To ascribe a finding to cancer requires proof. Modern medical oncologists will need to both understand the histologic appearance of malignant and premalignant lesions and be able to understand the interpretation of complex profiles of nucleic acid sequences (DNA and RNA), gene transcription and protein translation, as well as chromosomal abnormalities to properly diagnose and manage their patients. These advances will lead to an even greater number of individuals who know that they are at risk of developing cancer, living with a diagnosis of cancer, or putatively cured of cancer but are concerned about recurrence due to the presence of minimal residual disease. It is an exceptional case when a medical oncologist can consider treatment without a firm diagnosis. Certain oncologic emergencies, such as spinal cord compression or superior vena cava syndrome, were once considered exceptions, but with modern imaging and biopsy techniques, a tissue diagnosis can usually be made rapidly and safely. Cytologic diagnoses may provide sufficient information in the presence of unambiguous clinical syndromes, but cytology of the bronchus, stomach, cervix, and body fluids has produced sufficient numbers of false-positive identifications to show that corroborating evidence is essential. The use of circulating tumor cells and free tumor DNA can aid in diagnosis and monitoring of patients, but as yet these surrogates have not been fully validated. Highly specific biochemical and molecular markers may be helpful when clinical and radiologic findings are characteristic and when a major intracavitary (cranial, thoracic, or abdominal) biopsy procedure would constitute an ominously serious event for a particular patient. It is always preferable to have histologic evidence whenever possible.

The management of cancer patients requires an understanding of the genetics, biology, and pharmacology of neoplasia and the psychosocial impact of a cancer predisposition or diagnosis on patient and physician

The practice of medical oncology requires wisdom, sensitivity, and resourcefulness. For the patient in whom relatively asymptomatic findings lead to a diagnosis of cancer, it is useful to consider that the day before the discovery, the patient was living with cancer. It is a source of some encouragement to patients to know that a diagnosis of cancer does not lead immediately or inevitably to death. The medical oncologist may be able to stress the long-term evolution of a cancer, the several stages that intervene between the carcinogenic stimulus, genetic mutations, selection of cells with a survival advantage, and the appearance of an autonomous neoplasm. Because this process usually takes years and often decades, it is

of value to place the neoplastic process in perspective (vide infra). This is particularly important when a patient is being urged to make an immediate decision regarding surgery, radiation, or chemotherapy. When one considers that, on average, it will take more than 5 years for a malignant cell to undergo the requisite 30 doublings to achieve a 1 cm mass (one billion cells) required for most diagnoses, an additional week or two to gather information and opinions is unlikely to have a negative impact on the ultimate course of the disease. In contrast, the situation with certain malignancies such as acute myelogenous leukemia requires immediate action as the diagnosis is made when the near-fatal 10^{12} malignant cells exist.

Increasingly, individuals are recognized to harbor genetic predispositions to cancer owing to subtle genomic and epigenomic alterations. The oncologist must combine an understanding of the impact of these changes on the probability of being diagnosed with cancer and weigh the risks and benefits of medical intervention while being sensitive to the emotional impact that this knowledge has on individuals and their families. In some, cancer or the prevention of cancer may become a chronic process requiring ongoing treatment analogous to the management of diabetes or hypertension. Similarly, oncologists must recognize environmental exposures that increase the risk of cancer and attempt intervention to mitigate that risk.

The medical oncologist must distinguish between a neoplasm in which a chance for cure exists versus one that is currently incurable (precurable). Most cancers are curable if detected early, and most cancers are incurable if detected late. Whereas the former is likely to be driven by few genomic alterations and confined to one or two critical pathways, the latter is likely to harbor multiple changes in several pathways that make successful treatment less likely. The medical oncologist must therefore appreciate the importance of prevention, screening, and early detection and must actively educate colleagues and patients.

Advances in our understanding of cancer biology encourage the belief that one day all cancers will be prevented or cured. It is axiomatic that the day before the first metastatic choriocarcinoma was cured with high-dose methotrexate,^{3, 4} metastatic cancer, in general, was considered incurable by most observers. Similar considerations apply to every neoplastic disease that is now curable ([Table 2](#)). Other neoplasms are currently not cured by medicines alone but require participation of surgery or radiotherapy as an intrinsic part of the therapeutic process ([Table 3](#)).

[Table 2](#) Cancers curable with chemotherapy

Choriocarcinoma
Acute lymphocytic leukemia of childhood
Burkitt's lymphoma
Hodgkin's disease
Acute promyelocytic leukemia
Large follicular center cell lymphoma
Embryonal carcinoma of testis
Hairy cell leukemia

Table 3 Cancers subcurable with chemotherapy^a

With regional therapy
Wilms' tumor
Osteosarcoma
Ewing's sarcoma
Embryonal rhabdomyosarcoma
Adenocarcinoma of breast
Small cell carcinoma of lung
Squamous cell carcinoma of upper aerodigestive tract ¹
Adenocarcinoma of ovary
Thymoma without regional therapy
Acute lymphocytic leukemia of adulthood
Acute myeloid leukemia
Lymphomas, some subsets

^a By definition, <50% curable with chemotherapy alone; cure rates obtained with chemotherapy plus regional therapy are significantly superior to those with regional therapy alone (i.e., chemotherapeutic cure of micrometastatic disease only).

^b Cure rates <50% in most series.

Patients are often influenced by their present state of subjective well-being. It is the responsibility of an oncologist to recognize the often pernicious behavior of cancer in its potential for recurrence and metastasis. In this context, the medical oncologist must interact directly with the patient and family, as well as with the medical record, films, slides, and other critical raw data. It is important to understand how patients make choices so as to present information in a way that does not bias an eventual decision. In addition, there is an opportunity to alter behaviors of patients and their families at the time of a cancer evaluation.⁵ For example, following a “scare” that a lung nodule could have been malignant may be the best time to treat nicotine addiction in the patient and in members of the family. The diagnosis of cancer constitutes a serious emotional burden that may distort ordinary reason. By firsthand intimacy with the diagnosis, the extent of the disease, and the patient's attitudes and infirmities, the medical oncologist can make rational recommendations to the patient and to the other physicians involved.

Explanations of disease, anticipated therapies, randomized protocols, and unknowns must be tailored to the intellectual and emotional levels of the particular patient. It is never permissible to lie, but it may be prudent not to deposit all of the truth at once on a patient who cannot accept the full details and ramifications of diagnosis and management. “Your patient has no more right to all the truth you know than to all the medicine in your saddle-bags” was a humane and ethical tenet advanced by Oliver Wendell Holmes more than a century ago.⁶ It is dishonest to twist facts or to deny specific features, such as the existence of metastases. It is also wrong to deny a patient an opportunity to make final dispositions with respect to self, family, religion, the law, and business by falsely stating that a disease is benign or cured. Families who assert that the patient must not know because the patient could not stand it are usually twice wrong: the patient often knows already or may be more distraught by being excluded from knowing, and the patient ordinarily incorporates the information into his or her life equation indistinguishably from other patients. A reading of Tolstoy's masterful *The Death of Ivan Ilyich* should convince any doubting oncologist about the terror of uncertainty and the value of direct and honest, yet humane, interactions with

the patient. When a patient asks, “There is hope, isn't there?” the oncologist can always be positive. Hope is a uniquely human characteristic that sustains the will to continue, and all oncologists and all patients do hope for a better outcome.

The treatment of patients with life-threatening disease can take its toll on providers of care. A sense of frustration can affect anyone who encounters barriers to successful completion of an important task. This is particularly true of intellectual tasks and invisible barriers. When the barrier is a lethal disease about which the oncologist can do little that is effective, the frustration can be all consuming. Oncologists who encounter several instances of recrudescence or refractory disease in a short time (especially if punctuated by the deaths of young or favorite patients, uninterrupted by counterbalancing compensatory successes) may well experience frustration, a sense of inadequacy, and depression. Frequent repetition of this cyclic phenomenon may lead to burnout.

The medical oncologist knows that many of today's cancers are not yet curable. To the extent that the medical oncologist can be involved, actually and conceptually, in the solution to these complex mysteries, the frustration is lessened. Cancer research, whether at the basic or the clinical level, is held in high esteem by our fellow citizens. Group identity, “being one of the team,” helps offset the self-deprecation when human tragedies mount despite one's best efforts. The camaraderie of other oncologists helps because they battle the same enemy with the same primitive weapons. Another oncologist can understand the trauma and the distress; it is an encounter on familiar terrain.

The appreciation that the horizon is distant, and that oncologists are all working intently to see beyond it, puts present frustration in a more appropriate perspective. Involvement in the systematized academic pursuit, whether in an academic setting, a medical school outreach, an oncology society, or a local collaborative group, provides the security of collegial support. A sound mind in a sound body implies rest, exercise, nutrition, and enjoyment. To ensure the last, the first three are prerequisites. Avocation and vacation are a portion of good mental health, included in the terms rest and exercise.

Finally, all oncologists can benefit from the vast array of continuing medical education programs given at academic medical centers, on the World Wide Web, at national meetings such as the American Association for Cancer Research and the American Society of Clinical Oncology, the American Society of Hematology, and through textbooks such as *Cancer Medicine*.

Prevention is more effective than treatment

The seminal work of Dr. Bert Vogelstein of John Hopkins Medical School demonstrated that as a normal epithelium transforms through dysplasia, anaplasia, and, eventually, neoplasia, that there is a progressive increase in genomic alterations, a process that may take many years.⁷ Similarly, as chronic myelogenous leukemia progresses from the chronic phase, through the accelerated phase to blast crisis, more chromosomal and genetic abnormalities are acquired. Exposure to environmental carcinogens, most commonly through tobacco use owing to nicotine addiction, accelerates the oncogenic process most prominently in the bronchial mucosa. These nucleic acid changes can activate complex signaling pathways that favor cell viability and inactivate pathways that normally balance uncontrolled growth through mechanisms of cell death. Not surprisingly, many of these molecular changes impart resistance to cancer treatment. It follows that the earlier a cancer is diagnosed and treated, the more effective the treatment. Furthermore, the oncogenic process provides substantial time for interventions that could prevent the formation of cancer in susceptible individuals, so-called disease interception.

Inhibition of cyclooxygenases within the intestinal epithelium with nonsteroidal anti-inflammatory drugs prevented many cases of colorectal cancer.^{8,9} Hepatitis B vaccines dramatically reduced the incidence of

hepatoma, once the Eastern world's most common malignancy, by preventing the chronic inflammation and cellular damage produced by chronic hepatitis.¹⁰ New curative treatments for hepatitis C should also decrease the burden of hepatocellular carcinoma.¹¹ Retinoic acid can decrease the appearance of second malignancies in heavy smokers¹²; tamoxifen and raloxifene can prevent breast cancer in patients at substantial risk.¹³ Minor surgical interventions, such as colonic polypectomy¹⁴ and loop electrosurgical procedure for carcinoma *in situ* of the cervix,¹⁵ can prevent colon and cervical cancer, respectively.

Increasingly, the medical oncologist will be called on to decide whether medical or surgical prevention is indicated in individuals without cancer but for whom cancer is a significant risk. This will ultimately extend to subtle genetic abnormalities, such as single nucleotide polymorphisms and circulating biomarkers. In addition, the use of preventive drugs will require long-term monitoring if used each day for years. Currently, the medical oncologist is asked to decide who should receive tamoxifen for prevention of breast cancer, retinoids for prevention of head and neck cancer, and oral contraceptives for prevention of ovarian cancer. Medical oncologists frequently advise patients regarding the benefits of prophylactic oophorectomy and mastectomy in patients with *BRCA1* and *BRCA2* mutations. Similarly, oncologists must be aware that the hepatitis B vaccine will prevent hepatoma, and a vaccine against human papillomavirus will prevent many cases of cancer of the uterine cervix.¹⁶ The oncologist must take a leading role in treating addiction to nicotine in all of its manifestations and must educate physicians and the public on the importance of early detection through appropriate screening.

Medical oncologists should counsel patients and families about good nutrition and healthy sexual practices as well as screening tests available for some cancer types. Several chapters of this treatise deal with prevention and early detection, and numerous publications that deal with these topics are available for distribution to patients and families from the National Cancer Institute (NCI) and the American Cancer Society (ACS). The NCI Cancer Information Service (800-4-CANCER) and the ACS National Cancer Information Center (800-ACS-2345) will send available publications free of charge and publish this information on their web sites.

Cancer therapeutics is evolving

The origins of cancer chemotherapy began with the observation that mustard derivatives such as mechlorethamine could treat patients with lymphoma, evolved through targeting biochemical pathways involved in DNA synthesis (antimetabolites) and microtubule function (vinca alkaloids and taxanes), through combination chemotherapy to the era of targeted therapies. These new medications are likely to be less toxic than traditional cancer chemotherapy drugs that most commonly target DNA or microtubules. The proper use of the new-targeted therapies will require an understanding of the molecular pathways responsible for malignancy in general and possibly in each individual's tumor. Recent examples include imatinib to inhibit the transforming oncogenic protein in chronic-phase chronic myelogenous leukemia (*Bcr-Abl*)¹⁷; gefitinib to effectively treat patients with nonsmall cell lung cancer by targeting those individuals whose tumors harbor activating mutations in the epidermal growth factor receptor (EGFR)¹⁸; erlotinib to extend survival in patients with nonsmall cell lung cancer¹⁹; trastuzumab to treat metastatic breast cancer in patients whose cancers have amplification of the HER2/neu oncogene²⁰; cetuximab to treat colorectal cancers by targeting the EGFR²¹; bevacizumab to treat colorectal cancer by targeting the vascular endothelial growth factor receptor and blocking angiogenesis,²² and vemurafenib to inhibit mutant BRAF in patients with melanoma.²³

Today, we are in the modern era of immuno-oncology, which began with the pioneering work of Dr. Steve

Rosenberg at the NCI who demonstrated that certain T-cell subsets could be harnessed to treat refractory melanoma and renal cell carcinoma.²⁴ Today, with the advent of immune check point inhibitors (e.g., ipilimumab), the medical oncologist is faced with a new set of therapeutic challenges based on autoimmune side effects that require additional skills to manage.

