reduced doses and attenuated schedules in this population as well ([Table 7](#)).

Table 7 Novel agent induction for newly diagnosed transplant-ineligible patients

Study	Regimen	Number of patients	Median follow-up (Mo)	Median OS (Mo)	Median PFS (Mo)
IFM 99-06 ³⁰⁵	MP	196	51.5	33.2	17.8
	MPT	125		51.6	27.5
	MEL100	126		38.3	19.4

^a 4-year OS.

In the transplant-eligible patients, two studies combined thalidomide with dexamethasone as initial therapy for MM and achieved rapid responses in two-thirds of patients, allowing for successful harvesting of PBSCs for transplantation.^{308, 309} Thal/dex has been compared with VAD (vincristine, doxorubicin, dexamethasone) and with dex, as initial therapy for patients before collection of autologous stem cells and transplantation. In a case control analysis, Cavo et al.³¹⁰ showed that thal/dex achieved higher overall response rates, whereas a randomized phase III (EGOG) trial showed statistically significantly higher response rates for thal/dex than dex-treated patient cohorts.³¹¹ This study provided the rationale for FDA (Food and Drug Administration) approval of this regimen for initial treatment of MM. Moreover, early studies show 91% responses, including 6% complete and 32% near complete/VGPRs to lenalidomide combined with dex.³¹² On the basis of these promising results, a phase III trial in the United States headed by ECOG investigated the role of len/dex in newly diagnosed MM. The study design allowed all patients to stay on-study for the first four cycles only for response assessment, after which patients could go off-study to proceed with stem-cell transplant. Safety data from this trial found that combining lenalidomide with the low-dose dexamethasone regimen was preferable to the combination with high-dose dexamethasone, with a reduction in grade 3 or higher nonhematologic adverse events

(48% vs 65%), including thromboembolism (12% vs 26%), and infections (9% vs 16%) in the two treatment arms of the trial.^{313, 314} The low-dose dexamethasone-containing regimen did lead to an increased occurrence of grade ≥ 3 neutropenia (20% vs 12%). Importantly, the combination with low-dose dexamethasone had a survival benefit over combination with high-dose dexamethasone, with a 1-year OS of 96% and 87%, respectively.^{313, 314} Prophylaxis against clotting with aspirin, warfarin, or subcutaneous low molecular weight heparin is needed when patients are treated with lenalidomide.^{315, 316}

Proteasome inhibitors

Richardson et al.³¹⁷ examined single agent bortezomib and Jagannath et al.³¹⁸ tested bortezomib combined with dex as initial therapy; in both cases, high frequency and extent of response were noted. In a phase I/II trial, Richardson et al.³¹⁹ demonstrated the safety and efficacy of the combination of lenalidomide, bortezomib, and dexamethasone (RVD), which showed an unprecedented overall response rate of 100%. Building upon this work, the benefits of combination therapy with RVD as first-line therapy were seen in the results of two-phase II trials—the IFM 2008 trial and the EVOLUTION trial.^{320, 321} The ORR after induction in the IFM trial was 97% (13% sCR, 16% CR, and 54% \geq VGPR). The EVOLUTION trial was designed to compare RVD with CyBorD (cyclophosphamide, bortezomib, and dexamethasone) in a randomized, multicenter setting. The ORR for the RVD arm after primary treatment followed by maintenance with bortezomib for four 6-week cycles was 85% (24% CR, 51% \geq VGPR).

Carfilzomib is an epoxomicin analog second-generation proteasome inhibitor that binds to the 20S proteasome in a highly selective and irreversible manner. Given its approval in the treatment of relapsed disease, it is now being studied in the upfront setting.³²² In a dose escalation study conducted by Jakubowiak et al.,³²³ the combination of carfilzomib, lenalidomide, and dexamethasone (CRD) has been evaluated where patients received carfilzomib (20, 27, or 36 mg/m², days 1, 2, 8, 9, 15, and 16 for 8 cycles then days 1, 2, 15, and 16) with lenalidomide 25 mg days 1–21 and dexamethasone 40 mg weekly cycles 1–4 then 20 mg weekly cycles 5–8 in 28-day cycles. After eight cycles, patients received the regimen every other week for eight cycles. After 24 cycles, maintenance with lenalidomide was recommended off-study. After a median of 12 cycles, 62% achieved at least a near-CR and 42% an sCR. 24-Month PFS was estimated at 92%. The toxicity profile was acceptable and notable for limited peripheral neuropathy.

Doublet and especially triplet regimens of novel drugs in combination with dexamethasone can induce complete remission rates comparable to transplantation regimens,^{310, 324} as described. Examples of modern regimens in use include doublet combinations of lenalidomide and dexamethasone and bortezomib and dexamethasone, as well as, the triple combination of RVD, CyBorD, and CRD ([Table 8](#)).

Table 8 Novel agent induction for newly diagnosed transplant-eligible patients

Study	Regimen	Number of patients	Cr/nCR (%)	ORR (%)	Outcome
Rajkumar et al. ³¹³	RD	223	18	79	OS: 87% at 1 year
	Rd	222	14	68	OS: 96% at 1 year
Harousseau et al. ³²⁵	VAD	121	6.4	62.8	PFS 30 months
	Bd	121	14.8	78.5	PFS: 36 months
Reeder et al. ³²⁶	CyBorD	33	39	88	N/A
Richardson et al. ³¹⁹	RVD	66	39	100	OS 97% at 18-months
Jakubowiak et al. ³²³	CRD	53	62	98	PFS 92% 24-months

RD, lenalidomide, high-dose dexamethasone; Rd, lenalidomide, low-dose dexamethasone; VAD, vincristine, doxorubicin, dexamethasone; Bd, bortezomib, low-dose dexamethasone; CyBorD, cyclophosphamide, bortezomib, dexamethasone; RVD, lenalidomide, velcade, dexamethasone; CRD, carfilzomib, lenalidomide, dexamethasone; OS, overall survival; PFS, progression-free survival; N/A, not available.

In patients where stem-cell collection is planned, combinations that include alkylating agents such as melphalan should be avoided as damage to normal hematopoietic stem cells can be incurred, which may render it impossible to collect stem cells for auto-HSCT. Lenalidomide may also hamper the collection of stem cells, although stem cell mobilization with growth factors and chemotherapy may overcome the myelosuppressive effects of lenalidomide.^{327–330} The number of cycles of treatment, especially with lenalidomide-containing regimens, is limited to roughly four cycles, as additional cycles may compromise the ability to collect stem cells.^{327, 331}

Combination therapy with novel drugs achieves complete remission rates comparable to those obtained with auto-HSCT. This has led to the design of ongoing studies that compare novel agents followed by auto-HSCT with novel agents and then auto-HSCT in case of disease relapse. Novel agents seem to be able to overcome some of the cytogenetic adverse prognostic factors such as del 13, t(4;14), and del 17p. It is too early to abandon auto-HSCT as the follow-up in clinical trials with new agents is too short to determine whether increased complete remission rates translate into durable remissions and EFS and OS. Complete remission rates as a surrogate marker for eventual outcome may prove to be inadequate. The DETERMINATION trial (NCT01208662) is an ongoing phase III, multicenter randomized trial of upfront high-dose melphalan with autologous stem-cell transplant versus transplant at relapse for myeloma patients up to age 65; all patients receive RVD as induction. This trial is designed to address this question of the role of autologous transplant, upfront or at time of relapse, in the context of novel drugs. It is likely that autologous transplant will add to the benefits noted with new drugs.

Radiation therapy

Radiation therapy for MM is used for treatment of localized disease, including plasmacytoma or spinal cord compression syndrome, and is frequently used for palliation. Hemibody radiation therapy has been utilized, either as a consolidation following induction CCT or as salvage therapy for chemotherapy-resistant MM.^{332, 333} Total body irradiation (TBI) has been used as a component of ablative therapy before hematopoietic stem-cell grafting but is rarely used as high-dose melphalan has equivalent efficacy and less toxicity.³³⁴

High-dose therapies

The rationale for the administration of alkylating agents (melphalan, cyclophosphamide, and busulfan) in a

higher-than-conventional dose with or without TBI, followed by transplantation of syngeneic, allogeneic, and autologous BM or peripheral blood progenitor cells (PBPCs) is as follows: plasma-cell dyscrasias remain uniformly fatal; multiple studies document sensitivity of MM cells to chemotherapy and radiotherapy; and CRs can be obtained with HDT.

Autologous stem cell transplantation

High-dose chemoradiotherapy followed by transplantation of either autologous BM or PBPCs has also achieved high (40%) CR rates, but the median duration of these responses has unfortunately only been 24–36 months.^{335, 336} Patients with sensitive disease and who are less heavily pretreated have the most favorable outcomes. Most importantly, a national French trial of 200 patients with MM who received two courses of VMCP alternating with VBAP and were then randomized to receive either conventional chemotherapy (eight additional courses of VMCP/VBAP) or HDT (melphalan and TBI) followed by autologous BMT has demonstrated significantly higher response rates, EFS and OS for those patients treated with high dose compared to those receiving conventional therapy.³³⁷ A second randomized trial in MM examined the relative merits of HDT either early versus late as salvage therapy for relapse after conventional therapy.³³⁸ The OS was 64 months in both groups, but the quality-adjusted time without symptoms and toxicity (Q-TWIST) strongly favored the early transplant cohort. The United States Intergroup Trial supports this view.³³⁹ The IFM has conducted a randomized trial comparing high-dose melphalan at 200 mg/m² versus melphalan at 140 mg/m² plus TBI as ablative therapies.³³⁴ Although response rates and EFS were comparable, toxicity and OS were superior in the high-dose melphalan alone arm, suggesting that TBI should not be considered part of the ablation regimen. A Scandinavian population-based study demonstrated prolonged survival for patients with MM <60 years of age treated with intensive therapy compared with historical controls who received conventional therapy.³⁴⁰ An additional randomized MRC trial confirmed a 12-month survival benefit in patients receiving high dose compared to conventional therapies.³⁴¹ Although these studies are encouraging, it is unlikely that patients are cured after a single high dose and stem-cell autografting regimen. In all the studies, the median EFS was prolonged; in four of five studies, transplant led to higher CR rate; and in three of five trials OS was improved ([Table 9](#)).

Table 9 Autologous transplantation versus conventional chemotherapy for newly diagnosed myeloma

Author	Therapy	Patients (n)	CR (%)	EFS (median months)	OS (median months)
Barlogie et al. ³⁴²	Conventional ^a	116	—	22	48
	HDT	123	40	49	62
Lenhoff et al. ³⁴⁰	Conventional ^a	274	—	—	46% at 48
	HDT	274	34	27	61% at 48
Attal et al. ³³⁷	Conventional	100	5	18	37
	HDT	100	22	27	52% at 60
Fermand et al. ³³⁸	Conventional	96	—	18.7	50.4
	HDT	94	—	24.3	55.3
Blade et al. ³⁴³	Conventional	83	11	34.3	66
	HDT	81	30	42.5	61
Child et al. ³⁴¹	Conventional	200	8.5	19.6	42.3
	HDT	201	44	31.6	54.1

CR, complete response; EFS, event free survival; HDT, high-dose therapy; OS, overall survival.

^a Historical controls.

Improving outcome of autografting

Attempts to improve the outcome of HDT followed by autografting include the use of autologous BM or PBPCs either depleted of tumor cells^{344–346} or processed to select normal hematopoietic progenitor cells by virtue of CD34 expression.^{347, 348} These have not translated to improved outcome. Barlogie et al.^{349, 350} are performing multiple high-dose therapies and stem-cell transplantation. Response rates are higher relative to historically matched controls, but the impact on long-term disease-free survival (DFS) requires further follow-up. A recent comparison of tandem transplant with or without thalidomide has not prolonged OS.³⁵¹ In a French-randomized trial comparing a single versus double HDT and stem-cell transplantation, there was no significant difference in the CR rate between single and double transplantation arms, and EFS and OS curves separated only after 3 years.³⁵² This suggests that only a subset of patients may benefit, and indeed only those patients who did not achieve a CR to the first transplant appeared to benefit from the second.³⁵³ The Bologna 96 study also showed that double autografting mainly benefited patients who did not achieve near CR.³⁵⁴ The role of tandem transplant is being addressed by the ongoing phase III, multicenter trial of single autologous transplant with or without consolidation therapy versus tandem autologous transplant with lenalidomide maintenance (BMT CTN 0702).

Giralt et al. have reported on the use of cyclosporine to induce GVHD postautografting in an attempt to generate associated autologous graft versus MM effect.³⁵⁵ It may be possible to stimulate autologous immunity to MM to treat MRD postautografting and thereby improve outcome. We have previously attempted to generate and expand anti-MM-specific autologous T cells *ex vivo* for adoptive immunotherapy of MRD in the patient post-autotransplant. It is now possible to clone the gene for the patient's specific idiotypic protein, identify gene sequences encoding for peptides predicted to be presented within the groove of class I HLA of a given patient's HLA type, and expand peptide-specific T

cells *ex vivo*.³⁵⁶ A similar strategy can be used to expand T cells against peptides within shared antigens that are overexpressed on MM cells, such as the telomerase catalytic subunit (hTERT), MUC-1, or the cytochrome CYP1B1.^{35, 357, 358} Immunologic responses are also being tested to enhance the immunogenicity of the whole tumor cell. We have shown that MM cells can be fused to DCs and that the use of the MM DC fusion as an antigen-presenting cell presents the entire MM cell as foreign. In a syngeneic murine MM model, vaccinations with MM cell-DC fusions, but not with either MM cells or DCs alone, demonstrate both protective and therapeutic efficacy.³⁵⁹ Most important, we have shown that patient MM cells can be fused to autologous DCs, which are readily isolated from either patient BM or peripheral blood, and that autologous MM cell-DC fusions can trigger specific cytolytic autologous T-cell responses *in vitro*.^{360, 361} We are translating these findings into clinical trials of MM-DC fusion vaccines to assess *in vivo* MM-specific T-and B-cell responses, as well as clinical efficacy.³⁶²

Maintenance therapy

Maintenance regimens have been proposed to extend the duration of complete remission following autologous stem cell transplant. The increased tolerability and efficacy of newer antimyeloma agents has increased the attractiveness and the applicability of this approach; previous attempts at maintenance therapy with older conventional chemotherapy agents such as melphalan or interferon were not beneficial.³⁶³

A meta-analysis of randomized controlled trials comparing thalidomide maintenance with other regimens after induction chemotherapy that included 2786 patients from six trials, demonstrated that patients receiving thalidomide maintenance had marginally better OS (HR 0.83, $p = 0.07$). The difference was most prominent in groups who receive both thalidomide and corticosteroids (HR 0.70, $p = 0.02$). Thalidomide improved PFS (HR 0.65, $p < 0.01$) but was associated with a higher thrombotic risk (risk difference 0.024, $p < 0.05$) and increased peripheral neuropathy (risk difference 0.072, $p < 0.01$).³⁶⁴

Three randomized trials have explored the use of lenalidomide as maintenance therapy, with two of the trials following autologous stem-cell transplant^{365, 366} and one trial after 9 months of melphalan-based therapy in patients ineligible for high-dose treatment.³⁰¹ In all three trials, there was a near doubling in PFS with lenalidomide maintenance, for example, from 27 to 46 months in the CALGB 100104 study.³⁶⁶ Furthermore, the CALGB study showed an OS benefit with lenalidomide: 15% of the lenalidomide group had died compared to 23% in the placebo group ($p < 0.03$) and at 3 years, the OS was 88% in the lenalidomide group compared to 80% in the placebo group.

A significant concern with maintenance therapy with lenalidomide is the risk of secondary malignancy. The risk of second primary cancers was roughly double in the maintenance group (7–7.7%) compared to the placebo group (2.6–3%). The secondary cancers observed included both hematological malignancies such as acute myelogenous leukemia as well as solid tumors. The risk of a secondary hematologic malignancy appears to be greatest when lenalidomide is given in combination with oral melphalan (HR 4.86, $p < 0.0001$).³⁶⁷ This increased risk of secondary malignancies and the risk benefit ratio of maintenance therapy should be considered and discussed with the patient when initiating maintenance therapy.

Bortezomib has also been studied as maintenance therapy. In the HOVON-65/GMMG-HD4 study, bortezomib was given every 2 weeks and was associated with increasing the near CR and CR rate from 31% to 49%.³⁶⁸ [Table 10](#) provides a summary of recent maintenance trials.

Table 10 Maintenance therapies

Study	Regimen	Number of patients	Outcome
IFM 2005-02 ³⁶⁵	Lenalidomide versus placebo as maintenance following first or second ASCT	614	PFS 41 months versus 23 months
CALGB 100104 ³⁶⁶	Lenalidomide versus placebo as maintenance therapy after ASCT	460	TTP 46 months versus 27 months
HOVON-65/ GMMG-HD4 ³⁶⁸	VAD versus PAD followed by ASCT, then thalidomide or bortezomib as maintenance	827	PFS 28 months versus 35 months

ASCT, autologous stem-cell transplantation; CR, complete response; PAD, bortezomib, doxorubicin, dexamethasone; VAD, vincristine, doxorubicin, dexamethasone; PFS, progression-free survival; TTP, time to progression.

Consolidation therapy

The use of short consolidation treatment after autologous SCT increases the CR rate and relapse-free survival. Ladetto et al.³⁶⁹ have reported that post-transplant consolidation using the combination of bortezomib, thalidomide, and dexamethasone made it possible to convert 22% of VGPR into full, lasting molecular responses (PCR negative). Enhanced rates of CR, ranging between 10% and 30%, have been reported with post-ASCT (autologous stem-cell transplantation) use of bortezomib and lenalidomide as single agents.^{370, 371} In the IFM 2008 study, the usefulness and safety of post-transplant consolidation with two cycles of the RVD regimen was evaluated. This study showed that consolidation was feasible, well-tolerated, and effective, resulting in improving the sCR rate from 27% to 40% after consolidation.³⁷²

Continuous therapy

Recent data in the upfront setting, both in transplant-eligible and -ineligible patients, suggest that continuous therapy may result in improved disease control.^{373, 374} Several clinical trials have demonstrated superiority of maintenance strategies using thalidomide, lenalidomide, and bortezomib in transplant-eligible patients.

Thus far, the results from lenalidomide trials are perhaps the most convincing. The IFM 2005-02 and CALGB 100104 studies have both demonstrated a doubling of PFS^{365, 366} although only the CALGB trial has suggested an OS advantage. Lenalidomide certainly fits the requirements of a maintenance drug for continued use in myeloma, as it is administered orally and is generally well tolerated. Most recently, the FIRST trial comparing continuous Rd with Rd for 18 cycles and MPT demonstrated that continuous treatment with lenalidomide is superior to a finite therapy. Median PFS for the continuous Rd arm was 25.5 months versus 20.7 months for Rd18 and 21.2 months for MPT.³⁰⁴ However, the risk of second primary malignancies, although low, does need to be discussed and balanced in the decision-making process when considering continuous therapy with this agent.

Allogeneic stem-cell transplantation

Syngeneic transplantation has been done infrequently in MM, but some patients reported from Seattle³⁷⁵ and in European Bone Marrow Transplant Group (EBMT)³⁷⁶ remain progression free at long intervals post-BMT. The EBMT has reported on allografting in MM.^{377–379} Actuarial OS was 32% at 4 years and 28% at 7 years for the 72 (44%) patients who achieved CR after BMT. However, overall PFS was 34%

at 6 years, and few patients remain in continuing CR at > 4 years postallograft. Favorable pre-BMT prognostic factors for both response to and survival after BMT were female sex, IgA MM, low serum β 2M, stage I disease at diagnosis, one line of previous treatment, and being in CR before BMT. Of major concern is the early 41% transplant-related mortality (TRM; 50% in males) in the EBMT report,³⁸⁰ which has subsequently been reduced to 20–30% owing to better patient selection, early transplantation, and less pretransplant treatment.³⁷⁹ In the allografting experience in Seattle, actuarial probabilities of OS and EFS for the 36% patients achieving CR were 50% and 43%, respectively, at 4.5 years.³⁸¹ Adverse prognostic factors included transplantation >1 year from diagnosis; serum β 2M > 2.5 mg/dL at transplant; female patients transplanted from male donors; having received > eight cycles of chemotherapy; and Durie–Salmon stage III disease at presentation. Again toxicity was common, with 35 (44%) patients dying of transplant-related causes within 100 days of BMT.^{381, 382} In an attempt to improve the outcome of allografting in MM by avoiding TRM, we carried out T (CD6)-depleted allografting using histocompatible sibling donors in 61 patients with MM whose disease remained sensitive to conventional chemotherapy.^{346, 383–386} There were 17 (28%) CR and 34 (57%) PR, 2 (3%) NR (not reached), and only 3 (5%) transplant-related deaths. However, DFS after allo BMT was 1 year, with only 20% patients disease free at \geq 4 years post-transplant.

Molecular remissions are more common after allografting than after autografting,^{387–390} and donor lymphocyte infusions (DLI) can treat relapsed MM postallografting,^{391–393} indicating a clinically significant graft-versus MM (GVM) effect. At our center, relapses postautografting versus the higher toxicity and lower relapse rates in allograft recipients result in equivalent long-term outcomes.³⁹⁴ In an effort to reduce toxicity and exploit GVM, we have utilized CD4+ DLI at 6 months post-CD6-depleted BM allografting in order to enhance GVM and thereby improve outcome.³⁸⁶ Although prophylactic DLI induces significant GVM responses after allogeneic BMT, only 58% of patients were able to receive DLI despite T-cell-depleted BMT.

The use of nonablative transplantation is an alternative strategy to preserve GVM while avoiding the toxicity of allografting.³⁹⁵ Melphalan at a dose of 100 mg/m² has been used in combination with DLI in high-risk MM patients.³⁹⁶ Although disease control was achieved in some patients, significant GVHD was noted in this group of patients. Autografting has been performed before nonmyeloablative transplant by several investigators, demonstrating the feasibility of this approach to cytoreduce tumor and then enhance anti-MM immunity.^{397, 398} For example, Maloney et al.³⁹⁸ report an overall response rate of 83% with 57% CRs. Chronic GVHD, transplant-related toxicity, and relapse of disease remain a problem. One randomized trial in high-risk MM showed that the combination of autologous stem-cell transplant followed by dose-reduced allogeneic transplant (IFM 99-03) was not superior to tandem autotransplant (IFM 99-04),³⁹⁹ but a second randomized trial showed superior survival in those patients receiving autologous followed by allogeneic grafts.^{400, 401} The median OS was 80 months for allografting versus 54 for double autografting. The CR rate after allografting was 55% versus 26% after double autograft. In contrast, a randomized trial in high-risk MM showed that the combination of autologous stem-cell transplant followed by dose-reduced allogeneic transplant (IFM 99-03) was not superior to tandem autotransplant (IFM 99-04).³⁹⁹ BMT CTN 0102 also evaluated autologous SCT followed by second autologous versus nonmyeloablative allogeneic SCT. In both standard- and high-risk patients, nonmyeloablative allogeneic HSCT after autologous HSCT was not more effective than tandem autologous HSCT.⁴⁰² Bjorkstrand et al. conducted a prospective study of single or tandem autologous SCT versus reduced-intensity allogeneic SCT based on availability of an HLA-identical sibling. Long-term follow-up of 357 patients who received either autologous SCT (single or double) or auto-allo with HLA-identical sibling matched donor demonstrated that PFS was superior 35% versus 18% ($p = 0.001$)

at 60 months for those receiving an auto-allo. Nonrelapse mortality was 12% after auto-allo versus 3% in the auto group ($p < 0.001$), and the incidence of limited to extensive GVHD was 31% and 23%.⁴⁰³

The use of allogeneic transplant as salvage therapy, while feasible, is unlikely to be of significant benefit in the heavily pretreated population. The EBMT reported on the outcomes of 229 patients who received reduced-intensity conditioning allogeneic SCT. TRM at 1 year was 22% and 3-year OS and PFS were 41% and 21%, respectively. Twenty-five percent of patients had extensive chronic GVHD.⁴⁰⁴ The best outcomes were seen in patients who received a transplant in remission and early in the course of the disease. Adverse OS was associated with chemoresistant disease, more than one prior transplant, and male patients with female donors.

Allografting should only be undertaken in the context of clinical trials, which aim to reduce chronic GVHD, separate GVM from GVHD, and amplify the GVM effect to improve outcome by ameliorating toxicity and maximizing the antimyeloma effect of immunologic effector cells.

Relapsed disease

Almost all patients with MM who initially respond to chemotherapy eventually relapse. In order to overcome resistance to current therapies and improve patient outcome, novel biologically based treatment approaches are needed, which target the mechanisms whereby MM cells grow and survive in BM.⁴⁰⁵ To achieve this goal, we have developed systems for studying growth, survival, and drug resistance mechanisms intrinsic to MM cells. Importantly, we have also developed both *in vitro* systems and *in vivo* animal models to characterize mechanisms of MM cell homing to BM, as well as factors (MM cell–BMSC interactions, cytokines, and angiogenesis) promoting MM cell growth, survival, drug resistance, and migration in the BM microenvironment.^{73, 80, 85–87, 406–408} These model systems have allowed for the development of several promising biologically based therapies that can target the MM cell and its BM microenvironment, those which target the MM cell only, and those which target only the BM microenvironment ([Figure 7](#)).

Figure 7 Inhibition of signaling pathways by novel therapeutic agents in multiple myeloma.

Immunomodulatory drugs

Drugs that target the MM cell and its BM milieu and thereby can overcome classical drug resistance *in vitro* include IMiDs such as thalidomide, lenalidomide, and pomalidomide⁶⁴ and proteasome inhibitors such as bortezomib⁶⁶ and carfilzomib. The bench to bedside translation of the IMiD drug lenalidomide has been very rapid. It was shown to target both the MM cell and BM microenvironment *in vitro* and *in vivo* in 2000^{64, 409}; completed phase I testing which identified an MTD, lack of toxicity, and remarkable anti-MM activity in 2001⁴¹⁰; and completed phase II testing in 2002.⁴¹¹

Two large phase III trials comparing lenalidomide/dex with dex/placebo were unblinded because of statistically significantly higher response rates, as well as increase in TTP and OS in the lenalidomide/dex treated cohort, providing the basis for its FDA approval to treat relapsed MM after one prior therapy.^{412, 413} Pomalidomide has also demonstrated potent anti-myeloma effects. Several studies have looked at pomalidomide in combination with low-dose dexamethasone in the relapsed population culminating in the approval of pomalidomide 4 mg orally on days 1–21 of 28-day cycles until progression. The phase II, randomized, open-label study compared pomalidomide and low-dose dexamethasone with single-agent pomalidomide in patients with relapsed, refractory myeloma. Median

PFS for the combination arm was 4.2 months versus 2.7 months (HR 0.68, $P = 0.003$). ORR was 33% with combination versus 18% for pomalidomide alone. Median OS was 16.5 months versus 13.6 months, respectively. Refractoriness to lenalidomide and bortezomib did not affect outcomes with pomalidomide and dexamethasone.⁴¹⁴ A phase III study European study comparing pomalidomide and low-dose dexamethasone with high-dose dexamethasone alone showed a longer PFS of 4 months in the combination arm versus 1.9 months for dexamethasone alone (HR, 0.48; $P < 0.0001$). The most common side effects were myelosuppression and infections.⁴¹⁵

Recently, the mechanism of action of IMiD drugs in MM (as well as their teratogenicity) has been better elucidated, when it was first appreciated that these drugs bind to cereblon (CBN)⁴¹⁶ Binding of IMiD drugs to CBN prevents auto-ubiquitylation of CBN, enhancing CBN-dependent proteasomal degradation of transcription factors IKZF1 (Ikaros) and IKZF3 (Aiolos), which are important to MM proliferation.^{417–419}

Proteasome inhibitors

The bench to bedside translation of a boronic acid proteasome inhibitor bortezomib and subsequent FDA approval was also very rapid. Initial rationale to use bortezomib in MM is to block NF- κ B activity as NF- κ B was identified as a therapeutic target in MM, conferring drug resistance, modulating adhesion molecule expression on MM cells and BMSCs, and modulating constitutive and MM binding-induced transcription and secretion of cytokines.⁵⁰ In MM cells, bortezomib leads to the accumulation of unfolded proteins and endoplasmic reticulum stress, followed by activation of the unfolded protein response and arrest of the cell cycle.⁴²⁰ Phase I trials showed tolerability and early evidence of anti-MM activity.⁴²¹ The phase II SUMMIT trial demonstrated responses, including CRs, prolongation of TTP and survival, and associated clinical benefit, forming the basis for accelerated FDA approval for treatment of relapsed refractory MM.⁴²² The APEX trial compared dex versus bortezomib therapy of relapsed MM was unblinded owing to a statistically significant prolongation in TTP in the bortezomib-treated cohort, forming the basis for its FDA approval extending to relapsed MM.³¹⁷ With follow-up, TTP and OS is significantly improved with bortezomib and neurological complications manageable.⁴²³ Which of its many activities account for its MM cytotoxicity is unclear.

A next generation epoxyketone proteasome inhibitor, carfilzomib, was granted accelerated FDA approval as a single agent for the treatment of patients who have received at least two prior lines of therapy based on the results of the phase II of single-agent carfilzomib twice weekly that showed an ORR of 23.7% in patients who had a median of five prior lines of therapy. Median duration of response was 7.8 months and median OS was 15.6 months. The drug was well tolerated. The most common side effects were fatigue, anemia, nausea, and thrombocytopenia with 13.9% reporting peripheral neuropathy (majority of patients had baseline peripheral neuropathy).⁴²⁴ Cardiac failure events such as pulmonary edema were seen in 7.2% of patients. The ASPIRE trial recently reported on the results of the combination of carfilzomib with lenalidomide and dexamethasone compared to lenalidomide and dexamethasone in relapsed disease.⁴²⁵ This combination was well tolerated and afforded a nearly 9 month improvement in PFS underscoring the benefits of combinations even in the relapsed setting.

Oral proteasome inhibitors, ixazomib and oprozomib, are in clinical trials now and will likely gain approval. Ixazomib has already demonstrated safety and efficacy in phase 1 trials in the relapsed, refractory population. Of 60 patients who had received a median of 6 prior regimens including bortezomib (83%), there were 41 evaluable patients. Responses included 1 VGPR, 5 PR, 1 MR, and 15 with SD. Only 10% of patients had drug-related peripheral neuropathy and none \geq grade 3.^{426, 427} In a

phase I/II trial, weekly ixazomib was evaluated in combination with standard dose lenalidomide and dexamethasone in patients with newly diagnosed myeloma. Preliminary results from 58 response evaluable patients demonstrated a 93% overall response rate, with 67% of subjects achieving VGPR or better, including a CR rate of 24%.^{426, 428} On the basis of these results, ixazomib is being evaluated in combination with lenalidomide and dexamethasone in two large, international phase III trials: TOURMALINE MM1 for relapsed, refractory myeloma patients and TOURMALINE MM2 for newly diagnosed patients. Another oral proteasome inhibitor oprozomib is also under investigation for the treatment of MM.⁴²⁹ These drugs could significantly impact the treatment of myeloma allowing for completely oral treatment regimens and consequently, completely outpatient care for patients. This could have a measurable quality of life benefit for patients, particularly in the elderly population, and may provide a convenient way of incorporating proteasome inhibitor-based maintenance strategies. [Table 11](#) summarizes some of the therapies used in relapsed disease.

Table 11 Novel therapy for relapsed, refractory multiple myeloma

Trial	Phase	Agent	Number of patients	ORR (%)	OS (Mo)	Outcome (months)
Richardson et al. ³¹⁷	Ph3	Bortezomib	669	38	29.8	TTP 6.2 versus 3.5

Histone deacetylase (HDAC) inhibitors

Histone deacetylase (HDAC) inhibitors are another class of drugs that have recently demonstrated activity in relapsed, refractory myeloma when used in combination with bortezomib. The phase III, randomized trial, called VANTAGE 088, showed that the combination of a nonselective HDAC inhibitor vorinostat and bortezomib was active and well tolerated. When this combination was compared with bortezomib alone, the ORR for vorinostat and bortezomib was 56.2% versus 40.6% for bortezomib alone ($p < 0.0001$), similarly, PFS was 7.63 months versus 6.83 months, respectively ($p = 0.01$).⁴³¹ More recently, another nonselective HDAC inhibitor panobinostat has been combined with bortezomib and dexamethasone in a phase II study⁴³⁶ and compared with bortezomib and dexamethasone alone in the relapsed, refractory population in a phase III study, PANORAMA-1.⁴³² PFS was 12 months versus 8.1 months ($p < 0.0001$) for patients treated with the triple therapy. ORR was 61% versus 55% and duration of response of 13.1 months versus 10.9 months. OS data is not yet mature. Common side effects included myelosuppression and diarrhea.⁴³⁶ Based on these findings, panobinostat was approved by the FDA in 2015 and is the first in class HDAC inhibitor to receive this indication in MM.⁴³² Ricolinostat (ACY-1215) is a selective HDAC6 inhibitor is being investigated in combination with both lenalidomide and bortezomib with dexamethasone.^{437–439} In combination with lenalidomide and dexamethasone, ORR was 69%. Thirteen of the 16 patients had prior lenalidomide and 3/6 were refractory to lenalidomide.⁴⁴⁰ In combination with bortezomib and dexamethasone, the ORR was 44%.⁴⁴¹

Monoclonal antibodies

Several monoclonal antibodies are being investigated and demonstrated activity in myeloma. Specifically, novel drugs that target CD38, CS1, and BAFF are in ongoing clinical trials.^{427, 442} Daratumumab, a monoclonal CD38 antibody, was granted Fast Track Designation and Breakthrough Therapy Designation by the FDA based on results of a phase I/II trial that demonstrated single agent activity in relapsed, refractory myeloma. In the ≥ 4 mg/kg groups ($n = 12$), 5 PRs and 3 MRs were observed. Median PFS had not been reached by a data cutoff of 3.8 months.⁴³³ Daratumumab is now being studied in combination with lenalidomide and dexamethasone in relapsed, refractory disease. SAR650984, another CD38 inhibitor, had an ORR of 30.8% as a single agent in the dose-escalation study in RR patients at the MTD.⁴⁴³ Daratumumab is also being studied in smoldering MM (NCT02316106).

Elotuzumab, a humanized monoclonal IgG1 antibody directed against human CS1 (also known as CD2 subset-1, SLAMF7, CRACC, and CD319), a cell surface antigen glycoprotein that is highly expressed on MM cells and normal plasma cells, has also been granted Breakthrough Therapy Designation by the FDA. In the phase I study, no objective responses were seen, although 26.5% had stable disease (SD) by EBMT myeloma response criteria.⁴⁴⁴ In combination with lenalidomide and dexamethasone, objective responses were obtained in 82% (23 of 28) of treated patients. After a median of 16.4 months follow-up, the median TTP was NR for patients in the 20-mg/kg cohort who were treated until disease progression.⁴⁴⁵ An ORR of 92% and a median PFS was NR after a median follow-up of 20.8 months at the 10 mg/kg dose, which was the dose used in the ongoing phase III trial, ELOQUENT-2.⁴³⁴ Phase I results of elotuzumab in combination with bortezomib and dexamethasone are also favorable, with a PR or better in 48% of 27

evaluable patients with relapsed, refractory disease.⁴⁴⁶ Elotuzumab in combination with lenalidomide +/- dexamethasone is also being studied in high-risk smoldering MM (NCT02279394).

Tabalumab is a fully human monoclonal antibody designed to have neutralizing activity against both membrane-bound and soluble BAFF and has been combined with bortezomib and dexamethasone in a phase I study. In this study, the ORR was 45.8%.⁴⁴⁷ A phase II trial of this combination has been completed and results are forthcoming.

Other treatments

Bendamustine as a single agent or in combination with lenalidomide and dexamethasone is another option for patients with relapsed, refractory myeloma. The combination of bendamustine, lenalidomide, and dexamethasone was evaluated in a phase I/II trial. The median PFS was 6.1 months, PR rate 52%, and VGPR rate 24%.⁴³⁵ The MTD of bendamustine was 75 mg/m² as compared with prior studies using 100 mg/m². Toxicity was mainly hematologic arguing in favor of the lower dose, particularly in light of the fact that this population is heavily pretreated.

Other regimens have been explored as well, bortezomib and pegylated liposomal doxorubicin (Doxil) and bendamustine with prednisone and thalidomide.^{430, 448}

There are currently many new drugs in development that target novel pathways.^{449, 450} For example, filanesib, a kinesin spindle protein inhibitor, which induces aberrant mitotic arrest and rapid cell death and preferentially acts on MCL-1-dependent cells including myeloma cells, has demonstrated activity in combination with lenalidomide and bortezomib. Several other classes of novel drugs are currently under investigation including the bromodomain inhibitors, cyclin-dependent kinase inhibitors, and inhibitors of the ubiquitin pathway. Data generated from these early studies will provide a better understanding of how these will be incorporated into the continuum of myeloma care.^{451–453}

Another area of interest and therapy development is the blockade of interactions between the tumor cells and immune cells. PD-1 and PD-L1 are two targets of interest. PD-1 is a receptor present on T cells that interacts with PD-L1 expressed on tumor cells. Patients with persistent MRD and at relapse have upregulation of PD-L1 and PD-1.⁴⁵⁴ There are ongoing clinical trials exploring PD-1 blockade in combination with dendritic cell/myeloma fusion vaccine^{362, 455} and with, for example, pembrolizumab, lenalidomide, and dexamethasone (NCT02036502).

The choice of therapy for relapsed or refractory patients depends on a number of factors including time since last therapy, prior exposure to novel agents, alone or in combination, and drug-induced comorbidities, for example, neuropathy, renal malfunction, and loss of patient physiologic reserve. In the past decade, there has been a dramatic increase in the number of therapies available to patients with RR myeloma. This is a very dynamic area within oncology and will continue to evolve as more new therapies enter trials and gain approval.

Future directions

Evolution of a new treatment paradigm for MM

Our *in vitro* and animal model studies have demonstrated the importance of the BM in promoting MM cell growth, survival, drug resistance, and migration in the BM microenvironment and have already derived very promising therapies based on targeting the MM cell in its BM milieu. These studies provide the

framework for development of a new treatment paradigm in MM, targeting both the tumor cell and its microenvironment, which is urgently needed as MM remains incurable despite all available therapies.

Identification and validation of novel-targeted MM

Importantly, in our *in vitro* gene array studies with conventional dex¹⁶⁹ and bortezomib¹⁷⁰ therapies, samples obtained from patients treated on these protocols help to identify *in vivo* targets and mechanisms of novel drug action on the one hand, versus mechanisms of drug resistance on the other, and also aid in determining whether *in vivo* targets of these novel therapies correlate with their *in vitro* anti-MM activities. Excitingly, preclinical studies suggest enhanced activity when these novel agents are combined with conventional agents or with each other. These studies have established a new treatment paradigm targeting the MM cell in its BM microenvironment to further elucidate MM pathogenesis as well as overcome drug resistance and improve patient outcome.

Novel single agents of great promise include new proteasome inhibitor marizomib (NPI-0052), FGFR3 inhibitors,^{456, 457} MEK inhibitor AZD6244,⁴⁵⁸ and Hsp90 inhibitors.⁴⁵⁹ Marizomib⁴⁶⁰ is a next-generation proteasome inhibitor and active against bortezomib-resistant MM and nontoxic in preclinical models, and is already in clinical trials in relapsed MM. FGFR3 inhibitors are specifically targeting those 15–20% patients with t(4:14) translocation. Hsp90 inhibitors as single agents can achieve responses in relapsed refractory MM.

Profiling of gene and protein expression can also provide the preclinical rationale for clinical protocols combining novel targeted therapies. For example, our studies demonstrate that bortezomib treatment of MM cells *in vitro* induces death signaling, downregulates survival signaling, and upregulates both ubiquitin/proteasome and stress response gene transcripts.¹⁷⁰ Specifically, bortezomib upregulates Hsp90, which not only is a stress response protein but also plays a major role in protein unfolding required before proteins can be degraded by the proteasome. Our *in vitro* studies show that Hsp90 inhibitor 17-AAG (KOS953) can block the Hsp90 stress response induced by bortezomib and thereby increase MM cell apoptosis. These gene microarray studies therefore provided the framework for a clinical trial coupling these agents in MM, which shows that Hsp90 inhibitor KOS953 can sensitize to and even overcome resistance to bortezomib,⁴⁶¹ and a phase III clinical trial of bortezomib versus bortezomib with KOS953 in relapsed MM is ongoing.

Proteomic studies can also provide the preclinical basis for clinical application of novel targeted therapies. For example, our *in vitro* studies demonstrate that exposure of MM cells to bortezomib induces cleavage of DNA repair kinases such as DNA PKcs in a dose- and time-dependent manner.⁴⁶² This observation for the first time suggested that bortezomib inhibited DNA repair. Subsequent *in vitro* studies demonstrated that coupling bortezomib with DNA damaging agents (alkylating agents and anthracyclines) can enhance sensitivity or even restore sensitivity to these agents in resistant MM cells.⁴⁶³ Already clinical protocols coupling bortezomib with Doxil⁴⁶⁴ and with melphalan⁴⁶³ have demonstrated promising clinical results. Specifically, a large randomized trial of Doxil and bortezomib versus bortezomib in relapsed MM showed significantly increase OR, EFS, and OS in the patients receiving combined therapy, setting the stage for its FDA approval in June 2007.⁴³⁰

In order to provide the framework for coupling these novel agents in rational clinical trials, we have also characterized the apoptotic signaling cascades triggered in MM cells by both conventional and these novel agents.⁷⁰ For example, use of IMiDs with TRAIL provides dual triggering of caspase 8 death signaling, whereas treatment with IMiDs such as lenalidomide and bortezomib triggers both caspase 8- and caspase 9-mediated MM cell death. The combination of lenalidomide and bortezomib has

demonstrated remarkable activity, even in patients resistant to either agent alone.⁴⁶⁵

The mTOR inhibitor rapamycin sensitizes MM cells to both conventional and novel therapies^{466, 467}; temsirolimus has anti-MM activity in xenograft models.⁴⁶⁸ A phase I trial of the combination of the oral mTOR inhibitor everolimus with lenalidomide in relapsed/refractory myeloma was well tolerated and had responses in a heavily pretreated population.⁴⁶⁹ Bortezomib inhibits growth (MEK/ERK) and survival (Jak/STAT) signaling, but activates Akt, providing the preclinical rationale for combining bortezomib with the Akt inhibitor perifosine.⁴⁷⁰

Our recent signaling studies have defined the role of the aggresome in degrading ubiquitinated protein in MM, and specifically used the HDAC6 inhibitor tubacin to inhibit its transport to the aggresome for degradation. Blocking the aggresome with tubacin induces a compensatory upregulation of the proteasome; conversely, blocking the proteasome with bortezomib triggers a compensatory upregulation of the aggresome. Importantly, blocking both the proteasome and aggresome with bortezomib and tubacin, respectively, induces synergistic toxicity.⁴⁷¹ The HDAC6 inhibitor ricolinostat (ACY-1215) is currently in clinical trials in combination with lenalidomide, pomalidomide, or bortezomib.^{440, 441}

It is also possible to combine monoclonal antibodies with novel drugs. Lenalidomide, for example, can markedly augment ADCC induced by anti-CD40 in MM.¹¹⁰ Finally, gene expression profiling in correlative science studies of patients on clinical protocols will both identify targets of drug sensitivity versus resistance and allow for predicting those patients most likely to respond to conventional and novel targeted therapies. For example, gene expression profiling of patient tumor samples showed genes upregulated in patients responding to bortezomib versus those patients who did not respond. Hsp27 upregulation correlated with intrinsic or acquired bortezomib resistance. Preclinical studies showed that p38MAPK inhibition downregulated Hsp27 expression and restored bortezomib sensitivity in resistant MM cell lines and patient samples,⁴⁷² providing the basis for a trial combining these two agents.

Other plasma cell dyscrasias

Plasmacytomas

Clinical characteristics

Plasmacytomas are collections of monoclonal plasma cells originating either in bone (solitary osseous plasmacytoma, SOP) or in soft tissue (extramedullary plasmacytoma, EMP). They comprise <10% of plasma-cell dyscrasias. MM must be excluded before the diagnosis of either SOP or EMP can be made. MRI can be useful to show additional marrow abnormalities consistent with MM.⁴⁷³ The median age of diagnosis of either SOP or EMP is approximately 50 years, nearly 10 years younger than that for MM.^{474–476} Although patients with SOP and EMP can both progress to MM, persons with SOP progress in the majority of cases, in contrast to EMP, where only up to 50% eventually develop MM. The median survival of 86.4 and 100.8 months for patients with SOP and EMP, respectively, is similar; however, PFS is markedly different, 16% for SOP patients versus 71% for EMP patients. The persistence of stable monoclonal Ig in serum and/or urine after primary treatment of plasmacytoma does not necessitate additional therapy, as it does not influence survival or DFS.⁴⁷⁴ In contrast, rising monoclonal Ig levels in a patient with a history of either SOP or EMP should trigger a work-up for either recurrent plasmacytoma or MM. It has been suggested, as is true for MM, that serum β 2M has prognostic value in patients with SOP. Specifically, 17 of 19 patients with elevated serum β 2M had transformation to MM and shorter

survival (31 months) than those with normal serum β 2M levels.⁴⁷⁷

Treatment

Treatment of SOP and EMP is local therapy, primarily radiotherapy with surgery as needed for structural anatomic support.^{474–476} The benefit of chemotherapy, either alone or in combination with radiotherapy and surgery, as primary therapy for SOP or EMP, has not been proven. Moreover, the benefit of adjuvant chemotherapy, given to prevent recurrent disease and/or progression to MM, is also undefined. Disappearance of protein after involved-field radiotherapy predicts for long-term DFS and possible cure.⁴⁷⁸

Immunoglobulin M monoclonal gammopathy

Excess monoclonal IgM in the serum can occur in a variety of diseases. In a Mayo Clinic series of 430 patients in whom a monoclonal IgM protein was identified, 242 (56%) had MGUS, 71 (17%) had Waldenström's macroglobulinemia, 28 (7%) had lymphoma, 21 (5%) had chronic lymphocytic leukemia, 6 (1%) had primary amyloidosis, and 62 (14%) had other malignant lymphoproliferative diseases.⁴⁷⁹ The duration of time from the recognition of the M protein to the development of a malignant lymphoid disease ranged from 4 to 9 years, suggesting that long-term follow-up of such patients is necessary.

Waldenström macroglobulinemia

The diagnosis of Waldenström macroglobulinemia (WM) is based on the presence of an IgM monoclonal protein and 10% or more the BM biopsy showing involvement with small lymphocytes with lymphoplasmacytic features and an immunophenotype characteristic of lymphoplasmacytic lymphoma (see the following discussion).⁴⁸⁰ WM corresponds most closely to the lymphoplasmacytic lymphoma (LPA) under the World Health Organization (WHO) classification of lymphoid tumors [LPL/immunocytoma of the Revised European–American (REAL) classification of lymphoma]. WM accounts for approximately 2% of all hematologic malignancies and is more common in men than in women. Its incidence increases with age, and it is more common among whites than among African-Americans.^{481, 482} Although the etiology of WM is unclear, genetic factors may contribute to the pathogenesis of this disease, as there are reports of families with WM in association with other lymphoproliferative and immunologic disorders.⁴⁸³ Cytogenetic abnormalities occur in 15–90% of cases, but none are specific for WM.^{484, 485} The WM B-cell clone demonstrates interclonal differentiation from small lymphocytes with large focal deposits of surface immunoglobulins to lymphoplasmacytic cells and mature plasma cells that contain intracytoplasmic immunoglobulin. This morphologic heterogeneity is reflected by variable expression of phenotypic markers. All WM cells express monoclonal IgM and most cells are CD19, CD20, CD22, and FMC7 positive. High density of CD38 is also detected with variable intensity of the PCA-1 antigen. Predictably, CD45 isoform expression is heterogeneous, probably reflecting ongoing monoclonal B-cell differentiation. In approximately 20% of cases, CD5 and CD23 expression are seen, but their coexpression is uncommon.⁴⁸⁶ Circulating clonal B cells in WM increase in patients who fail to respond to therapy or who progress.⁴⁸⁷ Recent studies suggest that WM originates from a postgerminal center B cell that has undergone somatic mutations and antigenic selection in the lymphoid follicle and has the characteristics of an IgM-bearing memory B cell.^{488–490}

The median age of onset of WM is 61 years. Symptoms are characteristically vague and nonspecific, with the most common being weakness, anorexia, and weight loss. Symptoms due to peripheral neuropathy and

Raynaud's phenomenon can precede more serious manifestations. Lymphadenopathy, splenomegaly, and/or hepatomegaly are present in 30–40% of cases, and at least 20–25% lymphoplasmacytoid cells are usually present in the marrow. Visceral involvement of small bowel and peripheral nerves can cause the clinical sequelae of malabsorption and neuropathy, respectively. Hemorrhagic complications may be present, attributable to abnormal bleeding times, decreased platelet adhesiveness, or direct interference by the IgM protein with the release of platelet factor 3 and with coagulation factors. An important part of the differential diagnosis is to exclude the less common entity of IgM MM, which is characterized by lytic bone disease and an absence of organomegaly and/or lymphocytic involvement; rarely, WM can itself progress to IgM MM.⁴⁹¹ Amyloidosis occurs rarely in WM.⁴⁹² Hyperviscosity syndrome, described earlier as a rare complication in MM, occurs more commonly in the setting of excess IgM and is characterized by mucosal bleeding and neurologic, ocular, and cardiovascular abnormalities.²⁵⁹ Therapy with plasmapheresis is more useful to remove excess IgM than it is in the setting of excess IgG monoclonal proteins and related hyperviscosity in MM.

Treatment

The median survival is approximately 50 months, not that dissimilar from the best-reported series of patients with MM. In contrast to persons with MM, however, many individuals with WM have indolent disease requiring no therapy for long periods of time, with survivals in excess of 20 years. Although high-dose therapy with autologous stem-cell support has been shown to be effective in many patients with MM or with low-grade lymphoma, relatively few patients with WM have undergone transplant. Nonetheless, preliminary data suggest that high-dose therapy is associated with a high CR rate and acceptable toxicity, and this approach therefore warrants further investigation, particularly in younger patients with poor prognostic features.⁴⁹³ Splenectomy has been reported to be effective in chemotherapy-resistant patients with WM and results in a major decrease in monoclonal protein concentration and durable remission.^{494, 495} Monoclonal antibody therapy with rituximab, a chimeric anti-CD20 monoclonal antibody, produces responses in both treated and untreated patients with low-grade lymphoma. Given that the CD20 antigen is typically present in WM, rituximab has been given to patients and a clinical response was seen in about one-third of previously treated patients in early studies.^{496, 497} Combinations of rituximab with cyclophosphamide⁴⁹⁸ or bortezomib⁴⁹⁹ are increasingly used. Rituximab use in WM can be associated with a paradoxical increase in IgM (or flare) with increase in serum viscosity.⁵⁰⁰

Recent evidence suggests the presence of the *MYD88* L265P mutation in the majority of WM patients.⁵⁰¹ Moreover, mutations in the CXCR4 pathway may affect disease presentation.⁵⁰² The Burton tyrosine kinase (BTK) is a downstream target of MYD88, an adaptor molecule for Toll-like receptors.⁵⁰³ Ibrutinib is an oral inhibitor of BTK, and a phase II trial of ibrutinib in 63 patients with previously treated WM demonstrated decrease in monoclonal protein of 50% or better in 73% of patients with a median time to PR of 8 weeks.⁵⁰⁴ These findings led to FDA approval of ibrutinib in WM.

Heavy-chain diseases

Since the original description by Franklin et al.⁵⁰⁵ of a patient with malignant lymphoma whose serum and urine contained large amounts of the Fc fragment of IgG, the clinical and immunochemical scope of gamma heavy-chain disease (γHCD) has broadened. These diseases are characterized by the presence of a portion of the Ig heavy chain in the serum or urine or both. The median age at diagnosis is similar to that for MM, approximately 60 years.⁵⁰⁶ The clinical and laboratory features can be heterogeneous. Most

common presenting symptoms are weakness, fatigue, and fever, associated with lymphadenopathy and hepatosplenomegaly. In addition to Ig heavy chain in serum or urine, a lymphoplasmacytic marrow infiltrate is noted in most cases. The clinical course can be fulminant and rapidly progressive; alternatively, the monoclonal heavy chain can persist for years in otherwise asymptomatic patients. Thus, survival is variable, but the median is only 12 months. Treatment options for patients with active disease are similar to those used for lymphoma or MM, whereas patients with indolent disease should be followed expectantly without therapy. Cases of α HCD, μ HCD, and δ HCD have also been described. HCD is typically associated with non-Hodgkin's lymphoma in the gastrointestinal tract, beginning with plasma cells that produce a heavy chain and aggregate in the intestinal tract and subsequent transformation into a malignant non-Hodgkin's lymphoma of the immunoblastic type, probably arising from the more mature plasma cells.⁵⁰⁷ The ideal therapy for heavy-chain disease is not known because of its rarity, but intensive chemotherapy including intravenous cyclophosphamide, doxorubicin, vincristine, and oral prednisone appears to offer some patients long-term remissions.

Amyloidosis

Amyloidosis is relatively rare as a clinically significant disease. It has been classified into five categories. These include (1) primary, with or without plasma cell and lymphoid neoplasms; (2) secondary, associated with chronic infections or autoimmune disease; (3) hereditary, associated with familial Mediterranean fever, Portuguese lower limb neuropathy, and others; (4) amyloidosis associated with aging; and (5) amyloidosis of endocrine glands, with medullary thyroid carcinoma and multiple endocrine neoplasia type 2.^{492, 508} The amyloid found in most cases of amyloidosis can be assigned to one of two types, according to whether the fibrils consist mainly of the variable region of Ig light chains (AL, or primary amyloidosis) or protein A (AA, or secondary amyloidosis). Protein A has a molecular weight of 8500 Da and consists of 76 amino acids; it is not related to any known immunoglobulin. Establishing the correct diagnosis is key, as monoclonal gammopathy of unknown significance is common, and in a series of 350 patients with suspected AL amyloidosis, 9.7% of patients actually had mutations in the fibrinogen A alpha-chain or transthyretin.⁵⁰⁹ Direct classification of the amyloid protein through laser microdissection and mass spectrometry can help improve the accuracy of diagnosis of AL amyloidosis.⁵¹⁰

In AL amyloidosis, amyloid primarily involves the heart, tongue, gastrointestinal tract, and/or skin, whereas AA primarily results in fibril deposition in liver, kidney, and spleen. A review of 229 patients with AL documented MM in 47 (21%) patients.⁵⁰⁸ Initial presenting symptoms were fatigue and weight loss, with pain more common in those who also had MM. Hepatomegaly and macroglossia were present in up to one-third of patients with AL; renal insufficiency was present in one-half of patients, and proteinuria (defined as albuminuria with immune globulin seen, only in MM) was documented in 82% of patients. Nephrotic syndrome, CHF, orthostatic hypotension, carpal tunnel syndrome, and peripheral neuropathy were all more common in those without MM (30–70% of patients studied) than in persons with MM (<20%). Overall median survival was 12 months, 5 months for those with MM in contrast to 13 months for individuals without MM. Although it has been difficult to monitor the distribution and progression of disease, it has been shown that radiolabeled serum amyloid P component, which has specific binding affinity for amyloid fibrils, can be given intravenously and localizes rapidly and specifically in amyloid deposits.^{511, 512} This technique may therefore facilitate diagnosis and monitoring of the extent of systemic amyloidosis, including the effects of therapeutic interventions.

Treatment

Treatment of AL is making progress. Early studies looked at colchicine or MP or all three, with low response rates.⁵¹³ Initial experience with^{514, 515} dose-intensive melphalan with autologous stem-cell support can achieve CRs, with improvement in performance status and clinical remission of organ-specific disease, guidelines have been developed for patient selection to maximize benefit and minimize TRM and guidelines have been.^{516–518} As in MM, patients eligible for high-dose treatments may also do well with chemotherapy.⁵¹⁹ To address this, a randomized trial compared high-dose melphalan and autologous stem-cell transplant with standard melphalan and dexamethasone, and this study did not find a benefit with intensive therapy.⁵²⁰ A notable limitation of this trial was the high mortality rate in the intensive arm, which has not been seen in other sites, suggesting that the trial may not be generalizable.

Attempts to improve outcomes for patients with symptomatic and advanced multisystem disease may require both solid and stem-cell transplantation, as well as the use of less intensive conditioning regimens. For example, patients with cardiac involvement have unusually high TRM during autologous stem cell mobilization and transplant, and these patients may be managed with a combination of cardiac transplant followed by autologous stem cell transplant.⁵²¹ Newer drugs now routinely used in MM are increasingly used in patients with AL amyloidosis, such as the combination of CyBorD, with durable responses.⁵²²

Chapter 122

Myeloproliferative neoplasms: essential thrombocythemia, primary myelofibrosis, and polycythemia vera

Ayalew Tefferi, MD

Overview

The chronic myeloid neoplasms are a diverse group of malignant bone marrow conditions that originate in a transformed multipotential hematopoietic progenitor cell. This heterogeneous group of diseases shares an initially indolent clinical course with a variable degree of risk to evolve into overt acute leukemia. Even in the absence of leukemic transformation, the consequences of the cellular excesses or deficiencies characteristic of these disorders are troublesome for patients and all too frequently fatal; some of these disease complications include thrombosis, bleeding, marked hepatosplenomegaly, profound constitutional symptoms, and cachexia.

Under the revised 2008 World Health Organization (WHO) classification system, the broad category of chronic myeloid neoplasms include the myelodysplastic syndromes (MDS, discussed in [Chapter 113](#)), myeloproliferative neoplasms (MPN), “MDS/MPN overlap,” and a fourth subcategory that is characterized by both prominent blood eosinophilia and a mutation involving either platelet-derived growth factor receptor (PDGFRA or PDGFRB) or fibroblast growth factor receptor 1 (FGFR1).^{1, 2} The 2008 WHO MPN category includes the four classic “myeloproliferative disorders,” which includes chronic myeloid leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF) as well as chronic neutrophilic leukemia (CNL) chronic eosinophilic leukemia not otherwise specified (CEL-NOS) mastocytosis and MPN, unclassifiable (MPN-U). The “MDS/MPN” category displays features that are characteristic of both MDS (dyserythropoiesis or dysgranulopoiesis) and MPN (peripheral blood granulocytosis, monocytosis, eosinophilia, or thrombocytosis).³ Included in this category are chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia (JMML), “atypical chronic myeloid leukemia, *BCR-ABL1*-negative” (aCML), and “MDS/MPN, unclassifiable.”² “MDS/MPN, unclassifiable” includes the WHO provisional entity of “refractory anemia with ring sideroblasts associated with marked thrombocytosis (RARS-T).”³

The first clear descriptions of ET, PV, and PMF were relatively recent; credit for priority is customarily given to Epstein and Goedel (Vienna, 1934) for ET, Vaquez (Paris, 1892) for PV, and Heuck (Heidelberg, 1879) for PMF.⁴ Since 1960, CML has been defined by the presence of the Philadelphia chromosome, t(9;22)(q34q11).⁵ In the 1980s, the aberrant *BCR-ABL* translocation—the molecular equivalent of the Philadelphia chromosome—was found to be diagnostic of CML and sufficient to cause the disease in a mouse model. Today, CML is the most well-defined and molecularly characterized of Dameshek's original MPD group.⁶ This chapter considers the three *BCR-ABL*-negative classic MPN (i.e., ET, PV, and PMF).

Essential thrombocythemia

Epidemiology

ET is an uncommon disorder; estimates of its age- and gender-adjusted incidence range widely, from 0.2 to 2.5 cases per 100,000 persons per year.^{7–9} Among younger people (ages 30–50), the disease appears to be more common in women, but this gender imbalance is not as clearly found in other age groups. No clear environmental risk factor has been identified. The incidence of ET (and also of PV and PMF) appears to be increased among Ashkenazi Jews.¹⁰ The median age at diagnosis for all three MPN is approximately 60 years. Familial clustering of ET has been described but is exquisitely rare; some familial cases are associated with mutations in the thrombopoietin (*TPO*) gene that result in increased Tpo production (a megakaryocyte growth factor) with consequent megakaryocyte hyperstimulation.^{11, 12}

Diagnosis

The chief clinical challenge with respect to ET diagnosis is differentiating genuine autonomous thrombocytosis from the myriad causes of “secondary” or “reactive” thrombocytosis (RT). In more than 80% of routine cases of thrombocytosis, the elevated platelet count is polyclonal and represents a reaction to the presence of a nonmyeloid disorder.^{13, 14} The thrombocytosis associated with inflammatory, infectious, and malignant conditions is thought to be due to the action of megakaryocyte stimulatory cytokines such as interleukin-6 (IL-6), whereas the peculiar thrombocytosis seen occasionally in iron-deficient states remains poorly understood and may be mediated by erythropoietin (Epo) cross-stimulation of precursor cells committed to platelet production.¹⁵

The distinction between ET and RT is clinically important because there is an increased risk of thrombosis and bleeding associated with ET, but the risk with RT appears to be much lower.¹³ If the presence of RT is not obvious, serum ferritin, and C-reactive protein (CRP—a surrogate marker for IL-6 levels) may be diagnostically useful in excluding iron deficiency and inflammation, respectively.¹⁵ Elevated CRP levels suggest RT and should prompt a more thorough search for an obscure source of reactive cytokines. Of course, an elevated CRP does not strictly rule out ET, for a patient may potentially have ET and a comorbid inflammatory condition, but this is uncommon.¹⁵ Ferritin levels must also be interpreted with caution: although a low value is consistent with iron deficiency, and a high value suggests RT, neither definitively excludes ET.

Surgical hyposplenism is usually obvious from a patient's history, but functional hyposplenism due to amyloidosis, celiac sprue, or another cause may not be so blatant.¹⁶ Therefore, examination of a blood smear, searching specifically for Howell–Jolly bodies, should be made during the initial evaluation of each patient with chronic thrombocytosis.

Once these steps have been taken and there is no evidence for RT or hyposplenism, ET increases in likelihood and peripheral blood mutation screening for *JAK2*, *CALR*, and *MPL* mutations might facilitate the diagnosis of an underlying MPN without distinguishing ET from PV or PMF. ET should also be distinguished from other myeloid disorders that may have a very different prognosis and require different therapy. ET look-alike myeloid neoplasms include some cases of MDS, CML, and the other two non-ET classic MPN (i.e., PV and PMF, including the potentially confusing “cellular phase or prefibrotic” PMF). If conventional cytogenetic analysis in a suspected ET patient does not reveal a Philadelphia chromosome, it is prudent to obtain peripheral blood or bone marrow fluorescent *in situ* hybridization (FISH) studies at least once to exclude the possibility of karyotypically occult CML.

Distinguishing ET from PMF is usually not difficult, but there can be exceptions. Mild (grade 1 or 2) reticulin fibrosis can be found in approximately 15% of ET cases.¹⁷ However, cellular phase or

prefibrotic PMF, characterized by marrow hypercellularity with florid atypical megakaryocytic hyperplasia but not heavy fibrosis, can mimic ET in presentation and requires careful morphologic examination for distinction.¹⁸ Abnormal megakaryocyte clusters on the bone marrow biopsy are characteristic of all three BCR-ABL-negative PMF. Cytogenetic abnormalities are present in fewer than 10% of patients at diagnosis.¹⁹

Pathogenesis

As mentioned earlier, clonal myeloproliferation involving the megakaryocytic lineage and sometimes other myeloid lineages (even in cases where the white count and hematocrit are normal) is demonstrable in the majority of female patients with ET via X-chromosome-linked DNA or gene product analysis.^{20, 21}

In 2005, a *JAK2* gain-of-function mutation (*JAK2V617F*) has been described in the majority of patients with ET as well as those in PMF and PV.^{22–25} A much smaller proportion of patients with ET (~5%) carry an *MPL* mutation.^{26–29} Most recently in 2013, a third mutation involving the calreticulin gene (*CALR*) was described in about half of the patients with *JAK2*-unmutated ET or PMF.³⁰ However, the precise pathogenetic contribution of these mutations is not clear.

In ET, megakaryocyte proliferation and platelet production are apparently autonomous, and normal regulatory pathways are apparently defective. The mechanism remains obscure in most cases. Megakaryocytes from ET patients are not inhibited by antibodies against key growth and differentiation cytokines, including IL-3, IL-6, granulocyte-monocyte colony-stimulating factor (GM-CSF), and Tpo.^{31, 32} Tpo and its receptor, c-Mpl, comprise the major feedback loop controlling megakaryocyte growth and development, but Tpo and c-Mpl dynamics in ET and related disorders appear to be complex. Tpo levels are often normal or elevated in ET despite the increased megakaryocyte mass but are not reproducibly different among normal marrow and ET or RT cases, while c-Mpl expression is often (but not always) markedly down-regulated in ET ([Figure 1](#)). However, c-Mpl expression is also down-regulated in other MPNs, so its diagnostic utility for ET is limited.^{33, 34} The specific cytokines driving megakaryocyte proliferation in ET have not been worked out in detail, but megakaryocyte progenitors from ET patients may display unexplained hypersensitivity to both IL-3 and Tpo.^{35, 36}

Figure 1 (a) Normal megakaryocyte c-Mpl immunohistochemical staining and (b) decreased megakaryocyte c-Mpl staining in a myeloproliferative disorder.

Clinical manifestations

At least half of patients with ET are asymptomatic at presentation; with appropriate therapy many can remain asymptomatic throughout the course of their illness although life expectancy is significantly shorter than the sex and age-matched control population.^{37–39} At presentation, microvascular and vasomotor symptoms are found in 25–50% of ET patients. Major thrombosis is seen in 11–25% of patients at diagnosis and 10–22% during follow-up, while major hemorrhage is observed in 2–5% at diagnosis and 1–7% during follow-up.^{9, 38, 40, 41} Bleeding complications can be exacerbated by the use of aspirin (ASA) and non-steroidal anti-inflammatory drugs (NSAIDs), which have platelet inhibitory effects. In contrast to other MPN, where splenomegaly is very common, less than 25% of ET patients have palpable splenomegaly at the time of initial presentation.³⁷

Vasomotor disturbances (e.g., headaches, lightheadedness, visual symptoms such as blurring and scotomata, palpitations, chest pain, erythromelalgia, and distal paresthesias) are troublesome but not generally life threatening. The proximate cause of such symptoms remains poorly defined; speculation has focused on abnormal platelet-endothelium interactions in the microvasculature, which can be associated with inflammation and transient thrombotic occlusion.⁴² Various platelet products such as thromboxane A2 are vasoactive, and some of these probably also play a role in the pathobiology. Erythromelalgia is the most dramatic vasomotor symptom, characterized by erythema, warmth, and pain in distal extremities; this symptom is rare but not entirely specific for ET.⁴³ The presence of vasomotor microvessel disturbances does not clearly predict hemorrhage or thrombosis in large vessels.

There are several potentially life-threatening complications of ET: large-vessel thrombosis (both arterial and venous), hemorrhage, and transformation of the disease into either a fibrotic phase resembling PMF or acute myeloid leukemia (AML). Arterial thrombosis can lead to cerebrovascular events, cardiovascular ischemia, organ infarction, and digital gangrene. Venous thrombosis in ET occurs both in sites common to other thrombotic diatheses (e.g., pulmonary embolism and lower extremity deep venous thrombosis) and also in more unusual sites (e.g., cerebral sinus thrombosis, retinal vein thrombosis, and hepatic and portal vein thrombosis).³⁸

Mucocutaneous bleeding (epistaxis, gingival bleeding, ecchymoses, and petechiae) can be a major nuisance. This is the most common hemorrhagic problem in ET.⁴⁴ Because epistaxis and easy bruising are very common in the general public, it can be difficult to assess the contribution of ET to these symptoms in afflicted patients. If careful control of the platelet count controls the mucocutaneous symptoms, it is reasonable to assume that thrombocytosis was contributory. Serious hemorrhage in ET is most common in the gastrointestinal tract and may be precipitated by ASA or NSAID use.⁴⁵ Hemorrhage also occurs in the central nervous system (CNS) and the retina, but such events are, fortunately, uncommon. Paradoxically, patients with extreme thrombocytosis may be at special risk for bleeding, in part related to the development of an acquired von Willebrand factor (vWF) deficiency that is thought to be related to platelet adsorption of large multimers of vWF. This phenomenon can be seen with extreme thrombocytosis of any cause.⁴⁶

Fibrotic and leukemic evolutions of ET are rare events (<5% of patients) during the first 10 years after diagnosis.^{37, 38}

Prognosis and therapy

When considering therapy for ET, it is important to keep in mind two facts: (1) ET is generally an indolent disorder, with a life expectancy (at least in the first decade of the disease) quite close to that of an age- and gender-matched control population, and (2) no treatment to date has been shown to influence overall survival.^{37, 47} Therefore, the maxim *primum non nocere* should not be forgotten. Therapy for ET is usually initiated to palliate microvascular symptoms or prevent thrombotic or hemorrhagic complications. Vasomotor disturbances in ET can often be relieved with low dose ASA; 81 mg/day is usually enough. When ASA does not alleviate these symptoms, it is reasonable to add a platelet-lowering agent and this is often successful.

There are only a few randomized trials assessing the most appropriate therapy for diminishing the thrombotic risk in patients with ET, so clinical decisions must usually be based on prospective cohort studies and large retrospective analyses. Therapy should be guided by an individualized assessment of thrombotic risk. Two clinical parameters appear to be quite important in making this judgment: a history of thrombosis and age above 60 years.^{41, 48} On the basis of the presence or absence of these two risk factors, patients with ET have been grouped into low-, high-, and indeterminate-risk groups and therapeutic decisions have been made accordingly ([Tables 1](#) and [2](#)).⁴⁹ This classification has recently been refined with the identification of *JAK2* mutation and cardiovascular risk factors as additional independent risk factors for arterial thrombosis in ET.⁵⁰ Accordingly, “low risk,” as opposed to “very-low-risk” disease category, is defined by age <60 years and without history of thrombosis, but with either *JAK2* mutation or cardiovascular risk factors. Such patients without *JAK2* mutation or cardiovascular risk factors are assigned a “very-low-risk” disease category. The definition of high-risk disease remains unchanged and includes patients with age ≥60 years or presence of thrombosis history. *JAK2*V617F allele burden has limited relevance in ET prognosis.

Table 1 Risk stratification in polycythemia vera and essential thrombocythemia

Low-risk	Age below 60 years, and No history of thrombosis, and Platelet count below 1 million/ μ L
Low-risk with extreme thrombocytosis	Age below 60 years, and No history of thrombosis, and Platelet count above 1 million/ μ L
High-risk	Age 60 years or older, or A positive history of thrombosis

Table 2 Proposed risk-adjusted therapy in essential thrombocythemia

Risk category ^a	Cytoreductive therapy	Aspirin therapy	Childbearing potential ^b
Low	No	Yes	ASA
High	Yes	Yes	Interferon α + ASA
Indeterminate	Sometimes	Yes (unless aVWD)	ASA (unless acquired VWD)

^a See [Chapter 113](#) for algorithm regarding risk category assignment.

^b Suggestions for drug therapy in women of childbearing potential are based on anecdotal evidence of safety.

Abbreviations: ASA, low-dose aspirin; aVWD, acquired von Willebrand disease.

The use of ASA (81–325 mg/day) to decrease thrombotic risk in low- and high-risk ET seems reasonable in view of demonstrated antithrombotic benefit in PV.^{51, 52} However, patients with very-low-risk disease, as defined earlier, might not require aspirin therapy. The more common approach for high-risk ET patients is to try to lower the platelet count into the normal range. One important randomized trial demonstrated a 20% absolute risk reduction (24–3.6%) in thrombotic events with the use of hydroxyurea (HU) in ET patients in a high-risk group.⁵³ Other cytoreductive agents have not yet been shown in a randomized manner to reduce thrombotic events. It is not clear precisely how low the goal platelet count should be in the high-risk group—thrombotic events can happen even with a platelet count in the normal range—but <400,000/ μ L seems to be a reasonable target and is supported by retrospective data.^{54, 55} For low- and very-low-risk patients, it is not clear that platelet-lowering agents are of any benefit, as thrombotic events are much less common in this group.

HU should be the first cytoreductive drug of choice in high-risk ET because of the high-quality evidence supporting its use. There has been concern about the leukemogenicity of HU, but in two recent studies of HU-treated patients with ET, no cases of leukemia were reported after 5–14 and 2–12 years of therapy.^{56, 57} Interferon- α 2A (IFN α) and, more recently, longer-acting pegylated forms of interferon provide therapeutic alternatives in HU intolerant or refractory cases, but interferon's well-known toxicity limits use as first-line therapy, especially as many high-risk ET patients are elderly and have a difficult time tolerating the necessary doses.^{58–60} IFN α is the drug of choice for ET patients requiring cytoreduction during pregnancy (see below).

Major bleeding (i.e., enough blood loss to drop hemoglobin level or cause bleeding in a critical organ, like the CNS) occurs in less than 10% of ET patients.^{37, 38} Extreme thrombocytosis (e.g., platelet count >1 million/ μ L) appears to be a risk factor for bleeding, in part because of the acquired vWF deficiency described earlier. Therapy designed to lower the platelet count and indirectly raise vWF levels may be

indicated in the presence of a substantial reduction in large vWF multimers. In an emergency situation, platelet apheresis is the fastest way to lower the platelet count, but its utility has not been proven conclusively.

Special considerations

Pregnancy in ET is associated with increased risk (~35%) of first trimester spontaneous abortions.⁶¹ There does not appear to be a postpartum thrombosis risk.⁶² There is no clear association between the increased risk of spontaneous abortion and the degree of thrombocytosis, nor is there any clear benefit from prophylactic platelet apheresis.⁶¹ High-risk pregnant women with ET (i.e., women with previous thrombosis) require cytoreductive therapy just like other high-risk patients. There is anecdotal evidence of the safety of IFN α in pregnancy but no controlled data. HU and pipobroman are considered teratogenic (FDA pregnancy class D) and anagrelide also crosses the placenta and has unknown effects on the developing fetus (FDA pregnancy class C). The teratogenicity of HU, however, does not appear to be severe enough to justify elective abortion in cases of inadvertent early fetal exposure.⁶³

Primary myelofibrosis

Epidemiology

Among the three classic MPN, PMF is the most aggressive. Fortunately, PMF is a rare scourge; the incidence is only 0.4–1.5 cases per 100,000 persons per year, with a median age at diagnosis above 60 years and a slight male predominance.^{7, 8} PMF has been associated with exposure to ionizing radiation (e.g., in Hiroshima survivors), heavy exposure to petroleum derivatives, and thorium dioxide (Thorotrast) contrast medium, but in the vast majority of cases, there is no such exposure history.^{64, 65}

Pathogenesis

As with other MPN, myeloid-derived cells in PMF have been shown to be monoclonal by analysis of X-linked genes and gene products.⁶⁶ In contrast, the marrow fibroblasts in PMF are polyclonal.^{66, 67} The florid bone marrow stromal reaction that is so characteristic of PMF includes fibroblast hyperproliferation, a dramatic increase in extracellular matrix proteins such as collagen (mostly type I and type III), increased blood vessel formation (angiogenesis), and increased bone synthesis and osteoblast activity (osteosclerosis).^{68, 69} Such marrow microenvironmental changes are mediated by a cytokine storm elaborated by the clonal myeloid cells. Indeed, increased cellular and extracellular levels of multiple cytokines with fibrogenic, angiogenic, and/or osteogenic potential have been detected in PMF, lending support to this hypothesis.⁷⁰

There are several murine models in which marrow fibrosis and/or extramedullary hematopoiesis (EMH) have been observed. Mice forced to over-express TPO develop of marrow fibrosis and osteosclerosis, which may be due to hypersecretion of osteoprotegerin, an osteoclast-inhibiting factor.^{71, 72} Mice that under-express the transcription factor *GATA-1*, which is important in the development and differentiation of hematopoietic cells, suffer impaired megakaryocyte differentiation and diminished platelet production and eventually develop EMH and marrow fibrosis.⁷³ However, it is not clear to what extent these germ line mouse mutants are faithful models of the neoplastic disorder in humans, where any mutations would be expected to be restricted to hematopoietic cells. Mutations or expression changes in TPO or its receptor (c-Mpl) or *GATA-1* have not been found in human PMF, and mutations in FOG-1, the major

GATA-1 cofactor, are also generally absent.⁷⁴

The molecular lesions underlying PMF are beginning to become apparent. Most notable is the 2005 report of a *JAK2* gain-of-function mutation (*JAK2*V617F) that was discovered in the majority of patients with PMF, ET, and PV.^{22–25} In 2006 and 2007, other *JAK2* (in PV) and *MPL* (in ET and PMF) mutations were described in *JAK2*V617F-negative cases.^{26–29} Most recently in 2013, a third driver mutation in MPN involving the calreticulin (*CALR*) gene has been described and is found in approximately 25% of patients with PMF and is mutually exclusive of *JAK2* or *MPL* mutations.⁷⁵ However, the precise pathogenetic contribution of these mutations is not clear. Recurrent karyotypic abnormalities seen in PMF include del(13q), del(20q), trisomy 8, trisomy 9, del(12p), and abnormalities of chromosomes 1 and 7, all of which are found in other chronic myeloid disorders and have no specificity for PMF.⁷⁶ About half of patients with PMF have a cytogenetic abnormality at diagnosis, but there is no predominant lesion and no individual cytogenetic abnormality affects more than 15–20% of patients.

Diagnosis

Characteristic features of PMF include a hypercellular marrow with fibrosis; EMH, which is most often manifest as splenomegaly; anemia; and a so-called myelophthasic peripheral blood picture.⁷⁰ Marrow fibrosis and a myelophthasic blood picture alone are not diagnostic of PMF, as myelofibrosis is associated with a diverse litany of conditions, including metastatic cancer, other hematologic disorders, and rheumatologic and granulomatous diseases ([Table 3](#)). Myelophthasic peripheral blood findings include marked anisocytosis, poikilocytosis, teardrop-shaped red cells (dacryocytes), and left-shifted granulocytopoiesis. The mechanism is unclear. Even EMH is not completely specific for PMF, as it can be observed in other conditions where the bone marrow is replaced (e.g., metastatic cancer) or marrow hematopoiesis is inadequate (e.g., β -thalassemia).^{77, 78}

Table 3 Causes of bone marrow fibrosis

Myeloid disorders	Nonhematological disorders	Other hematologic disorders
Myelofibrosis with myeloid metaplasia	Metastatic cancer	Hairy cell leukemia
Chronic myeloid leukemia	Connective tissue disorders (e.g., lupus and systemic sclerosis)	Multiple myeloma
Essential thrombocythemia		Lymphoproliferative disorders
Atypical chronic myeloid disorders	Infections (granulomatous disease, tuberculosis, kala-azar, etc.)	Gray platelet syndrome
Hypereosinophilic syndromes		
Polycythemia vera	Vitamin D deficiency—rickets	
Myelodysplastic syndrome with fibrosis	Renal osteodystrophy	
Malignant histiocytosis	Paget disease	
Systemic mastocytosis	Hyperparathyroidism	
Acute myelofibrosis		
Acute megakaryoblastic leukemia (AML-M7)		
Other acute myeloid leukemias		

^a See [Chapter 113](#) for algorithm regarding risk category assignment.

^b Suggestions for drug therapy in women of childbearing potential are based on anecdotal evidence of safety.

Abbreviations: ASA, low-dose aspirin; aVWD, acquired von Willebrand disease.

Because of hypercellularity and fibrosis, the bone marrow in PMF is often difficult to aspirate, resulting in a dry tap. Core marrow biopsy usually shows heavy collagen fibrosis, osteosclerosis, intra-sinusoidal hematopoiesis, and atypical megakaryocyte hyperplasia. Marrow fibrosis can be difficult to assess on standard hematoxylin and eosin stains and may be better estimated by the use of special stains, such as that for reticulin (a silver impregnation technique that stains a glycoprotein elaborated by stromal cells) or the trichrome stain for collagen. In some cases of PMF, the degree of bone marrow fibrosis may initially be minimal. This finding is often called the “cellular phase” of PMF and can be diagnostically challenging. Fibrosis grading schemes have been developed but are of relatively limited clinical utility.⁷⁹

The bone marrow morphologic features of PMF may sometimes be difficult to distinguish from those of myelodysplastic syndromes with fibrosis (MDS-*f*) and the so-called acute myelofibrosis. The latter entity has substantial overlap with megakaryocytic acute leukemia (AML-M7).⁷⁹ Megakaryocytes alone often appear dysplastic in routine cases of PMF, but significant dysplasia in other cell lines favors a diagnosis of MDS-*f*.⁷⁹ Acute myelofibrosis (also known as malignant myelosclerosis or acute myelosclerosis) is suggested when constitutional symptoms are prominent, development of the illness is rapid (i.e., over the course of a few weeks), and the spleen is not palpable. Special stains for megakaryoblasts (e.g., CD61 or vWF) may reveal the presence of an otherwise unrecognized cell population. Sometimes, despite the best efforts of clinicians and pathologists, the diagnosis is simply not clear and patients must be treated

expectantly.

Clinical manifestations

About 25% of patients with PMF are asymptomatic at diagnosis. Most patients have anemia and at least some degree of splenomegaly at presentation. The anemia of PMF is multifactorial. Contributing problems include replacement of normal hematopoietic tissue with fibrosis, ineffective hematopoiesis in the remaining myeloid tissue, and hypersplenism. Splenomegaly in PMF may be massive, and the spleen is usually very firm. Spleen and liver enlargement in PMF is secondary to EMH and may be associated with hypercatabolic symptoms (profound fatigue, weight loss, night sweats, and low-grade fever), peripheral edema (from venous compression), diarrhea, early satiety (from gastric compression), and, occasionally, portal hypertension.

Splenomegaly in PMF may be complicated by infarction, an event heralded by moderate to severe pain that may be referred to the left shoulder and often requires opiate analgesics to control.⁸⁰ CT imaging in such cases can be unremarkable or may show wedge-shaped or rounded low-attenuation lesions in the spleen. EMH occurs in a great diversity of sites throughout the body. Common sites besides spleen and liver include lymph nodes, skin, pleura, peritoneum, lung, and the paraspinal and epidural spaces. The latter may result in spinal cord and/or nerve root compression, which is a medical emergency requiring corticosteroids to reduce edema and immediate radiotherapy.⁸¹ It is fortunate that localized EMH responds promptly to low doses of gamma irradiation (100–150 cGy).

Red cell transfusion dependence in PMF is widespread. Serum levels of LDH are often elevated, reflecting both ineffective hematopoiesis and injury to the liver by EMH. Hyperuricemia and consequent episodes of gout are not uncommon and reflect ineffective hematopoiesis with high cell turnover. Bone pain is seen and is multifactorial, related to marrow replacement and periostitis. Sweet syndrome (neutrophilic dermatosis) is sometimes associated with PMF, and this lesion must be distinguished from cutaneous EMH since treatment differs.⁸²

Death in PMF can come from many directions. Fatal infection and transformation to a resistant myeloid leukemia are common. Overt leukemia occurs in approximately 20% of patients over the first 10 years.⁸³ Less frequent causes of death include thrombohemorrhagic events and heart failure, often secondary to pulmonary hypertension.

Prognosis

Current risk stratification in PMF is based on eight clinical parameters forming the Dynamic International Prognostic Scoring System (DIPSS)-plus.⁸⁴ The eight parameters include unfavorable karyotype (i.e., complex karyotype or sole or two abnormalities that include +8, -7/7q-, i(17q), inv(3), -5/5q-, 12p- or 11q23 rearrangement),^{85, 86} red cell transfusion need^{87, 88} platelet count $<100 \times 10^9/L$, age >65 years, hemoglobin <10 g/dL, leukocyte count $>25 \times 10^9/L$, circulating blasts $\geq 1\%$ and presence of constitutional symptoms.⁸⁹ The four DIPSS-plus risk categories based on the aforementioned eight risk factors are low (no risk factors), intermediate-1 (one risk factor), intermediate-2 (two or three risk factors) and high (four or more risk factors) with respective median survivals of 15.4, 6.5, 2.9, and 1.3 years.⁸⁴

Since the publication of DIPSS-plus, several studies that suggest additional prognostic information have been published. For example, a $>80\%$ 2-year mortality in PMF was predicted by monosomal karyotype, inv(3)/i(17q) abnormalities, or any two of circulating blasts $>9\%$, leukocytes $\geq 40 \times 10^9/L$ or other unfavorable karyotype.⁹⁰ Similarly, inferior survival in PMF has been associated with nullizygosity for

JAK2 46/1 haplotype,⁹¹ low *JAK2*V617F allele burden,^{92, 93} or the presence of *IDH*,⁹⁴ *EZH2*,⁹⁵ *SRSF2*,⁹⁶ or *ASXL1*⁹⁷ mutations.

Most recently, Tefferi et al. studied 254 patients with PMF and reported mutational frequencies of 58% for *JAK2*, 25% *CALR*, 8% *MPL*, and 9% wild-type for all three mutations (i.e., triple-negative).⁹⁸ *CALR* mutational frequency in *JAK2*/*MPL*-unmutated cases was 74%. *CALR* mutations were associated with younger age, higher platelet count, and lower DIPSS-plus score. *CALR*-mutated patients were also less likely to be anemic, require transfusions, or display leukocytosis. Spliceosome mutations were infrequent in *CALR*-mutated patients. In a subsequent international study of 570 patients,⁹⁹ the authors reported the longest survival in *CALR*⁺*ASXL1*⁻ patients (median 10.4 years) and shortest in *CALR*⁻*ASXL1*⁺ patients (median 2.3 years). *CALR*⁺*ASXL1*⁺ and *CALR*⁻*ASXL1*⁻ patients had similar survival and were grouped together in an intermediate risk category (median survival 5.8 years). Guglielmelli et al.¹⁰⁰ subsequently demonstrated the additional value of the number of prognostically detrimental mutations.

Therapy

Conventional therapy for PMF is largely palliative and has not been shown to improve survival. Patients should be considered for clinical trials of new treatments whenever feasible. Older treatments for anemia include androgen preparations (e.g., oral fluoxymesterone 10 mg two times a day or danazol 400–600 mg/day), which, given the older age of the typical male PMF patient, should be initiated only after ruling out occult prostate cancer.¹⁰¹ Corticosteroids may also give transient benefit in this setting (e.g., oral prednisone at a starting dose of 30–40 mg/day for first month and then taper off over the second month). Unfortunately, responses to androgens and steroids are uncommon; they occur in less than one-third of PMF patients and are usually of brief duration. In the case of an endogenous Epo level that is less than 100 mIU/mL, it is tempting to consider a brief trial of treatment with erythropoiesis stimulating agents (ESAs).¹⁰² However, such therapy exacerbates PMF-associated splenomegaly, does not work for transfusion-dependent patients, and may be associated with increased risk of leukemic transformation.¹⁰³ For symptomatic splenomegaly in PMF, HU is the first choice and ruxolitinib the second drug of choice.¹⁰⁴ An initial dose of 500 mg of HU three times per day typically brings salutary results within 1–2 weeks, and the dose can then be adjusted to optimal effect.

Thalidomide can improve cytopenias and reduce spleen size in PMF.¹⁰⁵ Reported response rates range between 20% and 62% for anemia, 25% and 80% for thrombocytopenia, and 7% and 30% for splenomegaly.^{105, 106} In conventional doses similar to those used for multiple myeloma (e.g., 200 mg/day and above), thalidomide has been associated with severe myeloproliferative reactions, including accelerated EMH.¹⁰⁷ Lower doses of thalidomide (e.g., 50 mg/day) appear to be better tolerated and responses are often durable.^{106, 108} The addition of prednisone to the lower dose schedule improves tolerance and may enhance the erythropoietic activity of the drug.^{106, 108}

Several new drugs have been evaluated in PMF, post-PV/ET MF, and other related MPN, including additional immunomodulators and JAK inhibitors.¹⁰⁹ Pomalidomide, an immunomodulatory drug, improved anemia in 25% of patients when was used alone (2 mg/day) or in combination with prednisone (0.5 or 2 mg/day).¹¹⁰ In a second phase II study, anemia response was observed only in cases with *JAK2*V617F mutations (24% vs 0%).¹¹¹ Platelet response occurred in 58% of patients, but there was little impact on spleen size. Drug-associated neuropathy or myelosuppression was observed infrequently. Use of doses >2 mg/day failed to increase activity but did produce greater myelosuppression.¹¹² A phase-3 study comparing pomalidomide with placebo did not demonstrate a significant difference in anemia

response, but platelet response was significantly improved with pomalidomide.¹¹³

A number of JAK inhibitor ATP mimetics have been evaluated in patients with MPN including ruxolitinib (INCB018424), fedratinib (SAR302503), momelotinib (CYT387), lestaurtinib (CEP-701), pacritinib (SB1518), AZD1480, BMS911543, LY2784544, and XL019 (*clinicalTrials.gov*). Ruxolitinib, a JAK1/JAK2 inhibitor, was initially evaluated in a phase I/II study of 153 patients with PMF or post-PV/ET MF.¹¹⁴ Toxicities included thrombocytopenia, anemia, and a “cytokine rebound reaction” on stopping the drug, with an acute relapse of symptoms and splenomegaly.¹¹⁵ Improvement in constitutional symptoms and weight gain were seen in the majority of patients and 44% experienced $\geq 50\%$ decrease in palpable spleen size. Transfusion independence was achieved in 4 of 28 transfusion-dependent patients (14%). A major reduction in proinflammatory cytokines (e.g., IL-1RA, IL-6, TNF- α , and MIP-1b) was measured and correlated with improvement in constitutional symptoms.