In addition, one must appreciate the importance of drug resistance and recognize it when it occurs. When choosing treatment for recurrent disease, one should consider the likely cross-resistance to several natural products owing to the multidrug resistance phenotype mediated by the adenosine triphosphate-binding cassette family transporters [(e.g., P-glycoprotein, MRPs (multidrug resistance proteins))], the low probability of response to drugs of the same drug class (e.g., taxanes), or sequential hormonal therapies when selecting drugs with the same mechanism of action (e.g., aromatase inhibitors). Furthermore, the medical oncologist be familiar with mutations within drug targets that lead to either sensitivity or resistance to a given class of drug, for example, EGFR inhibitors, bRAF inhibitors, abl inhibitors, and inhibitors of BTK (Bruton's tyrosine kinase) to name a few.

Treatment of cancer patients includes the use of drugs for host support. The effects of the tumor and its products on the structure and function of the patient's normal tissues, as well as the mind and emotions, define an understanding of the disease process and of the patient in whom it takes place. It is not sufficient to order a therapy with the appropriate dose and schedule. There must be a broad understanding of and attention to potential toxicities, which represent the drug's effects on normal tissues. A medical oncologist should understand the interaction of the administered drug with target molecules present in normal tissues and the potential for drug-drug interactions to avoid unnecessary toxicities.

The availability of effective antibiotics and the use of platelet transfusions were intrinsic to early cures of the acute leukemias. Colony-stimulating factors (filgrastim and sargramostim) have significantly altered the prospect of drug-induced granulocytopenia, and recombinant erythropoietin can diminish drug-induced anemia. Means to ameliorate thrombocytopenia, other than with platelet transfusions, are now available.

The use of cytokines to collect circulating hematopoietic progenitor (CD34) cells enabled the convenient collection of marrow-repopulating precursors, allowing autologous stem cell transfusions to substitute for autologous marrow transfusion. New antibiotics make granulocytopenia less ominous, and oral prophylaxis with antibiotics and antifungal agents has decreased hospital admissions. These assets allow chemotherapy to be given more safely at the intended dose and schedule without delay or dose reduction.

The availability of highly effective antiemetics makes cancer chemotherapy less dreaded than in the past. The emergence of psycho-oncology as a widely appreciated discipline has also made it possible for patients to strengthen their resolve to undertake approaches aimed at cure or to accept the unlikelihood of cure with greater serenity.

Intravenous medications that may be toxic to the venous wall, and vesicant if extravasated, require the use of central venous access. When venipuncture is difficult because of anatomy or obesity, repeated needle sticks and much time are wasted in attempting peripheral cannulation. Needle phobia is a perverse part of being under treatment; establishing permanent venous access can largely obviate it.

Most patients with cancer are over the age of 60 and are receiving treatment for comorbid conditions. Therefore, care must be taken when prescribing treatments that could have dire drug interactions, leading to untoward side effects. No modern physician should be without ready access to the Internet for a compendium of drug interactions, drug descriptions, and appropriate methods of monitoring for efficacy and toxicity. A medical oncologist benefits from using an electronic medical record system that saves time and prevents errors through online calculation of dosing and electronic ordering. These systems also allow the creation of databases that can be queried for identification of trends and unexpected results.

Therapies that are totally appropriate for someone whose disease might be cured by judicious application of surgery, radiotherapy, and/or chemotherapy might be totally inappropriate when applied to another person with widely metastatic disease for whom no known cure exists. Therapy with curative intent may be toxic but of relatively short duration. On the one hand, conservatism aims at saving a life, not avoiding toxicity; on the other hand, treatment for palliative purposes would not ordinarily condone similar risks and iatrogenic effects that diminish the quality of life, even temporarily. The same is true for therapies aimed at cancer prevention because these may be taken by asymptomatic individuals for prolonged periods of time. The recent experiences with high-dose cyclooxygenase II inhibitors over long periods, which caused increased cardiovascular side effects in patients participating in one of two cancer prevention studies, resulted in serious consequences for the pharmaceutical manufacturers.²⁵

Certain principles govern the application of therapies, no matter what the disease. These were enunciated more than a half-century ago by Robert F. Loeb, Bard Professor of Medicine at Columbia University's College of Physicians and Surgeons. These simple rules have profundity and nearly universal applicability but must be tempered, however, by an understanding of the neoplastic process.

The first law is if what you are doing is “doing good,” keep doing it. It is implicit that a physician measures the effects of any intervention on both the tumor and the host. However, the lessons learned from the treatment of acute lymphocytic leukemia of childhood are noteworthy. For example, vincristine plus prednisone is an excellent induction treatment, but in 1968, a question was raised: why not keep administering this highly active induction regimen rather than shifting to antimetabolite management? A cohort of children who were induced into remission by vincristine and prednisone were randomized to continue the induction treatment or shift to the antimetabolite. They rapidly became resistant and relapsed, whereas those who were shifted to the antimetabolite experienced long-term sustained remissions and cures (Cancer and Leukemia Group B, unpublished data). Thus, the first law of therapeutics does not always apply to cancer for which sequential treatment regimens may have special importance. Much of curative oncology relates to the biology of the unseen tumor (minimal residual disease), for which the current clinical status may not be informative. The first law seems more applicable to clinically recognizable disease.

The second law of therapeutics states that if what you are doing is not “doing good,” stop doing it. Most therapeutic regimens have little chance of success if after 8 weeks of treatment they have failed to elicit therapeutic benefit. It is, nonetheless, advantageous to undertake a second month of treatment in most instances because a well-documented early increase in tumor diameter on radiographic examinations or increased pain can, indeed, be followed by tumor regression, notably for certain forms of hormonal therapy as well as immunotherapy. Before stopping treatment, corroborating information should be sought by direct measurements, biomarkers that include circulating tumor cells and circulating tumor DNA may aid in the decision to stop an ineffective treatment. Increased bony uptake of radionuclides can be a sign of bone healing, even of a previously unsuspected lesion, and is not a suitable end point. The appearance of a new metastatic deposit or the continued growth of a previously documented tumor despite treatment speaks against continuing that regimen.

Hippocrates' admonition, *Primum non nocere* (first do no harm), is also subject to careful cautious consideration in oncology.²⁶ Thus, the second law of therapeutics does not extend to toxic effects unless they are life-threatening or profoundly disabling. With many of the therapeutic agents available today, complete avoidance of toxicity would doom many patients to death from their neoplasm. Some patients can obtain cure, and more can achieve meaningful remission by accepting the transient effect of intensive therapy that kills tumor cells and normal cells alike. The patient almost always recovers, but the less resilient tumor may not. To treat a population of patients at so low a dose that it would avoid toxic harm

to any patient would surely exact a higher price in depriving others of adequate doses to achieve maximum benefit. Curative and subcurative cancer chemotherapy as well as newer immunotherapies, as we know it today, are often toxic but rarely fatal. Attempts to abrogate toxicity for all by reducing the dose of an established regimen might compromise benefit for the majority.^{27, 28} Dose adjustment for an individual may be necessary and prudent but must always be considered with respect to other means of mitigating toxicity without dose reduction.

The third law of therapeutics—"if you do not know what to do, do nothing"—counsels against uninformed action. In many circumstances, a rush to judgment or, worse, a rush to do something, anything, can be disastrous. Aside from oncologic emergencies and certain forms of leukemia, there is rarely an occasion when observing the evolution of symptoms and findings or seeking consultation with another individual for a fresh viewpoint is contraindicated because of time pressure. In the presence of pain, one should not delay pain relief, but other therapy may be delayed to build an informed formulation. In the presence of a differential diagnosis that includes diseases other than cancer, particularly infections, one must be certain that delay does not risk mortality or morbidity from the other possible disorders. Thus, the time invested for observation and consultation should not be extravagant. In circumstances where the benefits of existing treatment are poor or unknown, clinical trials should be a first consideration.

The fourth law of therapeutics is "never make the treatment worse than the disease." This relates to total life equation: the price the oncologist knows the patient may be obliged to pay in present side effects to attain future real effects. Often, the patient's vision is foreshortened because today's symptoms caused by drug toxicity can be more severe than the original complaints related to the cancer. The medical oncologist must ascertain the patient's attitude toward quality of life versus duration of life. It is a medical oncologist's responsibility to counsel the patient concerning this weighty topic. With the rapid appearance of new oncology products and numerous new types of treatments available through clinical trials, it is becoming increasingly difficult to distinguish therapy with curative intent from a palliative orientation, except in the extreme situations of newly diagnosed, low-stage and grade disease versus palliative care for the terminally ill. In all cases, the proper goal is maximal life at maximal quality. For some patients, the toxic effects of treatment outweigh the value of possible extension of life. This perception is often related directly to age. Pain and disability from cancer may temper the desirability of certain therapies, which offer only temporary and partial relief. It is not a kindness to defer death only transiently by rescuing a dying patient back to a raft of suffering. Heroic efforts are justified only when a meaningful therapeutic option exists.

It is inappropriate for the medical oncologist to substitute professional judgment for a patient's ardent wishes when the patient strives to accomplish something that is a reasonable therapeutic goal. The medical oncologist must serve as a bastion of reality, however, advising the patient of what is possible and of what is likely. In the course of doing this, the laws of therapeutics and of humanity always include hope.

Finally, the medical oncologist must remember that patients do not fail treatments; rather, treatments fail patients. The careless use of the former, inadvertently implies a disrespect for the patient and a lack understanding of the extremely fragile state of patients whose disease is unresponsive to treatment.

Early stage cancers are more curable than late-stage cancers; the first treatment is more effective than the next

As no method of prevention is likely to be completely effective, medical oncologists must recommend appropriate tests to detect cancer at its earliest possible stage. They include mammography, colonoscopy,

occult blood in the feces, digital rectal examination of the prostate, Papanicolaou smears, and examination of the skin and body orifices for signs of premalignancy, such as leukoplakia and dysplastic nevi. Soon, a variety of validated biomarkers will likely be available to identify early cancer or the presence of premalignancies, for example, ductal carcinoma *in situ*, prostatic intraepithelial neoplasia, colonic polyps, and cervical dysplasia. As described earlier, progression of cancer leads to the acquisition of changes in the host and the cancer genome that select for cell survival over cell death. Many of these changes allow tumor cells to exist in harsh environments characterized by hypoxia and a low pH. These same changes produce tumor cells that are increasingly resistant to cancer therapies.

Cancer cells that emerge following initial treatment often represent clones of cells with intrinsic resistance or cells in which the treatment has selected for drug resistance mechanisms. For example, treatment of patients with adenocarcinoma of the lung who progress after initial response to inhibitors of EGFR may acquire a mutation that renders these kinase inhibitors ineffective.²⁹ This reality places a premium on getting it right the first time so that medical oncologists and their team must be certain that they have all of the requisite information at hand to allow the best choice for initial treatment. For example, treating a breast cancer patient without knowledge of the status of estrogen and progesterone receptors and the *HER2/neu* oncogene correctly measured, or subtyping nonsmall cell lung cancers in terms of EGFR, alk, and other genomic alterations would likely compromise initial treatment. Similarly, embarking on the treatment of acute myelogenous leukemia without full genotyping and phenotyping risks making the wrong choice for initial treatment. Furthermore, resistance to imatinib is associated with both P-glycoprotein and specific mutations in the *BCR : ABL* gene. These changes are defined, and new drugs are available to overcome these forms of resistance. Finally, the proper approach to patients with lung cancer and melanoma requires molecular characterization to select the proper treatment.

The advantage of treating early stage patients has proved so persuasive that the profession and patients have accepted the technique of postsurgical or adjuvant chemotherapy, acknowledging that this entails treating some if not the majority of patients whose risk of relapse is already zero. Adjuvant therapy after surgery has been demonstrated to be curative in several diseases for which surgery alone has low cure rates and where chemotherapy alone cannot cure metastatic disease. Breast cancer, Wilms tumor, and osteosarcoma are the prime examples. In many diseases, there is evidence of prolonged disease-free survival and of longer survival, such as stage II and III breast cancer,^{30, 31} stage III ovarian cancer,³² and stage III colon cancer.³³ Recent evidence suggests that transcriptional profiling of breast cancer specimens may help identify patients for whom adjuvant therapy is unnecessary.³⁴

Because adjuvant treatment is aimed at micrometastatic disease remote from the primary tumor, exploration of chemotherapy before surgery (neoadjuvant) has been undertaken in a few types of cancer. In addition to earlier exposure of the micrometastases, this approach has two other beneficial characteristics. First, regression of the primary lesion predicts that the micrometastases will also likely be sensitive.³⁵ Second, regression of the primary tumor may make primary surgery unnecessary or less debilitating or disfiguring, allowing curative radiotherapy, as in some head and neck cancers and as shown in a large series of patients with breast cancer.³⁶ In other instances, surgery after chemotherapy may be technically easier, although not always less radical, because there is no certainty that every cell has been eradicated at the original boundaries. Induction or concurrent chemotherapy may also significantly enhance the effectiveness of radiotherapy for other tumors, such as anal carcinoma, thereby decreasing the need for surgery.

In the past, treatment of recurrent disease was too often empiric. The response to these subsequent treatments predictably diminishes over time. For example, a breast cancer patient whose tumor strongly expresses the estrogen and progesterone receptor has more than a 50% chance of responding to first-line

hormonal therapy, with a likely duration of response of approximately 18 months.³⁷ On relapse, that same patient's probability of response to second-line therapy is cut in half, as is the likely duration of response.³⁸ Today, the use of dynamic monitoring of circulating tumor cells, circulating tumor DNA, and re-biopsy with genomic analysis promises to help select the most appropriate treatment for the relapsed patient.

The best treatment is often found through participation in clinical trials

The most common and lethal cancers, including metastatic lung, colon, and breast, are often incurable by approved treatments. Furthermore, most approved treatments have significant risks of side effects and produce limited prolongation of life. Yet, under these circumstances, most patients receive standard rather than experimental therapies. For many, the best choice of treatment may be available only through clinical trials.

Patients are increasingly involved in decisions regarding the choice of therapy, having been empowered by information widely available through the Internet. Patients with cancer are often apprehensive that they may not receive the best treatment and will challenge us with appropriately tough questions before moving ahead. The medical oncologist can speak with greater authority when a deliberate comparison is being made because the goal of such studies is toward improvement on the standard, not toward finding treatments that are equally good.