Two randomized studies have compared ruxolitinib with either placebo or best supportive care.^{116, 117} In the COMFORT-1 trial, comparing the drug to placebo ($n = 309$),⁷⁵ ruxolitinib significantly not only improved spleen response (42% vs $<1\%$) and constitutional symptoms (46%) but also produced greater anemia (31% vs 13.9%) and thrombocytopenia (34.2% vs 9.3%). In the COMFORT-2 trial, comparing the drug with “best available therapy” ($n = 219$),¹¹⁷ ruxolitinib improved spleen response (28.5% vs 0%) but also worsened thrombocytopenia (44.5% vs 9.6%), anemia (40.4% vs 12.3%), and diarrhea (24.0% vs 11.0%). Long-term follow-up in patients with MF indicated that a high fraction discontinued the drug after a median time of 9.2 months. Severe withdrawal symptoms were observed after stopping the drug with acute relapse of disease symptoms, accelerated splenomegaly, worsening of cytopenias, and occasional hemodynamic decompensation, including a septic shock-like syndrome. In COMFORT-2, 55% of patients discontinued the drug within 3 years. A slight but statistically significant improvement in survival was observed, despite cross-over of the arms. Recent reports have associated ruxolitinib use with serious opportunistic infections.¹¹⁸

Fedratinib, a selective JAK2 inhibitor, was initially evaluated in a phase I/II study of 59 patients with PMF or post-PV/ET MF.¹¹⁹ A $>50\%$ decrease in palpable spleen size was observed in 39% and 47% of patients, after 6 or 12 months of treatment, respectively. The majority of patients reported a durable resolution of their symptoms. Side effects included nausea (3%), vomiting (3%), diarrhea (10%), asymptomatic mild increases in serum amylase/lipase (27%), transaminases (27%) or creatinine (24%), thrombocytopenia (24%), and anemia (35%). In general, the presence of *JAK2V617F* did not correlate with response. A phase-III study ($n = 289$) comparing fedratinib at two different doses (500 or 400 mg/day) with placebo confirmed the efficacy of the drug in relieving symptoms and reducing the spleen size (49%, 47% and 1%, respectively), but reports of encephalopathy associated with the use of the drug resulted in its withdrawal from further development.¹²⁰

Momelotinib (MMB, GS-0387, and CYT387), a JAK1 and JAK2 inhibitor, has been evaluated in a phase I-II study where response in anemia and spleen size were observed in 59% and 48% of participants, respectively. Decreased transfusion requirement for at least 12 weeks (range 4.7 to >18.3 months) was observed in 70% of 33 patients who were red cell transfused in the month before study entry.¹²¹ Most patients experienced an improvement in constitutional symptoms. Grade 3/4 adverse reactions included thrombocytopenia (32%), hyperlipasemia (5%), elevated liver transaminases (3%), and headache (3%). New-onset treatment-related peripheral neuropathy was observed in 22% of patients (sensory symptoms, grade 1). The study was subsequently expanded to include 166 patients treated at either 150 or 300 mg once-daily, or 150 mg twice-daily for 9 months, with similar results.¹²² The drug is currently being compared to ruxolitinib in a phase-III study.

Pacritinib (SB1518) is a JAK2/FLT3 inhibitor that produced an MRI spleen response rate of 32% accompanied by improvement in symptoms but with an anemia response in only 6% of 34 participants in a phase II study.¹²³ The most common treatment-related adverse events were gastrointestinal, especially diarrhea.

Splenectomy can be considered for patients with refractory splenic pain, disabling constitutional symptoms, symptomatic portal hypertension, and/or a need for frequent red cell transfusions. In one series of 223 PMF patients who underwent splenectomy, durable remissions in constitutional symptoms, transfusion-dependent anemia, portal hypertension, and severe thrombocytopenia were achieved in 67%, 23%, 50%, and 0% of patients, respectively.¹²⁴ However, even in experienced centers, the perioperative mortality rate of splenectomy in PMF may be as high as 9%, and overall survival may not be affected; the median postsplenectomy survival is about 2 years.¹²⁴ An elevated D-dimer, even in the absence of overt disseminated intravascular coagulopathy, may predict a higher surgical risk. Up to 25% of surgical survivors will develop marked hepatomegaly or extreme thrombocytosis.¹²⁴ Presplenectomy thrombocytopenia correlates with the risk of postsplenectomy leukemic transformation, for unclear reasons. Extreme postsplenectomy thrombocytosis is significantly associated with perioperative thrombosis. HU can be used perioperatively to prevent a postsplenectomy rise in platelet count. In poor surgical candidates with symptomatic splenomegaly, the palliative use of splenic irradiation is reasonable, but success is irregular and of brief duration.¹²⁵

The use of allogeneic hematopoietic stem cell transplantation (allo-SCT) in PMF was initially limited because of concerns regarding potential failure of stem cells to engraft in the fibrotic marrow. This concern has not been substantiated. Marrow fibrosis delays post-transplantation platelet recovery by about 3 days and increases platelet transfusion needs slightly, but is not clearly associated with graft failure or other unique transplant-related problems.¹²⁶ Interest in allo-SCT in patients with PMF is now growing, but appropriate patient selection and timing remain challenging. While engraftment has not been especially problematic, toxicity continues to be a major issue, even with the newer reduced-intensity “non-myeloablative” conditioning regimens.¹²⁷ In one study of allo-SCT in myelofibrosis, the 5-year survival was only 14% for patients older than 44 years, and in another study, the 2-year survival was just 41%.^{128, 129} Rates of chronic graft-versus-host disease of up to 59% have been reported.¹³⁰ Younger patients do somewhat better, with post-transplant survival rates of up to 60%, but the decision to proceed to transplant must only be made after careful deliberation, and patients chosen should be those with particularly limited life expectancy.^{128, 130}

Polycythemia vera

Epidemiology

The incidence of PV is 0.8–2.6 cases per 100,000 persons per year, with most studies giving figures at the upper end of that range, and this incidence appears to be relatively stable over time.^{131, 132} As is the case with the other MPN, the incidence of PV increases with age. The median age at diagnosis is approximately 60 years; the disease can also be seen in young people, and 7% of cases are diagnosed before the age of 40.^{133, 134} There may be a slight male preponderance (on the order of a 1.2:1 male-to-female case ratio), and the disease is more common in Jews, especially Ashkenazi Jews.^{10, 135} In a few cases, true PV may be familial, but apparently familial erythrocytosis is often proven to be a result of a shared high-oxygen-affinity hemoglobin or a common exposure (e.g., a residence at high altitude or cobalt intoxication).^{136, 137}

Pathogenesis

X-linked (G6PD) enzyme analysis first demonstrated the clonal nature of hematopoietic cells in PV in 1976.¹³⁸ In 2005, a *JAK2* gain-of-function mutation (*JAK2*V617F) that was discovered in the majority of patients with PV.^{22–25} In 2007, other *JAK2* mutations were described in *JAK2*V617F-negative cases.²⁸ *JAK2*V617F is an exon 14G to T somatic mutation. The nucleotide change at position 1849 results in the substitution of valine to phenylalanine at codon 617. *JAK2*V617F is also present in patients with PV, ET, and PMF.^{22–25} The mutation has also described in other myeloid neoplasms.^{139, 140} As of the time of this writing, *JAK2*V617F has not been reported in lymphoid disorders,^{141–144} solid tumor,^{145–147} or secondary myeloproliferation.^{148, 149} In general, mutational frequency is estimated at over 95% in PV, 50% in ET or PMF, 20% in certain other MPNs including refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T) and less than 5% in AML or MDS.^{150–153}

*JAK2*V617F induces a PV-like phenotype in murine transplant models.^{24, 154, 155} Mutant allele burden in patients with ET is significantly lower than that seen in patients with either PV or PMF.^{156–160} At least in PV, a higher allele burden is the result of *JAK2*V617F homozygosity, which is accomplished by mitotic recombination.^{22, 23, 25} In humans, *JAK2*V617F occurs at a primitive stem cell level and is chronologically an early event.^{161–163} Some but not all¹⁶⁴ studies have suggested *JAK2*V617F clonal involvement of NK,¹⁶⁵ T,¹⁶⁶ and B¹⁶⁶ lymphocytes. Regardless, there is evidence to suggest that *JAK2*V617F may not be the initial clonogenic event in either PV or other MPNs and that its presence might not be mandatory for endogenous colony formation.^{167–169} The recent demonstration of *JAK2*V617F-negative leukemia clones arising in *JAK2*V617F-positive MPN patients lends further support in this regard.^{170, 171}

In 2007, a set of *JAK2* exon 12 mutations were described in *JAK2*V617F-negative patients with PV in whom erythrocytosis was the predominant feature.¹⁷² Because of the latter feature, some of the cases were assigned the diagnosis of “idiopathic” erythrocytosis although their serum Epo level was almost always below the reference range and EECs were demonstrated in every instance when tested. The majority of the cases (10 of 11) in the original report¹⁷² were found to harbor one of four exon 12 *JAK2* mutant alleles: N542-E543del (four cases), F537-K539delinsL (three cases), K539L (two cases), H538QK539L (one case). All four exon 12 mutant alleles induced cytokine-independent/hypersensitive proliferation in erythropoietin receptor-expressing cell lines and constitutive activation of JAK-STAT signaling.¹⁷² In addition, *JAK2*K539L induced a PV phenotype in a mouse transplant model. Many other studies have now confirmed the observations from the above-mentioned study^{28, 173–177} and in the process, most^{28, 173, 174} but not all^{175, 177} of the studies suggested that exon 12 mutations occurred in virtually all *JAK2*V617F-negative PV cases (i.e., ~3% of all PV cases). Furthermore, several other exon 12 mutation variants were added to the list including R541-E543delinsK, I540-E543delinsMK, V536-I546dup11, F537-I546dup10+547L, and E543-D544del.^{174–176}

The erythroid colony-forming progenitor cells (BFU-E and CFU-E) in PV are very sensitive to or independent of normal growth and differentiation signals, including Epo, GM-CSF, stem cell factor, and IL-3.^{178, 179} Although this finding is characteristic of PV, it is not specific and is also observed in ET and PMF. Serum Epo levels in PV patients are generally very low or inappropriately normal in the setting of erythrocytosis, and excessive Epo-independent BFU-E and CFU-E proliferation leads to an increased red cell mass (RCM).^{180, 181} As is the case with the Tpo receptor in ET, some families with recurrent PV have been found to harbor Epo receptor mutations, but structural changes in the Epo receptor have been diligently sought in nonfamilial PV but not found.^{182, 183} Epo receptor expression patterns may be abnormal in PV (e.g., loss of the normal high-affinity Epo receptor) but this finding is not consistent.¹⁸⁴

Cells from patient with PV are consistently observed to be hypersensitive to insulin-like growth factor-1 (IGF-1), which appears to be due to alterations in IGF-1 binding proteins, including increased baseline phosphorylation of the IGF-1 receptor.¹⁸⁵ Decreased activity of the SHP-1 phosphatase (which associates with the receptors for Epo, stem cell factor, and IL-3, and is a negative regulator of signals generated during ligand binding), constitutive activation of STAT-3, increased levels of anti-apoptotic proteins such as Bcl-X_L, and several other biochemical abnormalities have been reported in subsets of patients; their general pathobiologic relevance is yet unclear.^{186–188}

Karyotypic abnormalities are found in about 10–20% of untreated patients.^{189, 190} The lesions seen are those nonspecific abnormalities typical of chronic myeloid disorders, such as trisomy 8, trisomy 9, del(20q), del(13q), loss of the Y chromosome in men, and abnormalities of chromosomes 5 and 7.¹⁹⁰

Clinical features

Signs and symptoms frequently associated with PV are listed in [Table 4](#). Many of the clinical features of PV are a direct consequence of the increased RCM and are common to all causes of erythrocytosis, but pruritus and splenomegaly strongly suggest PV. Increased RCM can lead to blood hyperviscosity, which leads to a plethora of symptoms and signs. Headaches are frequent, but blurry vision, altered hearing, mucous membrane bleeding, shortness of breath, and malaise are also observed. Hypertension may be a consequence of increased RCM. At least two-thirds of PV patients have splenomegaly, so the combination of splenomegaly and erythrocytosis should strongly suggest PV.¹⁹¹ Thrombosis occurs in about 40% of patients, most commonly arterial thrombosis.¹³³ Clots occur at a rate of about 3.9% of patients per year.¹³³ Arterial thromboses are more likely to be fatal than venous thromboses. As in ET, venous thrombosis can occur in unusual sites, such as mesenteric or hepatic vessels. Bleeding, especially gastrointestinal, is seen in PV but less often than thrombosis.¹³³ Pruritus is a common and classic PV-associated complaint, which may be provoked by warm water (aquagenic); its pathogenesis is unclear.^{192, 193} Erythromelalgia (described above under ET) might also trouble patients with PV, as do other vasomotor symptoms; paresthesias and headaches. Leukocytosis and thrombocytosis are present in less than half of PV patients.

Table 4 Polycythemia vera-related clinical and laboratory features

Symptoms and physical findings	Frequency (%)
Systolic hypertension	72
Splenomegaly	70
Skin plethora (ruddy cyanosis)	67
Conjunctival plethora	59
Headache	48
Weakness	47
Engorged retinal veins	46
Pruritus	43

Diagnosis

The major diagnostic difficulty with respect to PV is distinguishing PV from the many other causes of erythrocytosis ([Table 5](#)).

Table 5 Classification of erythrocytosis

1) Apparent Polycythemia <ul style="list-style-type: none">a) Relative polycythemia due to major fluid shiftsb) Extreme “high-normal” values
2) True Polycythemia <ul style="list-style-type: none">a) Polycythemia verab) Secondary polycythemia<ul style="list-style-type: none">i) Erythropoietin (EPO)-mediated<ul style="list-style-type: none">(1) Hypoxia-driven

- (a) Central hypoxic process
 - (i) Chronic lung disease
 - (ii) Right-to-left cardiopulmonary vascular shunts
 - (iii) High-altitude habitat
 - (iv) Carbon monoxide poisoning and smoker's polycythemia
 - (v) Hypoventilation syndromes including sleep apnea
- (b) Peripheral hypoxic process
 - (i) Localized
 - 1. Renal artery stenosis
 - (ii) Diffuse
 - 1. High-oxygen-affinity hemoglobinopathy (*congenital; autosomal-dominant*)
 - 2. 2,3-Diphosphoglycerate mutase deficiency (*congenital; autosomal-recessive*)
- (2) Hypoxia-independent (pathologic EPO production)
 - (a) Malignant tumors
 - (i) Hepatocellular carcinoma
 - (ii) Renal cell cancer
 - (iii) Cerebellar hemangioblastoma
 - (iv) Parathyroid carcinoma
 - (b) Non-malignant conditions
 - (i) Uterine leiomyomas
 - (ii) Renal cysts (polycystic kidney disease)
 - (iii) Pheochromocytoma
 - (iv) Meningioma
 - (c) Abnormally elevated set point for EPO production (*congenital*)
 - (d) Chuvash polycythemia (*congenital; abnormal oxygen homeostasis?*)
- (3) Intentional EPO doping

ii) EPO receptor-mediated

- (1) Activating mutation of the erythropoietin receptor
- (2) Some cases of autosomal-dominant congenital polycythemia

iii) Drug-associated

- (1) Treatment with androgen preparations
- (2) Treatment with novel erythropoietic agents such as CERA

iv) Unknown mechanisms

- (1) Most cases of autosomal-dominant congenital polycythemia
- (2) Some forms of autosomal-recessive congenital polycythemia
- (3) Post renal transplant erythrocytosis

The 1975 Polycythemia Vera Study Group diagnostic criteria¹⁹¹ were an advancement in their time, but are now chiefly of historical interest.^{194, 195} These criteria included direct measurement of the RCM, which is a cumbersome procedure that is no longer strictly necessary in most cases. The availability of new diagnostic tools, as well as better appreciation of the tight relationship between hematocrit and RCM, has undermined the use of RCM measurement in the diagnosis of PV.

Because more than 95% of patients with PV carry the *JAK2V617F* mutation, one could initiate the workup of a patient with suspected PV with peripheral blood mutation screening for *JAK2V617F*. In order to minimize the consequences of false-positive or false-negative test results, as well as capture the few cases that are *JAK2V617F*-negative PV, I recommend concomitant measurement of serum Epo level, which is abnormally low in more than 90% of patients with PV.¹⁹⁶ If the results of both tests are suggestive of PV (i.e., mutation-positive and low serum Epo), then the diagnosis is likely and bone marrow examination is encouraged but not essential for making the diagnosis. If the *JAK2V617F* and serum Epo test results are both not consistent with the diagnosis of PV (i.e., mutation-negative and either normal or increased Epo), then further investigation is not advised unless dictated otherwise by the clinical scenario. If there is discrepancy between the molecular test and serum Epo level, one should first repeat both tests and then proceed with bone marrow examination if the results are unchanged. In this regard, the possibility of exon 12 *JAK2* mutations should be entertained in *JAK2V617F*-negative cases with low serum Epo level.

When congenital polycythemia is suspected, initial laboratory testing should include measurement of the oxygen tension at which hemoglobin is 50% saturated (p50). Left-shifted oxygen dissociation curve, suggested by decreased p50, suggests the presence of either high oxygen-affinity hemoglobinopathy (autosomal dominant)¹⁹⁷ or 2,3-bisphosphoglycerate (2,3-BPG) deficiency, usually a consequence of BPG mutase mutation (autosomal recessive).¹⁹⁸ If the p50 is normal, then the possibility of *VHL* mutations should be considered first because they constitute the most frequent mutations in congenital polycythemia. In this regard, Russian ethnic origin would suggest Chuvash polycythemia, which is characterized by increased serum Epo.¹⁹⁹ However, Chuvash-type or other *VHL* mutations have also been described in other ethnic groups and therefore worth considering in the presence of any congenital polycythemia associated with increased serum Epo. There is currently limited information on *HIF-1α* prolyl hydroxylase gene mutation,²⁰⁰ which incidentally is associated with normal serum Epo level. On the other hand, *EPOR* mutations are well described and should be considered in congenital polycythemia associated with either low or normal serum Epo level.²⁰¹

Prognosis

The median life expectancy for patients diagnosed with PV exceeds 10 years but is worse than a gender- and age-matched control population.⁴⁷ Thrombohemorrhagic complications and transformation into AML account for much of the inferior survival.²⁰² As with ET, older age (>60 years) appears to be a risk factor for thrombosis.²⁰³ Other clearly prognostic factors in PV beyond old age and a history of thrombosis have not been determined. In about 15–20% of cases, PV terminates in a “spent phase,” a PMF-like state. This

transition is usually characterized by worsening anemia and increasing white count and spleen size.

Treatment

As is the case with ET, PV-associated vasomotor symptoms are usually alleviated by low doses of ASA. PV-associated pruritus can be treated with selective serotonin reuptake inhibitors, such as paroxetine.¹⁹² Antihistamines such as hydroxyzine and diphenhydramine are less effective.

The primary goal of treatment in PV is to prevent disastrous thrombotic events without increasing the risk of other life-threatening problems, such as bleeding, or altering the potential for transformation to a fibrotic marrow or acute leukemia. The main tool used to accomplish this goal is therapeutic phlebotomy. The importance of regular phlebotomy as part of a successful treatment program for PV cannot be overemphasized; marrow-suppressing drugs play only a supplementary role. In the first few decades after the disease's description, before aggressive phlebotomy became *de rigueur*, the median survival for patients with PV was on the order of 2 years, and most deaths were due to thrombotic events.^{204, 205} Today, most PV-related deaths are still due to thrombosis, but patients treated initially with phlebotomy alone have a median survival of more than 15 years.¹³³

On the basis of the studies that have shown an improved cerebral blood flow and normalization of blood viscosity with a hematocrit below 45%, as well as less thrombosis in patients with hematocrits in this range, dropping the hematocrit to below this level and keeping it there should be the goal of phlebotomy-based treatment in PV.^{206, 207} It has also been widely recommended that females be reduced to a hematocrit of less than 42% because their normal hemoglobin range is lower, but this has not been rigorously tested and whole blood viscosity should not depend significantly on gender.

There has been a long-standing interest in the addition of other therapies to try to further decrease thrombotic risk. Just when these other agents should be added to phlebotomy is controversial. An elevated platelet count does not appear to be a major thrombotic risk factor in PV, and a very elevated platelet count (e.g., >1 million / μ L), as in ET, is a risk factor for bleeding in PV.²⁰⁸ Therefore, young PV patients without a history of thrombosis and with a near-normal platelet count are probably quite safe with phlebotomy alone.

In view of a recent large randomized placebo-controlled study that showed a large reduction in thrombotic events (but not an overall survival improvement) with low-dose aspirin (100 mg/day—a dose not available in the US) aspirin, all patients with PV who do not have a contraindication should receive aspirin.⁵¹ In this trial, the combined endpoint of nonfatal myocardial infarction, nonfatal stroke, or death from cardiovascular causes and the risk of the combined end point of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular causes were both reduced (relative risk 0.41 and 0.40 compared with placebo, respectively.) The risk of bleeding at this dose was elevated slightly above those treated with placebo (relative risk 1.6).⁵¹

There has been interest in myelosuppressive agents in PV for several decades, and opinion about the optimal regimen continues to evolve. In a landmark three-arm-randomized study that originated in the 1960s, two specific agents, oral chlorambucil and intravenous radioactive phosphorus (³²P), were each found to decrease the risk of thrombosis when added to phlebotomy.²⁰² However, overall survival was inferior with either of the additional treatments because of an increased incidence of acute leukemia compared with phlebotomy alone. The incidence of acute leukemia over 13–19 years was 1.5%, 9.6%, and 13.2% for phlebotomy, ³²P, and chlorambucil, respectively, and the corresponding median survivals were 12.6, 9.1, and 10.9 years.²⁰² Several cases of lymphoma were seen in patients treated with

chlorambucil, and the incidence of gastrointestinal and skin cancer was also increased.

Other agents have the potential to decrease thrombosis without the same degree of leukemia risk as ³²P or alkylators. One of these agents is HU, which decreases thrombotic risk when used as a supplement to phlebotomy, but which appears less leukemogenic than chlorambucil and ³²P. In one PVSG study, HU was associated with lower risk of thrombosis in the first 2 years after diagnosis (6.6% vs 14%) when compared to a historical cohort of patients treated with phlebotomy alone, and only 5.9% of patients had transformed to acute leukemia after a median follow-up of 8.6 years.²⁰⁹ Because the true leukemogenic risk of HU is unknown, it is used most often as a supplement to phlebotomy for groups at especially high risk for thrombosis, such as the elderly and those with prior thrombosis ([Table 6](#)).

Table 6 Suggested treatment algorithm for patients with polycythemia vera

Risk category ^a	Age < 60 years	Age ≥ 60 years	Women of childbearing age
Low	Phlebotomy + ASA	Not applicable	Phlebotomy + ASA
Indeterminate	Phlebotomy + ASA if no aVWD	Not applicable	Phlebotomy + ASA if no aVWD
High	Phlebotomy + ASA + HU or IFNα	Phlebotomy + HU + ASA	Phlebotomy + ASA + IFNα

Abbreviations: ASA, low-dose aspirin (if no contraindications); HU, hydroxyurea; IFNα, Interferonα2A; aVWD, acquired von Willebrand disease.

^a See [Chapter 113](#) for risk stratification algorithm.

IFNα2A has salutary effects in PV and is the drug of choice for PV patients who do not tolerate HU or wish to become pregnant because of anecdotal reports of successful maternal and fetal outcomes. This drug controls erythrocytosis in approximately 80% of the patients who can tolerate the necessary dose, which ranges from 4.5 to 27 million units per week (the usual starting dose is 3 million units subcutaneously three times a week), and IFNα2A has a beneficial effect on thrombocytosis.^{58, 210, 211} IFN can also reduce spleen size and frequently gives relief from intractable pruritus. However, at least 20% of patients discontinue therapy because of drug side effects, including fatigue, malaise, fevers, psychological effects, myalgias, and arthralgias.²¹¹ IFNα2A is also more expensive than HU. In addition to women of childbearing potential, it is reasonable to choose IFNα2A for high-risk patients who need a supplement to phlebotomy where the potential benefit of relief from refractory pruritus is desired, or for patients who are particularly concerned about the potential leukemogenicity of HU.

As elaborated earlier, cytoreductive therapy, for prevention of thrombosis, is currently recommended in high-risk (age ≥60 years or presence of thrombosis history) patients with PV based on evidence from controlled studies.^{4, 5} In this regard, HU is the evidence-based choice for first-line therapy, whereas noncontrolled studies have supported the use of interferon-α and busulfan as second-line drugs of choice.¹ We do not use ruxolitinib in PV, despite its recent FDA approval in HU refractory cases,²⁰ unless in the presence of severe pruritus or symptomatic splenomegaly that is shown to be refractory to adequate doses of HU, interferon-α, or busulfan.

Part 12

Management of Cancer Complications

Chapter 123

Neoplasms of unknown primary site

John D. Hainsworth, MD ■ F. Anthony Greco, MD

Overview

Cancer of unknown primary site (CUP) is a clinical syndrome accounting for 2–3% of all cancer diagnoses. This heterogeneous group is comprised of patients who have no anatomic primary site identified after a standard clinical evaluation. Complete pathologic evaluation is essential. Accurate prediction of the tissue of origin, based on examination of a biopsy from a metastatic lesion, is now possible in most patients using improved immunoperoxidase stains and molecular gene expression profiling. After completion of clinical and pathologic diagnostic evaluation, approximately 20% of patients with carcinoma of unknown primary site are included in favorable prognosis subsets and require specific treatment as detailed in this chapter. Until recently, the remaining 80% of patients have been treated with empiric combination chemotherapy. However, as therapy for various solid tumors improves and becomes more site specific, empiric chemotherapy is less likely to provide optimal treatment. Site-specific therapy directed by the tissue of origin predicted by molecular profiling or immunoperoxidase staining is now appropriate for these patients. New data supporting the use of site-specific therapy are reviewed.

Cancer of unknown primary site (CUP) is a common clinical entity, accounting for 2–3% of all cancer diagnoses.^{1, 2} Patients with CUP are heterogeneous with respect to clinical features, pathology, response to treatment, and prognosis. The typical patient develops symptoms at a metastatic site, but routine history, physical examination, imaging studies, and laboratory studies fail to identify a primary site. Biopsy shows carcinoma in most patients; however, histologic examination is insufficient to fully characterize most of these tumors.

Until recently, the major advance in the management of CUP was the identification of several treatable subgroups within this heterogeneous population. Identification of these patients, based on the presence of specific clinical and/or pathologic features, is critical as specific first-line treatment is required for optimal results. For the remainder of CUP patients (about 80%), the development of empiric “broad spectrum” chemotherapy regimens has resulted in modest benefit. However, as treatment improves and becomes more tumor specific in many types of solid tumors, the idea that a single chemotherapy regimen can provide optimum treatment for a heterogeneous group of CUP patients seems increasingly outdated.

In recent years, improved diagnostic techniques, including more precise immunohistochemical (IHC) stains and molecular gene expression tumor profiling (GEP), have enabled accurate prediction of the site of tumor origin in many patients with CUP, even when anatomic primary sites cannot be demonstrated. Although still developing, current data strongly suggest that site-directed treatment based on the predicted site of tumor origin improves treatment outcome as compared to empiric chemotherapy.

Pathologic evaluation

Examination of tumor histology by light microscopy is the critical first procedure in the pathologic

evaluation and provides a practical classification system to direct subsequent evaluation. Almost all patients with CUP have carcinoma, which can be divided into five categories by light microscopic evaluation: (1) poorly differentiated neoplasm, (2) poorly differentiated carcinoma, (3) adenocarcinoma, (4) squamous carcinoma, and (5) neuroendocrine carcinoma. Occasionally, melanoma or sarcoma is identified at the initial examination.

As histologic examination rarely results in the identification of the site of tumor origin, additional pathologic evaluation is important in almost every patient with CUP. For this reason, the initial biopsy should be planned so as to yield an adequate amount of tissue for all required pathologic studies; material produced from a fine-needle aspiration biopsy is insufficient in these patients. Close communication between the oncologist and the pathologist is necessary so that the available biopsy material can be “managed” judiciously, ensuring that the most critical studies are obtained.

Poorly differentiated neoplasm

The diagnosis of poorly differentiated neoplasm is made when histologic features do not allow the pathologist to distinguish between carcinoma and other cancers, such as sarcoma, melanoma, and hematopoietic neoplasms. This diagnosis occurs in approximately 5% of CUP patients after standard histologic examination but only rarely after specialized tests (IHC staining, GEP) are performed. Establishing a more precise diagnosis is essential in this group of patients, because highly treatable cancers (e.g., non-Hodgkin lymphoma, poorly differentiated neuroendocrine carcinoma, melanoma) are common.^{3–5}

Poorly differentiated carcinoma

Patients with poorly differentiated carcinoma account for approximately 20% of patients with CUP; an additional 10% of patients have poorly differentiated adenocarcinoma. Examination of poorly differentiated carcinoma using routine light microscopy alone is inadequate to assess these tumors optimally. In one series of 87 patients with poorly differentiated carcinoma, other diagnoses were suggested in 16 patients (18%) after IHC studies were done.⁶ The use of panels of IHC stains and GEP results in more specific diagnoses in many of these patients.

Adenocarcinoma

Adenocarcinoma is the most frequent light microscopic diagnosis in patients with neoplasms of unknown primary site and accounts for approximately 70% of cases. Because various adenocarcinomas share histologic features, the site of the primary tumor cannot usually be ascertained. Certain histologic features are typically associated with a particular cancer type (“papillary features” with ovarian and thyroid cancer, “signet ring cells” with gastric cancer); however, even these are not specific enough to be used as definitive evidence of the primary site.

In recent years, the ability to accurately predict the site of origin in patients with adenocarcinoma of unknown primary site has improved. The identification of relatively cell-specific proteins by IHC staining allows accurate prediction of the primary site in 35–55% of patients.^{7,8} Panels of IHC stains are most useful and are often directed by clinical features (e.g., gender, sites of metastases). In addition, GEP enables prediction of the site of origin in most patients with adenocarcinoma of unknown primary site, including those in which IHC stains are nondiagnostic. Complete evaluation of adenocarcinoma of unknown primary site therefore requires the use of these specialized pathologic techniques.

Squamous carcinoma

Squamous carcinoma accounts for approximately 5% of patients with CUP. The large majority of these patients have specific clinical syndromes for which effective treatment is available. A definitive diagnosis of squamous carcinoma can usually be made by histologic examination.

Neuroendocrine carcinoma

A broad spectrum of neuroendocrine neoplasia is now recognized, owing in part to improved pathologic diagnosis. Approximately 3% of CUP patients have neuroendocrine carcinoma and can be divided into three groups including low-grade tumors (carcinoid/islet cell type), high-grade neuroendocrine tumors (small-cell carcinoma, atypical carcinoid, large-cell neuroendocrine carcinoma), and poorly differentiated carcinoma (neuroendocrine features apparent only with specialized pathologic tests). The distinction between low-grade and high-grade carcinoma is critical in determining treatment.

Immunohistochemical staining

IHC staining is the most widely available adjunctive tool for the classification of neoplasms. Specific IHC staining patterns can usually establish the tumor lineage of poorly differentiated neoplasms ([Table 1](#)).^{7, 9–11} Examples include the distinction between carcinoma and lymphoma, the identification of poorly differentiated neuroendocrine carcinoma, and the occasional identification of melanoma and sarcoma.^{5, 7, 12–14}

Table 1 Poorly differentiated neoplasms: IHC staining patterns useful in determining tumor lineage

Tumor type	Cytokeratin	Epithelial membrane antigen	Leukocyte common antigen	S-100 protein, HMB45, Melan-A	Vimentin	Desmin	Factor VIII antigen	Chromogranin
Carcinoma	+	+ ^a	–	–	–	–	–	±
Lymphoma	–	± ^b	+	–	–	–	–	–
Melanoma	–	–	–	+	+	–	–	–
Sarcoma	–	± ^c	–	–	+	+ ^d	+ ^e	–
Neuroendocrine tumor	+	+	–	–	–	–	–	+

^a Adenocarcinoma.

^b Anaplastic large-cell lymphoma (Ki-1 or CD30-positive lymphoma).

^c Epithelioid sarcoma, synovial sarcoma.

^d Leiomyosarcoma, rhabdomyosarcoma.

^e Angiosarcoma.

When used to evaluate carcinoma of unknown primary site, the accuracy of IHC staining in identifying the tissue of origin has improved. [Table 2](#) shows typical staining patterns for a number of carcinomas. These results must be interpreted in the context of clinical and histologic features, as staining patterns overlap and few IHC stains are entirely specific. The prostate-specific antigen (PSA) stain is an exception and is

specific for prostate adenocarcinoma.¹¹ For other carcinomas, panels of IHC stains have been shown to improve specificity; such panels can accurately identify the primary site in approximately two-thirds of biopsies taken from advanced carcinomas of various known primary sites.^{15–18} A few classic staining patterns have been described that are usually diagnostic (e.g., CK7+/CK20–/TTF-1+ for lung adenocarcinoma, CK7–/CK20+/CDX2+ for colorectal adenocarcinoma). Four IHC stains (CK7, CK20, CDX2, TTF-1) form the basis of several diagnostic patterns and are appropriate initial stains in the evaluation of most CUP biopsies.

Table 2 Carcinoma of unknown primary site: IHC staining patterns useful in identifying the tissue of origin

Specific carcinomas	Immunohistochemical (IHC) staining
Bladder (transitional cell)	CK20 (+), CK5/6 (+), p63 (+), GATA3 (+), urothelin (+)
Breast	CK7 (+), ER (+), PR (+), GCDFP-15 (+), Her2/neu (+), mammaglobin (+), GATA3 (+)
Colorectal	CK20 (+), CK7 (–), CDX2 (+)
Germ cell	PLAP (+), OCT4 (+)
Liver	hepar1 (+), CD10 (+)
Lung: adenocarcinoma	TTF1 (+), CK7 (+), CK20 (–), P63 (+), CK5/6 (+)
Lung: neuroendocrine (small cell/large cell)	TTF1 (+), chromogranin (+), synaptophysin (+)
Lung: squamous	CK7 (+), CK20 (–), P63 (+), CK5/6 (+)
Ovary	CK7 (+), ER (+), WT1 (+), PAX8 (+), mesothelin (+)
Pancreas	CK7 (+), CA19-9 (+), mesothelin (+)
Prostate	PSA (+), CK7 (–), CK20 (–)
Renal	RCC (+), PAX8 (+), CD10 (+), pan-cytokeratin AE 1/3 (+)
Thyroid (follicular/papillary)	thyroglobulin (+), TTF1 (+), PAX8 (+)

Electron microscopy

The identification of specific ultrastructural features by electron microscopy enables a definitive diagnosis in some poorly differentiated neoplasms. Because it is less widely available, requires special tissue fixation at the time of biopsy, and is relatively expensive, electron microscopy should be reserved for the study of neoplasms whose lineage is unclear after routine light microscopy, IHC staining, and GEP.

Tumor-specific chromosomal abnormalities

Several tumor-specific chromosomal abnormalities are occasionally important in the diagnosis of CUP. Most B-cell and T-cell lymphomas are associated with tumor-specific rearrangements of immunoglobulin genes or T-cell antigen-receptor genes.¹⁹ In the unusual case when the diagnosis of lymphoma cannot be definitively established with either IHC staining or flow cytometric immunophenotyping, the detection of these specific gene rearrangements provides definitive diagnostic information. Specific abnormalities associated with solid tumors include a chromosomal translocation (rcp [11:22][q24; q12]) in all peripheral neuroepitheliomas and most Ewing tumors,^{20, 21} t(15:19) in children and young adults with

carcinoma of midline structures or uncertain histogenesis,²² and an isochromosome of the short arm of chromosome 12 (i12p) in a large percentage of testicular and extragonadal germ cell tumors.²³ Extragonadal germ cell tumors identified on the basis of i(12p) abnormalities are highly responsive to cisplatin-based chemotherapy.²³ Most of the neoplasms identifiable by specific chromosomal abnormalities can now be identified using methods that are more widely available, including IHC staining and GEP.

Gene expression profiling

Specific gene expression profiles are now recognized in cancers based on their sites of origin, reflecting differences in the gene expression profiles present in their normal tissues of origin.²⁴ By measuring differential expression of key sets of genes, this method is applicable to many cancer types and is therefore a potentially important diagnostic tool in the evaluation of CUP.

During the last 15 years, a number of assays have been developed for the purpose of predicting the tissue of origin in patients with CUP. Early tests measured only a few gene expression markers, allowing diagnosis of relatively few tumor types.^{25–28} More recently, application of either reverse transcriptase polymerase chain reaction (RT-PCR) or gene microarray techniques, coupled with improved bioinformatics systems, has allowed the development of assays capable of detecting more than 40 tumor types/subtypes.^{29–37} In the majority of recent studies, one of three commercially available assays has been used: CancerTYPE ID (bioTheranostics, Inc.),^{34, 35} Cancer Origin Test (Rosetta Genomics),^{36, 37} or the Tissue of Origin Test (Pathwork, Inc.).^{32, 33}

In validation studies, tumor biopsies from patients with advanced cancer (primary site known) were assayed in a blinded study; all commercially available assays accurately predicted the tissue of origin in 85–90% of cases.^{33, 35, 37} Accuracy was high regardless of the biopsy site (primary site vs metastasis) or tumor grade (well differentiated vs poorly differentiated).

Accuracy of GEP in predicting CUP tissue of origin

The accuracy of GEP in CUP has been more difficult to assess, as an anatomic primary site is not identified in most patients. However, evidence from several studies strongly suggests that accuracy in CUP is similar to that previously demonstrated in the validation studies using advanced cancers of known primary site. The most direct evidence comes from a study of GEP in patients with CUP who subsequently had primary sites identified during their disease course (9–314 weeks after initial evaluation).^{8, 38} In 18 of 24 such patients (75%), GEP of the original biopsy specimen resulted in correct prediction of the anatomic primary site. Despite concerns regarding the unique biology of CUP, most of these cancers apparently retain enough of the gene expression profile of their tissues of origin to allow identification with current assays.

GEP has also been evaluated in patients with poorly differentiated neoplasms of unknown primary site who had undefined tumor lineage after standard pathologic evaluation (including a median of 18 IHC stains).³⁹ Molecular tumor profiling gave a lineage prediction in 25 of 30 patients (carcinoma 10, melanoma 5, sarcoma 8, hematopoietic malignancy 2) and predicted a tissue of origin for all 10 carcinomas. Additional studies and/or response to treatment supported the molecular profiling results in most patients.

Comparisons of IHC versus GEP

Two large studies have compared the accuracy of IHC staining panels versus GEP in the identification of the primary site in patients with metastatic cancer.^{40, 41} In both studies, pathologists were provided with formalin-fixed biopsy specimens; patient gender and biopsy site were the only clinical details provided. Both methods showed considerable accuracy in these patients with known primary sites. In both studies, GEP provided the correct diagnosis more often than did IHC staining (79% vs 69%; 89% vs 83%, respectively). The accuracy of IHC staining decreased in patients with poorly differentiated histology.⁴¹ Performing similar comparative studies in patients with CUP is not possible, as the primary site usually remains unknown. In one study, IHC staining suggested a single site of origin in 52 of 149 patients (35%).⁸ In these 52 patients, GEP predicted the same site of origin in 77%. However, when IHC did not allow prediction of a single site of origin, the correlation between IHC and GEP predictions was poor. The major findings of this study are diagrammed in [Figure 1](#).

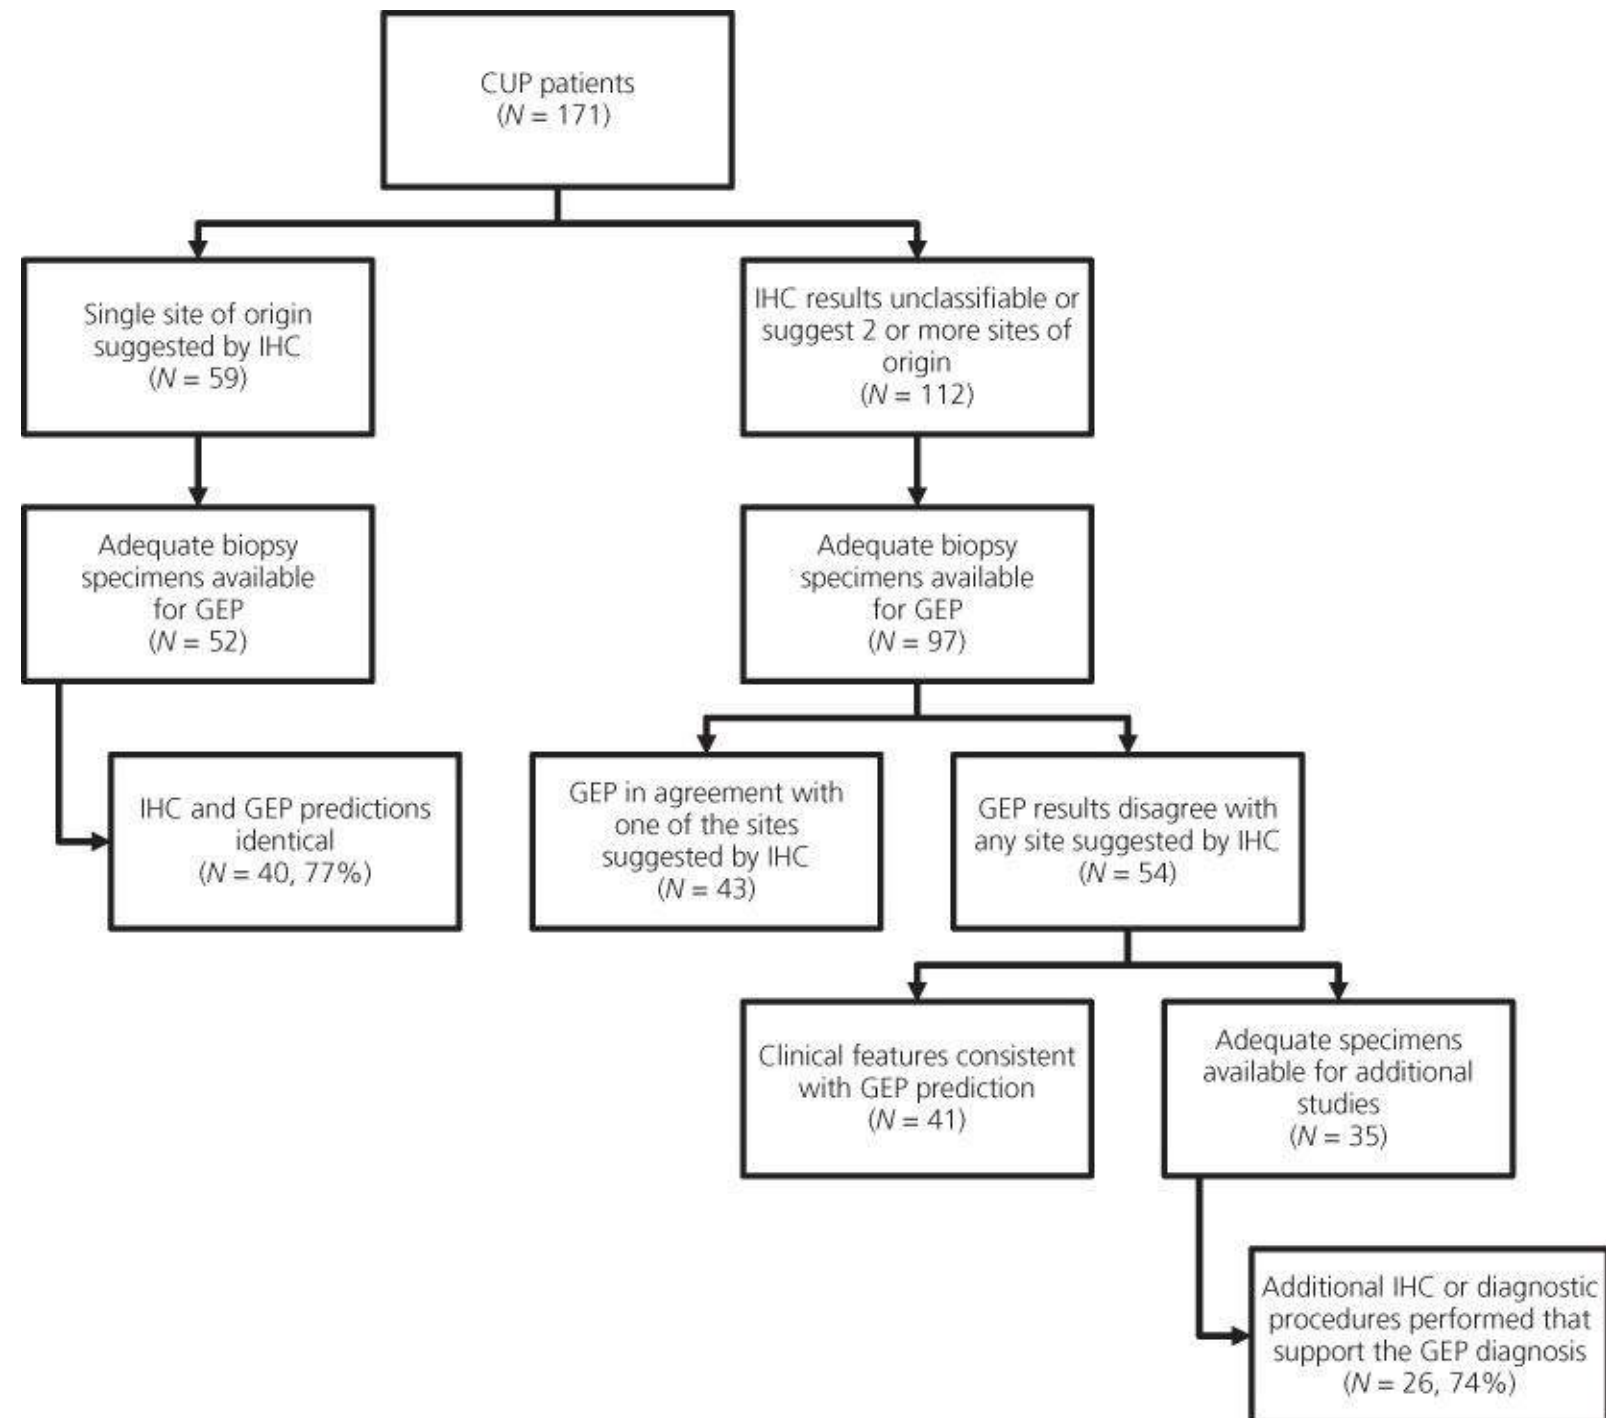

Figure 1 Comparison of IHC and GEP tissue of origin predictions in CUP.

Four smaller studies also demonstrated good correlations between GEP and IHC staining when a single diagnosis is suggested by IHC.^{42–45} Overall, 78% of 117 patients reported in these five studies had matching diagnoses when IHC staining predicted a single tissue of origin. However, the ability of IHC staining to make a single diagnosis occurred in <55% of patients in all studies.

Summary and conclusions

Although validation of the accuracy of diagnostic tests is difficult in CUP, data from various studies are generally consistent and have recently been reviewed in detail.⁴⁶ Several conclusions are now supported by data:

1. GEP using commercially available assays provides a prediction of the tissue of origin in >90% of patients with CUP. These predictions are accurate in approximately 75% of patients.
2. IHC staining panels predict a single site of origin in 35–55% of patients with CUP. In these patients, IHC and GEP results are usually identical (78% of cases). Oncologists have often been reluctant to make treatment decisions based on IHC predictions; however, this may be a group of patients in whom GEP is not necessary and site-specific therapy can be directed by IHC results.
3. IHC staining results are not helpful unless a single tissue of origin can be predicted. In the remaining patients, GEP greatly increases the chance of accurate prediction of the tissue of origin.

As GEP is incorporated into the diagnostic evaluation of patients with CUP, several potential problems should be considered. First, GEP diagnoses are not 100% accurate, even in the validation studies that used cancers of known primary site. These diagnoses should always be considered in conjunction with clinical features and results of other pathologic studies. Second, several neoplasms have overlapping gene expression profiles, which can occasionally cause a misdiagnosis (e.g., breast, salivary gland, and skin adnexal tumors share similar gene expression profiles). Third, tumor types that are not included in the particular GEP assay being used cannot be diagnosed. When this situation occurs, the tumors are either considered unclassifiable or misdiagnosed as a cancer with an overlapping gene expression profile. Finally, performing additional diagnostic studies requires additional biopsy material. The relative priority of available tests should be carefully considered. At times, a repeat biopsy should be considered.

Clinical evaluation

Most patients with CUP develop signs or symptoms at the site of a metastatic lesion and are diagnosed with advanced cancer. Common metastatic sites include the liver, lungs, lymph nodes, and bones; most patients have metastatic tumor at more than one site. The subsequent clinical course is usually dominated by symptoms related to the sites of metastases. During the clinical course, the primary site becomes obvious in only 5–10% of patients.

At autopsy, primary sites can be found in approximately 70% of patients and are usually less than 2 cm in size. Unfortunately, the only large autopsy series were conducted before the routine availability of modern imaging techniques and may therefore not be representative of the current CUP population. The most common primary sites identified in historical autopsy series included the pancreas, hepatobiliary tree, and lung, accounting for approximately 40–50% of all cases.^{47, 48} Adenocarcinomas of the breast and prostate were identified infrequently, despite being common cancer types.⁴⁸

It is of interest to compare the anatomic primary sites identified at autopsy⁴⁸ with the primary sites predicted in a large group of CUP patients recently evaluated with GEP⁴⁹ ([Table 3](#)). The frequent

prediction of primary sites in the gastrointestinal tract (hepatobiliary, pancreas, colon/rectum) and lung by GEP is consistent with autopsy findings. However, the frequent prediction of the urothelium as a primary site and the relatively frequent prediction of breast and ovarian cancers differ from autopsy results. These differences may have practical importance, as breast and ovarian cancers are relatively responsive to treatment.

Table 3 Sites of origin—Comparison of historical autopsy results and molecular tumor profiling predictions

Primary site	Molecular tumor profiling predictions ⁴⁹ (N = 252)	Autopsy results ^{a 48} (N = 133)
Biliary tract	52 (21%)	0
Urothelium	31 (12%)	0
Lung	28 (11%)	29 (22%)
Colon/rectum	28 (11%)	6 (2%)
Pancreas	12 (5%)	28 (22%)
Breast	12 (5%)	1 (1%)
Ovary	11 (4%)	4 (3%)
Gastric/gastroesophageal	10 (4%)	8 (6%)
Kidney	9 (4%)	8 (6%)
Liver	8 (3%)	16 (12%)
Sarcoma	6 (2%)	0
Cervix	6 (2%)	0
Neuroendocrine	5 (2%)	0
Prostate	4 (2%)	4 (3%)
Skin	4 (2%)	0
Germ cell	4 (2%)	0
Carcinoid, gastrointestinal	3 (1%)	0
Mesothelioma	3 (1%)	0
Other (1 each)	3 (1%)	6 (6%)
Thyroid	2 (1%)	1 (1%)
Endometrium	2 (1%)	0
Melanoma	2 (1%)	0
Skin, basal cell	2 (1%)	0
Unlocated/unclassifiable	5 (2%)	23 (17%)

^a Three patients who had primary sites located antemortem are included.

Adenocarcinoma or poorly differentiated carcinoma

As there is much overlap in the clinical features of patients with adenocarcinoma and those with poorly differentiated CUP, initial clinical evaluations of these two groups are identical ([Table 4](#)).

Table 4 Recommended initial clinical evaluation

- Complete medical history—including detailed review of systems
- Complete physical examination—including pelvic examination, stool for occult blood
- Laboratory evaluation—complete blood count, comprehensive metabolic panel, lactate dehydrogenase, urinalysis
- Computed tomography—chest, abdomen, and pelvis
- Mammography (women)
- Serum prostate-specific antigen (men)
- Positron emission tomography scan in selected patients
- Pathologic evaluation—including initial IHC evaluation (CK7, CK20, TTF-1, CDX2)

Many of the procedures included in [Table 4](#) (medical history, physical examination, complete blood counts, chemistry profile, computed tomography) are done in the process of arriving at the diagnosis of CUP. Specific signs and symptoms should be evaluated with directed radiologic or endoscopic studies. All men should have a serum PSA level measured. Women with a clinical presentation compatible with metastatic breast cancer should have mammography and breast MRI exams. The role of positron emission tomography (PET) is controversial. Although a number of studies have suggested that PET scanning can identify the primary site in up to 30% of patients,⁵⁰ the single prospective study showed no superiority of PET scanning when compared to CT scanning.⁵¹

Specific features of the initial evaluation, including clinical presentation and pathologic results, should be used to direct further focused evaluation. Several common patient groups, identified by initial clinical and pathologic evaluations, are outlined in [Table 5](#), with recommendations for further evaluation.

Table 5 Additional evaluation of specific patient subsets identified by initial evaluation

Patient group	Clinical evaluation	Pathologic evaluation
Women with features of breast cancer (bone, lung, liver metastases; CK7+)	Breast MRI	IHC: ER, GCDPF-15, GATA 3 FISH: HER2 GEP (if necessary)
Women with features of ovarian cancer (pelvic/peritoneal metastases; CK7+)	Pelvic/intravaginal ultrasound	IHC: WT-1, PAX8 GEP (if necessary)
Features of lung cancer (hilar/mediastinal adenopathy; TTF-1+)	Bronchoscopy	IHC: Napsin A FISH: ALK/ROS-1 Mutation: EGFR GEP (if necessary)
Features of colon cancer (liver/peritoneal metastases; CK20+/CK7–, CDX2)	Colonoscopy	Mutation: KRAS GEP (if necessary)
Mediastinal/retroperitoneal mass	Testicular ultrasound Serum HCG, AFP	IHC: OCT4, PLAP FISH: i(12p) GEP (if necessary)
Poorly differentiated carcinoma, with or without clear cell features	—	IHC: chromogranin, synaptophysin, RCC, Hepar-1, HMB-45, Melan-A, serum AFP (if Hepar-1+), octreoscan (if neuroendocrine stains +) Mutation: BRAF (if melanoma stains +) GEP

Squamous carcinoma

Squamous carcinoma of unknown primary site usually presents with isolated metastases in the cervical or inguinal lymph nodes. As curative therapy is available for many of these patients, the initial clinical evaluation is critical for the purposes of (1) identifying a regional primary site and (2) identifying the extent of local tumor involvement.

The cervical lymph nodes are the most common metastatic site for squamous carcinoma of unknown primary site. Patients are usually middle-aged or elderly, and many have a history of substantial tobacco and alcohol use. Optimal evaluation includes a thorough examination of the oropharynx, hypopharynx, nasopharynx, larynx, and upper esophagus by direct endoscopy, with biopsy of suspicious areas. Computed tomography of the neck is useful in defining the extent of disease and occasionally in identifying the primary site. PET scanning identifies a primary site in 25% of patients even after other procedures are unrevealing and should be included as a standard diagnostic procedure.⁵² When the lower cervical or supraclavicular lymph nodes are involved, a primary lung cancer should be suspected. Fiber-optic bronchoscopy is indicated if computed tomography and head/neck evaluations are unrevealing.

Ipsilateral or bilateral tonsillectomy has been advocated as a diagnostic modality if the primary site remains unidentified after the evaluation described above.⁵³ In one series, tonsillectomy identified a tonsillar primary site in 23 of 87 patients (26%).⁵⁴

Most patients with squamous carcinoma involving inguinal lymph nodes have a detectable primary site in the genital or anorectal area. In women, careful examination of the vulva, vagina, and cervix is important, with biopsy of suspicious areas. Men should undergo a careful inspection of the penis. Digital examination and anoscopy should be performed in both sexes to exclude lesions in the anorectal area. Identification of a primary site in these patients is important, as potentially curative therapy is available for carcinomas of the vulva, vagina, cervix, and anus even after metastasis to regional lymph nodes.

Metastatic squamous carcinoma in areas other than the cervical or inguinal nodes usually represents metastasis from a primary lung cancer. Computed tomography of the chest and fiber-optic bronchoscopy should be performed if other clinical features suggest the possibility of lung cancer.

Neuroendocrine carcinoma

The initial clinical evaluation of patients with neuroendocrine carcinoma is the same as described in [Table 4](#); however, special consideration is required in determining appropriate treatment.

Low-grade neuroendocrine carcinomas have the histologic appearance of typical carcinoid or islet cell tumors. When presenting with an unknown primary site, these tumors most frequently involve the liver. Some patients have clinical syndromes produced by tumor secretion of bioactive substances. Additional clinical evaluation in these patients should include serum or urine screening for these substances. An octreotide scan and upper and lower gastrointestinal endoscopy should be performed.

High-grade neuroendocrine carcinomas include typical small cell or large cell neuroendocrine carcinomas, as well as poorly differentiated carcinoma that is only recognized as neuroendocrine after IHC staining or GEP. Patients with high-grade neuroendocrine carcinomas usually have multiple metastases at the time of diagnosis and rarely have syndromes mediated by secretion of bioactive peptides. Patients with a history of cigarette smoking should be suspected of having an occult lung primary site, and bronchoscopy should be considered. Patients with IHC staining for thyroid transcription factor-1 (TTF-1) should also be considered for bronchoscopy. Extrapulmonary small cell carcinomas arising from various primary sites (salivary glands, esophagus, pancreas, bladder, prostate, colon/rectum, uterus, cervix) are occasionally identified during clinical evaluation. Patients with IHC staining for CDX2 should be considered for colonoscopy.

The origin of these high-grade neuroendocrine carcinomas remains unclear. Some patients may have small-cell lung cancer with an occult primary site. However, many of these patients have no smoking history, and the absence of pulmonary involvement makes this diagnosis unlikely in most patients. It has been speculated that high-grade neuroendocrine carcinomas share the same origin as low-grade neuroendocrine tumors but represent the opposite ends of a “spectrum” of tumor biology. However, it now seems more likely that high-grade neuroendocrine carcinomas have a different oncogenesis; many share the same chromosomal abnormalities commonly seen in small cell lung cancer (deletions of 3p, 5q, 10q, and 17p), while there are no shared molecular abnormalities with the group of carcinoid-type carcinomas.^{55, 56}

Treatment

Following the initial diagnostic evaluation, several groups of patients emerge. In a few patients, evaluation leads to the identification of an anatomic primary site; these patients no longer have CUP and should be treated appropriately for their defined cancer type. A second group of patients (~20%) fit into various favorable subgroups based on clinical and/or pathologic features, even though an anatomic

primary site is not identified ([Table 6](#)). The management of each of these subsets is detailed in this section. Finally, the largest group (~80%) consists of patients who do not fit any favorable subset. Empiric chemotherapy has been the treatment standard for this group for many years and will be briefly reviewed. However, increasing evidence supports the use of site-specific therapy for these patients, guided by IHC and GEP predictions of the tissue of origin. These new data will also be reviewed.

Table 6 Summary of favorable treatment subsets

Subset	Typical histology	Therapy
Women, isolated axillary LN	Adenocarcinoma	Treat as stage II breast cancer
Women, axillary LN + other metastases	Adenocarcinoma	Treat as metastatic breast cancer
Women, peritoneal carcinomatosis	Adenocarcinoma (often serous) or poorly differentiated carcinoma	Treat as stage III ovarian cancer
Men, blastic bone metastases or high serum PSA or PSA tumor staining	Adenocarcinoma	Treat as metastatic prostate cancer
Colon cancer profile (intra-abdominal metastases + typical histology/IHC)	Adenocarcinoma	Treat as metastatic colon cancer
Single metastatic site	Adenocarcinoma or poorly differentiated carcinoma	Definitive local therapy (resection and/or radiation therapy)
Isolated cervical LN	Squamous carcinoma	Treat as locally advanced head/neck cancer
Isolated inguinal LN	Squamous carcinoma	Definitive local therapy (inguinal node dissection and/or radiation therapy) ± chemotherapy
Extragonadal germ cell syndrome	Poorly differentiated carcinoma	Treat for poor prognosis germ cell tumor
Neuroendocrine carcinoma, low grade	Carcinoid/islet cell features	Treat as advanced carcinoid tumor
Neuroendocrine carcinoma, aggressive	Small cell or poorly differentiated carcinoma	Treat as small cell lung cancer

Favorable subsets

Women with peritoneal carcinomatosis

In women, adenocarcinoma causing diffuse peritoneal involvement usually originates in the ovary, although carcinomas arising in the gastrointestinal tract or breast can occasionally produce this syndrome. However, peritoneal carcinomatosis also occurs in women with normal ovaries and no other evident primary site. This syndrome has occasionally developed in women from families at high risk for ovarian cancer despite prophylactic oophorectomy⁵⁷ and is increased in incidence in women with BRCA1 mutations.⁵⁸ Many of these patients have histologic features typical of ovarian carcinoma, such as

papillary configuration or psammoma bodies. Clinical features are typical of advanced ovarian cancer, with tumor involvement usually limited to the peritoneal surfaces and elevated serum levels of CA 125 antigen. When histologic features suggest ovarian carcinoma, this syndrome has been termed “multifocal extraovarian serous carcinoma” or “peritoneal papillary serous carcinoma.” Rarely, men with peritoneal carcinomatosis, papillary adenocarcinoma, and elevated serum CA 125 levels have also been reported.⁵⁹

Patients with this syndrome often respond well to the chemotherapy regimens effective in the treatment of advanced ovarian carcinoma. Several investigators documented initial response rates of 39–66%, with long-term remissions in 15–20% of patients.^{60–65} As in ovarian cancer, most long-term remissions occurred in patients who had successful surgical cytoreduction prior to receiving chemotherapy. Optimal management therefore includes initial maximal surgical cytoreduction followed by taxane/platinum chemotherapy.

Women with axillary lymph node metastases

Metastatic breast cancer should be suspected in women who have axillary lymph node involvement with adenocarcinoma.⁶⁶ Breast MRI or PET scanning can identify a primary site even when mammography is normal and should be performed.^{67, 68} Pathologic evaluation of the axillary lymph node biopsy should include measurement of estrogen and progesterone receptors, HER2 expression, and other IHC breast markers ([Table 2](#)). When positive, these findings provide strong evidence for the diagnosis of breast cancer.

Women with isolated axillary lymph node metastases are potentially curable and should be managed according to standard guidelines for stage II breast cancer. Primary therapy should include either modified radical mastectomy or axillary lymph node dissection followed by radiation therapy to the breast.^{69–71} When mastectomy is performed, an occult breast cancer is identified in 44–82% of patients, even when physical examination and mammograms are normal.⁷⁰ Primary tumors are usually less than 2 cm in diameter; in occasional patients, only carcinoma *in situ* is identified in the breast.⁷² Selection of adjuvant therapy should follow standard guidelines for node-positive breast cancer.

Women with metastatic sites in addition to axillary lymph nodes may also have metastatic breast cancer. These women should receive a trial of systemic therapy using guidelines for the treatment of metastatic breast cancer, particularly if IHC stains or GEP support a breast cancer diagnosis. Hormone receptor status and HER2 expression should guide therapy, as in patients with metastatic breast cancer.

Men with skeletal metastases

Serum PSA levels should be measured in all men with adenocarcinoma of unknown primary site. Men with elevated serum PSA levels (or positive tumor staining with PSA) should be treated according to guidelines for metastatic prostate cancer, even if clinical features are atypical.^{73, 74} Osteoblastic bone metastases are also an indication for a trial of prostate cancer treatment, even in the absence of PSA findings.

Colorectal cancer profile

During the last 20 years, the introduction of more effective cytotoxic agents and targeted therapies for the treatment of metastatic colorectal cancer has increased the median survival of these patients from 8 to 24 months.⁷⁵ Therefore, the ability to identify these patients from among the heterogeneous group of CUP patients is potentially important, as many of the standard agents used for colorectal cancer are not contained in the empiric chemotherapy regimens used for CUP.

A colon cancer “profile” has recently been defined, which allows prediction of CUP patients likely to have a colorectal site of tumor origin.^{76, 77} The colon cancer profile includes (1) typical clinical features (liver, peritoneal metastases), (2) histology compatible with lower gastrointestinal tract adenocarcinoma, and (3) typical IHC staining (CK20+/CK7– or CDX2+). In a group of 68 such patients, treatment according to standard guidelines for metastatic colorectal cancer produced a median survival of 28 months.⁷⁷ It is important to note that colonoscopy did not identify an anatomic primary site in any of these patients. Although this approach has not been formally compared to standard empiric CUP therapy, the favorable median survival (as compared to the usual median survival of 8–10 months with empiric chemotherapy) strongly suggests the merit of this approach.

Carcinoma presenting as a single metastatic lesion

Occasionally, only a single metastatic lesion is identified after a complete clinical evaluation. Single lesions have been described in a variety of sites, including lymph nodes, brain, lung, adrenal gland, liver, bone, and skin. The possibility of an unusual primary site (e.g., primary cutaneous apocrine, eccrine, or sebaceous carcinoma) mimicking a metastatic lesion should be considered, but this possibility can usually be excluded on the basis of clinical or pathologic features.

In most of these patients, other metastatic sites become evident within a relatively short time. However, local treatment sometimes results in long disease-free intervals, and occasional patients have prolonged survival.⁷⁸ Before initiating local treatment, a PET scan is useful to rule out the presence of other metastatic sites.⁷⁹ If no other metastases are detected, the solitary lesion should be resected, if technically feasible. In some instances (e.g., after resection of a solitary brain metastasis), local radiation therapy may also be appropriate to maximize the chance of local control. The role of systemic chemotherapy in addition to definitive local therapy is undefined; however, adjuvant or neoadjuvant chemotherapy should be considered if a sensitive tumor type is suggested by IHC staining or GEP.

Extragonadal germ cell tumor syndrome

A few patients with poorly differentiated carcinoma of unknown primary site have extragonadal germ cell tumors that are unrecognizable by standard histologic criteria.^{23, 80, 81} These patients are usually young males with predominant tumor location in the mediastinum or retroperitoneum. Some also have marked elevations of the serum tumor markers hCG or alpha-fetoprotein. In most of these patients, the diagnosis can be confirmed using IHC, GEP,³⁹ or identification of the i(12p) chromosomal abnormality specific for germ cell tumors.²³

These patients should receive treatment for extragonadal germ cell tumor with four cycles of cisplatin-based chemotherapy followed by resection of residual tumor masses. Treatment results are similar to those achieved in the treatment of typical extragonadal germ cell tumors.^{23, 80}

Squamous carcinoma involving cervical or supraclavicular lymph nodes

Squamous carcinoma of unknown primary site most frequently presents with unilateral involvement of the cervical lymph nodes. The recommended clinical evaluation (previously described) results in the identification of a head and neck primary site in 85% of patients.⁸²

When no primary site is identified, patients should be treated according to guidelines for locally advanced squamous carcinoma of the head and neck; approximately 50% have long-term disease-free survival.^{83–88} As in patients with known primary sites in the head and neck, extensive involvement in neck nodes and poorly differentiated tumor histology are poor prognostic features.^{84, 89}

Patients with low cervical or supraclavicular lymph nodes are more likely to have a primary lung cancer, and treatment results are inferior. Nevertheless, patients with no detectable disease below the clavicle should be treated with the same approach as are patients with higher cervical nodes, as occasional patients will have long-term survival.

Squamous carcinoma involving inguinal lymph nodes

Most patients with squamous carcinoma involving inguinal lymph nodes have a detectable primary site in the anogenital area. For the occasional patient in whom no primary site is identified, definitive local therapy with inguinal node dissection or radiation therapy sometimes results in long-term survival.⁹⁰ Because combined modality therapy has improved survival of patients with squamous cancer arising in this region (e.g., cervix, anus), the addition of chemotherapy should be considered in patients with an unknown primary site.

Low-grade neuroendocrine carcinoma

Carcinoid or islet cell tumors of unknown primary site usually exhibit an indolent biology, and management should follow guidelines established for metastatic tumors of these types with known primary sites. Treatment with octreotide long-acting release (LAR) lengthens the time to tumor progression with low toxicity.⁹¹ Depending on the clinical situation, appropriate management may also include local therapy (resection of isolated metastasis, radiofrequency ablation, cryotherapy, or hepatic artery chemoembolization). Several cytotoxic agents have some activity (5-FU, streptozocin, capecitabine, temozolomide), and results with targeted agents (sunitinib, everolimus) are promising.

High-grade neuroendocrine carcinoma

This group of patients includes small-cell and large-cell neuroendocrine carcinomas (histologic diagnoses) and patients with poorly differentiated carcinoma recognized to have neuroendocrine carcinoma by IHC staining. These patients should receive treatment with combination chemotherapy used for small-cell lung cancer; high response rates and a minority of long-term survivors (10–15%) have been reported.^{92–95}

Poorly differentiated carcinoma

Patients with poorly differentiated carcinoma of unknown primary site form a large and heterogeneous group. The recognition that some of these patients had highly chemotherapy-sensitive neoplasms first occurred in the 1970s.^{80, 81, 96} However, it is likely that currently available diagnostic methods identify the highly responsive patients in this group. The remaining patients with poorly differentiated CUP have a prognosis similar to patients with adenocarcinoma of unknown primary site. These patients should be evaluated using recommendations for adenocarcinoma, with particular attention to determining the tissue of origin using IHC staining and/or GEP.

Empiric chemotherapy for CUP

Approximately 80% of patients with CUP do not fit into any of the favorable subgroups outlined above. For many years, empiric chemotherapy has been the treatment of choice for most of these patients, as their tissue of origin could not be determined. At the time empiric chemotherapy regimens were designed, treatments were poor for many types of solid tumors. In addition, similar cytotoxic agents and regimens were used in the therapy of a variety of cancers. Therefore, it was possible to design “broad spectrum” regimens with reasonable activity against most sensitive tumor types.

Combination regimens containing most of the commonly used cytotoxic agents (taxanes, gemcitabine, topoisomerase I inhibitors, anthracyclines, vinca alkaloids) have been evaluated in the empiric treatment of patients with CUP. Combinations containing a platinum agent and a taxane have been most widely studied and are commonly used.^{97–103} Several other combinations (i.e., gemcitabine/platinum, gemcitabine/taxane) have similar activity.^{104–106} Several randomized phase II trials have compared various two-drug combinations and have usually yielded similar results.^{105, 107–111} The addition of a third drug has not improved efficacy.^{109, 112–115} Although response rates have varied, most trials have reported median survivals within a narrow range of 8–11 months, with 2-year survival rates of 14–24%. In larger trials (containing 100 or more patients), the median survival is consistently about 9 months.^{107, 112, 114, 116, 117}

Empiric second-line therapy has been evaluated in a few phase II trials. Single-agent gemcitabine and the combinations of gemcitabine/irinotecan, capecitabine/oxaliplatin, and bevacizumab/erlotinib have had modest activity.^{118–121}

Although no definitive studies have compared survival with empiric chemotherapy versus best supportive care alone, evidence from several large tumor registries suggests that current treatment results in an improved survival.^{122–129} The Swedish Cancer Registry documented an improved median survival for patients with CUP during the years 2001–2008 (6 months) versus 1987–1993 (4 months).¹³⁰

In spite of these modest improvements, the authors are convinced that the era of empiric chemotherapy for CUP is coming to an end. Accurate identification of the tissue of origin is possible in most CUP patients and provides a more rational framework for decisions regarding therapy.

Site-specific treatment directed by the predicted tissue of origin

The tissue of origin can now be accurately predicted in most patients with CUP. Although it is logical to assume that site-specific treatment based on the predicted tissue of origin would be superior to empiric chemotherapy, clinical data to support this assumption have only recently accumulated and remain incomplete. One cause for skepticism regarding a site-specific approach relates to the unique biology of CUP (evidenced by the fact that the primary site does not become apparent). This fundamental clinical difference has led to the speculation that these cancers may also respond differently to systemic therapy. However, increasing evidence indicates that most cancers of unknown primary site retain the characteristics of cancers with known primary arising from the same site.

Several biological and clinical observations now support these similarities. First, gene expression profiles in CUP remain similar to advanced cancers from the same tissue of origin. Second, no unique molecular “signature” common to CUP has been identified. Third, successful treatments for patients in several of the clinically recognized favorable CUP subsets are based on the presumption that they have specific cancer types (e.g., women with axillary nodes are treated for breast cancer and women with peritoneal carcinomatosis are treated for ovarian cancer). Fourth, retrospective studies containing CUP patients predicted to have a colorectal site of origin by either IHC staining^{76, 77} or molecular tumor profiling^{131, 132} and treated with standard colorectal cancer therapy documented median survivals >20 months, similar to the survival of patients with metastatic colon cancer.

The strongest support for site-specific therapy comes from a recent large, prospective trial in which previously untreated CUP patients had GEP (92-gene RT-PCR assay³⁵). In this trial, a tissue of origin was predicted in 242 of 253 patients (98%). Twenty-six different tissues of origin were diagnosed ([Table 3](#)). Patients received site-specific therapy based on the GEP predictions and had a median survival of 12.5

months.⁴⁹

Within this large group, 41% of patients had predicted tissues of origin known to be relatively resistant to standard therapy and were therefore unlikely to benefit much regardless of the treatment used. As predicted, this group did poorly, with a median survival of only 7.6 months. However, the remaining patients (59% of the group) were predicted to have more responsive tumor types and had a median survival of 13.4 months with site-specific therapy ($p = 0.04$). Although the numbers of patients with individual cancer types were small, median survivals within most of these groups were similar to those expected for the predicted tumor types (median survivals, months: ovary 30, breast 28, NSCLC 16, colorectal 13, pancreas 8, biliary tract 7).

In addition to the results from this prospective study, several small retrospective studies and case reports have documented benefits of site-specific treatment directed by the predicted tissue of origin.^{133, 134} Not all results have been consistent; in one study of 67 CUP patients who had anatomic primary sites identified as part of the initial evaluation, molecular profiling using an early assay predicted the correct primary site in only 35% of patients.¹³⁵

Screening CUP for “actionable” molecular abnormalities

Many new cancer therapies exploit cancer-specific molecular abnormalities critical to cancer cell growth and metastasis. The identification of appropriate patient populations for these agents therefore depends not only on the tumor type but also on the presence of specific targeted molecular abnormalities. Screening of patients with specific cancer types for targeted molecular abnormalities is already a standard part of clinical practice, and screening for broader panels of potentially “actionable” abnormalities is becoming more commonplace.

Limited information currently exists regarding the prevalence of various molecular abnormalities in CUP. However, given the heterogeneity of cancers represented in the CUP population, it is likely that some potentially “actionable” abnormalities are represented. Previous studies and case reports have documented the existence of specific molecular abnormalities including HER2 overexpression and various mutations (EGFR, PI3KCA, MET, others).^{136–140} Further characterization of these abnormalities and their frequency is important and may lead to additional treatment options for some CUP patients.

The identification of the tissue of origin of CUP may also lead to directed assessment of specific molecular abnormalities. For example, CUP patients predicted to have nonsmall-cell lung cancer should be evaluated for EGFR-activating mutations and ALK and ROS1 rearrangements. In a small group of such patients where studies identified ALK rearrangements, treatment with crizotinib resulted in therapeutic benefit.¹⁴¹ The coordinated use of GEP for diagnosis and additional molecular assays to identify “actionable” molecular abnormalities is the likely direction of CUP treatment in the future.

Current management of patients with CUP—A new treatment paradigm emerges

[Figure 2](#) diagrams the proposed management of patients with CUP. After initial clinical and pathologic evaluations (including IHC staining), patients in whom the anatomic primary site is identified should be treated accordingly, and patients who fit into a favorable treatment subset should receive appropriate therapy. Patients who have a single tissue of origin predicted by IHC staining should receive site-specific therapy; GEP may help to verify IHC results. When initial IHC evaluation does not suggest a single site of origin, GEP should be performed, and site-specific therapy should be based on the results. Empiric chemotherapy is indicated for patients in whom the tissue of origin is unclear after complete diagnostic

evaluation.

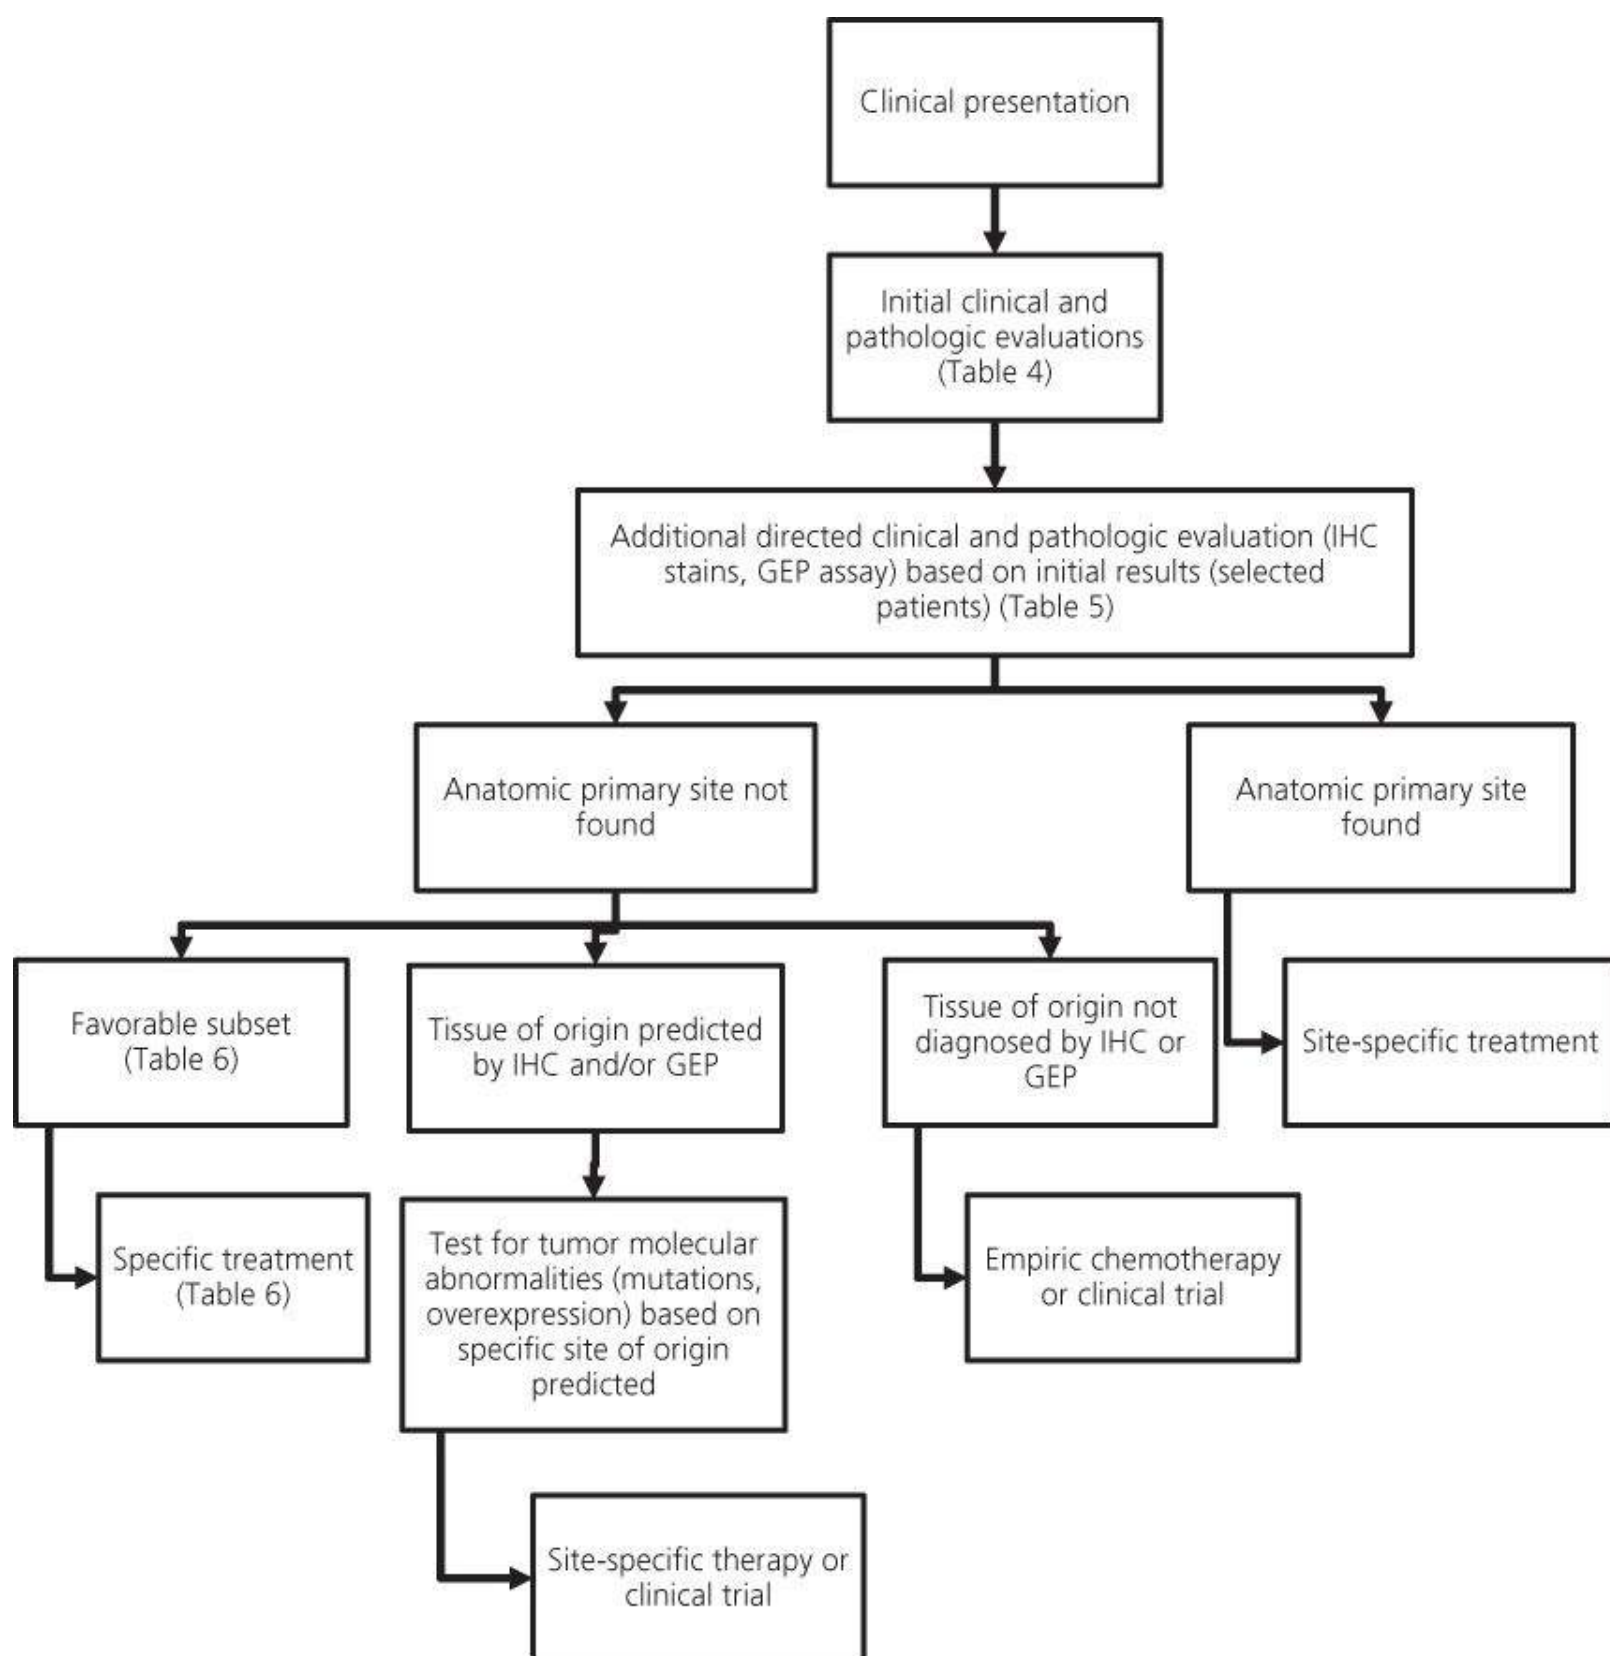

Figure 2 Management of patients with carcinoma of unknown primary site: overview.

The integration of molecular diagnostics into the management of CUP is already supported by clinical data, but continued investigation is necessary to refine management recommendations. The evolution of improved therapy for CUP patients also depends on improvements in therapy of other cancer types and is linked to the increasing number of precision therapies for these tumors. Optimum and timely integration of new agents into the treatment of patients with CUP will require ongoing efforts to define critical molecular abnormalities as a part of treatment planning for each patient.

Chapter 124

Anorexia and cachexia

Takao Ohnuma, MD, PhD

Overview

Cancer cachexia is a wasting syndrome with extensive loss of skeletal muscle mass with or without adipose tissue. It may be contrasted with simple starvation in which fat replaces glucose as the preferred fuel to spare lean body mass. It results from altered metabolism rather than just an energy deficit, and cannot be reversed by conventional nutritional support. The causes of cancer-related cachexia are multifactorial including production of procachectic cytokines and metabolic derangements. European cancer community is credited in developing new definition and classification of cancer cachexia. Recent studies identified anamorelin, an oral ghrelin analogue, as a new agent for the treatment of cancer cachexia.

Introduction

Cachexia is a wasting syndrome that may accompany a plethora of diseases, including cancer, chronic obstructive pulmonary disease, AIDS, and rheumatoid arthritis. It is associated with central and systemic increases of pro-inflammatory factors, and with decreased quality of life, poor responses to pharmacological treatment and shortened survival.^{1, 2}

Extensive loss of skeletal muscle mass with or without adipose tissue in cachexia may be contrasted with simple starvation in which fat replaces glucose as the preferred fuel to spare lean body mass. Cancer cachexia results from altered metabolism rather than just an energy deficit, and it cannot be reversed by conventional nutritional support.^{3, 4}

Cachectic patients have a poor tolerance for surgery, chemotherapy, and radiotherapy.^{5–8} Cross-sectional images at the level of the fourth lumbar vertebra in patients who underwent surgery revealed that covariate-adjusted mortality increased significantly as lean core muscle area decreased.^{7–9}

A lack of universally accepted definitions, diagnostic criteria and classification has impeded progress in both clinical trials and clinical practice. The definition and the classification of cancer cachexia developed in 2010 are shown in [Tables 1](#) and [2](#).¹⁰

Table 1 Diagnosis of cancer cachexia

Measurement	Amount	Comments
Weight loss	>5%	In past 6 months (in absence of simple starvation)
or		
Body mass index	<20	If weight loss >2%
or		
Appendicular skeletal muscle index		Consistent with sarcopenia
Dual energy X-ray	Men < 7.26 kg/m ²	If weight loss >2%
	Women < 5.45 kg/m ²	
Absorptiometry	Men < 32 cm ²	Upper arm
	Women < 18 cm ²	
Anthropometry	Men <55 cm ²	Lumbar CT imaging
	Women <39 cm ²	
Bioelectrical impedance	Men <14.6 kg/m ²	Unreliable if obese or edematous
	Women <11.4 kg/m ²

Table 2 Stages of cancer cachexia

<i>Precachexia</i>
Anorexia, metabolic change, weight loss <5%
<i>Cachexia</i>
Weight loss >5% in past 6 months (without starvation)
or
Body mass index <20 and weight loss >2%
or
Anorexia and systemic inflammatory changes and sarcopenia and weight loss >2%
<i>Refractory cachexia</i>
Progressing catabolic state in a cancer usually unresponsive, low performance score and predicted survival < 3 months

Source: Fearon et al. 2011.¹⁰ Reproduced with permission from Elsevier.

There is consensus that focus should move from end-stage wasting to supporting patients' nutritional and functional state throughout the course of anticancer treatment. When inadequate nutrient intake predominates (malnutrition), this can be managed by conventional nutritional support. In the presence of systemic inflammation/altered metabolism that characterizes cachexia, a multimodal approach including

novel therapeutic agents will likely be required. Three supportive care issues are critical: ensuring sufficient energy and protein intake, maintaining physical activity to maintain muscle mass, and (if present) reducing systemic inflammation. The results of phase II/III trials based on novel drug targets (e.g., cytokines, ghrelin receptor, androgen receptor, and myostatin) are expected by 2016. If effective therapies emerge, early detection of malnutrition and cachexia will be increasingly important.¹¹

Etiology and mechanisms

The causes of cancer-related cachexia are multifold and can be grouped into three interrelated categories: anorexia and early satiety, mechanical obstruction of the alimentary tract, and metabolic derangement.

Anorexia in cancer patients can be disease-related, treatment-related and emotional distress-related. Anorexia may result from early satiety, nausea, or dysgeusia, a change in taste. Potential etiologic factors of anorexia and early satiety are presented in [Table 3](#). Abnormalities of taste sensation and olfaction for specific food aromas have been demonstrated in cancer patients.⁴⁸

Table 3 Possible causes of cancer anorexia

Name	Character	References
Cytokines	TNFα	121314
	IL-1	141516
	IL-6	14 17181920212223242526272829303132
Neuropeptides	Dysfunction in the brain circuits	33
Serotonin	Increases in serum and central nervous system (CNS)	34 35
Serum lactate	Tumor product	36 37
Glucagon and similar peptides		38 39
Satietyins	Proteins isolated in plasma	40 41
Hypercalcemia	Occasional paraneoplastic findings	42
Bombesin	Neuropeptide from small-cell lung cancer	43 44
Toxohormone-L	Lipolytic factor purified from ascitic fluid of patients with hepatoma	45 46
Anticancer agents (emetogenic)	Cisplatin, doxorubicin, nitrogen mustard, others	47

Cytokines

TNF-α, IL-1, IL-6 [and its subfamily members such as ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF)], and IFN-γ produced by host immune cells and/or tumor cells have all been implicated as mediators of cancer cachexia.^{49–51} These cytokines, called procachectic factors, are characterized in animals by the induction of anorexia, weight loss, an acute-phase protein response, protein and fat breakdown, rises in levels of cortisol and glucagon and falls in insulin level, insulin

resistance, anemia, fever, and elevated energy expenditure. Direct interaction may occur with leptin, neuropeptides, or serotonin as mechanisms of induction of cancer anorexia. Anticachectic factors, IL-4, IL-10, IL-12, IL-15, IFN- α , and insulin-like growth factor I (IGF-I), act in opposition to procachectic factors.