A number of ethical issues are abrogated by the certainty that a specific patient's disease is not currently curable. For metastatic disease for which no cure is known, it is not only ethical but also important that a systematically designed investigation of new treatments through participation in clinical trials be undertaken early in the course of the patient's disease. This allows assessment of a drug's activity before toxicity arises from conventional therapies that might limit dosing. Conventional therapies might also elicit resistance of one or another kind or immune system depression, which might foreclose the opportunity to recognize the activity of the candidate compound.

For diseases with an especially unfavorable outlook and rare therapeutic success, delays in introducing candidate compounds to ensure that they carry little or no risk of toxicity are an unwise investment of resources and time, let alone the patient's short-lived opportunity for possible benefit. The outcome of unsuccessfully treated cancer is more ominous than the hazards of clinical investigation.

Patients should be made aware of clinical trials as part of the initial discussions regarding treatment. Too often patients are not aware of clinical trials and discover this option through friends or the Internet rather than through their physicians. A trial of candidate phase II agents prior to conventional chemotherapy for metastatic breast cancer has been conducted without significant compromise in response to the established regimen.³⁹ Today, therapies aimed at validated molecular targets may enter the clinic once proof-of-principle is obtained in cell lines and safety and efficacy are confirmed in animal models. Major differences in pharmacokinetics exist between mouse and man, and the ultimate test remains the carefully designed, meticulously conducted clinical trial. The testing of new, targeted therapies is likely to change how we view early trials of anticancer drugs. For example, the phase I trial of imatinib did not reach a maximum tolerated dose. Rather, the dose was determined based on "maximum biological dose," that is, the dose in which the target enzyme was maximally inhibited.⁴⁰ Similarly, dynamic imaging techniques, such as positron emission tomography, predict the responsiveness to imatinib in patients with gastrointestinal stromal tumors well before changes occur in tumor size.⁴¹ Finally, several newer agents are showing promising activity in very early phase studies, further compelling patients and their physicians to participate in properly designed studies.

Therefore, until the day arrives when all cancers are preventable or curable, enrollment of patients in clinical trials will be the hallmark of the practice of the best medical oncologists. No cancer is so well treated that an improvement in outcome or therapeutic approach cannot readily be imagined. Thus, research is imperative.

An individual in practice cannot devote the same time and energy to clinical research as one who serves full time on the faculty of a university, research institute, or hospital. However, the private practitioner has an opportunity to participate in clinical trials through cooperative groups or in collaboration with cancer centers; this opportunity should not be wasted. Every oncologist should participate in clinical research during his or her training, and the oncologist's office should include the capacity to perform clinical research. It is the responsibility of the medical oncologist to discuss clinical trials with patients in a way that does not bias an ultimate decision. There is much reason to anticipate that progress would be more rapid if clinical research were accepted as an integral part of the practice of medical oncology, as it is in pediatric oncology. The technology exists in medical informatics for community oncologists to ally themselves with their alma mater or other academic centers to participate in diagnostic, preventive, and therapeutic research trials using the computer, electronic mail, and fax as expedient tools. Those oncologists who have so heavy a workload that it prevents their devoting the necessary time to participate in clinical research risk depriving their patients of access to research advances. Clinical investigation should serve as the bridge to fundamental science and the excitement generated by the new molecular biologic understanding of cancer as a malignant tissue.⁴²

Cancer surveillance must be based on validated assumptions

Following completion of curative therapy and attainment of a complete remission or following adjuvant therapy, surveillance for early signs of recurrence is based on the logical assumption that the earlier a recurrence is detected, the better the outcome of a therapeutic intervention. Although true in principle, in practice, this is rarely the case. There are several reasons for this illogical result, including the possibilities that surveillance tests are insensitive or nonspecific or that further treatment options are ineffective. Over testing of patients at low risk of recurrence increases the probability of a false-positive result and the attendant morbidity, psychological or physical, associated with attempting to make a definitive diagnosis. In contrast, under testing in patients at risk of recurrence of a form of cancer for which effective salvage therapy is available (e.g., germ cell tumors, large cell lymphoma, Hodgkin disease, osteosarcoma, breast cancer, prostate cancer) is inexcusable. Thus, the oncologist must be aware of the predictive value of surveillance tests (tumor markers and imaging studies) in the context of specific malignancies and apply them accordingly.

Standards for quantifying diagnostic tests used frequently in surveillance have been adopted in most parts of the world [Système Internationale (SI) units], except the United States. It is impossible to read an international medical journal without being thoroughly familiar with SI units. They are presented in [Table 4](#) so that readers can have ready access to a source for translation from the old nomenclature, characteristically American, which pervades this treatise.

Table 4 Representative Système International units for laboratory tests of importance in oncology

Component	Present reference interval	Present unit	Conversion factor	Intervals	Unit symbols
Albumin	4.0–6.0	g/dL	10.0	40–60	g/L
α-Fetoprotein, radioimmunoassay	0–20	ng/mL	1.00	0–20	g/L

Bilirubin					
Total	0.1–1.0	mg/dL	17.10	2–18	μmol/L
Conjugated	0–0.2	mg/dL	17.10	0–4	mol/L
Calcium	8.8–10.3	mg/dL	0.2495	2.20–2.58	μmmol/L
Cholesterol	<200+	mg/dL	0.02586	<5.20	μmmol/L
Cortisol	4–19	g/dL	27.59	110–520	nmol/L
Creatinine	0.6–1.2	mg/dL	88.40	50–110	mol/L
Fibrinogen	200–400	mg/dL	0.01	2.0–4.0	g/L
Glucose	70–110	mg/dL	0.05551	3.9*6.1	μmmol/L
Hemoglobin					
Male	14.0–18.0	g/dL	10.0	140–180	g/L
Female	11.5–15.5	g/dL	10.0	115–155	g/L
Immunoglobulins					
IgG	500–1200	mg/dL	0.01	5.00–12.00	g/L
IgA	50–350	mg/dL	0.01	0.50–3.50	g/L
IgM	30–230	mg/dL	0.01	0.30–2.30	g/L
IgD	<6	mg/dL	10	<360	mg/L
IgE	20–1000	ng/mL	1.00	20–1000	g/L
Iron	80–180	g/dL	0.1791	14–32	μmol/L
Iron-binding capacity	250–460	g/dL	0.1791	45–82	μmol/L
Lipoproteins					
Low-density lipoproteins (LDL), as cholesterol	50–190	mg/dL	0.02586	1.30–490	mmol/L
High-density lipoproteins (HDL), as cholesterol	30–70	mg/dL	0.02586	0.80–1.80	mmol/L
Magnesium	1.8–3.0	mg/dL	0.4114	0.80–1.20	mmol/L
	1.6–2.4	mEq/L	0.500	—	—
Metanephrines (as normetanephrine)	0–2.0	mg/24 h	5.458	0–11.0	μmol/day
Osmolality	280–300	mOsm/kg	1.00	280–300	nmol/kg
Phosphate (as inorganic P)	2.5–5.0	mg/dL	0.3229	0.80–1.60	mmol/L
Potassium	3.5–5.0	mEq/L	1.00	3.5–5.0	mmol/L

Protein, total	6–8	g/dL	10.0	60–80	g/L
Serotonin	8–21	g/dL	0.05675	0.45–1.20	mol/L
Thyroxine, free (T ₄)	0.8–2.8	ng/dL	12.87	10–36	pmol/L
Triiodothyronine (T ₃)	75–220	ng/dL	0.01536	1.2–3.4	nmol/L
Urate (as uric acid)	2.0–6.0	mg/dL	59.48	120–360	μmol/L
Urea nitrogen	8–18	mg/dL	0.3570	3.0–6.5	mmol/L
Vanillylmandelic acid	<6.8	mg/24 h	5.046	<35	μmol/day

Oncologic care is for life

The relationship of a medical oncologist with patients is intimate and should not end once therapies aimed at controlling the spread of cancer are no longer effective. The medical oncologist must be skilled in the principles and practice of palliative care and collaborate actively with specialists in symptom control, for example, neurologists, psychiatrists, and hospice staff. No greater feeling of abandonment can occur than when a patient is abruptly released from care by an oncologist who fails to recognize this lifelong responsibility.

It is, however, also the responsibility of the medical oncologist to address end-of-life planning with the patient and the family. Advice regarding living wills, power of attorney, and resuscitation falls squarely within the purview of the medical oncologist. This responsibility is highlighted in states that require that do not resuscitate (DNR) orders be written on patient charts prior to death. In the absence of such orders, when a nurse finds a patient apparently dead, she must, by law, initiate emergency calls for resuscitative efforts.

When death comes from cancer as the expected final event of a gradual deterioration of vital forces, resuscitative efforts do not succeed. When we are unable to keep someone alive, the likelihood of bringing him or her back to meaningful life is infinitesimal. Resuscitative efforts should be applied to patients with cancer who were not expected to die because reversible phenomena, such as pulmonary emboli, cardiac arrhythmias, aspiration, and similar events, can provoke unexpected death in a patient with a neoplasm, just as in any other hospitalized or ambulatory patient. Many patients, particularly the elderly and those apprised of the progress of their disease, can discuss the decision not to resuscitate with equanimity and, indeed, with a certain personal satisfaction of avoiding the fruitless anguish that such a procedure entails for the surviving family. Most patients sign living wills or appoint a health care proxy if these possibilities are presented to them.

Because of the legal implications involved, where particular religious scruples obtain or where families have emotionally uncontrolled members who cannot accept the anticipated death of a loved one, the medical oncologist should spend considerable time planning for an eventual death. DNR forms are a technique of documentation and constitute further evidence that society has moved medicine onto a new plateau of accountability.

The medical oncologist should make known his or her intentions concerning the advisability of resuscitative efforts for each particular patient in advance to forestall unnecessary trauma to the patient, family, and staff; to forestall litigation; and to settle in advance any serious disagreements with the patient or family. An impasse might occasion a medical oncologist to find a suitable substitute physician if there is irresolvable conflict concerning the plans surrounding an anticipated death.

DNR orders do not imply that there be diminution of effort to control or palliate the disease before death. However, if good judgment indicates that continued efforts are fruitless and can only inflict suffering, with no prospect of benefit, discontinuation of active therapy should always be accompanied by DNR orders.

Summary

The medical oncologist stands at the crossroads of modern molecular biology and medical practice and often serves as the final common pathway for the application of cancer research to patients. A complex corpus of information is available that expands rapidly, both deeper into the nature of the cancer process and wider into new approaches that provide demonstrated effectiveness in therapy, prevention, or support.

The increasing appreciation that oncogenes and tumor suppressors act through usurpation of normal autocrine and paracrine signaling pathways and that cancer is in reality not merely a disease of cancer cells but of a cast of supporting characters that form a malignant tissue (blood vessels, fibroblasts, smooth muscle cells, macrophages, lymphocytes, etc.) provides a variety of new targets for therapy. The realization that malignant transformation is a multistep process of accumulation of genetic abnormalities over long periods of time gives impetus for the design of rational preventive strategies and guidance to target patients at highest risk. These pathways have already led to effective targeted therapies that are less toxic than traditional cancer chemotherapy. Thus, the tide of fundamental discovery is washing away many of the unknowns. It is axiomatic that certain cancers can be cured today without knowing the intimate nature of neoplasia. How better the day, perhaps soon upon us, when we are more confident that we know what we are doing!

Clinical accomplishments have similarly been exceptionally productive in the 60 years since the first cancer was cured with drugs.³ A large assortment of drugs has since been provided. A new array of genetically engineered drugs support host function, and others that are still early in their development are on the way. Imaging technologies will continue to revolutionize the ability to detect, stage, treat, and monitor cancers. Biochemical markers of tumor behavior will provide increasing diagnostic and monitoring capacity and may offer new targets for therapy.

There is probably no cancer in which some progress in diagnosis or therapy has not been achieved in the last decade. Similar achievements for cancer prevention are materializing. Oncologists must assume greater responsibility for health preservation. Much could be accomplished by applying what is already known about lifestyle, diet, and exercise. Medical facts without political action were slow to change the tax on health that tobacco levies. A concerted effort within most states has begun, but a federal role in managing the tobacco plague has been thwarted.

The horizon has never been closer. Although still distant, there are enough promising paths to follow that one of them may prove considerably faster than even reasonable optimism would suppose. The information that serves as our foundation, its rate of accrual, its revelations, and the demonstrated success of translating science to clinical applications augur well for the future of medical oncology and for cancer patients.

Chapter 46

Palliative care and pain management

Cardinale B. Smith, MD, MSCR

Overview

Palliative care is an essential component of comprehensive cancer care. Palliative care is given concurrently with other disease-modifying, life-prolonging, and curative therapy. Palliative medicine specialists focus on helping patients and their families with a variety of care needs including symptom control, psychosocial support, physician-patient communication, addressing care goals in relation to the patient's condition, prognosis, values, and preferences, as well as with transitions in care. Cancer patients often experience significant symptom distress either from the illness itself or from the associated treatments. The beneficial effects of palliative care have been well documented. When integrated into early oncologic care, palliative care is associated with a significant improvement in quality of life, depression, and survival. As such, palliative care should be given throughout the trajectory of cancer care whether during early stage disease in which the focus is on cure or in more advanced disease when the focus is on maximizing quality of life. Currently, national and international organizations have clinical guidelines that recommend palliative care be routinely integrated into comprehensive cancer care.

Palliative care

Palliative care is medical care focused on the relief of suffering and support for the best possible quality of life for patients and their families facing serious, life-threatening illness.¹ It aims to identify and address the physical, psychological, and practical burdens of illness and is provided as an extra layer of support for seriously ill patients. Palliative care is delivered simultaneously with all appropriate curative and life-prolonging interventions. Palliative care specialists provide assessment and treatment of pain and other symptoms; employ communication skills with patients, families, and colleagues; support complex medical decision making and goal setting based on identifying and respecting patient wishes and goals; promote medically informed care coordination, continuity, and practical support for patients, family caregivers, and professional colleagues across health care settings and through the trajectory of an illness. Palliative care in cancer patients should begin at the time of diagnosis. The emphasis of care will vary over the course of illness, with anticancer therapy provided concomitantly with supportive care and symptom management.