Procachectic cytokines are produced by host immune cells including T helper 1 cells, macrophages, and myeloid-derived suppressor cells as part of a persistent inflammatory response. Proteolysis inducing factor (PIF) appears to be produced exclusively by tumors. PIF and TNF- α appear to induce cachexia through a similar pathway, by activating nuclear factor kappa B (NF- κ B) transcription factor in muscles.^{52, 53}

An elevated adrenergic state appears to be similar across tumor types resulting in elevated rates of energy expenditure.^{54, 55} The primary site of lean body mass depletion is the skeletal muscle, due to an increased protein turnover without equivalent protein synthesis.⁵⁴ Available data suggest loss of myosin heavy chain (MyHC) and reduction in fiber size.^{54, 56} The adenosine triphosphate-ubiquitin-dependent pathway regulating protein breakdown is upregulated in certain cases of cancer cachexia.^{54, 57}

IL-6 is a multifunctional cytokine involved in a variety of host defenses and pathological processes.¹⁷ IL-6-secreting cells can induce wasting of both muscle and fat stores and ultimately death.^{18, 19} Serum IL-6 levels were elevated in most experimental models of cachexia. IL-6 was demonstrated to be a sensitive predictor of weight loss in a number of series, including patients with advanced small-cell lung cancer²⁰ and colon cancer.^{21, 22} Elevated IL-6 levels were associated with reduced survival in a variety of cancer types.²³ In addition to IL-6 itself, other IL-6 family cytokines have also been implicated in muscle wasting, including CNTF^{24, 25} and LIF.^{26, 27}

IL-6 and related ligands activate signaling by binding to ligand-specific α -receptors (IL-6 receptor- α , also known as gp80) in either membrane-bound or soluble forms.²⁸ These ligand receptor complexes induce activation of three major pathways: the signal transducers and activators of transcription 1 and 3 (STAT1/3), ERK, and phosphatidylinositol 3-kinase/Akt pathways.²⁹ These pathways interact with downstream kinases to influence gene expression.³⁰

One pathway activated strongly by IL-6 family ligands is the JAK/STAT3 pathway. STAT3 activation was shown to be a common feature of muscle wasting, activated in muscle by IL-6 *in vivo* and *in vitro* and by different types of cancer and sterile sepsis. Moreover, STAT3 activation proved both necessary and sufficient for muscle wasting. Conversely, inhibiting STAT3 pharmacologically with JAK or STAT3 inhibitors reduced muscle atrophy downstream of IL-6. These results indicated that STAT3 was a primary mediator of muscle wasting in cancer cachexia and other conditions of high IL-6 family signaling.^{31, 32}

Although the underlying mechanisms of muscle cachexia in cancer appear non-overlapping to those in the muscular dystrophies, a dysfunctional dystrophin glycoprotein complex (DGC) appears to be a common link between these two disease states.^{58–60}

Tumor-induced alterations in DGC represent a key early event in cachexia.⁵⁹ DGC was examined in muscle biopsies. Compared to healthy controls, in 60% of patients with gastrointestinal cancer, dramatic reduction in dystrophin was found, linked with hyperglycosylation of DGC proteins.⁵⁹

While TNF- α induces IL-1, both cytokines exercise their anorectic effect through the brain as well as directly on the gastrointestinal tract, for example, slowed gastric emptying.^{12, 15} In carcinogen-induced tumors in rats, despite changes in other tissues, IL-1 β and its receptor mRNA were the only ones upregulated in the brain, suggesting that they played a major role in this model of cancer-associated

anorexia.¹⁶

Serum levels of circulating TNF- α , IL-1, IL-6 and IFN- γ did not correlate with the anorexia/weight loss syndrome in cancer patients.^{13, 14} A central mechanism of action in the production of cachexia has been postulated for many cytokines, including IL-1, IL-6, IL-8, TNF- α , IFN- α and other chemokines. Additional comments are pertinent for serotonin and dysfunction of neuropeptidergic circuits. A close relationship between elevated plasma-free tryptophan and anorexia was observed in patients with cancer.³⁴ Increase in blood tryptophan results in elevated tryptophan levels in the cerebrospinal fluid, inducing increased synthesis of serotonin, a major mediator of cancer anorexia.³⁵

Involvement of proteasome activity appears to be a rare event in cancer patients.^{54, 61} Some findings suggest involvement of the autophagic-lysosomal proteolytic system and cathepsin B during cancer cachexia development in humans.^{61, 62}

Insulin and ghrelin

Insulin, secreted from the exocrine pancreas, and leptin, produced primarily by adipocytes, both circulate at levels proportional to body fat content. They enter the central nervous system (CNS) in proportion to their plasma levels. As weight increases, insulin secretion is increased both at the basal state and in response to meals. Insulin promotes fat storage and leptin synthesis by fat cells. Leptin has a more important role than insulin in the CNS control of energy homeostasis, for example, leptin deficiency causes obesity with hyperphagia that persists despite high insulin levels, whereas obesity is not induced by insulin deficiency.^{63, 64} Endogenous control of appetite by the neuropeptide network can be categorized as orexigenic and anorexigenic ([Table 4](#)). In cachectic tumor-bearing animals, lower circulating levels of leptin and decreased adipose tissue leptin mRNA content have been described.⁶⁵ Similarly, serum leptin levels were reduced in patients with both advanced lung cancer and colon cancer.^{66, 67} Plasma leptin levels showed gender-dependent associations, and significantly lower levels were found among cachectic women than among cachectic men.⁶⁸

Table 4 Orexigenic (anabolic) and anorexigenic (catabolic) neuropeptides

<i>Orexigenic molecules</i>
Neuropeptide Y (NPY)
Agouti-related protein (AGRP)
Melanin-concentrating hormone (MCH)
Hypocretin 1 and 2 (orexins A and B)
Galanin
Norepinephrine
Opioids
Ghrelin
<i>Anorexigenic molecules</i>
α-Melanocyte-stimulating hormone (α-MSH)
Corticotropin-releasing hormone (CRH)
Thyrotropin-releasing hormone (TRH)
Cocaine- and amphetamine-regulated transcript (CART)
Pro-opiomelanocortin (POMC)
Insulin
IL-1β
Urocortin
Glucagon-like peptide 1 (GLP-1)
Oxytocin
Neurotensin
Serotonin
Dopamine
Histamine
Cholecystokinin
Bombesin
Calcitonin-gene-related peptide
Pituitary adenylate-cyclase-activating polypeptide
Leptin

Source: Data from Refs. ³³ and ⁶³.

Ghrelin, the “hunger hormone,” which functions as a neuropeptide in the CNS, is a peptide produced by ghrelin cells in the gastrointestinal tract. When the stomach is empty, ghrelin is secreted. When the stomach is stretched, secretion stops. Ghrelin acts on hypothalamic brain cells both to increase hunger and to increase gastric acid secretion and gastrointestinal motility in preparation for food intake. The receptors for ghrelin and leptin, with opposing effects, are found on the same brain cells. Ghrelin also plays an important role in regulating reward perception in the ventral tegmental area (a site that plays a

role in processing sexual desire and developing addictions) through its interaction with dopamine and acetylcholine.

Ghrelin is encoded by the *GHRL* gene and is produced from the presumed cleavage of the prepropeptide ghrelin/obestatin. Full-length preproghrelin is homologous to promotilin and both are members of the motilin family.

Ghrelin's peculiar structure, consisting of 28 amino acids with a single fatty acid *n*-octanoylated at Ser 3, not only allows binding to the growth hormone (GH) secretagogue receptor but also confers on the molecule a large variety of pleiotropic effects on different metabolic pathways.⁶⁹ Two different forms of ghrelin originating from the same precursor are detectable in serum: an unacylated ghrelin (UnAG) and a lower concentration of acylated ghrelin. The acylation of ghrelin is performed mainly in the stomach by the intracellular ghrelin-*O*-acyltransferase, an enzyme only discovered in 2008. Acylated ghrelin, but not UnAG, can bind the growth hormone secretagogue receptor-1a (GHSR-1a), widely expressed in hypothalamic and pituitary regions, mediating GH release, able to enhance appetite and increase adipose tissue deposits. In a large variety of high-affinity binding sites, UnAG and acylated ghrelin act together, modulating the release of downstream mediators. In addition, novel receptors for UnAG in brain, gut, fat and muscle have been identified, which might promote cell proliferation, differentiation and survival.⁷⁰

Ghrelin's physiological functions include appetite modulation, enhancement of GH release, energy homeostasis, glucose homeostasis, anti-inflammatory action, effects on cardiovascular system, regulation of gastrointestinal tract motility, sexual function, and osteogenesis. GHSR is widely expressed in brain regions controlling body weight, emotional responses, memory, and learning.

The circulating level of ghrelin was reported to be increased in patients with muscle wasting and cancer cachexia. Ghrelin counteracted tumor-induced anorexia in animal systems, and its administration increased food intake and body weight gain.^{71–73}

The main molecular mechanisms regulating the cancer anorexia-cachexia syndrome include alterations in brain neurochemistry. In particular, the hypothalamic melanocortin system appears not to respond appropriately to peripheral inputs, and its activity is diverted largely towards the activation of catabolic stimuli promoting metabolism of carbohydrates, lipids, and proteins in peripheral tissues leading to insulin resistance, increased lipolysis, and accelerated muscle proteolysis.⁷⁴ Proinflammatory cytokines (TNF- α and IL-1 β) and hypothalamic serotonergic neurons have been implicated in the dysfunction of the hypothalamic melanocortin system.³³ Two peptide systems in particular appear to be strongly influential in the control of feeding behavior: these are the orexigenic neuropeptide Y (NPY), and the anorexigenic POMC (pro-opiomelanocortin) systems.⁷⁵ Many of these mediators exert their effects through changes in the NPY/POMC systems. Both originate in the hypothalamic arcuate nucleus (ARC) and extend projections widely over the brain.⁷⁵ The role of cytokines in cancer anorexia may depend on both the NPY and POMC systems. Hypothalamic IL-1 mRNA has been shown to be significantly increased in methylcholanthrene-induced sarcoma bearing rats. Levels of IL-1 in cerebrospinal fluid of these rats are also increased.^{76, 77} Injection of IL-1 β into the hypothalamus causes significant change in gene expression in skeletal muscle within hours including upregulation of the ubiquitin proteasome pathway. This clearly demonstrates the potential for neural control of muscle protein synthesis and degradation.⁷⁸ It has not yet been fully explored in patients with cancer cachexia.⁵⁴

Alimentary tract dysfunction

Abnormalities in perception of taste and smell have been described in cancer patients. Tumors of the

mouth, oropharynx, esophagus, stomach, pancreas, liver, and peritoneum may compromise oral intake by mechanical interference. Intestinal obstruction is a common complication of cancer. Malabsorption often occurs secondary to enzymatic insufficiency in pancreas carcinoma or secondary to lymphoma of the intestine or mesentery.^{79, 80}

Delayed gastric emptying and slowing of peristalsis are pathogenic mechanisms that may contribute to early satiety.⁸¹ Early satiety is common in patients with decreased upper gastrointestinal motility.^{82, 83}

Biochemical and metabolic derangement

High rates of glucose utilization with production of lactic acid are characteristic features of the neoplastic cell (Warburg effect). Glucose utilization by transplanted tumors in mice was second only to the brain.⁸⁴ Hexokinase, which catalyzes the first step of the glycolytic pathway, often highly overexpressed in tumor cells, is a major player in this process. Binding of tumor hexokinase to the outer mitochondrial membrane provides the enzyme with preferential access to ATP generated in the mitochondrion and increases the activity and stability of the enzyme.⁸⁵ The end product of the hexokinase reaction, glucose-6-phosphate, serves not only as a source of ATP via glycolysis but is also a key intermediate in the metabolic processes essential for cell growth and proliferation. Lactic acid produced via glucose metabolism may be utilized by other tissues for energy purposes or may be transported to the liver for resynthesis to glucose. The cyclic metabolic pathway, in which glucose is converted to lactic acid by glycolysis in tumor tissue and then reconverted to glucose in the liver, is referred to as the Cori cycle. Conversion of glucose to lactate in cancer cells yields two ATPs, whereas lactate to glucose conversion in the liver requires six ATPs. Thus, a systemic energy losing or futile substrate cycle, involving this interplay of tumor glycolysis and host gluconeogenesis, may be an important cause of cancer cachexia.⁸⁶ Assuming that all lactate produced is recycled to glucose, the cancer cell acts as an energy parasite. It may be calculated, however, that if 85% of lactate passes through the gluconeogenic pathway and 15% is oxidized, the host's handling of tumor-produced lactate would be energetically neutral. It has been suggested that the increase in the Cori cycle is insignificant in terms of energy expenditure and that increased glucose catabolism itself is responsible for weight loss and development of cachexia.⁸⁷

Another mechanism of futile cycle is activation of the uncoupling proteins (UCPs) in brown adipose tissues (UCP1) and in skeletal muscles (UCP2 and 3).^{88–91} UCPs-3 mRNA levels were higher in the muscle of six patients with gastrointestinal adenocarcinomas with major weight loss than in six similar patients with stable weight and six controls. UCPs-2 mRNA levels did not differ significantly between groups.⁹⁰ Elevations in muscle UCPs-3 activity may enhance energy expenditure and this in turn could contribute to tissue catabolism. Other mechanisms of muscle wasting such as mitochondrial dysfunction and activation of PPAR γ coactivator-1 may also exist.^{92–95}

Recently, extensive re-examination of Warburg effects has been made.⁹⁶ Unlike most normal cells, many cancer cells derive a substantial amount of their energy from aerobic glycolysis converting most incoming glucose to lactate even in the presence of oxygen. Although ATP production by glycolysis can be more rapid than by oxidative phosphorylation, it is far less efficient in terms of ATP generated per unit of glucose consumed. This shift therefore demands that tumor cells implement an abnormally high rate of glucose uptake to meet their needs for energy, biosynthesis, and redox. Aerobic glycolysis putatively provides a biosynthetic advantage for tumor cells in that a high flux of substrate through glycolysis allows for effective shunting of carbon to key subsidiary biosynthetic pathways. A key molecule produced as a result of altered cancer metabolism is reduced nicotinamide adenine dinucleotide phosphate (NADPH), which functions as a cofactor and provides reducing power in many enzymatic reactions crucial for

macromolecular biosynthesis. NADPH is also an antioxidant and forms part of the defense against reactive oxygen species (ROS) that are produced during rapid proliferation. High levels of ROS can damage macromolecules, inducing senescence and apoptosis. Glutathione (GSH) and thioredoxin (TRX), antioxidant molecules, are maintained in reduced form by NADPH. In addition to the genetic changes that alter tumor cell metabolism, factors of the microenvironment such as hypoxia, pH, and low glucose concentrations play a major role in determining the metabolic phenotype of tumor cells. It has been shown that cancer cells secrete hydrogen peroxide. As a consequence, oxidative stress in cancer-associated fibroblasts drives autophagy, mitophagy, and aerobic glycolysis. This “parasitic” metabolic coupling converts the stroma into a “factory” for the local production of recycled and high-energy nutrients (such as L-lactate) to fuel oxidative mitochondrial metabolism in cancer cells. A loss of stromal Cavolin-1 (Cav-1) is identified as a new biomarker for hypoxia, oxidative stress, autophagy, and the “reverse Warburg effect”, leading to early tumor recurrence and poor clinical outcome.^{97, 98}

Reactive oxygen species (ROS) and oxidative stress

Metabolic reprogramming of distant adipose tissues and muscle occurs in cancer cachexia. Fatty acids are taken up and catabolized by cancer cells to generate ATP and promote tumor growth. Cancer cells frequently invade adipose tissue, inducing the release of free fatty acids from adjacent adipocytes and this release promotes tumor growth.

High levels of free fatty acids in the plasma are a key feature of cancer cachexia and advanced cancer. Fatty acids are the preferred plasma catabolites utilized in cancer cachexia, as measured by comparing plasma disappearance of 14C-labeled palmitate and glucose and measuring generation of 14C-labeled CO₂. Free fatty acids are catabolized to generate acetyl-CoA, ketone bodies, and ATP in tumors. In sum, the catabolic effects exerted by cancer cells on remote adipocytes and myocytes are similar to those that cancer cells exert on fibroblasts adjacent to cancer cells or cancer-associated fibroblasts.

Adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL) are key enzymes in the generation of free fatty acids by adipocytes and ultimately in ketogenesis. High ATGL and HSL activity is implicated in cancer cachexia with myocyte apoptosis and loss of muscle mass. Muscle wasting is induced by autophagy and lysosomal degradation in cancer cachexia. ATGL and HSL knockdown studies reveal that they mediate muscle degradation. This highlights the significant reciprocal interactions between metabolism, autophagy, and cachexia.⁹⁹

MicroRNA (miR-), Hormonal Aberration, and Tumor Parasitism, Signaling pathway

Regulation of gene expression has been linked to miR-378 in a human cachexia model.^{100, 101} Low levels of testosterone in males with advanced cancer^{102, 103} and high plasma cortisol values in patients with malignant tumors have been reported.^{104, 105} These findings may be involved in the increased protein catabolism of skeletal muscles and other organs in cachectic cancer patients.

Signaling pathways involved in cancer cachexia are shown in [Table 5](#).

Signaling pathways involved in muscle atrophy are interdependent. Activation or inhibition of a single pathway may have a cascade of effects on muscle protein balance. No pathway is the sole regulator of the process.¹³²

Table 5 Signals involved in cancer-cachexia

--	--	--	--

Signals	Expression	Function	References
NF-κB-dependent pathway	↑	↑Apoptosis	12 15, 106107108
(IL-1/TNFα/TWEAK (and PIF)↑ → TRAF6 → NF-κB/JNK/p38/ERK → Caspases → MyoD mRNA) (also TWEAK → NF-κB↑ → MuRF1↑ → MyHC loss)		Promotes protein degradation	109110111112113
Ubiquitin-proteasome pathway (UPP) (muscle-specific ubiquitin ligases MAFbx/atrogin-1↑ and MuRF1↑ → degradation of myofibrillar protein)	↑	Promotes degradation of myofibrillar protein	58 61 ^a 62 ^a 114 ^a 115116117118119 ^a 120 ^a 121122123
Myostatin/activin pathway (myostatin/ActRIIB → SMAD2,3 → UPP, → AKT, → MAFbx and MuRF1)	↑	Negatively regulate myofibrillar protein	60 124125126
Autophagic-lysosomal pathway (FOXO3A → autophagy → cathepsin B/L)	↑	Promotes protein degradation	61 62, 127
IL-6, JAK/STAT pathway (IL-6 → gp130 → JAK → STAT3 → pSTAT3)	↑	Promotes protein degradation (myofibrillar and sarcomeric protein)	17181920212223242526272829303132
Dystrophin glycoprotein complex (DGC) (Defects in myofiber outer membranes and alterations in extracellular matrix proteins → MAFbx/atrogin-1↑ and MuRF1↑)	↑	Muscle membrane damage and muscle wasting	59
Calcium-dependent proteolysis system (IL-1/TNFα → p38/JAK → catepsin → calpains and caspase-3 → apoptosis)	↑	Degrading muscle protein (no precise muscle locations have been reported in cancer cachexia)	61 120, 128
IGF-1 pathway (IGF-1↓ → PI3K → AKT → mTOR → ↓protein synthesis)	↓	Promotes protein degradation and increased apoptosis	129
		Antagonize with	

		MAFbx and MuRF1	
Mitogen-activated protein kinases (MAPKs), PGC-1 α and caspase pathway (p38 MAPKs \rightarrow PGC-1 α \rightarrow ERK $\frac{1}{2}$ \rightarrow JAK \rightarrow Caspase 8)	\uparrow	Inhibits thermogenic action, inhibits skeletal muscle	94
Poly(ADP-ribose)polymerase (PARP $\uparrow \rightarrow$ apoptosis $\uparrow \rightarrow$ MyoD protein \downarrow)	\uparrow	Muscle DNA fragmentation and apoptosis as well as downregulation of MyoD	130 131 ^a

PIF, proteolysis-inducing factor; MyHC, myosin heavy chain; PGC-1 α , PPAR γ coactivator-1 α ; PPAR γ , peroxisome proliferator-activated receptor- γ ; PARP, poly(ADP-ribose)polymerase.

^a Animal data are not necessarily reproducible in patients. The references report negative clinical data.

Treatment

The definitive treatment of cancer cachexia is removal of the causative tumor. Short of achieving this goal, various measures have been undertaken with limited success.

Supportive care

Intervention from the stage of precachexia helps. Early nutritional intervention can lead to improvement in nutritional status and reduction of the inflammatory response.¹³³ Body weight stabilization during chemotherapy is associated with reduced toxicity and a longer overall survival.⁵

Exercise is effective in preventing cancer,¹³⁴ safe during active cancer treatments,¹³⁵ and healthy for cancer survivors,¹³⁶ improving bone health, muscle strength, quality of life, fatigue, psychosocial distress, depression, and self-esteem.¹³⁷ Risk of comorbidities, frequent among cancer survivors, can be significantly reduced through increased physical activity. Moreover, exercise is associated with reduced overall mortality.¹³⁸ Physical activity may attenuate the effects of cachexia by modulating muscle metabolism, insulin sensitivity, and inflammation.^{137–139} Exercise has been shown to have anti-inflammatory properties, through the upregulation of the anti-inflammatory cytokines both in skeletal muscle and adipose tissue. Exercise should be recommended at the earliest phase of cancer treatment¹³⁹ often with the helpful presence of a caregiver or exercise professional during exercise sessions.

Pharmacologic management

Olanzapine is a selective monoaminergic antagonist with a strong affinity for serotonin and dopamine receptors. Low doses of Olanzapine have been well tolerated with promising clinical activity on weight, nutrition, and function in cancer cachexia.¹⁴⁰

Ghrelin and its analogs, anamorelin, BIM-28131, BIM-28125 and RC-1291.

In 2010, long-term dosing of ghrelin was begun in 17 weight-losing cancer patients with solid gastrointestinal tumors.¹⁴¹ In a randomized study of high- or low-dose ghrelin, high-dose improved

appetite and reduced the loss of whole body fat ($P < 0.04$) and serum GH ($P < 0.05$). No adverse effects were observed. These data led investigators to test the efficacy of a number of synthetic ghrelin analogs including anamorelin, BIM-28125, BIM-28131 (RM-131), L163 255, and RC-1291.

Anamorelin (ONO-7643) (Helsinn Healthcare S.A., Switzerland) is a novel, oral, ghrelin-receptor agonist.

In a short crossover study with placebo in cachectic cancer patients, IGF-1, appetite and weight significantly increased.¹⁴²

In ROMANA 1 and 2, identically designed phase III studies, 484 and 495 patients with inoperable stage III and IV non-small cell lung cancer and cachexia with life expectancy of >4 months were randomly assigned in a 2:1 ratio to receive either anamorelin at 100 mg/day or placebo for 12 weeks. The majority of patients were receiving chemotherapy, and one-eighth were receiving radiotherapy. Cachexia was defined as more than 5% weight loss within the past 6 months or body mass index less than 20 kg/m². Both studies found that patients randomly assigned to placebo continued to lose weight and lean body mass over the 12-week study period, while those assigned to anamorelin gained lean body mass. The differences between the two groups for weight were highly significant at weeks 3, 6, 9, and 12, plus 1.10 and 0.75 kg medians in lean body mass respectively versus minus 0.44 and 0.96 kg in the placebo groups. Body weights increased by an average of 2.2 and 0.95 kg on anamorelin versus 0.14 and 0.57 kg on placebo. Both groups declined in hand grip strength over the course of the study. Quality of life as assessed by the Functional Assessment of Anorexia/Cachexia Therapy (FAACT) also showed a significant difference favoring anamorelin. The most common adverse events were manageable nausea and hyperglycemia (expected as a part of the mechanism of action).¹⁴³

BIM-28125 is another synthetic ghrelin analog with similar actions in experimental models of cancer cachexia.¹⁴⁴ Clinical trials have not yet been reported. Effects of ghrelin and its analogs on cancer cachexia have recently been reviewed.^{145, 146}

Anabolic androgenic steroids have been used by athletes to promote muscle growth and strength. Randomized clinical trials were carried out to test whether supplements of nandrolone decanoate influenced the outcome of chemotherapy in patients with non-small cell lung cancer.^{147, 148} Although the treated group experienced less weight loss, response to chemotherapy and survival were comparable. In a three-arm phase III randomized clinical trial for the treatment of cancer anorexia/cachexia, fluoxymesterone, an anabolic steroid, showed significantly less appetite enhancement and did not have as favorable a toxicity profile as megestrol acetate, a progestational agent, or dexamethasone, a corticosteroid.¹⁴⁹

Enobosarm (GTx-024) is an androgen receptor modulator (SARM) that has tissue-selective anabolic effects in muscle and bone. In 159 cancer patients (stratified by cancer type), once-daily oral enobosarm or placebo was administered for up to 113 days. Significant increases in total lean body mass occurred. The data suggest that enobosarm might lead to improvements in lean body mass, without the toxic effects associated with androgens and progestational agents.¹⁵⁰

Megestrol acetate and medroxyprogesterone acetate

Significant reduction in serum levels of IL-1a and b, IL-2, IL-6, and TNF- α were observed in cancer patients treated with megestrol acetate which may bear on the mechanism of improved appetite and body weight gain.¹⁵¹

In a review of 15 randomized clinical trials including more than 2000 patients, there was a statistically significant advantage for high-dose progestins in regard to improved appetite and gain of body weight.¹⁵² Weight gain produced by megestrol acetate was found to be mainly from increased body fat rather than accretion of lean tissue.^{153, 154} It has been argued that the gain of adipose tissue as opposed to lean tissue during treatment with megestrol acetate, although suboptimal, should not be disparaged because depletion of body fat is generally an undesirable outcome of cancer.

Megestrol acetate is contraindicated in pediatric cachectic patients, as a significant proportion of such patients developed adrenal insufficiency.¹⁵⁵ Megestrol acetate should also be used with caution in geriatric cancer patients because they are prone to develop deep vein thrombosis because of immobility and increases in serum fibrinogen levels.

Medroxyprogesterone acetate is a more widely used synthetic progestin. Medroxyprogesterone reduced production of cytokines and serotonin.¹⁵⁶ Two placebo-controlled randomized studies have been reported in which increased appetite was described.^{157, 158} Despite increased appetite, no weight gain was produced in either study.

In advanced cancer patients with delayed gastric emptying or gastroparesis, oral administration of a prokinetic agent, metoclopramide, 10 mg orally four times daily before meals and at bedtime, was shown to be effective in stimulating appetite and relieving other dyspeptic symptoms associated with anorexia.^{159, 160} A controlled release preparation appears to be more effective than immediate release drug due to its control of nausea associated with advanced cancer even without demonstrated abnormalities of the GI tract.¹⁶¹

Dronabinol (delta 9-tetrahydrocannabinol, THC) was studied in patients with cancer.^{162, 163} All patients reported improvements in appetite but all groups nonetheless continued to lose weight. Recently, a randomized study was carried out to compare dronabinol, megestrol acetate, and the combination for palliating cancer-associated anorexia.¹⁶⁴ Megestrol acetate provided superior anorexia palliation among advanced cancer patients, and compared with dronabinol alone. The combination of megestrol and dronabinol did not appear to confer additional benefit.

Marijuana powder and smoke contains many different cannabinoids and reportedly is superior to synthetic dronabinol. Scientific trials have not been done, but with widespread legalization are now possible.

Cancer cachexia is different from simple starvation, in that nutritional support, either enteral or parenteral, has only limited value.

No significant benefit of TPN has been demonstrated in patients undergoing chemotherapy and/or radiotherapy in terms of treatment tolerance, response to chemotherapy or radiotherapy, or in survival.^{165, 166} Furthermore, other authors have reported that TPN is detrimental. Controversies related to TPN in the treatment of cancer cachexia have been reviewed.^{167–169}

From the above discussions, one can speculate that one single therapy may not be successful in the treatment of cachexia. Treatment involving different combinations may be more likely to be useful.¹⁷⁰

Future directions and summary

It has been realized that diagnosis of cancer cachexia was recognized often too late to reverse by nutritional supplementation. This made early recognition and intervention of cachexia important. Now that it appears nutritional intervention at precachexia is effective, the concept of precachexia is more

meaningful. With recognition of precachexia together with the advent of a variety of anticachexia agents, we are at the stage of accomplishing an effective treatment of cachexia.

Physical exercise should be a part of any anticachexia protocol.

Several potentially promising leads beg for well-designed clinical trials. Drugs in need of more clinical studies include GH/insulin,¹⁷¹ GHRP-2 (growth hormone releasing peptide 2),^{172, 173} and growth hormone releasing hormone (GHRH) expression plasmids.¹⁷⁴

The most promising anticachexia agents appear to be ghrelin analogs, such as anamorelin.¹⁴³ Additional anticachectic agents potentially useful for supplementation include medroxyprogesterone acetate,^{156–158} celecoxib,^{175, 176} antioxidants,^{177, 178} olanzapine,¹⁴⁰ native marijuana, and β -hydroxy- β -methylbutylate/L-arginine/L-glutamine.^{179–183}

Investigational drugs of potential benefit include ghrelin mimetics such as BIM-28131,¹⁴⁴ BIM-28125,¹⁴⁴ L163 255,¹⁸⁴ and RC-1291¹⁸⁵; androgen receptor modulator enobosarm (GTx-024)¹⁵⁰; anabolic catabolic transforming agents MT-102 and espidrol^{186, 187}; anti-IL-1 α antibody MABp1^{188, 189}; anti IL-1 receptor antagonist IP-1510¹⁸⁹; anti-IL-6 antibody ALD518^{189–191}; myostatin inhibitors such as Bimagrumab (BYM338)¹⁸⁹ and REGN1033,¹⁸⁹ as well as OHR/AVR118, a broad-spectrum peptide-nucleic acid immunomodulator.¹⁸⁹

Cachexia has been the major underestimated and unmet medical need. Development of new definition of cancer cachexia and start of anticachexia treatment from precachexia onward should revolutionize treatment of this complex disease with major benefit to all types of cancer therapy.

Chapter 125

Antiemetic therapy

Patrick M. Forde, MD, MBBCh ■ David S. Ettinger, MD, FACP, FCCP

Overview

Dramatic progress has been made in the prevention and treatment of chemotherapy-induced emesis, especially since the introduction of the 5-HT₃ receptor antagonists in the early 1990s and the 2003 introduction of the NK-1 receptor antagonist, aprepitant. Recent surveys indicate the need for heightened awareness of the frequency and severity of acute and, especially, delayed nausea and vomiting from chemotherapy. Fortunately, new agents have been added to the antiemetic arsenal to further enhance the efficacy of antiemetic prophylaxis. Complementary therapies such as acupuncture and mind–body interventions appear promising in controlling nausea, and are being explored further. Appropriate implementation of guidelines for prophylaxis based on the specific chemotherapy agents used will ensure that fewer patients experience these most distressing of side effects.

Overview

Chemotherapy-induced nausea and vomiting (CINV) remains a significant problem for many cancer patients despite recent advances in pharmacologic therapy.¹ It may have a dramatic impact on a patient's quality of life, in addition to physical consequences, including dehydration, nutritional compromise, and metabolic disturbances.² Despite the publication of guidelines for preventive antiemetic therapy, some patients continue to receive suboptimal prophylaxis against CINV. Nausea and vomiting occurring after chemotherapy may be more difficult to manage than if the symptoms had been prevented with appropriate pharmacologic intervention. In addition, patients may develop a psychological component to their nausea and vomiting as a result of inadequate management in the past. Thus, optimal control of CINV is a crucial aspect of symptom management among cancer patients.

Historically, approximately 70–80% of all cancer patients receiving chemotherapy experienced emesis,³ and, fortunately, there have been dramatic improvements since the introduction of effective antiemetic therapy.¹ Studies over the past 25 years have attempted to quantify the impact of chemotherapy side effects on cancer patients. Repeatedly, nausea and vomiting are mentioned as the “major physical,” and the “most troublesome and unpleasant” side effects associated with chemotherapy.^{4,5} Although there have been recent advances in pharmacologic prevention of CINV, a 1997 study by de Boer-Dennert and colleagues revealed that nausea and vomiting ranked as the first and third most distressing side effects of chemotherapy, despite a decrease in the overall incidence and severity with the introduction of 5-hydroxytryptamine 3 (5-HT₃) antagonists.⁶ Grunberg and colleagues surveyed patients, medical oncologists, and oncology nurses in 2001–2002 to assess the frequency and provider perception of CINV.¹ Although improvements in the prevention of acute nausea and vomiting were seen (acute nausea in approximately 35% and acute emesis in 13%), delayed symptoms were seen more frequently (50–60% with nausea and 30–50% with emesis, depending on the chemotherapy used). Strikingly, more than 75%

of physicians and nurses underestimated the occurrence of delayed nausea and vomiting. Progress in relieving the symptoms of CINV will only come with greater awareness of the problem and more aggressive use of current medications.

This chapter highlights the pathophysiology of CINV, the emetogenic potential of common chemotherapeutics, classes of antiemetic therapy including complementary therapies, and guidelines for prevention and acute management of CINV.

Pathophysiology of nausea and vomiting

Vomiting is controlled by the central nervous system via a complex pathway of varied afferent inputs and neurotransmitters. In the 1950s, studies by Borison and Wang identified two areas of the brainstem involved in nausea and vomiting: the chemoreceptor trigger zone (CTZ) and the emetic center.⁷ The CTZ is located in the area postrema in the floor of the fourth ventricle. Because it lies outside the blood–brain barrier, the CTZ is susceptible to emetogenic stimuli from the bloodstream, such as chemotherapeutic drugs or, more likely, their metabolites.⁸ Muscarinic, dopamine D₂, serotonin (5-HT₃), neurokinin 1 (NK-1) and histamine H₁ receptors have been identified in the CTZ. Impulses from the CTZ are then transmitted to the emetic center. In addition to those from the CTZ to the emetic center, afferent pathways from the gastrointestinal tract and pharynx via the vagus and splanchnic nerves are coordinated in the emetic center.⁹ Inputs from the cerebral cortex may also be involved, especially in anticipatory emesis. The emetic center receives afferent impulses and coordinates the efferent activities of the salivation center, abdominal muscles, respiratory center, and autonomic nerves that result in vomiting. The emetic center, composed of these indistinct receptor and effector nuclei, is located in the nucleus tractus solitarius of the brainstem.⁸

The most critical neurotransmitters involved in these afferent and efferent pathways are serotonin (5-HT₃), dopamine, and substance P. Others include acetylcholine, corticosteroid, histamine, cannabinoid, opiate, and gamma-aminobutyric acid (GABA).¹⁰ Blockade of these neurotransmitters and their receptors forms the basis of action of various antiemetic drugs. The most significant advance in antiemetic therapy came in the early 1990s when the 5-HT₃ receptor antagonists became available.⁶ Substance P, which binds to the NK-1 receptor, is an emerging target in antiemetic therapy,¹¹ and one Food and Drug Administration (FDA)-approved NK-1 receptor antagonist, aprepitant, has clinical utility and is in widespread use.^{12–14} Drugs such as prochlorperazine, haloperidol, and metoclopramide exert their antiemetic effects by inhibiting dopamine. However, it is not fully known how and where along these pathways chemotherapy and its metabolites have their emetic effects. Metabolites may stimulate the CTZ directly. Serotonin and other neurotransmitters may be released from intestinal cells damaged by chemotherapy. Sensory neurons release substance P, and numerous NK-1 receptors have been identified in both the CTZ and the nucleus tractus solitarius. Despite increasing knowledge of the central nervous system and pathways involved in control of vomiting, no single common pathway has been discovered, and it is unlikely that any single agent will be able to provide complete antiemetic protection from chemotherapy.

Types of nausea and vomiting

Three distinct types of chemotherapy-induced emesis have been identified: acute, delayed, and anticipatory.

Acute emesis is defined as nausea and vomiting within 24 h of chemotherapy. It has its onset within 1–2 h of chemotherapy and peaks in the first 4–6 h without adequate prophylaxis.

Delayed emesis refers to symptoms that start more than 24 h after chemotherapy. It typically peaks at 48–72 h and may last for 6–7 days. Although delayed emesis may be less frequent and severe than acute emesis, it is less well controlled than acute emesis. Cisplatin is most frequently associated with delayed emesis, and it is also seen with carboplatin, cyclophosphamide, and anthracyclines.

Anticipatory emesis is seen in patients who have previously experienced significant nausea and vomiting following chemotherapy. In these patients, symptoms develop as a conditioned response before the chemotherapy is administered. It may be triggered by sights and activities associated with the chemotherapy (e.g., driving to the treatment center). As anticipatory emesis is a conditioned reflex, it is predominantly mediated by the cerebral cortex. As control of CINV has improved, the incidence of anticipatory emesis has declined.¹⁵

Breakthrough emesis refers to symptoms that occur despite prophylactic treatment and which require rescue therapy. This is a difficult clinical problem to manage and there is little clinical trial data to guide antiemetic selection in this setting.^{16, 17} Several agents are used empirically, including haloperidol, olanzapine, and lorazepam.^{16, 17}

Refractory emesis refers to symptoms that occur during a chemotherapy cycle after prophylactic treatment and/or rescue therapy has failed in earlier cycles of chemotherapy.¹⁷

In addition to chemotherapy-induced emesis, other potential causes of nausea and vomiting in cancer patients include partial or complete bowel obstruction, brain metastases, uremia, electrolyte disturbances (i.e., hyperglycemia, hypercalcemia, hyponatremia), and gastroparesis. Other medications commonly prescribed in cancer patients, such as opiates, may cause emesis as well.

Emetogenic chemotherapy

The severity and frequency of CINV are affected by variables of both the patient and the chemotherapy. Patient-related factors predicting a higher incidence of CINV include a history of chemotherapy, a history of CINV, female sex, younger age, and a history of motion sickness, anxiety, and no/minimal history of alcohol use. Chemotherapy-related factors include the route and rate of administration and drug dosage. The most predictive factor is the specific chemotherapy agent used.¹⁸

There is no universally accepted classification system of chemotherapy agents by emetogenic potential ([Table 1](#)). The most widely accepted, devised by Hesketh and colleagues, divides chemotherapy into five levels of emetogenicity based on the percentage of patients who experience nausea and vomiting following each without any antiemetic prophylaxis. Level 1 drugs result in emesis in less than 10% without antiemetic therapy; level 2, 10–30%; level 3, 30–60%; level 4, 60–90%; and level 5, more than 90% of patients experiencing emesis without prophylaxis.¹⁹ A proposed modification to this classification would classify chemotherapy into four risk categories²⁰:

High risk (level 5): more than 90%

Moderate risk (levels 3 and 4): 30–90%

Low risk (level 2): 10–30%

Minimal risk (level 1): <10%

Table 1 Emetogenic potential of single antineoplastic agents

Level	Agent
High risk, level 5 (>90% predicted frequency of emesis without prophylaxis)	Carmustine >250 mg/m ² Cisplatin ≥50 mg/m ² Cyclophosphamide >1500 mg/m ²
	Dacarbazine
	Mechlorethamine
	Streptozocin
Moderate risk, level 4 (60–90% predicted frequency of emesis without prophylaxis)	Amifostine >500 mg/m ² Busulfan >4 mg/dCarboplatinCisplatin <50 mg/m ²
	Cyclophosphamide >750 mg/m ² and ≤1500 mg/m ²
	Cytarabine >1 g/m ²
	Dactinomycin
	Doxorubicin >60 mg/m ²
	Epirubicin >90 mg/m ²
	Melphalan >50 mg/m ²
	Methotrexate >1000 mg/m ²
	Procarbazine (oral dosing)
Moderate risk, level 3 (30–60% predicted frequency of emesis without prophylaxis)	Amifostine >300 mg/m ² and ≤500 mg/m ² Arsenic trioxideBendamustineCyclophosphamide ≤750 mg/m ²
	Cyclophosphamide (oral dosing)
	Doxorubicin 20 and <60 mg/m ²
	Epirubicin ≤90 mg/m ²
	Ifosfamide
	Interleukin-2 >12–15 million units/m ²
	Irinotecan
	Lomustine
	Methotrexate 250–1000 mg/m ²
	Mitoxantrone <15 mg/m ²
Low risk, level 2 (10–30% predicted frequency of emesis without prophylaxis)	Oxaliplatin >75 mg/m ²
	Amifostine ≤300 mg/m ² BexaroteneCytarabine 100–200 mg/m ²
	Capecitabine
	Docetaxel
	Doxorubicin (liposomal formulation)
	Etoposide

	5-Fluorouracil <1000 mg/m ²
	Gemcitabine
	Methotrexate >50 and <250 mg/m ²
	Mitomycin
	Mitoxantrone
	Paclitaxel
	Pemetrexed
	Temozolomide
	Topotecan
Minimal risk, level 1 (<10% predicted frequency of emesis without prophylaxis)	AlemtuzumabAsparaginaseBevacizumab
	Alpha Interferon
	Bleomycin
	Bortezomib
	Cetuximab
	Chlorambucil (oral dosing)
	Cladribine
	Dasatinib
	Dexrazoxane
	Denileukin diftitox
	Erlotinib
	Fludarabine
	Gefitinib
	Gemtuzumab ozogamicin
	Hydroxyurea
	Imatinib mesylate
	Melphalan (low dose, oral dosing)
	Methotrexate ≤50 mg/m ²
	Pentostatin
	Rituximab
	Sorafenib
	Sunitinib
	Thioguanine (oral dosing)
	Trastuzumab
	Valrubicin
	Vinblastine

	Vincristine
	Vinorelbine

It should be noted that these classification systems were developed with a focus on acute emesis. It is clear from recent data that the frequency and severity of delayed emesis are often underestimated and remain a significant problem for many patients.¹ Adequate antiemetic prophylaxis is required for the duration of days that symptoms are anticipated.

Classes of antiemetics

Our knowledge of the known neurotransmitters involved in the central nervous system pathways that regulate the vomiting response has provided targets for antiemetic therapy ([Table 2](#)). In return, successful clinical application of these agents has confirmed the importance of these neurotransmitters and receptors in the vomiting pathway. Neuroreceptors involved in the control of emesis include muscarinic (M1, receptor site for acetylcholine), dopamine (D2, receptor site for dopamine), histamine (H1, receptor site for histamine), 5-HT3 (receptor site for serotonin), NK-1 (receptor site for substance P), and GABA (receptor site for benzodiazepines).^{21, 22} The most effective and most commonly used antiemetics are the 5-HT3 receptor antagonists, the dopamine antagonists, and corticosteroids. A newer class of agents, the NK-1 receptor antagonists, further expands the repertoire of antiemetic agents.

Table 2 Classes and recommended doses of selected antiemetics

Agent	Class	Route	Dose
Ondansetron	5-HT3 receptor antagonist	IV	8–12 mg
—	—	PO	12–24 mg
Granisetron	5-HT3 receptor antagonist	IV	1 mg or 0.01 mg/kg
—	—	PO	2 mg
Dolasetron	5-HT3 receptor antagonist	IV	100 mg or 1.8 mg/kg
—	—	PO	100 mg
Palonosetron	5-HT3 receptor antagonist	IV	0.25 mg
Aprepitant	NK-1 receptor antagonist	PO	125 mg day 1
—	—	—	80 mg day 2, 3
Dexamethasone	Steroid	IV	8–20 mg
—	—	PO	8–20 mg
Prochlorperazine	Dopamine receptor antagonist	IV	10 mg
—	—	PO	10 mg
—	—	Rectal suppository	25 mg
Metoclopramide	Dopamine receptor antagonist	IV	1–2 mg/kg
—	—	PO	20–40 mg
Haloperidol	Dopamine receptor antagonist	IV	1–3 mg
—	—	PO	1–2 mg
Dronabinol	Cannabinoid	PO	5–10 mg

Abbreviations: IV, intravenous; 5-HT3, 5-hydroxytryptamine 3; NK, neurokinin; PO, orally.

Serotonin/5-HT3 receptor antagonists

Since the early 1990s, four 5-HT3 receptor antagonists have been approved in the United States: ondansetron, granisetron, dolasetron, and, most recently, palonosetron. These agents revolutionized the antiemetic prophylaxis of highly and moderately emetogenic chemotherapy. Studies of 5-HT3 receptor antagonists used alone demonstrated superior efficacy compared with high-dose metoclopramide alone²³ and equivalence to the combination of high-dose metoclopramide and dexamethasone, the previous standard of care for these patients.²⁴ However, the combination of 5-HT3 receptor antagonist and dexamethasone was the most effective combination tested.²⁵ The 5-HT3 antagonists remain the cornerstone of prophylaxis for both highly and moderately emetogenic chemotherapy.

Before 2003, there were three 5-HT3 receptor antagonists approved by the FDA: ondansetron, granisetron, and dolasetron. Numerous subsequent clinical trials demonstrated the clinical equivalence of these three agents, despite differences seen in preclinical models.^{26–31} A single-dose prechemotherapy was shown to be as effective as repeat dosing.^{32–34} In addition, there was no significant difference whether the agent was given orally or intravenously.^{35, 36}

In July 2003, a new 5-HT3 receptor antagonist, palonosetron, was approved by the FDA for antiemetic

prophylaxis. Palonosetron may have advantages over the other serotonin antagonists because of its higher binding affinity to the 5-HT₃ receptor and its longer half-life. Two phase 3 randomized clinical trials demonstrated the superiority of palonosetron compared with ondansetron and dolasetron, particularly in preventing delayed nausea and vomiting.^{37, 38} In the first, 592 patients were randomized to receive palonosetron at either 0.25 or 0.75 mg or dolasetron at 100 mg 30 min prior to moderately emetogenic chemotherapy. Less than 5% of patients received concomitant corticosteroids. A statistically significant difference was observed between the palonosetron 0.25 mg and dolasetron arms in complete response (CR), defined as absence of emesis and no rescue medication in the first 24 h). CR rates were 63% in the palonosetron 0.25 mg arm versus 52.9% in the dolasetron arm ($p = 0.049$) and 57% for the palonosetron 0.75 mg arm ($p = 0.412$). For complete control (defined as no emesis, no need for rescue medication, and no symptoms other than mild nausea) of delayed nausea and vomiting (24–120 h), palonosetron 0.25 and 0.75 mg demonstrated statistically significant improvements compared with dolasetron 100 mg (48.1% for palonosetron 0.25 mg compared with 36.1% for dolasetron, $p = 0.027$; 51.9% for palonosetron 0.75 mg, $p = 0.016$). There was no difference among the groups in observed adverse effects, including headache, constipation, and fatigue.³⁷ In the second study, palonosetron was compared with ondansetron 32 mg. Five hundred and seventy patients receiving moderately emetogenic chemotherapy were randomized to one of two doses of palonosetron (0.25 or 0.75 mg) or ondansetron 32 mg on day 1 of chemotherapy. No patient received corticosteroids. CR rates were superior for the palonosetron 0.25 mg arm compared with the ondansetron group in prevention of both acute (81% vs 68.6%, $p = 0.009$) and delayed (74.1% vs 55.1%, $p < 0.001$) symptoms. Although palonosetron 0.75 mg demonstrated numeric improvement over ondansetron, the results were not statistically significant. Side effects were similar in all groups and included headache, diarrhea, constipation, and fatigue.³⁸ While palonosetron might be superior to other 5-HT₃ agents, particularly in the prevention of delayed symptoms, further studies are needed to evaluate this. All of the 5-HT₃ antagonists are well tolerated; the most common adverse effect is headache, occurring in 15–20% of patients. Less common side effects include constipation and dizziness.

More recently, granisetron has been incorporated in a transdermal system (*Sancuso*) for the prevention of CINV. In a phase 3 study, the transdermal granisetron patch was compared to oral granisetron in the management of CINV. The patch formulation contained 34.3 mg of granisetron with the active ingredient being released slowly over 7 days. In a multicenter study involving 641 patients receiving highly or moderately emetogenic chemotherapy, the granisetron patch was not inferior to repeat doses of oral granisetron.³⁹

Dopamine receptor antagonists

Three classes of dopamine receptor antagonists are effective in the prevention and treatment of nausea and vomiting: phenothiazines, butyrophenones, and benzamides. In the 1960s, the phenothiazines were the first drugs proved to have efficacy in the prevention of CINV. *Prochlorperazine* is the most commonly used in this class and has efficacy in all classes except the most highly emetogenic chemotherapy.⁴⁰ Extrapyramidal effects, including dystonia, may be seen. These are treated with diphenhydramine and cessation of the drug. The butyrophenones, including *haloperidol*, are less frequently used for CINV and have adverse effects similar to those of the phenothiazines. They may be effective in the treatment of breakthrough nausea and vomiting.

Of the benzamides, *metoclopramide* is the best studied and most widely used in CINV. It blocks central and peripheral dopamine (D₂) receptors at low doses and exhibits weak 5-HT₃ inhibition at high doses. In addition, it speeds gastric emptying and increases sphincter tone at the gastroesophageal junction. Prior

to the introduction of the 5-HT₃ antagonists, a combination of high-dose intravenous metoclopramide and dexamethasone was the most effective antiemetic prophylaxis for highly emetogenic chemotherapy.⁴¹ Because metoclopramide crosses the blood–brain barrier, side effects, including dystonia and tardive dyskinesia, may be seen, particularly at high doses and in aged patients. Diphenhydramine was commonly given as part of the combination regimen to prevent these adverse effects. This regimen has been replaced by a combination containing a 5-HT₃ receptor antagonist because of its improved efficacy and safety profile.^{23–25}

Corticosteroids

Corticosteroids, most commonly *dexamethasone*, are effective in preventing nausea and vomiting when used alone or in combination for all emetogenic classes of chemotherapy. For moderately to highly emetogenic chemotherapy, dexamethasone plus a 5-HT₃ receptor antagonist +/- an NK-1 receptor antagonist is used. A meta-analysis of 32 randomized clinical trials including 5613 patients from 1984 to 1998 demonstrated the efficacy of dexamethasone in both moderately and highly emetogenic chemotherapy either alone or in combination with other agents.⁴² Later studies revealed the superiority of a combination of 5-HT₃ receptor antagonist and dexamethasone compared with either agent alone in highly emetogenic chemotherapy.⁴³ The site of action of corticosteroids along the vomiting reflex pathway is unknown. Side effects may include insomnia, increased energy, and mood disturbances.

NK-1 receptor antagonists

NK-1 receptors are found in the nucleus tractus solitarius and the area postrema and are activated by substance P.¹¹ Inhibitors of the NK-1 receptor have demonstrated antiemetic effects and represent a new target for antiemetic therapy. The first approved medication in this class, *aprepitant*, has been shown to prevent both acute and delayed emesis resulting from highly emetogenic chemotherapy.^{13, 14}

Following promising preliminary data, two randomized phase 3 multicenter trials demonstrated the efficacy of aprepitant for the prevention of both acute and delayed nausea and vomiting. Five hundred and twenty-three patients receiving highly emetogenic chemotherapy (cisplatin >70 mg/m²) were administered emetic prophylaxis using either aprepitant in combination with 5-HT₃ receptor antagonists and dexamethasone (aprepitant 125 mg PO, ondansetron 32 mg IV, and dexamethasone 12 mg PO on day 1, followed by aprepitant 80 mg PO and dexamethasone 8 mg PO on days 2–3 and dexamethasone 8 mg PO on day 4) or a regimen of a 5-HT₃ receptor antagonist and dexamethasone alone (ondansetron 32 mg IV plus dexamethasone 20 mg PO on day 1, followed by dexamethasone 8 mg PO twice daily on days 2–4). In the first study, the overall CR (absence of emesis and no need for rescue medication in the first 24 h) was 62.7% in the aprepitant arm versus 43.3% in the standard therapy arm ($p < 0.001$). CR rates for the aprepitant arm and the standard therapy arm, respectively, for acute (82.8% vs 68.4%, $p < 0.001$) and delayed (67.7% compared with 46.8%, $p < 0.001$) symptoms demonstrated the superiority of the aprepitant arm.¹³ The second study, which evaluated the same regimens in 521 patients receiving high-dose cisplatin chemotherapy, confirmed these results. Overall CR rates were 72.7% in the aprepitant group versus 52.3% in the standard arm ($p < 0.001$). CR rates in both acute and delayed emesis were also superior in the aprepitant arm (89.2% vs 78.1%, respectively, $p < 0.001$, and 75.4% vs 55.8%, respectively, $p < 0.001$).¹⁴ These data led to the FDA approval of aprepitant in 2003.

Fosaprepitant is a water-soluble phosphoryl prodrug for aprepitant. Fosaprepitant at a dose of 150 mg has been approved by the FDA as a parenteral alternative on day 1 in place of a 3-day, three-drug oral aprepitant regimen.⁴⁴

Aprepitant is a substrate for and moderate inducer and moderate inhibitor of the cytochrome P-450 enzyme 3A4 (CYP3A4).⁴⁵ Chemotherapy and other drugs are metabolized by this enzyme, and caution must be used when adding aprepitant in these patients. Docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vinblastine, and vincristine are metabolized by CYP3A4. Although, in clinical trials, aprepitant was given to patients receiving these agents without any alteration in dose and no observed adverse effect or decreased efficacy, caution is urged. In addition, aprepitant may interact with other, non-chemotherapy agents. It may induce metabolism of warfarin, leading to reduced levels. Aprepitant appears to increase the active levels of oral dexamethasone and methylprednisolone, and reduced dosing of prophylactic dexamethasone is recommended when used in combination with aprepitant. Other drugs with interactions include oral contraceptives, midazolam, ketoconazole, erythromycin, carbamazepine, rifampin, and phenytoin.

Netupitant is a novel NK-1 receptor antagonist which has a high binding affinity and long half-life (90 h).⁴⁶ In a recently reported phase 3 study, 1455 patients receiving moderately emetogenic chemotherapy (AC or EC) were randomized in a 1 : 1 ratio to either *NEPA*, a single fixed-dose oral combination of netupitant and palonosetron plus standard oral dexamethasone or oral palonosetron plus standard oral dexamethasone.⁴⁷ Efficacy endpoints included acute (0–24 h), delayed (25–120 h), and overall (0–120 h) CRs; CR was defined as no emesis and no requirement for rescue medication. The results of this study favored the combination of netupitant and palonosetron for all endpoints with a statistically significant 7–14% absolute increase in CR from 67–75% to 74–84% over the planned four cycles of chemotherapy. Rates of adverse events did not differ significantly between the two arms.

Other classes of antiemetics

Additional classes of antiemetic agents that may be useful in patients include the benzodiazepines, anticholinergics, and cannabinoids. The most commonly used benzodiazepines, lorazepam and alprazolam, block GABA receptors, particularly in the cerebral cortex, and have their greatest utility in the treatment of anticipatory nausea and reduction in the anxiety associated with chemotherapy.⁴⁶

The cannabinoids are likely to become an increasing focus of attention given the legalization of medical marijuana in several parts of the United States. It should be noted that while synthetic cannabinoids have some evidence to support their use for intractable nausea in general, they should be reserved for refractory cases; and further research is required before their use can be recommended on a general basis.^{48, 49}

Olanzapine, a thienobenzodiazepine, has been found to be effective in preventing acute and delayed emesis.^{17, 50} It is included in the NCCN guidelines to treat both highly emetogenic and moderately emetogenic chemotherapy-induced emesis.¹⁷

Anticholinergics such as promethazine or diphenhydramine and, less frequently, transdermal scopolamine may be used for treatment of breakthrough CINV. There are fewer randomized clinical trial data to recommend the use of cannabinoids such as marijuana or its synthetic versions, nabilone and dronabinol,⁴⁶ although there is anecdotal evidence to support their use in patients who do not respond to conventional antiemetics.

Complementary and alternative medicine (CAM) therapies

The past decade has witnessed a great interest in complementary and alternative medicine (CAM) therapies, particularly among cancer patients. Various CAM therapies such as acupuncture, hypnosis,

massage, and music and herbal supplements such as ginger have been tried to control nausea. Of these, acupuncture and certain mind–body therapies appear promising,⁴⁷ but further research is needed before they can be recommended in routine clinical practice.

Acupuncture has been traditionally used in China for symptom management of various conditions, including nausea. A recent meta-analysis involving 11 randomized trials ($N = 1247$), evaluated the effect of acupuncture in controlling CINV among patients who received moderate to high emetogenic chemotherapy.⁴⁸ The study found that patients receiving acupuncture had lower acute vomiting than the control group (22% vs 31%, $p = 0.04$). Nonetheless, there was no benefit for delayed CINV. It should be noted that all these studies were done before aprepitant was approved, and thus utility of acupuncture in the current era is not well established.

Mind–body therapies such as *hypnosis*, *guided imagery*, and *progressive muscle relaxation therapy* (PMRT) have been reported to significantly reduce CINV.^{49–52} In a randomized clinical trial in Hong Kong, 71 breast cancer patients receiving antiemetic therapy with metoclopramide and dexamethasone were randomized to progressive muscle relaxation training and imagery (1 h before chemotherapy and then daily for 5 days), versus no intervention. Patients in the intervention arm had decreased duration of CINV ($p = 0.05$) and lower frequency of CINV ($p = 0.07$) as compared to controls. However, the study participants did not receive standard prophylaxis with either 5-HT₃ inhibitors or NK-1 inhibitors, limiting the clinical applicability of the study.

Other relaxation therapies such as *music* and *massage* have also been reported to be successful as adjunct antiemetic therapies, in small clinical trials involving about 30 patients.^{53, 54} These relaxation therapies affect the cerebral cortex, and thus are particularly helpful for decreasing the perception of nausea and in anticipatory nausea.

On the other hand, two trials evaluating efficacy of *ginger* for treatment of CINV were negative.^{55, 56} A number of clinical trials assessing various CAM therapies are currently under way and would provide further useful information regarding efficacy of these therapies (or lack thereof), facilitating optimal inclusion of these therapies in traditional clinical oncology practice (integrative oncology).⁴⁷

Recommendations for prevention and treatment of chemotherapy-induced emesis

The goal of antiemetic therapy is complete prevention of CINV ([Table 3](#)). In patients receiving highly and moderately emetogenic chemotherapy, the period of risk for nausea and vomiting lasts at least 4 days following chemotherapy, and protection with antiemetics is needed throughout this period. The choice of antiemetic prophylaxis is driven by the emetogenic potential of the specific chemotherapy agents as outlined below.¹⁸

Table 3 Guidelines for prevention of acute and delayed nausea and vomiting in patients depending on emetic risk

Emetic risk	Acute	Delayed
High (>90%)	Aprepitant + 5-HT3 antagonist + dexamethasone	Aprepitant + dexamethasone
Moderate (30–90%)	5-HT3 antagonist + dexamethasone	Dexamethasone
Low (10–30%)	Dexamethasone or phenothiazine or metoclopramide	None
Minimal (<10%)	None	None

Abbreviations: 5-HT3, 5-hydroxytryptamine 3.

Highly emetogenic chemotherapy

Cisplatin and cyclophosphamide are the most frequently used highly emetogenic chemotherapy agents. Nausea and vomiting are virtually ensured without adequate prophylaxis. Prior to the approval of the NK-1 receptor antagonist aprepitant, the previous recommendation was a combination of a 5-HT3 antagonist and dexamethasone. A regimen of a 5-HT3 receptor antagonist, aprepitant (125 mg PO day 1, 80 mg daily on days 2 and 3) or fosaprepitant 150 mg IV day 1, and dexamethasone (12 mg PO or IV on day 1 and 8 mg PO daily on days 2–4) with oral aprepitant (80 mg PO on days 2–4) or dexamethasone (12 mg PO or IV on day 1, 8 mg PO day 2, then 8 mg BID on days 3 and 4 with fosaprepitant) on days 2–4 is recommended in all patients receiving highly emetogenic chemotherapy. All prophylaxis should begin prior to the administration of chemotherapy.

Moderately emetogenic chemotherapy

A combination of a 5-HT3 receptor antagonist and dexamethasone is recommended in all patients receiving moderately emetogenic chemotherapy. Given recent data and its superior efficacy in preventing delayed symptoms, palonosetron (0.25 mg on day 1 only) is the preferred 5-HT3 receptor antagonist. If others are used, they should be given on day 1 prior to chemotherapy and then repeated daily on days 2–3. Dexamethasone is given as 12 mg IV or PO on day 1 and then at a daily dose of 8 mg on days 2–3 (either 8 mg daily or 4 mg in divided doses twice daily). In selected patients (those with breakthrough nausea and vomiting despite adequate prophylaxis or those with other patient variables that suggest a higher risk of symptoms), aprepitant (125 mg PO or fosaprepitant 150 mg IV on day 1 followed by 80 mg PO on days 2–3) should be considered. Recent data with netupitant and palonosetron are encouraging; however, netupitant has yet to be approved by the FDA for use in the United States.

Low-risk chemotherapy

Options for antiemetic prophylaxis in patients receiving chemotherapy of low emetogenic potential include dexamethasone (12 mg PO or IV) or prochlorperazine (10 mg PO or IV every 4–6 h) or metoclopramide (20–40 mg PO every 4–6 h or 1–2 mg/kg IV every 3–4 h with diphenhydramine to prevent extrapyramidal symptoms). All prophylaxis should be given prior to the administration of chemotherapy.

Minimally emetogenic chemotherapy

No routine prophylaxis is recommended. If nausea and vomiting do occur, the use of dexamethasone, prochlorperazine, or metoclopramide is recommended. Prophylactic use of these medications should be considered prior to the next cycle of therapy.

Special situations

Breakthrough nausea and vomiting

Ideally, the best treatment for breakthrough nausea and vomiting is to prevent it from occurring at all. At times, despite aggressive prophylaxis, symptoms still occur. The best therapy for breakthrough symptoms is the addition of agents from another class of antiemetics. In addition, an alternative route other than oral, such as intravenous or rectal, may need to be used. These medications work best if taken on a schedule rather than on an as-needed basis. When breakthrough nausea and vomiting occur, the prophylactic regimen should be reevaluated and enhanced prior to the next cycle of therapy.

Anticipatory nausea and vomiting

The key to preventing anticipatory nausea and vomiting is preventing symptoms from occurring with each cycle of chemotherapy. Once the symptoms have developed, agents such as the benzodiazepines may be added to the prophylactic regimen.⁵⁷ As outlined above, mind–body therapies such as behavioral therapy, systemic desensitization, and hypnosis have also been proved useful.^{49–53}

Multiple-day chemotherapy-induced nausea and vomiting

Patients receiving multiple-day chemotherapeutic regimens to treat a variety of malignancies (e.g., germ cell tumors, lymphoma, multiple myeloma with stem cell transplantation, etc.) are at risk for both acute and delayed nausea and vomiting. Although the NCCN has a section in their guidelines entitled “Principles of managing multiday emetogenic chemotherapy regimens,” they state that the antiemetic therapy should be selected based on the chemotherapy drug with the highest emetic risk. The risk of delayed nausea and vomiting will depend on the specific chemotherapeutic regimen used and the emetogenic potential of the last chemotherapeutic drug used in the regimen.

Studies have evaluated the use of repeat dosing of palonosetron in managing multiple-day emetogenic chemotherapy regimens; however, no definitive conclusions can be made and further studies are needed to answer whether a need exists for repeat dosing of palonosetron.^{1, 2}

With regard to aprepitant, it has been evaluated in the antiemetic management of multiple-drug chemotherapeutic regimens.^{3–5} While it may be used in such situations, it is difficult to recommend a specific antiemetic regimen for each day that a multiple drug emetogenic chemotherapeutic regimen is utilized.

The NCCN in their Antiemesis Guideline outlines the general principles for using corticosteroids (dexamethasone), serotonin antagonists (palonosetron), and neurokinin antagonists (aprepitant) in managing multiday chemotherapy regimens.¹²

Radiation-induced nausea and vomiting

Radiation-induced nausea and vomiting (RINV) is seen in nearly all patients receiving total-body irradiation prior to bone marrow transplantation and in more than 80% of those receiving radiation to the upper abdomen.⁵⁸ Studies have demonstrated the efficacy of prophylactic 5-HT₃ receptor antagonists compared with placebo⁵⁹ and the superiority of prophylaxis with 5-HT₃ receptor antagonists compared with combinations with metoclopramide and prochlorperazine.^{60, 61} The recommendation is for all patients undergoing either upper abdominal radiation therapy or total-body irradiation to receive

prophylaxis with an oral 5-HT₃ receptor antagonist dosed either 2 or 3 times daily with or without oral dexamethasone.⁶²

Conclusions

Prevention and treatment of chemotherapy-induced emesis have advanced significantly in recent years. Recent surveys indicate the need for heightened awareness of the frequency and severity of acute and, especially, delayed nausea and vomiting from chemotherapy. Fortunately, new agents have been added to the antiemetic arsenal to further enhance the efficacy of antiemetic prophylaxis. Complementary therapies appear promising in controlling nausea, and are being explored further. Appropriate implementation of guidelines for prophylaxis based on the specific chemotherapy agents used will ensure that fewer patients experience these most distressing of side effects.

Chapter 126

Neurologic complications of cancer

Lisa M. DeAngelis, MD, FAAN

Overview

Neurologic complications of cancer are common and being seen with increased frequency as patients survive longer with better systemic disease control. Metastases can involve the brain, dura, subarachnoid space, spinal cord, roots, and nerve plexus. Chemotherapy can cause acute toxicities, such as encephalopathy from ifosfamide, which impede the delivery of a full course of effective anticancer treatment. In addition, the long-term complications of radiotherapy such as radiation myelopathy, and chemotherapy such as peripheral neuropathy, can markedly impair quality of life. Early identification, treatment, and prevention strategies can reduce these toxicities in our growing population of survivors.

Neurologic complications of cancer can be either metastatic or nonmetastatic ([Table 1](#)). Metastatic lesions affect the nervous system by direct invasion (e.g., brachial plexus metastasis), compression [e.g., epidural spinal cord compression (SCC)], or compromise of vascular supply (e.g., sagittal sinus occlusion from skull metastases). Brain metastases are discussed in 78. Although any tumor can metastasize to the nervous system, certain tumors have a predilection for causing particular central or peripheral nervous system disorders (e.g., leukemias frequently metastasize to the leptomeninges, but rarely to the brain). Prostate cancer commonly causes epidural SCC because of its tendency to metastasize to the vertebral bodies, but leptomeningeal or brain involvement is much less common.^{1, 2}

Table 1 Neurologic complications of cancer

Metastatic
Intracranial (usually to brain; see Chapter 70)
Spinal (usually epidural)
Leptomeningeal (usually base of brain and cauda equina)
Cranial nerves (usually from base of skull lesions)
Peripheral nerves (usually brachial or lumbosacral plexus)
Muscle (rare)
Nonmetastatic
Complications of treatment (radiation, chemotherapy)
Vascular disorders (hemorrhage, infarcts)
Metabolic, nutritional disorders
Paraneoplastic syndromes
Infections

Nonmetastatic neurologic complications are often tumor specific. Metabolic derangements are more likely to occur with tumors that metastasize widely to vital organs, such as liver (colon cancer), or that cause changes in fluid and electrolyte balance, such as hypercalcemia (breast cancer) or inappropriate antidiuretic hormone secretion (small-cell lung cancer). Central nervous system (CNS) infections are more common in patients whose cancer is associated with immune suppression, as in Hodgkin disease. Vascular complications are more common in hematologic malignancies than in solid tumors.⁷ Paraneoplastic syndromes affecting the nervous system are much more frequent with certain tumors, such as small-cell lung and ovarian cancers.³ Clinically, identifying the site of neurologic dysfunction by the patient's symptoms and signs will help to determine the diagnosis ([Table 2](#)).

Table 2 Neurologic complications in cancer patients by site

Site	Usual causes	Typical symptoms and signs
Brain	Metastasis	Headache
	Leptomeningeal metastasis	Confusion
	Metabolic/toxic encephalopathy	Hemiparesis
	Infection (meningitis, brain abscess)	Seizures
	Radiation encephalopathy	Ataxia
	Cerebral hemorrhage or infarction	
	Paraneoplastic (limbic encephalopathy)	
Spinal cord and cauda equina	Epidural metastasis	Back pain
	Leptomeningeal metastasis	Paraparesis
	Intramedullary metastasis	Sensory level
	Epidural abscess or hematoma	Incontinence
	Radiation myelopathy	
	Myelopathy following intrathecal chemotherapy	
	Paraneoplastic myelopathy	
Cranial and peripheral nerves	Extrinsic compression by tumor or other mass (e.g., hematoma)	Focal pain Sensory loss
	Direct infiltration by tumor	Motor weakness
	Drug toxicity	Decreased reflexes in nerve distribution (focal lesion) or distally in hands and feet (polyneuropathy)
	Varicella-zoster infection	
	Radiation plexopathy	
	Paraneoplastic neuropathy	
Neuromuscular	Drugs (aminoglycoside antibiotics)	Weakness without sensory loss

junction		
	Paraneoplastic disorders (Lambert–Eaton myasthenic syndrome, myasthenia gravis)	Respiratory insufficiency
Muscle	Metastasis	Proximal weakness
	Steroid myopathy	Weakness without sensory loss
	Cachectic myopathy	
	Paraneoplastic polymyositis or dermatomyositis	

Vertebral metastases are common in patients with metastatic cancer, but skeletal complications, including SCC, have been reduced by the use of bisphosphonates.⁶ SCC usually results when a vertebral body metastasis extends into the spinal canal or paraspinal tumor invades the epidural space through a neural foramen ([Figure 1](#)). Lymphomas may invade the spinal canal through neural foramina without destruction of bone. Epidural lesions may also result when tumors in the colon, kidney, prostate, or head and neck area grow directly into the spinal bony structures. When a metastasis causes the vertebral body to collapse, bone, tumor, and ligament may extend into the spinal canal to compress the spinal cord.

Metastases

Spinal metastases

Metastatic lesions compressing the spinal cord or cauda equina are, after brain metastases, the most common symptomatic neurologic complication of metastatic cancer.^{1, 2, 4} The spinal cord ends at the L-1 or L-2 vertebral body but compression of the cauda equina below that level is usually also considered SCC because the diagnosis and treatment are identical.¹ SCC causes pain and, if untreated, paralysis and incontinence. Patients who become paraplegic as a result of cancer usually die within a matter of months; however, studies indicate that early diagnosis and treatment maintain a patient's independent ambulation and usually result in longer survival.

Approximately 5% of patients dying of cancer have evidence of SCC at autopsy, suggesting 18,000–20,000 new cases of SCC annually in the United States.^{1, 5} Breast, lung, prostate, and lymphoma are the most common primary cancers causing SCC ([Table 3](#)). SCC usually occurs in the late stages of metastatic cancer, but in up to 20% of patients, cancer was unsuspected before the neurologic symptoms.

Table 3 Primary cancer causing symptomatic spinal cord compression in 583 patients at Memorial Sloan Kettering Cancer Center (MSKCC)

Primary tumor	No. of patients (%)
Breast	127 (22)
Lung	90 (15)
Prostate	58 (10)
Lymphoreticular	56 (10)
Sarcoma	52 (9)
Kidney	39 (7)
Gastrointestinal	29 (5)
Melanoma	23 (4)
Unknown primary	21 (4)
Head and neck	19 (3)
Miscellaneous	69 (12)
Total	583

The thoracic spine is the most common location of SCC, followed by the lumbosacral and cervical spine in a ratio of about 4 : 2 : 1. Two or more contiguous vertebral bodies are involved by metastatic disease in approximately 25% of patients with SCC, but, unlike infection, the intervertebral disc is preserved. As many as 32% of patients have other sites of SCC in addition to the clinically suspected location, emphasizing the importance of imaging the entire length of the spinal canal when evaluating a patient for suspected epidural disease.

Pathophysiology of spinal cord compression

Epidural tumor is found both anterior and posterior to the spinal cord in almost 50% of patients; in approximately 20%, the tumor is circumferential. Histologic studies show that the most common abnormalities are demyelination with infiltration by lipid laden macrophages, interstitial edema, and focal axonal swelling, but infarction is rare, even in patients who develop the sudden onset of paraplegia. Compression of the epidural venous plexus (possibly contributing to spinal cord edema) occurs early in SCC, whereas decreased spinal cord blood flow takes place much later; therefore, venous infarction may contribute to the acute paraplegia, which can happen unpredictably, making SCC a neurologic emergency. The release of potentially neurotoxic substances, including prostaglandins and serotonin, by compressed neural tissue may also play a role in neurologic disability.

Figure 1 Neoplastic epidural spinal cord compression results from direct extension of a bony metastasis to the vertebral body (1a) or posterior elements (1b), by paraspinal neoplasm infiltrating through neural foramina (2), or a direct metastasis to the epidural space (3). Unusual causes of spinal metastases include subdural metastasis (4), intramedullary metastasis (5), and paraspinal metastasis to the radicular vessels (6) or root (7).

Clinical findings and diagnosis

The symptoms and signs depend on the level of compression (e.g., cervical vs thoracic). Back pain is the first symptom of SCC in virtually all patients ([Table 4](#)).⁵ The pain may be local (at the involved area of the spine), radicular (radiating into arm, trunk, or leg), or both. Local pain is dull, aching, and progressive and usually localizes to the involved area of the spine. Local pain aggravated by movement implies spinal instability. In the cervical and lumbosacral regions, radicular pain is often unilateral, but in the trunk, it is usually bilateral (band-like), a finding highly suggestive of epidural disease. Pain from SCC is typically worse when the patient is supine, which helps to distinguish SCC from a herniated disc where the pain improves with recumbancy. The pain of SCC is exacerbated by coughing, straining, or valsalva. Pain may be absent in patients whose SCC is identified incidentally on chest or abdominal CT or MRI done to evaluate the patient's primary cancer.

Table 4 Symptoms and signs of spinal cord compression in 213 patients at Memorial Sloan Kettering Cancer Center (MSKCC)

	First symptom		Present at diagnosis	
	No.	%	No.	%
Pain	201	94	207	97
Weakness	7	3	157	74
Autonomic dysfunction	0	0	111	52
Sensory loss	1	0.5	112	53
Ataxia	2	0.9	8	4

Weakness is the second most common feature of epidural SCC; it usually follows the onset of pain by weeks to months and is most obvious in proximal muscles of the legs. By the time weakness occurs, tone in the lower extremities is usually increased, reflexes are hyperactive, and the plantar responses are extensor. If the SCC occurs below the cord involving the cauda equina, hyporeflexia or areflexia is found. If pain limits strength testing, analgesics should be administered to permit adequate evaluation.

Bowel and bladder dysfunction usually occur late in SCC. However, when the conus medullaris is the site of compression (vertebral lesions from T-10 to L-1), bladder dysfunction may be the first and only sign. The patient may be unaware of urinary retention because bladder sensation is lost; examination reveals a distended bladder, and a postvoid ultrasound reveals urinary retention. The anal sphincter is usually flaccid. Sensory symptoms include numbness and paresthesias that begin in the toes and spread proximally. Except in conus compression, the sacral segments may be spared, even when a sensory level is found on the trunk. In a few patients, gait or truncal ataxia mimicking cerebellar disease may be the only neurologic finding although back pain usually precedes the ataxia. Varicella-zoster eruption may occur at the dermatomal level of epidural metastasis. If it precedes the diagnosis of the spinal metastasis, it can delay recognition of SCC.

None of the clinical symptoms or signs of epidural SCC are specific ([Table 5](#)). Some disorders that mimic SCC such as herniated disc or spinal stenosis are common and may confuse the initial evaluation of an individual cancer patient. Others, such as epidural hematomas and abscesses, may be directly related to the cancer or its treatment.

Table 5 Differential diagnosis of epidural spinal cord compression

Diagnosis	Example(s)	Diagnostic test
Intramedullary tumor	Glioma	MRI with gadolinium
	Metastasis	
Extramedullary-intradural tumor	Meningioma	MRI with gadolinium
	Neurofibroma	
Leptomeningeal tumor	Metastasis	MRI with gadolinium, CSF cytology
	Primary lymphoma	
Radiation myelopathy	Previous RT to spine	MRI with gadolinium
Arteriovenous malformation	Post-RT cavernous angioma	MRI with gadolinium, myelogram, arteriogram
Transverse myelopathy	Postinfectious myelopathy, multiple sclerosis	MRI with gadolinium
Epidural hematoma	Thrombocytopenia (history of lumbar puncture)	MRI or CT
Epidural abscess	Sepsis, epidural catheter	MRI with gadolinium/culture
Degenerative spinal disorder	Herniated disc, spinal stenosis	MRI
Osteoporosis	Vertebral collapse	MRI/biopsy

Abbreviations: CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; RT, radiation therapy.

Patients with cancer who develop back pain have SCC until proved otherwise. Evaluation should proceed urgently because high-grade compression may cause abrupt compromise of the spinal cord and severe neurologic dysfunction. The only necessary diagnostic test for spinal lesions caused by cancer is an MRI ([Figure 2](#)). The entire spine should be imaged, but contrast is not necessary to detect spine metastasis or epidural tumor. However, contrast is essential to identify intramedullary or leptomeningeal metastasis (LM). Patients unable to have an MRI (e.g., pacemaker) should be imaged by CT-myelography where full reconstructed images can provide excellent views of the spine in all dimensions.

Figure 2 MRI demonstrating spinal cord compression from metastatic breast cancer. (a) Tumor in the vertebral body compressing the spinal cord anteriorly. (b) Axial image at the same level demonstrating anterior and lateral compression and distortion of the cord.

Treatment

SCC requires urgent therapy directed at reduction of tumor mass and prevention of regrowth.^{1, 4} Radiation therapy (RT) is the primary treatment for most patients, but surgery and chemotherapy are important modalities in individual patients. The initial treatment for all patients is corticosteroids, which can have an oncolytic effect relieving SCC by shrinking tumors, especially lymphoma, but in most instances, their salutary effects result from the reduction of spinal cord edema. Other treatment is usually started concurrently so the effect of corticosteroids is difficult to evaluate, and the optimal dose has not been determined.

For patients with pain only, dexamethasone at 16 mg every 24 h can be started increasing the dose if pain persists or new symptoms develop. For patients with severe pain, or evidence of myelopathy, an intravenous bolus of 100 mg of dexamethasone should be administered, followed by 100 mg every 24 h in divided doses. The drug should be tapered as the patient is treated with more definitive modalities. Corticosteroids cause side effects, and some may be more prominent in patients with epidural SCC. Perforation of the gastrointestinal (GI) tract may occur in as many as 1% of patients; constipation, a frequent complication of SCC, appears to increase the risk of GI rupture. Thus, a rapid taper, particularly of high initial doses, is essential.

RT is the most common treatment for patients with SCC, many of whom are poor surgical candidates because of advanced cancer or multiple vertebral body metastases.^{1, 5} RT to a total dose of 3000 cGy (300 Gy \times 10 fractions) is administered to the site of compression and one or two vertebral bodies above and below that level. Multiple courses of RT for patients who respond initially but then relapse may be helpful and carry only modest risk.⁷ Intensity-modulated stereotactic radiotherapy (IMRT) is effective and safe and can be administered with good results to a previously irradiated site or in place of standard external beam RT.^{8–10}

Surgery plays an increasingly important role in SCC treatment. Traditionally, surgery was restricted (1) to patients who developed SCC at sites already irradiated, (2) to patients in whom a diagnosis of cancer had not been established, (3) when epidural defects result from displaced bone or disc fragments, (4) when spinal instability results from bone destruction, and (5) to patients with radio resistant tumors (e.g., renal cancer). However, a prospective phase III trial demonstrated the superiority of surgery plus RT compared to RT alone for SCC.^{11, 12} Tumor resection that usually required resection of the vertebral body had a superior outcome with significantly better neurologic function for longer, including a greater proportion of patients who regained ambulation and continence. Length of survival was not significantly different between the two groups, but there was a trend toward longer survival with surgery (129 days vs 100 days, $p = 0.08$). These data suggest that surgery should be a consideration in all patients with SCC. However, the patients enrolled in the study were highly selected and it is not clear that the excellent outcome reported can be expected for all patients with SCC. More recently, vertebroplasty and kyphoplasty have proven effective for selected patients with SCC, especially those with vertebral compression fractures and severe pain.¹³

Chemotherapy, with or without RT, is useful in some patients with tumors that are sensitive, especially lymphoma and occasionally other solid tumors.¹⁴ Excellent responses of SCC from chemosensitive tumors to appropriate chemotherapy are seen, but this approach is limited to those who have minimal to no neurologic compromise. If myelopathy is present, RT or surgery must be the primary therapy. Regardless of treatment type, the majority of patients who are ambulatory at the beginning of therapy remain ambulatory. Some paraparetic patients will recover sufficient function to walk again, but only a few who are paraplegic recover useful function.

Leptomeningeal metastasis

LM is less frequent than brain metastasis or SCC but is becoming increasingly common, particularly in patients with small-cell lung, breast, and ovarian cancers. Quality of life and duration of survival are both severely compromised by LM, and fewer than one-half of those treated by currently available therapy receive benefit.

Reliable estimates of the incidence of LM are difficult to obtain, but LM is found in approximately 5% of patients with metastatic cancer. Few studies of LM give incidence figures and the diagnosis is heavily dependent on the diligence with which it is pursued. Recognizing these limitations, the frequency of LM in different cancers varies widely ([Table 6](#)).

Table 6 Frequency of leptomeningeal metastases (LM) in various cancers

Cancer	Percent developing LM	Features
Carcinoma		
Breast	5	Incidence may be increasing, more common with infiltrating lobular carcinoma
SCLC	9–25	Incidence is increasing, risk increases with duration of survival
NSCLC	?	Less common than breast
Melanoma	23	50% at autopsy
Leukemia		
AML	<5	10% without prophylaxis; associated with high WBC count, elevated LDH, extramedullary disease at diagnosis, and monocytic morphology
ALL	11	30% without prophylaxis; associated with T-cell phenotype, Burkitt morphology, and high WBC count
CLL	Rare	May occur during blast crisis
Lymphoma		
NHL	4–10	Associated with diffuse large B-cell and lymphocytic histology, bone marrow involvement
HD	Rare	
Overall	8.6	LM present at autopsy in 56 of 649 brains examined at Memorial Sloan Kettering Cancer Center

Abbreviations: ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; HD, Hodgkin disease; LDH, lactic acid dehydrogenase; NHL, non-Hodgkin lymphoma; NSCLC, nonsmall-cell lung cancer; SCLC, small-cell lung cancer; WBC, white blood cell.

Pathophysiology

Malignant cells may enter the subarachnoid space by several routes ([Figure 3](#)). Subarachnoid invasion can occur via infiltration of the wall of veins and of the marrow trabeculae; malignant cells can attach to leptomeningeal capillaries and move directly into the subarachnoid space. Brain parenchymal lesions can erode into the ventricle or subarachnoid space or be spilled at surgery, causing LM. LM develops in 40% of patients following resection of a cerebellar metastasis, but in only 2–3% of those who had resection of a supratentorial lesion. The choroid plexus is a rare route of entry. Malignant cells may invade the subarachnoid space by direct infiltration along nerve roots, and possibly via epineural lymphatics.

Figure 3 Pathophysiology of leptomeningeal metastases. (a) Mechanisms of tumor cell entry into the spinal subarachnoid space. Tumor may invade the vertebral body (1a) and grow along vertebral veins (1b) into the subarachnoid space (1c). Tumor may invade peripheral nerves or nerve roots outside the vertebral canal (2a) and grow along the nerve sheath into the spinal canal to seed the leptomeninges (2b). The tumor can invade blood vessels outside the central nervous system (3a) and transverse subarachnoid veins into the subarachnoid space (3b). Source: From Ref. 1. (b) Possible mechanisms of tumor entry into the cerebral subarachnoid space. Tumor may enter the cranial subarachnoid space via metastases either to the skull or brain, to the diploic veins of the skull, or directly from subarachnoid veins. The choroid plexus (not shown) is also an occasional site for the formation of leptomeningeal tumor.

LM causes nervous system dysfunction by several mechanisms:¹ (1) direct infiltration of malignant cells into the brain, spinal cord, cranial nerves, or spinal roots that interferes with neural function, (2) interruption of CSF flow leading to increased intracranial pressure (ICP) with or without hydrocephalus, and (3) infiltration of tumor along the Virchow–Robin spaces may reduce blood supply to the brain causing cerebral infarction.

Symptoms and signs

LM is strongly suggested by the patient having symptoms or signs at multiple sites of the neuraxis.^{1, 2} These include (1) headache, particularly early in the morning or posturally induced headache in the absence of brain metastases; (2) cranial nerve palsies, particularly, diplopia or facial weakness; (3) neck pain in the absence of cervical spine metastases; (4) radicular pain in the arms or legs, particularly when accompanied by weakness but without local spine pain; (5) unexplained constipation, impotence, or urinary incontinence or retention; (6) asymmetric leg weakness and diminished reflexes in the absence of pain or sensory changes; and (7) confusion, memory loss, or other cognitive abnormalities.

Diagnosis

The diagnostic gold standard of LM is the demonstration of malignant cells in the CSF. However, imaging is a much more common means of diagnosis currently.¹⁵ A cranial MRI may reveal enhancing cranial nerves or enhancing tumor in cortical sulci; communicating hydrocephalus may suggest LM. A gadolinium-enhanced spine MRI may demonstrate tumor nodules on spinal roots, particularly in the cauda equina, even when symptoms of nerve root dysfunction are absent ([Figure 4](#)). The whole neuraxis should be imaged to identify sites of bulky disease. When characteristic findings are identified, this suffices to establish the diagnosis. MRI is 76% sensitive and 77% specific. Occasionally, FDG-PET imaging may identify LM.¹⁶ However, negative imaging does not exclude the diagnosis in a patient with typical features. A lumbar puncture should be performed and the opening pressure, cell count, protein, glucose, and bacterial and fungal studies should be obtained; the cytology specimen should contain at least 10 mL of CSF optimally and should be processed quickly according to the laboratory's protocol.

Figure 4 Gadolinium-enhanced MRI demonstrating leptomeningeal metastases from lung cancer. (a) Sagittal and (b) axial images demonstrating enhancing nodules within the thecal sac. This patient had a positive cerebrospinal fluid cytology for malignant cells.

Malignant cells are found in the initial CSF sample in 50–60% of patients with LM.¹ Cytologic examination is 75% sensitive, but almost 100% specific; additional samples increase the yield, and occasionally cisternal CSF may be positive when lumbar CSF is negative. Likewise, cytology may be positive in ventricular fluid but negative in lumbar fluid or vice versa. Rare cell capture technology may enhance the identification of malignant cells in CSF over routine cytology.¹⁷

Tumor markers, deoxyribonucleic acid (DNA) studies, and immunocytochemistry may help confirm LM when cytologic studies are negative. In the presence of a normal blood–brain barrier (suggested by a

normal CSF protein concentration), the level of tumor antigens, such as carcinoembryonic antigen (CEA), beta human chorionic gonadotropin (β HCG), cancer antigen (CA) 125, CA 27.29, CA 19–9, and prostate-specific antigen (PSA), should be no greater than 1% of the serum level. When that amount is exceeded, and particularly if the CSF level is higher than the serum level, the diagnosis is established, even without a positive cytology. When LM is suspected in patients with lymphoma or leukemia, flow cytometry or molecular markers may demonstrate a clonal excess of cells similar to the systemic neoplasm, suggesting LM.

Treatment

If untreated, LM usually causes relentless progression of neurologic dysfunction and death within weeks. Treatment is not very effective, and it usually does not reverse fixed neurologic deficits. Nevertheless, therapy alters the clinical course in about one-half of patients and often improves symptoms.^{1, 18} Occasionally, the course may be indolent especially in patients with LM from lymphoma or breast cancer.

The type of primary cancer is the best predictor of response to treatment; the majority of lymphoma and breast cancer patients respond because these tumors are relatively sensitive to RT and systemic and intrathecal chemotherapy. Patients with lung cancer or melanoma respond in about one-third and one-fifth of cases, respectively. Patients with severe neurologic disability from LM are less likely to derive benefit because neural damage is often irreversible. Unlike brain metastases, dexamethasone provides little symptomatic relief unless there is elevated ICP.

Among patients receiving therapy for LM, survival is prolonged only in those whose disease responds to treatment;¹ however, the inability to predict which patients will respond to treatment makes prognostication difficult. In addition to surviving longer (4–6 months median vs 1–2 months median in nonresponders), patients who respond to therapy are less likely to die from their LM than are patients whose disease progresses despite therapy.

Radiation therapy

RT should be administered to symptomatic sites even if subarachnoid tumor is not evident radiographically at the symptomatic location. Entire neuraxis RT is rarely used because of its acute morbidity and myelosuppression that interferes with subsequent chemotherapy. Neuraxis RT is not used even when bulky LM is seen on MRI along the entire spinal axis. The brain is the most common site to which RT is administered, usually in a dose of 3000 cGy, but the cauda equina also requires RT frequently.

Chemotherapy

Intrathecal chemotherapy is used commonly to treat LM and when it is administered intraventricularly, there is better distribution and greater ease and reliability of delivery than drug administered by lumbar puncture. The most commonly used agent is methotrexate (MTX), which is active against breast cancer, lymphoma, and leukemia, but has poor activity against some of the other common cancers that cause LM. An Ommaya reservoir is usually placed to access the right lateral ventricle. MTX is administered intrathecally to adults in doses of 12–15 mg, diluted in preservative-free saline. With this dose, MTX levels in the CSF exceed the therapeutic concentration of 10^{-6} M and remain above this level for 36–48 h.

Studies of CSF flow dynamics using indium¹¹¹-DPTA (diethylenetriamine penta-acetic acid) cisternography have found impaired CSF flow in a high percentage of patients with LM. Indium¹¹¹ studies predict CSF MTX distribution and indicate that drug reaches all areas of the subarachnoid space unless a

complete block is present.¹⁹ Patients with impaired CSF flow have a worse prognosis and increased incidence of leukoencephalopathy. If a patient has symptoms of elevated ICP with or without hydrocephalus, this takes priority and requires placement of a ventriculoperitoneal shunt; no patient with hydrocephalus or a shunt should receive intrathecal chemotherapy, even if a valve can turn off drainage temporarily. Obstruction of CSF flow should be suspected in patients with LM who develop focal leukoencephalopathy around the ventricular catheter track of an Ommaya reservoir (see Methotrexate).

MTX appears in the serum for prolonged periods following intrathecal administration, and myelosuppression and stomatitis may result. Oral leucovorin can avert these complications starting 12 h after MTX injection. Leucovorin does not appear in the CSF, but its active conversion product, 5-methyltetra-hydrofolate (5-methylTHFA), does; however, the CSF levels of 5-methylTHFA are very low after oral leucovorin and are incapable of rescuing tumor cells in the CSF.

Two studies have found that intrathecal MTX as a single agent is equal in efficacy to multiagent intrathecal chemotherapy and has significantly less systemic toxicity. Patients treated with MTX plus RT respond more often than those treated with either alone. Cytarabine (cytosine arabinoside [ara-C]) and thiotepa may also be useful, particularly in LM from lymphoma, leukemia, or breast cancer. Liposomal cytarabine has a long CSF half-life and can be given every 14 days; it has been reported effective against LM from solid tumors not usually considered sensitive to cytarabine.²⁰ However, it can cause a severe chemical meningitis and patients must receive prophylactic steroids beginning one day before a dose is administered and continued for at least 2 days following the dose. Intrathecal antibodies such as rituximab and trastuzumab have been effective in LM from lymphoma and HER2+ breast cancer, respectively.²¹ There are few data to guide decisions regarding the duration of therapy in patients who are clinically stable and whose CSF remains free of malignant cells after 6 months of therapy. Neurotoxicity from intrathecal drug can occur and is discussed later in this chapter.

Because LM disrupts the blood–brain barrier, systemic chemotherapy, particularly when administered in high doses, may also be effective. High-dose intravenous MTX (e.g., 3–8 g/m²) with leucovorin rescue after 24 h may result in CSF MTX levels that exceed 10^{−6} M and may represent an alternative to intrathecal delivery, particularly in patients with impaired CSF flow. Systemic drugs may also treat bulky LM, whereas intrathecal chemotherapy has insufficient penetration into tumor nodules. Other agents that can reach the CSF or have been reported effective for LM include high-dose cytarabine for hematologic malignancies and capecitabine for breast cancer.²² Newer agents, including the tyrosine kinase inhibitors and even bevacizumab, have been reported effective in individual patients and should be chosen on the basis of the likely sensitivity of the primary to a given drug.^{23, 24}

Cranial and peripheral nerve metastases

Lesions of cranial or peripheral nerves often cause severe pain and, depending on the nerve involved, substantial neurologic disability. The frequency of metastatic disease causing cranial and peripheral nerve dysfunction is unknown because only a few studies address this issue in particular tumors. For example, facial nerve paralysis occurs in 5–25% of malignant parotid neoplasms, the lower figure associated with acinous cell carcinomas and the higher with undifferentiated neoplasms. Primary lung cancer arises in the superior sulcus in approximately 3% of patients, the vast majority presenting with pain caused by infiltration of the brachial plexus (Pancoast syndrome). Individual nerves either alone or in combination (mononeuritis multiplex) may be compressed or invaded by tumor.

Pathogenesis

Tumors affect cranial and peripheral nerves either by compression or invasion along perineurial and endoneurial planes. Pancoast tumors and breast carcinoma metastatic to supraclavicular lymph nodes compress the brachial plexus but usually do not invade it, whereas squamous cell carcinoma of the face, certain melanomas, and prostate cancer can be neurotropic, tracking microscopically along the course of a nerve, often reaching the spinal canal or even the brainstem.²⁵ A blood–nerve barrier similar to the blood–brain barrier may exclude water-soluble chemotherapeutic agents from nerve and provide a “sanctuary” for tumor cells.

Symptoms

The specific symptoms and signs of cranial and peripheral nerve dysfunction depend on the nerves involved and the mechanism of involvement. With compressive lesions, pain at the site of compression or more distantly in the sensory distribution of the nerve or plexus involved is usually the first symptom. In invasive lesions of nerves, pain and neurologic dysfunction develop simultaneously. In general, when mixed nerves are involved, motor function is affected out of proportion to sensory loss, no matter what the mechanism of nerve involvement is. Compressive lesions of nerves can generally be identified by MRI directed at the area of dysfunction ([Figure 5](#)).^{1, 25} When the lesion is infiltrative, imaging studies may be normal and the diagnosis must be established clinically or by biopsy. Occasionally infiltration of large nerves such as a plexus or root can be imaged by an enhanced MRI or PET.

Figure 5 Coronal-enhanced MRI demonstrating a metastasis to the left cavernous sinus (*arrowhead*) from breast carcinoma. Patient presented with retro-orbital pain and had evidence of a partial third, sixth, and V1 palsy.

Cranial and peripheral neuropathies also occur as side effects of radiation, chemotherapy, or as paraneoplastic syndromes. It is frequently difficult to distinguish these nonmetastatic peripheral nerve lesions from those caused by metastases, but in general, the former are usually painless, whereas the latter

tend to be painful. Furthermore, most paraneoplastic and drug-induced neuropathies are bilateral and symmetric, whereas metastatic neuropathies are unilateral or at least asymmetric.

Cranial neuropathies

Cranial nerves may be affected by metastases at any point from within the brainstem to their end organ ([Table 7](#)). Brainstem metastases occasionally cause isolated cranial nerve dysfunction, but usually other signs reveal the central location of the lesion. LM is a common cause of cranial neuropathies that are often multiple. Base of skull metastases often cause recognizable patterns of cranial nerve dysfunction that localize the lesion.^{1, 2} Finally, the cranial nerves may be damaged after exiting their foramina.

Table 7 Metastatic lesions causing cranial neuropathies

Lesion site	Findings	Comments
Eye	Decreased visual acuity; retinal detachment	Choroidal lesions are more common than retinal: pain, proptosis and diplopia are rare; breast and lung cancer are common causes
Orbit	Pain, proptosis, diplopia; sensory loss V1; decreased visual acuity in one-third of cases, usually late	As common as choroidal metastases; breast and prostate cancer and lymphoma are common causes
Parasellar	Unilateral frontal headache, oculomotor palsies (3, 4, 6), sensory loss V1	Vision rarely affected, no proptosis; lymphoma common
Sella	Diabetes insipidus	Anterior pituitary insufficiency and visual loss are rare; when present, they suggest a primary pituitary tumor. Breast cancer is a common cause
Middle cranial fossa	Facial numbness (V2, 3), VI palsy in some	Lightning-like facial pains (trigeminal neuralgia) rare in patients with neoplastic compression
Jugular foramen	Hoarseness, dysphagia, pain in pharynx (IX, X), sternocleidomastoid weakness (XI), occasionally tongue weakness (XII)	Papilledema may occur if dominant jugular vein is compressed. Glossopharyngeal neuralgia is uncommon
Occipital condyle	Unilateral occipital pain and neck stiffness, unilateral tongue weakness (XII)	Pain may radiate to forehead
Mandible	Unilateral numb chin and gum (“mental neuropathy”)	Also results from meningeal or skull base metastases; breast cancer and lymphoma are common causes
Carotid sinus or glosso-pharyngeal nerve	Syncope, pharynx or neck pain on swallowing	Cardioinhibitory, vasodepressor syncope, or both; head and neck cancer, indicates recurrent tumor; may be life-threatening
Left upper mediastinum	Hoarseness, recurrent laryngeal paralysis	Lung, breast and head and neck cancers

Evaluation should include an enhanced MRI to visualize the involved cranial nerve along its entire course. Lumbar puncture should be performed even when an appropriately placed skull base metastasis is discovered because LM may coexist. Nonmetastatic causes of cranial neuropathies are also common in cancer patients (Table 8). RT is usually employed for skull base and orbital metastases. Chemotherapy can be used in appropriate circumstances.

Table 8 Nonmetastatic causes of cranial neuropathy in cancer patients

Cranial Nerve (Symptom)	Causes
II (unilateral vision loss)	Gallium, interferon alpha, RT, temporal arteritis, retinal diseases including hemorrhage
III (diplopia, ptosis)	Diabetes (usually spares pupil), aneurysm, increased intracranial pressure (uncal herniation); myasthenia gravis and Grave disease ^a
IV (jaw pain; facial pain)	Vincristine, trigeminal neuralgia (sudden, lancinating pains without sensory loss)
VI (diplopia)	Vincristine, increased intracranial pressure, head trauma, diabetes, drug toxicity (e.g., narcotics, anticonvulsants), strabismus
VII (facial weakness)	Bell palsy (idiopathic), varicella-zoster infection (Ramsay Hunt syndrome), diabetes
VIII (hearing loss, dysequilibrium)	Cisplatin, aminoglycosides, degenerative disease, acoustic neuroma, RT-induced serous otitis
X (weak phonation, laryngeal paralysis)	Vincristine

^a Common causes of diplopia, but are not cranial nerve diseases.

Abbreviation: RT, radiation therapy.

Brachial plexopathy

Brachial plexopathy in cancer patients usually results from metastatic cancer in axillary or cervical lymph nodes, local bony structures (e.g., clavicle), or from superior sulcus lung tumors.^{1, 2} Because most metastatic tumors compress the plexus from below, the initial symptom is usually pain in the posterior shoulder or pain radiating down the medial aspect of the arm, elbow, and forearm to the fourth and fifth fingers (C-8 or T-1 distribution). Weakness usually begins in the hand and sensory loss begins in the fourth and fifth fingers; both may progress to affect the entire arm. This initial presentation is helpful in distinguishing tumor from the more common cervical disc herniation where pain commonly affects the outer arm and dorsal surface of the forearm, with weakness in the triceps and wrist extensors (C-7 radiculopathy). Tumor masses are occasionally palpable in the axilla or supraclavicular area. When present, an ipsilateral Horner syndrome (ptosis, miosis, and anhydrosis) indicates the tumor has involved the stellate ganglion in the paraspinal region and, therefore, epidural extension must be sought on cervical MRI.

The differential diagnosis includes radiation-induced plexopathy, trauma (e.g., intraoperative positioning, or following central line placement), idiopathic plexopathy, and radiation-induced malignant peripheral nerve sheath tumor. A common diagnostic dilemma is the differentiation of metastatic from radiation-induced plexopathy. Clinical features that distinguish these two conditions include (1) initial symptom of

pain in metastatic plexopathy and paresthesias in RT-induced plexopathy; (2) Horner syndrome, which is more consistent with metastatic plexopathy; (3) more rapid progression of symptoms and signs in metastatic plexopathy; (4) supraclavicular fullness in metastatic plexopathy; and (5) lymphedema, which suggests RT-induced plexopathy. CT or MRI may demonstrate a mass in the plexus (metastatic plexopathy) or loss of soft-tissue planes from fibrosis (RT-induced plexopathy). When findings are equivocal, a PET scan may help.

RT is the best available treatment for metastatic plexopathy; chemotherapy may be useful for some previously irradiated patients (e.g., those with breast cancer or lymphoma). There is no satisfactory treatment for radiation-induced plexopathy. Surgical lysis of fibrotic tissue surrounding the nerves has not been helpful, nor has systemic corticosteroid, local steroid injection, hyperbaric oxygen, or bevacizumab. Treatments for pain include carbamazepine, opioids, gabapentin, pregabalin, and neurosurgical ablative procedures.

Lumbosacral plexopathy

The lumbosacral plexus is formed from spinal nerve roots L-2 to S-5. The upper lumbar portion (L-2 to L-4) exits the pelvis mainly as the obturator (adductor muscles) and femoral (quadriceps muscles) nerves, whereas the remainder of the leg is innervated by the sciatic nerve (L-5 to S-1). The bladder, rectum, and anus are innervated by roots S-3, S-4, and S-5. Symptoms are usually unilateral leg weakness and numbness although 25% of metastatic plexopathies may be bilateral. Incontinence requires bilateral loss of innervation and, therefore, its presence suggests central (i.e., cauda equina) or sacral involvement. Clear differentiation requires enhanced spinal MRI and CSF analysis. Local extension of pelvic and abdominal tumors is the predominant cause of metastatic lumbosacral plexopathy. The differential includes herniated lumbar disc, epidural and meningeal metastases to the cauda equina, radiation-induced plexopathy (usually from brachytherapy for pelvic neoplasms), intraoperative trauma, hematoma, abscess, and diabetic or idiopathic lumbosacral plexopathy. The differential features of metastatic and radiation-induced plexopathy are similar to those for brachial plexopathy. CT or MRI often demonstrates a mass in the region of the lumbosacral plexus. Biopsy is indicated if an abscess or a secondary tumor is suspected. RT is the most commonly employed treatment for metastatic lumbosacral plexopathy. If metastatic disease approaches the spine, epidural disease may be present and should be included in the RT port.

Peripheral neuropathy

Single peripheral nerves are sometimes damaged by metastatic cancer, and more widespread invasion of peripheral nerves, causing either a mononeuritis multiplex or diffuse polyneuropathy, may complicate the course of leukemia or lymphoma; PET imaging of the limbs may be diagnostic.²⁶ However, when polyneuropathy occurs in cancer patients, it usually results from toxin exposure or paraneoplastic disorders, both of which are discussed below.

Nonmetastatic complications of cancer therapy

Many cancer treatments are neurotoxic ([Table 9](#)). Some drugs (e.g., vincristine) cause neurotoxicity even at low doses, whereas others (e.g., cytarabine) cause neurotoxicity only during intensive therapy. Neurologic toxicity is a dose-limiting factor in several cancer treatments, such as RT, and patients may suffer more from these toxicities than from the cancer itself.^{1, 2, 27} The more commonly encountered neurologic toxicities from cancer treatment are discussed in the following section.

Table 9 Neurotoxicity of agents commonly used in cancer patients

<i>Acute encephalopathy (delirium)</i>	<i>Headache without meningitis</i>
Corticosteroids	Retinoic acid
Methotrexate (high-dose IV, IT)	Trimethoprim-sulfamethoxazole
Cisplatin	Corticosteroids
Vincristine	Tamoxifen
Asparaginase	Ondansetron
Procarbazine	<i>Seizures</i>
5-Fluoracil (\pm levamisole)	Methotrexate
Cytarabine (high-dose IV, IT)	Etoposide (high-dose)
Nitrosoureas (high-dose or arterial)	Cisplatin
Ifosfamide/mesna	Vincristine
Interferons	Asparaginase
Chronic encephalopathy (dementia)	Nitrogen mustard
Methotrexate	Carmustine
Carmustine Cytarabine Fludarabine	Dacarbazine (intra-arterial or high-dose) Busulfan (high-dose)
Visual loss Tamoxifen Cisplatin Interferon alpha	Myelopathy (intrathecal drugs) Methotrexate Cytarabine Thiotepa
Cerebellar dysfunction/ataxia Cytarabine Phenytoin Procarbazine Aseptic meningitis Trimethoprim-sulfamethoxazole IVIg NSAIDs Monoclonal antibodies Bortezomib Carbamazepine Cytarabine (IT) Methotrexate (IT) Corticosteroids (IT)	Peripheral neuropathy Vinca alkaloids Cisplatin Oxaliplatin Etoposide Teniposide Paclitaxel Suramin Docetaxel Bortezomib

Abbreviations: IV, intravenous; IVIg, intravenous gammaglobulin; IT, intrathecal; NSAID, nonsteroid anti-inflammatory drugs.

Source: Modified from Ref. 1.

Chemotherapy

Vinca alkaloids

Vinca alkaloids cause nerve damage by binding tubulin in peripheral nerves and disrupting the formation of microtubules that mediate fast axonal transport. Neurotoxicity is a dose-limiting side effect of all the vinca alkaloids, but especially of vincristine; vinorelbine can also cause peripheral neuropathy particularly when combined with or following other neurotoxic agents. Central neurotoxicity is rare because vincristine does not penetrate the normal blood–brain barrier. Vinca alkaloids should never be given intrathecally.

Vinca alkaloid neurotoxicity is age (more severe in adults) and dose dependent and appears to be more prominent in patients with hepatic dysfunction, and in those who have received other potentially neurotoxic therapies. Tingling paresthesias develop in the fingertips, and usually in the toes, of virtually all patients treated with vincristine, although clinically detectable sensory loss is often absent. Loss of ankle reflexes is an early and almost universal sign, and with continued therapy, all reflexes may diminish or disappear. Weakness occurs as therapy continues and is of two types: (1) A generalized distal neuropathy that preferentially affects the foot and hand extensors, causing impairment of fine motor function and foot drop. Weakness can become severe enough to render the patient immobile or bed-bound, but the drug should be discontinued before severe weakness. Pre-existing peripheral nerve diseases, especially Charcot–Marie–Tooth neuropathy and probably other neuropathies (e.g., diabetic polyneuropathy), increase the severity of vincristine neuropathy. (2) Some patients develop focal weakness (e.g., unilateral foot drop or cranial nerve palsies, such as ptosis or extraocular muscle, facial, or laryngeal paralysis). Although symptomatic toxicity is usually reversible after discontinuation of the drug, significant weakness may persist in severely affected patients. Autonomic dysfunction, particularly abdominal cramping and constipation, often occurs within hours to days of each dose. Adynamic ileus may result and can be life-threatening; a prophylactic bowel regimen is essential for all patients. Impotence has been reported.

Figure 6 Gadolinium-enhanced T1-weighted (a) and T2-weighted (b) MRIs of focal leukoencephalopathy in a patient with a malfunctioning Ommaya reservoir. This reservoir was obstructed but unrecognized. Multiple courses of methotrexate were instilled into the catheter. The drug dissected around the catheter and into the frontal lobe, causing a region of necrosis with prominent surrounding edema. Air can be seen in the central cavity of the lesion after a recent instillation. The patient presented with seizures and a left hemiparesis, both of which resolved with corticosteroids.

Less common complications of vincristine administration include aching bone pain, sharp stabbing pain in the jaw or throat, or an increase in any pre-existing pain; this typically occurs within hours of injection and subsides over several days. The symptoms appear with the first or second dose and rarely recur with subsequent doses. Hyponatremia from inappropriate secretion of antidiuretic hormone occurs within days of drug administration and may recur with subsequent doses.

Methotrexate

There are several clinically distinct forms of MTX toxicity.^{1, 2} An acute reaction with meningismus, confusion, fever, and CSF pleocytosis often occurs 4–6 h after intrathecal injection and resolves over several days. This syndrome is frequently confused with infectious meningitis, but the onset is too rapid after the injection for bacterial contamination; antibiotics are unnecessary unless Gram stain or cultures demonstrate organisms. Dexamethasone relieves or prevents some of these symptoms. Mild acute toxicity occurs in as many as 10% of patients, but further doses of intrathecal MTX are usually uneventful.

Paraplegia may follow instillation of MTX or cytarabine by lumbar puncture. The disorder is characterized by weakness and sensory loss in the legs, which evolves over several days to complete transverse myelopathy. Some patients recover, but most remain paraplegic. Extensive necrosis of the spinal cord is found at autopsy. The pathogenesis is unknown, but it appears to be idiosyncratic rather than dose related.

An early delayed reaction follows high-dose systemic MTX in about 4% of patients. The disorder usually

occurs 7–10 days after the third or fourth treatment and is characterized by stupor or coma, often associated with lateralizing neurologic signs that change from hour to hour. MRI may show diffusion-positive lesions suggestive of ischemia. Most patients recover completely and the disorder usually does not recur with subsequent doses of MTX. MTX leukoencephalopathy can occur in patients who have received a high cumulative dose of intrathecal or systemic MTX or MTX in combination with cranial RT. In adults, progressive cognitive impairment in the absence of lateralizing signs may be seen in patients who survive >6 months following treatment. Leukoencephalopathy, when clinically present, is always found on neuroimaging, but occasionally it may be found on MRI in asymptomatic patients. The neuropathologic findings consist of multifocal areas of coagulative necrosis and calcification in the white matter, often with a periventricular predominance. Unlike cerebral radionecrosis, fibrinoid necrosis of blood vessels is absent.

Alternatively, focal leukoencephalopathy may develop around an Ommaya reservoir catheter track. When MTX is injected into ventricles with elevated pressure, the drug tracks along the outside of the catheter, producing focal leukoencephalopathy seen on MRI as an enhancing mass ([Figure 6](#)); this may resolve on its own or require removal of the catheter.

Platins

Peripheral neuropathy is a dose-limiting toxicity of some platins, particularly cisplatin and oxaliplatin.^{1, 28} Neuropathic symptoms begin as tingling paresthesias in the toes and fingers; loss of reflexes and reduced vibratory and position sensation are characteristic but pain, temperature sensation, and strength are preserved. Severe, disabling sensory ataxia may result. Symptoms are often mild during treatment but they progress for months before stabilizing, making dose adjustment during treatment difficult. Gradual resolution follows, although some patients are permanently disabled. Lhermitte sign, an electric sensation in the arms, back, or legs upon neck flexion, is an occasional manifestation of platin neurotoxicity. Oxaliplatin may cause cold-induced paresthesias either during or shortly after an infusion and may also cause a sensory neuropathy.²⁸ Magnesium infusions do not prevent oxaliplatin neurotoxicity.²⁹

Ototoxicity caused by cisplatin is a result of damage to the organ of Corti. Toxicity severe enough to interfere with speech perception is uncommon, but hearing loss may or may not resolve. Seizures and encephalopathy have been reported in patients receiving cisplatin, independent of the magnesium and calcium wasting commonly caused by the drug. Vascular disease producing neurologic symptoms has been reported as a late delayed effect of cisplatin-based chemotherapy. Many such patients develop Raynaud phenomenon, and a few have developed transient ischemic attacks or cerebral infarctions. Other platinum drugs are less neurotoxic.

Taxanes

Paclitaxel and docetaxel both bind tubulin, stabilizing and promoting microtubular assembly. Both cause a predominantly sensory peripheral neuropathy, beginning with paresthesias of the toes and then fingers.^{1, 30} More severe sensory impairment and loss of reflexes develop with increasing duration of drug administration. Symptoms usually recover with drug discontinuation. Weakness is seen occasionally, but can be predominantly proximal, mimicking a myopathy, but this is likely secondary to neuropathy. Because taxanes are often used concurrently with or following other neurotoxic agents such as cisplatin, patients may develop significant symptoms with the first few doses because of additive neurotoxic effects. Nab-paclitaxel, the taxane bound to nanoparticles of albumin is less neurotoxic than the standard drug.

5-Fluorouracil

Generalized encephalopathy has been seen in association with severe systemic toxicity during therapy and may indicate an inherited deficiency of dihydropyrimidine dehydrogenase, the enzyme responsible for pyrimidine catabolism.³¹ Capecitabine, doubly esterified fluorouracil for oral use, appears to be less neurotoxic than intravenously administered fluorouracil.

Cytosine arabinoside

Intrathecal cytarabine can cause an acute chemical meningitis with confusion, fever, and CSF pleocytosis. This occurs in almost all patients who receive the liposomal preparation (DepoCyt)²⁰ and requires dexamethasone before and after every DepoCyt injection.

Intravenous high-dose cytarabine (e.g., 3 g/m² every 12 h for six doses) causes neurotoxicity in 10–25% of patients; the risk is increased with older age and poor renal function. Neurotoxicity has been documented with minimum cumulative doses of 18 g/m², but higher cumulative doses (e.g., 30–40 g/m²) are associated with a higher incidence and more severe toxicity. Commonly, a pancerebellar dysfunction starts several days after the initiation of therapy and worsens for several more days. Gradual recovery begins about 2 weeks after onset, but recovery may be incomplete especially in those with severe dysfunction. Pathologic changes include loss of cerebellar Purkinje cells and neurons in the deep cerebellar nuclei. Encephalopathy and seizures also occur, usually in the setting of cerebellar toxicity. A recrudescence of neurologic symptoms may occur with retreatment.

Other drugs

Other commonly used drugs that cause neurotoxicity include bortezomib,³² suramin, and procarbazine, all of which can cause peripheral neuropathy, although procarbazine does so rarely. Bortezomib neuropathy can be severely painful and predispose to compression neuropathies superimposed on the diffuse neuropathy. A second-generation proteasome inhibitor, carfilzomib, causes less severe peripheral neuropathy. Thalidomide causes peripheral neuropathy, but lenalidomide and pomalidomide are less neurotoxic. High-dose busulfan therapy, used to prepare patients for stem cell transplantation, can cause seizures; at standard doses, the drug is not neurotoxic. Gemcitabine, with or without radiation, has been reported to cause myositis with acute muscle pain and tenderness; it is responsive to steroids.^{1, 33} Selumetinib, an MEK inhibitor, can cause focal neck extensor weakness causing the dropped head syndrome.³⁴

Antibody-mediated neurotoxicity

Ipilimumab can cause hypophysitis with enhancing lesions seen in the hypothalamus on MRI. Chronic rituximab can induce persistent immunosuppression, which may lead to progressive multifocal leukoencephalopathy (PML) owing to reactivation of JC virus in the brain.³⁵ Restoration of immune function is the only effective therapy of this otherwise lethal disease which presents with confusion and lateralizing signs such as hemiparesis. MRI shows multiple, usually nonenhancing, white matter lesions.

Bevacizumab, and any anti-vascular endothelial growth factor (VEGF) agent, can cause hypertension, which may lead to confusion and seizures from posterior reversible encephalopathy syndrome (PRES).³⁶ PRES can be identified on MRI by the presence of white matter lesions best seen on MRI FLAIR sequence. PRES warrants immediate attention to blood pressure management. PRES has also been associated with other agents, such as tacrolimus, cyclosporin, and mycophenylate used after allogeneic stem cell transplantation along with many conventional chemotherapeutics such as the platins and gemcitabine. Blinatumomab is a bispecific T-cell receptor-engaging (BITE) antibody used to treat B-cell

acute lymphocytic leukemia (ALL). CNS toxicity with encephalopathy, seizures, and ataxia is seen in approximately 20% of patients.³⁵

Brentuximab vedotin, a CD30 antibody drug conjugate, can cause a predominantly sensory neuropathy that improves when the drug is held; it can be restarted when the neuropathy has improved.³⁵ Myalgias are also common with brentuximab vedotin.

Radiation therapy

Despite the fact that cells in the CNS turn over slowly or not at all, the brain, spinal cord, and, to a lesser degree, peripheral nerves are susceptible to damage by ionizing radiation that usually causes symptoms months or years after the radiation has been completed ([Table 10](#)).² With patients living longer after initial treatment, the problem of delayed radiation damage to the CNS is increasingly important.

Table 10 Neurologic complications of CNS irradiation

Complication	Latency	Symptoms and signs	Comments
Brain			
Acute	Hours	Increase in existing deficits, headache, nausea, vomiting, confusion, somnolence	Transient, corticosteroids help
Early	Weeks to months	Increase in existing signs, increased seizures, lethargy	Resolves over days to weeks, steroids help
Delayed			
a. Radionecrosis	6 months to years	Focal mass lesion	Treatment includes steroids and surgery, tumor often coexists
b. Dementia	1 year	Loss of cognitive function	May be subtle
c. Endocrine	Years	Hypothyroidism, amenorrhea/galactorrhea, changes in libido, growth failure	Hypothalamic or pituitary in origin
d. Secondary tumors	10–40 years, earlier if radiated as a child	Symptoms of brain tumor	Meningioma, sarcoma, malignant glioma
e. Stroke	Years	Abrupt onset of neurologic dysfunction	Large or branch vessels
Spinal cord			
Early	Weeks to months	Electric shocks with neck movement (Lhermitte symptom)	Usually transient
Delayed			
a. Myelopathy	Weeks to years	Progressive cord dysfunction, starts with sensory symptoms	Often fatal
b. Lower motor neuron syndrome	Months to years	Focal weakness and atrophy	May improve spontaneously

Brain toxicity

Acute reactions, occurring within hours of a dose of RT, are rare with current fractionation schedules when patients are pretreated with dexamethasone.¹ Patients with large or multifocal tumors and cerebral edema, especially those with symptoms of increased ICP, are more likely to experience this side effect. Symptoms and signs of acute RT toxicity include worsening of existing deficits, headache, nausea and vomiting, and lethargy. These are usually transient and respond to corticosteroids. The etiology has been ascribed to radiation-induced disruption of the blood–brain barrier with worsening cerebral edema.

Early delayed encephalopathy occurs a few weeks to a few months after RT. Patients being treated for cerebral tumors may develop worsening of lateralizing signs. Symptoms may persist for days to weeks and are often relieved by corticosteroids; complete resolution is usual. Early delayed encephalopathy is

often confused with tumor progression and is sometimes called pseudo-progression. MRI reveals an enhancing lesion indistinguishable from progressive tumor. Advanced imaging with PET or perfusion MRI sometimes clarifies the situation; however, gradual resolution of symptoms may be the only confirmation of the cause of the deterioration.¹

Delayed radiation toxicity is the most serious complication of brain RT, and radionecrosis is its most common manifestation, arising months to years after treatment.^{1, 2, 37} In one study, cerebral radionecrosis occurred in 6% of patients treated with 4500 cGy or more.³⁷ The total dose is the most important risk factor, and there is a threshold near 6000 cGy above which radionecrosis becomes common. However, high daily fractionation schedules also carry increased risk, and radionecrosis is seen most commonly after stereotactic radiosurgery (SRS) for brain metastases. Headache, focal deficits, and seizures are the usual symptoms. CT/MRI reveals a contrast-enhancing lesion with surrounding edema; PET or perfusion MRI may differentiate tumor that is hypermetabolic and hypervascular from necrosis that is hypometabolic and avascular. However, the differentiation between radionecrosis and tumor is often difficult, and biopsy may be required. Marked symptomatic improvement follows treatment with dexamethasone, and some patients remain well after steroids are discontinued. Surgical resection of the necrotic material is often necessary. Reports that anticoagulation or hyperbaric oxygen relieve symptoms require confirmation. Bevacizumab may prove effective.³⁸

Radiation may also cause dementia unassociated with necrosis.^{1, 2} The MRI shows ventricular dilatation, sulcal atrophy, and white matter hyperintensity. Some of these patients respond to ventriculoperitoneal shunting albeit incompletely and temporarily.¹ Cerebral infarction may result from occlusion of cervical or intracranial arteries that have received large doses of RT.³⁹ Vascular malformations may appear and bleed many years after brain RT. Complicated migraine-like episodes may occur in patients after cranial irradiation called SMART syndrome (stroke-like migraine attacks after RT).⁴⁰ Endocrinologic dysfunction may arise years after RT, resulting from either hypothalamic or pituitary failure. Brain tumors may occur decades after cranial RT or radiosurgery administered in adulthood, but latency is often much shorter (median 6 years) in those irradiated in childhood. Radiation-induced brain tumors include meningioma, sarcoma, and malignant glioma.¹

Spinal cord toxicity

Spinal cord damage caused by RT is uncommon. Transient, electric shock-like sensations following neck flexion (Lhermitte symptom) may occur weeks to months after RT to the cervical cord, including mantle RT for Hodgkin disease.¹ Spontaneous resolution is the rule. Progressive radiation myelopathy, on the other hand, is a devastating complication with onset months to years (median 20 months) following RT. The incidence of radiation myelopathy is affected by the total RT dose and dose per fraction; an estimate of the ED5 (5% incidence of complication) is between 5700 and 6100 cGy for RT delivered in 200 cGy fractions. Symptoms of radiation myelopathy usually begin with sensory changes in the legs and gradually progress to sensory loss, weakness, and sphincter dysfunction. Pain may be present at the level of the cord damage. Unlike SCC, sensory and motor findings are often asymmetric at onset and a Brown-Séquard syndrome is often present. The MRI reveals a normal, enlarged, or atrophic cord that may contrast enhance, but extrinsic compression is absent ([Figure 7](#)). Steroids do not reverse the deficits. Anticoagulants and hyperbaric oxygen have been reported to be effective, but this has not been verified, and myelopathy is usually permanent.¹

Figure 7 MRI demonstrating radiation myelopathy. The hypodense thoracic vertebral body is the site of a bone metastasis from breast cancer for which the patient was radiated. Some months later, the patient developed a myelopathy, and the contrast-enhancing lesion seen in the spinal cord represents radiation damage.

Cerebrovascular complications of cancer

Cerebrovascular lesions are the second most common neuropathologic finding, after metastases, in postmortem studies of cancer patients. Hemorrhage into a metastasis is the most common cause of intracranial hemorrhage in cancer patients;⁴¹ it is most common in lung cancer, but occurs proportionately more frequently in melanoma, thyroid, renal, and germ cell metastases. Nonmetastatic intracerebral hemorrhage is seen in patients with leukemia, thrombocytopenia, or coagulopathy.¹ Subdural hemorrhage may occur in association with dural metastases or coagulopathy.⁴² A hemorrhage may cause abrupt neurologic symptoms with headache, vomiting, lethargy, and focal deficits or may be unsuspected before obtaining a brain scan. For patients with intracerebral hemorrhage resulting from coagulopathy or thrombocytopenia, the underlying problem should be treated and the patient observed. Subdural hematomas and some hemorrhages into metastases may benefit from surgical evacuation.

Cerebral infarction is as common as hemorrhage.^{43, 44} Infarctions secondary to accelerated atherosclerosis take place decades following RT that has included cervical or cerebral vessels in the irradiated field. RT for head and neck cancer predisposes to carotid stenosis, and intracranial arterial stenosis with subsequent infarction may occur following cranial RT. Septic cerebral infarction is usually secondary to *Aspergillus*, *Candida*, or *Mucor*. These opportunistic organisms produce a vasculitis, and the infarctions are often multiple and hemorrhagic. *Aspergillus* is the most common causative agent and is always associated with pulmonary infection. Antifungal therapy is usually unsuccessful, and the outcome is often fatal.

Cerebral venous thrombosis (e.g., superior sagittal sinus thrombosis) may result from compression or invasion of vascular structures by a metastasis, or from a coagulopathy.¹¹² Clinical features include headache, focal deficits, and seizures. The diagnosis can be made by MRI combined with magnetic resonance venography. Lumbar puncture reveals an elevated opening pressure and frequently red cells in the CSF. Spontaneous resolution usually occurs unless dural metastasis is the cause, in which case RT is required. Anticoagulation is safe and should be considered for progressive neurologic symptoms, even when due to hemorrhage from venous infarction; however, most patients recover fully without treatment.

Cerebral embolism accounts for more than one-half of strokes in patients with cancer.^{43, 44} It may be cardioembolic, including nonbacterial thrombotic endocarditis (NBTE), which is most common with lung and GI carcinomas. Infarctions in patients with NBTE are often multiple and hemorrhagic. Diffuse encephalopathy and focal deficits usually coexist. Approximately one-third of patients with NBTE also have laboratory evidence of disseminated intravascular coagulation (DIC). Two-dimensional echocardiography is rarely helpful, but transesophageal echocardiography may demonstrate the valvular vegetations. Anticoagulation with heparin should be considered; evidence suggests that warfarin is not helpful. It is unknown if agents such as direct thrombin or factor Xa inhibitors are equally effective. DIC alone may result in cerebrovascular thrombosis. Neurologic symptoms usually begin abruptly with diffuse encephalopathy and fluctuating multifocal deficits. Enhanced MRI is typically negative, although small foci of ischemia are seen occasionally on diffusion-weighted sequences. Anticoagulation with heparin may prevent progressive neurologic dysfunction.

Paraneoplastic neurologic syndromes

Paraneoplastic syndromes refer to disorders of unknown etiology that occur with increased frequency in patients with cancer ([Table 11](#)).³ Compared with known complications of cancer, paraneoplastic syndromes are rare, seen in less than 1% of patients with cancer. As paraneoplastic syndromes precede the diagnosis of cancer in about two-thirds of cases, prompt recognition may lead to early diagnosis and cure of the underlying neoplasm. These disorders often debilitate the patient to a greater degree than the malignancy, but some of the syndromes improve with successful treatment of the cancer.

Table 11 Paraneoplastic neurologic syndromes

Syndrome	Associated cancer ^a	Clinical features
Brain		
Limbic encephalopathy ^b	SCLC	Depression, memory loss, confusion, abnormal CSF
Brainstem encephalopathy ^b	SCLC	Ataxia, cranial nerve dysfunction, corticospinal dysfunction, abnormal CSF
Subacute cerebellar degeneration	Breast, ovary, SCLC, Hodgkin	Ataxia, dysarthria, nystagmus, normal CSF
Opsoclonus, myoclonus	Lung	Jerky, irregular movements of eyes and skeletal muscles
Optic neuritis, retinal degeneration	SCLC	Painless loss of vision, transient visual obscuration
NMDA receptor encephalitis Spinal cord	Teratoma	Seizures, psychosis, rhythmic movements, impaired cognition
Necrotizing myelopathy	SCLC, lymphoma, leukemia	Ascending myelopathy
Subacute motor neuronopathy	Hodgkin and NHL	Patchy weakness, atrophy, and fasciculations
Dorsal root ganglia		
Subacute sensory neuronopathy ^b	SCLC	Dysesthesias, sensory ataxia, areflexia
Peripheral nerve		
Gammopathy associated neuropathy	Myeloma	Sensory loss, weakness, reflex loss
Acute polyradiculitis (Guillain–Barré)	Lymphoma	No cells in CSF; high CSF protein
Neuromuscular junction		
LEMS	SCLC	Proximal weakness, decreased reflexes, ocular muscles spared
Myasthenia gravis	Thymoma	Weakness, ocular muscles often involved
Muscle		
Dermatomyositis, polymyositis	Lung, breast, ovary, GI	Weakness, elevated CPK

^a The most commonly associated tumors are listed.

^b Often occur in association with each other.

Abbreviations: CPK, creatine phosphokinase; CSF, cerebrospinal fluid; GI, gastrointestinal; LEMS, Lambert–Eaton myasthenic syndrome, NHL, non-Hodgkin lymphoma; NMDA, *N*-methyl D-aspartate; SCLC, small-cell lung cancer.

The etiologies of these syndromes are not well understood, but most are suspected to have an autoimmune basis. The strongest evidence for an autoimmune disorder is for the Lambert–Eaton myasthenic syndrome

(LEMS), in which autoantibodies inhibit the function of presynaptic calcium channels at the neuromuscular junction, resulting in weakness. Examination demonstrates an increase in muscle power after repetitive muscle contraction (the opposite of myasthenia gravis) and absence of deep tendon reflexes. These findings, along with autonomic and sensory complaints of dry mouth, impotence, and thigh paresthesias, point to a nerve disorder. Several other paraneoplastic syndromes are associated with the presence of specific antibodies, including subacute sensory neuronopathy, limbic encephalitis, subacute cerebellar degeneration, and gammopathy-associated neuropathies. These specific antibodies serve as markers that not only identify the syndrome as paraneoplastic but also suggest the site of the underlying tumor.³

A variety of therapies directed at immunomodulation, including plasmapheresis, corticosteroids, and intravenous immunoglobulin, have failed to reverse the neurologic impairment associated with most paraneoplastic disorders. However, some syndromes, such as the LEMS and NMDA receptor encephalitis, respond to immunosuppressive treatments. Some patients with paraneoplastic neurologic disorders have reversal or stabilization of their neurologic dysfunction when the underlying malignancy is treated effectively and this should be a therapeutic priority for all of these patients.

Chapter 127

Dermatologic complications of cancer chemotherapy

Anisha B. Patel, MD ■ Madeleine M. Duvic, MD

Overview

Dermatologic complications of cancer chemotherapy have become increasingly significant, especially with the continued development of new targeted antineoplastic agents. The frequency of mucocutaneous complications in cancer chemotherapy is often a reflection of the increased proliferative nature of affected tissues, such as the mucous membranes, skin, hair, and nails, which renders them particularly susceptible to the actions of chemotherapeutic drugs. This chapter reviews the specific side effects associated with targeted therapies and the more classic side effects of cytotoxic chemotherapies and their associated drugs.

Diagnosis of cutaneous reactions in the cancer patient is complicated by the degree of their malignancy, concomitant diseases, polypharmacy, and immunosuppression. With the advances in bone marrow transplantation, graft versus host disease (GVHD), opportunistic infections, and malignancies are also being seen more frequently and may mimic and complicate the diagnosis of chemotherapy-induced reactions. The major cutaneous reactions and a variety of miscellaneous reactions are discussed in this chapter and are listed in [Table 1](#). As seen in [Table 2](#), these reactions occur in varying degrees of frequency and severity among the classes of chemotherapeutic drugs. Although dermatologic complications are rarely fatal, it is important to recognize potential reactions as they may result in significant morbidity, chemotherapy cessation or dose reduction, cosmetic disfigurement, and psychological distress. Proper treatment of potentially dose limiting cutaneous toxicity may also allow ideal schedules of chemotherapy administration and optimization of response.

Table 1 Immunologically mediated drug hypersensitivity reactions

<i>IgE-dependent drug reactions</i> (formerly type I)	L-asparaginase, paclitaxel, docetaxel, teniposide, cisplatin (intravesical)	Urticaria Angioedema Anaphylaxis
<i>Cytotoxic drug-induced reactions</i> (antibody against a fixed antigen; formerly type II)		Petechiae secondary to drug-induced thrombocytopenia
<i>Immune complex-dependent drug reactions</i> (formerly type III)		Vasculitis Serum sickness Urticaria (certain types)
<i>Delayed-type, cell-mediated drug reactions</i> (formerly type IV) versus undefined	Procarbazine Cytarabine Nucleoside analogues (both can also have IgE-dependent and immune-complex-mediated drug reactions)	Exanthematous/morbilliform eruption Fixed drug eruption Lichenoid drug reaction SJS/TEN AGEP DRESS
No reported immunologically mediated reactions	Nitrosoureas Vinca alkaloids Altretamine Dactinomycin	

Source: Adapted from Ref. 1.

Table 2 Major cutaneous reactions associated with chemotherapy

Drug hypersensitivity reactions (morbilliform, erythema multiforme/Stevens Johnsons/toxic epidermal necrolysis)
Mucosal reactions (stomatitis, aphthae)
Nail reactions (hyperpigmentation, onycholysis, paronychia)
Extravasation reactions (irritant, vesicant)
Pigmentary changes (hyperpigmentation, vitiligo)
Radiation-associated reactions (radiation enhancement, radiation recall, photosensitivity)
Alopecia (anagen effluvium, scarring alopecia)
Acral reactions (acral erythema/toxic erythema of chemotherapy, hand–foot skin reaction)
Neutrophilic dermatoses (Sweet's syndrome, erythema nodosum)
Cutaneous eruption of lymphocyte recovery
Neoplasms (keratoses, squamous cell carcinoma, lentigines, melanoma)

Drug hypersensitivity reactions

“Traditional” drug reactions have been categorized into immunologic and nonimmunologic or toxic. Of the immunologic drug reactions, there are four subtypes, formerly types I–IV, that are outlined in [Table 3](#).

The most common reactions are delayed-type, T-cell-mediated drug reactions and include the morbilliform or exanthematous drug eruption. They clinically present as erythematous macules and thin papules on the trunk spreading to the extremities and are usually asymptomatic. When the rash is painful, the differential diagnosis includes erythema multiforme (EM), Stevens Johnsons syndrome (SJS), and toxic epidermal necrolysis (TEN). EM is characterized by targetoid erythematous papules and plaques that tend to start on the extremities, can involve the palms and soles, and, when advanced, form central bullae and spread to the oral and genital mucosa. SJS and TEN, however, start with centrally distributed dusky papules and plaques that coalesce and vesiculate and have severe mucosal involvement. SJS involves <10% of body surface area and TEN involves >30% of body surface area. The mortality rate of SJS is 1–5% and that of TEN is 25–35%.¹

Table 3 Most common mucocutaneous reactions of the major classes of chemotherapeutic drugs

Alkylating agents	Antibiotics
Hyperpigmentation	Alopecia
Hypersensitivity	Stomatitis
	Chemical cellulitis
	Hyperpigmentation
	Radiation-associated reactions
Vinca alkaloids	Antimetabolites
Alopecia	Acral erythema
Chemical cellulitis	Alopecia
Inflammation of keratosis	Hyperpigmentation
Neutrophilic eccrine hidradenitis	Radiation-associated reactions

Drug reaction with eosinophilia and systemic (DRESS) and acute generalized exanthematous pustulosis (AGEP) have unclear pathogeneses. The cutaneous findings in DRESS are not specific; however, the peripheral edema, lymphadenopathy, and liver transaminitis are characteristic. Finally, AGEP presents with abruptly appearing sheets of cutaneous pustules. It usually begins on the face or intertriginous areas, perhaps with burning and itching. It can be accompanied by fever, neutrophilia, and eosinophilia.² Ninety percent of cases are drug induced, mostly with antibiotics such as β-lactams, cephalosporins, fluconazole, nystatin, and terbinafine.¹ Other reported triggers include the histone deacetylase inhibitor bryostatin,³ imatinib, mercury, thallium, iohexol, patch testing, pseudoephedrine, diltiazem, furosemide, and viral infections.⁴ These two reactions are less common than the exanthematous eruption and can be more severe.

Targeted cancer therapeutics

These drugs started to emerge in the mid-1990s and we are still delineating all of the side effects. Although the systemic toxicities are decreased, many of the signaling mediators targeted also affect the epithelium, and these effects are much more specific than previous chemotherapy cutaneous reactions. This change is reflected in the literature of even the clinical trials, where adverse events were previously described as a “rash” or “lesion,” the descriptions have become more specific, which makes it easier to anticipate and track different reactions.

Numerous targeted therapies are available; however, only those with specific cutaneous reactions occurring at high incidences are discussed below.

Epidermal growth factor receptor (EGFR) inhibitors

Epidermal growth factor receptor (EGFR) has been recognized as a significant regulator of cancer cell proliferation, apoptosis, angiogenesis, and metastasis. Ligand binding to the receptor causes receptor dimerization, which activates the intracellular tyrosine kinase domain.⁵ EGFR also plays a significant role in normal skin homeostasis.⁶ Activation of EGFR in epidermal keratinocytes promotes cell cycle progression, differentiation, and migration, which are all critical for normal skin function and wound healing.⁷ The most common cutaneous side effects for EGFR inhibitors are an acneiform eruption, paronychia, xerosis, eczema, mucositis, and geographic tongue. Acne folliculitis appears on the face and upper trunk 8–10 days after treatment initiation. In phase 1 trials, erlotinib at the maximally tolerated dose induced a pustular acneiform eruption in 50% of cases during the second week of therapy.⁸ The eruption can be extremely pruritic and EGFR inhibitors have cutaneous side effects that lead to dose alteration in >75% of patients.⁹ The presence and severity of acne folliculitis has been correlated with tumor response and survival.¹⁰ This reaction has been reported with cetuximab, panitumumab, nimotuzumab, erlotinib, and gefitinib.^{11–13} Oral tetracyclines combined with topical steroids are the gold standard treatment. Retinoids and topical antibiotics have not been proven useful in these patients as the etiology is not follicular plugging and rupture, but epithelial dysregulation.¹¹ *Staphylococcus* colonization can worsen the eruption and cultures and antibiotics are recommended if lesions are pustular or crusted ([Figure 1](#)).

Figure 1 Severe acneiform eruption of the face associated with cetuximab therapy.

The human epidermal growth factor receptor (HER)1/2 blockers have the same side effects as EGFR inhibitors, but are milder. Trastuzumab, lapatinib, dacomitinib, and afatinib all have had reported acneiform eruptions.^{14–17} Similarly, the vascular endothelial growth factor (VEGF) inhibitors have

overlap between the EGFR inhibitors, with mucositis and geographic tongue, and the multikinase inhibitors, with hand–foot skin reaction (HFSR), which is discussed below.¹⁸

BCR-ABL tyrosine kinase inhibitors

Imatinib mesylate targets the *BCR-ABL* gene and has been used in the treatment of chronic myeloid leukemia and acute lymphoblastic leukemia. It has been shown to frequently cause dose-dependent cutaneous reactions, including facial edema, morbilliform eruption, urticaria, eczematous dermatitis, and AGEP.^{19, 20} One patient developed an eczematous rash with histologic features of mycosis fungoides.²¹

Second- and third-generation Bcr–Abl-specific TKIs, dasatinib, nilotinib, and ponatinib have been associated with follicular lichenoid eruptions of the scalp, face, and body that can be pruritic and lead to scarring alopecia.²² This alopecia is irreversible, even upon dose cessation.

Multikinase inhibitors

Sunitinib and sorafenib are the multikinase inhibitors targeting VEGF receptor, platelet-derived growth factor receptor (PDGFR), c-Kit, and FLT-3. Sorafenib also inhibits RAF kinase. They were developed for advanced renal cell carcinoma but have also been used for hepatocellular carcinoma, gastrointestinal stromal tumors, and thyroid cancer. They are most associated with the HFSR as well as mucositis, alopecia, xerosis, and xerostomia. However, because they overlap with multiple groups of targeted therapies, the cutaneous squamous cell carcinoma (SCC) of BRAF inhibitors and the acneiform eruption of VEGF inhibitors can be seen as well.²³

HFSR appears within 2–4 weeks of starting the therapy and is present in one-fifth to one-third of patients, with sorafenib having a slightly higher incidence. Patients develop a focal keratoderma at points of friction and pressure, which can vesiculate, leading to painful blisters ([Figure 2](#)). The risk of developing HFSR depends on which drug the patient is on and which cancer type is being treated. The original proposed mechanism was that the VEGFR blocking capabilities of these drugs caused the patients to have a poor response to damage caused by pressure and trauma.^{24, 25} Most recently, the Fas/Fas ligand response was implicated, proven by blocking the reaction by administering anti-Fas ligand antibody. These are the same mediators of Stevens Johnsons and TEN.²⁶

Figure 2 Hand–foot skin reaction with sorafenib therapy.

Although more common in multikinase inhibitors such as sorafenib and sunitinib, these lesions have been

reported with BRAF inhibitors.²⁷ These are distinct from the more common hand–foot syndrome/acral erythema (AE)/toxic erythema of chemotherapy seen with cytotoxic chemotherapies. HFSR does not have the diffuse erythema and edema of hand–foot syndrome and also has a longer latency period before appearing (2–4 weeks). HFSR usually self-resolves with continued treatment with the multikinase inhibitors.²⁸

mTOR inhibitors

Overlapping with the EGFR signaling pathway is the PI3K/AKT pathway, which activates mammalian target of rapamycin (mTOR). This molecule is associated with cell growth and angiogenesis and sirolimus or rapamycin was the original drug in this category, followed by everolimus and temsirolimus. All are associated with the papulopustular rash of EGFR inhibitors, which has an incidence of 45.8% in the most recently developed drug, temsirolimus. They all also can induce the more classic morbilliform drug eruption and oral mucositis. As opposed to cytotoxic chemotherapies, individual deeper oral ulcerations more similar to aphthous stomatitis are present as well. Finally, everolimus and temsirolimus also had a population with eczematous dermatitides.²⁹

BRAF inhibitors

BRAF inhibitors, first introduced in metastatic melanoma patients, have significant cutaneous side effects that include inflammatory, follicular, and neoplastic eruptions. These side effects lead to dose cessation or reduction in <10% of patients.³⁰ Of the inflammatory cutaneous toxicities, neutrophilic dermatoses, including acute febrile neutrophilic dermatosis (Sweet's syndrome) and neutrophilic panniculitis, have been attributed to the use of BRAF inhibitors.^{30–36}

Two patients with the erythematous pseudovesicular papules and plaques of Sweet's syndrome of the trunk and extremities presenting with systemic symptoms of fever and arthralgias have been reported.^{36, 37} The patients with neutrophilic panniculitis presented with tender, erythematous nodules of the legs and occasionally arms, and had histology consistent with a neutrophilic lobular panniculitis.^{31–34} Vitiligo,³⁸ cutaneous sarcoidosis,³⁹ Grover's disease,⁴⁰ and hidradenitis suppurativa⁴¹ have been reported less commonly.

Patients on BRAF inhibitors also have increased radiation sensitivity to UV (ultraviolet) light and radiation therapy with quicker and more severe sunburns and acute radiation dermatitis, respectively.^{42, 43} Further, cases of radiation recall dermatitis have been reported as well.^{44, 45}

Epidermal and follicular dysregulation contribute significantly to BRAF inhibitor cutaneous side effects. Palmoplantar hyperkeratosis or keratoderma is a thickening of the epidermis without inflammation presenting as thick yellow plaques of the palms and soles similar to a large callus. Most commonly, the keratoderma is seen on the feet in pressure points, without vesiculation.⁴⁶ A superficial keratotic plugging of the follicle results in a keratosis pilaris-like eruption. This is seen frequently on the trunk and extremities and is more often asymptomatic than pruritic. It was noted in 5–9% of patients in phase 2 and 3 trials,^{47, 48} although this may be underreported.^{27, 49, 50}

Neoplastic lesions cause the highest morbidity in these patients. Actinic keratoses (AKs) represent precancerous epithelial lesions typically associated with chronic sun damage. The incidence of AKs is 6–16% in vemurafenib patients^{47–49} and 5–10% in dabrafenib patients.^{46, 51–53} Wart-like keratoses are papillated, hyperkeratotic, well-demarcated papules that are often inflamed and appear in an eruptive nature during BRAF inhibitor therapy. They appear about 3–4 months after therapy.⁵³ These lesions are

not true verruca as human papilloma virus testing has been negative in multiple reports.^{54, 55} Prompt treatment of both types of lesions with cryotherapy, photodynamic therapy, curettage, and topical 5-fluorouracil (5-FU) helps prevent SCC formation ([Figure 3](#)).

Figure 3 Squamous cell carcinoma with vemurafenib therapy.

Patients with SCC usually present with dome-shaped, well-demarcated, hyperkeratotic, erythematous papules, and nodules. They are quickly growing and more prevalent in older patients with chronic sun damage.⁴⁶

The incidence of SCC is 4–31% in vemurafenib patients^{47, 48, 56} and 6–11% in debrafenib patients.^{51, 52, 57, 58} Sosman et al. showed that they are predominantly well-differentiated or keratoacanthoma-type SCC, which are less aggressive than the normal array of sun-induced SCC. The median time to occurrence is 8 weeks. HRAS upregulation has been implicated in a portion of BRAF-induced SCC causing a paradoxical upregulation of the MAP kinase pathway.⁴⁷

Patients have been reported to have involution of nevi as well as new and darkening nevi. The new nevi have shown wild-type BRAF, lack the V600E mutation, and appear in 8–14 weeks.⁵⁹ These lesions have been biopsied as common nevi, dysplastic nevi, and new primary cutaneous melanomas. Five of 464 patients in the phase 2 and 3 clinical trials with vemurafenib had a new melanoma.⁶⁰

MEK inhibitors

Selumetinib and trametinib, two new MEK inhibitors, just downstream of BRAF have similar side effects to the EGFR inhibitors.⁶¹ Interestingly, the addition of a MEK inhibitor to a BRAF inhibitor decreases the squamous proliferations seen with the BRAF inhibitor alone, possibly addressing the HRAS mutation as well.

Immunomodulators

With advances in biotechnology, there have been increased developments of cytokines and

immunotherapeutic agents, which target cancer at the cellular level. This class of drugs is less specific than the targeted therapies described above and works by enhancing the inflammatory response to metastatic and hematologic tumors. The cutaneous side effects are less specific than those described above, and generally encompass reactive inflammatory processes.

Immune check point inhibitors

Immunomodulatory drugs used for melanoma include ipilimumab and nivolumab or pembrolizumab. Ipilimumab is a monoclonal antibody targeting CTLA4, which inhibits binding of the costimulatory molecule, CD28. Blocking CTLA4 allows unopposed activation of cytotoxic T cells and stimulates the immune response to metastatic melanoma. The main side effects are morbilliform or eczematous eruptions.⁶² Similarly, pembrolizumab blocks PD-1, which, when bound to its ligand, decreases the cytotoxic effects of T cells. This molecule is upregulated in tumor cells and is thought to be a more specific target than CTLA4. The cutaneous side effects are similar to ipilimumab, but also include vitiligo.⁶³

Cytokines

Roles have already been established for interleukin 2 (IL-2) as alternative treatment for advanced metastatic melanoma and renal cell cancer and for interferon- α (IFN- α) as standard treatment for chronic myelogenous leukemia, hairy-cell leukemia, cutaneous T-cell lymphoma, melanoma, and Kaposi sarcoma (KS). In addition to significant toxicities ([Table 4](#)) such as capillary leak syndrome, there is a 72% incidence of cutaneous reactions reported with IL-2.⁶⁴ Commonly, a pruritic diffuse erythroderma occurs 1–3 days after administration and resolves with desquamation 2 days after cessation of therapy ([Figure 4](#)).⁶⁴ This reaction is clinically similar to toxic shock syndrome and has been associated with staphylococcal sepsis in some patients. Intra-arterial IL-2 also causes hypersensitivity to iodine-containing contrast dyes in up to 30% of patients.⁶⁵ Of potential importance, one study of IL-2 for metastatic melanoma has reported a possible correlation between the development of vitiligo and good prognosis.⁶⁶ Although IFN- α is relatively less toxic than IL-2, several cutaneous reactions have been reported in the literature. Perhaps one-third of patients will develop a local injection-site reaction. In a study of 1000 patients receiving IFN- α , alopecia and herpes labialis exacerbation were common with 10% and 5% incidence, respectively.^{65, 67} Similar to nonmodified recombinant IFN- α , pegylated IFN- α has been shown to cause local cutaneous ulcerations at sites of subcutaneous injection.⁶⁸ Both IFN- α and IL-2 also induce and/or exacerbate seborrheic dermatitis and psoriasis.⁶⁵

Table 4 Cytokine reactions

Other INF- α reactions	Other IL-2 reactions
Eosinophilic fasciitis	Erosions in surgical scars
Exacerbation of herpes labialis	Hypersensitivity to iodine contrast dye
Increased growth of eyelashes	Linear IgA bullous dermatosis
Necrotizing vasculitis	Pemphigus vulgaris (de novo, recurrent)
Paraneoplastic pemphigus	Poly/dermatomyositis exacerbation
Psoriasis exacerbation and de novo	Psoriasis exacerbation
Thyroiditis	Staphylococcal infections
	TEN-like bullous desquamation
	Vitiligo

Figure 4 Erythematous rash associated with IL-2 therapy in a melanoma patient.

Alopecia

Alopecia is the most common dermatologic complication associated with chemotherapy. While most drug-induced alopecias involve a telogen effluvium pattern by inducing normal hairs to synchronize their cycles, the anagen effluvium pattern of hair loss is the most common type of alopecia produced by chemotherapeutic agents ([Table 5](#)), with the exception of IL-2 and IFN- α therapy. In chemotherapy, anagen effluvium is caused by the abrupt cessation of the high mitotic activity of hair matrix cells in the anagen phase of hair follicles.⁷⁰ Anagen effluvium manifests within 1–2 weeks after the beginning of chemotherapy but is most noticeable 1–2 months later.⁷¹ Hair regrowth can usually be expected 5 months after the end of chemotherapy, although hair color and texture may change.⁶⁹ Permanent alopecia has been reported with busulfan/cyclophosphamide therapy.⁷²

Table 5 Chemotherapeutic agents associated with alopecia

Most common or severe		Least common or severe	
Bleomycin	Ifosfamide	Amsacrine	Melphalan
Cisplatin	Interferon-a	Busulfan	Mercaptopurine
Cyclophosphamide	Irinotecan	Carboplatin	Methotrexate
Cytarabine	Mechlorethamine	Carmustine	Mitomycin
Dacarbazine	Nitrosoureas	Chlorambucil epirubicin	Procarbazine
Dactinomycin	Paclitaxel	Gemcitabine	Teniposide
Daunorubicin	Thiotepa	Hydroxyurea	Vinorelbine
Docetaxel	Topotecan		
Doxorubicin	Vinblastine		
Etoposide	Vincristine		
Fluorouracil	Vindesine		
Idarubicin			

Source: Adapted from Ref. 69.

Hair loss often has emotional impact on patients receiving chemotherapy. Unfortunately, there are currently no widely accepted methods of prevention and treatment for alopecia, although scalp hypothermia, minoxidil, vitamin D3, cyclosporine, and topical doxorubicin monoclonal antibody have been studied.^{73, 74}

Stomatitis

Stomatitis and other oral complications of cancer chemotherapy are discussed in 136 and 137.

Nail reactions

Hyperpigmentation is the most common nail abnormality encountered in patients receiving chemotherapy, particularly in dark-skinned patients.⁷⁵ Hyperpigmentation due to chemotherapy-induced melanocyte stimulation should be distinguished from yellow nail syndrome (YNS). YNS nails have increased transverse curvature, absent lunulae, and no cuticle. Suggested etiologies include paraneoplastic process, AIDS (acquired immune deficiency syndrome) association, and drug induction ([Figure 5](#)).⁷⁶

Figure 5 Docetaxel-induced nail hyperpigmentation and onychodystrophy.

Other common nail manifestations include horizontal depressions of the nail plate called Beau's lines ([Figure 6](#)), horizontal white discoloration of the entire width of the nail plate called Mees lines, horizontal white discoloration involving partial nail width called leukonychia, onycholysis, and onychodystrophy. Associations between bleomycin and nail loss; hydroxyurea and brittle nails; and etoposide and nail bed pigmentation have also been reported in the literature.^{75, 77} With the increased use of EGFR inhibitors, paronychia, inflammation of the nail fold, is seen more commonly and can be extremely painful. Superinfections with *Staphylococcus aureus* and *Candida albicans* are common. Other onychopathies and their associated chemoagents are summarized in [Table 6](#). Patients can be reassured that these nail changes are generally benign and resolve after discontinuation of the causative agent and the affected nails grow out. However, nails damaged by chemotherapy are more susceptible to infection by yeast, dermatophytes, and pseudomonas. Infections may cause lasting damage to the matrix that will not resolve.

Figure 6 Hyperpigmentation and Beau's lines.

Table 6 Summary of nail abnormalities and associated chemoagents

Onychopathy	Associated chemoagents
Beau's lines	Taxanes, bleomycin, cisplatin, doxorubicin, melphalan, vincristine
Transverse leukonychia	Adriamycin
Muehrcke lines	Doxorubicin, cyclophosphamide, vincristine, leucovorin, levamisole, methotrexate
Onycholysis	Taxanes, doxorubicin, fluorouracil, mitoxantrone, bleomycin
Onychomadesis, defluvium unguium	Taxanes, bleomycin, fluorouracil, mercaptopurine, mitoxantrone
Ischemic changes	Bleomycin, taxanes doxorubicin methotrexate nitrogen mustard etoposide cyclophosphamide busulfan melphalan
Melanonychia	Bleomycin, cyclophosphamide, daunorubicin, doxorubicin, fluorouracil, hydroxyurea, aminoglutethimide, busulfan, cisplatin, dacarbazine, docetaxel, idarubicin, ifosfamide, melphalan, methotrexate, mitomycin, and mitoxantrone
Nonmelanotic pigmentation	5-FU
Acute paronychia	Methotrexate taxanes
Pyogenic granuloma	Cetuximab, gefitinib

Extravasation reactions

Extravasation injury is a well-known adverse event that occurs when offending drugs escape from the veins or intravenous catheters into subcutaneous tissues. Accidental extravasation occurs in approximately 0.1–6% of patients receiving intravenous chemotherapy (Table 7).⁷⁸ The cutaneous manifestations of extravasation may range from discomfort and mild erythema to severely painful skin necrosis, ulcerations, and damage to deep tissue structures.

Table 7 Chemotherapeutic agents associated with chemical cellulitis

Most common	Least common		
Dactinomycin	Amsacrine	Esorubicin	Plicamycin
Daunorubicin	Bisantrene	Etoposide	Pyrazofurin
Doxorubicin	Bleomycin	Fluorouracil	Streptozocin
Mitomycin	Carmustine	Idarubicin	Vinblastine
	Chlorozotocin	Melphalan	Vincristine
	Cisplatin	Mechlorethamine	Vindesine
	Dacarbazine	Mitoxantrone	Vinorelbine
	Epirubicin	Paclitaxel	

Extravasated cytotoxic agents generally cause two types of local cutaneous reactions: irritant and vesicant reactions. Irritants cause a short-lived and self-limited phlebitis and tender, warm, erythematous reaction along the vein or at the site of intravenous administration. A variant of this local irritation is an erythematous and urticarial hypersensitivity flare reaction that has been associated with the anthracyclines. Vesicants initially cause a similar reaction; however, the irritation may worsen, depending on the amount of drug that has extravasated, leading to nerve and tendon damage and subsequent neurologic deficits, contractures, and joint stiffness. The extent of tissue damage in extravasation largely depends on the concentration, volume, and vesicant nature of the extravasated agent.^{78, 79}

Paclitaxel can induce an extravasation recall reaction, in which extravasation of the agent at one site has induced a cutaneous reaction, ranging from erythema to ulcerations, at a previous extravasation site.⁸⁰ Central lines may dislodge, or venous vessels may be perforated with potentially disastrous consequences, including mediastinitis presenting with fever, severe pleuritic pain, upper extremity and neck swelling, and a widened mediastinum.

Vesicant injury displays poor healing and often continues to worsen, necessitating surgical intervention. Vesicants delay fibroblastic wound contraction and have the ability to bind to DNA, possibly allowing them to be recycled and retained in the tissue to induce damage for a longer duration.⁷⁹ One-third of all vesicant extravasations will develop into ulcerations, and vigilant recognition and management of extravasation plays a major role in limiting tissue injury.⁸¹ When extravasation is suspected, prompt discontinuation of the infusion is recommended, followed by aspiration of residual drug and removal of the catheter. Local cold application and elevation of the affected extremity are commonly used and helpful.⁸⁰ Intermittent local cooling alone has an 89.1% success rate in preventing ulceration.⁸² For the vinca alkaloids, heat application is recommended instead, as cold application may actually induce ulceration.⁸¹

The use of antidotes is controversial, and some antidotes such as sodium bicarbonate may be harmful or ulcerative. Sodium thiosulfate (mechlorethamine), hyaluronidase (vinca alkaloids), granulocyte macrophage colony-stimulating factor (doxorubicin), and pyridoxine (mitomycin) have been

recommended as local injections.^{83–85} The success of locally injected corticosteroids has been variable as few inflammatory cells are involved in extravasation reactions.⁸⁵ Whether a local antidote has a specific effect or acts as a diluent is hard to determine. Locally injected saline alone has proven successful in resolving extravasation reactions and preventing ulceration.⁸⁶ Although conservative treatment is preferable for most vesicant extravasations, early excision is sometimes favored, especially when the most potent vesicants are involved.^{86, 87} For topical therapy, the free-radical scavenger dimethyl sulfoxide (DMSO) has shown consistent therapeutic success. In 1995, an analysis of 96 cumulative patients from multiple studies showed that DMSO protected 98.3% of extravasation cases from ulceration.⁸⁸

Pigmentary changes

Hyperpigmentation is a common cutaneous manifestation that may be of cosmetic concern to patients. The skin, mucous membranes, hair, teeth, and nails may be affected, and the reaction may be diffuse or localized. Hyperpigmentation most commonly accompanies use of alkylating agents, antitumor antibiotics, and gemcitabine (Table 8).⁷⁷ Among the antimetabolites, methotrexate (MTX) may produce a characteristic hair “flag sign” with horizontal hyperpigmented bands alternating with normal hair color in light-haired individuals.⁷⁷ Tegafur can induce hyperpigmentation of the palms, soles, nails, and glans penis in one-third of patients receiving the drug. A flagellate, band-like hyperpigmentation in areas of trauma also occurs with high incidence in 8–20% of patients receiving bleomycin (Figure 7). Busulfan's hyperpigmentation can mimic Addison disease, with symptoms of weakness, weight loss, and diarrhea, but with normal melanocyte stimulating hormone and adrenocorticotrophic hormone serum levels.⁶⁹ The mechanism of chemotherapy-induced hyperpigmentation reactions is unknown but may involve direct toxicity, melanocyte stimulation, and postinflammatory changes. Although these reactions may occasionally be permanent, in most cases, discoloration will gradually resolve after the discontinuation of the chemotherapy.

Table 8 Chemotherapeutic agents associated with hyperpigmentation

Alkylating agents	AntibioticsNucleoside analogues	Antimetabolites	Miscellaneous combined regimens
Busulfan	Bleomycin	Fluorouracil	Bleomycin/doxorubicin/vincristine
Cisplatin	Dactinomycin	Methotrexate	Busulfan/cyclophosphamide
Cyclophosphamide	Daunorubicin	Tegafur	Cyclophosphamide/doxorubicin/vincristine/
Fotemustine	Doxorubicin	Brequinar sodium	Cyclophosphamide/etoposide/carboplatin
Ifosfamide	Mitoxantrone	Docetaxel	Doxorubicin/bleomycin/vinblastine/dacarba
Thiotepa	Plicamycin	Hydroxyurea	
Topical carmustine	Gemcitabine	Procarbazine	Ifosfamide/carboplatin/etoposide
Topical mechlorethamine	Troxacitabine	Vinorelbine	Methotrexate/cytarabine/L-asparaginase/daunorubicin/mercaptopurine/

Figure 7 Cutaneous flagellate hyperpigmentation of bleomycin.

Vitiligo, a complete absence of melanocytes resulting in depigmentation, is seen with targeted drug therapies, particularly those used in the treatment of metastatic melanoma ([Table 9](#)).^{38, 62, 63} It presents with asymptomatic, depigmented patches, often symmetrical in distribution, not necessarily related to sites of disease. Although speculated to be related to disease response, this has not been proven.

Vemurafenib	Gefitinib
Dabrafenib	Interferon
Pembrolizumab	IL-2
Imatinib	

Radiation-associated reactions

Radiation can include environmental exposure to UV rays as well as therapeutic radiation exposure. Three different types of reactions have been noted: enhancement, recall, and photosensitivity ([Tables 10](#) [11](#)).

Table 10 Chemotherapeutic agents implicated in radiation-associated reactions

Radiation enhancement	Radiation recall	
Bleomycin	Bleomycin	Hydroxyurea
Camptothecins	Cyclophosphamide	Idarubicin
Chlorambucil	Cytarabine	Lomustine
Cisplatin ^a	Dabrafenib	Melphalan
Cyclophosphamide ^a	Dactinomycin	Methotrexate
Dactinomycin	Daunorubicin	Oxaliplatin
Dabrafenib	Doxorubicin	Paclitaxel
Doxorubicin	Docetaxel	Tamoxifen
Fluorouracil	Edatrexate	Triazinate
Hydroxyurea	Etoposide	Trimetrexate
Interferons	Fluorouracil	Vemurafenib
Mercaptopurine	Gemcitabine	Vinblastine
Methotrexate		
Triazinate		
Vemurafenib		
Vincristine ^a

Dabrafenib	Mitomycin C
Dacarbazine	Porphyrins
Dactinomycin	Procarbazine
Doxorubicin	Tegafur
Fluorouracil	Thioguanine
Flutamide	Vemurafenib
Hydroxyurea	Vinblastine
	Vandetanib

Radiation enhancement

Enhancement of radiation therapy may occur when both chemotherapy and radiation therapy are given within 1 week of each other. Although other organs are also affected in this potentiation, the skin is the most common site of this toxicity. The reaction may appear as dry or moist desquamation, or as erythema and edema. When bullae, erosions, and ulcerations accompany erythema, *Staphylococcus* is usually the

causative factor.⁸⁹ The degree of enhancement of radiation damage depends on, and is inversely related to, the time interval between administration of the drug and radiation. The less time there is between chemotherapy and irradiation, the greater the enhancement effect.⁹⁰ Enhancement is also dependent on drug dosage and the pharmacologic mechanism of the drug.⁷⁵

Radiation recall

Radiation recall is an erythematous inflammatory reaction in areas of previously irradiated skin or sunburned skin. This includes the inflammation of AKs, which are caused by chronic sun exposure. Severe radiation dermatitis can even spread to areas outside the portal as an id reaction. Radiation recall occurs from 8 days up to 15 years after radiation therapy and may also occur in other organs.⁷⁷ The radiation dosage and the time interval between radiation and chemotherapy determine the occurrence and severity of recall, respectively.⁹¹ The UV recall reaction is observed with suramin (35% incidence), MTX, vemurafenib, and etoposide/cyclophosphamide therapy, which causes a sunburn reactivation if the drugs are administered within 1 week of obtaining a sunburn.⁹²

Inflammation of AKs is known as an AK recall reaction and is common in elderly patients with fair complexion and history of sun damage ([Table 12](#)). Suramin and cytarabine-induced inflammation of seborrheic keratosis and fludarabine-induced SCC have also been reported. The association between systemic fluorouracil and the irritation of clinical and subclinical AKs is well-known and resembles the effect produced by topical application of 5-FU. AK recall reactions usually appear 1 week following the initiation of drug administration; reactions usually resolve 1–4 weeks following the end of therapy, although they may regress during therapy as well.⁹³ This recall reaction may be due to a process similar to radiation recall or increased DNA synthesis in AK lesions and consequently higher chemoagent uptake.^{93, 94} Although these lesions are self-limiting, superficial ulceration and staphylococcal colonization can occur and necessitate antibiotics or corticosteroids. The reaction may or may not recur with drug readministration. Similar to the effect of topical 5-FU on AKs, systemic fluorouracil often clears the affected AKs after the inflammatory reaction resolves.⁹⁵

Table 12 Chemotherapeutic agents associated with inflammation of actinic keratoses

Dactinomycin/vincristine/dacarbazine
Docetaxel
Doxorubicin
Doxorubicin/cytarabine/thioguanine
Doxorubicin/vincristine
Fluorouracil
Fluorouracil/cisplatin
Pentaostatin

The mechanism of the recall reaction is currently unknown, although it has been theorized that impaired tissue repair may be a result of inadequate stem cell reserve or mutations in cells that survived radiation.⁹⁶

Generally, the treatment for radiation-associated reactions is symptomatic with an effort to avoid or treat secondary infections with appropriate antibiotics. Severe ulcerative and necrotic reactions may necessitate debridement. Topical mupirocin and systemic corticosteroids are mainstays in the treatment of

radiation recall and may even allow continuation of the offending drug without further recall effects.⁹⁶

Photosensitivity

Finally, cutaneous reactions related to chemotherapy and UV light exposure have been well documented, although they are relatively infrequent ([Table 11](#)). Generally, most of these reactions involve exogenous phototoxicity with the agents acting as chromophores. Both clinically and histologically, these phototoxic reactions appear as exaggerated sunburns. Phototoxicity has also been reported to affect the nails in the form of mercaptopurine-induced photo-onycholysis, which is tender and usually involves the distal third of the nail.

Another form of photosensitivity is the photoallergy that has been described with flutamide and tegafur, in which the photodistributed cutaneous reaction recurs with readministration of the implicated agent. This has also been observed with vandetanib.⁹⁷

Therapy for photosensitivity reactions is symptomatic with topical corticosteroids and antipruritics. Severe cases may require systemic steroids. Chloroquine and β -carotene have been used for prophylaxis but were not effective in controlled studies.⁹⁸ As the agent may remain in the patient's skin for several weeks, patients should be advised to take sun-avoidance measures.

Acral reactions

Two types of acral reactions have been described; the more classical AE and HFSR seen with targeted therapies. AE has many names, including hand–foot syndrome and toxic erythema of chemotherapy ([Table 13](#)).

Table 13 Chemotherapeutic agents associated with acral erythema

Most common		Least common	
Capecitabine	Cisplatin	Idarubicin	Paclitaxel
Cytarabine	Cyclophosphamide	Lomustine	Pegylated liposomal doxorubicin
Doxorubicin	Daunorubicin	Melphalan	Floxuridine
Fluorouracil	Docetaxel	Mercaptopurine	Suramin
	Doxifluridine	Methotrexate	Troxacitabine
	Etoposide	Mitomycin	Tegafur
	Hydroxyurea	Mitotane	Vincristine

Table 14 Miscellaneous reactions and reactions associated with chemotherapy

Bullous pemphigoid	Erythema nodosum	Flushing (cont)	Hirsutism (cont)
Dactinomycin/MTX	Busulfan	Plicamycin	Fluoxymesterone
Capillaritis	Diethylstilbestrol	Procarbazine	Tamoxifen
Aminogluthethimide	IL-2	Suramin	Nonmelanoma skin cancer
Cutaneous adherence, acquired	Fixed drug	Tamoxifen	Nitrogen mustard

	eruption		(topical)
Doxorubicin/ketoconazole	Dacarbazine	Teniposide	BRAF inhibitors
Cutaneous ulcers	Hydroxyurea	Trimetrexate	Porphyria
Hydroxyurea	Paclitaxel (bullous)	Folliculitis	Cisplatin
IFN- α , pegylated IFN- α	Procarbazine	Dactinomycin	Porphyria cutanea tarda
IL-2	Flushing	Daunorubicin	Busulfan
Methotrexate	L-Asparaginase	Fluorouracil	Cyclophosphamide
Dermatitis herpetiformis, flare	Bleomycin	Methotrexate	Diethylstilbestrol
Cyclophosphamide/doxorubicin/vincristine	Carboplatin	EGFR inhibitors	Methotrexate
Bleomycin	Carmustine (BCNU)	Furunculosis	Acute intermittent porphyria
Cisplatin	Cisplatin	Fluoxymesterone	Chlorambucil
Vincristine	Cyclophosphamide	Methotrexate	Cyclophosphamide
Dermatomyositis-like reaction	Dacarbazine	Dactinomycin	Pustular psoriasis
Hydroxyurea	Didemnin B	Medroxyprogesterone	Aminoglutethimide
Tamoxifen	Diethylstilbestrol	Procarbazine	Pegylated liposomal doxorubicin
Tegafur	Docetaxel	Vinblastine	Seborrheic dermatitis, flare
Bleomycin	Doxorubicin	Hair color change	Fluorouracil
Docetaxel	Etoposide	Bleomycin	IL-2
Drug-induced SLE	Fluorouracil	Cisplatin	IFN- α
Aminoglutethimide	Flutamide	Cyclophosphamide	Telangiectasia
Diethylstilbestrol	IL-2	Methotrexate	Carmustine (BCNU)
Hydroxyurea	Leuprolide	Tamoxifen	Fluorouracil (topical)
Leuprolide	Lomustine	Hirsutism	Hydroxyurea
Tegafur	Paclitaxel	Diethylstilbestrol	IFN- α
IFN- α			

Abbreviations: EGFR, epidermal growth factor receptor; IFN- α , interferon- α ; IgA, immunoglobulin A; IL-2, interleukin-2; MTX, methotrexate; SLE, systemic lupus erythematosus.

AE was first reported in association with chemotherapy by Zuehlke in 1974.⁹⁹ Other names include palmoplantar erythrodysesthesia, palmoplantar erythema, hand–foot syndrome, peculiar AE, and Burgdorf reaction. There is a prodrome of dysesthesia of the palms and soles, evolving into painful, tingling, symmetric, well-demarcated swelling and erythema ([Figure 8](#)), followed by a desquamative phase on

resolution. Erythema and swelling usually appear on the thenar and hypothenar eminences, lateral aspect of the fingers, and the pads of the distal phalanges. The hands are more often affected than the feet. In its various manifestations, AE may appear as alternating bands of erythema and sparing and may also be accompanied by a mild erythema or a morbilliform eruption on the trunk, neck, chest, scalp, and extremities.¹⁰⁰ MTX and cytarabine can reportedly induce a bullous variant of AE, which may progress to full-thickness epidermal necrosis before resolving.¹⁰¹

Figure 8 Chemo-induced acral erythema of the palms.

AE occurs with an incidence of 6–42% in different series and occurs mostly in adults.¹⁰² AE appears to be dose dependent on peak levels and total cumulative dose, as it occurs earlier and more severely after bolus infusions (24 h to 3 weeks), as compared with continuous low-dose administration (2–10 months).^{100, 103} AE tends to persist and worsen with further continuation of chemotherapy and may be dose limiting, as the associated pain may progress to become physically and functionally limiting. Cessation of the causative agent will allow resolution of AE in 1–2 weeks, with desquamation and re-epithelialization ([Figure 9](#)). AE may or may not recur with readministration. The treatment of AE is symptomatic and aimed at increasing tolerability to allow continued chemotherapy. Corticosteroids have shown variable success. Supportive treatment includes topical wound care, elevation, and pain medication. Similar to the concept of scalp hypothermia for alopecia, the cooling of hands and feet may help prevent AE.¹⁰³ Celecoxib, a cyclooxygenase 2 (COX-2) inhibitor, was shown to decrease the incidence of AE in a retrospective study of 67 patients with metastatic colorectal cancer who took capecitabine.¹⁰⁴ Celecoxib also attenuated capecitabine-induced diarrhea, increased tumor response, and increased median time to tumor progression compared with capecitabine alone. Pyridoxine may also reduce dysesthesia and pain to allow continuation of therapy.¹⁰⁵

Figure 9 Desquamation phase of hand-and-foot syndrome, secondary to capecitabine.

The pathogenesis of AE is currently unknown, but it is likely multifactorial. Biopsies of AE appear histologically nonspecific but are consistent with a toxic reaction.¹⁰³ In the setting of chemotherapy, diagnosis of AE is a relatively simple matter. However, in bone marrow transplant (BMT) patients, it may be difficult to differentiate from acute GVHD. There is a 35% incidence of AE in BMT patients, which may be due to the use of higher doses of chemotherapy and total body irradiation.¹⁰⁶ Histologically and clinically, AE may resemble acute GVHD in the first 3 weeks: as in AE, the palms are commonly affected in acute GVHD although it usually progresses with involvement of other areas of the body. Since early biopsies of acute GVHD mimic AE, serial biopsies at 3–5-day intervals are helpful in establishing patterns of progression supportive of acute GVHD.¹⁰⁶ Distinguishing AE from acute GVHD is important because the latter requires greater intervention with further immunosuppression; without treatment, it usually progresses and may be fatal.

HFSR is most commonly seen with multikinase inhibitors, sorafenib and sunitinib. It has also been reported with MEK inhibitors. It is distinguished from AE by the focal nature, overlying calluses, and tendency to vesiculate.

Cutaneous eruption of lymphocyte recovery

The cutaneous eruption of lymphocyte recovery (ELR) may be seen in patients receiving intensive marrow aplasia-inducing chemotherapy.¹⁰⁷ As with ESS, the ELR phenomenon has been observed with various cytotoxic agents but is not associated with a particular agent. Clinically, ELR has the appearance of variably distributed erythematous and pruritic macules, papules, and plaques, which may become confluent and erythrodermic, and is often associated with a couple of days of fever. In the setting of chemotherapy, this reaction has been found to occur 6–21 days after the chemotherapy-induced nadir of the leukocyte count, which correlates with the time of the initial recovery of peripheral lymphocytes. ELR may reflect the return of highly alloreactive immunocompetent lymphocytes to the peripheral circulation and skin.¹⁰⁷ ELR is self-limited and resolves over several days with desquamation and mild residual hyperpigmentation. The differential diagnosis includes acute GVHD, sepsis, viral exanthem, leukemia or lymphoma cutis, eccrine syringosquamous metaplasia, and drug hypersensitivity. Of these types of eruptions, acute GVHD is similar in time of onset to ELR in the setting of bone marrow transplantation.

The similarity with ELR is especially true in the case of autologous GVHD, as both involve a lymphocytic recovery in which histocompatibility is present. However, acute autologous GVHD cannot be reliably distinguished from ELR by skin biopsy.¹⁰⁸ As theorized by Horn, GVHD may represent a prolonged form of ELR.¹⁰⁹

Chapter 128

Skeletal complications

Michael A. Via, MD ■ Ilya Iofin, MD ■ Jeffrey I. Mechanick, MD

Overview

Metabolic bone disease is highly prevalent among cancer patients, owing to the systemic effects of malignancy, the humoral response, and to commonly prescribed cancer therapies. Surgical approaches to acute fracture can drastically impact quality of life. The use of bone antiresorptive agents can prevent fractures in this population and can reduce bone pain in patients with skeletal metastases.

Introduction

Cancer continues to remain a major public health concern as 44% of American men and 38% of women develop cancer at some point in their lifetime. It is estimated that there will be 1,658,370 new cancer cases in the United States in 2015.¹ As cancer treatments evolve and survival of patients with cancer continues to improve, skeletal complications of cancer are becoming more prevalent. These complications include pain associated with metastases to bone, fractures, and hypercalcemia of malignancy. The skeleton is the most common site of metastatic disease with ~70% of patients dying of cancer having skeletal metastases detected on autopsy. A significant portion of these metastases will be clinically relevant and require treatment (*see* 112, Table 8).² Once a patient develops skeletal metastases, cure is very unlikely and it must be understood by both the patient and the treating physicians that the goal of treatment is palliation and not cure.² The five most common cancer types that metastasize to bone are breast, prostate, lung, renal, and thyroid. Almost any cancer subtype can metastasize to bone; however, multiple myeloma is the most common malignancy originating in bone and is responsible for significant skeletal-associated morbidity. As in cases of metastatic carcinoma, cure is unlikely, though systemic control is possible and survival times are improving with evolving therapies. The treatment of problems arising from malignant disease affecting bone requires a multidisciplinary approach involving medical, orthopedic, and radiation oncologists.

Evaluation of a patient with bone lesions

Evaluation of a patient starts with a careful history and physical examination. Location of pain, inciting and alleviating factors, prior history cancer, and of prior treatments are all required to formulate an appropriate treatment plan. In addition to metastases being the potential source of disability, coexisting arthritis and other orthopedic conditions may be the cause of the patient's pain while the presence of the metastasis may be purely incidental. Imaging of the bone affected by metastatic disease is first done with orthogonal plain radiographs visualizing the entire length bone as the process may be multifocal ([Figure 1](#)). Bone lesions may be purely lytic (where only bone destruction is seen, as is typical of lymphoma, multiple myeloma, lung, renal, and thyroid cancer metastases), blastic (where abnormal bone deposition is seen, as is common in metastatic prostate cancer), or mixed (usual for breast cancer metastases). While

radioactive technetium bone scans and MRI are very sensitive modalities for detecting metastases, a noncontrast computed tomography (CT) is superior for the evaluation of bone integrity and is often needed to make decisions regarding potential need for surgical intervention. Again, the entire length of the involved bone should be imaged in order to accurately assess fracture risk and help guide potential surgical intervention.

Figure 1 (a) An 81-year-old woman with metastatic breast cancer with a chief complaint of knee pain. Note the destructive lesion in the distal femoral metaphysics above a well-fixed total knee arthroplasty (b) A noncontrast CT of the entire femur was obtained, demonstrating an additional destructive lesion in the femoral neck. While the lesion was asymptomatic, it was at high risk of sustaining a displaced pathologic fracture. Significant degenerative changes are also seen in the hip joint. (c) and (d) The distal femoral lesion was treated with intralesional curettage, internal fixation with a locking plate, and packing with PMMA bone cement. A press-fit long stem total hip arthroplasty was performed to treat the femoral neck lesion and the arthritis. Note the overlap of the two implants that minimize the risk of periprosthetic fracture and protects the entire length of the bone.

Solitary lesions of bone

Special attention needs to be drawn to the patient with a solitary bone lesion but no biopsy-proven metastatic disease. While prior cancer history makes it likely that the newly seen lesion is a metastasis of that cancer, there is no guarantee of that, so a thorough evaluation is required before any intervention. One of the worst errors one could make is to presume that a patient has metastatic disease and failing to recognize a primary bone sarcoma that might be curable. While sarcomas usually affect teenagers and young adults, they can occur in all age groups. The treatment of sarcoma is radically different from treatment of metastatic carcinoma, multiple myeloma, and lymphoma. Bone sarcoma surgery usually entails wide resection of the tumor with curative intent, while most metastatic lesions are treated with intralesional procedures where palliation is the goal. One of the most common orthopedic procedures done for metastatic disease is intramedullary nailing. An intramedullary nail inadvertently placed through a bone sarcoma leads to contamination of the entire length of the bone as well as of the surrounding soft tissues. A patient in whom limb salvage maybe have been possible before intramedullary nailing will require a much more disabling resection at best and a high-level amputation such as a hemipelvectomy at worst. In addition, reaming of the medullary canal pushes sarcoma cells into the systemic circulation and the lungs, making metastatic disease and death more likely.³ Even in the presence of a pathologic fracture through a sarcoma, limb salvage with modern chemotherapy and surgical modalities is possible in most cases if fracture healing can be achieved with cast immobilization or minimally invasive fixation methods that do not lead to tissue contamination.⁴ Knowledge of the exact tumor diagnosis is required to guide appropriate treatment.

Thus, when presented a patient with an uncertain cancer diagnosis, in addition to evaluation of the affected bone, further staging studies should be undertaken. A CT of the chest, abdomen, and pelvis with oral and IV contrast should be performed to look for visceral metastases and a potential primary tumor. Other skeletal metastases can be detected with a technitium-99 whole body bone scan while detection of a monoclonal spike in serum and/or urine by immunofixation or protein electrophoresis can help establish the diagnosis of multiple myeloma.⁵ Bone scintigraphy detects new bone deposition in response to tumor activity, trauma, or degenerative joint disease. While it is a sensitive modality for detecting skeletal metastases in most cases, multiple myeloma, metastatic renal cell, and thyroid carcinomas are usually purely lytic in nature where there is little bone deposition. Lesions from these tumors can be missed by bone scintigraphy. When one of these diagnoses is suspected, a skeletal survey (which consists of AP radiographs of the long bones, chest, and pelvis and lateral radiographs of the spine and skull) should be obtained. Positron emission tomography (PET) CT is another sensitive modality for staging, though its exact indications are still being determined. All discovered sites of skeletal involvement should be further evaluated for risk of fracture that may require treatment. Prostate-specific antigen (PSA) levels, usually elevated in patients with metastatic prostate cancer, should be checked in men where this diagnosis is suspected.

This systematic approach will distinguish patients with multiple bone and visceral lesions in whom metastatic disease or multiple myeloma or lymphoma is suspected from the rare patients with solitary bone lesions in whom suspicion of primary bone sarcoma is higher. There are additional benefits to this evaluation algorithm. The most accessible site for biopsy can be found, which can be different from the site of the patient's original complaint. Metastatic renal cell and thyroid carcinomas are well known to be hypervascular and can hemorrhage significantly during biopsy. Prior knowledge of these diagnoses is useful, as preoperative tumor embolization can be performed and preparations made accordingly.

The final diagnosis, though often suspected based on the radiographic evaluation, is confirmed with a tissue biopsy. If the treating physician is confident of the diagnosis before surgical intervention based on radiographic findings or a known history of metastatic carcinoma or multiple myeloma with confirmatory

laboratory findings, an intraoperative frozen section can be used to confirm the diagnosis. Care must be exercised, though, as frozen section is not 100% accurate and provides the correct diagnosis only in 86–94% of biopsies of skeletal lesions.⁶ If a sarcoma is suspected, then definitive treatment should be delayed until final histologic diagnosis is made. In addition, the reliability of frozen section is dependent on the experience of the pathologist. Most pathologists have limited experience with primary bone tumors. It is important to note that the biopsy tract, especially in cases of an open biopsy, is contaminated by tumor cells and needs to be resected. While that is of little consequence in metastatic disease or multiple myeloma, in cases of sarcoma, inappropriate placement of the biopsy has been shown to adversely affect outcomes, even leading to unnecessary amputations in 4.5% of cases.⁷ Therefore, biopsy should be performed at a tertiary referral center by, or at least in coordination with, a surgeon with training and expertise in the treatment of bone sarcomas.

Options for treatment of skeletal lesions

A range of treatment options exists for skeletal lesions: it spans the spectrum from observation for asymptomatic lesions that do not present a fracture risk to operative intervention for displaced and impending pathologic fractures. In addition to systemic therapy for the cancer, treatment with bisphosphonates or denosumab has been shown to reduce the number of skeletal events, such as compression fractures of the vertebrae and need for surgery or radiotherapy in patients with metastatic bone disease and multiple myeloma.⁸ Radiation therapy provides pain relief in about 70% of treated lesions. Various therapeutic regimens exist: 8 Gy single-dose treatments have shown similar efficacy to the more traditional and longer 30 Gy 10-day course. Occasionally, the cancer pain recurs, requiring repeat treatment, which is easier to perform with the single-dose treatments.⁸ Tumors of different histology have different sensitivity to radiation. Multiple myeloma, lymphoma, prostate, and breast cancers are known for their radiosensitivity while renal cell carcinoma is relatively radioresistant.⁹ Sensitivity to systemic and radiation therapies is one of many factors when choosing most appropriate treatment for a patient with a skeletal lesion. Radiation is most appropriate for lesions that do not present a significant fracture risk. The pelvis, spine, ribs, and scapulae are appropriate sites for radiation treatment in the majority of cases, while lesions of the long bones, especially in the lower extremity, present a higher fracture risk and should be evaluated for potential surgical intervention.

In patients with small lesions that are not structurally significant, where radiation has not provided pain relief, radiofrequency ablation (RFA) and cryoablation are useful minimally invasive treatment options. Under CT guidance, a probe is placed into the lesion to allow local treatment. In RFA, the needle probe delivers a high-frequency alternating current into the surrounding tissues, resulting in heat necrosis. Polymethyl methacrylate (PMMA bone cement) may be injected into the void left by the tumor to provide structural support and additional pain relief.¹⁰ Cryoablation is a thermal technique that is conceptually similar to RFA, in which the tumor cells are destroyed not by heating but by cycles of rapid freezing with pressurized argon gas passing through the probe placed in the lesion, followed by slow thawing. Unlike RFA, the zone of thermal necrosis can be visualized on CT. Both modalities can be combined with percutaneous PMMA injection.¹¹ Such image guided thermal ablation techniques are most appropriate for lesions that present minimal risk of fracture, such as vertebral body, sacral and iliac wing lesions, and many acetabular lesions. Once fracture is present or the bone is at significant risk of fracture due to loss of structural integrity, surgery is usually required. Where clinical considerations weight against surgical intervention, particularly in vertebral metastases, PMMA stabilization can relieve pain and restore patient mobility.