Several randomized studies have demonstrated a benefit of incorporating early palliative care into standard oncologic care.^{2, 3} In these studies, palliative care has been shown to improve mood, quality of life, and potentially survival among patients with advanced cancer. As such, oncology guidelines now recommend the routine integration of palliative care into routine oncologic care. In 2012, the American Society for Clinical Oncology (ASCO) issued a provisional opinion recommending incorporation of palliative care “for any patient with metastatic cancer and/or high symptom burden.”⁴ In 2013, The Institute of Medicine's report, *Delivering High-Quality Cancer Care*, recommended that cancer care teams

“place primary emphasis on palliative care, psychosocial support and timely referral to hospice for end of life care.”⁵

There are several core components involved in providing quality palliative care for oncology patients. These include the following:

- Whole patient assessment
- Effective communication
- Advanced care planning
- Symptom management
- Care at the end of life
- Grief and bereavement support

Whole patient assessment

The whole patient assessment is guided by the National Comprehensive Cancer Network (NCCN) guidelines and core elements of palliative care as detailed in the National Quality Forum and involves evaluating all aspects of the impact of cancer and its treatments on the patient and family.⁶ In addition to routine medical history, patient assessment explores the patients' social and community support, impact of the cancer diagnosis and treatment on patients' quality of life, spiritual and social well-being, as well as patients' expectations of therapy and goals of care. The whole patient assessment improves patient–physician communication and assists the physician in understanding potential barriers to patient adherence with treatment plans. This assessment is optimized by utilization of the interdisciplinary team to attend to all medical and psychosocial aspects of diagnosis, treatment, and to assist with patient and family distress.

Communication

Effective communication is an important component of the oncologist–patient relationship and assists in providing the highest quality cancer care. In an ASCO survey conducted in 1998, approximately 60% of respondents indicated that they broke bad news to patients from 5 to 20 times per month. Despite these challenges, <10% of respondents received formal training in breaking bad news.⁷ Similarly, in a survey conducted at the 2004 ASCO meeting, oncology fellows reported being more likely to have observation and feedback on bone marrow biopsies than on goals of care discussions.⁸ This lack of training can have a negative impact on cancer patients and providers. Poor communication skills have been associated with decreased patient participation in decision making,⁹ missed opportunities to respond empathically to patient concerns, ignored patient wishes to discuss health-related quality of life issues, and an increased likelihood of receiving anticancer treatment at the end of life.¹⁰ Alternatively, effective communication has been shown to influence desirable outcomes such as patient satisfaction, adherence with treatments, decreased patient distress, and reduces physician burnout.^{11, 12}

There are existing protocols to help deliver bad news and address goals of care ([Table 1](#)).^{13, 14} These protocols can be applied to most situations including a new diagnosis of cancer, cancer recurrence,

progression of disease, and transition to hospice. This communication process attempts to achieve four main goals: gathering information from the patient to elicit readiness to hear the news; providing information in accordance with the patient's needs and desires; reducing the emotional impact and isolation experienced by the recipient of the bad news; and developing a treatment plan that aligns with patient preferences. When communicating with patients and families, it is important to use open-ended questions such as “What are your hopes and fears?” and “What is important in your life?”¹⁴ It is important to avoid language with unintended consequences such as “There is nothing more we can do for you” and “Do you want everything done for you?”¹⁴ Instead, try saying “We will do everything to give you the best quality of life” or “We will manage your symptoms very aggressively.” Additionally, it is important to avoid jargon or euphemisms, and instead use plain, simple language. Once the goals of care are established, it becomes much easier to construct a plan of care centered on those preferences. There are currently training programs that are offered to train oncologists in these specific skills, a list if available resources can be found in [Table 2](#).

Table 1 Protocol for breaking bad news and addressing goals of care

Recommendation	Comments
Create the proper setting	<ul style="list-style-type: none">• Prior to the meeting determine the most appropriate participants (family members and other health care providers)• Allow adequate time• Determine what to say prior to the meeting
Clarify what the patient and family already know	<ul style="list-style-type: none">• “What have you been told about your medical situation so far?”• This allows you to correct any misinformation and tailor the conversation based on their prior knowledge
Explore hopes and expectations of patient and family	<ul style="list-style-type: none">• Allows you to distinguish between attainable and unattainable goals
Suggest realistic goals	<ul style="list-style-type: none">• Suggest attainable goals based on the present clinical scenario and how they can best be achieved• Review appropriateness of disease-modifying treatments• Try to explain using simple language why unrealistic goals cannot be met
Use empathic responses	<ul style="list-style-type: none">• Very important to allow silence and to listen• Let patient and family express emotions• Once emotions are expressed use a connector such as “I can see how upsetting this is to you”
Make a plan and follow through	<ul style="list-style-type: none">• Summarize the plan to ensure that your interpretation of the conversation and decisions is in concordance with patient and family and how the plan of care will meet their goals• Make a plan for continued follow-up• Inform the patient and family how to contact you if they have further questions or concerns• Continue to review and revise the plan as needed

Advance care planning

Once the patients' goals of care are established, they should be documented in the form of advance directives. Advance directives consist of two main components: the health care proxy or durable power of attorney for health care and treatment directives.¹⁵ A commonly used comprehensive advance directive is the medical orders for life-sustaining treatment (MOLST) or physician orders for life-sustaining treatment (POLST) and is currently in use or under development in over 40 states.¹⁶ POLST is appropriate for people with cancer and a prognosis measured in 1–2 years. It specifically addresses medical decisions and options that are likely to arise in the near future, including cardiopulmonary resuscitation, antibiotics for infections, artificial food and fluids, and whether or not the patient would want to be re-hospitalized. Additionally, it can be transported across care settings. POLST appears to be associated with better receipt of medical care reflecting patient treatment preferences (decreased hospitalization and life-sustaining treatments) when compared to traditional practices, improved surrogate understanding of patient goals and preferences and an improved prevalence, clarity, and specificity of preferences documented.^{17–19} It is important for every cancer patient to have advance directives to help avoid confusion and conflict, to prepare for future medical care, and to ensure that patients' wishes will be followed.

Symptom management

Patients with cancer experience many physical and psychosocial symptoms either as a consequence of therapy or as a result of the disease itself. The essential components of symptom management include (1) routine and repeated formal assessment, (2) expertise in prescribing medications, including the safe use of

opioid analgesics, adjuvant approaches to pain management, and management of a wide range of other common and distressing symptoms and syndromes, and (3) skillful management of treatment side effects. Currently, there is no gold standard for symptom assessment in palliative care. Although several tools exist, the most commonly used is the Edmonton Symptom Assessment System, which consists of nine visual analog scales or numerical rating scales that evaluate a combination of the most common physical and psychological symptoms.²⁰ The most common symptom experienced by cancer patients is pain.²¹ The most frequent nonpain symptoms are constipation, nausea and vomiting, anorexia/cachexia, dyspnea, delirium, and anxiety.²¹ The management of some of these symptoms will be discussed in the following sections.

Pain

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”²² Although the cause of the pain and the type of injury vary, the constellation of complex neurophysiologic phenomena of pain includes two broad categories, nociceptive pain, which include both somatic and visceral pain, and neuropathic pain.²³ Somatic pain is characterized as well localized, intermittent, or constant and is described as aching, gnawing, throbbing, or cramping (e.g., bone metastases). Visceral pain is mediated by discrete nociceptors in the cardiovascular, respiratory, gastrointestinal (GI), and genitourinary systems. It is usually described as deep, squeezing, or colicky and is commonly referred to cutaneous sites, which may be tender. Neuropathic pain is clinically described as a burning, tingling, or numb sensation with paroxysms of shock-like pain. Cancer history should include description of the pain complaint, including the patient's description of pain and intensity; its quality, exacerbating, relieving factors, and its radiation if any; its exact onset and temporal pattern. Impact of pain on the activities of daily living, sleep, mood, and affect should be assessed.

The guiding principles of a therapeutic strategy for cancer pain should include (1) detailed assessment of the patient's pain, (2) making a pain diagnosis, (3) understanding the goals of care and the patient's preferences, (4) developing and implementing the best therapeutic and diagnostic strategy, (5) continual reassessment of the degree of pain and analgesia, and (6) expertise to provide alternative therapeutic strategies. Of greatest importance, no patient should be inadequately evaluated because of patient's experiencing “too much pain.” A series of algorithms have been developed for the management of cancer pain.^{24, 25} The World Health Organization Cancer Pain and Palliative Care Program advocates a three-step approach, which advocates starting with nonopioid analgesia [e.g., nonsteroidal, anti-inflammatory drugs (NSAIDs)] and then titrating up to low- then high-potency opioids.²³ Similarly, NCCN pain management guidelines provide an algorithm of a stepwise approach to the treatment of mild, moderate, and severe pain and strategy of rapid but safe opioid titration to provide analgesia.²⁶ General guidelines of cancer pain treatment are listed in [Table 3](#). Management of cancer pain can be divided into pharmacologic approaches, interventional approaches, and psychological management.

Table 3 Guidelines for the use of analgesic drugs in cancer pain management

Start with a specific drug for a specific type of pain
<div><div>1.</div><div>Clarify the patient's pain, its nature, site, duration, and intensity, and the degree of pain relief from prior nonopioid and opioid drug use</div></div> <div><div>2.</div><div>Complete a careful medical and neurologic history and examination. Assess the potential role of radiotherapy, surgery, and/or chemotherapy in pain control</div></div>

- 3.** Assess the psychological factors contributing to the pain complaint and understand the meaning of the pain for the patient
- 4.** Choose the route of administration to fit the needs of the individual patient
 - i.** Choose the oral route as the simplest approach
 - ii.** Consider the buccal or rectal routes for patients who cannot tolerate oral drugs and refuse parenteral routes. Start intravenous intermittent boluses or continuous infusions in patients requiring rapid escalation of opioids for pain control
 - iii.** Use intermittent boluses or continuous subcutaneous infusions for patients without venous access or in patients at home
 - iv.** Choose the epidural or intrathecal route in patients who develop limiting side effects from systemic opioids
 - v.** Use PCA pumps for selected patients in hospital and at home
- 5.** Know the pharmacology of the available opioid drugs. Titrate the dose to the individual needs of the patient
 - i.** Start with a dose that is at least equivalent or slightly greater than the equianalgesic dose of the previous analgesic used
 - ii.** Order the medication on a regular basis (oral—every 3–4 h, intravenous—every 15–60 min as needed)
 - iii.** Instruct the patient to take the medication on a PRN basis if the patient is opioid naive
 - iv.** Order “rescue medication” equivalent to 10% of the standing 24-h dose to begin with on a PRN basis
 - v.** Inform the patient of options in taking the medication and request that he or she report side effects of excessive sedation or confusion. Monitor the side effects closely
- 6.** Use a combination of drugs to provide additive analgesia to reduce side effects or to control other symptoms
 - i.** Know the various adjuvant drugs that provide additive analgesia, for example, anticonvulsants, corticosteroids
 - ii.** Use neurostimulants to reduce sedative effects, for example, caffeine, dextroamphetamine, methylphenidate, modafinil
 - iii.** Use antidepressant, anticonvulsant, and other analgesics to manage neuropathic pain
- 7.** Anticipate and treat side effects
 - i.** Watch for respiratory depression and use naloxone if needed (in diluted doses to prevent acute withdrawal)
 - ii.** Counteract sedation with neurostimulants
 - iii.** Use antiemetics to suppress the emetic effect of opioids
 - iv.** Define an individualized bowel regimen to prevent and manage constipation
 - v.** Treat myoclonus by switching to an alternative analgesic, or suppress it with anxiolytic drugs

8. Watch for the development of tolerance

- i. Distinguish tolerance from progression of tumor
- ii. Recognize that there is no limit to tolerance
- iii. Switch to an alternative opioid if the dose of the current opioid cannot be escalated
- iv. Consider opioid rotation if one or more intractable side effects are noted

Abbreviations: PCA, patient-controlled analgesia; PRN, pro re nata (according as circumstances may require).

Pharmacological approaches are the most commonly used method for managing cancer pain. The brief outline of pharmacologic approach is detailed in [Table 4](#). The selection of the right analgesic to maximize pain relief and minimize adverse effects begins with the use of nonopioids for mild pain. In patients with moderate pain that is not controlled with nonopioids such as acetaminophen, NSAIDs, and adjuvant medications (WHO step 1), the so-called weak opioid agonists (codeine, hydrocodone, and tramadol) alone or in combination are prescribed (step 2). In patients with severe pain, a strong opioid (morphine, hydromorphone, fentanyl, methadone, oxycodone, oxymorphone, or levorphanol) is the drug of choice (step 3). At all levels, certain NSAIDs and adjuvant drugs may be used for specific indications. A number of opioid analgesics is available for clinical use and are listed in [Table 4](#).

Table 4 Opioid analgesics commonly used for moderate to severe pain narcotic agonists

	Parenteral (mg)	Oral (mg)	Conversion factor (IV to PO)	Comments
Morphine	10	30	1 : 3	Standard of comparison for opioid analgesics; lower dose for aged patients
Hydromorphone	1.5	7.5	1 : 5	Slightly shorter-acting
Fentanyl	25 µg = 1 mg morphine IV	—	—	Short half-life; transdermal and transmucosal preparations available
Codeine	130	200	1 : 1.5	Often used in combination with nonopioid analgesics; biotransformed, part, to morphine
Oxycodone	—	20	—	Also in combination with nonopioid analgesics that limit dose escalation
Oxymorphone	1	10	1 : 10	Not available orally
Methadone ^a	—	—	—	—

^a Methadone has a complex pharmacokinetic and pharmacodynamic profile that makes equianalgesic dosing particularly difficult. Consult with an experienced clinician before initiating or adjusting the dose of methadone.

Selection of the opioids should be based on patient's analgesic history, renal and hepatic function ([Table 5](#)), side effects, and severity of pain. Short-acting opioids are usually used for opioid titration and as needed (PRN, pro re nata) for breakthrough pain. After an effective stable 24-h opioid requirement is established, a switch to a long-acting formulation should be considered. Long-acting opioids allow patients to achieve more consistent blood levels, reduce pain recurrence, improve compliance, and reduce the iatrogenic dependence. Rescue medications equivalent to 10% of the standing 24-h dose should also be made available to patients.^{27, 28} Overall, opioid dose, route, and titration schedule should be tailored to the patient's medical needs, treatment goals, and side-effect profile. There is no minimum or

maximum dose. The opioid dose needs to be titrated to maintain the patient's desired balance between pain relief and opioid-related side effects.