Principles of pathologic fracture treatment

The goals of pathologic fracture treatment are to improve function and provide pain relief. The patient and his or her family must be informed and have to understand that the goal of treatment is palliative in nature and will not result in cure. Risk of complications has to be carefully balanced against the potential benefit. Though survival time of cancer patients is difficult to predict, it should exceed the expected surgical recovery time. Pathologic fractures often fail to heal and when they do heal, they are slow to do so. In a series of 123 patients with 129 pathologic fractures, the overall fracture healing rate was only 35%. In patients who survived for more than 6 months, that rate went up to 74%.¹² This, and the fact that patients with pathologic fractures have multiple systemic comorbidities, must be kept in mind when selecting the optimal treatment approach. Unlike conventional fractures without an underlying malignancy, where union is likely after a relatively short period of restricted weight bearing, in pathologic fractures, such expectation cannot be made. Fixation must be sufficiently durable to allow nearly immediate almost unrestricted weight bearing and last for the entire lifetime of the patient. Multiple surgeries are not a desirable option. Chemotherapeutic regimens are cytotoxic and are often interrupted to allow wound healing from surgery. As systemic disease can progress during such interruptions of systemic treatment, all efforts should be made to minimize the duration and number of interruptions by minimizing the need for multiple surgeries.

The bone affected by tumor is of poor structural integrity, which is what led it to fracture in the first place. Intralesional resection of the tumor and augmentation of the fixation with PMMA bone cement are often required to both provide sufficient stability to the fixation construct and to obtain better local control of the tumor. Addition of bone cement to internal fixation has been shown to provide pain relief that is superior to internal fixation alone¹³ and provides a more biomechanically stable construct.¹⁴ Bone grafting is not used in the treatment of metastatic disease or multiple myeloma as the bone graft cannot be expected to incorporate in a patient being treated with chemotherapy and radiation. PMMA bone cement provides immediate stability, is cheap and easy to use, making it preferable to bone grafting. Fracture healing can occur in the presence of bone cement ([Figure 3](#)). In addition to tumor debulking with curettage and high-speed burring to lower risk of recurrence, cryosurgery can be used as a treatment modality in cases of relatively radioresistant tumors where prolonged patient survival is likely, such as in cases of oligometastatic renal cell carcinoma.¹⁵

Treatment options for pathologic fractures consist of intramedullary nailing, fixation with plates and screws, endoprosthetic replacement, and resection of bone without reconstruction. Choice of treatment depends on tumor biology, location, and surrounding bone integrity. For example, a pathologic fracture of the clavicle due to multiple myeloma, which is both chemo- and radiosensitive, will usually respond well to nonoperative treatment, whereas the same clavicle fracture due to metastatic renal cell carcinoma is best treated with resection of the clavicle. Radiation treatment is an important adjunct to surgical treatment of bone lesions as it reduces the likelihood of tumor progression that might require reoperation and improves function. In one series, it has been shown to reduce the need for reoperation from 15% seen in the group that received surgery alone to only 3% in the group that had radiation treatment after surgery.¹⁶

Intramedullary nailing

Intramedullary nailing is the most commonly used surgical method of treatment of metastatic disease affecting appendicular bones because of its many advantages. The entire length of the bone is protected by

the length of the nail, so if other lesions develop within the same bone, further surgery may not be necessary. The surgery can be done in a minimally invasive manner, allowing for a quicker recovery and a lower surgical risk. In some cases though, depending on fracture characteristics and the sensitivity of the tumor to chemotherapy and radiation, an open approach and placement of PMMA bone cement is required. Relatively radiation-resistant tumors such as metastatic renal cell carcinoma are more likely to require an open approach to lower the risk of complications associated with local tumor progression. The nail can be embedded into the bone cement that has been injected along the entire length the intramedullary canal to enhance construct stability ([Figure 2](#)) or, alternatively, cement can be packed around the nail into the defect left by the tumor ([Figure 3](#)).

(a)

(b)

(c)

(d)

(e)

Figure 2 (a) A 67-year-old lady who underwent an intramedullary nailing at an outside institution for a painful lesion in the right femoral neck. No preoperative staging was performed. Femoral canal reamings that were sent to pathology showed metastatic renal cell carcinoma. Note the minimal amount of bone destruction present. A small amount of bone cement was injected along the lag screw at the time of surgery. (b) X-rays obtained 6 weeks after surgery show rapid progression of the tumor and destruction of much of the femoral neck and greater trochanter with failure of hardware. (c) CT of the pelvis demonstrates a large tumor mass engulfing the proximal femur. (d) and (e) The patient underwent resection of the tumor, removal of hardware, and a modular proximal femoral replacement. This case underscores the importance of a preoperative staging evaluation of a patient with bone lesions. Had it been performed and the diagnosis of renal cell carcinoma been known at the time of the initial procedure, extensive tumor curettage with an adjuvant and a hemiarthroplasty could have been done, saving the patient from the morbidity of a second more extensive surgical procedure.

Figure 3 (a) A 49-year-old woman with multiple myeloma who sustained a pathologic right proximal humerus fracture. (b) The fracture was sufficiently distal to allow the use of a cemented intramedullary nail. Note the cement mantle going up to the proximal diaphysis. Distal interlocking screws were not used as the entire nail is supported by bone cement.

The femur is the most common bone to be treated with intramedullary nailing. A cephalomedullary nail is preferable as the lag screw provides fixation of the femoral neck, a site that is commonly affected by metastatic disease or multiple myeloma. Metaphyseal and diaphyseal humeral lesions are also amenable to intramedullary nailing. The tibia is rarely affected by metastatic disease or multiple myeloma, but intramedullary nailing can be performed in those rare cases. Even more rare are lesions of the long bones of the forearm; however, in selected cases, intramedullary nailing of pathologic forearm fractures can be used safely and effectively instead of the more traditional fixation with plates and screws used in that location.

There must be sufficient bone in both the proximal and distal aspects of the long bone to allow the nail to have sufficient fixation and biomechanical stability. While it is best suited for diaphyseal lesions, intramedullary nailing can be safely used in metaphyseal locations where there is sufficient distance from

the joint to allow good fixation. Lesions of the femoral neck are best suited for treatment with arthroplasty and lesions of the humeral head are treated with arthroplasty or plate and screw fixation with cement augmentation.

Plate and screw fixation

The locking plate technology has revolutionized fracture fixation in general and has also become an invaluable tool in the treatment of pathologic fractures. In contrast to traditional plating techniques that rely on friction of the plate against bone, locking plate technology creates a fixed-angle device where the head of each screw is secured into the plate. Thus, for the construct to fail, all the screws need to fail together, requiring far greater force. In conventional plating, screws can fail sequentially, requiring less force for failure of the entire construct. Locking plates have been shown to be an excellent choice for treatment of fractures close to joints where traditional fixation methods have not provided optimal results.¹⁷ Locking plates in conjunction with liberal use of PMMA bone cement should be used in preference to conventional plates whenever possible. They are best suited for locations near a joint, such as the distal femur, proximal tibia, and proximal and distal humeri where there is insufficient fixation for an intramedullary nail. They are preferable to a joint arthroplasty as they potentially provide better functional results.¹⁸ In addition, this fixation method can be used when another implant, such as a total joint arthroplasty or previous fracture fixation would interfere with placement of an intramedullary device ([Figure 1](#)).

Arthroplasty

Joint arthroplasty is reserved for lesions that are so close to the joint that neither intramedullary nailing nor plate and screw fixation will provide reliable stable fixation. It is most commonly used for lesions of the femoral head and neck, especially because even conventional displaced fractures in the geriatric patients have a low union rate. Arthroplasty has even been shown to have superior results to internal fixation for intertrochanteric and subtrochanteric lesions, though the subgroup of patients in whom tumor was removed and internal fixation was augmented with PMMA bone cement fared much better than those in whom internal fixation alone was performed.¹⁹ In cases of diaphyseal fractures where the tumor involves the point of interlocking screw fixation, the use of arthroplasty is preferred over the use of an intramedullary nail as the interlocking screws will not have sufficient support within bone weakened by tumor and are likely to cut out of the bone ([Figure 4](#)). Pain from acetabular wear is not a significant concern in oncology patients with a limited life expectancy, so the higher dislocation risk and the longer surgical time associated with a total hip arthroplasty are not justified. A hemiarthroplasty is preferable except in cases of severe pre-existing arthritis or an acetabular lesion requiring surgical intervention ([Figure 1](#)). Hemiarthroplasty can also be used for lesions of the proximal humerus where there is not sufficient bone stock to allow fixation with joint sparing implants.

Figure 4 (a) A 57-year-old woman with metastatic cancer who sustained a left femoral midshaft diaphyseal fracture. (b) and (c) The patient underwent resection curettage of the tumor, intramedullary nailing, and packing of PMMA bone cement around the nail into the defect left by the tumor. (d) 4 months later, the fracture line over the lateral cortex is no longer visible and bone callus is seen, indicating healing of the fracture. Note the fracture callus forming on the medial side around the cement.

For isolated lesions of the head and neck of the femur, a conventional arthroplasty is used by some surgeons while others use a cemented long stem hemiarthroplasty to protect much of the length of the femur from progression of metastatic disease. In lesions affecting much of the proximal femur, a long stem hemiarthroplasty is needed (Figure 4). This procedure is affected by an approximately 2% risk of intraoperative cardiac arrest and 1% risk of intraoperative or early postoperative mortality associated with the use of pressurized bone cement. As the risk of such an adverse event can be lowered, communication with the anesthesia team is mandatory before and during cementation of the prosthesis. Placement of venting holes in the distal femur before cementation has been shown to lower the intramedullary pressure, but unfortunately no data exist that would demonstrate that this translates into a lower clinical risk of intraoperative cardiac arrest.²⁰ The venting hole can theoretically act as a stress riser, leading to a fracture distal to the prosthesis.

Megaprotheses

While large oncologic endoprosthetic devices are usually used to reconstruct the large defects left by resection of bone sarcomas, occasionally their use is required in the treatment of metastatic disease and multiple myeloma. The main indications for their use are threefold. One is when the tumor is so extensive and bone stock is so poor, that neither an osteosynthetic device nor conventional arthroplasty is feasible. The second indication is for prior failed fixation due to tumor progression or hardware failure due to a nonunion. The third indication is for the rare patient with a solitary metastatic lesion where resection of the lesion may improve long-term survival. While megaprotheses are an appropriate choice in selected cases, they are associated with a longer operative time, higher complication rate, such as infection and dislocation, and prolonged recovery. Location of the lesion also plays a role as excellent function can be expected in the distal and proximal femoral replacements, while the function of proximal tibial and proximal and distal humeral replacements is inferior. In cases where there is a large diaphyseal defect, an intercalary prosthesis can be used instead of an intramedullary nail. This device has been shown to be

more biomechanically stable than an intramedullary nail even with cement augmentation.²¹ At least 5 cm of intramedullary canal length is required on each side of the prosthesis to allow the cementation of the stems.

Treatment of periacetabular lesions

Surgical treatment of periacetabular lesions can be associated with significant morbidity, complications, and intraoperative blood loss. Fortunately, many of these lesions respond well to nonoperative measures such as weight bearing restrictions and radiation. Small lesions resistant to radiation may be treated with cementoplasty that can be combined with ablative techniques such as cryosurgery or RFA. However, surgery is required in selected patients with sufficient life expectancy who fail nonoperative treatment. In cases where there is sufficient bone stock and the subchondral plate is preserved, intralesional curettage and PMMA cement packing can be effective. In cases of displaced pathologic acetabular fractures or large lesions affecting the medial wall and/or the subchondral plate, a complex total hip arthroplasty is required. The goal of the reconstruction is to distribute the forces from the acetabulum to the portions of the pelvis, such as ilium and ischium, that are not affected by the disease process. Antiprotusio acetabular cages, Steinmann pins embedded in the ilium, and bone cement to fill the defect left by the tumor are commonly used. In rare cases where bone destruction is so significant that even reconstruction with a cage will not provide sufficient mechanical support, the use of a partial pelvic prosthetic replacement can be considered, though it is associated with a high complication rate. The last surgical option for treatment of acetabular lesions is resection arthroplasty without reconstruction. It is associated with limb length inequality of about 5 cm and a decline in ambulatory capacity, though ambulation is not precluded, but holds the advantages of having a low complication rate and being a technically quick and relatively simple surgery. This option is most appropriate for patients in whom a more extensive reconstruction would be medically contraindicated or who are nonambulatory at baseline.²² Periacetabular tumors, especially due to multiple myeloma and renal cell and thyroid carcinoma may be quite vascular, so appropriate preparation for potential transfusion is required and preoperative tumor embolization should be considered.

Resection without reconstruction

While metastatic disease most frequently affects the axial skeleton and proximal femora and humeri, there are instances of metastatic disease to smaller bones such as the clavicle, proximal radius, distal ulna, and proximal fibula. These bones are very slender and implanted hardware has a high risk of failure, even if fixation is augmented with bone cement. Fortunately, excellent function can be obtained with resection of bone from these locations without reconstruction. Once the fractured bone segment or the entire bone is resected, there is no fracture to heal, and excellent pain relief is obtained. This approach allows reduction of surgical time and lower risk of complications while providing results that are equivalent, if not superior, to fracture fixation. As discussed earlier, resection of the femoral head and hip joint without reconstruction is also a good surgical option for patients with large painful periacetabular lesions whose baseline performance status is poor or if there are medical contraindications to performing large periacetabular resections with extensive reconstruction.

Spine lesions

While the spine is the most common site of metastatic disease, fortunately most spine metastases do not require surgery. They are usually incidentally detected on staging studies such as bone scintigraphy or CT of the chest, abdomen, and pelvis. Mechanical integrity of the spine is usually not compromised, so radiation therapy for axial back pain is usually effective. In cases of compression fractures without neurologic compromise, kyphoplasty combined with radiation has been shown to provide pain relief in over 90% of cases.²³ Kyphoplasty is a technique in which a balloon is percutaneously inserted into the vertebral body through the pedicle under image guidance and inflated to restore vertebral body height, which is then maintained by injection of PMMA bone cement into the resultant void. Surgical decompression and fusion are indicated in cases of severe and progressive deformity or neurologic compromise from compression of neural structures ([Figure 5](#)). In cases of spinal cord or caudal equina compression, surgical intervention provides superior pain relief and is more likely to allow the patient to maintain or even restore ambulatory capacity compared to radiation therapy alone.²⁴ Timely surgical decompression before irreversible neural damage is critical. In cases of neurologic compromise from radiosensitive lesions such as multiple myeloma and lymphoma, emergency radiotherapy is the preferred treatment modality. Corticosteroids should be administered to relieve edema around the spinal cord and attempt to preserve neurologic function while treatment is being instituted (see Ref. 24).

Figure 5 (a) A 69-year-old man with multiple myeloma who sustained bilateral pathologic forearm fractures through one of multiple radiolucent lesions involving much of the length of bilateral radii and ulnae. (b) and (c) Intramedullary nailing of bilateral radii and ulnae was performed. There was insufficient bone stock to allow fixation of the right distal ulna, so it was resected with minimal functional compromise. Intramedullary nailing was done in a minimally invasive manner and was preferable to fixation with plates and screws that would have required exposure of the entire length of the radius and ulna bilaterally in this already debilitated patient.

Treatment of painful metastases and impending fractures

Besides a displaced pathologic fracture, the indications for surgery are impending pathologic fractures and painful lesions that are not responsive to radiation or other nonoperative treatments. Prophylactic surgical intervention has been shown to be associated with a quicker recovery and superior functional results compared to treatment of a fracture that has already occurred.^{25, 26} Several systems have been devised to identify the patients at risk of fracture. The one used most commonly was described by Mirels in 1989. The lesion is assigned a score based on four categories (see 112, Table 4A).²⁷ A score of 1 to 3 is given in each category and the sum of the scores is obtained (Figures 6–10). The parameters are:

(a)

(b)

Figure 6 (a) A 40-year-old woman with metastatic breast cancer who sustained a subtrochanteric right femur fracture. Note the mixed lytic and blastic changes seen in the femoral head as well as in much of the pelvis. (b) A long-stem cemented hip hemiarthroplasty was performed. A femoral nail would not have been an appropriate choice for this patient as the bone in the femoral head is compromised by metastatic tumor. With an intramedullary nail, risk of lag screw cut-out would have been unacceptably high. The arthroplasty stem serves the same function as a nail in fixing the fracture while the compromised bone in the head of the femur is replaced with the prosthetic head.

Figure 7 (a) A 71-year-old woman with metastatic renal cell carcinoma and a pathologic fracture through a large area of bone destruction in the diaphysis of the humerus. (b) There was not enough bone support for the use of an intramedullary nail or plate and screws, so an intercalary prosthetic replacement was used to reconstruct the defect. Stems cemented into the distal and proximal diaphyseal segments make the construct similar to a fully cemented nail.

Figure 8 (a) A 60-year-old woman who sustained a displaced femoral neck fracture in a fall. Note the subtle cortical irregularity at the lateral border of the acetabulum. (b) Coronal CT shows a large destructive lesion in the supra-acetabular area with destruction of the subchondral plate. Biopsy revealed this to be due to metastatic breast cancer. The femoral neck fracture was not related to the patient's cancer. (c) The patient underwent curettage of the tumor and reconstruction of the defect with a total hip arthroplasty with an acetabular cage. The void left by the tumor was filled with PMMA bone cement.

Figure 9 (a) A 60-year-old woman who sustained a pathologic fracture of her right clavicle through a radiolucent lesion. As a teenager she had a traumatic clavicle fracture that went on to asymptomatic nonunion. (b) Resection of the lateral clavicle, which included the pathologic fracture site, was performed, allowing the patient to return to her baseline status within 2 weeks of surgery.

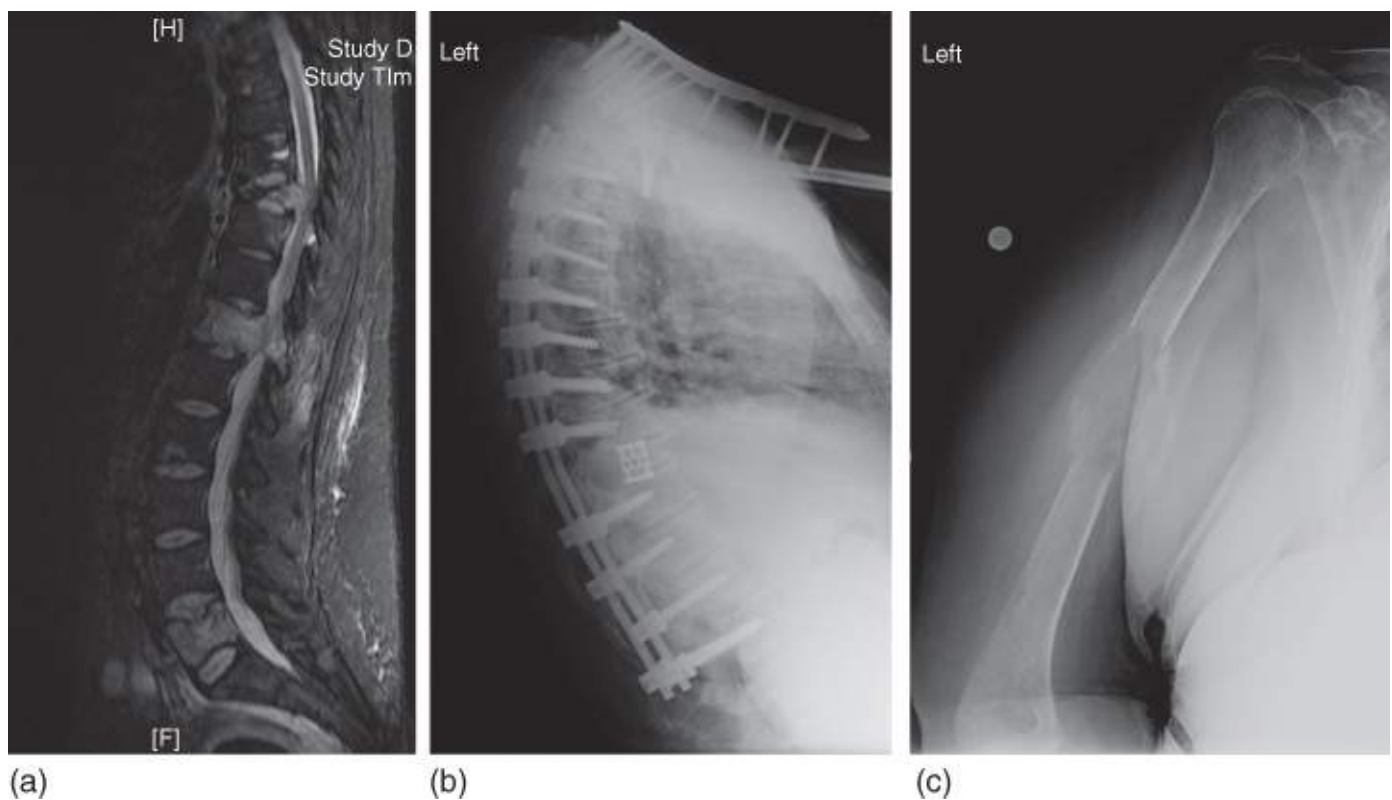

Figure 10 (a) A 56-year-old woman with metastatic endometrial carcinoma who developed significant lower extremity weakness due to spinal cord compression from a pathologic fracture of the T9 vertebral body. Metastatic deposits in other vertebral bodies are seen. (b) and (c) The patient underwent resection of the T9 vertebral body and fusion with a cage, posterior T8–T10 hemilaminectomy, and instrumentation and fusion from T1 to L1.

1. Location of the lesion. The peritrochanteric femur experiences the highest forces and is assigned a score of 3, whereas the upper extremity is nonweight bearing and is thus assigned a score of 1.
2. Pain quality. Pain exacerbated by activity is the most ominous sign as it implies a mechanical instability at the site of the lesion. All patients with activity-related pain went on to fracture in Mirels' study, whereas only 10% of patients without functional pain sustained fractures.
3. Lesion type. Lytic lesions are the most susceptible to fracture as native bone is destroyed by tumor

and not replaced, so a score of 3 is assigned. Blastic lesions are composed of abnormal tumor bone that does not undergo normal remodeling. It is therefore weaker than native bone, but stronger than bone affected by purely lytic lesions, so a score of 1 is given.

4. Size of the lesion as seen on plain radiographs. Larger lesions present a higher fracture risk and therefore get a higher score.

The scores from the four categories are added up to obtain a total score from 4 to 12. Score of 9 is associated with a 33% fracture risk, so surgery is recommended for scores of 9 and above, whereas radiation is recommended for scores of 7 or less. Score of 8 is associated with a 15% fracture risk, so patient factors, such as activity level, body weight, life expectancy, and sensitivity of the tumor to chemotherapy and radiation must be considered (see 112, Table 4B). While Mirels system is 91% sensitive, its specificity is only 35%,²⁸ so more specific CT-based systems are being sought.²⁹

Chapter 129

Hematologic complications and blood bank support

Richard M. Kaufman, MD ■ Kenneth C. Anderson, MD

Overview

Many of the fundamental therapies used to treat cancer (chemotherapy and stem cell transplantation) disrupt normal hematopoiesis in the bone marrow. As a result, blood transfusion for patients with cancer is an essential supportive modality. The primary focus of this chapter is on “classical” blood component support: how red cells, plasma, platelets, and granulocytes are collected, tested, stored, and administered to address specific deficiencies in patients with cancer. Particular attention is paid to studies of prophylactic platelet transfusion, which over the past several decades has been critical in allowing myelosuppressive treatments to be applied to a variety of malignant disease states. Current infectious risks of blood products are reviewed.

Hematologic complications occur commonly in patients with cancer, related either to the underlying disease or to its treatment.^{1, 2} Abnormalities in the red blood cell (RBC), leukocyte (WBC), and platelet number and function require transfusion medicine expertise for the provision of appropriate blood component support.^{3, 4} Indeed, the therapeutic advances made using high-dose combination chemotherapeutic approaches to date would not have been possible without the parallel development of technology to support patients through the hematologic complications of therapy.

Causes of pancytopenia

Cancer and its treatment may alter normal hematopoiesis either by direct effects on hematopoietic stem cells or by inhibiting production of and responsiveness to hematopoietic growth factors ([Table 1](#)).

Table 1 Causes of anemia, thrombocytopenia, and leukopenia in cancer

Bone marrow replacement by primary tumor (e.g., leukemia)
Bone marrow involvement by metastatic tumor (e.g., breast and prostate)
Derangement of normal physiology <ul style="list-style-type: none">• Nutritional (e.g., folate, iron, and negative nitrogen balance)• Abnormal feedback (e.g., stimulation/inhibition of hematopoiesis)• Bone-marrow reaction (e.g., fibrosis)• Peripheral destruction (e.g., immune hemolysis, diffuse intravascular coagulation, and splenomegaly)• Blood loss
Myelosuppression by chemotherapy or radiotherapy

Disease related

Bone marrow hematopoietic cells can be replaced either by primary tumor derived from marrow cells, or by metastatic spread of tumor to the marrow from neoplasms of other organs. Hodgkin and non-Hodgkin lymphoma (NHL), malignant melanoma, neuroblastoma, as well as carcinoma of the breast, prostate, lung, adrenal, thyroid, and kidney commonly manifest marrow involvement. Ultimately, diffuse involvement of marrow with tumor can lead to either marrow fibrosis or necrosis, which may be associated with splenomegaly, thrombocytopenia, and immature cells of all lineages in the peripheral blood.⁵

Chemotherapy related

The role of treatment in marrow injury and recovery varies both with the drugs employed and with the normal turnover rate of cells of different hematologic lineages. The characteristic effects of several drugs on marrow are shown in [Table 2](#). The bone marrow has a storage compartment that can supply mature cells to the peripheral blood for 8–10 days after the stem-cell pool has ceased to function. Events in the peripheral blood are therefore a week behind the events in the bone marrow. In previously untreated patients, leukopenia and thrombocytopenia are described on the ninth or tenth day after treatment, with the nadir of counts on days 14–18. Recovery of counts is evident by day 21 and complete by day 28. The cytotoxic dose–response effect is usually related to the nadir WBC and platelet count, not the duration of cytopenia. This is due to the resting state of the stem cells of normal bone marrow, which protects them from damage.

Table 2 Characteristic effects of drugs and treatments on bone marrow

Treatment	Hematologic complication
Most chemotherapeutic agents	Leukopenia and thrombocytopenia at 9–10 days; nadir counts at 14–18 days; recovery of counts at 21–28 days
Nitrosourea	Myelosuppression at 4–6 weeks
Vincristine, 1-asparaginase, bleomycin, myelosuppression methotrexate with leucovorin	No myelosuppression
Gamma irradiation	Chronic lymphopenia
Whole-body irradiation	Profound suppression of humoral and cellular immune response

Gamma radiation related

Cells damaged by irradiation may divide one time or more before all progeny are rendered reproductively sterile; thus, an irradiated cell will not appear damaged until it divides.⁶ At the time of the first postirradiation subdivision, the cell may die, divide aberrantly and produce unusual forms, be unable to divide and remain physiologically functional, or give rise to one or more generation of progeny until cells become sterile. As bone marrow stem cells have a very low capacity for repair of sublethal irradiation damage, multiple smaller radiation fractions may preserve other normal tissues (e.g., lung and intestine), but will not spare bone marrow.

Associated processes

It is essential to remain cognizant of derangements in normal physiology that may occur in the setting of cancer and/or treatment and that contribute to pancytopenia. These include nutritional factors, such as

folate, iron, or vitamin deficiencies. There may be abnormal feedback loops in hematopoiesis, such as cell-mediated suppression of hematopoiesis in aplastic anemia or stimulation of thrombopoiesis in the setting of antibody-mediated platelet destruction.⁷ Fibrosis can occur either as part of a disease process or as a reaction to therapy, thereby compromising bone marrow reserve. Immunologically mediated destruction of cells and other factors, such as splenomegaly, can result in cytopenias. Moreover, occult bleeding must always be considered as a cause of persistent anemia and refractory thrombocytopenia. These clinical examples emphasize the importance of carefully assessing patients with cancer for treatable medical etiologies of their hematologic complications before attributing these effects to their underlying neoplasms.

Abnormalities of red cells and red cell support

Anemia

Anemia in patients with cancer can be mild to severe and may be attributable to many causes. Hematopoiesis in patients with early stages of cancer may be normal. On the other hand, replacement of marrow cells by tumor is not essential for the development of anemia, even in patients with metastatic cancer. Most commonly, the incidence and magnitude of anemia in patients with cancer increase as the disease progresses. This anemia is designated as anemia of chronic disease only if the cellular pattern in the marrow is nearly normal, the serum iron and iron-binding capacity are low, the iron content of the marrow is normal or increased, and the serum ferritin is elevated.⁸ The coexistence of low plasma iron levels with adequate amounts of storage iron helps distinguish anemia of chronic disease from iron-deficiency anemia. Moreover, other causes of anemia, for example, overt hemolysis, bleeding, nutritional deficiency, or marrow replacement, must be ruled out. In some patients, such as those with Hodgkin disease (HD), erythrophagocytosis or hypersplenism may account for this decrease in red-cell survival, but in others its etiology is unclear.

Red-cell transfusion

Red-cell transfusions are indicated to increase oxygen-carrying capacity in patients with anemia that is not adequately compensated by normal physiologic mechanisms. Sufficient oxygen-carrying capacity to maintain cardiopulmonary function can be met by a hemoglobin of 7 g/dL (a hematocrit of approximately 21%) when the intravascular volume is adequate for perfusion.⁹ In a multicenter randomized trial of critical care patients, a restrictive transfusion strategy (maintaining hemoglobin levels between 7 and 9 g/dL) was demonstrated to be at least as safe as a more liberal transfusion strategy, with the possible exception of patients with acute myocardial infarction or unstable angina.¹⁰ Subsequent randomized trials have compared restrictive versus liberal RBC transfusion strategies in patients with cardiovascular disease having hip surgery¹¹ or cardiac surgery,^{12–14} in patients with sepsis,¹⁵ and in patients with upper gastrointestinal bleeding.¹⁶ A restrictive transfusion strategy (hemoglobin transfusion threshold of 7–8 g/dL) appears to be safe and appropriate for the vast majority of hospitalized inpatients. Currently, however, high-quality clinical trial data to guide RBC transfusion in patients with malignancy are still awaited. Overall, there is no single hemoglobin level that can be universally applied as a “transfusion trigger.” In deciding whether to transfuse a specific patient, the physician should consider the patient's age, degree of anemia, the intravascular volume, and the presence of coexisting cardiac, pulmonary, or vascular conditions.¹⁷ To meet oxygen needs, some patients may require RBC transfusions at higher hemoglobin levels. In particular, hemoglobin levels are commonly maintained at levels of 8 g/dL in the setting of cancer and its therapy. Transfusing one unit of RBC will usually increase the hemoglobin by 1

g/dL and the hematocrit by 2–3% in the average adult weighing 70 kg.

Packed red blood cells (PRBC) are prepared either from whole blood (WB) by the removal of plasma or by erythrocytapheresis. Red cells can be depleted of leukocytes by filtration to produce leukoreduced red cells (LRBC). Leukoreduction can prevent a significant percentage of febrile nonhemolytic transfusion reactions and cytomegalovirus (CMV) infection in transfusion recipients.¹⁸ In the United States and internationally, there is a trend to universally transfuse leukoreduced cellular components to avoid the multiple adverse sequelae of leukocytes. Washed RBCs are prepared by further removal of plasma from PRBCs. These products are sometimes indicated to prevent allergic reactions to plasma proteins.¹⁹ PRBCs are currently stored for up to 42 days at 4°C. Retrospective studies have suggested that transfusing older stored PRBC units may be associated with adverse consequences for the recipient.²⁰ However, older RBC units have not been demonstrated to increase morbidity or mortality when compared with fresher RBC units in multiple randomized controlled trials.^{21–23}

Leukopenia and white cell support

Leukopenia

Leukopenia may occur related to cancer and its treatment. In 1965, Hersh and colleagues summarized the causes of death in patients with acute leukemia treated at the National Cancer Institute and noted a marked decline in fatal hemorrhage, owing to the availability of platelet transfusions, with a concomitant increase in the occurrence of infection alone as a cause of death.²⁴ A quantitative relationship between circulating leukocytes and infection was established in patients with leukemia; in particular, the probability of being infected is proportional to both the severity and duration of leukopenia.²⁵

Granulocyte transfusion

Therapeutic granulocytes were first utilized nearly 30 years ago in leukemic patients with leukopenia and serious infection. The earliest trials, which demonstrated the potential value of granulocyte transfusions, utilized granulocytes harvested from patients with chronic myelogenous leukemia and achieved cell dosages never approached when normal donors were utilized.²⁶ The importance of dose was defined: less than 10^{10} granulocytes were ineffective whereas greater than 10^{11} cells were effective. Indeed, in an afebrile, uninfected man, the half-life of granulocytes in the circulation is 6.7(4–10) h and the daily turnover rate is 230%. Parallel work in canine models had also demonstrated that dogs deliberately made leukopenic by irradiation and given Gram-negative bacteremia and pneumonia could be successfully treated with granulocyte transfusions.²⁷

There have been six randomized prospective trials of prophylactic leukocyte transfusions, given to prevent infections in leukopenic recipients.^{28, 29} However, none of the studies demonstrated improved survival because alloimmunization, transfusion reactions, CMV infection, and pulmonary infiltrates occurred more frequently in the transfused group. These studies have been criticized owing to inadequate donor-recipient matching and inadequate doses of granulocytes transfused. A large randomized trial of high-dose granulocytes collected from donors mobilized with a combination of G-CSF and dexamethasone has been completed.²⁹ Currently, the role for granulocyte transfusions remains controversial. When granulocyte transfusions are used, the products must be irradiated to prevent graft-versus-host disease (GVHD) when transfused to an immunocompromised host.

Thrombocytopenia and platelet support

Thrombocytopenia

Thrombocytopenia in cancer patients is usually attributable to treatment with chemotherapy and radiotherapy. Impaired production of platelets due to a decrease or absence of megakaryocytes is therefore the most common cause of thrombocytopenia in patients with cancer ([Table 3](#)). However, thrombocytopenia may also be due to splenic sequestration in patients who have splenomegaly as part of their primary neoplastic process. In this setting, increased numbers of megakaryocytes are evident unless extensive marrow infiltration is present. Immune-mediated thrombocytopenia may also occur related to antihuman leukocyte antigen (anti-HLA) or antiplatelet-specific alloantibodies. Finally, thrombocytopenia may be related to diffuse intravascular coagulation (DIC), especially in patients with acute myelocytic leukemias, lymphomas, and carcinoma of lung, breast, gastrointestinal, or urologic origin. DIC commonly complicates acute promyelocytic leukemia owing to the presence of both thromboplastic material and fibrinolytic proteases in the promyelocytic subcellular components.³⁰

Table 3 Causes of thrombocytopenia

Acute thrombocytopenia due to increased <ul style="list-style-type: none">• Platelet depletion (utilization, sequestration, or destruction)• Massive blood replacement• Cardiac surgery• Splenomegaly

Abnormalities in platelet function

Platelet function can be abnormal in several chronic myeloproliferative disorders. Although most bleeding in patients with acute myeloid leukemia (AML) is related to thrombocytopenia, intrinsic abnormalities in platelet function have been described including decreased platelet procoagulant activity and decreased aggregation and serotonin release responses to ADP, epinephrine, or collagen.³¹ Platelet dysfunction is evident in a fraction of patients with IgA myeloma or Waldenstrom macroglobulinemia, multiple myeloma, and monoclonal gammopathy of undetermined significance.³²

Platelet transfusion support

In 1910, fresh WB was first transfused to thrombocytopenic patients, resulting in a significant rise in the platelet count, hemostasis, and improvement of the bleeding time.³³ In the 1950s, platelets were first used for the treatment of thrombocytopenia related to combination chemotherapeutic treatments of leukemias.³⁴ Data from the National Cancer Institute in the early 1960s clearly demonstrated that leukemia patients died of hemorrhage during induction of remission with chemotherapy and established the quantitative relationship between platelet count and hemorrhage.³⁵ It was shown that platelet therapy could modify the course of hemorrhage in both pediatric and adult settings, the only difference being the doses required. Two recent randomized trials compared a prophylactic platelet-transfusion strategy with a therapeutic platelet-transfusion strategy in patients with hypoproliferative thrombocytopenia. Both studies demonstrated a benefit, albeit limited, of platelet prophylaxis, and both showed that prophylaxis has a greater effect on bleeding risk in patients treated with chemotherapy for leukemia compared with autologous stem cell transplant recipients.³⁶

Single- and multiple-donor platelets

In the United States, one unit of platelet concentrate is obtained from one unit of WB by centrifugation, and contains approximately 5.5×10^{10} platelets/unit. (This method of preparing platelets is known as the “platelet-rich plasma” (PRP) method. In other countries, platelet concentrates are prepared from WB using the alternate “buffy coat” method.) Concentrates from multiple (4–6) donors are pooled to produce a single component for transfusion. Apheresis technology has permitted harvesting the equivalent of several platelet concentrates from a single donor during a single donation. A single-donor platelet unit typically contains at least 3×10^{11} platelets/unit. The use of single-donor platelets is increasing; they are generally considered to be the platelet product of choice for patients being treated for malignancy.³⁷ Single-donor platelet collections are utilized to provide HLA-matched donors for alloimmunized recipients who have not responded to platelets from random donors. In the United States, platelet units may be stored at room temperature for up to 5 days.

Indications for therapeutic and prophylactic platelet transfusion

Platelets are commonly transfused to patients with cancer. The majority of platelet transfusions are given prophylactically to prevent bleeding, as opposed to therapeutically, to treat active bleeding.³⁸ The appropriate indications for transfusion of platelets have been the subject of a recent clinical practice guideline from the AABB.³⁹ At present, one dose of one apheresis platelets (or equivalent pool of random donor-platelet concentrates) is routinely transfused to cancer patients with platelet counts less than $10,000/\text{mm}^3$ to reduce the risk of hemorrhage. Data from Gmur and colleagues suggested that the threshold for prophylactic platelet transfusion can safely be set at $5 \times 10^9/\text{L}$ in patients with acute leukemia without fever or bleeding manifestations and at $10 \times 10^9/\text{L}$ in patients without such signs.⁴⁰ Prospective clinical trials have shown that the risk of major bleeding was similar whether $10 \times 10^9/\text{L}$ or $20 \times 10^9/\text{L}$ was used as the platelet-transfusion threshold in patients with acute leukemia, and that the lower threshold reduced platelet use.^{41–43}

The risk of bleeding at a given platelet count may vary in distinct clinical settings. For example, patients with thrombocytopenia due to AML were reported to have increased bleeding at less than $10,000/\text{mm}^3$ platelets, in contrast to patients with acute lymphocytic leukemia (ALL), who had similar risk of hemorrhage at less than $20,000/\text{mm}^3$ platelets.⁴⁴ Patients with chronic thrombocytopenia due to decreased

platelet production (i.e., myelodysplastic disorders) may require transfusions, in contrast to patients with accelerated destruction but active production of platelets (i.e., idiopathic thrombocytopenic purpura), who may not require routine platelet transfusions. Moreover, patients with chronic thrombocytopenia may tolerate lower absolute platelet counts without transfusion. In patients with abnormalities of platelet function, it is not the absolute platelet count but rather the number of functional platelets that is important for the prevention of bleeding. Thus, it is difficult to define an absolute platelet threshold for transfusion for all patients, and both the timing and the dose of prophylactic platelet transfusion must therefore be determined on a clinical basis.^{39, 45–47}

The multicenter randomized PLADO (PLAtelet DOsing) study demonstrated that prophylactic transfusion with low-dose platelets does not increase the risk of Grade 2 or higher bleeding as compared with standard-dose prophylaxis among inpatients with hypoproliferative thrombocytopenia. Patients receiving low-dose prophylaxis do require more frequent platelet transfusions, although fewer total platelets are required overall.⁴⁸

Clinical and laboratory assessment of the effectiveness of platelet transfusion

The effectiveness of platelet transfusion can be assessed by laboratory parameters (the platelet count increment 1 h or 10–15 min after transfusion) and by the observed clinical outcome after transfusion.^{49–52} The corrected count increment is defined as the increment in platelet counts from pre- to post-transfusion corrected for the number of units transfused and for the body surface area of the recipient. A CCI of 15,000–20,000/mm³ is usual at 18–24 h, provided fresh, properly stored platelets have been transfused.⁵²

Post-transfusion increments in platelet count may be lesser than expected due to splenic sequestration, especially in the setting of splenomegaly.⁵⁰ Drug-induced platelet antibodies, which mediate immune destruction of platelets, have been demonstrated. The survival of transfused platelets can also be compromised if the recipient possesses antibodies against donor antigens of HLA-A and HLA-B loci, the ABO system, or platelet alloantigens. Response to platelet transfusion in recipients of hematopoietic stem-cell transplantation has been specifically studied.

Alloimmunization

Platelets bear HLA-A and -B but lack HLA-C and -DR Antigens, and there is a high correlation between the development of lymphocytotoxic anti-HLA antibodies in the recipient and refractoriness to random-donor platelets.⁵³ Currently, anti-HLA antibodies are most easily detectable using the patient's serum in a flow cytometry assay using HLA antigen-coated beads.

Yankee and colleagues first demonstrated that platelets obtained from HLA-identical siblings or from unrelated donors matched at the HLA-A and -B loci (grade A or B matches) could result in satisfactory post-transfusion increments in alloimmunized recipients who were refractory to random-donor platelet transfusions.⁵⁴ Subsequently, Duquesnoy and colleagues found that donors whose HLA antigens were the same (B match) or cross-reactive with the patient's antigens (BX match) were equivalent.⁵⁵

The recognition of the refractoriness associated with the development of anti-HLA antibodies led to attempts to either avoid or delay alloimmunization by modifying the platelets to be transfused. As HLA antigens are expressed on leukocytes, and platelets themselves are poor immunogens, investigators have attempted to (1) remove WBCs from platelets or treat platelets with ultraviolet (UV) irradiation to

abrogate the leukocyte antigen-presenting function; (2) use single rather than multiple-donor platelets to minimize exposure to HLA; and (3) transfuse only HLA-matched or leukocyte-depleted HLA-matched platelets. The multicenter prospective Trial to Reduce Alloimmunization to Platelets (TRAP) study confirmed that the incidence of anti-HLA and platelet-specific antibodies alone, as well as the incidence of antibodies associated with platelet refractoriness, was reduced in leukemic recipients who received either filtered or UV-treated pooled random-donor concentrates or filtered single-donor platelets compared to similar patients who received nonfiltered pooled random-donor concentrates.⁵⁶ Only 13% of patients developed platelet refractoriness associated with lymphocytotoxic antibodies, suggesting that the majority of unresponsiveness to platelet transfusion is related to other factors. When sensitized recipients remain refractory to HLA-matched platelets, cross-matched platelets are sometimes provided. A third method of dealing with HLA immune refractoriness is to provide antigen-negative platelets, analogous to providing antigen-negative RBCs for patients with RBC alloantibodies.

ABO blood group determinants are intrinsic to platelet membranes.⁵⁷ Unlike the case with RBC transfusion, ABO mismatch between donor and recipient is not an absolute contraindication to platelet transfusion. That said, ABO-identical platelet transfusions are preferred. Transfused ABO major-incompatible platelets (e.g., A donor and O recipient) demonstrate recoveries that are about one-third lower than those seen with ABO-identical transfusions.^{58, 59}

In addition, passively transfused high-titer isohemagglutinins present within the plasma in the transfused platelet concentrates (e.g., donor O and recipient A) have occasionally caused severe hemolysis. The United Kingdom, notably, has instituted routine screening of platelet units for anti-A/B to prevent this problem. Other countries, including the United States, have not adopted a uniform strategy of prevention.⁵⁹

Other therapeutic modalities

Transfusion of fresh frozen plasma

Fresh frozen plasma is the fluid portion of 1 unit (450 mL) of WB that is centrifuged, separated, and frozen at -18°C or lower. It contains physiologic levels of coagulation factors. Fresh frozen plasma is utilized to correct coagulation factor deficiencies; to reverse warfarin effect; and to treat thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, coagulopathy of liver disease, thrombolytic agent overdose, and protein C or S deficiency.^{60, 61} In addition to the plasma obtained from donated WB, it can be collected using plasmapheresis procedures for the production of derivatives: coagulation factors (factors VIII and IX), immunoglobulin, and albumin preparations.

Effects of transfusion on the immune system

Alloimmunization

The most firmly established effect of transfusion is the stimulation of antibodies in the recipient against antigens in the transfused products. Both cellular and plasma antigens in transfused blood expose the recipients to hundreds of known alloantigens.

Over 400 RBC antigens have been identified, yet we routinely ensure compatibility for only three of them: A, B, and D. More than 100 HLA antigens, as well as granulocyte- and platelet-specific antigens, have also been identified. Genetic alleles can result in structural and therefore antigenic differences among all plasma proteins, leading to recipient alloantibodies to the donated immunoglobulins. Most alloantigens

are ignored in transfusion therapy, as they are poor immunogens. However, studies clearly demonstrate that the development of recipient antibodies to antigens in transfused products relates not only to the number of transfusions but also to their timing. Specifically, individuals who receive equal numbers of transfusions are more likely to develop antibodies if the transfusions are given repeatedly over a longer period than if given within a shorter interval. Some cancer patients, by virtue of receiving repeated transfusions over a longer period, may therefore be more likely to become alloimmunized. Alloantibodies to RBCs can lead to recipient morbidity and shortened RBC survival; antibodies to leukocytes are associated with febrile transfusion reactions and can impair effectiveness and survival of transfused granulocytes.⁶² Anti-HLA-A and -B antibodies as well as platelet-specific alloantibodies impair survival of transfused platelets. Finally, anti-IgA sometimes causes anaphylactic reactions in IgA-deficient recipients, but anti-IgG or -IgM or antilipoproteins are not clinically significant.⁶³

Transfusion-associated GVHD

Historic perspective

GVHD is commonly observed after allogeneic bone marrow transplantation (BMT), but is rarely recognized after transfusion or transplantation of other organs. Transfusion associated (TA)-GVHD usually occurs in the immunosuppressed recipient (e.g., BMT recipients), but it can also occur in immunocompetent recipients in the setting of a one-way HLA mismatch.⁶⁴ The clinical manifestations include fever and skin rash, anorexia, nausea, vomiting, and watery or bloody diarrhea with or without elevated liver enzymes and hyperbilirubinemia. As there are no pathognomonic features of GVHD, this syndrome is sometimes difficult to distinguish from viral infections or drug eruptions. TA-GVHD is usually severe, and, unlike the situation after allogeneic BMT, it frequently results in pancytopenia secondary to marrow aplasia. The majority of reported cases of TA-GVHD have not responded to immunosuppressive therapies and have been fatal.

Definition of those at risk

In 1986, the National Institutes of Health Consensus Development Conference defined patients who have undergone BMT or those with other forms of immunodeficiency as candidates for irradiated platelet concentrates to avoid GVHD. Patients with leukemias and other cancers who may be immunosuppressed secondary to chemotherapy and/or radiation therapy, or due to intrinsic immune dysfunction (e.g., HD), may be at risk for TA-GVHD. Among patients with HD, it had previously been assumed that combined radiation and chemotherapy were necessary as predisposing factors for the development of TA-GVHD, but several cases of TA-GVHD have recently been documented in patients with HD who were treated with chemotherapy alone. Patients receiving high-dose chemotherapy followed by autologous bone-marrow support are also at risk for TA-GVHD.⁶⁵ Finally, immunocompetent patients who share an HLA haplotype with HLA-homozygous blood donors also appear to be at risk for TA-GVHD.^{66, 67} Homozygosity for HLA types is more likely to occur among first-degree family members (e.g., parents, children, and siblings). It has, therefore, recently been recommended that cellular blood components from such donors be irradiated with at least 25 Gy before transfusion. Indeed, products from all family member-directed donors should be irradiated, given that TA-GVHD has now been reported after transfusion of blood from a second-degree relative.⁶⁸ Reports of TA-GVHD after transfusion of cellular blood components from homozygous blood donors to heterozygous nonblood relatives suggest that indications for gamma irradiation may need to be broadened.^{69, 70} The risk of transfusion of blood from

HLA homozygous donors to unrelated HLA heterozygous patients is 1 in 874 in Japan and may be as high as 1 in 7174 in the United States.⁷¹ Finally, reports confirm that all HLA-matched cellular components should be irradiated.^{69–72}

Strategies for prevention

The only currently effective method to prevent TA-GVHD is gamma irradiation of blood products before transfusion. Studies suggest that irradiation at 15–20 Gy can reduce mitogen-responsive lymphocytes by 5–6 logs compared to unirradiated controls.⁷¹ The standards of the AABB (formerly, the American Association of Blood Banks), as well as those of the FDA, now require that blood and cellular components be irradiated with a midplane dose of a minimum of 25 Gy.⁷² Studies to date suggest no adverse effects of irradiation on storage of platelets, but the clinical significance of potassium release on storage of irradiated red cells is not yet defined, and post-transfusion red-cell recovery of irradiated units may be decreased.^{73, 74}

Transfusion-related infectious diseases

Hepatitis B

Although hepatitis B (HB) was formerly a common transfusion-related infection, the use of several generations of HB surface antigen assays to screen potential donors and the use of volunteer versus commercial donors has markedly reduced the incidence of HB transmitted by transfusion.⁷⁵ Nucleic acid testing (NAT) is now often performed to test for HB as well. The current estimated per-unit risk of HB is approximately 1 in 200,000 ([Table 4](#)).⁷⁶

Table 4 Risks of transfusion

Complication	Frequency (episodes:unit)
<i>Reactions</i>	
Febrile nonhemolytic	1–4:100
Allergic	1–4:100
Transfusion-related acute lung injury	1:10,000
Acute hemolytic	1:250,000
Delayed hemolytic	1:1,000
Anaphylactic	1:150,000
<i>Infections</i>	
Hepatitis C	1:2,000,000
Hepatitis B	1:200,000
HIV-1	1:2,000,000
HIV-2	None reported
HTLV-I and II	1:250,000–1:2,000,000
Malaria	1:4,000,000
Bacteria red cells	1:500,000
Bacteria platelets	1:75,000
<i>Other complications</i>	
RBC allosensitization	1:100
HLA sensitization	1:10
Graft-versus-host disease	Rare

Abbreviations: HIV, human immunodeficiency virus; HLA, human leukocyte antigen; HTLV, human T-cell leukemia/lymphoma virus; RBC, red blood cell.

Hepatitis C

Following the identification of hepatitis A and HB viruses, it was quickly appreciated that neither agent was responsible for most cases of post-transfusion hepatitis. Thus, the term non-A non-B Hepatitis (NANBH) was introduced. In the mid-1980s, donors were screened for alanine aminotransferase (ALT) as well as anti-HBc; these served as “surrogate” markers for individuals having a 20% chance of transmitting NANBH.^{77, 78}

The causative agent of NANBH was finally discovered by cloning a fragment of viral cDNA from a chimpanzee infected with NANBH.⁷⁹ Subsequently, the entire genome of what is now called hepatitis C virus (HCV) was cloned. A specific assay was developed for bloodborne NANBH, in which a recombinant HCV polypeptide is used to capture viral antibodies.⁸⁰ Subsequent testing using multiple-antigen HCV enzyme assays confirmed that nearly all cases of post-transfusion NANBH are caused by HCV. Uniform screening of blood donors for anti-HCV antibodies was implemented in 1990. NAT is now being employed to enhance sensitivity in detecting infection.⁸¹ Along with HIV (discussed below), all blood donations in the United States are now screened for HCV. By narrowing the preseronconversion

window period from about 75 days to less than 30, the use of NAT has reduced the per-unit risk of HCV to approximately 1 in 2,000,000.⁷⁶

Cytomegalovirus

Cellular blood components transfused from CMV-seropositive donors to CMV-seronegative transplant recipients and neonates can cause CMV seroconversion and infection. Although equivalent numbers of autologous and allogeneic BMT recipients either seroconvert to or excrete CMV, recipients of autologous BMT rarely develop clinical sequelae. The traditional CMV-seronegative blood products are red cells and platelets harvested from CMV-seronegative donors. LRBC and platelets have been shown to decrease transfusion-acquired CMV infection in infants, in patients undergoing treatment for acute leukemia, and in autologous and allogeneic BMT recipients.^{82–85} A multicenter-randomized trial compared seronegative with filtered cellular blood components in CMV-sero-negative patients undergoing autologous BMT and seronegative patients receiving allografts from CMV seronegative donors.⁸² Rates of CMV seroconversion and infection were equivalent in recipients of seronegative and filtered components, but significant clinical sequelae were noted only in those patients receiving filtered, unscreened components. These results suggest that filtering can markedly reduce CMV transmission, and filtered components are now considered “CMV safe”; however, it may be premature to conclude that filtered and seronegative components are exactly equivalent.

West Nile virus

West Nile virus (WNV) is a mosquito-borne flavivirus that can be transfusion transmitted. The vast majority of WNV infections result from mosquito bites. About 80% of individuals infected with WNV are asymptomatic. Of the 20% who manifest symptoms, most will have a mild illness (WNV fever). Less than 1% of infected individuals develop a severe meningo-encephalitis, with advanced age being the strongest risk factor.⁸⁶ WNV first appeared in the United States in 1999. In 2002, over 4000 clinically significant cases of WNV were reported, including 23 cases determined to have been transfusion associated. In 2003, NAT of blood products was begun nationwide under an FDA investigational new drug (IND) protocol. This testing has eliminated most of the risk of transfusion-transmitted WNV.

Bacterial sepsis

Bacteria very rarely survive in WB stored at 4°C. In contrast, platelets are stored at room temperature on an agitator and are a potential source of bacterial contamination, which can result in transfusion-related sepsis.⁸⁷ Blood collection facilities in the United States are now required by AABB to both detect and limit bacterial contamination of platelets.⁷⁶ A variety of screening techniques to address bacterial contamination within platelets, such as automated culture systems, are now in use.^{88, 89}

Human immunodeficiency virus (HIV)

Since 1985, all American blood donors have been screened for anti-HIV antibody using ELISA. Transfusion-transmitted HIV is now exceedingly rare; the few cases that do occur result almost exclusively from seronegative window period donations. Following the initial implementation of HIV antibody screening, improvements in the sensitivity of the HIV-1 and HIV-2 ELISA limited the seronegative window period to approximately 22 days⁹⁰ All units donated in the United States are now tested by minipool NAT. NAT (transfusion-mediated amplification, TMA, or polymerase chain reaction,

PCR) is performed on pools of 16–24 samples; this technology shortens the window period to approximately 10 or 11 days from the time of exposure. It is estimated that the current residual per-unit risk of HIV transmission is less than 1 in 2,000,000.⁷⁶

Human T-cell lymphotropic virus type 1

Human T-cell lymphotropic virus type 1 (HTLV-1) is associated with adult T-cell leukemia/lymphoma (ATL) and tropical spastic paresis (TSP)/HTLV-1-associated myelopathy (HAM), and clusters geographically in endemic areas such as parts of Japan and the Caribbean. In the United States, ATL incidence is similar to that in the Caribbean, as the cases in the United States are all among African-Americans or in patients born outside the United States.⁹¹

In 1988, blood-collection agencies initiated testing of all blood donors for anti-HTLV-1 antibodies at the time of all donations, with permanent deferral of individuals with confirmed seropositivity. Studies in the United States document that HTLV-1 has been transmitted via transfusion and demonstrate the efficacy of screening. The risk per unit transfused is between 1 in 250,000 and 1 in 2,000,000.⁷⁶

Parasitic diseases

As there is no practical laboratory screening test for malaria, exclusion of donors who have either traveled to or emigrated from endemic areas is the only effective measure to prevent transfusion-related infection. Other parasitic diseases, such as babesiosis or Lyme disease, can be transmitted by an asymptomatic donor who has been bitten by a tick and may be of particular importance in immunocompromised or asplenic patients. Transfusion-transmitted babesiosis is a regional disease. At this time, there are seven endemic US states: Massachusetts, Connecticut, Rhode Island, New York, New Jersey, Wisconsin, and Minnesota.⁹² Although transmission of syphilis by transfusion is possible, it requires that blood be drawn during the rather short period of spirochetemia and that the organisms remain viable at the time of transfusion. Although performing a serologic test for syphilis does not prevent transmission of syphilis because this test does not become positive until well after the brief period of infectivity, US federal regulations do require its use as a screening test of potential donors.

Another recognized transfusion-related infection is Chagas disease.⁹³ In the majority of cases, spontaneous resolution occurs, and patients enter the indeterminate phase with lifelong, low-grade parasitemia, antibodies to parasite antigens, and absence of symptoms. Between 10% and 30% of persons in the indeterminate phase eventually develop symptoms. However, in immunocompromised patients, this illness may take a more fulminant course. The diagnosis of acute infection is made by detection of parasites on blood smear and the diagnosis of chronic infection by the detection of serum antibodies.

Creutzfeldt–Jakob disease

Prospective donors of blood products who have a familial history of dementia and have undergone corneal or brain surgery are deferred.^{94–97} Owing to the identification in 1996 of a variant Creutzfeldt–Jakob disease (vCJD), which may be associated with bovine spongiform encephalopathy (BSE), or “mad cow disease,” potential donors who resided in the United Kingdom for 3 months from 1980 to 1996 are deferred from donating. Donors residing in Europe for 5 years cumulatively from 1980 onward are also deferred. These travel restrictions are expected to eliminate 90% of person-days of exposure to the causative agent of vCJD at a cost of eliminating 5% of US blood donors. In the United Kingdom, a small

number of human cases of transfusion-transmitted vCJD have been reported. Universal use of leukoreduced components for transfusion is recommended in many countries, based on the fact that the vector for transmission of vCJD appears to be the B lymphocyte.

Blood Component Support Post-transplantation. After BMT, there is a period of pancytopenia, when patients require multiple RBC and platelet transfusions. In cases of donor-recipient ABO incompatibility (about one-third of allogeneic transplants), particular care must be paid to blood provision. In these situations, blood products are selected to be ABO-compatible with both the donor and recipient.

ABO incompatibility between marrow donor and recipient may be either major, with isohemagglutinin in the recipient directed against donor RBC antigens, or minor, with isohemagglutinin in the donor directed against recipient RBC antigens. Major ABO incompatibility has the potential risk of severe hemolytic reactions, graft rejection, or delayed engraftment.^{98–100} Attempts to overcome major ABO incompatibility have included depletion of RBCs from the bone-marrow graft before BMT and/or removal of isohemagglutinin from the recipient by large-volume plasma exchanges or immunoadsorption, but these maneuvers are not done routinely.^{101, 102} Although studies suggest that major ABO incompatible HLA-matched transplants have resulted in no increase in patient mortality, incidence of rejection, delayed reconstitution, or GVHD compared to ABO compatible controls, some reports suggest that RBC reconstitution can be delayed in this setting.^{98, 103} Red-cell engraftment may be especially delayed in the setting of major ABO-incompatible nonmyeloablative stem-cell transplantation, where host antidonor isohemagglutinin levels tend to decrease more slowly than in myeloablative BMT.¹⁰⁴

Potential adverse outcomes of minor ABO incompatibility between marrow donor and recipient include rapid immune hemolysis at the time of infusion of donor marrow resulting from passive transfer of isohemagglutinin in the marrow plasma, or delayed immune hemolysis caused by anti-RBC antibodies produced by donor lymphocytes.¹⁰⁵ There is no effect of minor ABO incompatibility on graft rejection, the incidence and severity of GVHD, or patient survival. Although exchange transfusion of the recipient before BMT using red cells of the donor's blood group has been utilized to prevent hemolysis caused by passive transfer of isohemagglutinin in the marrow product, this is rarely a clinically significant problem and can more easily be avoided by removing plasma from the marrow before infusion. Minor ABO incompatibility can result in adverse reactions owing to the production of anti-A and/or anti-B antibodies by donor-marrow lymphocytes early (1–3 weeks) following transplantation, particularly in patients on cyclosporine therapy or those receiving T cell-depleted allografts.^{106, 107} In this setting, transfusions of either group O or donor group RBCs are utilized to dilute the recipient red cells; in some cases, exchange transfusion has been required owing to very rapid engraftment of donor lymphocytes and production of anti-RBC antibodies.

Conclusion

The development and implementation of new and aggressive therapies for patients with cancer to date would not have been possible without parallel developments for the provision of blood-component support. In the future, the blood-component laboratory will provide specialized cellular components to facilitate the use of new and promising transplantation and cellular therapies for patients with hitherto incurable diseases.

Chapter 130

Coagulopathic complications of cancer patients

Maria T. De Sancho, MD, MSc ■ Jacob H. Rand, MD

Overview

Bleeding and thrombotic complications are common in cancer patients. The bleeding complications usually result from abnormalities in platelets or deficiency of coagulation factors and require specific blood or coagulation factor replacement. Thromboembolic events including deep venous thrombosis and pulmonary embolism are common and associated with serious complications. New biomarkers, diagnostic imaging approached and anticoagulant therapies have significantly improved the care of these patients. Ongoing research in the understanding of the various disturbances in hemostasis, application of innovative treatment modalities, and use of appropriate thromboprophylaxis in cancer patients should lead to further decreased morbidity and improved survival.

Bleeding and thrombotic complications are major causes of morbidity and mortality in cancer patients. As a result of advances in cancer treatment, the prevalence of these complications has been progressively rising in recent years. Bleeding is common in patients with leukemias, particularly those with acute promyelocytic leukemia (APL); however, due to improved targeted therapies, early hemorrhagic deaths have decreased to 5–10% within the context of clinical trials, but not replicated in clinical practice as evidenced from recent-population-based registries.¹ In general, bleeding complications occur relatively infrequently in patients with solid tumors, except those with melanoma, germ cell tumors, carcinoma of the cecum and prostate cancer,² although carcinomas of the kidney, bladder, endometrium, and cervix may first time be recognized by bleeding. In particular, gemcitabine and bevacizumab-based therapies are associated with an increased risk of high-grade hemorrhage in patients with solid tumors.^{3,4} Cancer-mediated hypercoagulability occurs as a consequence of direct activation of procoagulant pathways by cancer cells. Cancer patients account for about 20% of newly diagnosed venous thrombosis events (VTEs) and in up to 50% in postmortem studies.⁵ This chapter reviews the physiology of normal hemostasis, and then discusses the relationship of the coagulation system and cancer, and the pathophysiology of bleeding and thrombosis in the cancer patient. Next, the diagnostic and treatment approaches to the disorders most frequently encountered in cancer patients are described. Finally, the new generation of direct oral anticoagulants (DOACs) such as anti-Factor Xa and anti-Factor IIa inhibitors are addressed.

Physiology of normal hemostasis

Hemostasis dependent on both cellular components and soluble plasma proteins is the physiologic mechanism that halts bleeding after injury to the vasculature. Circulating platelets adhere and aggregate at sites of blood vessel injury. Platelet adhesion is dependent on the presence of the von Willebrand factor (vWF) and is followed by an aggregation response. Activation of platelets results in a flipping of the polarity of inner and outer leaflets of the cytoplasmic membrane and consequent exposure of anionic

phospholipids that serve as platforms for the assembly of blood coagulation enzyme complexes. The extrinsic pathway of blood coagulation is initiated when blood is exposed to tissue factor (TF), a transmembrane protein expressed in the deeper portions of the blood vessel wall that may also be present in stimulated endothelial cells. Thrombus propagation occurs via incorporation of active, blood-borne TF into the growing clot.⁶ TF binds activated factor VII (factor VIIa) and the resulting complex activates factors X and IX. Activated factor IX (factor IXa) combines with factor VIIIa to provide a second pathway to activate factor X. Factor Xa complexes with factor Va and prothrombin to form prothrombinase, which cleaves prothrombin to generate thrombin, the key enzyme in hemostasis. In the final step of the coagulation cascade, thrombin cleaves fibrinogen to generate fibrin monomers, which then polymerize. This polymer is covalently cross-linked by factor XIIIa (itself generated from factor XIII by thrombin) to form a chemically stable clot. Thrombin also feeds back to activate cofactors V, VIII, and XI further amplifying the coagulation system.⁷

Fibrin deposition is limited by an endogenous anticoagulant system. Antithrombin (AT) is a plasma protein member of the serpin (serine protease inhibitor) family that inhibits the activities of all of the activated coagulation enzymes particularly factors IIa and Xa. Protein C is a vitamin K-dependent protein that proteolyzes factors Va and VIIIa to inactive fragments. Protein C binds to an endothelial cell protein C receptor (EPCR)⁸ and is activated by thrombin bound to thrombomodulin, another endothelial cell membrane-based protein, in a reaction that is modulated by a cofactor, protein S. TF pathway inhibitor is a plasma protein that forms a quaternary complex with TF, factor VIIa, and factor Xa, thereby inhibiting the extrinsic coagulation pathway.

There has been increasing intriguing evidence that, in addition to its role in hemostasis, factor XI plays a role in venous thrombosis. This has been supported by a recent clinical trial of a factor XI antisense oligonucleotide in patients who were at increased risk for DVT because of knee replacement surgery in which this strategy significantly reduced venous thrombosis. This type of anticoagulant strategy has the possibility of yielding important clinical benefits for cancer patients as it appears that factor XI level did not need to be reduced below a homeostatic level of 20% in order to gain a prophylactic effect. It is therefore possible that this strategy may be able to reduce the rate of thrombosis without significantly increasing the risk of bleeding.⁹ However, this possibility will require testing in well-designed clinical trials.

The fibrinolytic system refers to a cascade of serine proteases that result in fibrin degradation and clot dissolution. The final step in this process is the conversion of the circulating zymogen plasminogen into its active form plasmin. In the circulation, this is mainly achieved by tissue-type plasminogen activator (t-PA). This catalysis is highly dependent on the presence of fibrin, as binding of both plasminogen and t-PA to fibrin increases plasmin generation by more than two orders of magnitude. Mechanistically, plasminogen binds to exposed lysine residues formed in fibrin and these binding sites increase in number during fibrin cleavage allowing more plasminogen binding to occur, thereby amplifying the process allowing more plasmin to be generated. Naturally occurring plasma inhibitors [α 2 antiplasmin, plasminogen activator inhibitor (PAI)-1, and PAI-2] also exist to limit plasmin activity or its generation in the circulation. The most potent of these is α 2 antiplasmin. Plasmin is largely protected from α 2 antiplasmin while bound to fibrin, allowing fibrin cleavage to occur. Other key regulatory steps occur at the level of the plasminogen activators, as the activity of t-PA and also urokinase-type plasminogen activator (u-PA), the second important endogenous plasminogen activator, are both regulated by PAI-1 and PAI-2.

The most recently described mechanism that limits the fibrinolytic system is via “thrombin activatable fibrinolysis inhibitor.” The protein, thrombin activatable fibrinolysis inhibitor (TAFI), is a

carboxypeptidase that specifically removes exposed lysine residues from fibrin, thereby removing the ability of plasminogen and t-PA to dock onto lysine binding sites in fibrin. As it requires activation by thrombin, TAFI becomes engaged as a direct consequence of coagulation to stabilize and protect clots from premature removal by the fibrinolytic system.¹⁰

Relationship of coagulation system, inflammation, and cancer

The relationship between blood coagulation and cancer was first described in the medical literature during the latter half of the nineteenth century with Trousseau's classic report of the association of migratory thrombophlebitis and gastric carcinoma.¹¹ In 1878, Billroth demonstrated cancer cells within a thrombus and theorized that tumor cells were spread by thromboembolism.¹² The interaction between blood coagulation and tumor angiogenesis and growth is supported by the involvement of several coagulation factors, specifically TF and thrombin in cancer neoangiogenesis, growth, and dissemination. Cancer cells or host cells in response to the neoplastic process cause local and systemic inflammatory stimuli that can switch the endothelium to a prothrombotic surface.¹³ Endothelial damage leads to exposure of subendothelial VWF and TF. VWF in turn induces platelet and tumor cell adhesion, with subsequent platelet activation and aggregation. TF plays a key role in the initiation of the coagulation cascade. TF is aberrantly expressed on the surface of activated endothelial cells, monocytes, and tumor cells.¹⁴ TF is upregulated in endothelium in pathologic states such as cancer as evidenced by the expression of TF and cross-linked fibrin on the endothelium of newly formed blood vessels within human tumors.¹⁵

Microparticles

Cell-derived vesicles, in particular extracellular vesicles (EVs) such as microparticles (MPs) and microvesicles, besides exosomes, are raising more and more attention as a novel and unique approach to detecting diseases.¹⁶ MPs are generally defined as 0.1 to 1 µm membrane particles that expose the anionic phospholipid phosphatidylserine and membrane antigens representative of their cellular origin. Platelet-derived microparticles (PMPs) represent the most abundant MP subtype. Their presence reflects platelet activity, physiopathology, and the thrombotic state of cancer patients. Because platelets play a key role in cancer progression, as well as formation of metastasis, PMPs also may be important in the proliferation of cancer cells, cancer cell interactions, metastatic progression, angiogenesis, and inflammation.¹⁷

While this is of great research interest and has diagnostic potential, the methodology(ies) for MP analysis has not yet been sufficiently standardized for routine clinical use. The authors of a recent consensus workshop concluded that there was significant variability among laboratories even when a common protocol was utilized.¹⁸

Bleeding disorders

Cancer can cause both quantitative and qualitative changes in platelets.¹⁹ Reactive thrombocytosis occurs in approximately 60% of cancer patients, while thrombocytopenia occurs in up to 11% of patients with untreated malignancy ([Table 1](#)).

Table 1 Hemostatic abnormalities in cancer patients

Abnormality	Mechanism
-------------	-----------

<i>Platelets</i>	
Thrombocytopenia	Marrow infiltration by tumor Chemotherapy effects Biological response modifiers Monoclonal antibodies and immunotoxins Proteasome inhibitor (bortezomib) Disseminated intravascular coagulation (DIC) Hypersplenism Immune mediated (autoimmune, alloimmune) Thrombotic microangiopathies (TMA)
Thrombocytosis	Increased production: <ul style="list-style-type: none"> • reactive • primary myeloproliferative disorders
Platelet function abnormalities	Uremia Acquired von Willebrand syndrome Myeloproliferative disorders
<i>Abnormalities in coagulation factors and clinically available coagulation activation markers</i>	
Hypofibrinogenemia	Asparaginase, DIC
Dysfibrinogenemia	Hepatocellular carcinoma
Factor X (decreased)	Amyloidosis
Decreased coagulation factors	Impairment in hepatic synthesis, DIC, vitamin K deficiency
Elevated D-dimer and fibrin degradation products	Inflammation, thrombosis, fibrinolysis, DIC, renal insufficiency, hepatic failure
Elevated prothrombin fragment 1 + 2	Disseminated malignancies, DIC
<i>Fibrinolysis</i>	
Increased secretion of plasminogen activators	Acute promyelocytic leukemia (APL)
Overexpression of annexin II	APL
Decreased levels of plasminogen activator inhibitors	Increased fibrin(ogen) degradation products and D-dimer
<i>Acquired thrombophilias</i>	
Antithrombin deficiency	Impaired hepatic synthesis of anticoagulant proteins, DIC, L-asparaginase, unfractionated heparin (UFH), and low-molecular-weight heparin (LMWH)
Protein C deficiency	Impaired hepatic synthesis, DIC, vitamin K antagonists (VKA)

Protein S deficiency	Impaired hepatic synthesis, DIC, VKA
Tissue factor pathway inhibitor deficiency (TFPI)	Impaired hepatic synthesis, DIC
<i>Cytokines and hemostasis</i>	
Proinflammatory cytokines (IL-1, IL-6, TNF)	Key role in tissue factor expression in monocytes and endothelial cells

Elevated microparticles have increasingly been associated with thrombosis in cancer; however, these tests have not yet been sufficiently standardized to be useful.

DIC, disseminated intravascular coagulation; TMA, thrombotic microangiopathy; IL, interleukin; TNF, tumor necrosis factor.

The major bleeding problems are commonly caused by tumor invasion of blood vessels and adjacent organs, complications of treatment, and vitamin K deficiency. Bleeding in the cancer patient may present as either localized bleeding usually as a result of tumor invasion or as generalized bleeding diathesis caused by thrombocytopenia, thrombocytopathies, specific coagulation factor deficiencies, disseminated intravascular coagulation (DIC), or hyperfibrinolysis.¹⁹ Appropriate treatment of bleeding in cancer patients needs to address the underlying disorder responsible for the bleeding.

Thrombocytopenia

Thrombocytopenia is the most frequent hemostatic disorder in cancer patients, occurring in approximately 10% of cases, even before starting chemotherapy. In the acute setting, thrombocytopenia is usually caused by decreased production either secondary to chemotherapy and/or radiation therapy or bone marrow infiltration, platelet sequestration in the spleen, or increased peripheral destruction, as in sepsis, disseminated DIC, and thrombotic microangiopathies (TMA)²⁰ ([Table 2](#)). Bortezomib, a proteasome inhibitor used in newly diagnosed and relapsed multiple myeloma, causes a transient, cyclical, and reversible thrombocytopenia.²⁰ Thrombocytopenia as a result of bone marrow infiltration commonly occurs in patients with small-cell lung cancer, breast cancer, and prostate cancer, as well as in patients with acute leukemia. On the other hand, thrombocytopenia secondary to splenic sequestration is usually observed with myeloproliferative disorders and less commonly with lymphomas and chronic lymphocytic leukemia. Clinically evident bleeding episodes are more likely to occur when thrombocytopenia is caused by diminished production of megakaryocytes rather than by immune destruction.

Table 2 Differential diagnosis of thrombocytopenia in cancer patients

<i>Decreased platelet production</i> <ul style="list-style-type: none">• Metastases to bone marrow• Acute and chronic leukemias• Lymphomas• Plasma cell dyscrasias• Medications including cytotoxic chemotherapy and targeted therapies• Radiation therapy
<i>Platelet destruction</i> <ul style="list-style-type: none">• Medications• Immune mediated• Bacterial sepsis• Viral, fungal, and protozoal infections• DIC• Heparin-induced thrombocytopenia• Thrombotic microangiopathies

Combination of the above mechanisms

DIC, disseminated intravascular coagulation; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.
May consider adding liver insufficiency as etiology of thrombocytopenia due to decrease in thrombopoietin synthesis.

The most common clinical manifestation of thrombocytopenia is mucocutaneous bleeding. This can occur in the form of petechiae, or ecchymoses, and epistaxis, oral, gastrointestinal, or genitourinary bleeding. Spontaneous bleeding usually does not occur unless the platelet count is less than 5000–10,000/mm³. However, in the presence of sepsis, uremia, trauma, or surgery, bleeding complications, including into the central nervous system, may occur with a higher platelet count.

The clinical history, physical examination, review of medications, and timing of prior chemotherapy, immunotherapy, or radiation therapy must be reviewed. In addition, examination of the peripheral blood smear is vital in the diagnostic work-up of thrombocytopenia. Spurious thrombocytopenia manifested by platelet clumping on the peripheral smear or platelet satellitism (platelets surrounding the polymorphonuclear leukocytes) must be excluded.

The treatment of bleeding associated with thrombocytopenia in the cancer patient is often managed

empirically even when a specifically defined cause cannot be identified. [Table 3](#) lists the critical platelet counts in various situations and general guidelines for platelet transfusion. Prophylactic transfusion of platelets is not indicated in patients who are asymptomatic for bleeding unless the platelet count is below 5000/mm³. However, in cancer patients undergoing chemotherapy and those with leukemia, prophylactic platelet transfusions are generally beneficial in decreasing the risk of bleeding when the platelet count is below 10,000/mm³.^{21, 22} For cancer patients undergoing major surgery or invasive procedures such as central venous catheterization, bronchial or endoscopic biopsy, lumbar puncture, thoracentesis, thoracostomy tube placement, and abdominal paracentesis, it is generally recommended that platelet transfusions should be administered in thrombocytopenic patients to a target level of greater than 50,000.²³ For minor invasive procedures such as arterial puncture or cannulation, prophylactic transfusion is not necessary if the platelet count is at least 20,000/mm³ and local pressure is applied at the puncture site until hemostasis is achieved.²³ Platelet transfusions are usually indicated in thrombocytopenic patients to keep the platelet count above 50,000/mm³ when evidence of microscopic or gross bleeding is detected, as manifested by either occult blood stool tests and mucocutaneous bleeding. The risk of central nervous system bleeding is generally low and bleeding depends on several factors such as concurrent anticoagulant therapy, etiology of thrombocytopenia, coagulation abnormalities, impaired renal or hepatic function, severe sepsis, trauma, and the use of mechanical ventilation. Subdural and intracerebral hematomas occur in approximately 2.5–5%²⁴ and 2%, respectively, of leukemic patients following hematopoietic stem cell transplantation.^{25, 26} Comparative studies show that platelets derived from single or random donors produce similar posttransfusion increments, hemostatic benefits, and side effects.²³

Table 3 Critical platelet counts and recommendations for transfusion in cancer patients^a

Platelet count threshold	
Mucocutaneous or gastrointestinal bleeding	>50,000
Leukemias	
Preinduction chemotherapy	>20,000
Acute promyelocytic leukemia	>5000 to 10,000
Prophylaxis	
Asymptomatic	>5000
Major surgery	>50,000
Invasive procedures	
Major	>50,000
Minor	>20,000

^a These are intended to serve as general guidelines. Actual treatment will vary depending on specific circumstances.

Thrombocytopathies

In addition to quantitative platelet changes, cancer can also cause qualitative platelet abnormalities. The main disorders are described in the following sections.

Acquired von Willebrand Syndrome

Several types of cancer have been reported in association with acquired von Willebrand syndrome (aVWS). Among the lymphoproliferative disorders, monoclonal gammopathy of undetermined significance (MGUS) is the condition most frequently associated with aVWS. It can also be associated with multiple myeloma, Waldenstrom macroglobulinemia, chronic lymphocytic leukemia, hairy cell leukemia, and non-Hodgkin lymphoma. Among the myeloproliferative disorders, essential thrombocythemia (ET) is the most common while polycythemia vera (PV) and chronic myeloid leukemia are less frequent. Solid tumors including Wilms tumors and carcinomas have also been associated with aVWS.²⁷

The clinical manifestations of aVWS are similar to those seen in patients with the hereditary form of the disease except for the notable absence of a family history or lifelong personal history for bleeding. Spontaneous mucocutaneous and gastrointestinal bleeding may be present. Postsurgical bleeding may also occur. Laboratory screening tests generally reveal a prolonged activated partial thromboplastin time (aPTT) and a normal or borderline prolonged bleeding time, or by prolonged closure times of the PFA-100. Treatment is directed to the underlying malignancy and supportive measures such as corticosteroids, deamino-8-D-arginine vasopressin (desmopressin acetate or DDAVP), factor VIII/vWF concentrate, and intravenous immunoglobulin.^{27, 28}

Acquired hemophilia (factor VIII autoantibodies)

Patients with solid tumors, plasma cell dyscrasias, and lymphoproliferative disorders may develop an acquired hemophilia as a consequence of autoantibodies against factor VIII, often referred to as “acquired inhibitors.” The inhibitors are almost always immunoglobulin G (IgG) molecules. The most common presenting complaint is bleeding into the skin or muscles in patients with no previous history of bleeding diathesis. The hallmark finding is a prolongation of the aPTT in the presence of a normal prothrombin time (PT) along with plasma mixing studies that demonstrate an aPTT that remains prolonged after incubation at 37 °C for 1–2 h. In contrast, in patients with coagulation factor deficiencies, plasma mixing studies normalize the aPTT. Contamination of the blood sample with heparin, which frequently is the inadvertent result of instillation for maintaining vascular access line patency, may artifactually prolong the aPTT and affect the mixing tests. Heparin that has entered the sample may be removed in the testing laboratory with the enzyme heparinase or resin absorption, after which the plasma may be retested. The acute bleeding can be managed with desmopressin acetate if there is a low inhibitor titer [<5 Bethesda units (BU)] or with human or porcine factor VIII. Factor VIII bypassing agents such as recombinant human factor VIIa or activated prothrombin complex concentrate are used in case of moderate- to high-titer inhibitor (>5 BU). Immunosuppressive therapy such as corticosteroids, cyclophosphamide, vincristine, cyclosporine, and intravenous immunoglobulin (IVIg) may be used in addition to the treatment of the underlying neoplasm. Rituximab should be considered in patients who are resistant to first-line therapy or cannot tolerate standard immunosuppressive therapy.²⁹

Uremia

Platelet dysfunction is common in cancer patients with chronic renal failure and causes significant bleeding. The pathophysiology of uremic bleeding is multifactorial and includes dysfunctional vWF, increased levels of cyclic adenosine monophosphate and nitric oxide generated by platelets, uremic toxins, and anemia that causes the platelets to be displaced from the vascular endothelium, thereby decreasing their ability to adhere and aggregate in response to endothelial damage.²⁵ Treatment is recommended for patients with active bleeding or for those undergoing an invasive procedure, such as placement of hemodialysis catheters. Patients usually respond to hemodialysis and administration of

DDAVP at a dose of 0.3 µg/kg intravenously; cryoprecipitate (10 bags given intravenously over 30 min) and conjugated estrogens (0.6 mg/kg over 30–40 min once daily for 5 consecutive days) may occasionally be required. Erythropoietin-stimulating agents such as recombinant human erythropoietin and darbepoetin have been shown to reduce and prevent bleeding in uremic patients and have a more sustained effect than either DDAVP or conjugated estrogens.³⁰

Myeloproliferative disorders

Among the myeloproliferative conditions, PV and ET are the most likely to be associated with hemorrhagic and thrombotic complications. Thrombosis represents the initial manifestation for 12–39% of patients with ET and PV.²⁸ Increasing age (>65) and a previous history of thrombosis were identified as major risk factors for thrombosis.³¹ An acquired point mutation in the pseudokinase domain of Janus kinase 2 (JAK2(V617F)) is found in approximately 97% and 50% of patients with PV and ET, respectively.

Other potential determinants of thrombotic risk include cardiovascular risk factors. Leukocytosis was reported to be an independent risk factor for thrombosis and survival both in PV and ET.^{32, 33} All patients with PV are managed with phlebotomy and low-dose aspirin. The recommended HCT target is below 45%.³⁴ ET patients at low risk for major vascular complications should be observed without treatment. Low-dose aspirin is given in the presence of microvascular symptoms. A careful correction of concomitant cardiovascular risk factors should be pursued. In high-risk patients, hydroxyurea (HU) remains the first choice drug for most PV and ET patients requiring a cytoreductive therapy because it is the only treatment proven to be effective in reducing life-threatening thrombotic complications.^{34, 35} IFN-α and anagrelide may be considered in younger patients, pregnancy (for IFN-α), and in cases resistant or intolerant of HU. JAK2 inhibitors with limited side effects can be considered for patients with PV and/or ET if therapy is required.³⁶

Coagulation factor deficiencies

Cancer patients may develop various coagulation factor abnormalities resulting from vitamin K deficiency as a consequence of malnutrition, diarrhea, liver disease, biliary obstruction, use of oral anticoagulants, and antibiotic therapy. Patients with primary or metastatic hepatocellular carcinoma have deficiency of vitamin K-dependent factors (factors II, VII, IX, and X and proteins C and S), similar to that seen with liver cirrhosis. These patients almost always have increased levels of fibrinogen, unlike patients with cirrhosis or acute liver failure who have decreased fibrinogen levels. Acquired inhibitors of coagulation factors are frequently seen in multiple myeloma and other plasma cell dyscrasias.

The treatment of cancer patients with coagulation factor deficiencies, aside from the treatment of the underlying neoplasm, is generally supportive, and consists of vitamin K, fresh-frozen plasma, and cryoprecipitate. Oral vitamin K is the treatment of choice. Cryoprecipitate is administered IV, generally at a dose of 1 unit of cryoprecipitate for every 5 kg of body weight.³⁷

Amyloidosis

Haemostatic disorders are common in amyloidosis. Laboratory abnormalities include a prolongation of the PT and the aPTT. Moreover, prolongations of the thrombin time (TT) that have been associated with hepatic amyloid infiltration and reptilase time (RT) have also been found. The PT, but not the TT, appears to be a clinically useful predictor of bleeding tendency.³⁸

Drug effects (L-asparaginase)

L-Asparaginase is used in combination with other agents, for induction of remissions in acute lymphocytic leukemia. L-Asparaginase can cause depletion of many of the coagulation factors with an associated risk for thrombosis and hemorrhage. Levels of t-PA and PAI were increased during treatment while cross-linked fibrin degradation products remained within normal limits, excluding the presence of DIC.³⁹

Acute promyelocytic leukemia

APL-associated hemostasis disorders result from at least two distinct mechanisms, the release of procoagulant activities and plasminogen activators from the leukemic cells. The T15–17 translocation induces hyperexpression of TF and renders the patient hypercoagulable. It appears that plasmin-dependent primary fibrinogenolysis is the major etiologic factor for low fibrinogen levels in APL patients. *In vivo* differentiation therapy with all-trans-retinoic acid induces a rapid decrease in plasmin activation and a normalization of fibrinogen level, and was associated with a significant decrease in TF gene expression in bone marrow cells.⁴⁰ Administration of heparin in APL has been discontinued in current treatment regimens that include ATRA. Heparin has been thought to control the coagulopathy associated with APL by inhibiting intravascular fibrin formation and reducing the consumption of clotting factors and platelets, thereby decreasing the bleeding tendency.¹

Thrombotic complications

The pathogenesis of thrombotic complications in cancer patients is multifactorial. In addition to the common predisposing factors for thrombosis such as immobility, venous stasis, advanced age, history of previous thrombosis, sepsis, and the use of central venous access devices, tumor cells have unique prothrombotic characteristics. Transformed malignant cells can induce platelet abnormalities, abnormal activation of the coagulation cascade, decreased hepatic synthesis of anticoagulant and coagulant proteins, fibrinolytic abnormalities, acquired thrombophilias, and expression of inflammatory and angiogenic cytokines ([Table 1](#)). Multiple biomarkers have been linked to cancer-associated thrombosis. The highest level of evidence currently exists for pre-chemotherapy-elevated platelets and leukocyte counts and low hemoglobin levels. D-Dimer is also predictive of cancer-associated VTE. Many cancer patients have elevated D-dimer levels without obvious thrombosis and there is no consensus on the cutoff levels that would be predictive of cancer-associated thrombosis. TF, the physiologic initiator of hemostasis, is widely expressed across many types of cancer. TF is released into the circulation in the form of MPs, and levels can be detected in cancer patients. There is no consensus “standard” TF assay however. Initial reports suggested a significant association of elevated TF with subsequent VTE. The majority of these data were derived from patients with specific cancers, particularly pancreatic cancer.

Several factors contribute to the increased risk for bleeding and thrombotic complications in the cancer patient ([Table 4](#)). Thrombotic manifestations in cancer patients may present as one of the following: migratory thrombophlebitis or Trousseau syndrome, venous thromboembolism (VTE), thrombotic microangiopathy (TMA), arterial thrombosis, and DIC.

Table 4 Risk factors for bleeding and thrombotic complications in cancer patients

Use of indwelling catheters— <i>Thrombosis</i>
Systemic inflammatory response syndrome (SIRS)— <i>Thrombosis</i>
Sepsis— <i>Thrombosis and bleeding</i>
Prior chemotherapy and radiation treatment— <i>Mainly bleeding but also thrombosis</i>
Selective estrogen receptor modulators (SERMs): tamoxifen, raloxifene
Concomitant use of hormone replacement therapy or oral contraceptives— <i>Thrombosis</i>
Antiangiogenic agents (thalidomide, lenalidomide, bevacizumab ^a , sunitinib, sorafenib) — <i>Thrombosis</i>
Erythropoiesis-stimulating agents— <i>Thrombosis</i>
Metastatic disease to the liver and/or bone marrow— <i>Mainly bleeding</i>
Vitamin K deficiency— <i>Mainly bleeding</i>
Acute peptic ulcer— <i>Bleeding</i>
Slipped ligatures from recent surgery— <i>Bleeding</i>

^a Also bleeding.

Migratory thrombophlebitis (Trousseau syndrome)

Trousseau syndrome is a classically described variant form of venous thrombosis characterized by a recurrent and migratory pattern preferentially involving superficial veins of the arms and chest.¹¹ This syndrome should precipitate the search for an occult malignancy, especially in patients with recurrent and migratory venous thrombosis affecting unusual sites such as subclavian veins, or veins of upper extremities, axilla, or neck. Trousseau syndrome is highly associated with mucin producing adenocarcinomas.⁴¹ Its clinical manifestations also include chronic DIC associated with microangiopathy, non-bacterial endocarditis, and arterial emboli in patients with cancer. Migratory thrombophlebitis has also been associated with the use of somatostatin or octreotide therapy for malignant carcinoid syndrome.

Venous thromboembolism

VTE, involving DVT and pulmonary embolism (PE), may occur in 4–20% of cancer patients and is one of the leading causes of death. The overall incidence of cancer-related VTE in postmortem studies has been reported as high as 50%. In patients presenting with *de novo* idiopathic VTE, there is a high risk for a concurrent cancer, especially within the first year after the diagnosis of thromboembolism. Cancer patients at greatest risk for VTE include those with mucin-secreting tumors (e.g., pancreatic and gastrointestinal cancer), cancers of the lung, brain, prostate, breast, and ovary, and patients with APL and myeloproliferative disorders, specifically PV and ET. VTE often complicates the care of cancer patients after major surgery and of patients receiving chemotherapy and/or hormonal therapy.⁵

The risk of developing thrombosis in cancer patients is influenced by the age and hormonal status of the patient. Postmenopausal women with advanced breast cancer receiving tamoxifen or aromatase inhibitors in addition to adjuvant chemotherapy have a higher risk for thrombotic events than do premenopausal women with breast cancer.⁴² Thromboembolic events have also been reported with angiogenesis inhibitors (thalidomide, lenalidomide, and bevacizumab).^{15,43} The pathogenic mechanisms of thromboembolic events associated with thalidomide are thought to be related to the development of

acquired activated protein C resistance and a reduction in thrombomodulin level.^{15,44} Endothelial injury produced by the combination of thalidomide with chemotherapy and subsequent restoration of endothelial cell PAR-1 expression are probably factors that promote thrombosis.⁴⁵ Cancer patients receiving erythropoiesis-stimulating agents for anemia have also been reported to have increased risks of thrombotic complications.⁴⁶

Major advances in the diagnosis of VTE generally—that is, not cancer-specific—include the development and validation of a standardized clinical model (Table 5)⁴⁷ to determine the pretest probability of VTE and the measurement of plasma D-dimer. The integration of these two advances has resulted in the formulation of safe, diagnostic algorithms that decrease the need for serial and/or invasive testing.⁴⁸ A study in oncologic patients has shown that D-dimer results have high negative predictive value and sensitivity for PE and, if negative, can be used to exclude PE in this population.⁴⁹

Table 5 Wells criteria for pulmonary embolism

Variables	Points
Previous DVT or PE	1.5
Heart rate ≥ 100 per minute	1.5
Surgery or immobilization within the past 4 weeks	1.5
Hemoptysis	1
Active cancer	1
Clinical signs of DVT	3
Alternative diagnosis less likely than PE	3

0–1 point: low clinical probability; 2–6 points: intermediate clinical probability; ≥7 points: high clinical probability for PE.

Source: Wells et al. 1997.⁴⁷ Reproduced with permission from Elsevier.

As with other patients, the majority of DVT in cancer patients originate in the iliofemoral venous system. Diagnostic imaging modalities for DVT include ascending contrast venography, compression ultrasonography, and magnetic resonance venography. Ascending contrast venography remains the gold standard for diagnosing DVT, but this procedure is invasive and requires contrast material, which is frequently irritating and may result in complications. The finding of an intraluminal filling defect caused by thrombus surrounded by contrast is diagnostic for DVT. Noncompressibility of a proximal lower limb vein on compression ultrasonography has a diagnostic sensitivity rate of 97% and a specificity rate of 94%.⁵⁰ Although compression ultrasonography is highly sensitive for detecting proximal DVT, it is not as accurate for diagnosing isolated distal DVT. Magnetic resonance venography has sensitivity and specificity rates of 92% and 95%, respectively, for proximal DVT.⁵¹ It is useful in diagnosing pelvic vein DVT, especially isolated iliac vein thrombosis, which is difficult to diagnose with compression ultrasonography.

Several studies conducted in cancer patients with suspected DVT have demonstrated that two of the following studies can reliably exclude DVT and decrease the need for invasive testing: a low pretest probability, a normal D-dimer level, and a normal compression ultrasonogram.⁴⁷

The standard treatment of VTE outside the setting of malignancy is to initiate anticoagulation with either intravenous or subcutaneous unfractionated heparin (UFH) or subcutaneous low-molecular-weight heparin (LMWH) or fondaparinux (an indirect Xa inhibitor) at therapeutic doses followed by oral

warfarin therapy for a minimum of 3 months to achieve an international normalized ratio (INR) between 2.0 and 3.0.⁵² However, in patients with active cancer, continued anticoagulation is recommended following the first episode of VTE.⁵² Intravenous UFH can be started with an initial bolus of 80 U/kg followed by a continuous IV infusion of 18 U/kg/h, adjusted to maintain the aPTT at 1.5–2.5 times the control value. Alternatively, LMWH can be administered in weight-adjusted, once- or twice-daily subcutaneous doses without the need for laboratory monitoring. Warfarin therapy can be commenced within 24 h after heparin treatment is started. Heparin therapy is continued for at least 5 days until the INR is within the therapeutic range for 2 consecutive days. However, in patients with large iliofemoral vein thrombosis or major PE, some investigators have recommended extending heparin treatment to 7–10 days.

Retrospective and prospective clinical trials have demonstrated a survival advantage in cancer patients treated with LMWH for established thrombosis.^{53, 54} LMWHs have several advantages when compared to UFH: laboratory monitoring is rarely required, only subcutaneous injection is necessary, and there are lower incidences of bleeding, heparin-induced thrombocytopenia (HIT),⁵⁵ and osteoporosis.⁵⁶ The use of long-term LMWH as an alternative to warfarin therapy in cancer patients with acute VTE has been analyzed in two clinical trials. The CANTHANOX trial compared 3 months of warfarin versus enoxaparin anticoagulation in cancer patients with DVT and/or PE. Although the risk of recurrent VTE was lower in the enoxaparin group, the difference was not statistically significant. Warfarin was associated with a high bleeding rate.⁵⁷ In the CLOT trial, which continued treatment for 6 months, the cumulative risk of recurrent VTE was reduced from 17% in the oral anticoagulant group to 9% in the LMWH group resulting in a statistically significant risk reduction for VTE.⁵⁸ Overall, there were no differences in bleeding between the groups. Current guidelines recommend the use of LMWH for the first 3–6 months as long-term treatment of VTE in cancer patients.⁵² Cancer patients with recurrent VTE tend to have a short survival. Escalating the dose of LMWH has not been shown to be effective for treating cases that are resistant to standard, weight-adjusted doses of LMWH or a vitamin K antagonist (VKA).⁵⁹

The use of systemic thrombolytic agents such as t-PA should be restricted to patients with massive iliofemoral DVT or massive PE and hemodynamic instability because of the significant risks of bleeding associated with thrombolysis.⁵² Furthermore, despite the proven efficacy of thrombolytic agents in achieving more rapid resolution of radiologic and hemodynamic abnormalities in patients with PE, studies to date have not shown any survival benefit with thrombolysis. At the present time, catheter-directed thrombolysis for initial treatment of VTE should be confined to selected patients requiring limb salvage. In general, thrombolytic therapy is contraindicated in cancer patients with brain metastases who develop VTE because of their significant risk for intracranial bleeding.⁶⁰ Surgical thromboembolectomy is restricted to patients with massive PE in extremis, or who have contraindications to or who do not respond to thrombolysis.⁵² For cancer patients with VTE who have contraindications to anticoagulant therapy or those with recurrent VTE despite anticoagulation, placement of a retrievable or permanent inferior vena cava (IVC) filter is generally recommended. However, IVC filters are associated with undesirable side effects, such as debilitating leg symptoms caused by filter-related thrombosis.⁶¹ A recent study reported that IVC filters were safe and highly effective in preventing PE-related deaths in patients with cancer with VTE disease.⁶² However, patients with a history of DVT and bleeding or a metastatic/disseminated stage of disease had the lowest survival after IVC filter placement.

The major concern about treatment of VTE in cancer patients is the higher risk of bleeding and VTE recurrence compared to non-cancer patients. A prospective cohort study demonstrated that the 12-month cumulative incidence of recurrent VTE in cancer patients was 20.7% versus 6.8% in patients without cancer, and the parallel estimate for major bleeding was 12.4% versus 4.9%, respectively.⁶³ Recurrence

and bleeding were both related to cancer severity and occurred predominantly during the first month of anticoagulant therapy and, remarkably, could not be explained by sub- or overanticoagulation. The risk of recurrent VTE has been reported to be two- to threefold higher and the risk of major bleeding is three- to sixfold higher in cancer patients than in patients without cancer.⁵⁸

Routine anticoagulant prophylaxis for central venous catheters is not recommended.⁶⁴ Recombinant t-PA is effective in restoring flow to indwelling catheters occluded by thrombus.⁶⁵ Perioperative cancer patients, particularly those with breast cancer undergoing chemotherapy or on selective estrogen receptor modulators and patients with advanced cancers that are associated with high risk of VTE such as brain tumors, and colorectal, pancreatic, lung, renal cell, and ovarian adenocarcinomas, should receive antithrombotic prophylaxis with intermittent pneumatic compression devices or compression elastic stockings and LMWH. The recommended doses are dalteparin 5000 U SC daily, enoxaparin 40 mg SC daily, or fondaparinux 2.5 mg SC starting 8–12 h postoperatively.^{64, 65} Two trials in cancer patients undergoing surgery reported that continuation of LMWH prophylaxis for 3 weeks after hospital discharge reduced the risk of late venographic DVT by 60%. Finally, cancer patients who are immobile or bedridden with an acute medical illness also should receive antithrombotic prophylaxis with low-dose UFH or LMWH. However, ambulatory cancer patients do not require VTE prophylaxis. Cancer patients receiving chemotherapy or hormonal therapy also do not require routine primary thromboprophylaxis.⁶⁶ Of note, thromboprophylaxis with aspirin, warfarin, or LMWH is widely used by clinicians for patients with multiple myeloma receiving thalidomide or lenalidomide in combination with chemotherapy or high-dose steroids.^{67, 68}

General prophylaxis and treatment

A recent consensus clinical practice guideline from ASCO described recommendations for VTE prophylaxis and treatment in patients with cancer, and based on a systematic review of the literature recommended that most *hospitalized* patients with cancer require thromboprophylaxis throughout hospitalization. Thromboprophylaxis was not routinely recommended for outpatients with cancer. It may be considered for selected high-risk patients. Patients with multiple myeloma receiving antiangiogenesis agents with chemotherapy and/or dexamethasone should receive prophylaxis with either LMWH or low-dose aspirin. Patients undergoing major cancer surgery should receive prophylaxis, starting before surgery and continuing for at least 7–10 days. Extending prophylaxis up to 4 weeks should be considered in those with high-risk features. LMWH is recommended for the initial 5–10 days of treatment for deep vein thrombosis and PE as well as for long-term (6 months) secondary prophylaxis. Use of novel oral anticoagulants is not currently recommended for patients with malignancy and VTE.⁶⁶

Anticancer effects of anticoagulation treatment

Experimental and indirect clinical evidence suggests that anticoagulants, particularly LMWH, may have antineoplastic effects. It has been suggested that anticoagulants can interfere with tumor angiogenesis, proliferation potential of cancer cells, and the immune system by augmenting the antitumor activity of tumor necrosis factor and interferon mediated by NK cells.⁶⁹ Anticoagulants may also interfere with the various stages of the metastatic cascade.

Heparin-induced thrombocytopenia (HIT)

HIT is an immune-mediated thrombocytopenia that occurs in approximately 1–5% of patients receiving

heparin.⁷⁰ The decrease in platelet count typically occurs 5–10 days after starting heparin but may develop within 24 h if there has been exposure to heparin during the preceding 3 months. Occasionally, the platelet count starts to fall only after heparin has been stopped (delayed-onset HIT). The frequency of HIT varies according to the type of heparin preparation (bovine UFH > porcine UFH > LMWH), the exposed patient population (postoperative > medical > pregnancy), and gender (female > male).⁷⁰ HIT is caused by heparin-dependent, platelet-activating antibodies that recognize platelet factor 4 (PF4) bound to heparin. The resulting platelet activation is associated with increased thrombin generation. Venous or arterial thromboses including deep venous thrombosis, PE, limb artery thrombosis, thrombotic stroke, and myocardial infarction can occur. A clinical pretest probability score known as the 4T's (degree of thrombocytopenia, timing of thrombocytopenia, other etiologies of thrombocytopenia, and thrombosis) is useful in clinical practice. HIT should be suspected and treatment rapidly instituted in a patient with an intermediate or high test probability.⁷¹ In clinical practice, the laboratory diagnosis of HIT is made with a positive PF4-dependent immunoassay. Management consists of discontinuing all forms of heparin and using direct thrombin inhibitors such as lepirudin or argatroban, which do not have any cross-reactivity to HIT antibodies. For patients receiving warfarin at the time of diagnosis of HIT, reversal of warfarin anticoagulation with vitamin K is recommended.

Thrombotic microangiopathies

TMA involves hemolytic anemia, thrombocytopenia, neurologic symptoms, renal dysfunction, and fever. The majority of these cases are reported in patients with adenocarcinoma, particularly gastric cancer; however, TMA also occurs in patients with breast cancer and lung cancer, and in Hodgkin and non-Hodgkin lymphomas.⁷² Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome also occurs in association with cancer chemotherapy, especially with mitomycin C, bleomycin, cisplatin, and tamoxifen,⁷³ use of cyclosporine,⁷⁴ and interferon,⁷⁵ after hematopoietic stem cell transplantation,⁷⁶ and with Sunitinib maleate, an oral multitargeting tyrosine kinase inhibitor approved for the treatment of metastatic renal cell carcinoma.⁷⁷

The pathophysiology of cancer-associated TMA is postulated to be similar to that of usual primary TMA. It involves injury to vascular endothelium with release of ultralarge vWF multimers due to a deficiency of a vWF-cleaving protease (ADAMTS-13) causing platelet aggregation.^{78, 79}

Typically, the microangiopathic hemolytic anemia and thrombocytopenia are severe and reticulocytosis is usually present, with increased levels of lactic acid dehydrogenase, reflecting intravascular hemolysis. The peripheral blood smear demonstrates numerous schistocytes. Renal failure and neurologic and pulmonary dysfunction are common. Standard treatment of TTP is plasmapheresis. Other treatment modalities that may be used in refractory cases include vincristine, intravenous gamma globulin, rituximab, and splenectomy.^{80–82} Platelet transfusions are usually contraindicated because infused platelets may amplify the extent and severity of the formation of microvascular thrombi. Regardless of treatment, the prognosis of cancer patients with TMA is generally poor.

Arterial thrombosis and nonbacterial thrombotic endocarditis

The association between arterial thrombosis and cancer is less well described. Isolated cases have been reported and chemotherapy has been implicated as a cause.⁸³ The selective estrogen receptor modulators tamoxifen and raloxifene increase the risk of stroke,⁸⁴ especially in postmenopausal women at increased risk for coronary events and in current smokers.⁸⁵ Importantly, patients with acute ischemic stroke in the

setting of active cancer (especially adenocarcinoma) have a significant short-term risk of recurrent ischemic stroke and other types of thromboembolism.⁸⁶

Nonbacterial thrombotic endocarditis (NBTE) represents a form of consumptive coagulopathy most commonly seen with adenocarcinomas of the lung and pancreas. The diagnosis should be suspected in any cancer patient who presents with ischemic embolic events. Echocardiography is diagnostic with the finding of sterile thrombotic vegetations on cardiac valves. In addition to valvular vegetations, ventricular segmental wall motion abnormalities resulting from silent embolization to the coronary arteries have been reported in 18% of cancer patients with NBTE. Management is essentially supportive and consists of treatment of the underlying cancer and anticoagulant therapy with unfractionated or low-molecular-weight heparin.

Disseminated intravascular coagulation (DIC)

DIC is a clinicopathological syndrome that complicates patients with malignancy. Patients with solid tumors (prostate, pancreas, lung, stomach, colon, and breast) and those with leukemia, especially APL, may be complicated by DIC that is manifested primarily by bleeding. Patients with hematologic malignancies often present with a state of chronic DIC in the absence of active thrombosis and/or bleeding. The bleeding disorder in APL is thought to be due to the abnormally high levels of expression of annexin A2 on APL cells, which leads to increased production of plasmin and ensuing bleeding from unopposed fibrinolysis. Annexin A2 is a phospholipid-binding protein on the surface of endothelial cells that serves to bind plasminogen and its activator, tPA. In APL cells, the t_{15-17} translocation induces hyperexpression of TF in the leukemic cell, linking the primary oncogenic event with induction of hypercoagulability.⁸⁷

Plasma MP-associated TF procoagulant activity may play an important pathogenic role in the evolution of overt DIC in various types of malignancy.⁸⁸

The thrombotic disorders associated with DIC include recurrent venous thrombosis, peripheral arterial thrombosis, cerebrovascular thrombosis, disseminated arterial disease with organ failure, peripheral limb ischemia, and gangrene. Chronic forms of DIC are characterized by less florid clinical findings and more subtle, but persistent, laboratory abnormalities. Metastatic cancer is a common cause of chronic DIC. Over time, approximately 25% of patients with metastatic cancer develop a thrombotic event. In cancer patients, the diagnosis of DIC is made clinically and corroborated by a constellation of laboratory abnormalities ([Table 6](#)).⁸⁹ There is no single laboratory test that can establish or exclude the diagnosis of DIC. In most cases, a combination of tests in a patient with a clinical condition that is associated with DIC can be used to diagnose the disorder with reasonable certainty. In the presence of an underlying disease associated with DIC, an initial platelet count of less than $100,000/\text{mm}^3$ or a rapid decline in the platelet count and prolongation of the PT and aPTT is seen in about 50–60% of cases of DIC, and the presence of fibrin(ogen) degradation products and D-dimers in plasma. Fibrinogen levels may remain in the normal range in the face of its consumption because of increased synthesis of this acute-phase reactant. A finding of hypofibrinogenemia is only useful diagnostically in very severe cases of DIC. The peripheral blood smear may also demonstrate the presence of red cell fragmentation or schistocytes, but rarely >10% of the red cells. Soluble fibrin (SF) monomer, which is only generated intravascularly, is a sensitive but not specific test for the diagnosis of DIC.⁹⁰ There appears to be no added value measuring the natural anticoagulant protein C and/or AT.⁹¹ The International Society of Thrombosis and Hemostasis (ISTH) sub-committee of the Scientific and Standardization Committee (SCC) on DIC has recommended the use

of scoring system for overt DIC.⁹¹ The sensitivity and specificity of the ISTH overt DIC score are 91% and 97%, respectively.⁹² It is important to repeat the tests to monitor the dynamically changing scenario based on the laboratory results and clinical manifestations.

Table 6 Abnormalities in cancer patients with disseminated intravascular coagulation

Thrombocytopenia
Prolongation of PT and aPTT
Hypofibrinogenemia ^a
Decreased levels of factors V and VIII ^b
Presence of fibrin(ogen) degradation products and D-dimer ^c with secondary interference with fibrin polymerization and platelet aggregation
Presence of schistocytes or fragmented red blood cells in the peripheral blood smear indicating microangiopathic hemolysis

^a Fibrinogen levels may remain in the normal range despite consumption because of increased production: a finding of hypofibrinogenemia is only useful diagnostically in very severe cases of DIC.

^b Factor VIII levels may be increased in some patients with early DIC because of thrombin activation of factor VIII.

^c Plasma D-dimers are specific cross-linked fibrin derivative generated when the endogenous fibrinolytic system degrades fibrin.

In general, the treatment of DIC is directed against the underlying cancer but supportive management to the bleeding or thrombotic manifestations is required. Cancer patients with DIC who are bleeding or at high risk for bleeding (patients undergoing surgery or invasive procedures) should receive platelet transfusions to maintain the platelet count greater than 50,000/ μ L and FFP (initial doses of 15 mL/kg, although a dose of 30 mL/kg produces a more complete correction of coagulation factor levels) if the PT or aPTT is prolonged. The administration of purified coagulation factor concentrates in DIC is not generally recommended unless patients are fluid overloaded and cannot receive FFP. Coagulation factor concentrates contain only specific factors, whereas in DIC, there is a global deficiency in coagulation factors. Severe hypofibrinogenemia (<1 g/L) needs to be treated with cryoprecipitate or fibrinogen concentrates if available. A dose of 3 g would raise plasma fibrinogen by 1 g/L, this can be given as two cryoprecipitate pools (10 donor units) or as 3 g of a fibrinogen concentrate. The response to the supportive transfusion therapy should be monitored clinically and with laboratory tests.⁸⁹ The bleeding associated with DIC in APL oftentimes responds dramatically to treatment with all-trans-retinoic acid.⁸⁶

Although there are no clinical randomized controlled trials demonstrating that the use of heparin in patients with DIC results in improved clinical outcome, intravenous heparin may be used in cancer patients with DIC-associated thrombosis for stabilization while the cancer is being treated unless moderate to severe thrombocytopenia or bleeding is present. The recommended dose of heparin is 10 U/kg/h by continuous IV infusion without a loading dose. Monitoring aPTT may be complicated but monitoring for signs of bleeding is important. In critically ill, nonbleeding patients with DIC, pharmacological thromboprophylaxis with either unfractionated or low-molecular-weight heparin is recommended.⁸⁹ In general, patients with DIC should not be treated with antifibrinolytic agents. However, in patients with DIC and bleeding secondary to primary fibrinolysis (e.g., prostate cancer), the fibrinolytic inhibitor, epsilon aminocaproic acid, can be administered with an initial IV loading dose of 4–6 g over 1 h followed by an IV infusion of 1 g/h while monitoring the clinical response. The recommended oral dose of aminocaproic acid is 50–60 mg/kg every 4–6 h.⁹³ However, in those patients

with a primary thrombotic presentation and secondary fibrinolysis, fibrinolytic inhibitors should be avoided until the thrombotic process is controlled.⁸⁹

Drugs for treatment of bleeding and thrombotic disorders

Recombinant factor VIIa

Recombinant factor VIIa (rFVIIa) is FDA approved for patients with bleeding secondary to hemophilia A or B who have inhibitors against factors VIII and IX and in patients with hereditary factor VII deficiency.⁹⁴ It has also been shown to be effective in controlling bleeding due to thrombocytopenia, thrombocytopathies, acquired coagulation factor deficiencies, and in patients undergoing cancer surgery. There is increasing evidence on the use of rFVIIa in patients with hematological malignancies and in patients who develop critical bleeding associated with hematopoietic stem cell transplantation.⁹⁵

Thrombopoietin receptor agonists

Thrombopoietin receptor agonists (TPO-RAs), romiplostim and eltrombopag, are FDA approved to increase platelet counts in patients with chronic immune thrombocytopenic purpura (ITP). They have shown benefit in splenectomized and nonsplenectomized patients. TPO-RAs are approved to treat thrombocytopenia in the setting of hepatitis C and cirrhosis and recently in aplastic anemia. Both agents, although not licensed yet, have efficacy in the treatment of MDS and in nonmyeloablative chemotherapy. Short-term efficacy and safety are well documented and long-term efficacy and safety are emerging. Potential risks include thrombosis, myelofibrosis, development of hematologic malignancies, and liver toxicity with eltrombopag.⁹⁶

Direct oral anticoagulants (DOACs)

Oral direct factor Xa inhibitors such as rivaroxaban, apixaban, and edoxaban and oral direct thrombin inhibitors such as dabigatran are being used in clinical practice for prevention of stroke and systemic embolism in the setting of nonvalvular atrial fibrillation and for the prevention and treatment of VTE. In the context of cancer patients, current clinical practice guidelines all recommend the use of therapeutic doses of LMWHs for the initial and long-term treatment of cancer-related thrombosis. The use of vitamin K antagonists (VKA) is acceptable if LMWH is not available. For the long-term treatment of VTE in patients with cancer, LMWH compared with VKA reduces venous thromboembolic events but not mortality. The decision for a patient with cancer and VTE to start long-term LMWH versus oral anticoagulation should balance the benefits and harms and integrate the patient's values and preferences for the important outcomes and alternative management strategies.

DOACs have been shown to be comparable to conventional therapy for the acute treatment of VTE but their efficacy and safety in cancer patients remain uncertain. Their use cannot be supported until trials comparing them with LMWH are available.^{97, 98}

Summary

Bleeding and thrombotic complications are common in cancer patients. Significant advances in the understanding of the interrelationship between cancer, blood coagulation, and tumor angiogenesis have occurred in recent years. Bleeding complications usually result from abnormalities in platelets

or deficiency of coagulation factors and require specific blood or coagulation factor replacement. Thromboembolic events including deep venous thrombosis and PE are not only common but also serious complications seen in cancer patients. Advances in novel biomarkers, diagnostic imaging, and availability of newer anticoagulant agents have greatly facilitated the care of these patients. Ongoing research in the understanding of the various disturbances in hemostasis, application of innovative treatment modalities, and use of appropriate thromboprophylaxis in cancer patients should ultimately lead to decreased morbidity and improved survival.

Overview

The management of patients with cancer requires anticipation and timely intervention for urologic complications including urinary tract obstruction, cystitis, nephritis, and nephrotoxicity from chemotherapeutic agents. In patients with limited-stage disease receiving therapy with curative intent, skilled management of urologic complications is crucial for delivering adequate doses of chemotherapy and avoiding dose reductions that may compromise the likelihood of cure. In the metastatic setting, skillful management of urologic complications including urinary obstruction can provide significant palliation of symptoms. This chapter reviews the diagnosis and management of urinary tract obstruction occurring at the level of the ureters, the bladder, and the urethra. Mechanisms of chemotherapy- and radiation-induced cystitis and nephritis and their management are reviewed. Finally, an overview of the most commonly used potentially nephrotoxic therapeutic agents is provided, with an emphasis on diagnosis, treatment, and prevention. In addition to cytotoxic chemotherapy, the nephrotoxicity caused by targeted therapies is discussed, and emerging insights into immune-related adverse events (irAE) that may affect the kidney are reviewed.

Introduction

Anticipation and timely intervention for urologic complications of cancer and its therapy may facilitate treatment of patients with localized disease and expand opportunities for the treatment of patients with metastatic disease. Management of obstructive uropathy, prompt detection of drug-induced renal toxicity, and the management of such toxicity without excessive dose reduction are critical to the successful treatment of cancer patients. Renally based dose adjustment and the monitoring of multiple agents with nephrotoxic potential are nuanced yet essential components of oncologic practice, and management of urologic complications often requires coordinated multidisciplinary care. This chapter reviews the most frequent urologic complications of cancer and its therapy.

Urinary tract obstruction

Obstruction of the urinary tract may occur at multiple levels (ureter, bladder, or urethra) due to direct extension, encasement, or invasion of these structures by cancer. The natural history and management of obstructive uropathy are determined by the obstruction's location, time course (acute versus chronic), and the anticipated responsiveness to therapy of the malignancy implicated in the obstruction. For curable cancers whose therapies contain essential components that are nephrotoxic [cisplatin, ifosfamide, and methotrexate (MTX)], prompt reversal of obstructive uropathy is important to permit adequate chemotherapy dosing. In patients with advanced cancers of the GU tract resulting in obstruction and debilitating urinary symptoms that compromise quality of life, urinary diversion is an important palliative

procedure aimed at relieving suffering and prolonging survival. In both scenarios, a range of less invasive interventions including stenting and external drainage of the urinary tract, which are performed by an urologist or an interventional radiologist, may allow early intervention and reduce the need for extensive surgical procedures.

The first suggestion of the presence of an obstructive uropathy may be a rising serum creatinine level, particularly in ureteral obstructions, which are often painless. Bladder outlet or urethral obstruction resulting in a distended bladder may be palpable on physical exam. Acute unilateral hydronephrosis may cause hypertension, due to activation of the renin-angiotensin system;¹ this hypertension is reversible with relief of the obstruction. Urinalysis may be bland, or may reveal significant hematuria.² The cornerstones of diagnostic imaging are ultrasound and CT with contrast, with the former often pursued first to avoid the potential nephrotoxicity of IV contrast and exposure to radiation. Detailed anatomic imaging may be obtained by MRI, but the use of this modality is limited in patients with GFR < 30 due to concerns about nephrogenic systemic fibrosis (NSF).

Regardless of the location of the urinary obstruction, with time, the inability to pass urine leads to increased pressure on the renal pelvis, hydronephrosis, and renal tubule atrophy. If allowed to continue, irreversible injury may occur.³ Urinary obstruction may also provide a nidus for infection. The radiographic appearance of the kidney under conditions of acute and chronic obstruction is distinct, with the former appearing as an enlarged kidney with a normal-to-thickened renal cortex, and the latter appearing smaller than average with a thinned cortex. Relief of the obstruction is unlikely to result in significant improvement in renal function with chronic obstruction, and the visualization of a small kidney with thinned cortex on ultrasound should usually halt a planned intervention.

Following relief of an acute obstruction, return of renal function is anticipated in 7–10 days, although longer periods of recovery may be observed.⁴ In the period immediately following relief of the obstruction, the renal tubule's concentrating capacity is abnormal, which may cause a period of postobstructive diuresis. This is most commonly observed with acute high-grade obstructions.

Ureteral obstruction

The ureters are located in the retroperitoneum, making them particularly vulnerable to mechanical obstruction by pathologic retroperitoneal lymphadenopathy or retroperitoneal fibrosis. Such obstructive uropathy is most frequently the result of either primary nodal diseases (lymphomas) or periaortic lymph node metastases of urologic neoplasms, particularly prostate cancer and germ cell tumors. In the case of retroperitoneal adenopathy due to highly chemotherapy-responsive malignancies, particularly some germ cell tumors or aggressive lymphomas, the expected prompt response to therapy may allow the clinician to avoid acute intervention to relieve the obstruction, particularly in the case of unilateral or partial obstruction. The need to administer nephrotoxic curative-intent chemotherapy (for example, cisplatin) may require intervention to bypass the obstruction even in chemoresponsive disease. The rate and degree of anticipated response to therapy and the degree of compromise in renal function together indicate whether placement of a percutaneous nephrostomy is necessary or whether a reasonable expectation exists that relief of obstruction can be achieved with cytotoxic chemotherapy alone.

When mechanical bypass of a ureteral obstruction is required, a ureteral stent or percutaneous nephrostomy may be employed. Multiple sites of ureteric obstruction, long occlusions, or a tortuous ureter may be indications to proceed directly with percutaneous nephrostomy.⁵ While a unilateral percutaneous nephrostomy may preserve adequate renal function for palliative therapy, patients whose long-term disease-free survival is dependent on nephrotoxic therapy require maximal preservation of renal function

and bilateral percutaneous nephrostomy is often required in this setting. Although they may be key to the delivery of therapy, percutaneous nephrostomies are not without risk and are a potential source of infection that may complicate, delay, or even require modification of treatment plans.^{6, 7} Attention to detail in the placement and care of nephrostomies is required. This includes the optimal placement of catheters to reduce pain, frequent changes of the catheter, and care of the insertion site.

During nephrostomy tube placement, the intrarenal collecting system is imaged with ultrasound and/or fluoroscopy to select a site of renal entry. In experienced hands, an appropriate nephrostomy tract can be established in 98% of cases, with major complications occurring in approximately 4%.⁵ Major complications may include hematoma formation, hemorrhage, vascular injury, sepsis, bowel or lung injury, or death. Following relief of the obstruction and the resultant intrarenal pressure by nephrostomy tube placement, an internal double-J stent may be placed. This is performed in an antegrade manner using the nephrostomy as an entry point. While intervention with percutaneous nephrostomy or stenting may allow for delivery of curative-intent treatment in a patient who might not otherwise be able to receive therapy, the risk-benefit analysis may be markedly different in a patient with advanced incurable disease. Recent studies show that intervention for urinary obstruction results in patients with metastatic cancer spending a significant percentage of their remaining life hospitalized,^{7, 8} and it has long been recognized that progressive uremia due to renal failure may provide a peaceful death for highly symptomatic patients suffering from terminal disease. A patient with severe pain (unrelated to obstruction) and very short life expectancy may be best served by no intervention, but rather implementation of comfort measures. This difficult decision requires careful communication between physician, patient, and the patient's family members.

Bladder outlet and urethral obstruction

Malignant bladder outlet and urethral obstructions are most commonly caused by prostate or bladder cancers, and may also be seen with ovarian, cervical, and uterine cancers. While ureteral obstruction is frequently asymptomatic, patients with bladder outlet and urethral obstruction often present with troublesome symptoms resulting from bladder irritation and distension. These may have a significant impact on a patient's perceived quality of life.^{9, 10} Prostate cancers that arise from the portion of the prostate immediately adjacent to the intraprostatic urethra need not be large to cause marked symptoms. Urine output may fluctuate, with periods of both relative oliguria and increased urinary output because of overflow incontinence.

The management of obstructions due to prostate cancer is guided by the stage of the prostate cancer. Newly diagnosed prostate cancer is likely to be exquisitely sensitive to hormonal manipulation, and prompt androgen deprivation therapy (ADT) with temporary foley catheter placement may result in relief of the obstruction with fairly prompt removal of the indwelling foley. In contrast, castrate-resistant prostate cancer, which nearly invariably develops after a period of response to ADT, will not exhibit this prompt response to therapy and will likely require more permanent relief of obstruction, either by nephrostomy or suprapubic catheter. In addition, very large prostate or bladder tumors, regardless of their anticipated response to therapy, may be indications to proceed directly with placement of percutaneous nephrostomy tubes.³ Bladder outlet or urethral obstruction may be managed by the placement of a suprapubic urinary catheter. Generally, this technique provides palliation of symptoms and should not be pursued in patients being treated with curative intent as it violates normal anatomic barriers of the GU tract.

For patients with urethral obstruction, symptoms are often difficult to relieve. Although percutaneous nephrostomies and suprapubic catheters can divert urinary flow, they do not fully relieve symptoms

related to urgency, hematuria, dysuria, and frequency. Transurethral resection of the prostate may be considered for palliation of symptoms in advanced disease, and definitive prostate surgery may provide significant relief in prostate cancers treated with curative intent. The management of these symptoms remains a therapeutic challenge for clinicians.

Cystitis and nephritis

Hematuria can be a frightening event for the cancer patient. Hematuria may result from bleeding anywhere along the urinary tract, and gross hematuria may require palliation to prevent excessive blood loss. The location of bleeding may be suggested by the appearance of the hematuria: long, vermiform clots typically indicate upper tract bleeding, while bright red blood without clots that partially clears with urination usually indicates a lower tract bleed. Recurrence of hematuria after treatment of malignancy may herald relapse within the GU tract.

Management of hematuria focuses on controlling blood loss and preventing retention of blood clots which may cause urinary obstruction and renal damage. The most common initial management of lower urinary tract bleeding is continuous bladder irrigation with normal saline. Cystoscopic evacuation of clots may be required for palliation. In selected patients, a bleeding tumor may be brought under control with radiation.¹¹ The management of cyclophosphamide-, ifosfamide-, or radiation-induced cystitis and bleeding is a challenging clinical problem. Embolization of bladder vessels or instillation of steroids has occasionally palliated such patients, but treatment is frequently unsatisfactory. Diluted formaldehyde may denature and fix superficial tissue layers. Emergency cystectomy has been undertaken to avoid exsanguination. Other treatments include hyperhydration,¹² bladder irrigation, oral or intravesical aminocaproic acid (for lower urinary tract bleeding only),¹³ intravesical alum,¹⁴ and intravesical prostaglandins.^{15, 16} Experimental approaches include argon laser coagulation,¹⁷ amifostine,¹⁸ hyperbaric oxygenation,¹⁹ and conjugated estrogens.²⁰

Chemotherapy-induced cystitis

Cyclophosphamide and ifosfamide are the most commonly used oxazaphosphorines. Other therapeutic agents that can produce gross hematuria include intravesical treatment with doxorubicin, mitomycin, and bacillus Calmette-Guérin.²¹ Both cyclophosphamide and ifosfamide are metabolized to acrolein, an urothelium-toxic metabolite.²² Chemotherapy-induced thrombocytopenia may exacerbate bleeding. Sterile hemorrhagic cystitis has been reported in up to 20% of patients receiving high doses of cyclophosphamide and in approximately 8% of patients receiving ifosfamide.²³ With conventional doses of cyclophosphamide, cystitis can be prevented by encouraging abundant oral hydration at the time of chemotherapy. With ifosfamide, this complication can be reduced with intravenous hyperhydration and the use of uroprotective mesna. Mesna is given as an intravenous bolus equal to 20% of the ifosfamide dose 15 min before ifosfamide administration, as well as 4 and 8 h later (the total dose of mesna should be equivalent to 60% of the ifosfamide dose). Mesna may also be given as a continuous infusion at a dose equivalent to the ifosfamide dose. Continuous infusion of mesna should be maintained for 4–8 h after completion of ifosfamide infusion. When given with cyclophosphamide, mesna is predominantly used with high-dose chemotherapy in bone marrow transplantation. The dose of mesna used is approximately 60–160% of the cyclophosphamide dose and is given intravenously in 3–5 divided doses or by continuous infusion.^{21, 24}

Hemorrhagic cystitis may occur with chemotherapy regimens that do not contain cyclophosphamide due to

chemotherapy-associated thrombocytopenia, and the presence of a GU malignancy may serve as a nidus for bleeding. Hemorrhagic cystitis in bone marrow transplantation due to chemotherapeutic regimens must be differentiated from infectious hematuria as a result of adenovirus²⁵ or BK human polyomavirus²⁶ infection.

Radiation-induced cystitis

Although relatively uncommon, hemorrhagic cystitis may develop following the treatment of pelvic neoplasms with either external beam radiation or brachytherapy. The pathophysiology of radiation-induced cystitis involves damage to vascular endothelium and endarteritis leading to progressive ischemia, inflammation, fibrosis, and ultimately tissue necrosis.²⁷ It may appear from 6 months to several decades following completion of radiation, and in one study, affected 6.5% of patients receiving pelvic radiation.²⁸ Total-body irradiation for bone marrow transplantation is associated with hemorrhagic cystitis in 10–17% of patients.^{14, 29} Patients at highest risk are those receiving concurrent cyclophosphamide or who have undergone urologic interventions. Radiation cystitis may develop decades after the completion of radiation therapy, but as this scenario may also represent disease recurrence, thorough investigation must be undertaken before ascribing new hematuria to radiation cystitis.

Radiation nephritis

Radiation is often delivered near the kidneys to control nodal metastasis from radiation-sensitive tumors (e.g., lymphomas and seminomas). Radiation-induced nephritis may develop as a result of irradiation of the kidneys, and is related to both the total dose of radiation and the volume treated.³⁰ However, modern shielding techniques have dramatically decreased the incidence of this complication. Renal dose tolerance (TD5/5) is estimated to be 20 Gy in adults, with glomerular function declining at 15 Gy and function nearly completely lost at 25–30 Gy. Radiosensitizers such as cisplatin, carmustine (BCNU), and actinomycin D tend to lower normal tissue radiation tolerance. Symptoms are rarely seen acutely (within 6 months of treatment). Six to twelve months after radiation, signs and symptoms including hypertension, edema, albuminuria, active urinary sediment, and rise in BUN and serum creatinine may be noted. In the chronic phase (>12 months), hypertension is the most common finding. Eventually, patients may develop hyperreninemic hypertension related to renal scarring, atrophy of cortical tubules, and glomerulosclerosis. Rarely, patients may develop progressive deterioration of renal function requiring hemodialysis or renal transplantation.³¹ Avoiding these debilitating complications is an essential aspect of sophisticated modern radiation techniques.

Total-body irradiation in bone marrow transplantation has been associated with dose-dependent long-term renal toxicities including hypertension, anemia, decreased glomerular filtration rate (GFR), hematuria, and proteinuria. Pathologic findings include necrosis of vascular structures and disruption of both endothelial and epithelial cells of the basement membrane.³² In a review of bone marrow transplant patients receiving total-body irradiation with 14 Gy, the incidence of nephropathy decreased with increased renal shielding: 30% of patients treated without shielding developed nephropathy, 15% of patients treated with partial shielding developed nephropathy, and no patients developed nephropathy with 30% shielding.³³

Diagnosis, treatment, and prevention of nephrotoxicity of cancer therapeutic agents

Many widely used chemotherapy agents have the potential for renal toxicity ([Table 1](#)). Adverse effects include tumor lysis syndrome, paraneoplastic glomerulonephritis, obstructive uropathy, and direct nephrotoxicity resulting in renal failure and electrolyte disturbances. These are more common in the geriatric population secondary to polypharmacy and comorbid conditions. The nephrotoxic effects of these agents are more commonly observed in bone marrow transplantation due to high-dose chemotherapy, polypharmacy, and total-body irradiation. In the following sections, we describe commonly used agents that cause serious renal toxicity. [Table 2](#) lists additional agents that may cause nephrotoxicity. [Table 3](#) lists the mechanism of renal injury for several drugs. Drug–drug interaction is another crucial consideration in the administration of potentially nephrotoxic agents; [Table 4](#) highlights some of these drug interactions. These tables are not comprehensive, and careful review of all prescription and over-the-counter medications is essential to the prevention of renal toxicity in the cancer patient. Dose adjustment for several essential chemotherapy agents is summarized in [Table 5](#).

Table 1 Therapeutic agents associated with nephrotoxicity

<i>Alkylating agent</i>
AZQ (diaziquone)
Carboplatin
Cisplatin
Cyclophosphamide
Ifosfamide
Nitrosoureas (streptozocin, carmustine, lomustine)
Oxaliplatin
<i>Antitumor antibiotic</i>
Mitomycin C
Plicamycin
<i>Antimetabolite</i>
5-Azacytidine
Clofarabine
Gemcitabine
High-dose methotrexate
<i>Folate antagonist</i>
Pemetrexed
<i>Targeted therapies</i>
VEGF inhibitors (bevacizumab, sunitinib, sorafenib, pazopanib, axitinib, cabozantinib)
mTOR inhibitors (everolimus, temsirolimus)
Cetuximab
<i>Biologic agent</i>
Aldesleukin (IL-2)
Interferon
<i>Immunotherapies</i>
Ipilimumab
<i>Other</i>
Asparaginase
Cyclosporine
Gallium nitrate
Gefitinib
Imatinib
Pentostatin
Tacrolimus

Table 2 Clinical and pathologic features of chemotherapy-associated nephrotoxicity

Drug	Type of injury	Clinical features	Urine analysis	Time of toxicity	Treatment/outcome	Prevention
5-Azacytidine	Acute tubular	Renal tubular acidosis	Bland, hypoosmolar on therapy	Polyuria and rising creatinine 7–10 days post dose	Replace HCO ₃ , PO ₄ , Mg; recovery is complete	Daily creatinine, BUN, and electrolytes
Bevacizumab	Glomerulopathy	Proteinuria	Proteinuria	Increasing with cumulative dose	Discontinue if nephrotic syndrome; hold therapy if urinary protein	Monitor regularly
Carboplatin	Tubular	Mg wasting	Bland	Rising creatinine 5–10 days after therapy	Cessation of drug; dialysis as necessary; recovery usually incomplete	Avoid other nephrotoxic drugs; Mg increase in patients previously treated with cisplatin
Cisplatin	Acute tubular	Mg wasting	Bland	Rising creatinine with cumulative dose	Cessation of drug; dialysis as necessary; recovery usually incomplete	Vigorous hydration; diuresis, mannitol diuresis, 100 mg sodium thiosulfate; avoid aminoglycosides
Cyclosporine	Tubular and afferent arteriole vasoconstriction	Increased K and decreased Mg; renal tubular acidosis; edema; hypertension	Proteinuria	Rising creatinine from days to months after initiation of therapy	Cessation of drug; dialysis as necessary; recovery usually complete	Periodic creatinine level; monitor creatinine, BUN, and electrolytes
AZQ (diaziquone)	Tubular and glomerular	Anuria, proteinuria, and renal tubular acidosis	Proteinuria	Rising creatinine 5–10 days after therapy	Cessation of drug; dialysis as necessary; recovery usually complete	Avoid doses >245 mg/m ²
Gallium nitrate	Glomerulopathy	Proteinuria and occasional	Proteinuria	Proteinuria followed by rising	Cessation of drug; recovery usually complete	Daily urine output >2 L; avoid doses >300 mg/m ²

		azotemia		creatinine during and shortly after therapy days		mg/m ² /day, consecutive days
Ifosfamide	Acute tubular	Oliguria	Bland	Rising creatinine within 1–2 days after therapy	Supportive dialysis; recovery usually complete	Oliguria and increased creatinine in patients with prior cisplatin therapy; no
Interleukin-2	Prerenal azotemia	Oliguria and hypotension	Proteinuria and hematuria	Rising creatinine during therapy	Stop drug when creatinine ≥4.5 mg/dL or >4 mg/dL with acidosis, fluid overload or increased K; creatinine >1.5 mg/dL with oliguria; recovery usually within 1–2 weeks	Dopamine renal doses, fluids
Ipilimumab	Interstitial nephritis	Rising creatinine	Proteinuria, few WBC, few RBC	Weeks	Drug withdrawal, steroids may be necessary	Careful monitoring of serum creatinine
Methotrexate	Acute tubular	Oliguria	Bland	Rising creatinine within 1–2 days of dose	High-dose leucovorin based on methotrexate level; high-volume urine output and alkalinization; recovery is complete	Vigorous hydration, urine alkalinization, dose reduction on renal dysfunction; avoid aminoglycosides and nonsteroidal anti-inflammatory drugs; leucovorin
Plicamycin	Acute tubular	Abrupt renal failure	Mild proteinuria	Rising creatinine during dosing	Cessation of drug; re-treat, if recovery complete	Alternate-dosing; check creatinine, BUN daily
Mitomycin C	Renal vascular lesions	Hypertension, anemia	Hematuria, proteinuria	Rising creatinine after two or more	Permanent cessation of drug; SPA immunoperfusion and dialysis; poor	Stop drug, cumulative dose of 60 mg

				doses (12–40 weeks from start)	recovery	
mTOR inhibitors	Acute tubular, FSGS	Rising creatinine	Proteinuria	Weeks to months	Cessation of drug; recovery may not be complete in patients with comorbidities	Regular monitoring
Nitrosoureas	Interstitial fibrosis, glomerular sclerosis	Late complications	Bland	Rising creatinine months to years after therapy	Supportive dialysis; recovery is complete	Stop BCNU if cumulative dose of 1200 mg/m ²
Streptozocin	Tubular	Proteinuria, occasionally severe	Proteinuria, aminoaciduria	Proteinuria followed by rising creatinine during dosing	Cessation of drug; recovery usually complete	Stop drug if evidence of severe proteinuria; hydration not prevent injury
VEGF inhibitors	Tubular, capillaries	Proteinuria, hypertension	Proteinuria, may be nephrotic range	Weeks to months	Hypertension: aggressive medical management Proteinuria: hold for moderate proteinuria until resolution. Nephrotic-range proteinuria should prompt permanent discontinuation	Regular monitoring

Abbreviations: BCNU, carmustine; BUN, blood urea nitrogen; SPA, staphylococcal protein A; FSGS, focal segmental glomerulosclerosis.

Table 3 Types of renal injury caused by cancer chemotherapeutic agents

Pathologic finding	Causative agent
Acute glomerulonephritis	None reported
Acute tubular necrosis	Plicamycin mTOR inhibitors
	Cisplatin
Interstitial nephritis	Nitrosoureas, ipilimumab
Membranous glomerulonephritis (protein losing)	AZQ (diaziquone), bevacizumab
Obstructive uropathy	Methotrexate
Renal tubular acidosis	5-Azacytidine
Renal vasculitis	Mitomycin C

Table 4 Drug interactions that can increase serum levels of antineoplastic agents or add renal toxicity

Axitinib	CYP3A4/5 inhibitors
Cabozantinib	CYP3A4 inhibitors
Capecitabine	Leucovorin
Carboplatin	Cyclophosphamide, aminoglycosides, topotecan
Cisplatin	Any nephrotoxic agent, ^a melphalan, paclitaxel, ^b rituximab, topotecan ^b
Cladribine	Cyclophosphamide (high dose)
Cyclophosphamide	Allopurinol
Cyclosporine	Any nephrotoxic agent, ^a vancomycin, melphalan, cimetidine, potassium-sparing diuretics, naproxen, sulindac, diclofenac, allopurinol, cytochrome P-450 inhibitors, ^c methotrexate
Etoposide	Aprepitant, cyclosporine, valspodar
Everolimus	Selected strong CYP3A4 inhibitors, many antivirals, ketoconazole
Gefitinib	Cytochrome P-450 3A4 inhibitors
Gemcitabine	5-Fluorouracil
Ifosfamide	Cytochrome P-450 inhibitors, ^c aprepitant
Interleukin-2	Any nephrotoxic agent ^a
Melphalan	Buthionine
Methotrexate	Organic acids, penicillins, cisplatin, NSAIDs, amiodarone, aspirin, ciprofloxacin, cotrimoxazole, cyclosporine, doxycycline, mercaptopurine, probenecid, procarbazine
Mercaptopurine	Allopurinol, methotrexate, TPMT inhibitors
Mitomycin	5-Fluorouracil-related hemolytic-uremic syndrome
Pazopanib	CYP3A4 inhibitors and inducers
Streptozocin	Any nephrotoxic agent ^a
Sunitinib	CYP3A4 inhibitors and inducers
Temsirolimus	CYP3A4 inhibitors and inducers, many antivirals, dexamethasone
Tacrolimus	Any nephrotoxic agent, ^a cyclosporine, cisplatin, drugs metabolized through cytochrome P-450 3A
Thioguanine	TPMT inhibitors
Topotecan	Cisplatin, ^b carboplatin ^b
Trimetrexate	Cimetidine, cytochrome P-450 inhibitors ^c

Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; TPMT, thiopurine methyltransferase.

^a For example, aminoglycosides, amphotericin B, intravenous contrast, NSAIDs.

^b Related to sequence of administration.

^c Azoles antifungals, macrolides, calcium channel blockers, corticosteroids, grapefruit juice.

Table 5 Adjustment of antineoplastic agents based on renal insufficiency

--	--

Azacytidine	Unexplained increase in creatinine or blood urea nitrogen; delay treatment until back to baseline, then reduce dose by 50%
Blemomycin	Creatinine clearance 10–50 mL/min: reduce dose by 25%
	Creatinine clearance <10 mL/min: reduce dose by 50%
Capecitabine	Creatinine clearance 30–50 mL/min: reduce dose by 25%
	Creatinine clearance <30 mL/min: not recommended
Carboplatin	Adjust according to Calvert formula:
	Total dose (mg) = (target AUC) × (GFR + 25)
Carmustine	Creatinine clearance <60 mL/min: omit dose
Cisplatin	Creatinine clearance 10–50 mL/min: decrease dose by 25%
	Creatinine clearance <10 mL/min: decrease dose by 50%
Clofarabine	Use with extreme caution
Cyclophosphamide	Creatinine clearance 10–50 mL/min: reduce dose by 25%
	Creatinine clearance <10 mL/min: reduce dose by 50%
Cytarabine	Creatinine clearance <60 mL/min, use caution; may decrease dose or change schedule
Daunorubicin	Creatinine >3 mg/dL: decrease dose by 50%
Etoposide	Creatinine clearance 15–50 mL/min: decrease dose by 25%
	Creatinine clearance <15 mL/min: consider 50% dose reduction
Fludarabine	Creatinine clearance 30–70 mL/min: decrease dose by 20–50%
	Creatinine clearance <30 mL/min: not recommended
Gefitinib	Use caution with severe renal impairment
Gemcitabine	Use caution with severe renal impairment
Hydroxyurea	Creatinine clearance <10 mL/min: reduce dose by 80%
Ifosfamide	Creatinine clearance 46–60 mL/min: reduce dose by 20%
	Creatinine clearance 31–45 mL/min: reduce dose by 25%
	Creatinine clearance ≤30 mL/min: reduce dose by 30%
Lomustine	Creatinine clearance <60 mL/min: omit dose
Melphalan	Dose reduction may be necessary; IV: BUN >30 mg/dL or creatinine >1.5 mg/dL: consider 50% dose reduction
Mercaptopurine	Decrease dose or increase interval
Methotrexate	Creatinine clearance 10–50 mL/min: reduce dose by 50%
	Creatinine clearance <10–30 mL/min: avoid use
Mitomycin C	Creatinine clearance <10–60 mL/min: reduce dose by 25%
	Creatinine clearance <10 mL/min: reduce dose by 50%
Oxaliplatin	Use with caution in mild to severe renal impairment
Pemetrexed	Hold therapy if creatinine clearance <45 mL/min: patient with grade 3/4;

	nonhematologic toxicity should decrease dose by 25%
Pentostatin	Creatinine clearance <30–60 mL/min: dose reduction may be necessary
Plicamycin	Creatinine clearance 10–50 mL/min: reduce by 25%
	Creatinine clearance <10 mL/min: reduce dose by 50–70%
Procarbazine	Creatinine clearance <30 mL/min: omit dose
Ralitrexed	Creatinine clearance <25–30 mL/min: reduce dose by 50%
	Creatinine clearance <25 mL/min: omit dose
Streptozocin	Use with caution
Teniposide	Dose reduction may be necessary
Thiotepa	Dose reduction may be necessary
Topotecan	Creatinine clearance 20–39 mL/min: decrease dose to 0.75 mg/m ²
	Creatinine clearance <20 mL/min: insufficient evidence
Tretinoin	Maximum dose of 25 mg/m ²
Trimetrexate	Hold therapy if creatinine >2.5 mg dL; dose adjustment may be necessary

Abbreviations: AUC, area under the curve; BUN, blood urea nitrogen; GFR, glomerular filtration rate; IV, intravenous.

Cisplatin

The introduction of cisplatin to the clinic highlighted the potential hazards of nephrotoxic chemotherapies.³⁴ Effective prevention and management of cisplatin's renal toxicity is critical to appropriate delivery of this drug, and development of platinum analogues has in part been motivated by cisplatin's renal toxicity. The study of cisplatin, the modification of its delivery, and the anticipation of and screening for nephrotoxicity provide a paradigm for the study of nephrotoxic agents in general.

Cisplatin is principally excreted by the kidneys; however, only a small portion of the total cisplatin dose can be identified in the urine in the first few days of therapy.³⁵ Much of the drug is irreversibly bound to protein, but active metabolites including the aquated diamino derivative and the parent are found in the ultrafiltrable plasma fraction. Clearance of this plasma component is triphasic, with nearly all drug eliminated in 4 h, but with a terminal half-life exceeding 24 h. Cisplatin nephrotoxicity is a result of necrosis of the proximal convoluted tubules, and its severity can be abrogated with aggressive hydration. As cisplatin is a highly emetogenic medication, brisk intravenous fluid administration and aggressive anti-emetics are central to avoiding dehydration, which may potentiate nephrotoxicity.^{36, 37}

Clinically, cisplatin-induced nephrotoxicity may be identified by a rise in serum creatinine and a decline in GFR. Other signs may include hypomagnesemia and moderate proteinuria, which is attributed to a tubular defect.³⁸ Hemolytic-uremic syndrome (HUS) has also been described, particularly when cisplatin is combined with bleomycin.³⁹ Routine monitoring of GFR as well as electrolytes including calcium, magnesium, and phosphorus is recommended. A minimum interval of 7 days between cisplatin doses is also recommended, as maximal nephrotoxicity frequently does not manifest in less than 7 days. A significant decline in the creatinine clearance should result in a delay of therapy.

Prevention of toxicity with hydration is crucial. Administration of normal saline supplies abundant chloride ions, which diminish the formation of the aquated species by mass action, thereby lessening

nephrotoxicity. Conflicting reports exist about the role of mannitol⁴⁰ and furosemide (Lasix)⁴¹ in cisplatin hydration. Coadministration with other nephrotoxic medications including ifosfamide and MTX can potentiate renal damage, and adequate hydration is crucial in this setting. Concurrent cisplatin and aminoglycoside antibiotic use have been reported to result in a significantly greater reduction in renal function.⁴² Meticulous attention to laboratory findings, adequate hydration, and avoidance of drug–drug interactions, when possible, are critical.

Methotrexate

Methotrexate (MTX) is principally excreted by renal glomerular filtration. Renal toxicity due to MTX may be particularly devastating, as prolonged exposure to the drug substantially increases bone marrow toxicity and mucositis. The renal toxicity of MTX is a dose-dependent phenomenon, and renal failure has been implicated in deaths associated with the use of this agent.⁴³ As it is highly protein bound, it is not readily cleared by dialysis in case of overdose.³⁹ The nephrotoxicity of MTX manifests primarily in the renal tubule, where extensive necrosis of the convoluted tubules occurs. The lesion has been termed crystalline hydronephrosis and has been attributed to deposition of the agent. The precipitation of MTX and its less soluble principal metabolite, 7-hydroxy-MTX, in the renal tubule results in changes in preglomerular vascular pressure and a direct decrease in glomerular filtration.

Avoidance of MTX nephrotoxicity can be accomplished by selecting patients with adequate renal function, ensuring appropriate hydration, and alkalinizing the urine to pH 7 or higher. MTX may accumulate in fluid collections; therefore, drainage of pleural effusions or ascites before administration is indicated. Before administration of MTX, adequate renal function should be ensured (normal serum creatinine and minimum urinary flow of 100 mL/h). Additional protective measures include administration of leucovorin starting 24–36 h after the start of therapy and continuing until plasma MTX levels fall to <0.1 micromolar. Monitoring for potential drug–drug interactions is crucial; weak organic acids such as salicylates increase MTX levels by displacing the drug from binding sites on plasma proteins. In addition, renal tubular transport is diminished by probenecid and salicylates. These agents should be avoided during MTX infusion.

Nitrosoureas

Each of the nitrosoureas (lomustine [CCNU], methyl-CCNU, and BCNU) was predicted to have significant nephrotoxicity^{44, 45} and this has been confirmed in large phase 3 trials.^{46, 47} Unlike MTX and cisplatin, nitrosoureas cause interstitial nephritis. Hydration does not appear to prevent nitrosourea-induced nephrotoxicity, and limiting the cumulative dose administered is the primary method of preventing renal damage.

Mitomycin C

Mitomycin C is an antibiotic isolated from *Streptomyces caespitosus*. Although it has demonstrated significant activity in a variety of tumors, its current use is limited due to adverse effects including prolonged thrombocytopenia. Mitomycin C has also been associated with HUS with a widely varying interval between drug exposure and onset of HUS.⁴⁸ Patients receiving mitomycin C should be carefully monitored for any early signs or symptoms suggestive of HUS (rising creatinine or LDH, anemia). Total cumulative doses of less than 30 mg/m² of body surface area are rarely associated with HUS and most cases occur with doses >60 mg.⁴⁹ While steroids can reduce the pulmonary toxicity of this agent, they have demonstrated no clear nephroprotective effect.

Targeted therapies

Mammalian target of rapamycin (mTOR) inhibitors, everolimus and temsirolimus, may produce proteinuria and acute kidney injury (AKI)⁵⁰ via a mechanism of biopsy-proven focal segmental glomerulosclerosis⁵¹ as well as acute tubular necrosis.⁵² Cases of irreversible renal injury requiring dialysis have been reported. AKI due to mTOR inhibitors should prompt drug withdrawal, and guidelines for medication rechallenge are lacking. As the likelihood of irreversible kidney injury is higher in patients over 65 with hypoalbuminemia, hypertension, or preexisting chronic kidney disease (CKD), these patients should not be rechallenged with mTOR inhibitors.⁵¹

Targeted therapies that inhibit angiogenesis via the VEGF pathway (bevacizumab, sunitinib, sorafenib, pazopanib, axitinib, and cabozantinib) may produce proteinuria and hypertension due to renal effects. VEGF is expressed by podocyte cells of the glomerulus as well as capillary cells, and VEGF inhibitors are thought to decrease podocyte tight junction expression, leading to proteinuria. The effects are dose dependent and reversible with drug withdrawal. Patients on VEGF inhibitors should have frequent monitoring of blood pressure, and antihypertensive medications should be initiated promptly if hypertension is noted. It is not uncommon to prescribe 2–3 medications for control of blood pressure; however, with aggressive medical management of blood pressure, VEGF therapy can be continued. The presence of both hypertension and proteinuria should prompt the use of an ACE inhibitor as first-line antihypertensive therapy. The management of proteinuria is by grade outlined in the package insert of each individual VEGF inhibitor; in general, therapy is temporarily suspended for moderate proteinuria, and permanently discontinued if the proteinuria reaches nephrotic range.⁵³

Immunologic agents

Interleukin-2 may cause renal insufficiency via a prerenal azotemia from capillary leak syndrome. This renal toxicity is reversible with discontinuation of the drug, intravenous hydration, and if needed, pressors and renal dose dopamine.⁴³ Cyclosporine produces renal vasoconstriction primarily at the afferent arteriole, causing arterial hypertension and renin-mediated renal dysfunction.⁵⁴ Acute nephrotoxicity is reversible with dose modification. In contrast, chronic administration may cause irreversible renal failure secondary to renal tubular fibrosis.⁵⁵

In the past few years, immune checkpoint blockade has become a very attractive strategy in cancer therapy. Ipilimumab, a fully human, IgG1 monoclonal antibody blocking cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), nivolumab, a fully human IgG4 antibody blocking the programmed death-1 (PD-1) receptor, and pembrolizumab, a humanized monoclonal IgG4-kappa isotype antibody against PD-1, have all become the new arsenals against cancer. Significant tumor regression is achieved by inhibition of T-cell activation (CTLA-4), T-cell exhaustion (PD-1), and blocking the negative immune regulatory signaling of the PD-1 receptor expressed by T-cells.⁵⁶ Ipilimumab has been associated with a number of autoimmune phenomena including colitis, pneumonitis, and rarely nephritis.⁵⁷ The injury is associated with infiltration of highly activated CD4 and CD8 T cells and elevated levels of inflammatory cytokines.⁵⁸ The mechanism of renal injury is usually interstitial nephritis, with rare reports of nephrotic syndrome.^{59, 60} Renal function returns to normal with drug withdrawal; steroids may be necessary.⁶¹ Nivolumab and pembrolizumab toxicity have been immune mediated; their toxicity has been less severe when compared with ipilimumab. A possible explanation is that PD1/PD-L1 checkpoint interaction takes place at the tumor site, whereas the CTLA4/B7 interaction occurs mostly in the lymphoid organs with more systemic effects,⁶² which may then spare the kidneys. Building on the efficacy of these drugs as monotherapy, and the potential synergy of PD-1 and CTLA-4 blockade, a natural next step was to combine

agents that target these two immune pathways. A phase I study in patients with advanced melanoma used a combination of ipilimumab and nivolumab, yielding 53% of patients having an objective response, all with tumor reduction of 80% or more.⁵⁶ The incidence of grade 3/4 adverse events (AEs) was the highest reported in the concurrent-regimen patients (53%), which was higher than reported with monotherapies. Serious AEs related to the treatment were hepatic events (in 15% of patients), gastrointestinal events (in 9% of patients), and renal events (in 6% of patients).⁵⁶

Other agents

Other agents with potential for nephrotoxicity are listed in [Table 2](#).

Monitoring for drug-induced nephrotoxicity

The anticipated mechanism of renal injury should guide what monitoring tests are employed. For example, tubular defects resulting from cisplatin nephrotoxicity may not be immediately reflected in GFR, whereas hypermagnesiuria and hypomagnesemia are characteristic of cisplatin nephrotoxicity. Monitoring patients for nephrotoxicity with agents that can cause interstitial nephritis (nitrosoureas) requires routine and frequent urinalyses, whereas agents that may cause HUS (mitomycin C and gemcitabine) should prompt attention to the relevant laboratory parameters. The appearance of microhematuria should lead physicians to further investigate drug-induced renal injury.

[Table 6](#) Cockcroft formula

$\frac{(14 - \text{Age}) \text{ Weight (kg)}}{72 \times \text{Serum creatinine}}$

The most common renal functional abnormality as a result of cytotoxic therapy is a decline in GFR, and this may prompt a dose adjustment or a change of therapy. Particular attention should be paid to the correct calculation of renal function by adjusting for weight. The creatinine clearance calculated by the Cockcroft-Gault formula ([Table 6](#)) is accurate in patients of average body habitus, but may result in erroneous predictions in patients who are significantly under- or overweight. The wide fluctuations in weight that may occur in patients undergoing cancer therapy require frequent monitoring of weight and recalculation of GFR with each chemotherapy dose.

Chapter 132

Cardiac complications

Michael S. Ewer, MD, MPH, JD, LLM, MBA ■ Steven M. Ewer, MD ■ Thomas Suter, MD

Overview

Patients with malignant diseases often have coexisting cardiovascular disorders or may face serious cardiovascular complications in the course of their disease. The disorders may result from underlying conditions such as atherosclerosis, hypertension, or valvular abnormalities, or they may result directly from cancer or its treatment ([Table 1](#)). In addition, cardiovascular disorders that are unusual in patients not afflicted with cancer may be more common in the cancer patient and sometimes are unsuspected. Furthermore, cardiovascular diseases common in the general population must not be overlooked in patients with cancer; the presentation of such entities may be unusual, and the diagnosis often is more complex. Increased clinical scrutiny is therefore necessary in this vulnerable population. Multiple clinical problems may also coexist and defy a simple illumination because of the complex interactions between the malignancy, its treatment, and the cardiovascular system; what affects one often alters the presentation and course of the others. This chapter will look at some of the more common cardiovascular complications of cancer and its treatment, and will also address some of the dilemmas encountered in cancer patients with concomitant cardiac conditions.

Table 1 Important cardiovascular complications of cancer

– Primary cardiac neoplasia
Malignancy
■ Cardiac tumors
■ Pericardial tumors
– Metastatic cancer
Pericardial metastasis
■ Pericardial effusion
■ Pericardial tamponade
Myocardial metastasis
■ Cardiomyopathy
■ Arrhythmias
• Tachyarrhythmias
• Conduction system disease
– Complication of cancer treatment
Coronary vasospasm

- Myocardial infarction
- Arrhythmias
 - Supraventricular
 - Ventricular
 - QT prolongation
- Cardiomyopathy
 - Type I dysfunction (irreversible)
 - Chronic heart failure
 - Sudden cardiac death
 - Type II dysfunction (reversible)
 - Disorders of diastolic filling
- Hypertension
- Effects of radiation
- Miscellaneous entities
 - Cardiac amyloidosis
 - Carcinoid heart disease
 - Thromboembolic phenomena
 - Pulmonary hypertension

Evaluation of the cardiovascular system in the cancer patient

The evaluation of the cardiovascular system in patients with cancer begins with a detailed history and a complete physical examination. Signs or symptoms suggestive of heart failure, dysrhythmia, ischemia, or pericardial disease—all of which are common in the cancer patient—trigger a more rigorous cardiovascular assessment.¹ The individual approach should be targeted to include the specific clinical entities that are enumerated in [Table 1](#). If clinical assessment of the patient indicates possible cardiac disease, further evaluation may include an electrocardiogram, chest X-ray, and echocardiogram. Additional imaging techniques or invasive modalities such as coronary angiography and electrophysiologic evaluation may be required for specific instances. The cardiac ultrasound or echocardiogram has enjoyed the widest usage in evaluating cancer patients. It plays an important role in evaluating cardiac contractile dysfunction and assessing the integrity of cardiac structures.² A complete echocardiographic evaluation involves several complementary techniques, each of which provides information about cardiac abnormalities from a different vantage point. Transthoracic two-dimensional echocardiography images large regions of the heart, and in some views, all four cardiac chambers can be seen and wall motion abnormalities reflecting regional or global dysfunction can be assessed. Localized or loculated pericardial effusions as well as primary and metastatic tumors can be appreciated using two-dimensional echocardiography although other imaging modalities may also supplement and reinforce information initially obtained from the cardiac ultrasound.³ In situations where ultrasound imaging is suboptimal, echo contrast agents may be employed to augment the echocardiographic interface. Such

agents are increasingly used and are generally regarded as safe.⁴

Spectral and color flow Doppler studies, which are performed routinely as part of a cardiac ultrasound evaluation, show the direction and velocity of blood flow in the cardiac chambers and across the valves. This information is graphically depicted and is often superimposed on the two-dimensional echocardiogram. Valvular hemodynamics, intracardiac shunts, turbulent blood movement, and abnormal direction of blood flow are best evaluated using Doppler studies. Doppler studies provide important information regarding diastolic function, an aspect of cardiac physiology that has become increasingly important. Strain (deformation) echocardiography provides information regarding active and passive repositioning of myocardial segments. While these newer techniques improve the predictive value of the ultrasound examination, their role in the routine management of cancer patients is evolving.⁵ Transesophageal echocardiography provides a higher resolution view of certain cardiac structures than does the transthoracic study. Although the technique is semi-invasive, the increased diagnostic sensitivity of the transesophageal studies often offsets this disadvantage. Transesophageal studies are especially useful in identifying vegetations and other valvular lesions or myocardial involvement of cancer, which may be extremely difficult to assess on transthoracic studies ([Figure 1](#)). The transesophageal study, in part because of the position of the probe, is an important adjunct for the evaluation of posterior accumulations of pericardial fluid, as may be seen post-operatively; they are also of considerable value in defining and monitoring intracardiac masses and thrombi ([Figure 2](#)).⁶ Intraoperative transesophageal echocardiography is helpful in documenting the extent of an inferior vena caval tumor as well as the result of resection of such tumors ([Figure 2](#)).⁵ Three-dimensional cardiac ultrasound now is available in many centers and provides enhanced information regarding spatial relationships of intracardiac structures including the cardiac valves. The technique allows the two-dimensional image to be rotated around a selected axis, providing images of improved special orientation.⁶

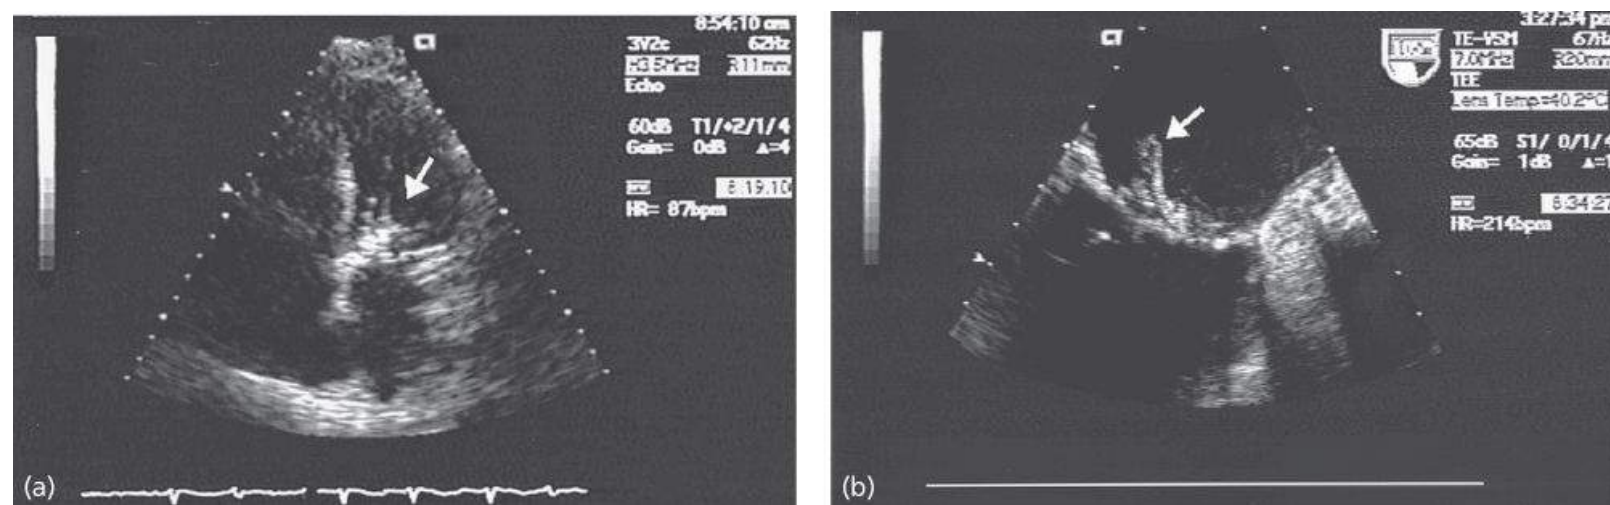

Figure 1 Echocardiogram frames of a patient with infective endocarditis involving the mitral valve. (a) Transthoracic 5-chamber image from a patient with suspected infective endocarditis involving the aortic valve. Note significant thickening of the aortic cusps. (b) Transesophageal image from the same patient recorded the same day, more clearly showing the bulky aortic valve vegetation.

Nuclear imaging techniques provide important information concerning both cardiac function and evaluation of ischemic heart disease. The multigated (MUGA) cardiac blood pool scan remains a common assessment tool for following left ventricular ejection fraction in patients being treated with agents known or suspected of being cardiotoxic. Nuclear imaging techniques may have a lower intra- and interobserver variability than do echocardiographic assessments. The technique requires electrocardiographic gating that can be problematic in patients with dysrhythmia; in addition, MUGA

scans acquire data over a period of several minutes, and therefore depend on patients being able to remain immobile during acquisition. Once the imaging data is acquired, it provides an estimation of ejection fraction, information regarding wall-motion abnormalities, and parameters of cardiac relaxation (diastolic function). While MUGA scans have previously been used to assess cardiac function in large oncologic clinical trials, the improvement in cardiac ultrasound imaging and the concerns regarding radiation exposure are providing an impetus toward the wider use of ultrasound in following patients both in and out of clinical trials. Regardless of the method used, it must be emphasized that the results of any estimation of cardiac function are affected by many noncardiac factors, and that alterations in cardiac function for a specific patient must be interpreted with some caution.⁷ Furthermore, it should be noted that small changes in the left ventricular function (LVEF changes of 10% points or less) frequently reflect conditions not associated with the cancer or its treatment but rather by physiological variations of cardiac function or by unrelated conditions such as metabolic state, anemia, or other conditions.

Magnetic resonance imaging (MRI) can delineate intracardiac pericardial, and great vessel anatomy, and can delineate intracardiac and pericardial masses.⁸ Rapid-acquisition MRI, MR angiography, and contrast-enhanced MRI techniques, while not having usurped cardiac ultrasound, are assuming a broader role in the routine evaluation of cancer patients.^{9, 10} To some extent, it now can be considered the new gold standard for quantification of ventricular volumes, function, and mass.¹¹ The cost of MRI remains considerable, and acquisition times are problematic for some patients; the technique is increasingly utilized to estimate ejection fractions for patients who cannot be otherwise evaluated. Cardiac computerized tomography is increasingly being used as an imaging modality and, like MRI, allows for excellent visualization of the pericardium and nearby extracardiac structures. Positron emission tomography (PET) has theoretical advantages over more traditional imaging techniques and is increasingly used to evaluate myocardial viability in cancer patients.¹²

Figure 2 Transesophageal echocardiogram demonstrating a large left atrial mass in a patient who presented with angina. Echocardiographic features were consistent with tumor, and pathology was consistent with a pleomorphic myxoid sarcoma.

Metastatic involvement of cardiac structures

Metastatic involvement of cardiac structures is common and is seen in approximately 8–10% of patients with cancer; the incidence is somewhat less in elderly patients.¹³ Involvement may constitute an incidental finding at autopsy or may be the initial catastrophic presentation of cancer. There are wide variations among primary disease sites and tumor types. Newer imaging techniques have made it possible to recognize cardiac involvement much earlier than was previously possible, often at a time when intervention can be efficacious. Tumor spread to cardiac structures may be by direct invasion (i.e., lung or esophagus), by retrograde lymphatic spread (i.e., lung and breast), or by hematogenous seeding (i.e., melanoma, leukemia, or lymphoma). In view of the relatively high incidence of lung and breast cancers, these neoplasms are the most common primary sites of metastatic lesions to cardiac structures. Malignant melanoma, once metastatic, is particularly likely to involve cardiac structures.¹⁴ While spread to the pericardium is much more common than is spread to other cardiac structures, metastatic involvement has the potential to involve myocardial and endocardial sites. The heart, therefore, should be included in routine examinations that seek metastatic involvement in patients with Hodgkin and non-Hodgkin lymphomas, leukemias, gastrointestinal, gynecologic cancers (especially ovarian), multiple myeloma, and sarcoma (Figure 2).¹⁵ In addition, renal cell cancer may spread to the inferior vena cava and extend into the right atrium and right ventricle; these lesions often are amenable to surgical resection.

Pericardial involvement

Pericardial effusion

Pericardial effusion in cancer patients may be malignant or nonmalignant in nature and may be related to the tumor, its treatment, or to underlying cardiac or systemic disease. Malignant pericardial effusion is defined as an effusion associated with pathologic evidence for tumor invasion of the pericardium. A malignant pericardial effusion, however, may still be present even when malignant cells are not demonstrable by routine cytologic examination of the fluid. Pericardial effusion is also seen following radiation, anticancer treatment, lymphatic obstruction, altered oncotic balance, or infection. Fluid may demonstrate considerable variability with regard to both the quantity of fluid that accumulates and the pressure exerted on the pericardium and the cardiac chambers. The rate of accumulation and the distensibility of the pericardial sac determine the hemodynamic effect and the symptoms of these effusions.¹⁶ As little as 100 mL of fluid may cause symptoms in a patient with a scarred or infiltrated nondistensible parietal pericardium, whereas large effusions containing as much as 1 L may remain relatively indolent when the pericardial sac is elastic and the effusion accumulates gradually. The finding of malignant pericardial effusion generally implies a poorer prognosis.¹⁷

Generally, pericardial fluid is not static but is in equilibrium with other body fluids. Abnormal fluid build-up occurs when fluid enters the pericardial sac more rapidly than can be reabsorbed. This disequilibrium may occur when the efferent lymphatic vessels are obstructed, or when subcarinal lymph node metastases mechanically prevent effective drainage. Malignant effusions are usually serosanguinous or frankly bloody and often (but not always) contain cytologically identifiable cancer cells. When chylous effusions are malignant, the most likely cause is lymphoma; chylous effusions also have been reported following radiation for gynecologic malignancy.¹⁸

The onset of symptoms in patients with malignant pericardial effusion may be insidious. Indeed, many patients with large effusions are totally asymptomatic, the effusion only suspected when cardiac silhouette enlargement is noted on the chest radiograph. Decreased mean electrocardiographic QRS voltage also suggests a pericardial effusion, but other causes of decreased voltage are common in cancer patients, making this finding less useful; a recent drop in voltage should raise suspicion of the presence of pericardial effusion. Pericardial effusions are often first discovered as incidental findings on ultrasound, radionuclide, or other cardiac imaging studies, with the fluid appearing as a relatively inactive area separating the cardiac from the hepatic and pulmonary blood pools. Occasionally, a rocking motion of the heart suggesting hemodynamic compromise (cardiac tamponade) is noted. Computed tomographic (CT) images of the chest also may demonstrate pericardial effusions but are not especially helpful for estimating the fluid volume. CT of the chest is frequently used to evaluate pulmonary or mediastinal tumor involvement, and therefore may provide the first indication of an unsuspected pericardial effusion. Once suspected, the diagnosis is usually confirmed by echocardiography, and its progression or resolution may be followed with serial studies.^{19–21}

Cardiac tamponade

The accumulation of pericardial fluid may lead to an increase in global or localized intrapericardial pressure and compromise cardiac output (tamponade).²² The symptoms include dyspnea and exertional intolerance; signs include hypotension, tachycardia, neck-vein distention, hepatomegaly, and cardiogenic shock. Heart sounds are often, but not always, distant and difficult to auscultate, and pericardial friction rubs may or may not be present. Vague chest discomfort or fullness is frequently noted. Most patients with significantly increased intrapericardial pressure also demonstrate an exaggeration of the decrease in pulse pressure during inspiration; when the systolic blood pressure decreases more than 10 mm Hg with normal inspiration, *pulsus paradoxus* is deemed to be present. A highly characteristic finding of cardiac

tamponade is electrical alternans, whereby the electrocardiographic QRS voltage becomes larger and smaller on alternate complexes. This phenomenon is caused by physical movement of the heart toward and away from the electrode as the heart rocks back and forth within the fluid-containing pericardial sac. While electrical alternans is not always seen in cases of cardiac tamponade, when present it is a very helpful finding. Cardiac tamponade can almost always be diagnosed on the basis of physical findings and noninvasive studies. Echocardiography confirms the diagnosis and characterizes the extent and location of accumulated fluid, which may vary considerably. Systolic inward motion (collapse) of the right atrium is a sensitive but not specific finding; collapse becomes more specific when it extends for more than one-third of the cardiac cycle. Diastolic collapse of the right ventricular wall becomes more pronounced as hemodynamic compromise progresses and is a much more specific finding. A dilated, incompressible inferior vena cava is uniformly present in the setting of tamponade. Doppler flow studies show exaggerated respiratory variation in aortic outflow and mitral inflow velocities. Cardiac catheterization is usually not required to confirm the diagnosis but may show a graphic representation of pulsus paradoxus, and elevation and equalization of the diastolic pressures in the cardiac chambers ensues as tamponade progresses. With tamponade, the pulse becomes weak or totally absent during inspiration, and patients develop symptoms of low-output cardiogenic shock. Death, sometimes preceded by profound bradycardia, may ensue if tamponade is not resolved promptly.

Management of malignant pericardial effusion and pericardial tamponade

The management of malignant pericardial effusion depends on a number of factors, including the likelihood of the tumor responding to local (surgical, radiotherapeutic, or intracavitary) or systemic anticancer therapy; the extent of and the symptoms attributable to the effusion; and the overall anticipated survival of the patient.^{23, 24} Patients with tumors highly likely to respond to the systemic therapy may proceed with their treatment; sometimes, the malignant effusion resolves in responses to the systemic anticancer therapy alone. Pericardial effusion diagnosed in patients with tumors unresponsive to treatment may require local intervention. In patients who have a more favorable oncologic prognosis and who are sufficiently strong to undergo general anesthesia and surgery, creation of a pleuropericardial window is both effective and generally considered the procedure of choice. Although the transthoracic and the subxyphoid approaches are equally efficacious, in-hospital mortality was significantly greater for patients treated with the subxyphoid approach.^{25, 26} Using either approach, the communication formed usually remains patent, and the larger surface area available in the pleural space permits more effective reabsorption of the excess fluid. Pericardial needle drainage may be required before surgery as a stabilizing measure in patients who have very large effusions or evolving tamponade. Symptoms often resolve dramatically after removal of fluid, allowing patients to again engage in activities that had become impossible.

Needle drainage is now almost always undertaken with either echocardiographic or fluoroscopic confirmation of the position of the draining catheter, whereby newer instrumentation using smaller penetrating devices and improved imaging techniques have lowered the pericardiocentesis risk.²⁷ Some patients experience transient left ventricular dysfunction after resolution of cardiac tamponade, and thus, a period of careful monitoring is important.²⁸ The advantages of the pericardial window over percutaneous pericardiocentesis have not been fully evaluated, but some studies suggest little advantage to the more invasive pericardial window procedure. The advisability of routine drainage of large pericardial effusions in patients without tamponade has also been questioned; Merce et al. point out the low diagnostic yield and the lack of therapeutic benefit.²⁹ The clinical management of such patients should be determined by their overall performance status, oncologic prognosis, and the expertise at the treatment center.

Sclerosis may be considered following needle drainage but is now employed much less frequently than heretofore, in part due to the significant patient discomfort associated with this procedure. A number of sclerosing agents have been studied, including hyperosmolar glucose, radioactive gold, bleomycin, sterile talc, doxycycline, and triethylenethiophosphoramide (thio-TEPA®).^{30, 31} Doxycycline, used at a dose of 250–500 mg, has received considerable attention as an effective sclerosing agent.³² In many instances, daily draining the fluid until the residual effusion is <50 mL without instilling a sclerosing agent is highly effective in preventing recurrent accumulations.³³ Balloon pericardiotomy has been largely replaced by surgical pericardiotomy, an intervention that can often be accomplished with minimal invasion.³⁴

Metastatic involvement of the myocardium

The spread of malignant tumors to the myocardium is being increasingly recognized *in vivo* through the broader use of imaging studies. While previously myocardial involvement was most commonly found at autopsy, this is no longer the case. Many patients in whom metastatic disease to the myocardium is identified before death also have evidence of concomitant pericardial involvement.

The most dramatic manifestation of myocardial metastatic disease is sudden dysrhythmia.^{35, 36} Sudden cardiac death can occur in this setting but is unusual. Cardiac perforation and erosion of the coronary vessels with hemorrhage or infarction may also occur but are exceedingly rare. More commonly, patients with myocardial involvement demonstrate signs of loss of functioning muscle mass and present with progressive shortness of breath or exercise intolerance; a decreased ejection fraction may be seen. The electrocardiographic representation of loss of electrical potential can be seen and may be indistinguishable from changes typically encountered with myocardial infarction due to coronary occlusion ([Figure 3](#)). ST segment elevations, T-wave inversions, or Q waves may be seen in such cases, even when the coronary arteries are normal angiographically.³⁷

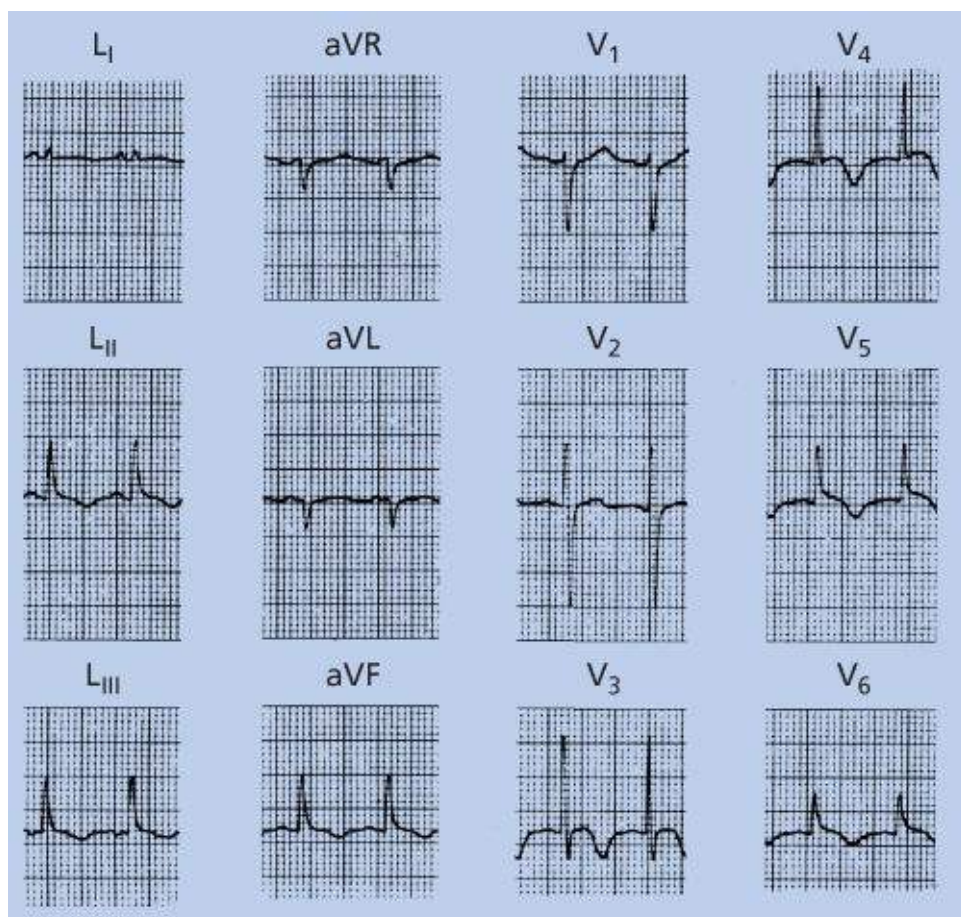

Figure 3 Electrocardiogram suggesting ischemia in a 26-year-old man with documented (by magnetic resonance imaging) myocardial metastatic disease and no history to suggest other causes of the electrocardiographic abnormality. Note T-wave inversions in the inferior leads (2, 3, and AVF) as well as in the precordial leads (V₄–V₆).

The diagnosis of metastatic involvement of the myocardium may be difficult to establish. A high suspicion may prompt special imaging, and MRI studies may be helpful in determining the presence and extent of metastatic myocardial disease. Although treatment of metastatic disease to the myocardium often is supportive, large lesions or those with impending valvular obstruction should be considered for surgical removal.^{38, 39}

Cardiac effects of mediator release, high output states, and infiltrative disorders in cancer patients

Metabolically active mediators commonly are associated with some forms of neoplastic diseases and frequently are the immediate cause of a patient's presenting signs and symptoms.⁴⁰ Such mediator-associated diseases, or paraneoplastic syndromes, may have a direct or indirect effect on the cardiovascular system.

Carcinoid heart disease

Carcinoid tumors arise from enterochromaffin cell-derived neuroendocrine tissue, most commonly in the gut or lungs; oncologic considerations regarding these tumors are considered elsewhere in this text. Carcinoid heart disease results from prolonged release of biologically active mediators from the tumor that stimulate the formation of a distinctive fibromuscular plaque that destroys the integrity of the cardiac valves.^{41–46} Carcinoid heart disease is seen most commonly in patients who have ileocecal carcinoid

tumors that have metastasized to the liver. Rarely, it occurs in patients with bronchial or ovarian carcinoid tumors, and, if outside the confines of the portal venous system, carcinoid heart disease may develop in the absence of hepatic metastases. The exact mechanism of plaque formation and cardiac injury remains elusive, but a number of possible mediators, including kinins, serotonin, 5-hydroxytryptophan, histamine, and prostaglandins, have been suggested; another as yet unidentified compound or combination of compounds may also contribute.⁴⁷

Mediator release into the hepatic vein from metastatic liver disease predisposes patients to right-sided cardiac lesions. Because these mediators are eliminated by the lungs, the left heart is spared unless a right-to-left shunt is present. The lesions generally appear along the intima of the great veins, the right atrium, and the coronary sinus. The margins and distal (ventricular or downstream) aspect of the tricuspid leaflets are often thickened, and the *chordae tendineae* may also be involved. The pulmonic valve may be thickened and retracted. The damage appears to be aggravated by turbulent blood flow, which explains the characteristic location of the lesions. When the primary tumor or metastasis is in the lung, the mediators are released directly into the pulmonary venous bed and bypass the inactivating properties of lung tissue; left-sided valvular lesions are seen in such cases.⁴⁸ Left-sided lesions are less frequent than right-sided ones but are more likely to result in hemodynamic compromise. A review of surgically excised valves noted considerable variation in the histological appearance of the material.^{49–51}

The most important consequence of carcinoid plaques is thickening and fibrosis of the valves with resultant distortion of the valvular apparatus and ring. Tricuspid regurgitation and pulmonic stenosis are typically seen, but in the case of progressive destruction, a rigid tricuspid valve with hemodynamic abnormalities reflecting both stenotic and regurgitant characteristics may be encountered. Significant pulmonic regurgitation is rare. Stiffening of the right atrium may be noted and contributes to the neck-vein distention commonly seen in patients with the carcinoid syndrome. A high-output state, probably due to mediator release, has also been described.⁵²

The clinical manifestations of carcinoid heart disease vary considerably. Some patients are able to tolerate the hemodynamic consequences of their valvular lesions well, whereas others develop symptoms early; this is especially so in the elderly or those with predisposing cardiac abnormalities.⁵³ Early symptoms include fatigue, dyspnea on exertion, and palpitations owing to a high-output state, dysrhythmias, or to both. Later, symptoms of right-sided congestive heart failure, including edema, hepatomegaly, and ascites, predominate. Cardiac murmurs often predate symptoms, and the murmur of tricuspid regurgitation may be an early finding. Most frequently, the murmur is appreciated as a loud, holosystolic, blowing sound heard along the left lower sternal border. The murmur may be augmented during inspiration. The murmur of pulmonic stenosis cannot always be distinguished from that of the often coexisting tricuspid regurgitation; when heard, the pulmonic murmur is usually harsher and is appreciated most prominently in the second left intercostal space.

The chest radiograph may reveal prominence of the right ventricle. Unlike congenital pulmonic stenosis, which often includes poststenotic dilatation of the pulmonary trunk, this finding is usually not seen with carcinoid heart disease. Electrocardiographic findings include changes suggestive of right ventricular volume or pressure overload with or without right atrial abnormalities, right ventricular hypertrophy, right bundle-branch block, and/or right axis deviation; low voltage in the standard (limb) leads may also be seen.

Echocardiography is the most useful noninvasive tool for diagnosing carcinoid heart disease ([Figure 4](#)). It not only identifies the valvular abnormality, but, when coupled with Doppler ultrasonography studies, also provides hemodynamic data for estimating the degree of valvular involvement.⁵⁴ Along with the

thickening and loss of mobility of the tricuspid leaflets, increased flow velocity across the tricuspid valve during diastole is often evident. A regurgitant jet can be seen in the right atrium during systole. Furthermore, echocardiography can quantify the right atrial and ventricular enlargement that is characteristic of this condition. When of sufficient size, echocardiography is helpful in recognizing metastatic carcinoid tumors that involve the heart.⁵⁵

(a)

(b)

Figure 4 Carcinoid heart disease: (a) two-dimensional four-chamber study showing the thickened retracted and mal-coapting tricuspid valve leaflets. (b) Image from the same study with color-flow Doppler views showing severe tricuspid regurgitation. Also evident is right atrial and right ventricular chamber enlargement and a small pericardial effusion.