Table 5 Guidelines for opioids in kidney and liver disease

	Kidney disease ^a		Liver disease	
	Renal failure	Dialysis	Stable cirrhosis	Severe disease
Morphine	Do not use	Do not use Not dialyzed	Caution ↓ dose ↓ frequency ^b	Do not use
Oxycodone	Caution ↓ dose ↓ frequency ^b	Caution	Caution ↓ dose ↓ frequency ^b	Caution ↓ dose ↓ frequency ^b
Hydromorphone	Preferred ↓ dose ↓ frequency ^b	Preferred Not dialyzed, but minimal toxicity	Caution ↓ dose ↓ frequency ^b	Caution ↓ dose ↓ frequency ^b
Fentanyl	Preferred	Preferred Not dialyzed, but minimal toxicity	Preferred	Preferred
Codeine	Do not use	Do not use	Do not use	Do not use
Methadone ^c	Preferred—with consultation only	Preferred—with consultation only. Not dialyzed, but minimal toxicity	Preferred—with consultation only	Preferred—with consultation only

^a Avoid sustained release oral opioids and fentanyl patches in kidney disease. Note that even the “safest” opioids are not dialyzable.

^b ↓ dose means reduce dose by 25–50%. ↓ frequency means reduce standing orders for short-acting opioids from q4h to q6h.

^c Consult with an experienced clinician before initiating or adjusting the dose of methadone.

Interventional approaches can be divided into six major types: (1) trigger-point injections, (2) peripheral nerve blocks, (3) autonomic nerve blocks, (4) epidural and intrathecal infusions, (5) surgical approaches, and (6) neurostimulatory approaches. The techniques for each of these procedures are outside the scope of this chapter, but have been described in detail elsewhere.²⁹

Psychological management of cancer pain includes the use of psychotherapeutic, cognitive-behavioral, and psychopharmacologic interventions. These techniques are most useful in three clinical situations: (1) in the management of patients with intermittent predictable pain (such as pain associated with procedures), (2) in the management of incident pain (e.g., in the patient with pain on movement), and (3) in the management of chronic cancer pain.^{30, 31}

Constipation

Constipation is defined as the infrequent and difficult passage of hard stool. It is a common cause of morbidity in the palliative care setting and affects more than 95% of patients who are treated with opioids for cancer-related pain.¹⁵ The two most common etiologies are related to the side effects of opioids and the effects of progressive disease. Severe constipation can lead to bowel obstruction and perforation and can be a cause of severe morbidity. In patients who are neutropenic, severe constipation can lead to bacterial transfer across the colon, resulting in bacteremia and potentially sepsis. The Rome criteria

defines constipation as the presence of two or more of the following symptoms³²:

- Straining at least 25% of the time
- Hard stools at least 25% of the time
- Incomplete evacuation at least 25% of the time
- ≤2 bowel movements per week.

Assessment of constipation should involve a history of the patient's bowel pattern, fluid intake, recent dietary changes, review of current medications, and a thorough physical examination, including a rectal exam—with caution in patients with neutropenia. In addition, abdominal radiography can be performed to look for the presence of stool if the diagnosis remains unclear.

Constipation can be managed with nonpharmacologic measures as well as pharmacologic interventions. Nonpharmacologic measures include increasing fluid intake if possible and regular toileting as colonic activity is highest early in the morning, after walking, and 30 min after meals. Pharmacologic interventions for the management of constipation may be administered orally or rectally and are summarized in [Table 6](#). There is no single correct management approach to laxative prescribing. Initial regimens often include a stimulant, such as senna, given once or twice per day and titrated according to response. Stool-softening agents, such as docusate, are commonly prescribed, but they have not been shown to be efficacious in this setting.³³ Whichever bowel regimen is initiated should be individualized and titrated to response. It is important to note that the best treatment of constipation is prevention. A prophylactic bowel regimen should be initiated at the time opioids are initially prescribed and should be continued for as long as the patient remains on opioids.

Table 6 Laxatives commonly used to treat constipation

Class of drug	Preparation	Starting dose	Mechanism of action	Comments
<i>Oral</i>				
Lubricant	Mineral oil	5–10 mL/day	Lubricates stool surface, allows easier passage	Adverse effects include lipoid pneumonia, leakage of oily fecal material. 255 paraffin and magnesium hydroxide considered safest
Bulk-forming agents	Methycellulose, bran, psyllium	Bran 8 g daily Others 3–4 g daily	Increases stool bulk, stimulating peristalsis	Good for mild constipation. Caution as needs to be taken with at least 200–300 mL of water. May precipitate obstruction in a debilitated patient by forming a viscous mass
				May cause flatulence and bloating
Osmotic (poorly absorbed sugars)	Lactulose	15–30 mL daily	Retention of water in the lumen via osmotic effects	Sweet taste that may not be well tolerated. Bloating, abdominal cramping, and flatulence are common

Saline	Magnesium hydroxide Sodium bisphosphonate	2.4–4.8 g daily	High osmolarity compounds causes retention of water in the lumen throughout the entire gut. Directly stimulates peristalsis	Strong cathartic. Mostly used as a bowel prep for endoscopic procedures. May alter fluid and electrolyte imbalance. Caution in patients with heart failure or renal insufficiency
Anthraquinones	Senna	Max 100 mg/day	Direct stimulation of myenteric plexus causing induction of peristalsis	Often combined with docusate. May cause abdominal cramping. Do not use if obstruction is suspected
Polyphenolic	Bisacodyl	10 mg daily	Stimulates secretion and motility of small intestine and colon	May cause abdominal cramping
<i>Rectal</i>				
Lubricant	Mineral oil enema	One enema	Used as retention enema to allow evacuation or manual removal of impacted stool	Efficacy is dependent on ability to retain the oil
Osmotic	Glycerin	One suppository	Softens stools via osmosis	
Saline	Sodium phosphate	One enema or suppository	Releases bound water from feces. May stimulate rectal or distal colonic peristalsis	May alter fluid and electrolyte balance. Caution in patients with heart failure or renal insufficiency
Polyphenolic	Bisacodyl	10 mg suppository	Promotes colonic peristalsis	Activity depends on bisacodyl reaching the rectal wall
<i>Subcutaneous</i>				
Peripheral opioid receptor antagonist	Methylnaltrexone	<38 kg: 0.15 mg/kg 38 to <62 kg: 8 mg 62–114 kg: 12 mg >114 kg: 0.15 mg/kg (round up)	Selectively blocks opioid binding at the mu receptor, in the GI tract	Only for opioid-induced constipation

Nausea and vomiting

Nausea and vomiting are reported to affect between 40% and 70% of patients with cancer.³⁴ Nausea and vomiting can cause substantial psychological distress for patients and families and impact overall quality

of life.³⁵ Nausea is subjective and is defined as an unpleasant sensation of the need to vomit and can be associated with autonomic symptoms, including pallor, cold sweats, tachycardia, and diarrhea. Vomiting is the forceful discharge of gastric contents via the mouth resulting from the contraction of the abdominal musculature and diaphragm. The pathophysiology of nausea and vomiting is complex and involves four pathways (chemoreceptor trigger zone, cortex, peripheral pathways in the GI tract, and vestibular system), which when stimulated can induce nausea and vomiting.^{36, 37}

The etiology of nausea and vomiting are varied, but it is important to determine the exact cause in order to select targeted and effective treatment. The most common etiologies in patients with cancer are chemotherapy-induced nausea and vomiting (CINV) and opioid-induced, bowel obstruction and constipation. Once the likely etiology of nausea and vomiting is identified, directed therapy can begin. There are guidelines for the prevention and treatment of CINV in patients on antineoplastic therapy.³⁸ The most commonly used approach is based on identifying the etiology and administering the most potent antagonist targeted toward the implicated receptors. This strategy has been shown to be effective in up to 80–90% of patients. Some practitioners recommend starting an empirical antiemetic regimen, typically with a dopamine antagonist, regardless of the presumed etiology.^{39–41} No direct comparisons currently exist between mechanism-based and empirical therapy.

Therapy should consist of nonpharmacologic and pharmacologic measures aimed at alleviating the cause of the symptoms. Nonpharmacologic measures include avoiding strong smells or other nausea triggers, eating small, frequent meals, limiting oral intake during periods of extreme emesis,⁴² relaxation techniques,⁴³ acupuncture, and acupressure.⁴⁴ Progressive muscle relaxation and guided mental imagery during periods of chemotherapy have also shown beneficial effects.⁴⁵ The most commonly used antiemetics worldwide are metoclopramide, dexamethasone, haloperidol, hyoscine butylbromide, and cyclizine. Antiemetics are available in the form of pills, orally dissolvable tablets, intravenous infusion, rectal suppositories, and subcutaneous infusions. Thought should be given to selection of the appropriate route of administration of the antiemetic to ensure maximum efficacy. A list of antiemetics, routes of administration, and their properties can be found in [Table 7](#).

Table 7 Antiemetics commonly used to treat nausea and vomiting

Receptor site of action	Drug name	Dosage/route	Adverse effects
Dopamine antagonists (D ₂)	Chlorpromazine	10–25 mg PO every 4–6 h, 25–50 mg IM every 3–4 h	Dystonia, akathisia, sedation, and postural hypotension
	Haldol	10–20 mg PO, IV/SQ before meals and at bedtime or every 6 h	Dystonia and akathisia
	Metoclopramide	10–20 mg PO every 6 h, 5–10 mg IV every 6 h or 25 mg rectally every 6 h	Dystonia, akathisia, abdominal cramping in obstruction
	Prochlorperazine	5–10 mg PO every 6–8 h or 25 mg rectally every 12 h	Dystonia, akathisia, and sedation
	Olanzapine	5–10 mg PO once daily for up to 5 days	
Histamine	Cyclizine	25–50 mg PO/SQ or rectally	Dry mouth, sedation, skin irritation

antagonists (H ₁)		every 8 h	at SQ sites may occur
	Diphenhydramine	25–50 mg PO/IV/SQ every 4–8 h	
	Promethazine (also has activity on D ₂ and ACH)	12.5–25 mg PO, IV/IM rectal every 4–6 h	Sedation, dry mouth, and urinary retention Dry mouth, dystonia, akathisia, and sedation
Acetylcholine antagonists (ACH)	Glycopyrrolate	0.2 mg IV/SQ every 4–6 h	Dry mouth, blurred vision, confusion, urinary retention, ileus
	Hycosamine	0.125–0.25 mg PO/SL every 4 h or 0.25–0.5 mg IV/SQ every 4 h	Dry mouth, blurred vision, confusion, urinary retention, ileus
	Scopolamine	0.1–0.4 mg IV/SQ every 4 h or 1.5 mg transdermal patch every 72 h	Dry mouth, blurred vision, confusion, urinary retention, ileus
Serotonin antagonists (5HT ₃)	Dolasetron	100 mg PO daily	Headache, diarrhea
	Granisetron	2 mg PO daily or daily	Headache, constipation, weakness
	Ondansetron	4–8 mg PO/IV or dissolvable tablet IV every 4–8 h (max 32 mg/day)	Headache, constipation, weakness
	Palonosetron	0.25 mg IV prior to start of chemotherapy ^a	Headache, constipation
Substance P antagonist	Aprepitant	125 mg PO on day 1 of chemotherapy	Headache
		80 mg PO on days 2 and 3 ^a	
	Fosaprepitant	150 mg IV day 1 of chemotherapy	Headache, infusion site pain
<i>Other</i>			
Corticosteroids	Dexamethasone	10–20 mg PO/IV each treatment day	Hyperglycemia, GI bleeding, insomnia, psychosis
Cannabinoids	Dronabinol	2–20 mg PO daily in divided doses	Dizziness, euphoria in the young and dysphoria in the elderly, paranoid reaction, somnolence
Benzodiazepines	Lorazepam ^b		
Somatostatin analog	Octreotide	0.5–2 mg PO/IV every 4–6 h	Sedation, respiratory depression
		100 mcg every 8–12 h IV/SQ or 100 mcg/h as continuous	Bradycardia, headache, malaise, hyperglycemia

^a Have not been shown to be effective in terminating nausea or vomiting once it occurs and should not be used for this purpose.

^b Best used for anticipatory nausea and vomiting.

Anorexia/cachexia syndrome (ACS)

ACS (anorexia/cachexia syndrome) is characterized by disproportionate and excessive loss of lean body mass. ACS may occur in up to 80% of patients with advanced cancer.⁴⁶ ACS is usually a marker of disease progression. In a multicenter retrospective review of 3047 cancer patients enrolled on clinical trials from the Eastern Cooperative Oncology Group, weight loss of more than 5% of premorbid weight prior to the initiation of chemotherapy was predictive of early mortality.⁴⁷ Weight loss was independent of disease stage, tumor histology, and patient performance status in its predictive value.⁴⁷

Management of this syndrome should first focus on trying to treat any of the contributing secondary causes. Because anorexia is a prevalent and distressing symptom suffered by most cancer patients, the basis of pharmacologic treatment has focused on alleviating this symptom. The two classes of drugs that have been shown to be effective in phase III clinical trials are corticosteroids and progestational agents.^{48, 49} These drugs do not appear to improve survival, but may improve quality of life. Corticosteroids, usually in the form of dexamethasone at a dose of 4 mg/day (although doses of 2–20 mg/day can be used), has been shown to alleviate cancer anorexia on a short-term basis. This finding has been replicated by other studies and both prednisolone and methylprednisolone have been shown to be effective.⁵⁰ As the duration of appetite stimulation is short lived, and the side effects increase over time, it is most useful for patients with a life expectancy of <6 weeks. Megestrol acetate has been shown to result in dose-dependent improvements in appetite, which usually occur in about 1 week. Improvement in overall well-being has been demonstrated in more than 60% of patients starting at doses of 160 mg/day. The optimal dosing for weight gain appears to be between 480 and 800 mg/day. Effects are seen after several weeks in only 25% of patients.⁵¹ It is important to start at a lower dose and titrate upwards as adverse events are dose related. Adverse events include deep vein thrombosis, especially in those concomitantly on chemotherapy, edema, hyperglycemia, and elevated liver enzymes. Cannabinoids, in its synthetic form of dronabinol, may have some limited effects on improving appetite, but it does not contribute to significant weight gain. In a randomized trial comparing dronabinol to megestrol acetate, significantly more patients had improvement in appetite and weight gain with megestrol acetate.⁵² Combined therapy with both megestrol acetate and dronabinol had no benefit beyond that obtained with megestrol acetate alone. Adverse events with dronabinol include sedation, confusion, and perceptual disturbances.

Dyspnea

Dyspnea is the awareness of an uncomfortable or unpleasant sensation of breathing. The prevalence of dyspnea varies greatly and ranges from 21% to 79% depending on primary disease site, stage of disease, and location of metastasis.⁵³ The sensation of dyspnea is a subjective experience with numerous etiologies. The presence of tachypnea and hypoxia does not adequately reflect the severity of symptoms felt by the patient.⁵⁴ It is not uncommon that patients with moderate to severe tachypnea will not complain of dyspnea. In contrast, patients who are not tachypneic may report severe dyspnea. It is therefore of utmost importance that assessment be based on patient report. The goal of treatment is symptomatic relief of the patient's expression of dyspnea, rather than the correction of objective variables (tachypnea and low oxygen saturation).

The most common modalities used to treat dyspnea include oxygen therapy and opioids. Three randomized controlled crossover studies have evaluated the use of oxygen (4 or 5 L/min) versus air in advanced cancer patients with dyspnea. Two of these studies evaluated patients with hypoxemia on room air and found that oxygen therapy was more beneficial.^{55, 56} The third evaluated nonhypoxemic cancer patients and found that there was no difference between oxygen therapy and air in reducing the intensity of dyspnea.⁵⁷ Opioids are the pharmacologic treatment of choice in the management of dyspnea. Several randomized controlled trials in cancer patients with dyspnea have demonstrated their benefit. In opioid-naïve patients, a starting dose of morphine sulfate 2.5–5 mg orally or its equivalent intravenously every 4 h can be effective. In those patients already on opioid therapy, an increase of 25% in the baseline dose may provide relief.⁵⁸

The terminal phase

Death is a natural process that will occur for every patient. About 10% of people will die suddenly and unexpectedly, while the other 90% die after a period of illness with gradual deterioration until an active dying phase occurs signifying the end of life.⁵ There are “two roads to death,”⁵⁹ the usual road that occurs in most patients and presents as decreasing level of consciousness that leads to coma and death, and the difficult road. The difficult road is marked by terminal delirium, which can manifest as restlessness, confusion, and agitation; it can be a source of great distress for patients, family, and loved ones.⁵⁹ The most common symptoms reported by families in the last week of life are fatigue, dyspnea, and dry mouth, while the most distressing are fatigue, dyspnea, and pain.⁶⁰ The Clinical Practice Guidelines for Quality Palliative Care emphasize that families should be educated regarding the signs and symptoms of approaching death in a manner that is developmentally, age, and culturally appropriate.⁶ While patients and families may still be focused on glucose or blood pressure control, such preventive measures must be taken into the context of the patients' life expectancy. Discontinuation of such medications often involves a detailed discussion about the risks and adverse effects outweighing the probable lack of benefit. The least invasive route of medication administration should be attempted initially using the most invasive route only when absolutely necessary. A variety of physiologic changes occur in the last hours to days of life and the following is a summary of the most common changes that occur^{61, 62}:

- 1. Weakness and fatigue.** Weakness and fatigue usually increase as the patient is approaching death. Patients will begin to spend all of their time in bed and will be less interested in participating in usual activities, including visiting with others.
- 2. Decreased oral intake.** Most dying patients lose their appetite and stop drinking. Many caregivers interpret this as a patient “giving up” or “starving to death.” It is important to explain to patients and their family members that there is a decreased need for food and drink during this phase. There is some evidence suggesting that prolonged anorexia is not uncomfortable. One study found that 97% of dying patients who stopped eating experienced no hunger or hunger only initially.⁶³ It has been proposed that terminal anorexia induces a ketosis that contributes to a sense of well-being and diminished discomfort and may in fact be beneficial to dying patients.^{61, 64} Two meta-analyses of studies of both parenteral⁶⁵ and enteral⁶⁶ nutrition in patients with metastatic cancer found that neither therapy resulted in an improvement in morbidity or mortality and actually resulted in an increased total complication rate. The evidence with respect to hydration in dying patients is less straightforward with many differing expert opinions.^{61, 67–69} Some studies suggest that parenteral hydration prevents and treats some cases of terminal delirium,^{67, 68, 70} and others correlate dehydration

with adverse symptoms such as thirst.^{69, 71, 72} Still others believe that the data does not support a correlation between dehydration and symptoms and that rehydration does not improve patient comfort.^{63, 70} A randomized control trial of advanced cancer patients within weeks of death demonstrated no improvement in symptoms, quality of life, or survival when compared to placebo.⁷³ It is important that each individual patient be evaluated to determine the risk benefit ratio. Attention should be placed on minimizing the sense of thirst and maintaining patient comfort even when dehydration is present, with oral hygiene. This can be achieved by using lollipop sponges dipped in cold fluids such as water, a lemon-flavored drink or sorbet.

3. Delirium. While reversible factors may be identified in up to half of cases, terminal delirium management typically focuses on symptom control with medications.⁷² Treatment should be aimed at the symptoms of delirium while simultaneously attempting to treat reversible causes. Although delirium is most often associated with the last hours to days of life, in some episodes it may be reversible with therapeutic intervention.^{72, 74} Neuroleptic agents are the mainstay of pharmacologic treatment as they are effective in both hypoactive and hyperactive delirium. Of these agents, haloperidol is the agent of choice as it has lower sedating properties, less anticholinergic and cardiovascular effects. The pharmacologic agents commonly used in the management of delirium can be found in [Table 8](#).

Table 8 Pharmacologic therapy of delirium

Drug name	Dosage/route	Comments
Haloperidol	0.5–5 mg PO/IV/IM/SC every 6–12 h	Most commonly used agent. Can prolong QT interval
Chlorpromazine	12.5–50 mg PO/IV/IM every 8–12 h	Has similar efficacy to haloperidol, but more sedating, anticholinergic and hypotensive effects
Lorazepam	0.5–2 mg PO/SL/IV every 4–8 h and titrate as needed	Most commonly used as a second agent in combination with haloperidol. Can also be used as a continuous infusion for refractory cases where deep sedation is needed. May worsen delirium in the elderly. Caution with liver failure
Risperidone	Start at 0.5–1 mg/day PO and titrate up to 4–6 mg/day	In one study shown to have no differences in side effects when compared to haloperidol. Limited use as only available in oral route
Olanzapine	5 mg PO qhs and titrated to effect (max 20 mg/day)	Risk factors for a poor response to olanzapine in cancer patients are: <ul style="list-style-type: none">• Age >70• History of dementia• CNS metastases• Hypoxia• Hypoactive delirium
Midazolam	1 mg/h IV and titrated to effect	Most commonly used for refractory cases where sedation is needed

Grief and bereavement

Bereavement is the state of loss as a consequence of death.⁷⁵ Grief is defined as the emotional response to loss and mourning, and often refers to social expressions associated with loss.⁷⁵ Several types of grief exist: anticipatory grief, uncomplicated grief, and complicated grief. Anticipatory grief refers to the mourning that occurs in patients and families prior to death and is a way to facilitate the adjustment to bereavement. Uncomplicated grief is the most common type of grief reaction and is socially perceived as normal. Complicated grief involves the persistence of grief reactions over a long period of time and is characterized by an inability to return to the pre-loss level of functioning.⁷⁶ Palliative care provides grief and bereavement services to patients and their caregivers before, during, and after death to help promote healthy grieving.

Both hospice and palliative care have been shown to provide effective pre-loss interventions for preventing complicated bereavement. These interventions are associated with a reduced risk of major

depressive disorder in caregivers.⁷⁷ The multidisciplinary palliative care team including physicians, social workers, nurses, psychologists, and chaplains performs a psychosocial assessment of the patient and caregiver in order to identify those that may be high risk for complicated grief. The palliative care team can provide basic practical help before death such as assisting with advanced directives, assistance with financial matters, and encouraging individual medical care of the caregiver as well as providing assistance after death by offering counseling or referral to other support services.

Hospice

Hospice is a philosophy of care. The goal of hospice is to focus on maintaining the best quality of life rather than length of life in patients who have a life expectancy of 6 months or less. It is different from palliative care in that palliative care is given simultaneously with other curative and life-prolonging therapies. Hospice services have been available in the United States since 1974 and have been funded by Medicare as part of the Medicare hospice benefit since 1982.⁷⁸

Hospice is the only Medicare benefit that includes medications, durable medical equipment, and continuous around-the-clock access to care and support. Bereavement services are also offered to family members after a patient's death. The Medicare hospice benefit covers all care related to the cancer diagnosis. The patient can still receive Medicare benefits for the treatment of other illnesses.

Most hospice care is delivered at home. It is also provided in other settings such as inpatient hospice facilities, nursing homes, assisted living facilities, and hospitals. It is estimated that approximately 45% of all people who died in the United States in 2011 were under the care of a hospice program and of all patients enrolled, 38% had a diagnosis of cancer.⁷⁹ In a study comparing survival of hospice to nonhospice patients, hospice care prolonged the lives of some terminally ill cancer patients.⁸⁰ The mean survival period was significantly longer for hospice patients with lung cancer (39 days longer) and pancreatic cancer (21 days), while marginally significant for colon cancer (33 days).⁸⁰

Summary

Palliative care is patient- and family-centered interdisciplinary care that focuses on relieving suffering and providing the best quality of life for patients undergoing curative and life-prolonging treatments as well as for patients in whom cancer specific treatments are no longer available. It is estimated that 35% of patients with cancer will die from their disease.⁸¹ Increasing attention has been given to improvements in quality of life issues in oncology, for patients undergoing chemotherapy, patients at the end of life as well as cancer survivors. Prevalence of symptoms during cancer treatment can be substantial. Palliative care is an integral part of comprehensive cancer care. Palliative care is most effective when initiated at the time of diagnosis allowing for patients to be followed through the trajectory of illness. The oncologist plays a key role in discussing treatment options, curative or palliative, from the outset of the diagnosis. Assessing the patients' goals is equally as important. Patients should be made aware that receiving anticancer treatments does not preclude them from access to palliative care services. Increasing the emphasis on palliative care in oncology should improve patient outcomes and can diminish some of the oncologist's stress of caring for patients with serious and life-threatening illness.

Palliative care has experienced a rapid growth in the last two decades in response to the increasing number of patients living with serious illness, an increased demand for high-quality symptom

control, desire for improved coordination of care across settings and increased need for advance care planning. The number of palliative care programs within hospital settings has increased by 138% since 2000.⁸² Expansion of palliative medicine education is supported by the Liaison Committee on Medical Education, which has mandated medical school education in palliative medicine, and the ACGME (accreditation council for graduate medical education), which requires oncology fellow training in palliative medicine. There is a plethora of Internet-based resources that provide physicians in practice with access to further information and education on palliative care (Table 2).

Chapter 47

Principles of psycho-oncology

Jimmie C. Holland, MD ■ Talia W. Wiesel, PhD

Psychiatric terms seem poorly descriptive of the emotional responses of cancer patients who are finding ways of coping with an overwhelming but “real” reality. Words such as courage and strength often appear more appropriate

J.C. Holland, Cancer Medicine, 1973, p. 992

Overview

This chapter provides oncologists with the present state of the art in psycho-oncology, a subspecialty that has evolved over the past 30 years. The basic treatment, particularly pharmacologic, is outlined for anxiety, depression, and delirium, as well as the psychotherapeutic interventions which are based on evidence. The field has come of age since it received the Institute of Medicine blessing in 2008 stating that quality cancer care must integrate the psychosocial domain in routine care. This was given a strong boost from the American College of Surgeons Commission on Cancer which made screening for distress a quality standard for accreditation in 2015, requiring that all cancer centers have in place—or in development—an on-site program to identify and triage patients who are distressed. This has resulted in a strong effort to develop routine screening of all new patients to assure that they are recognized early and treated appropriately. Implementation of programs is in progress across the country with assistance available from the American Psychosocial Oncology Society (APOS) which has organized training, consultation, and ongoing mentoring for cancer staff. Indeed, thanks to these changes in national policy related to cancer, it is a different experience for patients today to cope with cancer. Attention has turned to providing patient-centered care which encompasses care of the whole person.