The management of patients with carcinoid heart disease must be individualized and is often challenging. Although the carcinoid plaque is largely irreversible, controlling or eliminating the offending mediators can delay plaque progression. In this respect, treatment of the primary tumor or metastatic disease is crucial. Once the diagnosis is established, carcinoid heart disease is initially managed pharmacologically with diuretics, afterload reduction, and salt restriction; the benefit of β -adrenergic blockade is unproven. Surgical intervention in the form of valvuloplasty or replacement is being considered more frequently than heretofore and with improved outcome, and some suggest early intervention.⁴⁴

High-output states and high-output cardiac failure

Increased cardiac output occurs in many cancer patients and is most commonly due to anemia, hyperthyroidism, the syndrome of inappropriate antidiuretic hormone secretion, or the shunting of blood through tumors. High-output states are relatively common in patients with multiple myeloma.⁵⁶ In addition, liver disease (nutritional cirrhosis or infectious hepatitis), fever, emotional excitement, and hypoxemia are also common causes of increased cardiac output and hyperdynamic states. High-output states are seen as well following treatment with a number of biologic response modifiers, including the interferons (possibly related to fever and the influenza-like reaction) and interleukins, in which case the phenomenon usually is of short duration.

High-output states are associated with a moderately increased heart rate (usually 85–110 beats per minute, but sometimes higher) and with increased stroke volume. Physical examination typically reveals neck veins of normal appearance as right-sided pressures are generally not increased. Peripheral pulses, however, are often bounding and have a rapid upstroke and fall; systolic blood pressure is elevated, and diastolic blood pressure often is reduced. Auscultation may reveal a systolic murmur and demonstrate a presystolic (S4) gallop. Pulmonary congestion is not uncommon in severe hyperdynamic states.

Echocardiography or radionuclide imaging is helpful in establishing the diagnosis. Two-dimensional ultrasound studies show increased wall motion in all views. In extreme cases, the images appear to suggest an almost total obliteration of the left ventricular cavity during systole; the ejection fraction is increased. Doppler examination reveals uniformly increased flow across all four valves. MUGA scans may also offer important data concerning the left ventricular ejection fraction and cardiac output. Right heart catheterization with the measurement of cardiac output confirms the diagnosis, but the procedure is rarely justified. It is important not to confuse this clinical picture with that of the more commonly encountered low-output congestive heart failure, with which it shares a number of characteristics. The treatment of high-output states should be directed toward the underlying cause; in the cancer patient, metastatic disease with or without shunting, hyperthyroidism, hypoxia, anemia, and infection are the most common considerations. High-output states often respond to blood transfusion, diuretics, oxygen administration, or antipyretics. In selected cases, β -adrenergic blockers may be useful. Unless patients are symptomatic, the high-output state does not require specific therapy, and efforts should be directed at managing the underlying cause.

Cardiac amyloidosis

Amyloidosis, or the deposition of amyloid proteins, may occur in a variety of organs including the heart,

and may be caused by a number of pathologic processes.⁵⁷ Amyloid proteins are made up of fibrils consisting of anti-parallel beta-pleated sheets that deposit in the interstitial spaces and are resistant to proteolysis. They are formed from a wide variety of precursor proteins.^{57, 58} Clinically, significant cancer-related amyloidosis is encountered in patients with multiple myeloma and, rarely, in patients with Hodgkin lymphoma. The amyloid protein associated with these diseases is known as AL amyloid and is derived from light-chain immunoglobulin (both Igλ and Igκ). AL amyloid accumulates in the atrial and ventricular myocardium and leads to either a restrictive or less commonly a dilated cardiomyopathy. Endocardial deposition resulting in valvular abnormalities has also been described.

Clinically, patients with cardiac amyloidosis experience fatigue and show signs of decreased cardiac output. Dyspnea and edema are common symptoms, and anorexia, weight loss, and presyncope are also encountered. In addition to heart failure, atrial or ventricular dysrhythmias or cardioembolic events are reported. Physical signs include elevated jugular venous pressure, edema, hepatic congestion, ascites, hypotension, macroglossia, and periorbital purpura. Conduction abnormalities are seen and, when associated with low effective heart rates or low-output states, may be symptomatic; stress-precipitated syncope may be a precursor of sudden cardiac death.^{59, 60} Both systolic and diastolic function may be impaired. Restrictive cardiomyopathy can be difficult to distinguish from constrictive pericarditis clinically; even findings at cardiac catheterization are not always conclusive in establishing the correct diagnosis. The chest radiograph shows a normal-sized or slightly enlarged cardiac silhouette. When cardiac failure appears, pulmonary congestion or pleural effusion may be seen. Electrocardiographic findings can include decreased voltage, a pseudo-infarction pattern, conduction system abnormalities, and atrial arrhythmias.⁶¹ The echocardiogram is often helpful in suggesting the diagnosis of amyloidosis ([Figure 5](#)). Ultrasonic images may demonstrate a thickened septum and posterior wall with normal internal dimensions of the left ventricle; diastolic relaxation is often impaired. In addition, a spotted or stippled echogenic appearance is often seen, and pericardial effusion is not uncommon. Atria are enlarged and may show markedly reduced mechanical function, even in the absence of atrial dysrhythmias. The paradox of left ventricular hypertrophy on cardiac ultrasound with decreased electrocardiographic voltage should suggest cardiac amyloidosis.⁶² Antimyosin scintigraphy, showing left ventricular thickening and diffuse myocardial antimyosin uptake, has been reported to be highly suggestive of amyloid heart disease. Cardiac MRI may be a useful adjunct in diagnosing amyloid infiltration, as a characteristic pattern of late gadolinium enhancement helps distinguish amyloid heart disease from other cardiomyopathies.⁶³

Figure 5 Long-axis echocardiographic view from a patient with cardiac amyloid infiltration. Note thickened septum (S) and posterior wall (P) with stippled appearance (arrows).

Cardiac catheterization demonstrates elevated intracardiac pressures in all chambers, with the minimum left ventricular pressure often increased to at least 10 mm Hg. The “dip and plateau” pattern seen on intraventricular pressure tracings in patients with constrictive pericarditis may be absent. Prominent papillary muscles are demonstrated with angiography. Endomyocardial biopsy with specimens stained with Congo red are helpful in confirming the diagnosis.⁶⁴

The therapeutic interventions for cardiac amyloidosis are limited. Loop diuretics serve as the mainstay of medical treatment. Cardiac glycosides are dangerous in that they contribute to dysrhythmia; sudden death has been reported following their use.⁶⁵ Beta blockers and non-dihydropyridine calcium channel blockers can exacerbate a low cardiac output state and angiotensin-converting enzyme inhibitors can precipitate profound hypotension. In instances where malignant dysrhythmia is triggered, implantable defibrillators have been offered, but current evidence does not support their use in amyloid cardiomyopathy.⁶⁶ Clinical improvement may parallel control of the underlying process in patients with reactive forms of amyloidosis, and systemic treatment of myeloma may delay or alleviate the symptoms of myeloma-related cardiac amyloidosis.⁶⁷ Intracardiac thrombosis is a significant risk in patients with amyloid infiltration. In one autopsy series, thrombosis was encountered in 33% of patients coming to autopsy. Anticoagulation in the presence of significant cardiac amyloidosis has been suggested. Therapy with a number of antineoplastic agents, including melphalan, cyclophosphamide, carmustine, and vincristine, have been attempted, as has hematopoietic stem cell transplantation.⁵⁸ Restrictive cardiomyopathy due to light-chain deposition disease may, in rare cases, be reversible. Cardiac transplantation followed by autologous hematopoietic stem cell transplant has been successfully performed in selected patients.⁶⁸

Cardiac dysrhythmia in the cancer patient

Cardiac rhythm disturbances are common in cancer patients. Dysrhythmias may be caused by the tumor, but more often, they are a consequence of anticancer treatment, the result of metabolic abnormalities, or from a reduced dysrhythmic threshold associated with underlying heart disease. The rhythm disturbances seen in cancer patients are morphologically and functionally identical to those seen in patients without malignancy. In some settings, it is essential to suppress a cardiac dysrhythmia vigorously, whereas in

others, rhythm disturbances may be a transient manifestation of a temporary disturbance in homeostasis requiring little or no intervention. Many antineoplastic agents are associated with transient dysrhythmia, and because such rhythm disturbances are often asymptomatic, the phenomenon is not fully appreciated. Such chemotherapy-related rhythm disturbances generally are of short duration and little immediate clinical importance, yet they may be an indication of actual myocardial involvement that may become overtly manifest only at a later time. When associated with cancer treatment, most instances of dysrhythmia do not constitute an absolute indication to alter the chemotherapeutic regimen.

When faced with clinical decisions regarding which patients to treat, at what point in their management to initiate therapy, how long to continue treatment, and what form of therapy (pharmacologic or electrical) to use have been the focus of considerable debate. The wide assortment of antidysrhythmic drugs has not simplified these decisions. One useful approach is to distinguish dysrhythmias resulting from toxic substances or other metabolic abnormalities from those associated with structural abnormalities directly related to cardiac structures.³⁶

Categories of dysrhythmia: primary (structural) versus secondary (metabolic)

The structural abnormalities within the heart that can result in cardiac abnormalities encompass a broad group of cardiac disorders. Ischemic heart disease, muscle hypertrophy, valvular disease, and infiltrative processes all fall within this group of disturbances. In cancer patients, tumor infiltration, cell loss following chemotherapy, pharmacologically induced ischemia, and fibrosis following radiation should also be included. Severe dysrhythmias, both supraventricular and ventricular, may appear with little warning and progress to hemodynamic instability and sudden cardiac death. Sudden death is more common in the presence of infiltrative processes such as amyloidosis.

Dysrhythmias in cancer patients also may be the result of nonstructural abnormalities. Most commonly, these include alterations in volume status, electrolyte disturbances, drug effects, and hormonal alterations, but other metabolic abnormalities that effect cardiac pacemaker and conduction tissue should also be considered.

Treatment of cardiac rhythm disturbances

Acute rhythm disturbances that result from metabolic abnormalities and that are not life threatening may be managed conservatively; in such cases, careful observation during treatment of the underlying abnormality may suffice. Active intervention is required when the dysrhythmia results in significant hemodynamic embarrassment, when the rhythm disturbance is likely to progress and become life threatening, or when a protracted rhythm disturbance is of the type that results in an increased likelihood of a thromboembolic event. Ventricular ectopy is seen commonly and ranges from isolated ventricular extrasystoles and benign accelerated idioventricular rhythm to malignant forms such as ventricular tachycardia or fibrillation. Coexisting conditions, such as fever or debilitation, which may augment tissue hypoxia, especially in anemic patients, predispose patients to ventricular ectopy. Unexpected death in cancer patients is usually attributed to dysrhythmia. Hemodynamic instability, regardless of the underlying cause, constitutes a medical emergency requiring the use of advanced cardiac life-support protocols.

Once the decision has been made to treat a patient experiencing dysrhythmia, the choice between pharmacologic intervention and the use of internal nonpharmacologic therapy such as implantable pacemakers or defibrillator or the use of ablation therapy generally follows the usual guidelines for these therapies. In difficult cases, electrophysiologic studies or pharmacologic threshold analysis may be

useful. Implantable devices increasingly are being used in cancer patients; malignant disease *per se* should not be considered a barrier to their use, but should be balanced with the patient's prognosis.

An ever-increasing number of drugs are being implicated in causing a well-recognized variant form of ventricular tachycardia known as *torsades de pointes*. This polymorphic ventricular tachycardia ([Figure 6](#)) is frequently preceded by a prolonged QT interval on the standard electrocardiogram. The QT interval is measured from the onset of the QRS complex to the end of the T wave and is then corrected for heart rate. This form of ventricular dysrhythmia is also associated with some antibiotics (erythromycin, clarithromycin, and pentamidine) psychotropic drugs (haloperidol), anti-emetics, some forms of high-dose chemotherapy, and bone marrow transplantation.^{69–71} Arsenic trioxide, which is most commonly used in the treatment of acute promyelocytic leukemia, also prolongs the QT interval, and patients should be observed carefully for QT prolongation during treatment with this agent.^{72, 73} Prompt recognition of this potentially malignant dysrhythmia and withdrawal of the offending agent may be the most appropriate therapy. Anecdotally, *torsades de pointes* may be more likely in African-Americans. QT prolongation has been reported to be more frequent in male patients as well as in those with hypokalemia. Serial monitoring of the QT interval is advised in high risk individuals.⁷⁴ [Table 2](#) lists the most important agents associated with QT prolongation.

Figure 6 Rhythm strip of a patient with episodes of *torsades de pointes*. A previous rhythm strip (not shown) demonstrated prolongation of the QT interval.

Table 2 Drugs associated with QT prolongation and known risk of *torsades de pointes*

Amiodarone	Halofantrine
Anagrelide	Haloperidol
Arsenic trioxide	Ibutilide
Astemizole	Levofloxacin
Azithromycin	Levomethadyl
Bepriidil	Mesoridazine
Chloroquine	Methadone
Chlorpromazine	Moxifloxacin
Ciprofloxacin	Ondansetron
Cisapride	Pentamidine
Citalopram	Pimozide
Clarithromycin	Probucol
Cocaine	Procainamide
Disopyramide	Propofol
Dofetilide	Quinidine
Domperidone	Sevoflurane
Dronedarone	Sotalol
Droperidol	Sparfloxacin
Erythromycin	Sulpiride
Escitalopram	Terfenadine
Flecainide	Thioridazine
Fluconazole	Vandetanib
Grepafloxacin

Acute treatment of unstable patients with *torsades de pointes* is nonsynchronized electrical defibrillation. First-line medical management is intravenous magnesium sulfate, regardless of the serum magnesium level. Isoproterenol infusion or overdrive pacing can suppress *torsades de pointes* by increasing the heart rate and thus shortening the QT interval. Lidocaine and phenytoin are additional treatment options.^{75, 76} Maintenance of potassium and magnesium homeostasis is crucial in preventing recurrences of this dysrhythmia. The offending QT-prolong agent should be identified and discontinued, and other potential QT-prolong drugs avoided.

Cardiac complications of cancer treatment

Nonsurgical therapies used to treat patients with cancer can impact the heart in a variety of ways. These therapies consist of chemical and biologic agents as well as physical agents such as ionizing radiation

(Table 3). Individual modalities and combinations may act independently, additively or synergistically; for example, the combination of cardiac irradiation and anthracyclines produces additive or synergistic toxicity. Damage resulting from cancer treatment may affect the pericardium, the myocardium, the vasculature, the conduction system, and the heart valves. With some modalities, the heart may incur subclinical damage, and later insults or sequential stress may then trigger clinically relevant cardiac dysfunction.⁷⁷

Table 3 Anticancer treatments associated with cardiotoxicity

I. Drugs associated with Type I myocardial depression
Anthracyclines
Doxorubicin
Pirarubicin
Idarubicin
Epirubicin
Daunorubicin
Anthraquinones
Mitoxantrone
Potential toxicity intensifiers
Cyclophosphamide
Ifosfamide
Mitomycin C
Etoposide
Melphalan
Vincristine
Bleomycin
Paclitaxel
Toxicity inhibitors
Dexrazoxane
II. Drugs associated with Type II myocardial depression
Trastuzumab
Lapatinib
Sunitinib
Gleevec
Other monoclonal antibodies/tyrosine kinase inhibitors
III. Other cardiodepressant agents

Cyclophosphamide (high dose)

α -Interferon

IV. Antineoplastic agents associated with ischemia

5-Fluorouracil (5-FU)

Capecitabine

Vinblastine

Vincristine

Bleomycin

Cisplatin

Biological response modifiers

V. Antineoplastic agents associated with hypotension

Interleukin-2

Omacetaxinemepesuccinate-2

VI. Antineoplastic agents associated with hypertension

Bevacizumab

Sunitinib

VII. Antineoplastic agents associated with pulmonary hypertension

Desatinib

VIII. Miscellaneous agents with known or suspected cardiac toxicity

Paclitaxel (bradycardia)

Arsenic trioxide (prolonged QT interval/*torsades de pointes*)

Bleomycin

Actinomycin D

Mitomycin C

Alkylating agents

Cyclophosphamide

Ifosfamide

IX. Radiation (dose dependent; may affect any cardiac structure)

Cardiotoxic anticancer agents

Cardiotoxic anticancer agents may cause permanent or temporary contractile dysfunction, ischemia, rhythm disturbances, and fluctuation in blood pressure. The discussion will review the subject of specific cardiotoxic anticancer agents according to this classification.

Agents associated with left ventricular dysfunction

Anthracyclines and their related anthraquinones are the most widely studied agents associated with contractile dysfunction, but other agents may affect cardiac function through different mechanisms. From a functional standpoint, anticancer agents can be divided into two types, type I and type II, according to a number of characteristics.⁷⁸ Type I agents are associated with primary, or direct myocyte cellular injury that may progress to cell death with ongoing exposure or stress. Cardiac damage, once it has progressed beyond the threshold of cell death, is permanent. Type I drugs cause damage that is cumulative and dose related and is associated with typical endomyocardial biopsy changes. Agents associated with type II treatment-related cardiac dysfunction may cause myocyte dysfunction that resembles hibernation or stunning and are more likely to be reversible; in addition, they may contribute to injurious increases in wall stress through other mechanisms such as increased afterload or fluid retention that may compromise vulnerable myocytes. Type II agents do not demonstrate toxicity that is cumulative or dose related and they are not associated with the typical endomyocardial biopsy changes that are seen with anthracyclines.⁷⁷ These differences are summarized in [Table 4](#).

Table 4 Type I and type II treatment-related cardiac dysfunction

Type I (e.g., doxorubicin)	Type II (e.g., trastuzumab)
Cellular death	Cellular dysfunction
Damage starts with the first administration	
Biopsy changes (typical of anthracyclines)	No typical anthracycline-like biopsy changes
Cumulative dose related	Not cumulative dose related
Permanent damage (myocyte death; bad prognosis)	Predominantly reversible (myocyte dysfunction; good prognosis)
Risk factors: <ul style="list-style-type: none"> – Combination CT – Prior/concomitant RT – Age – Previous cardiac disease – Hypertension 	Risk factors: <ul style="list-style-type: none"> – Prior/concomitant anthracyclines or paclitaxel – Age – Previous cardiac disease – Obesity (BMI > 25 kg/m²)

CT, computed tomographic; RT, radiation therapy; BMI, body mass index.

Type I anticancer treatment-related agents: anthracyclines and related agents

The effects of anthracyclines on the heart have been the most extensively studied of all of the cardiotoxic agents; doxorubicin cardiotoxicity serves as a model for understanding anthracycline-associated and related type I cardiomyopathies.

Doxorubicin cardiotoxicity may be recognized early or late during a course of treatment, or it may present months or even years after the completion of treatment. Early manifestations of toxicity include electrocardiographic abnormalities and myopericarditis. Significant early cardiac dysfunction is rare with current dosing regimens, but cases of heart failure occurring within weeks of the first administration of the drug have been reported.^{79, 80} Early toxicity is more likely to occur in elderly patients or in patients who have received large single doses and has been reported more commonly in patients treated with daunorubicin than with doxorubicin. Sudden death following doxorubicin administration also has been

reported but is rare. Both ventricular and supraventricular cardiac dysrhythmias may be seen during the administration of doxorubicin but are seldom life threatening. It is now believed that these phenomena are manifestations of cell injury and death associated with anthracyclines, and this is supported by the finding that markers of acute cardiac damage such as troponin T are increased following exposure.^{81, 82} Early manifestations, therefore, may be more important than had heretofore been appreciated and troponin release following administration is an important marker and quantifier of early cell death. This initial damage marks the beginning of an ongoing process that may go largely unrecognized in view of the vast ability of the heart to compensate for myocyte loss, and our inability to measure small changes in myocardial reserves with the usually utilized parameter of ejection fraction.⁸³

The cumulative dose of anthracycline has been correlated with risk of clinically significant heart failure. Overt clinical manifestations are unusual when the cumulative dose is below 400 mg/m², but the risk becomes greater as the cumulative dose exceeds 450 mg/m² administered by the usual rapid-infusion schedule.⁸⁴ Cardiomyopathy may occur at lower doses when other cardiotoxic drugs are administered concomitantly (see later discussion). Considerable interpatient variability exists that often cannot be explained by the known risk modifiers of prior cardiac injury or conditions known to increase susceptibility to injury, and genetic differences may play a role—a subject of on-going interest and research. It follows that if cardiac decompensation occurs early, that is, <4 weeks from the last doxorubicin administration, it is much more likely to be serious or have a fatal outcome; patients who experience early toxicity probably have had more severe initial damage and or less baseline cardiac reserves. Doxorubicin cardiomyopathy may become manifest months, and even years, after an uncomplicated course of chemotherapy at or near the usual maximum recommended dose. Such late cardiomyopathy may involve additional insults or stresses.⁷⁷ Sequential stress or injury may explain some of the cases heretofore thought of as late cardiotoxicity. As the anthracyclines have been in use for more than 40 years, some of the patients cured of leukemias, lymphomas, sarcomas, and breast cancer may harbor subclinical cardiac damage that now makes them particularly prone to symptomatic heart failure in the event of additional cardiac insults. The effect of doxorubicin exposure on the genesis of coronary artery disease, myocardial infarction, and other cardiac injuries that occur with aging is unknown. In one older review, 12 of 43 patients with doxorubicin-induced cardiomyopathy died owing to progressive cardiac dysfunction.⁸⁵

Mechanism of anthracycline-associated cardiotoxicity

The mechanism of the cardiac damage caused by anthracycline exposure has not been fully elucidated; however, free radical formation is believed to be an important factor. Free radicals can injure lipid structures in the myocardial cell, and the resultant peroxidation of these lipid structures impairs the function of the sarcoplasmic reticulum and mitochondria. Cardiac myocytes are more prone to these degenerative changes as they lack catalase and superoxide dismutase and thus are less able to metabolize free radicals than are other cells.⁸⁶ Cell necrosis is the end result of this damage. It is evident that the mechanisms for cardiotoxicity are sufficiently different from those of oncologic efficacy that cardioprotection is possible. While the generation of the oxygen free radicals is associated with cardiotoxicity, there is increasing evidence that topoisomerase II β plays a major role, and that inhibition of topoisomerase, as may be associated with dexrazoxane, is cardioprotective.^{87, 88} It has been suggested that the level of atrial natriuretic peptide is increased in at least some patients with doxorubicin-associated cardiotoxicity, and this appears to correlate more with changes in diastolic than with changes in systolic function.⁸⁹

Clinical manifestations of anthracycline-associated cardiotoxicity

The clinical manifestations of doxorubicin-related cardiomyopathy are indistinguishable from other forms of congestive heart failure. Patients may be asymptomatic in the early stages or may exhibit only minimal signs of cardiac dysfunction. In many patients, the first sign of a cardiac abnormality may be a failure to return to baseline cardiac rate promptly following exertion. Resting tachycardia and loss of respiratory variation in heart rate may also be seen. As cardiac failure progresses, patients experience increasing dyspnea, with dyspnea at rest a poor prognostic sign.

The cardiac examination of a patient with fully developed cardiomyopathy often reveals an S3 gallop, an enlarged area of cardiac dullness, an exaggerated increase in cardiac rate with minimal activity, and, when pulmonary congestion ensues, diffuse rales. The chest radiograph shows nonspecific findings of an enlarged cardiac silhouette and engorged vasculature. Pleural effusion may be noted. The electrocardiogram may show nonspecific repolarization changes. B-type natriuretic peptide (BNP), a marker of volume expansion and high ventricular filling pressures is usually elevated, the elevation proportional to the degree of cardiac failure.^{90, 91} The left ventricular ejection fraction remains the most widely used parameter with which to monitor the cardiac status in patients receiving doxorubicin or related agents.

The structural changes in myocardial tissue seen on examination of cardiac biopsy specimens can provide vital information concerning the toxicity of doxorubicin and related compounds.^{92–94} In highly selected patients, biopsy may provide the essential information and is generally regarded as safe.⁹⁵ The cardiac biopsy specimens are graded according to ultrastructural changes seen by electron microscopy with both the degree and the extent of the abnormalities considered in determining the final grade. With the presently used anthracycline regimens, cardiac biopsy is no longer undertaken.

Several groups of patients are known to be at greater risk of developing cardiac dysfunction at relatively lower cumulative doses of anthracyclines. Among these are elderly patients, pediatric patients, those with pre-existing cardiovascular disease and those with low baseline ejection fraction.⁹⁶ It is now postulated that any patient with diminished cardiac reserve or where increased oxidative stress is present is at increased risk for anthracycline-associated cardiotoxicity.⁸¹ Despite some reports to the contrary, anthracyclines are generally not considered to be associated with coronary spasm or primary myocardial ischemia.⁹⁷ For all patients in whom an increased risk is present, heightened surveillance and implementation of cardiac-sparing regimens should be considered, as should, when feasible, nonanthracycline regimens. Irradiation through portals that include the heart is a well-documented risk factor for cardiomyopathy, and patients who are expected to undergo concomitant or sequential cardiac irradiation should be considered for cardioprotection and additional monitoring.^{98, 99}

A number of antineoplastic drugs have also been associated with increased anthracycline toxicity. Cyclophosphamide (discussed further below) may augment the cardiotoxic effect of doxorubicin toxicity, a matter of particular clinical importance because the drugs are often used together.¹⁰⁰ Dactinomycin, plicamycin, dacarbazine, and mitomycin C, all reportedly augment doxorubicin, but the evidence for the first three has not been persuasive.¹⁰⁰ Mitomycin C, however, appears to add substantially to the toxicity of doxorubicin, even when given after the completion of doxorubicin therapy.¹⁰¹ Paclitaxel has also been reported to increase the cardiotoxic effect of doxorubicin. In one study, however, patients receiving the combination at cumulative doses of doxorubicin of below 340–380 mg/m² did not demonstrate the additive effect.¹⁰² The higher incidence of cardiac toxicity observed when the two drugs are administered within a short time may be due to the fact that paclitaxel interferes with the pharmacokinetics of doxorubicin, leading to higher systemic levels of both doxorubicin and doxorubicinol, a metabolite.¹⁰³

Alternatively, the apparent increase in toxicity may simply be the result of increased surveillance using imperfect tests in patients undergoing frequent monitoring of cardiac function. Other anthracyclines and related agents, such as mitoxantrone (an anthraquinone), demonstrate intrinsic cardiac toxicity that is additive; as is noted below, changing from one anthracycline to another does not provide cardioprotection.^{104, 105}

Various strategies can lower the extent of doxorubicin cardiotoxicity. Limiting the cumulative dose is a strategy that grew out of the observation that clinically apparent cardiotoxicity is unusual at cumulative doses of $<300 \text{ mg/m}^2$ and that the incidence is about 5% at a cumulative dose of 400 mg/m^2 .⁸⁴ Limiting the cumulative dosage to these levels in patients without risk factors helps to keep the cardiotoxicity within an acceptable range. Dose limitation also decreases the need for cardiac monitoring, as the likelihood of cardiotoxicity is lower; the risk of stopping effective therapy early because of false-positive testing results may exceed the benefits of such testing. Dose limitation, however, does not take into consideration patients who are still responding after receiving the limiting dose. Most patients, including many who are identified as having “risk factors” tolerate 300 mg/m^2 of doxorubicin or the cardiotoxic equivalent of other anthracyclines.⁹⁶

Encapsulating the parent anthracycline compound in liposomes reduces the incidence and severity of cardiotoxicity.^{106–108} Both pegylated and nonpegylated preparations have been studied, and the pegylated preparation is approved for the treatment of Kaposi's sarcoma, ovarian carcinoma, and multiple myeloma in the United States. Pegylated liposomal doxorubicin is also effective in the treatment of breast and ovarian cancer; comparisons of liposome encapsulated and conventional doxorubicin in the treatment of that disease confirmed cardioprotection with comparable antitumor activity.^{109, 110} Pegylated liposomal doxorubicin appears to have a clinical efficacy similar to its parent compound in a subset of anthracycline-sensitive tumors.¹¹¹ Both pegylated and nonpegylated liposomal doxorubicin are clearly cardioprotective.^{112, 113} With the pegylated form, cardioprotection has been demonstrated both by cardiac biopsy as well as by noninvasive studies.¹¹⁰ The degree of cardioprotection is difficult to quantify, but studies suggest that at least twice the number of cycles of pegylated liposomal doxorubicin can be given with the same degree of cardiotoxicity as is seen with the unprotected parent compound ([Table 5](#)). The spectrum of oncologic efficacy may be slightly different for the liposomal-encapsulated preparation; the degree of stomatitis and hand-foot syndrome is higher.¹¹⁴

Table 5 Relative toxicities of anthracycline: a comparison of relative toxicities of different cardiotoxic drugs and dosage schedules

Drug	Schedule	Relative myelosuppressive potency compared with doxorubicin administered by standard schedule	Approximate relative cardiotoxicity ^a	Cardiotoxicity index compared with doxorubicin administered by standard schedule ^b	Recommended maximum dose (mg/m ²) ^c
Doxorubicin	Rapid infusion (20 min)	1	1	1	400
Doxorubicin	Weekly	1	0.73	0.73	550
Doxorubicin	24-h infusion	1	0.73	0.73	550
Doxorubicin	48-h infusion	1	0.62	0.62	650 ^d
Doxorubicin	96-h infusion	1	0.5	0.5	800–1000 ^d
	Rapid infusion	1	(substantial)		
Pegulated liposomal doxorubicin	Rapid infusion	1	Uncertain Probably <0.7	Uncertain Probably <0.7	Uncertain
Epirubicin	Rapid infusion	0.67	0.66	0.44	900
Mitoxantrone	Rapid infusion	5	0.5	2.5	160
Daunorubicin	Rapid infusion	0.67	0.75 ^e	0.5 ^e	800 ^e
Idarubicin	Rapid infusion	5	0.53	2.67	150
Pirarubicin	Rapid infusion	1	0.62	0.62	650 ^e
Doxorubicin + dexrazoxane	Rapid infusion	1 ^e	0.5	0.5 ^e	800–1000 ^e
Doxorubicin, 300 mg/m ² + dexrazoxane	Rapid infusion	1 ^e	0.73 ^e	0.73 ^e	550 ^e

^a Factor by which the cardiotoxic effects of the cumulative dose of rapid infusion doxorubicin can be compared with the cumulative dose of the agent, combination, and schedule listed, when given at an equivalent myelosuppressive dose.

^b Derived by dividing 400 mg/m^2 , the recommended maximum dose of rapid-infusion doxorubicin, by the recommended maximum dose for the agent in question. The cardiotoxicity index represents a factor by which to multiply the cumulative dose of a drug administered to obtain an approximation of toxicity that might be expected had the resultant amount of doxorubicin been given by rapid infusion. For example, if a cumulative dose of 120 mg/m^2 mitoxantrone had been administered, the patient would be expected to demonstrate cardiac damage approximately equal to 300 mg/m^2 of doxorubicin given by rapid infusion ($120 \times 2.5 = 300$). This value is useful when changing from one cardiotoxic regimen to another. When the sum of the products of the indexes and the cumulative doses administered exceeds 400, the risk of clinically significant cardiotoxicity exceeds 5%.

^c Dose-producing clinically significant congestive heart failure in 5% of patients.

^d Less toxic by endomyocardial biopsy.

^e Inadequate data.

Modification of the dose schedule has been clearly shown to decrease anthracycline cardiotoxicity. A series of trials of continuous-infusion doxorubicin using infusion times of 24–96 hours, gauging the cardiotoxicity on the basis of endomyocardial biopsy findings have been undertaken.^{115, 116} Patients treated with continuous infusions showed a significantly lower incidence of high-grade endomyocardial pathology in their biopsy specimens despite receiving a significantly higher cumulative dose. Efficacy is not compromised, but infusions longer than 96 h are limited by increasingly troublesome mucositis and hand-foot syndrome.¹¹⁷ Continuous infusion has also been evaluated in the pediatric population with conflicting reports as to cardioprotection.^{118, 119} The relative cardioprotection of various doxorubicin administration schedules is depicted in [Table 5](#). Despite clear evidence of cardioprotection, the inconvenience of portable infusion pumps and indwelling catheters that are required for continuous infusion as well as the trend to use lower cumulative dosages of doxorubicin has made many clinicians reluctant to use such schedules.

A number of compounds with possible cardioprotective properties have been investigated. The single approved cardiac protector to date is the iron chelator dexrazoxane. In a study of 92 patients randomly assigned to receive a doxorubicin-containing regimen (50 mg/m^2 doxorubicin with 500 mg/m^2 cyclophosphamide and 500 mg/m^2 fluorouracil given every 21 days) or the same regimen together with dexrazoxane, the investigators found a significant decrease in cardiotoxic effects demonstrated by ejection fraction measurements, biopsy grades, and clinical signs or symptoms of cardiac dysfunction.¹²⁰ Other toxicities and antitumor effects were unaffected. However, one subsequent study that confirmed the cardioprotective activity of dexrazoxane showed a decrease in antitumor effect as well.¹²¹ There was no suggestion of diminished antineoplastic activity, however, in patients given dexrazoxane after they had received 300 mg/m^2 of doxorubicin.¹²² Other studies have not found the efficacy of anthracyclines to be decreased by dexrazoxane. Dexrazoxane also has been studied in conjunction with epirubicin and mitoxantrone.^{123, 124} These studies suggest that dexrazoxane also reduces the cardiotoxicity of agents other than doxorubicin. Dexrazoxane also is used in children where there are special concerns regarding late toxicity.¹²⁵ Recent investigations suggest that dexrazoxane interferes with or inhibits topoisomerase II complexes, providing a possible explanation as to why dexrazoxane is cardioprotective while other antioxidants have not been shown to do so.¹²⁶

Cardiac monitoring of patients receiving doxorubicin

Most patients undergoing treatment for cancer, even elderly patients and those with known cardiac disease, can tolerate at least some doxorubicin.⁹⁶ Patients with significant dilated cardiomyopathy and patients who have experienced cardiotoxicity from the prior use of an anthracycline or related drug are the major exceptions. Most patients with reduced ejection fractions as the result of prior myocardial infarctions tolerate doxorubicin when it is given with some form of cardioprotection and when the

cumulative dose remains below 300–400 mg/m²; increased monitoring in those settings is prudent. Patients being considered for doxorubicin therapy generally undergo a cardiac evaluation including a determination of ejection fraction and a standard (12-lead) electrocardiogram to provide a basis for later comparison.^{127–130}

Patients without risk factors and who are without signs or symptoms suggesting cardiac compromise need not be reassessed before receiving a cumulative dose of 300–350 mg/m² by standard infusion or its equivalent when using alternate agents or administration schedules ([Table 5](#)). Thereafter, reassessment after each two additional cycles of treatment is appropriate. When cumulative doses exceed those noted in [Table 5](#), additional scrutiny is essential. At any dose level, patients with increased risk factors for early toxicity should be monitored more closely. At dosages suggested in [Table 5](#), the risk of heart failure approaches 5% in the absence of other cardiac risk factors.

Patients whose ejection fractions fall below 50% are at increased cardiac risk. If the ejection fraction has not changed, they may be treated up to 300 mg/m² with careful monitoring. For those whose ejection has either fallen by more than 15% points or has fallen to a value below 45%, strong consideration should be made to stop doxorubicin and substitute alternative therapy using noncardiotoxic agents.

Other anthracyclines and related (type I) agents

Clinically, the cardiotoxic effects of daunorubicin, idarubicin, epirubicin, pirarubicin, and mitoxantrone are identical to those of doxorubicin. As is the case with oncologic efficacy of these agents, the cumulative dosages, expressed in milligrams per square meter, that cause cardiotoxicity differ between the various agents. The cardiotoxicity of these agents has not been studied as extensively as has that of doxorubicin. Nevertheless, on the basis of ejection fractions and findings from cardiac biopsy specimen evaluation at equivalent oncologic doses, some data has emerged. Epirubicin is associated with a decrease in the incidence of cardiac toxicity compared with that seen for doxorubicin given by rapid infusion ([Table 5](#)).^{131, 132} The cardioprotection afforded by epirubicin, which is being used increasingly for the treatment of breast cancer, allows an additional margin of safety that may be especially important in populations at increased cardiac risk; a Cochrane review noted cardioprotection, however, suggested that the degree of protection may not be as high as was previously thought.¹³³ Some investigations have suggested that the combination of paclitaxel and epirubicin causes less cardiotoxicity than the combination of doxorubicin and paclitaxel, and they attribute this to the fact that paclitaxel interferes less with the metabolism of epirubicin than with the parent compound.^{134, 135} Available data regarding idarubicin suggest that 150 mg/m² is a safe cumulative dose for patients who have not yet been exposed to anthracyclines.¹³⁶ Data for pirarubicin (THP doxorubicin), a doxorubicin analog used extensively in Japan and France, but not approved for use in the United States, suggest that the agent is significantly less cardiotoxic than doxorubicin given by standard-infusion schedules.¹³⁷ Mitoxantrone, an anthraquinone, is considered less cardiotoxic than doxorubicin in equi-myelosuppressive dosages.^{104, 138} Switching from one agent to another does not offer cardioprotection, and considerable care must be exercised when considering a new cardiotoxic treatment in a patient who has previously been treated with other type I cardiotoxic agents, even remotely.

Type II anti-cancer treatment-related agents

Type II agents by definition do not demonstrate cumulative dose-related toxicity, and therefore, the cardiotoxic expression is much less predictable. The best studied of these agents is trastuzumab, but other agents should also be considered in this grouping. Trastuzumab, a humanized monoclonal antibody

directed against HER2, is effective for the treatment of breast cancers and other cancer types that overexpress this antigen (approximately 20–25% of breast cancers). Cardiomyopathy, with clinical signs and/or symptoms initially thought to be similar to those seen with anthracyclines, was observed in early clinical studies with trastuzumab. Concerns regarding cardiotoxicity led to a number of large multicenter trials that included more than 10,000 patients who received trastuzumab. A summary of the trials and their respective treatment arms is given in [Table 6](#).^{139–141} Several important conclusions have emerged, the most important from the perspective of cardiotoxicity are as follows: (1) cardiac dysfunction in treatment arms that include an anthracycline followed by trastuzumab are higher than similar arms without trastuzumab; the difference, however, is <4% but has, nevertheless, been of concern; (2) cardiac toxicity is largely but not invariably reversible; (3) cardiac deaths are extremely rare; (4) regimens that include trastuzumab without pretreatment with an anthracycline have a smaller incidence of cardiac dysfunction; and (5) the cardiotoxicity associated with trastuzumab, while different from that of doxorubicin, is clinically indistinguishable using MUGA or echocardiographic parameters of decreased systolic function. An additional factor that emerged from these trials is that the interval between the anthracycline and trastuzumab may be a crucial factor.^{129, 142}

Table 6 Summary of cardiotoxicity in adjuvant trials involving trastuzumab

Trial	Number of patients	Entry criteria	Arms	Reported cardiac events (%)	Reported reversibility	Follow-up (year)
NSABP B-31	2043	Node+	A) AC-T B) AC-TH	A) 0.8 B) 4.1	Yes	7
BCIRG 006	3222	Node + or high-risk node Age < 70	A) AC-T B) AC-TH C) TPH	A) 0.4 B) 1.9 C) 0.4	N/A	3
NCCTG N9831	1944	Node + or high-risk node	A) AC-T B) AC-T-H C) AC-TH	A) 0.3 B) 2.8 C) 3.3	Yes	3

A, anthracycline; C, cyclophosphamide; T, taxane; H, trastuzumab; P, carboplatin; Std, standard (neo)adjuvant regimen (94% contained anthracycline); V/T, vinorelbine or taxane; F, 5-fluorouracil; N/A, not applicable.

Follow-up time reflects most recently reported data.

Although the precise mechanism of trastuzumab-induced cardiomyopathy is not well understood, its specific binding to HER2 and disruption of the ErbB-2 signaling pathway in the heart is thought to be the primary event. ErbB-2 (HER2/neu) belongs to the epidermal growth factor receptor (EGFR) family of

receptor tyrosine kinases, of which there are four members: EGFR, HER2/neu, HER3, and HER4. These receptors are activated by the EGF family of ligands, including EGF itself, heregulin and neuregulins, which are expressed in the heart. Binding of these EGF ligands to EGFR, HER3, or HER4 induces heterodimer formation with HER2, triggers receptor autophosphorylation, and initiates downstream signaling. Among those pathways activated are Ras/Raf, PI3K/Akt, JNK, and MAPK, all important regulators of transcription in cardiac myocytes. An extensive body of work has implicated these pathways in cardiac development, maintenance of normal cardiac function, response to stress, hypertrophy, and regulation of apoptosis. Indeed, targeted deletion of HER2 in murine models has demonstrated a specific role for this receptor in mediating the growth, repair, and survival of cardiomyocytes after stress.¹⁴³ Temporary disruption of the HER2 signaling pathway by trastuzumab thus results in an inadequate or even maladaptive response to cardiac stress that can lead to systolic dysfunction and congestive heart failure.¹⁴⁴ Interference by trastuzumab in cardiomyocyte repair may also explain why patients previously exposed to anthracyclines are more susceptible to trastuzumab toxicity.

Cardiac dysfunction related to trastuzumab appears to be largely reversible.^{7, 139–142, 145} As it is an insult that involves an organ often previously damaged by exposure to an anthracycline, the question as to how great a portion of the observed dysfunction is likely to return arises. The dilemmas of whether and when to temporarily hold or permanently stop trastuzumab, how to assess the risk of restarting after functional recovery, and how to monitor such patients is under consideration. Several groups have suggested guidelines, all of which are based on expert opinion rather than on concrete data derived from prospective clinical trial.^{129, 146}

Other type II agents

In addition to trastuzumab, lapatinib, sunitinib, imatinib, and other agents have raised concerns of possible cardiotoxicity. Specifically myocardial dysfunction, QT interval prolongation, and ischemia have been considered as potential adverse events in these agents. To date, none have shown biopsy changes as are characteristic for anthracyclines, although some alterations in mitochondrial structure have been reported. Interestingly, these agents do not exhibit cumulative dose-related toxicity and can be given for extended periods of time in many patients. With regard to myocardial depression, a secondary effect may be implicated; in the case of sunitinib, significant hypertension is noted, and in the case of imatinib fluid, retention may be the crucial factor.^{142, 147–149}

Varying degrees of QT prolongation have been noted with a number of these agents, but severe lengthening as well as the need to hold or stop the medication due to QT prolongation is rare, as are ischemic events.⁷⁰ Lapatinib cardiac dysfunction was reported in 2.2% of patients previously treated with anthracyclines and 1.5% of patients without prior exposure to cardiotoxic regimens; most patients (88%) experienced some degree of reversibility with regard to cardiac dysfunction.¹⁴⁷

Other drugs that demonstrate a decrease in cardiac function

Significant decreases in myocardial function are occasionally noted for other agents that do not clearly fit within either the type I or type II classification. Rarely, α -interferon has been associated with a dramatic decrease in ejection fraction.¹⁴⁹ The mechanism is unknown; however, inflammation and increased metabolic requirements have both been implicated; patients who survive the initial episode usually go on to recover cardiac function.¹⁵⁰ An unusual form of cardiac damage is associated with high-dose cyclophosphamide administration. When severe, the damage takes the form of a hemorrhagic myocarditis.¹⁵¹ The process is often acute, is related to high individual doses (usually 4.5 g/m² or more)

rather than to the cumulative dose, and is associated with decreased ejection fractions and mean QRS voltage. Although severe hemorrhagic myocarditis may be fatal, milder presentations may be asymptomatic and reversible.

Treatment considerations of patients with treatment-related cardiac failure or dysfunction

The most important treatment consideration in patients who develop anthracycline-associated cardiac dysfunction is the avoidance of additional anthracyclines. Once established, anthracycline-associated cardiac dysfunction differs little from other forms of cardiomyopathy and it is treated in a similar way. The American College of Cardiology and the American Heart Association have issued guidelines for the diagnosis and management of chronic heart failure in adults.¹⁵² Patients who have been treated with anthracyclines but show no symptoms of cardiac dysfunction should have other conditions that exacerbate cardiac dysfunction aggressively treated. Hypertension should be controlled and lifestyle changes encouraged. Pharmacological intervention should also be considered for those who have ejection fractions below 45–50%. Some evidence suggests that medical therapy is most effective when given early, and therefore should be initiated as soon as LV dysfunction is appreciated.¹⁵³ Angiotensin-converting enzyme (ACE) inhibitors and β -adrenergic blockers are indicated for patients with LV dysfunction. For patients with symptomatic heart failure, salt restriction and diuretics may be added. Digitalis preparations may offer symptomatic relief and are useful in controlling the ventricular response in patients who experience atrial fibrillation; they probably do not prolong life. Anticoagulation may be appropriate if atrial arrhythmias are present. There is no specific therapy for anthracycline-related cardiomyopathy. An underlying malignancy should not, however, be considered a contraindication to aggressive heart failure therapy and, in selected patients, mechanical assist devices and cardiac transplantation may be considered for those who have achieved oncologic stability or cure.¹⁵⁴ Cardiac failure associated with type II agents different, in that there is higher likelihood of recovery, and rechallenge after recovery can be considered.

(a)

(b)

Figure 7 An electrocardiogram in a 44-year-old woman during an episode of chest pain while receiving 5-fluorouracil. Acute anterolateral ST elevation was due to coronary vasospasm (a). Electrocardiographic changes normalized shortly after nitroglycerin administration, with resolution of symptoms (b).

Agents associated with myocardial ischemia or thromboembolic events

A number of agents have the potential to cause myocardial ischemia, with or without frank myocardial infarction. The most extensively studied such agent is 5-fluorouracil (5-FU), especially when the agent is

administered in combination with cisplatin.¹⁵⁵ Capecitabine, a fluoropyrimidine carbamate, is currently used in the treatment of gastrointestinal and breast malignancy, and is an orally administered prodrug, which is enzymatically converted to 5-FU. Myocardial infarction and dysrhythmia have been reported with both drugs.^{156, 157} Ischemia is triggered through coronary artery vasoactivity or spasm. Isolated cases of myocardial ischemia have also occurred after the administration of vinblastine, vincristine, bleomycin, cisplatin, and biologic response modifiers. The wide spectrum of ischemic responses suggests that ischemia accompanying anticancer treatment is more common than is generally appreciated. Nonspecific electrocardiographic changes may be seen in nearly half the patients treated with 5-FU and as many as 16% show electrocardiographic evidence of ischemia including ST-segment depression or elevation and changes suggesting myocardial infarction ([Figure 7](#)). Many of the affected patients have underlying coronary artery disease, which suggests that pre-existing coronary artery abnormalities augment the ischemic potential of 5-FU and related agents. The use of a calcium channel blocker has been reported to prevent the ischemia.¹⁵⁸ Selected patients may also be treated with intravenous nitroglycerin while receiving 5-FU to prevent myocardial ischemia or infarction. When ischemia can be controlled treatment may be continued, albeit with increased monitoring and caution.

Treatment-related high-output states may also result in myocardial ischemia in patients with fixed atherosclerotic lesions that preclude increasing the blood supply because the vessels cannot dilate, a phenomenon known as “coronary steal.” The interferons are especially likely to initiate ischemia in this manner. Ischemia may also result from fever, often produced by biologic modifying agents, and from hyperthyroidism. Tumor necrosis factor has been associated with a hypercoagulable state, which suggests vascular occlusion as a possible alternative explanation for the ischemia that occurs in patients being treated with cytokines and other biologic response modifiers. Anemia is an important coexisting factor, as any cause of ischemia can be exacerbated by a diminished oxygen-carrying capacity.

Patients with evidence of myocardial ischemia, regardless of the mechanism, should be observed closely for rhythm disturbances, although the level of observation and intervention depends on the overall prognosis. Individuals with known preexisting coronary artery disease can be treated with β -adrenergic blockers and/or a long-acting nitrate to help reduce the likelihood of an ischemic event. Controlled underlying ischemia or evidence of ischemia associated with a particular therapy should not be considered an absolute contraindication to further treatment with the implicated agent or agents. Cancer patients with underlying coronary artery disease are often candidates for revascularization, which can significantly improve the patient's ability to tolerate therapy and their overall quality of life.

The cardiac events associated with hormonal therapy have been studied in large groups of postmenopausal breast cancer patients. Tamoxifen is associated with decreased cholesterol, and this may offer some cardioprotection; the agent, however, is associated with an increased risk of thromboembolic events. The aromatase inhibitors anastrozole, letrozole, and exemestane have been associated with hypercholesterolemia and have been shown to carry a small increased risk of cardiovascular disease when compared with tamoxifen; this observation may in part be related to the protective properties of the latter.¹⁵⁹

Agents associated with hypotension, hypertension, and vascular toxicity

Some degree of hypotension develops in many patients as a consequence of their chemotherapy. The most frequent cause is volume depletion, often as a result of nausea and/or vomiting. Other causes of hypotension related to chemotherapy are decreased cardiac output, loss of vascular tone, and increased permeability of the small vessels and capillaries (capillary leak). Most instances of hypotension in patients receiving chemotherapy are transient and can be managed with careful monitoring and the

administration of fluids or vasopressor agents. Rare instances of life threatening and profound hypotension have been reported.

Interleukin-2 use is associated with significant, but usually transient, hypotension, frequently requiring pressor agents.^{160, 161} Capillary leak has been implicated. Interleukin-2–related myocardial ischemia is possibly related to the hypotension, although a direct toxic effect has not been excluded. Interleukin-2 is also associated with an increased incidence of supraventricular dysrhythmias and myocarditis.¹⁶² The vasodilation that occurs in response to interleukin-2 appears to be mediated by the release of nitric oxide. Evidence has suggested that NG-monomethyl-L-arginine, an inhibitor of nitric oxide synthase, reverses the hypotension caused by interleukin-2, lending support to the role of nitric oxide in the production of hypotension and indicating the therapeutic potential of NG-monomethyl-L-arginine as well.¹⁶³

Omacetaxine mepesuccinate, previously called homoharringtonine, was approved for the treatment of refractory chronic myeloid leukemia. The drug is associated with dose-related, sometimes severe, hypotension arising immediately after its intravenous administration.¹⁶⁴ Intravenous epinephrine has been helpful in stabilizing patients in this setting.

Considerable interest has surrounded the possible cardiac effects of paclitaxel. In one study, asymptomatic bradycardia occurred in 29% of patients treated with maximally tolerated doses of paclitaxel. More severe rhythm abnormalities have also been reported, but they usually are seen in patients with underlying cardiac abnormalities or in the presence of electrolyte imbalance.¹⁶⁵ Serious cardiac problems are rare with paclitaxel, and most patients can be treated without special monitoring.¹⁶⁶ Hypersensitivity reactions are also known to occur.¹⁶⁷

Cisplatin, an agent widely used to treat genitourinary malignancy, head and neck tumors, and non-small cell lung cancer is known to induce hypertension. Thalidomide and paclitaxel may induce hypotension. Bevacizumab, a monoclonal antibody against vascular endothelial growth factor, has been associated with significant increases in blood pressure in more than 25% of treated patients. Serious and sometimes permanent hypertension has been reported in up to 14% of treated patients; rarely patients develop hypertensive crises. Patients with baseline hypertension are at increased risk and should be monitored during therapy.¹⁶⁸ Antihypertensive therapy and consideration of alternate treatment is appropriate for patients in whom the blood pressure is difficult to control. All antiangiogenic agents, including sunitinib, alemtuzumab, gemtuzumab, infliximab, muromanoab-CD3, rituximab, and sorafenib, are associated with increased incidence of hypertension, usually reversible upon holding or stopping the medication. Once hypertension is controlled rechallenge may be initiated, and many patients are able to continue treatment with acceptable cardiac risk.

Cardiac complications of radiation therapy

Links between radiation to the chest in the treatment for malignancy and subsequent heart disease have been clearly established. Inclusion of cardiac tissue in the radiation portals can lead to a broad spectrum of disease, which often presents decades after exposure. Recognition of these risks has led to dramatic improvements in radiation techniques over the years, but the degree to which the heart can be spared has not been fully determined, as long-term follow-up studies in patients treated with modern techniques are still underway.

The pathophysiology of ionizing radiation's cardiotoxic effects involves both DNA damage and generation of reactive oxygen species. Cells with higher turnover are more susceptible, particularly the vascular endothelium. Small vessel damage then leads to inflammation and ultimately fibrosis of cardiac tissue.

All layers of the heart are involved, leading to acute and chronic pericardial disease, accelerated coronary artery disease, cardiomyopathy, valvular disease, and conduction system abnormalities. Secondary cardiac malignancies attributed to radiation therapy (RT) have even been reported.¹⁶⁹ The heart responds to the radiation insult over time with late-presentation and chronic progressive functional decline showing a direct correlation with the radiation fraction to the heart. Animal models have demonstrated a radiation dose-dependent chronic congestive myocardial failure with damage to the myocardial microvasculature; histological examination shows a marked reduction in capillary density, myocardial degeneration, and necrosis with interstitial fibrosis.^{170, 171} Cell kinetic studies show increased endothelial cell proliferation about 30–100 days postradiation. The morphologic changes in animal models parallel the drops in cardiac output and left ventricular ejection fraction.

Figure 8 Parasternal long-axis echocardiographic view from a 40-year-old patient who received mantle radiation for lymphoma two decades prior. Note the severe thickening and calcification of the aortic and mitral valves. This patient also had severe coronary artery disease, cardiomyopathy, and abnormal pericardial thickening, all likely sequelae of his prior cancer treatment.

Human data on cardiac effects of RT have come mostly from patients with Hodgkin's lymphoma and breast cancer, who historically received significant doses of cardiac radiation and who also are available for long-term follow-up studies. In contrast, survival in lung cancer is generally too poor to allow significant development of cardiac complications. Risk factors include total radiation dose, volume of the heart exposed, and specific techniques used, but other factors play a role, including age at the time of exposure (younger patients are at higher risk), concurrent treatment with anthracycline-containing chemotherapy regimen, and traditional cardiac risk factors. Although exposure of the heart to >35 Gy is commonly considered to increase risk, recent studies have shown risk with lower doses as well. The Childhood Cancer Survivor Study found a greater than twofold increase in risk of heart failure,

myocardial infarction, pericardial disease, and valve disease at radiation doses of 15–35 Gy.¹⁷² Another smaller study found a relative risk of 12.5 for cardiac death for those exposed to cardiac doses of 5–15 Gy and relative risk of 25 at >15 Gy.¹⁷³

Radiation treatment for Hodgkin's lymphoma carries the highest risk of cardiac complications owing to proximity of mediastinal nodes to the heart, younger age at diagnosis, and good potential for long-term survival. The relative risk of fatal cardiac events has been reported as 7.2 after radiation-containing treatment.¹⁷⁴ Because it may take years or even decades for radiation-related heart disease to become clinically manifest, the discovery of major complication may not appear until late follow-up assessments are undertaken; in some instances, this may be years or decades after the initial exposure. The most common complications are valvular lesions (predominantly regurgitant) and myocardial infarction and also seen are restrictive cardiomyopathy, dysrhythmia, and autonomic dysfunction ([Figure 8](#)). Pericardial disease has become less prevalent with better cardiac shielding and other technical improvements.¹⁷⁵

Breast cancer cohorts provide us with the richest body of evidence regarding radiation effects on the heart, owing to both the overall disease prevalence and the opportunity to compare right-sided versus left-sided disease. Several studies have utilized this natural control group to distinguish between systemic effects of chemotherapeutics and those of localized cardiac radiation. A strong correlation between RT and increased cardiovascular mortality was established by many early randomized trials.¹⁷⁶ Improved techniques, including better cardiac shielding, tangential fields, and respiratory gating, have certainly reduced or delayed cardiac morbidity and mortality, yet significant risk probably remains, especially for left-sided cancers. Inclusion of the right or left internal mammary lymph node chain in the radiation field increases cardiac exposure and has been shown to increase subsequent cardiovascular complications. Similar to the data for Hodgkin's lymphoma, risk of cardiac events after RT increases with duration of follow up, treatment with anthracyclines, and traditional cardiovascular risk factors.

Clinical manifestations of radiation cardiotoxicity are broad. Acute pericarditis can occur at the time of radiation treatment, and pericardial effusion is commonly seen in the acute and subacute setting, but can also be chronic. Distinction from malignant pericardial effusion can be difficult and occasionally necessitates fluid analysis by cytology. Cardiac tamponade is rare. Chronic inflammation can manifest as constrictive pericarditis, which can be challenging to diagnose and carries a grave prognosis unless the patient is well enough to undergo surgical pericardiectomy.

Coronary artery disease after radiation can present as angina, myocardial infarction or sudden death; the risk increases with time. At least two mechanisms appear to be involved in macrovascular disease. First, radiation induces thickening of the arterial wall secondary to intimal and adventitial proliferation; the luminal area is thereby reduced. Second, radiation greatly accelerates atherosclerosis and acts synergistically with that process to enhance cholesterol deposition and luminal ulceration.¹⁷⁷ Thus, as noted earlier, traditional cardiac risk factors such as smoking and dyslipidemia play a key cooperative role in the pathogenesis. Because of its location, the left anterior descending artery is the most frequently affected.

The treatment of radiation-associated vascular injury is similar to the conventional treatment of ischemic cardiac disease; nitrates, β -adrenergic blockers, platelet inhibitors, and calcium channel blockers are the mainstays of pharmacological therapy. Invasive approaches for the management of ischemic heart disease are also often helpful; balloon angioplasty, however, often requires inflation pressures that are higher than those ordinarily used, and longer periods of balloon inflation may be required. Bypass surgery may prove more difficult than usual from a technical standpoint because of the smaller vascular lumens and because the surgeon must work in a previously irradiated field. Nevertheless, bypass surgery remains an important

option for these patients.

The spectrum of radiation-induced cardiomyopathy includes diastolic dysfunction, restrictive cardiomyopathy, and systolic dysfunction. Small vessel ischemic disease and fibrosis are the predominant underlying pathology, with subsequent ventricular remodeling possible. Restrictive cardiomyopathy can be very difficult to distinguish from pericardial constriction—especially as both may be present in the same patient. Endomyocardial biopsy is sometimes employed before pericardiectomy to rule out coexisting myocardial disease, which carries a prohibitive operative mortality.

Valvular involvement, while common, is usually not severe. Nevertheless, valve injury is progressive and can contribute to significant morbidity that accompanies the irradiated heart. The most common lesions found are tricuspid regurgitation, mitral regurgitation, and aortic regurgitation, but aortic stenosis is occasionally encountered.^{178, 179} Histologically, the valves show endocardial thickening resembling fibroelastosis.¹⁸⁰

Radiation injury to the cardiac conduction system has also been noted and is usually suggested by abnormalities on the electrocardiogram. Prolongation of the PR interval is often seen, as are supranodal and infranodal atrioventricular blocks. Complete heart block is occasionally encountered, and pacemaker implantation may prove lifesaving for such patients. Autonomic dysfunction can manifest with inappropriate sinus tachycardia, bradycardia, or inadequate heart rate response to exercise.

Overview

The respiratory system is particularly susceptible to complications of cancer and cancer therapy. This vulnerability arises from the stringent architectural requirements for gas exchange, the continuous exposure of the respiratory tract to the external environment, and the severe symptoms that can accompany respiratory compromise. Gas exchange requires patent airways, an effective musculoskeletal ventilatory pump, a thin alveolocapillary membrane, and adequate blood flow through the pulmonary circulation. In cancer patients, primary and metastatic tumors of the chest compromise major airways; pleural effusions externally compress the lungs and impair diaphragmatic function; direct, hematogenous, or lymphangitic spread of tumor replaces functioning lung parenchyma; resectional surgery reduces parenchymal volume; nonresectional surgery can transiently impair lung function; radiotherapy, chemotherapy, stem cell therapy, and infection injure the vulnerable alveolocapillary membrane; tumors directly or indirectly compromise the musculoskeletal pump; and venous thromboembolism (VTE) and pulmonary vasculopathy obstruct pulmonary blood flow.

The normal respiratory system contains considerable physiologic reserve, such that surgical loss of one lung is generally well tolerated. However, in cancer patients, insults to multiple components of the respiratory system may result in progressive loss of physiologic reserve and increasing dyspnea. Dyspnea, cough, wheezing, stridor, chest pain, and hemoptysis are common symptoms in the cancer setting that lead to pulmonary consultation.

In this chapter, we will discuss the pathophysiology, diagnosis, and management of the major respiratory complications of cancer and its therapy. We begin with the direct effects of cancer and cancer therapies on the lungs, review major indirect effects of cancer on the lungs, and end with respiratory failure in the cancer patient.

Malignant airway obstruction

Malignant airspace disease may be central or peripheral, focal or diffuse, or endoluminal or extraluminal or both. The dominant symptom complex associated with this process depends upon the location and extent of disease, which also dictates therapy.

Common cancer types and clinical presentation

The most common cause of malignant airway obstruction is direct extension from an adjacent tumor, particularly bronchogenic carcinoma. Esophageal and thyroid malignancies also frequently extend

directly into the airways. Primary tumors of the major airways are relatively rare, with squamous cell carcinoma, adenoid cystic carcinoma, and carcinoid tumors most often implicated.^{1, 2} Airway compromise can also occur from metastatic renal and breast carcinomas or intrathoracic lymphomas. Both endoluminal disease and extrinsic compression by tumor may severely compromise airway luminal diameter. Reduction in airway caliber and architectural distortion synergistically impair airflow obstruction and mucus clearance, leading to increased work of breathing and dyspnea.³ Luminal narrowing of the trachea and mainstem bronchi typically manifests as dyspnea, cough, wheeze, stridor, and atelectasis. Airway obstruction beyond the mainstem bronchi usually results in atelectasis, postobstructive pneumonitis, cough, and dyspnea. Individual patient presentations range from asymptomatic discovery on staging work-up to frank respiratory failure due to critical airway obstruction.⁴ Exertional dyspnea typically occurs when tracheal diameter is reduced below 8 mm. Further reduction in tracheal diameter to <5 mm is usually associated with dyspnea at rest.⁵ Chronic obstructive pulmonary disease (COPD) exacerbations or mucosal edema and increased secretions that accompany superimposed pneumonias may precipitate respiratory failure, even in patients with only moderate tumor-related airflow limitation. Symptoms may thus improve with measures directed at treating the infection or COPD exacerbation.

Differential diagnosis

While critical airway obstruction is not usually a diagnostic challenge, the clinical presentation of subcritical obstruction can be. Stridor indicates pathognomonic significant tracheal obstruction. Other findings, including dyspnea and wheezing, are prominent but nonspecific clinical symptoms that denote airflow limitation. Concurrent conditions such as congestive heart failure, pleural effusions, and pulmonary emboli may produce similar symptoms, obscuring the diagnosis.

Diagnostic evaluation

The diagnostic work-up is aimed at establishing a definitive diagnosis, quantifying airflow limitation, and delineating anatomic extent in an effort to optimize therapeutic strategies. The characteristic blunting noted in the flow-volume loop upon pulmonary function testing (PFT) often provides an indication of tracheal obstruction. However, this is a relatively insensitive test, with positive findings noted only with tracheal diameters below 10 mm.⁶ Spirometry may also precipitate frank respiratory failure in patients with severe airway obstruction and should be used with caution in this subgroup of patients. Rarely, deviation or compression of the trachea may be seen on plain chest radiographs. Plain chest films are otherwise not helpful in defining the anatomic extent of tumor or therapeutic options. Standard chest computed tomography (CT) as well as the latest iterations of low-dose multidetector scanners and advanced airway imaging techniques that allow multiplanar and three-dimensional (3D) reconstruction provides valuable additional information regarding the extent of the lesion and guidance in optimizing therapeutic strategies.⁷ Bronchoscopy, either flexible or rigid, remains the gold standard in the work-up of airway obstruction. Histologic confirmation of malignancy can be obtained at the time of the examination. Furthermore, bronchoscopy offers direct visualization of the lesion, which permits precise characterization of tumor vascularity and the extent of obstruction, as well as the degree of obstruction attributable to endoluminal versus extraluminal disease. Recent reports have also supported the use of endobronchial ultrasonography as an adjunctive tool in treatment planning.⁸

Management of malignant airway obstruction

Tumor characteristics, including histologic type, stage, and location, and patient attributes, such as

urgency of presentation and performance status, dictate management. Therapeutic strategies vary based on the location and type of obstruction, as well as the local expertise and available institution-specific resources. Surgical resection provides the best prospect for long-term disease control and should be considered in all patients during the initial evaluation. Localized involvement of the small airways and lung parenchyma is best treated by surgical resection, if feasible. In many cases, however, external beam radiotherapy or systemic chemotherapy may be the only treatment options. Patients with central airway obstruction often present with either medically or surgically unresectable disease. While a comprehensive review of the various modalities is beyond the scope of this chapter, some basic principles are outlined ([Figure 1](#)). In emergent cases, the barrel of the rigid bronchoscope may be used to mechanically core out the tumor and dilate the airways, providing palliation. Flexible bronchoscopy and balloon bronchoplasty may be used to dilate the airways in less urgent cases.⁹ Electrocautery, argon plasma coagulation, laser therapy, cryotherapy, brachytherapy, and photodynamic therapy are reasonable approaches for predominantly endoluminal disease ([Figure 2](#)). Extraluminal-predominant disease may be best treated with external beam radiotherapy and endobronchial stent placement ([Figure 3](#)). Since most lesions are mixed with endo- and extraluminal components, multimodality therapy, using endobronchial laser therapy with mechanical debulking followed by stent placement and subsequent consolidation with external beam radiotherapy, for example, is quite common. Symptom palliation, resulting in reduction in levels of care, may be accomplished in most instances with the judicious application of endoscopic techniques.¹⁰ Patients should be evaluated carefully with an early referral to an experienced bronchoscopist who can match the various therapeutic modalities available to the individual patient.

Figure 1 Approach to airway obstruction using interventional bronchoscopic therapy.

Figure 2 Left lower lobe collapse secondary to metastatic sarcoma (a and b). Complete obstruction of the LLL basilar segments due to a large obstructing tumor was noted at bronchoscopy (c) which was removed using snare forceps and argon plasma coagulation, revealing a patent distal airway (d).

Figure 3 Complete opacification of the right thorax secondary to obstruction of the right mainstem bronchus by a large, predominantly extraluminal mass (a). A wire stent was placed into the bronchus intermedius (b), resulting in partial reexpansion of the right lung.

Malignant pleural effusions

Malignant pleural effusion is a common clinical problem in the cancer setting that signifies distant spread of tumor and, hence, advanced disease. Malignant pleural effusions have significant therapeutic and prognostic implications. Estimates of the incidence of malignant pleural effusions in the United States approach 150,000 cases annually.¹¹ Malignant pleural involvement without effusion occurs in up to 45% of patients with metastatic disease to the pleura.¹² In primary pleural malignancies, such as malignant mesothelioma, pleural effusions may be absent. Nearly any type of neoplasm can affect the pleura. Lung cancer accounts for up to half of all malignant effusions, followed in frequency by breast carcinoma and lymphoma. Pleural effusions may occur with acute and chronic leukemias and myelodysplastic syndrome (MDS). Pleural effusions in patients with leukemia are most often due to infection and to a lesser extent leukemic infiltration of the pleura.¹³ Unfortunately, in 5–10% of patients, a primary tumor cannot be identified.^{14, 15} Most pleural malignancies arise from tumor emboli to the visceral pleura. The parietal pleura may be involved secondarily, presumably by seeding from the visceral pleura. Direct extensions of tumor from the lung, chest wall, mediastinal structures, or diaphragm and hematogenous metastasis to the parietal pleura are other mechanisms that contribute to the genesis of malignant pleural fluid formation.¹⁶ In addition to direct tumor involvement of the pleura, malignant pleural effusions can result from lymphatic blockage anywhere between the parietal pleura and the mediastinal lymph nodes.¹⁷ Elevations in the local production of vascular endothelial growth factor (VEGF), a potent mediator of increased vascular permeability, also play a significant role in the formation of malignant pleural effusions.¹⁸ Among VEGF homologs, VEGF-D showed a 92.6% rate of positive expression in a study of malignant pleural effusion and may be a useful marker in the diagnosis.¹⁹ Seventeen percent of all pleural effusions in patients with cancer are “paramalignant,” a term used for effusions that occur in the setting of cancer that are not caused by direct malignant involvement of the pleural space.¹⁶ These effusions develop as a

result of local or systemic effects of the tumor, complications of cancer therapy, or concurrent nonmalignant disease.²⁰ Lymphatic obstruction is associated with both malignant and paramalignant effusions and is the most common cause of paramalignant effusions. Other common causes include bronchial obstruction, trapped lung, and pulmonary embolism (PE).

Clinical manifestations, imaging studies, and diagnosis

Most commonly, patients present with symptoms of progressive exertional dyspnea. Cough may also be a troubling symptom with large effusions. Constitutional symptoms are common signals of advanced disease, and thus malaise, weight loss, and poor appetite may become more frequent as the performance status worsens. Hemoptysis and chest wall pain are less common symptoms and may indicate malignant endobronchial disease and tumoral invasion of the chest wall. Standard chest roentgenograms and bilateral decubitus films of the chest provide critical information in the initial evaluation of pleural effusions, including effusion size, position of the mediastinum and diaphragms, presence of loculations and air fluid levels within the pleural space, and characteristics of the underlying lung parenchyma. Knowledge regarding the position of the mediastinum is imperative in therapeutic decision making. Large pleural effusions with contralateral mediastinal shift typically require prompt therapeutic thoracentesis, while those with a centered mediastinum or ipsilateral shift of the mediastinum should be approached cautiously ([Figures 4](#) and [5](#)). In addition to pleural effusions, other disease processes that may cause an ipsilateral shift of the mediastinum or a centered mediastinum with hemithorax opacification include a frozen mediastinum associated with malignant mesothelioma or lymphoma, atelectasis related to occlusion of the ipsilateral central airway, or extensive tumoral infiltration of the ipsilateral lung simulating a large effusion.²⁰ CT is helpful in identifying loculated effusions; offers better anatomical information of the chest wall, parietal and visceral pleura, mediastinal structures, and lung parenchyma; and is especially valuable in delineating alternate diagnoses.²¹ Ultrasonography provides guidance in locating the optimal site for thoracentesis and is particularly helpful in the setting of loculated pleural effusions. The identification of entrapped lung by ultrasonography using tissue movement may permit deformation (strain) analysis prior to thoracentesis.^{22, 23} Positron emission tomography (PET) with ¹⁸F-fluorodeoxyglucose (FDG) and magnetic resonance imaging (MRI) are both helpful in highlighting extrapleural extension of disease.²¹ PET imaging provides valuable information associated with malignant mesothelioma; however, its utility in the evaluation of other malignant pleural diseases has not been established. Chemical analysis reveals an exudative effusion in most cases, with only 5% of malignant pleural effusions being transudates.²⁰ Positive pleural fluid cytology, noted in 62% of cases, represents the diagnostic cornerstone of malignant pleural effusions.²⁴ Tumor marker measurements improve the diagnostic yield of cytologically negative effusions by 33% and are particularly valuable when lymphoma, leukemia, or multiple myeloma is suspected.^{25, 26} The role of flow cytometry in the study of mesotheliomas remains controversial.²⁷ Pleuroscopic pleural biopsies have a 95% sensitivity in the diagnosis of pleural malignancies, and diagnostic yield increases only incrementally (1%) when combined with pleural fluid cytology. By contrast, closed pleural biopsy has a diagnostic yield of only 44% but improves to 77% when combined with an analysis of pleural fluid cytology.²⁴

Management of malignant pleural effusions

Because malignant pleural effusions often signal advanced disease and incurability, treatment efforts are frequently directed toward palliation. Hence, awareness of available therapeutic options tailored to individual patient needs is important. The patient's performance status and information regarding prior thoracenteses, including the volume of fluid evacuated, whether lung reexpansion and symptom palliation were obtained, and the time interval between repeated taps, are important components of the evaluation that help to guide further therapy. Performance status is the best predictor of survival in patients with

recurrent malignant pleural effusions.²⁸ The presence of local chest wall abnormalities, future cancer treatment plans, the patient's preferences, and the availability of family support influence the approach to these patients. Palliation with simple therapeutic thoracentesis represents a reasonable approach to patients with newly diagnosed chemo- or radiosensitive tumors, such as lymphoma and breast, small-cell lung, germ cell, ovarian, prostate, and thyroid neoplasms, while awaiting response to definitive therapy. After the initial clinical and roentgenographic evaluation, a symptom-limited therapeutic thoracentesis is recommended. A recent consensus statement by the American Thoracic Society and the European Respiratory Society recommends that not more than 1.0–1.5 L of fluid be slowly evacuated from the pleural space in one sitting and that drainage should be discontinued if the patient develops symptoms of dyspnea, cough, or chest discomfort.¹¹ In our experience, patients with radiographic evidence of contralateral mediastinal shift from large pleural effusions may safely tolerate the removal of 2–2.5 L of fluid in one sitting as long as there are no procedure-related symptoms of chest pain, cough, or dyspnea. However, large-volume pleural fluid drainage during a single procedure should be carried out cautiously, especially when radiological studies reveal a centered or ipsilaterally shifted mediastinum. Measurement of pleural pressures during the evacuation of large amounts of fluid may reduce procedure-related complications.²⁹ However, in light of the safety of symptom-limited evacuation, pleural pressure measurement may not be necessary, and its role requires further study. Lung reexpansion following thoracentesis may be assessed with posterior–anterior (PA) and lateral chest radiographs. Repeat thoracenteses spaced 1–2 days apart may be necessary to properly assess lung reexpansion associated with large effusions.³⁰ In 97% of patients, malignant pleural effusions will recur within 1 month, with most of these effusions reappearing within 1–3 days following fluid evacuation.³¹ Patients with limited life expectancies (<30 days) and poor performance status or those in which pleural fluid reaccumulation is slow are best treated with repeated therapeutic thoracentesis. Repeated thoracentesis is a reasonable approach for patients with malignancies that are expected to respond to chemotherapy and/or radiation therapy (RT). However, frequent thoracentesis may trigger the production of local cytokines and fibrin, resulting in pleural fluid loculation, which not only complicates further thoracenteses but also limits future modes of palliation.³² The use of indwelling pleural catheters has been accepted over the past few years as an alternative palliative option for patients with recurrent malignant effusions. Ideal candidates for this palliative modality include patients with life expectancies in excess of 30 days and in whom prior thoracenteses effected symptomatic relief. Considerations for pleural catheter implantation are valid in this group of patients regardless of lung reexpansion following thoracentesis. Indwelling pleural catheters may be placed in an outpatient setting. Following documentation of proper catheter position, the patient, trained family members, or caregivers may drain the fluid intermittently at home. Daily pleural fluid drainage is recommended initially. During each session, which typically lasts less than 15 min, drainage should be continued until the patient develops cough or chest discomfort, or the fluid stops flowing spontaneously, presumably because the pleural space has been emptied. At our institution, 92% of patients treated with indwelling catheters reported significant relief of dyspnea, and 52% achieved effective pleurodesis. The mean time from catheter insertion to catheter removal was 32 days. Catheter-related complications were observed in only 4% of the patients, including one patient with empyema and two patients with persistent pain at the insertion site. In another study, only 6% of patients required additional drainage of fluid following removal of the catheter.³³ Patients who have chemotherapy or radiation after catheter placement and those who are more short of breath at baseline have greatest improvements in utility.³⁴ In a subgroup analysis, patients meeting criteria for a pleurodesis procedure achieved 70% effective pleurodesis after insertion of indwelling pleural catheter.³⁵

Traditionally, chemical pleurodesis has been the most widely used method to control recurrent malignant pleural effusions. Unfortunately, the lack of prospective studies precludes comparative analyses of

efficacy, safety, and cost of the existing chemical agents and pleurodesis techniques. The results from available literature suggest that nonchemotherapeutic agents are more efficacious and the most cost-effective sclerosants.¹¹ Sterilized, asbestos-free talc is the preferred pleurodesing agent. Complications vary with the surface characteristics of the talc particles. The use of talc particles that are less than 5 mm in size has been associated with pulmonary injury, including acute pneumonitis and respiratory failure associated with adult respiratory distress syndrome, and should be avoided.³⁶ The safety of large-particle talc for pleurodesis was recently confirmed in a European multicenter trial in which no association with adult respiratory distress syndrome was identified.³⁷ The superiority of thoracoscopic talc insufflation over talc slurry as a method of administration of the sclerosant is a matter of debate. Success rates of >90% have been reported for both techniques, without significant differences in the rate of overall complications or disease recurrence.¹¹ The largest published prospective randomized trial comparing thoracoscopic talc insufflation and talc slurry included 501 patients with a performance status of 1 or 2. Results showed no difference in 30-day survival rates and pleurodesis success rates between chest tube talc slurry and thoracoscopic talc poudrage. Unexpected high morbidity and mortality rates were reported in both groups. A subset analysis suggested that thoracoscopic talc insufflation may be advantageous for patients with lung or breast cancer.³⁸ Based on the available information, our group considers all patients with a good performance status (ECOG 0, 1, or 2), and in whom symptomatic relief and lung reexpansion was achieved after initial drainage of the pleural fluid, for either indwelling pleural catheter placement or pleurodesis with pleuroscopic talc poudrage as the preferred palliative modalities. Rarely, alternative modalities such as pleuroperitoneal shunts and parietal pleurectomy are used in the management of recurrent symptomatic effusions following pleurodesis failures or effusions associated with trapped lung. Chylous effusions associated with malignancy are controlled by treating the primary tumor. Prolonged loss of chyle, a protein-rich, fat-laden, and lymphocyte-predominant fluid, may result in lymphopenia, severe nutritional depletion, and water and electrolyte loss. Mortality due to chylothorax can be as high as 50%. Among those patients with recurrent symptomatic chylothorax and cancer relapse or progressive disease despite adequate treatment, parenteral alimentation and talc pleurodesis³⁹ and indwelling pleural catheter placement represent reasonable treatment alternatives.⁴⁰ Pleuroperitoneal shunt placement is an attractive option, since chyle is not lost but mobilized from the thorax to the peritoneum where it is reabsorbed, thus mitigating the risk of malnourishment and immune suppression. Unfortunately, the pleuroperitoneal shunt pump mechanism displaces only 1.5–2.5 mL at a time, making its use cumbersome. In addition, the incidence of obstruction of the pump is high. Peritoneal tumor seeding through the shunt is a theoretical concern, although this has not been clearly documented. Embolization of the thoracic duct represents an alternative strategy in the management of recurrent chylous effusions. This procedure appears to be well tolerated, but definitive evidence of its efficacy in the cancer population is not available. Parietal pleurectomy, decortication, and pleuropneumectomy are associated with high mortality rates and do not provide better symptom control than other palliative options.¹¹ The utilization of compounds to block VEGF either alone or in combination with other palliative modalities is promising. Theoretically, decreasing production of pleural fluid with VEGF blockade followed by drainage of the pleural effusion and instillation of a chemical agent to obtain pleural symphysis could accelerate pleurodesis and reduce hospital stay.⁴¹ Regrettably, the final results of a single-arm phase II clinical trial of the VEGF receptor inhibitor, vandetanib, combined with intrapleural catheter placement in patients with non-small-cell lung cancer (NSCLC) and recurrent malignant pleural effusion did not significantly reduce time to pleurodesis.⁴²

In summary, in patients with limited life expectancies, modalities that offer the best chance for palliation of symptoms, the lowest procedure-related morbidity and mortality, and the shortest hospital stay represent a reasonable approach to the management of recurrent malignant effusions. A multidisciplinary

approach ([Figure 6](#)), involving oncology, pulmonary medicine, interventional radiology, and thoracic surgery, offers the best opportunities to achieve these goals.

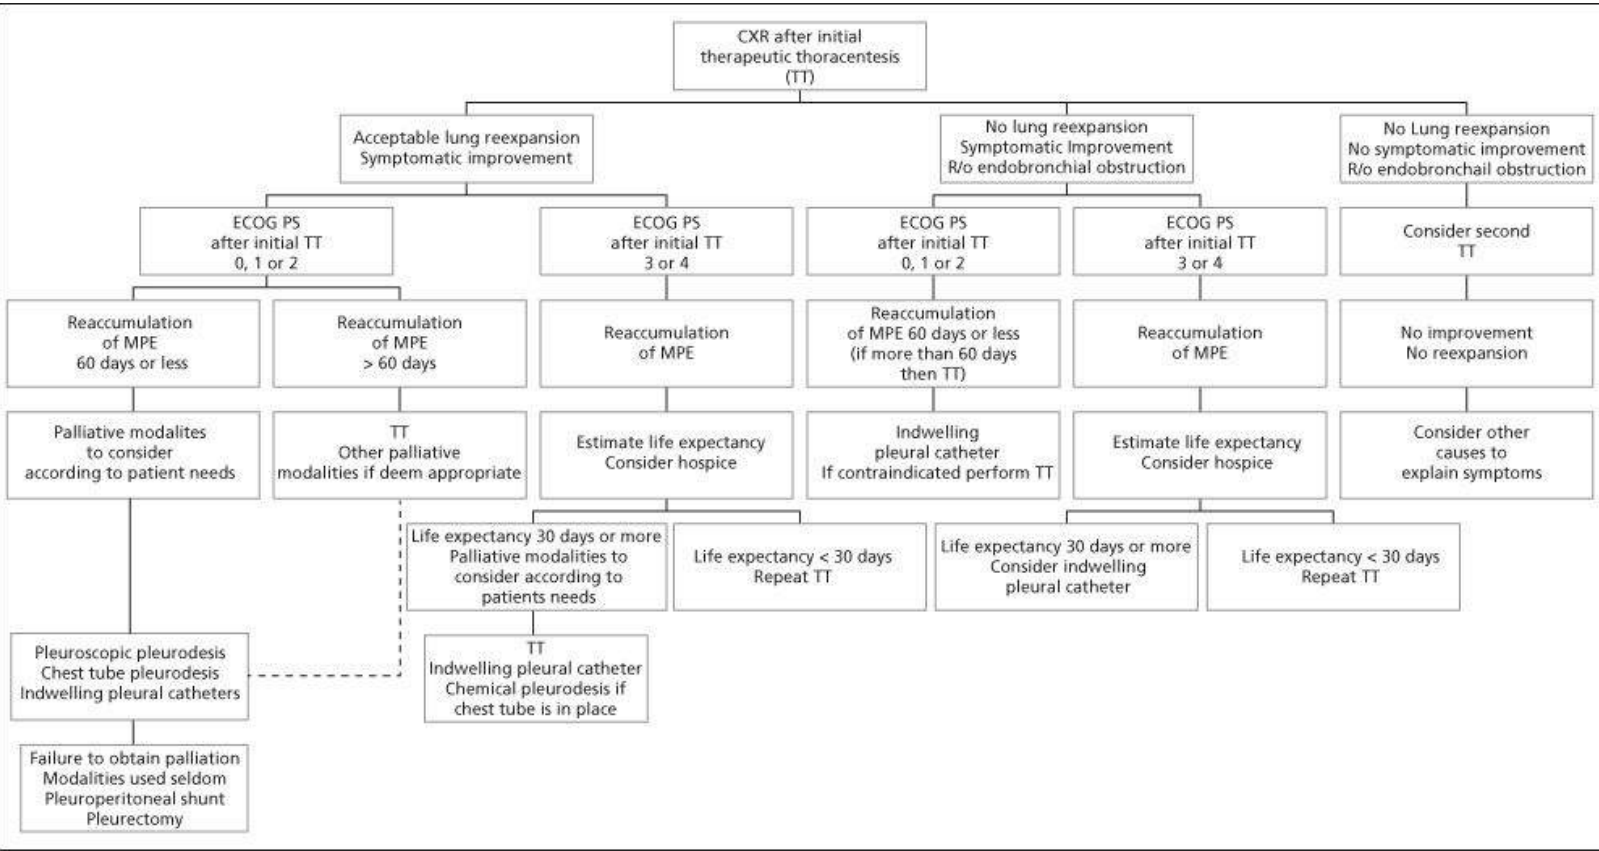

Figure 6 Management of malignant pleural effusions (MPE). Patients with chemo- or radiosensitive tumors on initial treatment (lymphoma, breast cancer, small-cell lung cancer, germ cell cancer, ovarian cancer, prostate cancer, and thyroid neoplasms) may be candidates for therapeutic thoracentesis while awaiting systemic treatment results.

Postsurgical respiratory insufficiency

Diagnostic evaluation

The initial approach to the patient with an anatomically resectable tumor includes strategies to determine the patient's functional operability and the predicted long-term pulmonary disability following the loss of the resected lung. This may be accomplished through pulmonary-specific testing as well as a general assessment aimed at identifying and optimizing control of any coexisting systemic diseases. The pulmonary evaluation consists of three sequential steps: (1) measurement of baseline pulmonary function, (2) quantitative radionuclide regional ventilation/perfusion (V/Q) pulmonary studies to calculate postoperative lung function, and (3) exercise testing for patients that do not meet acceptable results on the two previous steps.⁴³ Among the PFTs that have been used as predictors of postoperative outcome, reduced values of forced expiratory volume in 1 second (FEV₁) and diffusing capacity for carbon monoxide (DLCO) are the most reproducible and most frequently used for predicting complications of lung resection.⁴⁴ For decision making, values of FEV₁ reported as percent of predicted that take into account variations in patients' height, gender, and race are preferred over values reported in absolute units (L). In our laboratory, more than half of patients with an FEV₁ between 60% and 80% of predicted have an estimated postpneumectomy FEV₁ by radionuclide studies that is below acceptable values for safe

resection (<40% of predicted). Therefore, we recommend that only those patients with baseline FEV₁ and DLCO ≥ 80% of predicted and no clinical evidence of contralateral pulmonary disease be considered for resection without further testing. All other patients should undergo a “split function” evaluation, which is a quantitative radionuclide assessment of regional lung ventilation and/or perfusion. In this study, the uptake of radioactive ions by various regions in each lung is measured by inhalation of ¹³³Xe or by intravenous administration of ¹³³Xe dissolved in saline or ⁹⁹Tc macroaggregates. In practice, estimates of lung perfusion alone are easiest and most commonly measured. The percentage of radioactivity contributed by each lung correlates with the contribution to the overall function by that lung. The predicted postoperative FEV₁ (FEV₁ppo) and predicted postoperative DLCO (DLCOppo) are calculated by subtracting the percent functional uptake of the region to be resected from the total uptake. Several investigators have documented the usefulness of split function studies for predicting both the risk of complications and the loss of pulmonary function after pulmonary resection.^{45, 46} In these studies, preoperative predicted values are close to measured postoperative values for pneumonectomy and for resections involving more than three segments.⁴⁷ Pulmonary function remains relatively stable after pneumonectomy. Predictions for a smaller resection, such as a lobectomy, however, are less reliable, owing to a disproportionate early loss, followed by significant functional improvement with time.⁴⁸ Kearney et al.⁴⁹ also described a low FEV₁ppo as the only significant independent predictor of complications. Other variables, including age ≥ 60, male sex, history of smoking, pneumonectomy, hypercarbia, (pCO₂ ≥ 45 mm Hg), desaturations on exercise oximetry (SaO₂ ≤ 90%), and a preoperative FEV₁ ≤ 1 L were not predictive of complications. Markos et al.⁵⁰ reported that a DLCOppo <40% of predicted was associated with higher morbidity and mortality and was the best predictor of postoperative respiratory failure. In summary, an FEV₁ppo and DLCOppo of ≥ 40% of predicted on split function studies represent safe preoperative criteria for lung resection, including pneumonectomy. Patients that do not meet these criteria but are candidates for lesser surgeries, such as a lobectomy or segmentectomy, should undergo further evaluation with exercise testing.

The rationale for using exercise testing in these high-risk patients is based on two concepts: (1) lung function is not the only determinant of performance, and (2) losses for lobectomies or lesser resections improve over time and tend to be overestimated by radiospirometric studies.⁴³ Exercise testing also offers the advantage of examining cardiopulmonary and musculoskeletal interactions during stress in a single study. The most validated form of exercise testing is cycle ergometry with incremental workloads to the symptom-limited maximum ($\dot{V}O_{2peak}$). Using this method, Smith et al.⁵¹ found that only 1 of 10 patients with a $\dot{V}O_{2peak} > 20$ mL/kg/min developed complications postoperatively, whereas all patients with a $\dot{V}O_{2peak} < 15$ mL/kg/min had complications. We conducted two studies on patients that had been considered inoperable because of FEV₁ ≤ 40% of predicted, FEV₁ppo ≤ 33% of predicted, and/or arterial PCO₂ ≥ 45 mm Hg. Patients that reached a $\dot{V}O_{2peak} \geq 15$ mL/kg/min underwent surgical treatment; others were referred to radiation and/or chemotherapy. All surgically treated patients were extubated within 24 h, and the median time to discharge following surgery was 8 days. There were no inhospital deaths, although reversible postoperative complications occurred in 40% of the patients. Moreover, a survival benefit among these high-risk patients treated surgically was noted.^{52, 53} More recently, we determined that values of $\dot{V}O_{2peak}$ expressed as percent of predicted more accurately estimated surgical risk and helped to maximize the number of patients that can safely undergo lung resection. We concluded that high-risk patients that achieve a $\dot{V}O_{2peak} \geq 60\%$ of predicted during exercise have an acceptable outcome after lung resection, even if $\dot{V}O_{2peak} < 15$ mL/kg/min.³³ Our approach to preoperative

assessment for lung resection is summarized in [Figure 7](#). In addition to an estimation of surgical risk and postoperative function, the goals of preoperative assessment include the development of strategies to reduce the risk and maximize the number of patients that can benefit from surgical therapy. Finally, one must keep in mind that there is no test that will predict all complications and that the patient and the surgeon should make the final decision regarding the risk/benefit of surgical treatment.

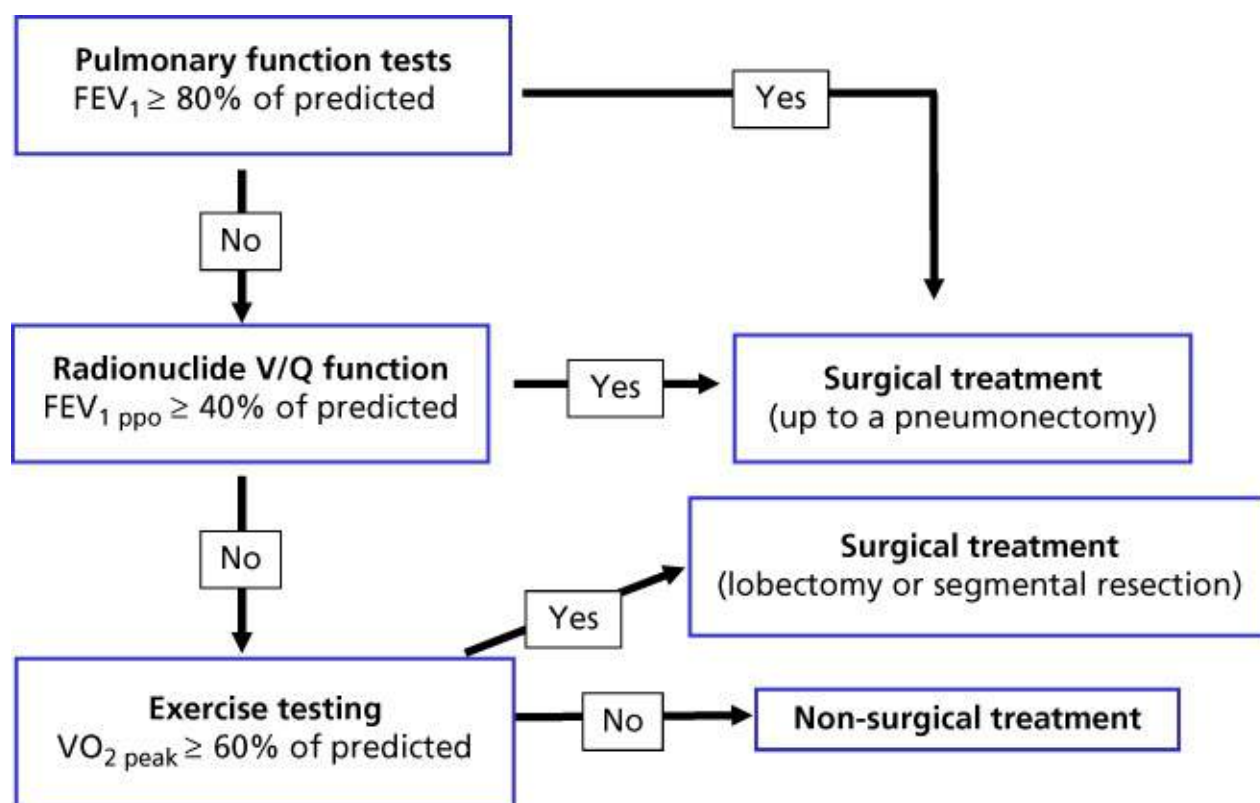

Figure 7 Approach to preoperative evaluation for lung resection.