Psychiatric terms seem poorly descriptive of the emotional responses of cancer patients who are finding ways of coping with an overwhelming but “real” reality. Words such as courage and strength often appear more appropriate

J.C. Holland, Cancer Medicine, 1973, p. 992

Introduction

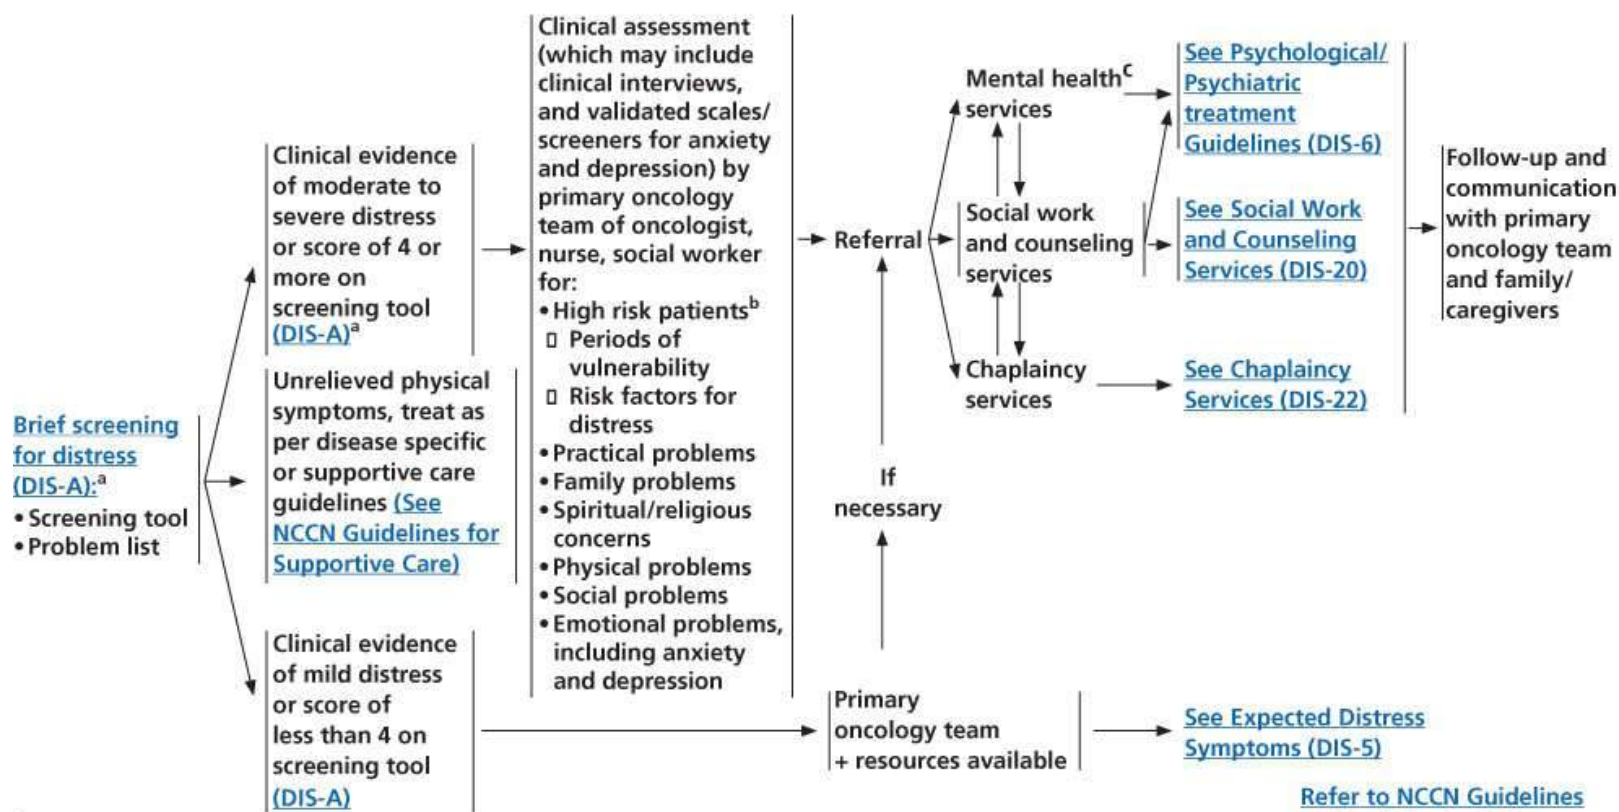

The above quote appeared in the first edition of Cancer Medicine in 1973. Over the past 40 years, the human aspects of cancer care have not changed in terms of patients' emotions. However, there is now a range of interventions to make the journey more tolerable. Part of this remarkable change relates to contributions from psycho-oncology. These changes were made possible by, first, the development of assessment tools, which quantitatively measured subjective symptoms that were previously considered unmeasurable. Second, these tools permitted conduct of clinical trials, which resulted in evidence-based interventions. These were integrated in the first NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®) for Distress Management, in the late 1990s.¹ The third event was the first policy statement

noting this body of work by the Institute of Medicine in its report in 2008, *Care of the Whole Patient*, which stated that the psychosocial domain must be integrated into routine care.² This was carried to an even higher policy level by the American College of Surgeons Commission on Cancer, which, in 2015, required accredited cancer centers to have a program in place to identify and refer distressed patients for appropriate care.³ This has led to efforts by psycho-oncologists to help the multidisciplinary teams at cancer centers implement this new policy.^{4, 5} Patients in the future should be identified earlier in the course of illness by these routine screening programs. However, the new procedure places a bigger burden on oncologists in busy practices to assure that patients with identified distress are treated by the primary team or referred for more specialized psychosocial care. [Figure 1](#) presents the NCCN Guideline® for evaluation and treatment suggesting that all new patients be screened for distress.⁶ [Figure 2](#) shows the NCCN single question recommended for identifying distressed patients in busy clinics. Patients and oncologists have found asking the question, “How is your distress level on a scale of 0 to 10” to be acceptable, brief, and nonstigmatizing. Called the Distress Thermometer, it is widely utilized internationally, containing the scale and a Problem List to identify frequent causes of distress. Validation studies have found that a score of 4 or more should prompt a second evaluation by a team member to determine the nature of the distress and if the patient should be referred to mental health, social work, or chaplaincy.

OVERVIEW OF EVALUATION AND TREATMENT PROCESS

EVALUATION

TREATMENT

[Refer to NCCN Guidelines Table of Contents for Supportive Care Guidelines.](#)

SCREENING TOOLS FOR MEASURING DISTRESS

Instructions: First please circle the number (0-10) that best describes how much distress you have been experiencing in the past week including today.

Extreme distress

No distress

Second, please indicate if any of the following has been a problem for you in the past week including today. Be sure to check YES or NO for each.

YES NO Practical Problems

- ☐ ☐ Child care
☐ ☐ Housing
☐ ☐ Insurance/financial
☐ ☐ Transportation
☐ ☐ Work/school
☐ ☐ Treatment decisions

Family Problems

- ☐ ☐ Dealing with children
☐ ☐ Dealing with partner
☐ ☐ Ability to have children
☐ ☐ Family health issues

Emotional Problems

- ☐ ☐ Depression
☐ ☐ Fears
☐ ☐ Nervousness
☐ ☐ Sadness
☐ ☐ Worry
☐ ☐ Loss of interest in usual activities

☐ ☐ Spiritual/religious concerns

Other Problems: _____

YES NO Physical Problems

- ☐ ☐ Appearance
☐ ☐ Bathing/dressing
☐ ☐ Breathing
☐ ☐ Changes in urination
☐ ☐ Constipation
☐ ☐ Diarrhea
☐ ☐ Eating
☐ ☐ Fatigue
☐ ☐ Feeling Swollen
☐ ☐ Fevers
☐ ☐ Getting around
☐ ☐ Indigestion
☐ ☐ Memory/concentration
☐ ☐ Mouth sores
☐ ☐ Nausea
☐ ☐ Nose dry/congested
☐ ☐ Pain
☐ ☐ Sexual
☐ ☐ Skin dry/itchy
☐ ☐ Sleep
☐ ☐ Substance abuse
☐ ☐ Tingling in hands/feet

This chapter outlines the basic information an oncologist needs for rapid assessment and management of the most common psychiatric complications.⁷

Clinical management

Vulnerable patients

Patients who are most vulnerable to distress are those with⁸:

- Prior psychiatric disorder (depression and substance abuse)
- Cognitive problems
- Language or communication problems

- Comorbid medical illnesses
- Social problems (family, financial, and living alone)
- Spiritual or religious concerns.

Points of increased vulnerability to distress for patients with cancer⁸

- Finding a symptoms suspicious of cancer
- Learning the cancer diagnosis
- Waiting for biopsy and genomic testing of tumor tissue to determine mutations to guide targeted treatment
- Awaiting initial treatment
- Transitions in treatment
- Finish of curative treatment
- Transition from curative to palliative care
- Advanced cancer and end of life
- Fears of recurrence during survivorship.

Among these patients, most are managed well by the primary oncology team. Situational anxiety, sadness, insomnia, fatigue, fears, and concerns are common and respond to reassurance and medication. However, some patients experience more difficulty coping and have significant distress that requires more aggressive interventions. Management of the most commonly occurring psychiatric disorders is outlined below for anxiety, depression, suicidal risk, delirium, and personality disorders.

Anxiety disorders

Anxiety occurs as a reaction to the threat of illness, but it also occurs from a range of metabolic states and medications, requiring a careful clinical review of these issues. It may occur with panic attacks (tachycardia and hyperventilation) and depressive symptoms. Treatment may be psychological by psychotherapy, particularly cognitive–behavioral approaches; relaxation and meditation are useful, as well as online interventions. If anxiety persists or is severe, several medications are useful. [Table 1](#) outlines the most commonly used drugs. However, olanzapine, an antipsychotic, is also often used off label to treat severe anxiety with good result.

Table 1 Pharmacological treatment of anxiety

Drug	Starting dose	Maintenance dose
<i>Selective serotonin reuptake inhibitors</i>		
Escitalopram (Lexapro®)	10–20 mg	10–20 mg/day PO
Fluoxetine (Prozac®)	10–20 mg qAM	20–60 mg/day PO
Citalopram (Celexa®)	10–20 mg	10–20 mg/day PO
<i>Benzodiazepines</i>		
Alprazolam (Xanax®)	0.25–1.0 mg	PO q 6–24 h
Clonazepam (Klonopin®)	0.5–2.0 mg	PO q 6–24 h
Diazepam (Valium®)	2–10 mg	PO/IV q 6–24 h
Lorazepam (Ativan®)	0.5–2.0 mg	PO/IM/IVP/IVPB q 4–12 h

Abbreviations: IM, intramuscular; IVP, IV push; IVPB, IV piggyback; PO, oral.

Data from *Psycho-Oncology: A Quick Reference on the Psychosocial Dimensions of Cancer Symptom Management*.⁷

Depressive disorders and suicidal risk

Depressive disorders

Sadness is part of the normal response to cancer; however, more significant symptoms are lack of pleasure (anhedonia), hopelessness, and despair. They often contribute to stopping or delaying treatment, and thereby, contribute to a poorer outcome. These symptoms may be accompanied by insomnia, fatigue, and anorexia, all of which must be differentiated from cancer-related causes. The symptoms may be psychological in origin, but drug side effects, metabolic abnormalities, and paraneoplastic disorders also cause depression.

Treatment may be psychological alone, using supportive and cognitive psychotherapy approaches, as well as behavioral interventions of relaxation and meditation. If the symptoms persist or are severe, a combined psychological and medication approach is useful. [Table 2](#) outlines the medications, which are recommended, including psychostimulants, which are increasingly used for patients with fatigue and poor concentration.

Table 2 Selected antidepressants to treat depression in cancer patients

Drug	Starting dose	Maintenance dose	Comments
<i>Selective serotonin reuptake inhibitors</i>			
Citalopram (Celexa®)	10 mg/day	20–40 mg/day	Soltabs available
Escitalopram (Lexapro®)	5–10 mg/day	10–20 mg/day	Possible nausea, sexual dysfunction
Fluoxetine (Prozac®)	10–20 mg/day	20–60 mg/day	Long half-life; possible nausea, sexual dysfunction; strong CYP450-2 D6 inhibitor
Paroxetine (Paxil®)	20 mg/day	20–60 mg/day	Possible nausea, sedation, strong CYP450-2D6

			inhibitor
Sertraline (Zoloft®)	25–50 mg/day	50–150 mg/day	Possible nausea
<i>Tricyclic antidepressants</i>			
Amitriptyline (Elavil®)	25–50 mg qhs	50–200 mg/day	Maximal sedation; anticholinergic effects; useful for neuropathic pain
Desipramine (Norpramin®)	25–50 mg/day	50–200 mg/day	Modest sedation; anticholinergic
Nortriptyline (Pamelor®)	25–50 mg qhs	50–200 mg/day	Moderate sedation; useful for neuropathic pain
<i>Other agents</i>			
Bupropion (Wellbutrin®)	100 mg/day	100–400 mg/ day 450 mg/day XL; 400 mg/day SR	Activating; sexual dysfunction; seizure risk in predisposed patients
Duloxetine (Cymbalta®)	20–40 mg/day	60 mg/day	Possible nausea, dry mouth; may be useful for neuropathic pain
Mirtazapine (Remeron®)	15 mg qhs	15–45 mg qhs	Sedating, variable appetite-stimulant, antiemetic effects
Desvenlafaxine (Pristiq®)	50 mg daily	50–100 mg daily	Nausea
Venlafaxine (Effexor®)	18.75–37.5 mg/ day	75–225 mg/day; XR once daily	May be used for neuropathic pain, hot flashes, nausea
<i>Psychostimulants</i>			
Dextroamphetamine (Dexedrine®)	2.5 mg BID	5-30 mg	Possible blood pressure/cardiac complications
Methylphenidate (Ritalin®)	5 mg BID	10-60 mg	Agitation, anxiety, nausea
Modafinil (Provigil®)	50 mg BID	50-200 mg	Activating, nausea, cardiac side effects; usually well tolerated
Armodafinil (Nuvigil®)	50 mg	50–200 mg	Morning only; headache, nausea, dizziness, dry mouth

Data from *Psycho-Oncology: A Quick Reference on the Psychosocial Dimensions of Cancer Symptom Management*.⁷

Suicidal risk

Many patients comment “If things get bad enough, I will kill myself.” Few rarely come to that point. It seems to represent a way to emotionally maintain control over the disease. However, any suicidal threat must be taken seriously and evaluated. Thoughts about it must be explored. Questions to open the discussion may be, “Have you felt like you did not want to live anymore?” There is greater concern if the person outlines a plan. Those at the highest risk of suicide are patients with

- [Prior psychiatric or suicide attempt history](#)

- Severe uncontrolled pain
- Advanced disease
- Mild delirium (interfering with rational judgment)
- Alcohol and substance use.

Recognizing patients at higher risk for suicide⁸

- Initial diagnosis of advanced disease
- Risk of suicide is highest within the first month and remains high for 6 months
- Lung cancer has the highest suicide rates followed by head and neck, stomach, pancreas, and colon
- Anticipation of debilitating or deforming surgery
- Patients with depression, hopelessness, or guilt for being a burden
- Severe pain that is constant and poorly controlled.

It is important in evaluating suicide risk to treat it as a possible psychiatric emergency. The person should not be left alone until the level of risk is fully assessed. If risk is high, referral to a safe environment may be necessary. However, this is often difficult in a patient with advanced cancer, and every effort should be made to maintain the patient in the same environment, controlling any physical symptoms, particularly pain. Consultation with a mental health professional may be needed, with full involvement of family to continue surveillance at home.

Delirium

Delirium is common in hospitalized patients, particularly in the postoperative state, and among older people who may have underlying mild cognitive impairment. It is often under-recognized and undertreated as it occurs commonly with fever, drugs, metabolic disturbances, central nervous system metastases, and paraneoplastic disorders. The classic symptoms are acute onset with fluctuating attention and confusion and either psychomotor slowing or agitation. Misperceptions (illusions) of the environment are common as are visual or auditory hallucinations, usually paranoid in nature. Medications that control these symptoms are antipsychotics, benzodiazepines, and short-acting anesthetics that are used primarily in intensive care units. The patient must be placed in a safe environment, which may include use of physical restraints to prevent self-harm from pulling out catheters and tubes. Constant observation initially is important, best in an intensive care unit or in a quiet room with familiar figures, including family members, who can reassure and reorient the patient to the environment. See [Table 3](#) for drugs that are commonly utilized.

Personality disorders

Patients with personality disorders are difficult because there is no distinct psychiatric disorder *per se* to treat, and the oncologist must deal with the unusual ideas and behaviors of the patient that can impact treatment. There are several personality types that are most difficult during cancer treatment.

Table 3 Selected medications for management of delirium in cancer patients

<i>Antipsychotics</i>		
Haloperidol ^a (Haldol®)	0.5–5 mg q 30 min–12 h PO, IM, IV	
Chlorpromazine ^a (Thorazine®)	25–100 mg q 4–12 h PO, IM, IV	
Risperidone (Risperdal®)	0.5–2 mg q 12 h PO	
Olanzapine (Zyprexa®)	2.5–5 mg q 12–24 h PO, IM	
Quetiapine (Seroquel®)	12.5–50 mg q 12 h PO	
<i>Benzodiazepines</i>		
Lorazepam ^a (Ativan®)	0.5–2 mg q 1–4 h PO, IM, IV	Only in the setting of alcohol withdrawal delirium
Midazolam ^a (Versed®)	0.003 mg/kg/h titrate to effect IV (per anesthesiologist)	
<i>Anesthetics</i>		
Propofol ^a (Diprivan®)	0.5 mg/kg/h titrate to effect IV	Rapid onset of sedation and recovery
<i>Alpha agonists</i>		
Dexmedetomidine (Precedex®)	1 mcg/kg over 10 min followed by continuous infusion 0.2–0.7 mcg/kg/h	Rapid onset sedation and recovery; no effect on cognition
<i>Intensive care setting: Propofol and dexmedetomidine provide rapid onset of sedation and recovery</i>		

^a May be administered by continuous infusion usually in the intensive care setting.

Data from *Psycho-Oncology: A Quick Reference on the Psychosocial Dimensions of Cancer Symptom Management*.⁷

- Paranoid disorder.* These patients are suspicious, quickly take offense, and can be argumentative and angry with oncology team members.
- Borderline disorder.* These patients act out their emotions and may make suicide attempts, have wide mood swings, and often challenge the team with demands that cannot be met. It is necessary to set boundaries and alert *all* team members about the treatment plan.
- Histrionic disorder.* These patients tend to dramatize symptoms. They express intense emotions that can be difficult to manage. They are suggestible and may be sexually provocative. Awareness of these qualities is important.
- Narcissistic disorder.* The patient is self-centered, is entitled, expects to be treated as “special,” is arrogant, and seems to care little for the problems of others.
- Obsessive compulsive.* These patients are concerned with minute details about illness and treatment and are demanding of self and others. They lack flexibility and may have compulsive rituals.

Dependent disorder. These are patients who lack self-confidence, need frequent reassurance, and have trouble making decisions. These traits interfere with treatment and often require greater time for emotional support.

The primary issue for the oncologist is to be aware of these characteristics in patients and not to respond personally to their quirks but recognize that they are part of a personality pattern. An oncology team does well to discuss those patients with severe disorders and share the emotional stress. Unfortunately, they are often angered by suggestion of a psychiatric referral and will refuse it.

Psychosocial interventions

A number of clinical trials have given an evidence base for several nonpharmacologic psychosocial interventions.^{5, 9}

Psychotherapies in cancer care

Cognitive therapies

While supportive psychotherapy is at the heart of relating to all patients, several cognitive-based therapies have shown efficacy. Cognitive-behavioral therapy (CBT) is widely used for anxiety and depressive symptoms¹⁰ as well as post-traumatic stress disorder (PTSD). It is a short-term therapy that addresses the current issues of coping with illness and assists the patient to perceive fears and concerns in a more constructive way. Problem-solving therapy encourages seeing illness in a new way, being optimistic, planning with family and patient to address the challenges together. Interpersonal psychotherapy concentrates on the changed relationships caused by illness and explores ways to relate to the altered roles. These therapies can be learned rapidly by psycho-oncology clinicians. There are also therapies now that are developed for special problems, such as grief. Others are directed for use at a particular stage of illness or age, particularly therapies developed for adolescents, young adults, and older patients. Dignity therapy and mindfulness-based therapy address the issues at the end of life, providing a comforting perspective.

Behavioral interventions

Behavioral interventions have also proven of value in cancer patients. Progressive muscle relaxation (PMR) exercises, guided by a person or a tape, are helpful for insomnia and anxiety, and once learned, they can be applied by the patient when needed. Mindfulness-based stress reduction/meditation has been studied and is widely practiced, coming from the eastern Buddhist tradition. It is learned in individual or group sessions and is best applied as a daily practice, which has a calming effect on anxiety. Similarly, guided imagery has a soothing effect. Physical exercise, on a daily basis, as illness will allow, is highly recommended today throughout treatment and as a health habit for survivors. It has both mental and physical benefits.

Group and online therapies

Groups for psychosocial support have proven their value over many years. They are most effective when they bring together patients who are coping with the same cancer. The sharing of experience is highly beneficial and supportive. Today, virtual groups are common, and they too have proven efficacious by telephone and online. Less research has been done on these newer approaches, but they are increasingly used with far less cost and likely will become more popular. Helplines are part of advocacy

organizations' services, such as Cancer Care and Cancer Support Community. All have web sites with reliable information and directories of mental health clinicians who accept referrals. Helplines for specific sites of cancer also provide a telephone "buddy" who matches the situation of the person calling for help. Excellent resources for information about psychological support are CancerCare 1800-813-HOPE (4673) (www.cancercare.org) and Cancer Support Community (CSC) 1-888-793-9355 (www.cancersupportcommunity.org).

Today, patients have access to a range of psychological supports that vary from free online telephone counseling to individual therapy sessions based on fee for service. Insurance for psychiatric and psychological visits is not yet on parity with medical coverage, but there is optimism that this may be achieved in the near future. There is a shortage of mental health professionals trained in psycho-oncology to meet the present clinical need, in part because reimbursement is so low.

Complementary therapies

Today, there is a range of interventions that patients may choose from which fit their lifestyle best. Art therapy is a very good way to express emotions. Music and dance therapies are available and also provide support. Writing and guided reading are both therapeutic. Most cancer centers have integrative therapies available for patients so that they can choose the complementary therapy they want, which includes acupuncture, nutritional advice, and psychological and behavioral interventions.

Burnout in oncology

Caring for patients with cancer demands time and emotional resources of the oncologist and the team. When the stress is severe or prolonged, it is called burnout syndrome. Surveys suggest that it affects approximately one-third of medical oncologists^{11–17} and may be higher for radiation oncologists.^{18–20} The syndrome was first described by Freudenberger²¹ in 1974. It comprised symptoms in three areas: emotional exhaustion, depersonalization (reduced capacity for empathy), and a sense of low achievement.²² The syndrome has professional and personal consequences for the physician. It impairs clinical judgment, which can lead to medical error.^{23, 24} Similarly, risk of suicide is greater.

A national study of 7000 physicians revealed a slightly lower prevalence of burnout for medical oncologists (37.9%) than other internal medicine physicians (48.8%).²⁵ They more often experienced depression. However, they more often said that they would repeat their choice of medical oncology if given the chance.

The causes of burnout are related to prolonged heavy work schedules, increased demands, and conflicts between work and personal life. Oncologists work a median of 63 h/week, compared to the average physician 50-h work week.²⁶ Malpractice suits increase the risk of burnout. Medical oncologists carry the highest risk among nonsurgical specialties.²⁷

Burnout is preventable and treatable, but it requires being alert to its diagnosis responds to early intervention. Prospective studies suggest that training oncologists through self-awareness techniques and mindfulness-based meditation results in improved empathy and less depression.^{28, 29} Physical exercise is useful for both its physical and mental effects. Studies are investigating teaching resilience in medical school curricula.^{30, 31} Physicians who note a high level of positive meaning in their work, who have a reasonable work–life balance, and who focus on clear priorities are less vulnerable to burnout.^{32, 33} There is also an advantage in working in an environment where referral for family or social problems is encouraged. Many physicians blame their distress on work when, in fact, they are suffering from serious

Summary

The person who is treated for cancer today experiences a far more psychologically supportive environment than 40 years ago. Society is better educated about cancer, which has reduced fears and stigma. The successes of cancer therapies have resulted in 14 million survivors. Today, patients have access to a more empathic primary oncology clinic team whom they come to know well and rely on. In addition, there are often social work and mental health resources available, as well as dietitians, rehabilitation medicine, and complementary therapies. Patients with significant distress are increasingly being identified earlier in their course of treatment through routine screening and are referred to counselors. As compared to the situation in 1973, as described in the first edition of *Cancer Medicine*, the 40 years has produced a remarkable increase in concern about patients' well-being during cancer treatment. Psycho-oncology has had a role in this change through the development of a science of its own, which has resulted in a range of evidence-based psychological, behavioral, and pharmacologic interventions. The challenge today is to implement the psychosocial domain into routine care so that no patients who are distressed go untreated.

chapter 48

Principles of cancer rehabilitation medicine

Michael D. Stubblefield ■ MD, David C. Thomas, MD, MHPE ■ Kristjan T. Ragnarsson, MD

Overview

Many of the more than 14 million cancer survivors in the United States suffer from complications of disease and treatments such as surgery, chemotherapy, and radiotherapy. Restoring and maintaining the cancer survivors' function and quality of life often requires specialized rehabilitative services. The cancer rehabilitation specialist is dedicated to the identification, evaluation, and rehabilitation of neuromuscular, musculoskeletal, pain, and functional disorders associated with cancer and its treatment. This discusses the principles and practice of rehabilitation in this challenging group of patients.

Introduction

The cancer rehabilitation specialist focuses on the identification, evaluation, and rehabilitation of neuromuscular, musculoskeletal, pain, and functional disorders associated with cancer and its treatment emphasizing the restoration and maintenance of function and quality of life. There are now more than 14 million cancer survivors in the United States.¹ This number is expected to grow to more than 18 million by 2020.² Many of these patients have complications of disease and treatment that are often compounded by medical comorbidities that require specialized rehabilitative services. This chapter discusses the role of the rehabilitation medicine specialist in restoring and maintaining function and quality of life to select groups of cancer survivors including those with cancer of the brain, head and neck, breast, and those with spinal cord dysfunction (SCD).

The rehabilitation team

Organized cancer rehabilitation programs can significantly improve a patient's physical function and community reintegration.^{3–6} An integral part of such programs is an interdisciplinary cancer rehabilitation and adaptation team. The exact composition of the team varies considerably, depending on the program's philosophy and size, the type of institution, and the range of disabilities encountered. Ideally, the team should be led by a physiatrist. The team members and their roles are described in [Table 1](#).

Table 1 Interdisciplinary cancer rehabilitation team

Team member	Role
Caregiver(s)	Participates as source of support for the patient as well as developing a relationship with the team as an extension of the patient
Chaplain	Evaluates and assists with the spiritual needs of the patient and caregivers
Nutritionist	Evaluates the patient's nutritional condition, assesses the additional metabolic demands that the cancer places on the body, and recommends the optimal diet with respect to specific clinical condition, caloric intake, food ingredients of choice, optimal consistency for easy swallowing, and the individual's tastes
Occupational therapist	Evaluates and develops a plan with a focus on the upper extremities range of motion and strength as well as training in self-care activities
Patient	Participates as an active member of the team in decisions regarding all aspects of treatment
Physical therapist	Evaluates and develops a plan to improve joint range of motion, strengthen muscles, increase stamina with a focus on improving functional skills such as bed mobility, transfers, wheelchair locomotion, and ambulation with or without assistive devices
Physician (physiatrist)	Leads the rehabilitation team to establish realistic goals and prescribe an appropriate rehabilitation program including a plan for preventive, restorative, supportive, and palliative therapies
Prosthetist–orthotist	Evaluate and fabricate artificial limbs (prostheses) or special braces (orthoses) according to the patient's needs
Psychologist	Assesses the patient's cognition and behavior, including intelligence, personality, personal history, motivation, and reaction to the illness, and assists the patient and the caregivers in developing a plan for coping with the medical illness
Recreational therapist	Offers various activities to each patient to meet their individual needs such as art and/or music therapy, attending events, and other social activities important to the patient
Rehabilitation nurse	Evaluates the patient's specific nursing needs and determines a plan including education of the patient and caregivers
Speech-language pathologist	Evaluates and provides therapy for impaired oral communication and works closely with the occupational therapist and nutritionist in the assessment and care of swallowing disorders
Social worker	Evaluates and plans for the psychosocial aspects of the patients treatment especially with respect to discharge planning, facilitating a smooth transition to the community, ensuring continuity of care, and securing appropriate follow-up services after discharge
Vocational counselor	Evaluate needs of patients who may potentially return to work and assist with planning re-entry to the workforce

Cancer of the brain

Brain damage may result from primary tumors of the brain, metastases, or treatments such as surgery, radiation, and chemotherapy. The symptoms and resulting disability vary extensively, but are often similar

to those seen after a stroke ([Table 2](#)). Functional recovery in patients with brain tumors is equivalent to that of patients with acute stroke.⁷ The deficits are determined by the location and size of the brain lesion, but their variability demands individual evaluation and treatment planning. All patients with brain cancer and impaired function in mobility and activities of daily living (