Chemotherapy-induced lung injury

Conventional chemotherapy, as well as a growing list of molecularly targeted antineoplastic agents, is frequently implicated in lung injury. Lung toxicity in this setting may be idiosyncratic, unpredictable, and highly variable from one therapeutic class of drugs to the next. In addition, individual agents within a certain therapeutic class may induce similar patterns of lung injury with widely varying frequencies. For example, among the class of small-molecule tyrosine kinase inhibitors (TKIs) that target the epidermal growth factor receptor (EGFR), gefitinib and erlotinib have been associated with sometimes fatal interstitial pneumonitis (IP), while lung toxicity following use of the dual EGFR-HER2 TKI lapatinib is very rare.⁵⁴ Similarly, fatal lung injury following administration of the cytotoxic alkylating agents busulfan and cyclophosphamide is well recognized, whereas lung injury from the alkylating agent chlorambucil is very unusual and has been confined to isolated case reports.^{55–57}

Lung injury associated with conventional chemotherapy

The pathogenesis of chemotherapy-related lung injury is poorly understood. Proposed mechanisms include direct cytotoxicity to type II pneumocytes and/or the alveolocapillary endothelium, cytokine release resulting in endothelial dysfunction and capillary leak syndrome, oxidative injury associated with the release of free oxygen radicals, and/or cell-mediated lung mechanisms.^{58–60}

Individual drug toxicities may be confined to the pulmonary interstitium, alveoli, pleura, pulmonary

circulation, or airways, or, alternatively, may involve multiple intrathoracic structures. The response of the lung to drug-induced injury (DLI) is very limited, resulting in stereotyped histopathologic injury patterns or syndromes. Predominant interstitial and alveolar injury patterns are most common and include various patterns of IP, such as nonspecific interstitial pneumonitis (NSIP), desquamative interstitial pneumonia (DIP), hypersensitivity pneumonitis (HP), organizing pneumonia (OP), and eosinophilic pneumonia (EP). Noncardiogenic pulmonary edema (NCPE), diffuse alveolar damage (DAD), acute respiratory distress syndrome (ARDS), and diffuse alveolar hemorrhage (DAH) are other forms of DLI-related injury patterns. In addition to direct lung injury, chemotherapy-induced immune suppression may predispose patients to life-threatening infections, of which pneumonia is most common. Drug-induced granulomatous disease and lymphadenopathy have also been described. These lung injury patterns have been reported following conventional chemotherapeutic regimens as well as molecular targeted and immune modulator therapies. Patterns of lung injury associated with conventional and molecularly targeted cancer therapies are shown in [Tables 1](#) and [2](#), respectively.

DAD, diffuse alveolar damage; ARDS, acute respiratory distress syndrome; DAH, diffuse alveolar hemorrhage; NCPE, noncardiogenic pulmonary edema; IP, interstitial pneumonitis; EP, eosinophilic pneumonia; IR, infusion reaction; BOOP, bronchiolitis obliterans with organizing pneumonia; PHTN, pulmonary hypertension; PVOD, pulmonary veno-occlusive disease; PAH, pulmonary arterial hypertension; VTE/PE, venous pulmonary embolism/pulmonary embolism; MetHgb, methemoglobinemia.

Estimates of the incidence of DLI caused by individual agents are hampered by the frequent use of complex multidrug and multimodality regimens given either concomitantly or sequentially. Predisposing factors such as older age, cumulative dose, concomitant or sequential radiotherapy, oxygen administration, prior lung injury, and the use of multidrug regimens significantly influence both the occurrence and latency periods between drug exposure and the development of clinical symptoms.

Overlapping clinical, radiographic, and pathologic manifestations of lung injury caused by cardiogenic and NCPE, infections, cancer relapse, or RT confound clinical distinctions between these entities and also render precise estimates of DLI difficult. Other conditions that may mimic DLI include aspiration pneumonitis, cardiogenic pulmonary edema, acute lung injury (ALI), and ARDS.^{61, 62} Clinical symptoms range from low-grade fever with dry cough and dyspnea to fulminant disease which may rapidly progress to respiratory failure and ARDS. Skin rash, flushing, and bronchospasm, when present, may suggest either an allergic hypersensitivity reaction or a non-IgE-mediated pseudoallergic reaction. These symptoms may occur within minutes to hours of therapy. In a recent study, direct activation of mast cells by cationic drugs was found to be the cause of pseudoallergic reactions.⁶³ Allergic reactions typically require a sensitization period, with symptom onset during the second or subsequent cycles of therapy. Pseudoallergic reactions, by contrast, may occur within minutes after administration of the first cycle of chemotherapy. Clinical manifestations of other forms of DLI, including IP, typically occur early, within weeks to a few months after initiation of therapy.^{59, 60} Delayed pulmonary fibrosis, occurring months to years after exposure to bleomycin, busulfan, cyclophosphamide, gemcitabine, and the nitrosoureas as a late manifestation of DLI, has also been described.^{64–67}

Systemic markers of inflammation, such as leukocytosis, elevated erythrocyte sedimentation rate, and C-reactive protein, are common but nonspecific findings. Derangements on PET are nonspecific but nonetheless important in assessing the degree of DLI-related pulmonary impairment. Reductions in the DLCO are generally accepted as the most sensitive parameter in the assessment of DLI, although the predictive potential for the detection of early change has been variable.^{68–73} With disease progression, a restrictive ventilatory defect may be seen.^{65, 74} Near-complete normalization of pulmonary function within 2 years of exposure is common following some forms of chemotherapy-induced lung injury.⁷³ Imaging studies, including high-resolution computed tomography (HRCT) scans, are important tools in the evaluation of patients with suspected DLI, although the findings are nonspecific. Interstitial and mixed alveolar–interstitial abnormalities, manifested as ground-glass opacities that localize to the peripheral and lower lung zones, are the most frequent radiographic findings on CT. Upper lung zone predominant infiltrates are also seen, particularly following drug-induced hypersensitivity reactions. Nodular lesions may mimic underlying malignancy. Reticular lines, septal thickening, and mosaic attenuation are also observed. Pulmonary fibrosis associated with traction bronchiectasis and honeycomb patterns may be seen as the disease progresses. Diffuse uptake of 18F-FDG on PET–CT imaging has been observed in patients with radiographic changes suggestive of pneumonitis following bleomycin-, etoposide-, and rituximab-based therapies. Similar findings may also be seen with lymphangitic spread of tumor.^{75, 76}

Bronchoscopy with performance of bronchoalveolar lavage (BAL) may be helpful in excluding competing diagnoses of infection or background disease. Studies have shown diagnostic yields as high as 70–90% for pulmonary infections and 35–70% for lymphoma and lymphangitic spread of lung cancers.^{77, 78} BAL fluid in DLI is typically hypercellular with increased numbers of neutrophils or lymphocytes. Decreased CD4/CD8 ratios on BAL fluid are supportive findings; however, ratios vary widely and cannot distinguish sufficiently between drug-induced versus other causes of interstitial lung diseases (ILDs).⁷⁹ Drug-induced HP is suggested by BAL lymphocytosis of greater than 50%, with a low CD4 to CD8 ratio. BAL eosinophilia of greater than 25% is supportive of drug-induced EP. The presence of DAH is supported by progressively bloody BAL samples on sequential saline aliquots and/or cytologic evidence of increased numbers of hemosiderin-laden macrophages on BAL fluid. Transbronchial and surgical lung biopsies may be helpful in documenting IP, DAD, EP, and OP and excluding competing diagnoses such as vasculitis, infection, and underlying malignancy. Although pathologic findings attributable to DLI may be seen in 20% of tissue biopsies, histopathologic criteria for DLI have not been established, and no findings

are considered pathognomonic. Nonetheless, lung biopsies are useful in excluding competing diagnoses and characterizing the histopathologic pattern of lung injury. This information is not only useful in diagnosing DLI but also in guiding therapeutic options. The diagnosis of DLI is usually based on the temporal association between drug exposure and the development of pulmonary injury; the integration of compatible clinical, radiographic, and laboratory findings; and the exclusion of competing diagnoses.

Treatment of chemotherapy-related DLI remains anecdotal and empiric, rather than evidence based. Withdrawal of the suspected offending agent is the mainstay of treatment in the majority of cases. Spontaneous improvement may be seen in most patients following drug withdrawal, although disease progression may occur even after withdrawal of the offending agent. General recommendations suggest discontinuation of the culprit drug once sufficient clinical suspicion to support its association with pneumotoxicity has been established. One clear exception to this recommendation has been in the setting of the differentiation syndrome following all-trans-retinoic acid (ATRA) or arsenic trioxide therapies for treatment of acute promyelocytic leukemia.⁸⁰ Systemic steroid therapy along with de-escalation of drug dose rather than drug withdrawal has been associated with successful resolution of toxicity in patients with mild to moderate forms of this syndrome.

Systemic glucocorticoids and supportive care (including inhaled bronchodilators, supplemental oxygen, and mechanical ventilation) should be initiated if clinically indicated. Corticosteroids have been shown to abrogate symptoms of DLI in certain steroid-responsive lung injury patterns, such as HP, EP, and bronchiolitis obliterans with organizing pneumonia (BOOP). In other entities, including pulmonary fibrosis, pulmonary vascular disease, and bronchiolitis obliterans (BO), corticosteroids have no beneficial role. Current expert opinion advocates close surveillance with high-resolution CT scans and continued therapy without dose interruption for asymptomatic ILD. For symptomatic patients, the grade of pneumotoxicity should be used to guide management decisions, which may include dose modification or interruption, with or without the institution of corticosteroid therapy.⁸¹ For patients with moderate (grade 2 or greater) IP, drug interruption and initiation of corticosteroid therapy, dosed at 0.75–1 mg/kg/day of prednisone or its equivalent, are recommended. Steroids are typically maintained at the higher dose until symptom improvement is established and then tapered over a 1–3-month time period, pending the response to therapy. Bronchoscopy with alveolar lavage is recommended to rule out competing diagnoses of infection and/or alveolar hemorrhage.⁸² Drug rechallenge is generally not recommended, except in specific settings, such as ATRA and arsenic-related differentiation syndrome.^{80, 83} The decision to reintroduce the offending targeted agent following the development of IP must be on a case-by-case basis and should be based upon the individual agent, the severity of the reaction, and the availability of alternative therapies.

Lung injury associated with molecular targeted and immunotherapies

The identification of aberrant proteins which are either overexpressed or dysregulated in cancer cells has resulted in a rapidly growing class of molecularly targeted antineoplastic agents. Because of their narrow spectrum of inhibition, these agents were thought initially to cause minimal end-organ toxicity, unlike conventional chemotherapeutic agents. Although the spectrum of toxicities due to targeted therapies (dermatologic, vascular, coagulation, ocular, pulmonary) may be dissimilar to that seen with conventional cytotoxic agents (alopecia, mucositis, severe myelosuppression, nausea, vomiting, pulmonary), the frequency and intensity of toxicities are similar between the two major classes of antineoplastic therapies. ILD, infusion reactions (IRs), vasculopathies, and pleural effusions are common sequelae of targeted therapies. Lung injury associated with targeted therapies may arise from on-target (inhibition of the intended targets) or off-target (inhibition of unintended targets) mechanisms. Overlapping toxicities may

also occur, due to cross-interaction of multiple signaling pathways.

Radiographic detection of ILD may be seen as early as 2 months following therapy, with clinical pneumonitis typically occurring within the first 6 months of targeted therapy. Symptoms of dry cough, dyspnea, and fever are most common. Fulminant respiratory failure is rare but has been described following rituximab therapy and also as a complication of mammalian target of rapamycin (mTOR) and EGFR inhibitors ([Figure 8](#)).

Figure 8 60-year old man presents with a maculopapular rash and progressive dry cough with shortness of breath that developed 12 weeks after starting erlotinib for advanced pancreatic cancer. The extensive, ground glass, and nodular pleural-based infiltrates (a) significantly improved within 2 weeks of discontinuation erlotinib and initiation of systemic steroid therapy (b).

Drug-induced lung syndromes

Interstitial lung disease (ILD)

NSIP represents the most frequent morphologic pattern of ILD caused by DLI. Injury is signaled by the insidious development of a nonproductive cough and dyspnea, which typically occurs within weeks to months following drug exposure. Symptom development may precede radiographic findings by days to weeks. Common radiographic changes include interstitial and mixed alveolar–interstitial abnormalities that localize to the peripheral and lower lung zones. Nodular lesions, reticular lines, septal thickening, mosaic patterns, and ground-glass attenuations are also observed. Risk factors for drug-induced ILD varies with the individual agents but in general include advanced age, concurrent radiation or multiagent therapy, preexisting lung disease, and the need for high-inspired supplemental oxygen. Early on, damage to epithelial and endothelial cells leads to alveolar edema and DAD, which may progress in some cases to end-stage fibrotic lung disease and respiratory failure despite drug withdrawal and corticosteroid therapy.

Bleomycin-induced pneumonitis (BIP) is seen in up to 20% of bleomycin-treated patients, with higher rates associated with total cumulative doses above 400 U. In addition, age greater than 70 years, uremia, bolus administration, multiagent therapy, multimodality therapy with concomitant or sequential radiation, and high-inspired oxygen administration have been associated with an increased incidence and severity of BIP.^{58, 84, 85} Evidence to suggest that high-inspired fractions of oxygen may provoke or exacerbate pulmonary toxicity in bleomycin-exposed patients is largely anecdotal. A threshold fraction of inspired

oxygen or duration of oxygen therapy that increases the risk of lung injury has not been definitively established. In addition, the time interval following bleomycin treatment after which the risk of hyperoxia-associated bleomycin toxicity is mitigated is unknown. Nonetheless, careful titration of supplemental oxygen to achieve an oxygen saturation at or above 89–92% is recommended. Symptoms of dry cough and exertional dyspnea typically evolve over 1–6 months after bleomycin exposure but have been described during therapy as well as a late manifestation (>6 months) of bleomycin toxicity ([Figure 9](#)). Bleomycin causes a predictable decline in DLCO, which was thought initially to be an early marker of lung injury and an indication for drug withdrawal. However, threshold cutoffs for drug withdrawal based on a declining DLCO have not been established. Furthermore, only a small percentage of bleomycin-exposed patients with changes in DLCO will develop clinical toxicity.⁸⁶ In our practice, monitoring DLCO with serial PFTs is reserved for patients with known lung disease and/or compromised lung function at baseline. Serial monitoring of DLCO is performed as cumulative doses of bleomycin approach 400 U or if clinical symptoms suggestive of bleomycin toxicity develop. The optimal dosing of corticosteroid therapy is not well defined. Starting doses of prednisone or its equivalent at 0.75–1 mg/kg (based on ideal body weight) per day to a maximum of 100 mg/day for the first 4–6 weeks is reasonable. Tapering of prednisone is usually accomplished over a few months, in accordance with the patient's condition and clinical response. Resolution of BIP typically occurs over time, with most patients showing improvements in pulmonary function and radiology at 15 months or greater. Delays in diagnosis, continuation of bleomycin, or the development of fibrosis portends a worse prognosis. Mortality rates are low (1–3%) but increase to 10% among patients with cumulative doses above 550 U.

Figure 9 24-year old woman who developed respiratory distress following abdominal surgery for an unrelated illness 3 months after completing bleomycin-based treatment for Hodgkin's lymphoma. CXR (a) and CT scan (b) showed bilateral patchy reticulonodular and airspace disease. Work-up was consistent with ARDS associated with bleomycin toxicity, presumably triggered by hyperoxia during surgery.

The nitrosoureas bis-chloroethylnitrosourea (BCNU) also cause a dose-dependent IP, with rates as high as 50% among patients whose cumulative dose exceeds 1500 mg/m². Unlike other forms of drug-induced IP, BCNU-induced lung injury exhibits a predilection for the middle and upper lobes. Upper lobe-predominant fibrosis and pneumothorax may occur years after completion of BCNU therapy. Late-onset pneumonitis has been reported also following cyclophosphamide and busulfan administration. Acute and subacute IP developing within hours or weeks following the taxane drugs, paclitaxel and docetaxel, has

been well documented.⁸⁷ Although the pneumonitis is typically mild, severe reactions, progressing to pulmonary fibrosis and death, have been reported with both drugs. The incidence and severity of taxane-related IP is influenced by dose and dosing schedule. The presence of prior fibrosing lung disease and the concomitant use of other agents that potentiate lung toxicity (such as gemcitabine) and concurrent RT increase the incidence of this disease.

IP has been reported following treatment with many classes of targeted agents, including mTOR inhibitors (everolimus, temsirolimus), EGFR inhibitors (gefitinib, erlotinib, cetuximab, panitumumab), multikinase angiogenesis inhibitors (sorafenib, sunitinib), the HER2 inhibitor (trastuzumab), multikinase Bcr-Abl inhibitors (imatinib, dasatinib, nilotinib, bosutinib), proteasome inhibitors (bortezomib, carfilzomib), the ALK inhibitor (crizotinib), c-Met inhibitor (tivantinib), and immunomodulatory agents (thalidomide, lenalidomide, pomalidomide). ILD is most common following mTOR therapy, occurring in up to 39% of mTOR-treated patients with solid tumors.^{81, 88–90} Most patients are asymptomatic; however, fulminant respiratory failure has been described. Recent studies suggest that the appearance of mTOR-induced ILD in patients with renal cancer may correlate with antitumor activity.⁸¹ This observation, if confirmed, should help to guide treatment strategies for asymptomatic patients with radiographic evidence of mTOR-related IP. Successful rechallenge following dasatinib, everolimus, and temsirolimus-related IP has been reported.^{81, 91}

Hypersensitivity pneumonitis (HP)

HP-like reactions are typically characterized by fever, dyspnea, dry cough, headache, fatigue, rash, and BAL lymphocytosis following repeated exposure to the offending agent. IP may evolve over the first 3–4 weeks after drug exposure and wax and wane without adjustments in therapy. Poorly formed granulomas with mononuclear cell infiltration are common histologic findings in subacute and chronic HP. Hilar adenopathy and pleural effusions occur in up to 10% of patients. Histologic evidence of ill-defined granulomas, together with a skin rash and radiographic findings of hilar adenopathy or pleural effusions, may help to distinguish methotrexate-induced lung injury. Radiographic changes include homogeneous opacities with upper lobe predominance, particularly in chronic forms of the disease. Among the drugs that have been implicated in the development of HP, methotrexate has been the most studied. Lung injury has been reported following oral, intravenous, intrathecal, and intramuscular routes of methotrexate administration. Overall, the prognosis for patients with chemotherapy-induced HP is very favorable. Complete resolution of clinical symptoms and radiographic findings is typical following steroid therapy in early-stage disease.

Alveolar processes

Noncardiogenic pulmonary edema (NCPE), diffuse alveolar damage (DAD), and adult respiratory distress syndrome (ARDS)

NCPE occurs as a result of injury to the alveolocapillary membrane, resulting in capillary leak and a noncardiogenic (permeability) pulmonary edema. With disease progression, severe physiological impairment consistent with ARDS and its histologic hallmark, DAD, may ensue. Drug-induced NCPE often occurs as an idiosyncratic reaction, unrelated to drug dosage or duration of therapy. Patients typically present with acute dyspnea, hypoxia, and alveolar infiltrates in the absence of heart failure. Reactions are typically mild and self-limited, although progression to ARDS with fatal outcomes occasionally occurs. Drug withdrawal, supplemental oxygen, and the judicious use of diuretics usually effect a rapid recovery. With the exception of ATRA- and arsenic-induced NCPE (see section titled “Lung

Injury Associated with Conventional Chemotherapy”), drug rechallenge with the offending drug often results in recrudescence of symptoms and is not recommended. Aggravating factors that potentiate disease progression to ARDS include multiagent protocols and the concomitant or sequential use of radiation or oxygen therapy, particularly following therapy with bleomycin or busulfan.^{92, 93} Once established, the response of ARDS to drug withdrawal and corticosteroid therapy is variable. Progressive respiratory impairment, leading to respiratory failure and death, has been reported with some agents (busulfan, cyclophosphamide, bleomycin) despite drug withdrawal. Among molecular targeted therapies, ARDS has been best described following agents that inhibit the EGFR (gefitinib, erlotinib, cetuximab), the antilymphocyte monoclonal antibodies (mAbs) (rituximab, alemtuzumab, ofatumumab), and the rapamycin inhibitors (everolimus, temsirolimus). Acute withdrawal of the JAK2 inhibitor, ruxolitinib, has been associated with the development of ARDS as a result of a cytokine rebound reaction. Preemptive use of corticosteroids, along with supportive therapy and a slow taper off this agent, is recommended to mitigate this potential problem.^{94, 95}

Diffuse alveolar hemorrhage (DAH) and other bleeding disorders

Drug-induced DAH most often occurs as a result of injury to the alveolocapillary membrane but may occasionally be seen as a consequence of bland alveolar hemorrhage without distortion of the lung architecture. DAH in the absence of DAD is a rare complication of rituximab⁹⁶ and alemtuzumab.⁹⁷ Tumor cavitation with sometimes fatal bleeding complications has been described during treatment of central airway tumors with bevacizumab therapy.⁹⁶

Eosinophilic pneumonia (EP)

EP is characterized by fever, dyspnea, hypoxia, and homogeneous ground-glass opacities that have a predilection for the periphery and upper lobes. Alveolar and peripheral blood eosinophils are common features. A leukocyte composition of >20% eosinophils of the total leukocytes recovered by BAL is consistent with EP. The “reverse pulmonary edema pattern” is a classic radiographic feature but is seen in only 33% of patients. A growing list of agents has been implicated in the development of EP, including bleomycin, busulfan, methotrexate, procarbazine, fludarabine, and, more recently, oxaliplatin- and taxane-based therapies. Drug withdrawal and initiation of high-dose steroids are associated with favorable outcomes.^{61, 98–101}

Pleural disease

Pleural effusions and fibrosis

Drug-induced pleural disease is typically a manifestation of a generalized pleuroparenchymal abnormality but may occur as an isolated event.¹⁰² Isolated pleural effusions are seen occasionally following administration of methotrexate, dasatinib, bosutinib, docetaxel, ATRA, and granulocyte-colony stimulating factor (G-CSF).^{103, 104} An exudative, lymphocyte-predominant effusion is typical, which may be unilateral or bilateral and small to moderate in size. Optimal therapy for drug-induced pleural effusions is not well defined, but thoracentesis, diuresis, and steroid therapies have been employed with varying rates of success. Spontaneous resolution of the pleural effusion may occur following drug withdrawal in some cases. Pleural thickening may accompany pulmonary fibrosis as a late manifestation of cyclophosphamide, BCNU, or bleomycin toxicity.

Pulmonary vascular disorders (PVD)

Thromboembolic disease, pulmonary hypertension, and pulmonary veno-occlusive disease

The adverse effects of chemotherapeutic agents on the pulmonary vasculature may result in thrombosis, pulmonary hypertension (PH), or pulmonary veno-occlusive disease (PVOD). The diagnosis of pulmonary vascular disease is suggested by an isolated reduction in DLCO or a DLCO that is disproportionately decreased relative to other lung function parameters on PFT. The prothrombotic effects of tamoxifen appear to be related to drug-related decrements in protein C and antithrombin III levels.¹⁰⁵ Combined therapy with tamoxifen and other chemotherapeutic agents, such as cyclophosphamide, methotrexate, and 5-fluorouracil, confers a threefold increased risk of thromboembolic phenomenon.^{106, 107} Thromboembolic events, with rates ranging from 14% to 43%, have been reported among recipients of thalidomide-based chemotherapy, given in combination with steroids, doxorubicin, or BCNU.^{108–111} The VEGF inhibitors, bevacizumab, sunitinib, and sorafenib, are also associated with thromboembolic events ([Figure 10](#)).^{2, 96, 112, 113} Pulmonary arterial hypertension (PAH) is a rare complication of antineoplastic agents, suggesting possible individual susceptibility. Severe PAH has been reported following treatment with the Bcr-Abl TKI dasatinib, which, in most cases, is only partially reversible after drug withdrawal.^{114–117} An off-target mechanism of drug-induced PAH following use of this multikinase inhibitor has been postulated. There have been no reports of PAH following exposure to the more selective Bcr-Abl TKIs. In fact, the safe use of selective Bcr-Abl TKIs, such as nilotinib and imatinib following dasatinib-associated PAH, is well described.^{115, 118} Once dasatinib-associated PAH is suspected, the drug should be withdrawn, and rechallenge is not recommended.¹¹⁹ PH following interferon therapy has been attributed to potential interferon-induced endothelial dysfunction.^{120, 121} Zinostatin, an antitumor antibiotic, causes hypertrophy of the pulmonary vascular wall leading to PH, possibly as a result of direct toxicity to the pulmonary endothelium.¹²² Chemotherapy-related PH may also present as PVOD, a process characterized by fibrous obliteration of pulmonary venules and small pulmonary veins (see section titled “Pulmonary Hypertension in the Cancer Patient”). Although several drugs have been implicated in the development of PVOD, bleomycin and BCNU have been associated with the most incriminating data.^{123, 124}

Figure 10 CT angiogram showing large central embolus in a patient treated with bevacizumab-based chemotherapy for cholangiocarcinoma (a). Associated pulmonary infarct is suggested by the wedge-shaped subpleural density overlying the lateral segment of the right middle lobe (b).

Drug-induced airway disease

Bronchospasm

Bronchospasm with associated dyspnea, wheezing, and hypoxia is a common and sometimes life-threatening manifestation of chemotherapy-related acute IRs. Virtually all chemotherapeutic agents may trigger an IR, defined as an adverse reaction that is temporally related to drug infusion with signs and symptoms inconsistent with the known toxicity profile of the drug. Until recently, all adverse events associated with drug infusions were referred to as “hypersensitivity reactions.” However, an allergic component is absent in many of these reactions, and, thus, “IR” is the preferred term. Acute IRs typically occur within the first few minutes to hours of drug exposure, although late reactions, occurring 10–12 h following drug administration, have also been reported. Events typically occur as an IgE-mediated hypersensitivity response to foreign proteins (type 1 hypersensitivity reaction) or as a non-IgE-mediated pseudoallergic response. The latter is caused by certain cationic drugs which may trigger the activation of mast cells and subsequent cytokine release (anaphylactoid reaction).⁶³ Following exposure to some agents, such as carboplatin, oxaliplatin, and L-asparaginase, IgE antibodies are produced and bind mast cells and basophils. Subsequent reexposure to the drug may reduce an explosive release of vasoactive mediators (histamines, leukotrienes, and prostaglandins) from basophil and mast cells, triggering a type 1 hypersensitivity reaction and anaphylaxis. Type 1 reactions typically occur within minutes of infusion.

Associated respiratory symptoms include cough, dyspnea, wheezing, and chest tightness. Stridor due to oropharyngeal and laryngeal edema may also occur. As the disease progresses, bilateral pulmonary infiltrates associated with permeability pulmonary edema may develop, which may progress to ARDS. Occasionally, these reactions may be sufficiently severe to lead to respiratory failure, shock, and death.¹²⁵

IRs associated with taxane administration (paclitaxel, docetaxel) are clinically similar to IgE-mediated type 1 reactions; however, the proposed mechanisms underlying taxane IRs may be different. Paclitaxel is formulated in a highly allergenic polyoxyethylated castor oil solvent, Cremophor EL, which may trigger mast cell/basophil activation and subsequent hypersensitivity reaction. Polysorbate 80, which is the vehicle used in formulating docetaxel, may induce IRs via similar mechanisms.¹²⁶ IRs due to taxane administration have been attributed to the taxane component as well as the vehicle used to solubilize these agents. Nonetheless, other antineoplastic agents that are formulated in Cremophor EL (cyclosporine, teniposide, ixabepilone) or polysorbate 80 (etoposide) should be avoided in patients with a history of IRs following taxane administration.¹²⁷ Typically, taxane-associated IRs occur early during the first or second infusion. Standard prophylaxis with histamine receptor antagonists and steroids has reduced the incidence of paclitaxel-induced bronchospasm from 30% to 2%.¹²⁸ Recent studies have shown the presence of BRCA1/2 mutations to be an independent risk factor for the development of IRs among women treated with carboplatin-based chemotherapies for breast or ovarian cancer. IRs in this setting tend to occur at lower cumulative dose exposure.¹²⁹

The infusion of most mAbs may provoke a cytokine release syndrome, an immune response characterized by dyspnea, wheezing, and “flu-like symptoms” which typically occurs within the first few hours of administration.¹³⁰ Symptoms are typically mild, with fatal reactions occurring in a minority of patients. The percentage of mouse protein is thought to correlate with the immunogenic response, including IRs. Thus, the earliest mAbs were murine derived and highly immunogenic in humans. One strategy to decrease the immunogenicity of mAbs has been the development of chimeric mouse–human (cetuximab, rituximab, brentuximab), partially humanized (bevacizumab, trastuzumab, alemtuzumab, gemtuzumab, obinutuzumab), and fully humanized (ipilimumab, ofatumumab, panitumumab, ramucirumab) antibodies. Reduced immunogenicity based on murine content of the mAB was suggested in a recent study in which the severity of IRs following panitumumab therapy (0.5%) was fourfold less than that following cetuximab therapy (2%).¹³¹ Risk factors for mAB-induced IRs include a prior history of allergic reaction to the drug, the route and rate of administration, drug form, and multiagent therapy. Test dosing prior to infusion does not reliably predict subsequent IRs. Mild IR events following mAb therapy may be managed with supportive care (supplemental oxygen, antihistamines, steroids, and nebulized β -agonists) either with or without cessation of therapy. Premedication with antihistamines, corticosteroids, and antipyretics is generally recommended for the chimeric mouse–human mAbs, such as rituximab and cetuximab. Among several of the humanized mAbs (alemtuzumab, trastuzumab) and fully human mAbs (ramucirumab, ofatumumab), the risk of IRs is also sufficiently high to warrant premedication therapy. Typically, decisions regarding the need for prophylaxis and safety of drug rechallenge are based on the severity of the hypersensitivity reaction and are made on a case-by-case basis.¹³² Breakthrough IRs may occur despite prophylaxis. Thus, close monitoring during and immediately following drug infusion is recommended.

One other class of agents that has been associated with bronchospasm includes the vinca alkaloids. Although vinorelbine and other vinca alkaloids are rarely associated with lung toxicity, acute reactions characterized by cough, bronchospasm, flushing, dyspnea, abdominal pain, and hypotension have been described when these agents are given either concurrently or sequentially with mitomycin chemotherapy.^{133, 134}

Other clinicopathologic syndromes

Granulomatous disease

The development of noncaseating granulomas is a rare manifestation of drug-induced lung injury that has been described most often following methotrexate and interferon therapy.^{135, 136} Methotrexate- and interferon-induced granulomatous lymphadenopathy is indistinguishable from sarcoidosis. In addition to methotrexate and interferon, procarbazine, ipilimumab, and sirolimus may also incite a granulomatous pneumonitis. Drug withdrawal may result in disease regression.

Pulmonary complications of thoracic radiation: Radiation pneumonitis and fibrosis

One of the many challenges of RT is the precise delivery of the radiation dose to target organs while sparing critical surrounding normal tissues. In thoracic neoplasms, where anatomical changes during treatment and tumor motion associated with respiratory variation are common, clinically significant lung injury following conventional thoracic radiation occurs in 5–20% of patients. Radiation-induced lung injury (RILI) is, in fact, the most common dose-limiting complication following thoracic radiation and chemoradiation regimens. Recent advances in radiation techniques, imaging, and delivery systems, such as proton therapy, 3D conformal radiation therapy (CRT), intensity-modulated radiation therapy (IMRT), and stereotactic body radiation therapy (SBRT), have the potential to achieve higher target doses of radiation while mitigating radiation exposure to adjacent normal tissues. Radiation damage does occur with the newer radiation strategies, however, and the associated radiographic patterns and severity of RILD may differ from lung injury caused by conventional radiotherapy. Factors such as total radiation dose, dose per fraction, the volume of irradiated lung, and beam characteristics and arrangements all influence the development of radiation pneumonitis (RP). Preexisting lung disease, underlying poor pulmonary reserve, prior radiotherapy, and rapid steroid withdrawal also influence the clinical appearance and severity of lung injury.¹³⁷ Multimodality regimens that combine radiation with chemotherapeutic agents such as mitomycin, cyclophosphamide, vincristine, adriamycin, bleomycin, gemcitabine, the taxanes, and actinomycin D may not only potentiate radiation pneumotoxicity but also shorten the latency period following radiation exposure.¹³⁸ Although data regarding optimal dose–fractionation and dose–volume relationships that mitigate lung injury are still evolving, it is generally agreed that a hyperfractionated course of radiation delivered to the smallest lung volume offers the lowest possibility of lung toxicity. Radiographically apparent lung damage is common with total doses of radiation that exceed 40 Gy. At doses >70 Gy, unusual pulmonary complications, including bronchial stenosis, bronchomalacia, mediastinal fibrosis, and injury to the recurrent laryngeal nerve, have been reported. Lung injury at radiation doses below 20 Gy is rare.¹³⁹

RP and radiation fibrosis (RF) represent acute and late phases of RILI, respectively, and are the most frequent forms of radiation toxicity. Acute pneumonitis is heralded by fever, dyspnea, and nonproductive cough which may develop insidiously 1–3 months after completion of RT and may precede the radiographic changes of RP. Radiographic changes may be seen as early as 3–4 weeks following RT, characterized by discrete ground-glass opacities, ill-defined patchy nodules, or consolidation with air bronchograms and volume loss within the irradiated field. In mild cases of acute RP, these changes may resolve within 6 months, leaving a linear scar. Regional scarring is seen in nearly all patients, including those without clinical symptoms. Measurable changes in PETs, including a reduction in lung volumes and diffusing capacity, may be seen as early as 2–3 months after irradiation. Histopathologic features of early

RP include interstitial edema, hemorrhage, and fibrinous exudates with reactive type II pneumocytes. With more severe injury, RF develops. RF is signaled by the appearance of a well-demarcated area of volume loss, linear densities, bronchiectasis, retraction of the lung parenchyma, tenting and elevation of the hemidiaphragm, and ipsilateral pleural thickening. Like RP following conventional RT, these changes usually occur within the irradiated field. RF usually evolves over 6–12 month posttreatment and stabilizes within 1–2 years following completion of RT. RP detection methods using 18[F]-2-fluoro-2-deoxyglucose positron emission tomography (FDG-PET) imaging permits quantitative assessment of RP, which manifests as enhanced FDG uptake. Higher standard uptake values (SUV) derived from PET–CT imaging have been associated with increased risks of symptomatic RP.^{140, 141} The utility of this imaging modality in identifying individuals at high risk for developing symptomatic RP is currently being investigated.

A less predictable or sporadic form of RP has also been recognized.¹¹⁶ Sporadic pneumonitis occurs in a minority (5%) of patients and is thought to represent a type of HP characterized by a bilateral CD4⁺ T-lymphocytic alveolitis that diffusely involves both lungs. Hence, radiation changes on imaging studies may extend well beyond the irradiated field. Patients present at 1–3 months following thoracic irradiation with symptoms of dyspnea and dry cough that are disproportionate to the volume of lung irradiated. This form of pneumonitis and its associated symptoms typically abate in 6–8 weeks without significant long-term sequelae.^{116, 142, 143}

Radiation recall pneumonitis describes a rare but well-recognized inflammatory reaction that occurs within a previously irradiated area of pulmonary tissue after application of certain chemotherapeutic agents. Recall pneumonitis has been observed most often following taxane- and anthracycline-based therapies. Gemcitabine, etoposide, vinorelbine, trastuzumab, and erlotinib have also been implicated as triggers for this disease ([Tables 1](#) and [2](#)).^{144, 145} Patients typically present with dry cough, low-grade fever, and dyspnea during the initiation of the precipitating agent or following several courses of therapy. Lung injury in recall pneumonitis typically occurs shortly after administration of the inciting antineoplastic agent, which may be weeks to years following completion of radiotherapy. Radiographically, ground-glass opacities and areas of consolidation that conform to the radiation treatment portal are seen. Drug withdrawal and initiation of corticosteroids and supportive care usually result in a favorable outcome. Rechallenge with the offending agent has been successful in some cases.¹⁴⁶

Radiation-related pleural effusions may occur as an early complication (within 6 months) of radiation pleuritis or as late sequelae (1–5 years) of mediastinal irradiation with associated mediastinal fibrosis, systemic PH, or lymphatic obstruction. These effusions are typically small, ipsilateral, and asymptomatic. Occasionally, patients may complain of shortness of breath or pleuritic chest pain. Pleural fluid cytology is negative. Reactive mesothelial cells within the pleural fluid are common. PVOD has also been reported as a rare complication of radiation-induced lung toxicity. Radiation-induced OP and EP involving nonirradiated areas in patients with breast cancer have also been documented.^{147, 148} Radiation-induced OP is thought to represent an immunologically mediated, lymphocyte-predominant hypersensitivity-like reaction. Both EP and OP may produce migratory pulmonary opacities on chest radiographs, which typically develop 1–3 months following radiotherapy. The presence of blood or tissue eosinophils, coupled with a prior history of asthma or atopy, favors the diagnosis of EP. Corticosteroid therapy is associated with prompt recovery of radiation-induced OP and EP, although relapsed disease may rarely occur after steroid withdrawal. Another intrathoracic complication of RT includes pulmonary congestion, which may occur as a sequela of radiation-induced myocardial and/or valvular dysfunction.

Factors such as the location, type, and extension of the primary tumor as well as the corresponding beam configuration and portals directly influence the shape and distribution of radiation-induced lung damage.

RILD associated with the newer modes of RT delivery and imaging, such as 3D-CRT and IMRT, may not result in the stereotyped straight-edged infiltrate but rather, assume a mass-like or whorled appearance or, alternatively, appear as poorly margined and irregular nodules. Thus, lung injury following newer radiation techniques may be remarkably difficult to distinguish from competing disease entities such as infection or recurrence of the underlying malignancy.¹⁴⁹ Postradiation volume loss, bronchiectasis, and consolidation may occur with these modes of RT delivery but typically are less extensive than injury patterns following conventional radiation.¹⁵⁰ Proton radiotherapy improves delivery of radiation dose to the tumor with less dispersion before reaching the tumor target. This observation may permit safe escalation of radiation dose to tumoricidal levels while sparing critical normal lung tissues.^{151, 152} In one small study, patients that received proton therapy for medically inoperable NSCLC tolerated higher doses of radiation with reduced rates of pneumonitis versus those who underwent conventional radiotherapy.¹⁵¹ Further studies are needed to investigate these radiation modalities and their true impact reducing the risk of RP.

Infection, drug toxicity, and recurrent tumor are major mimickers of RILI. Correlation with radiation treatment plans, knowledge of expected patterns of RILI, and temporal correlation with RT are important in the diagnosis of radiation damage. Lung opacities that develop prior to the completion of radiation should suggest an alternative diagnosis. Cavitation within the fibrotic area of irradiated lung may be due to a superimposed infectious process such as tuberculosis or *Aspergillus* species, recurrent tumor, or postradiation necrosis. The loss of bronchiectasis due to filling of the airways with tumor or infection is also an important radiographic indication of superimposed disease.

RILI represents a continuum of changes initiated by an inflammatory pneumonitis, which progresses to fibrosis, although whether pneumonitis and fibrosis represent a continuum or separate entities has not definitively resolved. Unfortunately, definitive pharmaceutical strategies in the successful prevention and treatment of RILI remain elusive. RP may respond to steroid therapy. Although evidence-based recommendations regarding dosing schedules and strategies are not available, in general, 40–60 mg of daily prednisone over several weeks, followed by a several-week taper provides relief of symptoms in most patients. There is no conclusive evidence that successful treatment of acute pneumonitis mitigates the later development of RF. Once established, steroids have not been shown to be of benefit in the treatment of this late sequela of RT.

Pulmonary complications of hematopoietic stem cell transplantation

Hematopoietic stem cell transplantation (HSCT) is the only curative option for many patients with relapsed and high-risk hematologic malignancies. Despite advances in treatment regimens and supportive care, pulmonary complications occur in up to 60% of HSCT recipients, accounting for significant morbidity and mortality.^{153–155} Pulmonary complications of HSCT are divided into “early” (those that occur during the first 100 days posttransplant) and “late” (those that occur > than 100 days posttransplant) ([Table 3](#)). These complications are due primarily to direct toxicities from conditioning regimens, delayed bone marrow recovery, prolonged immunosuppressive therapy, and graft versus host disease (GVHD). Infectious complications occur most commonly after allogeneic HSCT due to the high incidence of GVHD and prolonged use of immunosuppressive therapy. As successful prophylactic treatment strategies have effectively reduced the rates of infectious pulmonary complications, noninfectious pulmonary complications have emerged as a major cause of post-HSCT morbidity and mortality.

Table 3 Noninfectious pulmonary complications following hematopoietic stem cell transplantation

Early (<100 days)	Late (>100 days)
<ul style="list-style-type: none">• Pulmonary edema• Idiopathic pneumonia syndrome• Diffuse alveolar hemorrhage• Periengraftment respiratory distress syndrome• Secondary pulmonary alveolar proteinosis (rare)• Pulmonary venoocclusive disease (rare)	<ul style="list-style-type: none">• Bronchiolitis obliterans• Cryptogenic organizing pneumonia• Posttransplant lymphoproliferative disorders• Lymphocytic interstitial pneumonitis (rare)

Early-onset noninfectious complications of HSCT

Pulmonary edema and pleural effusions

Diffuse pulmonary edema is one of the most common early complications after transplantation. Etiologies include increased hydrostatic capillary pressure associated with the administration of large volumes of fluid and cardiac dysfunction. Increased pulmonary capillary permeability and NCPE owing to the preconditioning regimen also occur.^{155, 156} Hydrostatic and permeability etiologies of posttransplant pulmonary edema may be present simultaneously and overlap with other early-onset pulmonary complications. The abrupt onset of dyspnea, hypoxia, and bilateral pulmonary infiltrates coupled with the absence of infection on diagnostic evaluation are supportive findings. Pleural effusions may accompany pulmonary edema. Bilateral pleural effusions associated with weight gain may be approached conservatively without the need for diagnostic thoracentesis.

Periengraftment respiratory distress syndrome (PERDS)

Periengraftment respiratory distress syndrome (PERDS) is characterized by fever, NCPE, erythematous skin rash, and hypoxemia and occurs during the neutrophil recovery phase of HSCT. The NIH-sponsored Blood and Marrow Transplant Clinical Trials Network includes PERDS within the definition of idiopathic pneumonia syndrome (IPS); however, there may be value to considering it separately because of its favorable prognosis and lower mortality.¹⁵⁶ The reported incidence varies widely with disease definition and the population studied but generally occurs in 5–10% of autologous HSCT recipients when stringent diagnostic criteria are used.^{157, 158} While the pathophysiology is not well understood, proposed mechanisms include the release of proinflammatory cytokines during the engraftment period and endothelial damage from the conditioning regimen. Risk factors include the use of growth factors, the number of infused mononuclear or CD34 positive cells, the speed of neutrophil recovery, type of conditioning regimen, underlying disease, and peripheral blood as the source of stem cells. Some studies have shown improvement with corticosteroid therapy.^{158, 159}

Idiopathic pneumonia syndrome (IPS)

In 1993, a panel convened by the NIH proposed a broad working definition of IPS as widespread nonlobar radiographic infiltrates in the absence of congestive heart failure or evidence of lower respiratory tract infection.¹⁶⁰ IPS occurs in 10% of HSCT recipients, usually 14–90 days following transplantation. Mortality rates range from 50% to 70%.^{161–163} Risk factors include transplantation for

malignancy other than leukemia, older age, total body irradiation, type of pretransplant chemotherapy, high-grade GVHD, CMV (cytomegalovirus)-seropositive donor, HLA (human leukocyte antigen) disparity, and lower performance status.¹⁶² Possible etiologies of IPS include direct toxic effects of the chemoradiation conditioning regimen, occult infection, and release of inflammatory cytokines. However, the association of IPS with the presence of acute GVHD after allogeneic transplantation suggests that alloreactive T-cell injury may also be an important contributor.^{162, 163} The clinical presentation is nonspecific, with symptoms of acute dyspnea, cough, and fever associated with diffuse infiltrates on chest radiograph. The diagnosis of IPS relies largely on the exclusion of infection and absence of cardiac, renal, or iatrogenic fluid overload. Treatment includes high-dose intravenous corticosteroids and supportive care with supplemental oxygen and broad-spectrum antibiotics. Earlier preclinical and clinical data suggested a potential role for tumor necrosis factor- α (TNF- α) in the pathogenesis of IPS. However, a recent randomized trial found high early response rates to systemic corticosteroid therapy but no further increase in response to treatment with the addition of etanercept, a TNF receptor fusion protein.¹⁶⁴

Diffuse alveolar hemorrhage (DAH)

Posttransplant DAH is characterized by widespread lung injury and diffuse radiographic infiltrates in the absence of identifiable infection following allogeneic and autologous stem cell transplants.^{165–169} The Blood and Marrow Transplant Clinical Trials Network includes DAH within the definition of IPS. DAH has also been described in one-third of patients during the periengraftment period.^{157, 170} Bronchoscopically, DAH appears as progressively bloody returns on lavage fluid taken from three or more subsegmental bronchi. The bronchoscopic criteria for DAH diagnosis have expanded to include cytologic evidence of >20% hemosiderin-laden macrophages in the BAL fluid. Increased hemosiderin-laden macrophages and bloody lavage fluid may be seen in association with diffuse lung injury from a wide variety of causes in the posttransplant setting. Bloody BAL fluid is, thus, neither sensitive nor specific for DAH and may simply represent an index of severity of alveolar injury and concomitant hemostatic defects rather than a separate syndrome. More important, prognosis and therapy are determined by the underlying pathophysiologic process (engraftment syndrome, IPS, sepsis, etc.).¹⁷¹ There are no associations between the development of DAH and coagulopathy or thrombocytopenia. Furthermore, platelet transfusion does not improve respiratory status. Treatment of DAH includes high-dose intravenous corticosteroids and supportive care, such as supplemental oxygen, mechanical ventilation, and platelet transfusion. Recombinant human factor VIIa (rFVIIa) has been used to enhance hemostasis, but a recent retrospective analysis showed no survival advantage with the addition of rFVIIa to high-dose corticosteroid therapy.¹⁷²

Pulmonary venoocclusive disease (PVOD)

PVOD is a rare complication of HSCT in which progressive occlusion of pulmonary veins and venules caused by intimal proliferation and fibrosis leads to PH.¹⁷³ High-dose chemotherapy and infections are implicated as causes of PVOD. The onset is typically insidious, with progressive dyspnea and fatigue occurring several weeks to months after transplant.^{124, 174, 175} Current treatment options are limited, and mortality rates can reach up to 100% within 2 years.

Late-onset noninfectious complications of HSCT

Posttransplantation bronchiolitis obliterans syndrome (BOS)

Bronchiolitis obliterans syndrome (BOS) is the most common pulmonary complication among long-term survivors of allogeneic HSCT. It is a late manifestation of GVHD that leads to progressive respiratory insufficiency and sometimes death. BOS almost never occurs in the absence of GVHD and, thus, affects only allogeneic transplant recipients.^{154, 176, 177} The incidence of 5–26% varies with the diagnostic criteria used.¹⁷⁸ BOS affects small airways, causing chronic inflammation, epithelial mucous metaplasia, submucosal scarring, smooth muscle hypertrophy, and concentric bronchiolar fibrosis. The most commonly identified risk factors are chronic GVHD, older age, viral infections during the first 100 days after transplant, the presence of airflow limitation before transplant, low serum IgG, and the use of methotrexate or busulfan in the conditioning regimen.^{157, 179} Patients may be asymptomatic in early stages of BOS, which delays the diagnosis. Late presentations, including dyspnea, cough, and wheezing, are more common, as airflow obstruction progresses.^{180, 181} Chest radiographs are usually normal, but high-resolution CT scans may show evidence of air trapping, thickened or dilated small airways, and mosaic attenuation. Bronchoscopy with BAL and transbronchial lung biopsy is generally not helpful in establishing the diagnosis. PFTs are the primary tools used for diagnosis and follow-up. Evidence of airflow obstruction with reduction in FEV₁ and FEV₁/forced vital capacity (FVC) are supportive PFT findings. The NIH consensus guidelines for diagnosing PTCB include (1) FEV₁/FVC < 0.7 and FEV₁ < 75% of predicted, residual volume on PFTs > 120% predicted; (2) evidence of air trapping, small airway thickening, bronchiectasis on HRCT, or pathological confirmation of constrictive bronchiolitis; and the (3) absence of any infectious process on radiographic, laboratory, or clinical testing.¹⁷⁹ Typically, these diagnostic criteria are associated with delayed diagnosis, severe airflow obstruction, and development of airway fibrosis which contribute to poor prognosis and limitation of therapeutic interventions. Recent publications have proposed revising these criteria to facilitate the diagnosis of BOS at earlier stages.¹⁷⁸

Treatment options for BOS have not been evaluated in any prospective trials. Traditionally, augmentation of systemic immunosuppression with corticosteroids and calcineurin inhibitors has been the mainstay of therapy.¹⁶³ However, two retrospective analyses indicate that inhaled high-dose corticosteroid therapy is effective in stabilizing FEV₁ and reducing symptoms significantly.^{182, 183} A beneficial effect of azithromycin, possibly due to its anti-inflammatory effects, has also been reported in an observational study.¹⁸⁴ A recent retrospective analysis suggested the use of a less toxic combination (fluticasone, azithromycin, and montelukast) which helped in reducing systemic immunosuppressive therapy within a shorter period of time.¹⁸⁵ Lung transplantation is an option in selected patients. Chronic GVHD continues to be a major cause of mortality and morbidity in long-term survivors of HSCT. BOS is an important contributor to this process. The clinical course and disease progression are variable, but persistent airflow obstruction is associated with a significantly increased risk of death.¹⁷⁶ Early detection and properly conducted prospective trials for the management of BOS are crucial to improve survival.

Cryptogenic organizing pneumonitis (COP)

Also known as *idiopathic bronchiolitis obliterans organizing pneumonia (BOOP)*, Cryptogenic organizing pneumonitis (COP) occurs mostly in allogeneic HSCT recipients with GVHD. COP is a distinct entity that should not be confused with BOS.^{177, 186–188} It is less common than BOS, with an incidence of 1–2% in long-term survivors. Dry cough, dyspnea, and fever accompanied by patchy infiltrates on chest radiograph and CT scan are the predominant presenting signs and symptoms. The diagnosis is made with surgical lung biopsy. COP is usually responsive to corticosteroids with more favorable prognosis; however, no standard treatment guidelines are currently available.¹⁵⁶

Posttransplant lymphoproliferative disorder (PTLD)

Posttransplant lymphoproliferative disorder (PTLD) is an uncontrolled expansion of donor-derived Epstein–Barr virus (EBV)-infected B lymphocytes that develops in response to inadequate cytotoxic T cell function.^{154, 189} It occurs in approximately 1% of HSCT patients, usually within the first 4–12 months after transplant. The lung is involved only 20% of the time, most commonly with ill-defined nodular infiltrates. Treatment includes reduction of immunosuppressive therapy anti-CD20 monoclonal antibody (rituximab), antiviral drugs, and infusion of EBV-specific cytotoxic T lymphocytes.

Pneumonia

Pulmonary infections frequently complicate cancer and its therapy.^{190, 191} Classic clinical indicators to suggest the presence of lower respiratory infections include the development of pulmonary parenchymal infiltrates, leukocytosis, fever, and expectoration of purulent secretions. However, as a consequence of impaired immune responses, these typical clinical observations may be absent in cancer patients with pneumonia. Therefore, a high index of suspicion is required to avoid overlooking the diagnosis. Further, early radiographic imaging, often including CT scanning, is indicated in cancer patients with unexplained clinical deterioration or new infiltrates on conventional imaging.

The diagnosis of pneumonia is confirmed by recovery of the likely pathogen from an otherwise sterile source (e.g., blood, urine, pleural fluid) or isolation of a noncommensal organism in respiratory secretions. Although the utility of expectorated sputum in the diagnosis of pneumonia is debated, cytologically confirmed lower respiratory samples appear to be diagnostically useful. Fiberoptic bronchoscopy with BAL is considered the diagnostic tool of choice for obtaining lower respiratory samples. While this procedure is safe for most cancer patients,¹⁹² traditional culture methods yield the responsible pathogen in only 25–51% of cases.^{193–196} The benefit of BAL may be enhanced by early bronchoscopic evaluation, particularly if obtained before the initiation of antimicrobial therapy. Microscopic examination of transbronchial biopsy specimens can identify angioinvasion of commensal microbes (e.g., *Aspergillus* spp.). Culture of biopsy material, however, has not been proved diagnostically superior to BAL and is often precluded in cancer patients due to coagulopathy and/or thrombocytopenia. Culture results from BAL, or biopsy can be difficult to interpret due to frequent microbial colonization of the upper airway. Conversely, sterile respiratory tract cultures do not exclude an infectious etiology, particularly in the setting of recent administration of broad-spectrum antibiotics. Molecular techniques, including polymerase chain reaction (PCR) testing for pathogen genomic material or antigen detection methods (e.g., serum galactomannan, urinary *Histoplasma* antigen), can also supplement the diagnostic evaluation.

Early and accurate diagnoses are critical to a successful outcome, although treatment should not be withheld while diagnostic interventions are undertaken. Antimicrobial selections are based on knowledge of the infecting pathogen, if available, pneumonia severity, underlying immune status, and the presence of comorbid conditions^{197, 198} (see section entitled “Infection in the cancer patient”). Delays in appropriate antimicrobial therapy increase the risk of secondary complications and infection-associated deaths, especially in severely immunosuppressed individuals. Therefore, it is common practice to initiate empiric and/or preemptive antimicrobial therapy in patients in which the suspicion of infection is high. However, the clinician is cautioned to recall that cancer patients are prone to numerous causes of fever and pulmonary infiltrates other than infectious pneumonias, including toxicities of therapy, systemic inflammation associated with extrapulmonary infections, heart failure, parenchymal cancer involvement, or intrapulmonary hemorrhage.

Venous thromboembolism

PE and deep venous thrombosis (DVT) are manifestations of VTE. Approximately 20% of all VTEs are associated with cancer, and cancer increases the risk for VTE 4–6 fold. Surgery, chemotherapy, hormonal therapy, growth factors, angiogenesis inhibitors, erythropoietic agents, and central venous catheters (CVC) contribute to cancer-associated VTE.¹⁹⁹ The diagnosis and therapy of VTE may delay, discontinue, or preclude many forms of cancer therapy.^{200, 201} Cancer-related VTE is associated with significant overall mortality but is an infrequent cause of death.²⁰² One study found that 3.5% of cancer patients die from VTE.²⁰³

The clinical presentation of VTE is nonspecific. Scoring systems developed to estimate the pretest probability of DVT and PE (such as Well's scores) in combination with D-dimer testing can be used to rule out VTE in cancer patients; however, the likelihood of finding normal D-dimer levels among cancer patients is less than 30%. Furthermore, an elevated D-dimer has no significant positive predictive value in the cancer setting.²⁰⁴ Doppler/compression ultrasound is the preferred method to diagnose DVT, although MRI and CT may be required in special circumstances, such as internal iliac vein or vena cava thrombosis. HRCT or CT angiography is the best method for diagnosing PE and offers the advantage of providing additional information regarding thoracic pathology that may confound the diagnosis.²⁰⁵ Urgent bedside echocardiography should be considered for diagnosis and risk stratification of unstable patients with suspected massive PE.²⁰⁶

Pharmacological VTE prophylaxis should be considered in every hospitalized patient with cancer.²⁰⁷ Cancer patients undergoing abdominal or pelvic surgery should receive low molecular weight heparin (LMWH) prophylaxis extended for 4 weeks.²⁰⁸ Routine prophylaxis in ambulatory cancer patients undergoing active chemotherapy is recommended only for patients with myeloma receiving thalidomide or lenalidomide as part of combination chemotherapy.²⁰⁸ There is no evidence that anticoagulation prevents catheter-associated thrombosis and guidelines recommend against it.²⁰⁷

Routine VTE induction therapy is used in cancer patients. LMWH is the preferred drug for initial treatment of VTE in this setting. Unfractionated heparin should be used in patients with impaired renal function. Thrombolytics have not been studied systematically in patients with cancer, but their use may be considered in cases of massive PE. An IVC filter should be placed when anticoagulation is contraindicated.^{207, 209} Based on limited evidence, VTEs found incidentally should be managed as symptomatic VTE.²¹⁰ For maintenance therapy, LMWH rather than vitamin K antagonists (VKA) is preferred because LMWH is better at preventing recurrences.¹⁹⁹ When tolerated, maintenance therapy can be continued indefinitely for patients with active cancer.^{202–204} The use of the new oral anticoagulants in cancer patients is generally discouraged, as few patients with cancer were included in the major trials, and there are no established procedures for monitoring these agents.²⁰⁵

Pulmonary hypertension in the cancer patient

PH, defined as a mean pulmonary artery pressure (mPAP) ≥ 25 mmHg at rest, may be an underrecognized problem in the cancer setting. Transthoracic doppler echocardiography (TTE) provides an estimation of pulmonary artery systolic pressure (PASP) and serves as a noninvasive screening tool for PH. PAH denotes a subpopulation of PH characterized by the presence of precapillary PH based on an end-expiratory pulmonary artery wedge pressure (PAWP) ≤ 15 mm Hg and a pulmonary vascular resistance > 3 Woods unit.²⁰⁷ Right heart catheterization (RHC) is required for diagnosis of PH or PAH.²⁰⁸ RHC

allows assessment of hemodynamic impairments and evaluation of vasoreactivity of the pulmonary circulation, which may guide subsequent classification and management. In acute presentations of PH, secondary causes, such as acute thromboembolic disease, hypoxemic respiratory insufficiency, airway bronchoconstriction, or cardiac dysfunction, must be excluded.

PH may precede the cancer diagnosis or occur at any point along the continuum of cancer care. PH occurring after completion of cancer therapy has also been described. Estimates of cancer-related PH vary broadly with specific cancers, associated cancer therapies, and detection methods. Nonspecific signs and symptoms of exertional dyspnea and fatigue early in the disease process render diagnostic evaluations notoriously difficult and result in substantial delays in treatment. Therefore, a high degree of suspicion is needed to detect PH early, when treatments are more efficacious. Syncope, angina, peripheral edema, abdominal distention, and hemodynamic instability are signs of advanced disease which is often refractory to therapy. In acute presentations of PH, secondary causes, such as acute thromboembolic disease, hypoxemic respiratory insufficiency, airway bronchoconstriction, or cardiac dysfunction, must be excluded.

In the revised 2013 World Health Organization clinical classification scheme, PH is categorized into five groups which share similar etiologies, hemodynamic characteristics, and therapeutic approaches. These include PAH (Group 1), PH due to left heart disease (Group 2), PH due to lung diseases and/or hypoxia (Group 3), chronic thromboembolic pulmonary hypertension (CTEPH, Group 4), and PH with unclear multifactorial mechanisms (Group 5).²⁰⁹ Cancer-related PH is represented in several of these categories. For example, the TKI, dasatinib, is now considered a risk factor for PAH and is included in Group 1.²⁰⁹ This drug causes moderate to severe precapillary PH, which may improve or fully resolve following drug cessation.¹¹⁵ PVOD, a rare cause of PH that is characterized by occlusion or narrowing of the pulmonary veins, represents a subgroup of Group I PH. Infection, chemotaxins, thoracic radiation, and stem cell transplantation are postulated risk factors for PVOD, although no clear causal relationship has been established.^{101, 174, 211} The prognosis for PVOD is poor. Although some patients may tolerate arterial vasodilators, fatal pulmonary edema precipitated by pulmonary vasodilator therapy has been observed.

Chronic myeloproliferative disorders (MPDs) constitute a rare cause of PAH. Several potential mechanisms of MPD-associated PH include high cardiac output, splenectomy, direct obstruction of pulmonary arteries, chronic thromboembolism, portal hypertension, and congestive heart failure.^{209, 212} Other cancer- and cancer treatment-related entities that involve the pulmonary vasculature may also cause PH. These include external compression and/or entrapment of large pulmonary veins by adenopathy, neoplasms, or mediastinal fibrosis. Hodgkin's lymphoma and germ cell tumors underlie most causes of PH due to mediastinal compression. Fibrosing mediastinitis related to radiation and infection (*Aspergillus*, *Mycobacterium tuberculosis*, blastomycosis, mucormycosis, and cryptococcosis) has also been reported to cause PH.^{213–215} The principal primary malignancies involving the pulmonary vasculature are sarcomas. Typically, these rare and frequently fatal tumors arise from the main pulmonary arteries, although pulmonary venous sarcomas have also been described.²¹⁶ Patients with pulmonary arterial sarcomas often present with signs and symptoms that mimic CTEPH (dyspnea, chest pain, cough, hemoptysis). However, associated findings of unexplained fever, weight loss, clubbing, anemia, and elevated ESR should raise suspicion of malignancy. Secondary tumoral involvement of the pulmonary vascular bed may present as macrovascular central tumor emboli or tumor cell aggregates that occlude small vessels. The latter may occur with or without lymphangitic spread of disease. Choriocarcinomas and mucinous tumors originating in the breast, lung, gastrointestinal tract, and kidneys are associated with the highest rates of tumor embolization.²¹⁷ Clinical symptoms of tumor emboli range from the abrupt onset of dyspnea, chest pain, and cardiovascular collapse to subacute symptoms of cough, exertional dyspnea,

and exercise intolerance associated with unexplained PH. Pulmonary tumor thrombotic microangiopathy (PTTM) is an unusual cause of malignancy-related PH that is most often seen in patients with adenocarcinomas, particularly of the stomach.²¹⁸ Patients present with severe, refractory PH that rapidly progresses to sudden cardiovascular collapse and death. Findings on pulmonary microvascular cytology are diagnostically useful; however, the diagnosis of PTTM is most often made at necropsy. No definitive treatment has been identified thus far. Although in most major medical centers, CT angiography has replaced V/Q scans in the evaluation of thromboembolic events; in the setting of suspected tumor emboli, V/Q scans may be of greater diagnostic utility than the chest CT. Multiple subsegmental mismatched defects on V/Q scintigraphy are supportive findings. Pulmonary microvascular cytology of samples obtained from a wedged pulmonary artery catheter during RHC may offer additional support for tumor embolization.²¹⁷

Leukemic sequestration and leukocyte thrombus formation within the pulmonary microvasculature are rare complications of hyperleukocytosis (WBC > 50,000/dL) and blast crisis associated with myeloid and lymphocytic leukemias. Patients typically present with dyspnea, nonproductive cough and hypoxemia associated with interstitial infiltrates, and signs of PH and cor pulmonale. The clinical manifestations of macrovascular tumor emboli resemble acute pulmonary thromboembolic disease. Microvascular tumor embolization, however, typically presents with insidious symptoms of dyspnea, nonproductive cough, hypoxemia, and severe pulmonary artery pressure elevations. Cor pulmonale and diffuse interstitial infiltrates, suggestive of lymphangitic spread of disease, are common findings that worsen the already poor prognosis. Acute hypoxemic respiratory failure has also been reported following the initiation of chemotherapy for treatment of acute nonlymphocytic leukemia. This syndrome, known as leukemic cell lysis pneumopathy, typically occurs during the initial 48 h of treatment and is thought to be caused by chemotherapy-induced pulmonary leukostasis and perivascular hemorrhage. Measured PaO₂ may be artificially low in patients with hyperleukocytic leukemias in the absence of lung involvement, owing to leukocyte metabolism of oxygen within the arterial blood gas syringe. In this setting, oxygen saturations obtained by pulse oximetry are normal. Rapid analysis of an iced arterial blood gas specimen or the addition of cyanide to the blood gas syringe eliminates this problem.

The evolution of therapy guidelines for PAH over the past two decades has resulted in evidence-based treatment strategies that favorably impact survival and significantly improve the quality of life of these patients.²¹⁹ Treatment of PH should address the underlying cause. The need for supportive therapies, including supplemental oxygen, diuretics, anticoagulant therapy, and exercise should be assessed in all patients. More advanced therapies are directed at PAH itself and should be initiated based on the results of further testing and national guidelines. Current and emerging therapies for PAH target the endothelin, nitric oxide, and prostaglandin pathways. Specific treatment strategies may include monotherapy or, more frequently, combination therapy.²²⁰ Unfortunately, no cure exists for this devastating condition. Caution in extrapolating PAH treatment guidelines to other forms of PH is warranted. No studies have addressed the utility of pulmonary vasodilator therapy in the management of cancer-related PH. Dobutamine, milrinone, intravenous prostacyclin, inhaled vasodilators, and extracorporeal life support are accepted therapies for PH with hemodynamic decompensation in the general population.²²¹ Specific guidelines regarding the optimal use of vasopressor therapy in the critically ill cancer patient with PH and associated hemodynamic deterioration have yet to be delineated.

Sleep disorders in cancer patients

Sleep disturbance and chronobiology have important implications throughout the continuum of care of the

cancer patient, impacting cancer prevention, treatment, and survivorship.

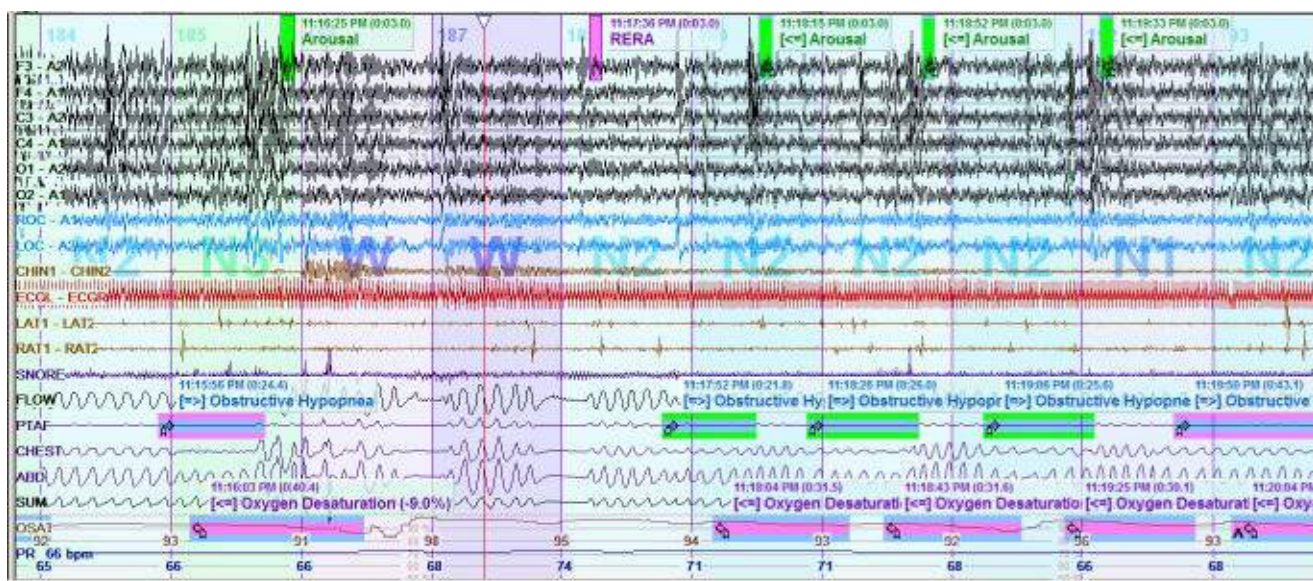

Cancer prevention

Prolonged sleep duration and disturbed circadian rhythms of sleep are associated with an increased risk of cancer. In a large Japanese cohort study, sleep durations of less than 5 h or greater than 9 h per night conferred higher cancer prevalence.²²² Chronic sleep disturbance caused by rotating and nocturnal shift work may also increase the risk of cancer. Nurses who worked rotating shifts for more than 30 years had an increased relative risk of breast cancer in one study. Suppression of melatonin, a naturally occurring hormone with oncostatic potential, occurs with nocturnal light exposure and may contribute to the increased cancer risk among patients with chronic sleep disturbance.^{223–225} Sleep disruption and abnormal circadian rhythms have been associated with impaired immune system-mediated tumor surveillance which may also increase cancer risk.^{226, 227} Obstructive sleep apnea (OSA) appears to confer an increased cancer risk, with higher rates associated with more severe nocturnal hypoxia.^{228–230} These findings implicate a link between sleep disturbance and cancer and highlight good sleep hygiene and treatment of sleep disorders as potential targets for cancer prevention.

Cancer treatment

Excessive daytime sleepiness and fatigue are associated with increased plasma cytokines, such as IL-6. A good night's sleep can decrease the levels of this cytokine. Inflammatory mediators produced by specific cancer interventions or the cancer itself may exacerbate sleep disruption. For example, chemotherapy regimens used to treat breast cancer may induce elevations in VEGF which is associated with disturbed sleep.²³¹ Sleep loss and, in particular, loss of rapid eye movement (REM) sleep are known to be hyperalgesic. Thus, reduced sleep conditions, including REM sleep deprivation, which is common in many cancer patients, confer increased sensitivity to pain.²³²

Primary sleep disorders, including restless leg syndrome and periodic leg movement disorders, are often associated with insomnia and daytime hypersomnolence. These disorders are more common among certain cancer subgroups, perhaps due to chemotherapy-related anemia and peripheral neuropathy.²³³ The OSA syndromes may also be more prevalent in certain cancers. In a study of 56 patients with tumor of the head and neck region, 84 percent met clinical criteria for OSA ([Figure 11](#)).²³⁴ Opioids are known to worsen symptoms of central sleep apnea. This form of sleep-disordered breathing may be problematic in cancer patients, as many are on opioid medications for cancer-related pain.²³⁵

W = awake; N1, N2, N3 = sleep stages

Figure 11 76-year old man who presented with loud snoring, witnessed apneas, and daytime hypersomnolence 9 years following completion of chemoradiation therapy for tonsillar squamous cell carcinoma. BMI at presentation was 22 kg/m². Severe obstructive sleep apnea–hypopnea syndrome with an apnea–hypopnea index of 32 events/hour of sleep and an oxygen saturation nadir of 72% was observed on polysomnography (5 min view).

Chronobiology and chronotherapy attempt to optimize the effects of cancer chemotherapy while minimizing toxicity by taking advantage of the differences in the circadian rhythm of the cell cycle of tumor cells versus host tissues. Clinical and animal studies have shown that dose intensity can be increased while simultaneously reducing toxicities and improving treatment outcomes.^{236, 237}

Cancer survivorship

Disturbed sleep, fatigue, and insomnia may occur in up to 51% of some cancer survivors.²³⁸ Cognitive and behavioral therapy (CBT) is the treatment of choice for insomnia and have been shown to improve symptoms of insomnia, decrease sedative-hypnotic medication use, and quality of life. CBT can also impact immune function in cancer patients by increasing levels of IL-1 β and γ -interferon, which are thought to promote sleep.²³⁹

Pulmonary rehabilitation

Pulmonary rehabilitation (PR) represents a multidisciplinary strategy that incorporates exercise training, patient and family education, psychosocial and behavioral interventions, and outcome assessment in the management of patients with chronic respiratory diseases. Evidence-based support for PR in the care of patients with COPD has led to the implementation of this treatment strategy as standard of care in the management of this group of patients. The systemic effects and comorbidities associated with cancer, in particular, fatigue, dyspnea, anemia, skeletal muscle impairment, muscle wasting, poor exercise intolerance, depression, deconditioning, and anxiety, add substantially to the burden of the disease. PR targets many of these symptoms, resulting in reductions in symptoms of dyspnea and fatigue, and improvements in exercise tolerance and quality of life. Poor exercise tolerance confers worse surgical outcomes following lung resection and limits the ability to withstand the potential toxicities of chemotherapy.^{240, 241} Thus, the rationale for providing PR to patients with cancer is quite strong,

particularly in the setting of lung cancer, where COPD and lung cancer often coexist. Recent small studies suggest that PR may impact lung cancer management favorably by improving a variety of clinically meaningful outcomes, such as performance status, chemotherapy-related fatigue, oxygen consumption, exercise tolerance, and health-related quality of life.²⁴² In a study by Bobbio and colleagues, an increase in work rate and oxygen consumption (VO_{2max}) following a 4-week course of preoperative PR permitted patients who were considered nonoperative based on presurgical VO_{2max} to undergo successful lung resection surgery.²⁴³ In other investigations, improvements in exercise endurance, muscle strength, and dyspnea scores following 6–8 weeks of postsurgical PR have led to reduced hospital stay and increased quality of life among patients that underwent thoracotomy and resection for lung cancer.^{243–248} In the nonsurgical setting, several small reports have suggested a beneficial role for PR in countering chemotherapy- and radiotherapy-related fatigue, ameliorating performance status, and reducing the length/frequency of hospitalizations among patients with cancer.^{249–252}

Acute respiratory failure

Acute respiratory failure (ARF) is the most common reason for ICU admission among adult patients with cancer. Predisposing conditions for both acute and chronic respiratory insufficiency in cancer patients can be divided into those that cause “lung” failure or “pump” failure. Lung failure is typically associated with ventilation/perfusion abnormalities, shunts, or alterations of alveolocapillary diffusion and leads primarily to hypoxia, at least in its early stages. A classic example of lung failure is ARDS. Lung failure may also develop in the absence of ARDS as a consequence of ventilation/perfusion mismatch associated with pneumonia, atelectasis, or PE or as a result of shunt associated with pulmonary edema. Other common causes of lung failure are listed in [Table 4](#). Pump failure, by contrast, results from primary failure of alveolar ventilation and leads to severe hypercapnia and acidosis with only mild hypoxemia. Multifactorial causes of ARF, such as severe COPD exacerbation with superimposed pneumonia, may lead to both lung and pump failure. This mixed picture is a common occurrence in the cancer patient and requires a systematic approach to each component of respiratory failure to devise appropriate treatment strategies.

Table 4 Lung versus pump failure in acute respiratory failure: characteristics and underlying causes

	Lung failure	Pump failure
Characteristic features	Hypoxemia	Severe hypercapnia and acidosis Mild hypoxemia
Pathogenesis	Ventilation/perfusion mismatch Shunts Alterations in alveolocapillary membrane	Exhaustion of ventilatory pump (CNS, PNS, or respiratory muscles)
Underlying conditions	Acute lung injury/ARDS Pneumonia Atelectasis Pulmonary embolism/tumor emboli Lymphangitic spread of tumor Chemotherapy Radiation therapy Pulmonary leukostasis Transfusion-related lung injury Postoperative respiratory insufficiency	Coexisting COPD Intrinsic or extrinsic airway compression Obstructive sleep apnea associated with head and neck malignancy

CNS, central nervous system; PNS, peripheral nervous system.

Causes of pump failure

Central nervous system disorders: impaired drive

Isolated central depression of ventilatory drive is a rare cause of pump failure that may result from insults to the central nervous system, such as medullary tumors or infarction and sedating or narcotic medications. Acquired central hypoventilation may occur following neurosurgical procedures for brainstem tumors, particularly those that are close to the fourth ventricle. Radiation to the base of the skull may have similar adverse effects. Occult hypothyroidism may also contribute to central hypoventilation and ventilatory failure, particularly in elderly women and following treatment for head and neck carcinoma. More often, respiratory failure owing to depressed central drive occurs as an additional insult, superimposed on chronic respiratory insufficiency. In this setting, small doses of narcotic or sedating medications may have a profound effect on alveolar ventilation. Respiratory muscle fatigue may also contribute to central hypoventilation by sending inhibitory signals to the respiratory center in the CNS to reduce drive, thereby protecting the muscles from injury and mitigating further muscle fatigue.

Peripheral nervous system disorders: inadequate neuromuscular competence

Transmission of signals from the CNS to the respiratory muscles occurs via the spinal cord and peripheral nerves. Hence, conditions causing neuromuscular dysfunction, such as primary neurologic diseases, spinal cord lesions, neuromuscular blocking drugs, and muscle weakness, may precipitate ventilatory failure. Systemic anesthetics cause potent neuromuscular blockade and ventilatory depression. Other agents, including sedatives, anxiolytics, hypnotics, and aminoglycosides, typically produce severe respiratory depression only in the setting of preexisting neuromuscular diseases such as myasthenia gravis and

myasthenic paraneoplastic syndrome or after massive overdose. One exception to this principle is methadone, which may cause ventilatory insufficiency with chronic administration. Muscle fatigue, a pervasive problem in the cancer setting, is central to the development of respiratory failure. An extensive list of factors may potentiate cancer-related muscle fatigue, including hypoperfusion states (cardiogenic, septic, or hemorrhagic shock), excess lactate or hydrogen ion production, severe anemia, and, thereby, respiratory failure. Malnutrition and cachexia are well-known complications of advanced cancer. One of the most relevant manifestations of cancer cachexia is muscle wasting, which contributes to markedly depressed strength and endurance of the skeletal muscles, including the diaphragm.²⁵³ Overinflation of the thorax and flattened diaphragms associated with COPD, a common comorbidity of lung cancer, further contribute to compromised respiratory muscle performance and ventilatory failure. Electrolyte disturbances such as hypophosphatemia, hypokalemia, and hypomagnesemia frequently complicate chemotherapy and may cause profound muscle weakness in the cancer patient. In addition, many of the drugs used in the treatment of ventilatory failure, including beta-agonists, diuretics, and corticosteroids may exacerbate hypophosphatemia and aggravate muscle weakness. Chemotherapeutic agents and other drugs used in cancer treatment may also have deleterious effects on the neuromuscular system. Although corticosteroid-induced myopathy has been well described, the role of these drugs in potentiating respiratory muscle dysfunction has been recognized only recently.^{254, 255} Among the chemotherapeutic agents, vinca alkaloids, cisplatin, and the taxanes are most frequently associated with peripheral neurotoxicity. The clinical manifestations of these drugs on lung function may be subtle in the absence of predisposing factors, such as preexisting neuromuscular abnormalities. In addition to their CNS effects, the use of anesthetic agents, in particular halothane, propofol, and nitrous oxide, may induce respiratory depression by decreasing diaphragmatic contractility.^{256, 257} Injury to the phrenic nerve following surgery for head and neck cancer or surgery to the anterior mediastinum, esophagus, or lungs may cause persistent diaphragmatic dysfunction and ventilatory failure. Loss of diaphragmatic function from direct phrenic nerve invasion by tumor may also be seen, particularly among patients with lymphoma or cancers of the lung or head and neck. Diffuse neural dysfunction resulting from paraneoplastic syndromes is another cause of respiratory failure in the cancer setting. Lambert–Eaton myasthenic syndrome, which affects about 3% of patients with small-cell lung cancer, myasthenia gravis, which occurs in 10–15% of patients with thymoma, and demyelinating peripheral neuropathy, seen in 50% of patients with the osteosclerotic form of plasmacytoma, are the most common types of paraneoplastic disorders of the peripheral nervous system. These disorders typically have a subacute and debilitating course that may lead to ventilatory failure.

Increased work of breathing: increased respiratory system load and chest wall abnormalities

A variety of cancer-related factors may result in acute or chronic escalations in the respiratory system load. Elevations in airway resistive workloads, characterized physiologically by abnormal airway resistance and increased elastance, are cardinal features of COPD, airway inflammation, airway edema, or physical obstruction by mucous, blood, or tumor. Upper airway obstruction caused by tracheal stenosis associated with prior intubation or radiation to the head and neck and intubation with a small (<7.5 mm internal diameter) endotracheal tube contributes significantly to increased airflow resistance and respiratory failure. Abnormalities involving the chest wall and thoracic spine caused by tumor, radiation, or surgery may cause increased chest wall elastic loads, increased work of breathing, and respiratory failure.

Lung failure(pulmonary edema, ARDS, ALI)

Pulmonary edema/acute respiratory distress syndrome/acute lung injury

The predilection for pulmonary edema in the setting of cancer arises from a broad array of insults to the lungs that may be sorted according to the underlying permeability characteristics of the microcirculation and the presence or absence of DAD histopathologically. In normal permeability pulmonary edema, increased hydrostatic pressure caused by an imbalance in Starling forces leads to fluid filtration into the lungs. Pulmonary edema of cardiogenic and neurogenic etiologies, as well as lung edema caused by lung reexpansion, lymphatic obstruction, and relief of upper airway obstruction, are typically associated with normal microvascular permeability.

The histopathologic hallmark of increased microvascular permeability is the accumulation of proteinaceous fluid within the interstitium and alveoli resulting from a breach in the integrity of the alveolar and microvascular surfaces. Increased permeability pulmonary edema, occurring in the absence of DAD, is referred to as capillary leak syndrome. In the cancer setting, this type of pulmonary edema may occur following the administration of cytokines such as interferon, IL₂, and TNF, which disrupt capillary endothelial integrity. These drugs may also cause direct toxicity to the myocardium, resulting in mixed or overlap edema associated with normal and increased permeability etiologies. Neurogenic and reexpansion pulmonary edema represent two other causes of mixed edema, which are observed frequently in the cancer setting. The frequent need for transfused blood products (packed red blood cells, platelets, and granulocytes) in the cancer setting predisposes the cancer patient to the syndrome of transfusion-related lung injury (TRALI), another form of NCPE. PH with normal left ventricular end-diastolic pressures is also a cardinal feature of this syndrome. The treatment is supportive. Resolution of clinical symptoms and radiographic changes typically occurs within 2–3 days of symptom onset without permanent pulmonary sequelae, although in 20% of patients, symptoms and radiographic changes may persist for a week and may be associated with lung injury (ALI/ARDS—see following text).^{258, 259}

ALI and ARDS are terms used for varying severity of pulmonary edema accompanying the histopathologic finding of DAD. ARDS is reserved for severe lung injury in which bilateral pulmonary infiltrates and severe hypoxemia (as defined by a ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen < 200) occur in the absence of clinical evidence of left atrial hypertension.²⁶⁰ ALI is reflective of a lesser injury, as indicated by a PaO₂/FiO₂ ratio between 200 and 300. The list of cancer-related precipitating conditions associated with ARDS is extensive. An etiological dichotomy that sorts the causes of ARDS into conditions that provoke direct lung injury (pneumonia, gastric aspiration) and those that are associated with systemic diseases that promote indirect lung injury (sepsis, TRALI) provides a simplistic approach to ARDS but is confounded by inciting events that are often multifactorial or unknown. Clinically, patients may present with ARF and associated hypoxemia within 24–48 h of the predisposing event. Fever and leukocytosis, owing to the inflammatory response associated with lung injury, may be prominent findings, even in the absence of infection. Although the radiographic changes in ARDS are not distinctive, the chest X-ray is important, nonetheless, in ruling out competing diagnoses such as pneumothorax, infections, and congestive heart failure. Patchy areas of lung involvement may be seen as ground glass opacifications early on which may progress to diffuse areas of consolidation. Radiographic findings suggestive of cardiogenic pulmonary edema such as Kerley B lines, cardiomegaly, and apical vascular redistribution are typically absent. Progression to the fibroproliferative phase is common, resulting in persistent hypoxemia associated with poor lung compliance, increased dead space, V/Q imbalance, and PH.

Management of respiratory failure

Medical therapy

The management of the critically ill cancer patient with respiratory failure involves aggressive supportive care as well as strategies that target the precipitating cause. Standard supportive measures include the provision of supplemental oxygen, inhaled bronchodilators, nutritional support, chest physiotherapy, and pulmonary toilet and the prudent use of diuretics, vasopressors and antibiotics, where indicated. Although fluid loading augments oxygen consumption and tissue oxygen delivery, careful attention to fluid homeostasis is imperative, as a persistent positive fluid balance has been associated with a poor outcome.^{261, 262} More specific interventions, such as administration of helium–oxygen (heliox) mixtures, may provide temporary relief of acute respiratory distress associated with proximal airway obstruction and serve as a bridge to more definitive therapy. Patients with DAH may benefit from the early use of high-dose steroids, DDAVP, and aggressive blood and blood product support.²⁶³ Recombinant factor VII (rFVIIa) and antifibrinolytics such as aminocaproic acid have been used to treat transplant-related DAH, although convincing evidence supporting this practice is not available.^{264–266} The effect of activated protein C administration in reducing sepsis-related ARDS mortality has been exciting; however, conflicting results in subgroup analysis and concerns regarding serious bleeding have led to removal of this from the market.^{267–269}

Advances in supportive care coupled with early identification and management of precipitating condition(s) and strategies that attenuate ventilator-associated lung injury have contributed to significant increases in ARDS-related survival rates over the past decade.²⁷⁰ Several trials of high-dose corticosteroids for early-phase ARDS failed to demonstrate a survival benefit. A salutary effect of high-dose glucocorticoids given during the fibroproliferative phase of ARDS was suggested in several small studies, though not borne out in a large, multicenter, NIH-sponsored (ARDS-Net) trial.^{271–274}

Mechanical ventilation

Noninvasive ventilation (NIV)

Assisted ventilation is often required to manage ARF that is nonresponsive to conservative medical therapy. Newer modes of mechanical ventilation as well as the use of noninvasive ventilation (NIV) have shown promising results and gained broad acceptance in the management of cancer patients with respiratory failure. The efficacy of NIV has been clearly demonstrated in several randomized, controlled studies in the management of pump failure^{275, 276} as well as selected cases of lung failure.²⁷⁵ In a recent retrospective study of the outcome of cancer patients following ICU transfer for ARF, the use of NIV was associated with marked improvements in patient survival.²⁷⁷ In addition, significant reductions in the need for conventional mechanical ventilation and declines in both ICU and post-ICU hospital mortality have been linked to the use of intermittent NIV during the early stages of hypoxemic ARF ($\text{PaO}_2/\text{FiO}_2$ ratio <250).^{278–280} Evidence favoring the early use of NPPV for ARF among immunocompromised patients is derived from several small studies which purport reduced rates of endotracheal intubation, length of ICU stay, and ICU mortality.^{278, 281, 282} Immunocompromised patients with respiratory failure who require mechanical ventilation have notoriously poor prognoses, with an estimated 1% increase of risk for pneumonia per day of mechanical ventilation.²⁸³ Thus, NIV in this setting has quickly gained broad acceptance in the management of cancer patients with respiratory failure.

Invasive mechanical ventilation (IMV)

Intermittent mandatory ventilation remains the standard of care for severe ARF and for NIV treatment

failures. Overdistension of the lungs at end-inspiration and repetitive collapse of the lungs at end exhalation that occurs with conventional mechanical ventilation at high tidal volumes may trigger further lung injury. This observation prompted the development of lung-protective ventilator strategies that mitigate alveolar overdistension and enhance recruitment of atelectatic alveoli, thereby reducing the incidence of ventilator-induced lung injury. Lung-protective ventilator strategies may be accomplished with conventional modes of ventilation such as assist-controlled and pressure-controlled ventilation with or without inverse ratio ventilation or alternative methods, such as biphasic positive airway pressure ventilation (BIPAP), airway pressure release ventilation (APRV), jet and high frequency oscillatory ventilation, and differential lung ventilation. None of these modes of ventilation have proven to be superior to conventional ventilatory strategies. Convincing evidence favoring the use of protective ventilator strategies is derived from the National Institutes of Health ARDS Network trial where lower tidal volumes (6 mL/kg of predicted body weight) and limited static inspiratory pressures (<30 cm H₂O) resulted in a 22% improved survival compared to patients mechanically ventilated using higher tidal volumes and inflation pressures.^{284, 285} Other adjuncts to ventilator management of patients with ARF, including extracorporeal membrane oxygenation (ECMO) and partial liquid ventilation (PLV), prone positioning, and surfactant instillation, have been proposed; however, the merits of these therapies over conventional treatment strategies have not been proven definitively. Early tracheostomy may be associated with improved outcomes in critically ill patients. Practice guidelines regarding the appropriate timing of tracheostomy in patients that require prolonged mechanical ventilation are based on a consensus statement, nearly two decades old, that suggested that tracheostomy be considered after 21 days of mechanical ventilation. Although these recommendations were based only on expert opinion, modern practice broadly continues to follow them. In a recent meta-analysis, an 8.5 day decrease in total mechanical ventilation days and significant reduction in ICU length of stay was seen among patients that underwent early tracheostomy (within 7 days of initiation of invasive mechanical ventilation) compared to those in which tracheostomy was performed late, although mortality was not altered significantly.²⁸⁶

Respiratory failure outcomes

The mortality rate of critically ill cancer patients with respiratory failure is at least threefold higher than that of concurrently admitted cancer patients without respiratory failure.^{287–289} Conditions common to the critically ill cancer patient, such as cardiac, renal, or hepatic dysfunction, disseminated intravascular coagulation, hemodynamic instability, and the need for mechanical ventilation, are independent predictive variables that portend a poor outcome.^{287, 288, 290} Early reports documented mortality rates in excess of 90% among mechanically ventilated cancer patients with ARF, especially among patients with hematologic malignancies and recipients of hematopoietic transplants.^{291–294} More recent investigations have offered a more favorable perspective, with mortality rates of 69–84%.^{288, 289, 295, 296} Survival gains may be attributable to better infection prophylaxis measures, improved transplantation techniques, standard use of preventive measures that mitigate aspiration, more aggressive use of hematopoietic growth factor support following transplantation, and trends toward the use of peripheral stem cells rather than bone marrow as a source of donor stem cells. In addition, the newer ventilation strategies including NIV and lung-protective ventilator strategies may play a role in improved survival.²⁸⁹ Finally, the implementation of programs for early identification and management of deteriorating patients on general hospital wards and improvements in ICU admission and triage criteria may not only contribute to overall improved ICU survival but also to the appropriate use of hospital resources.^{297, 298}
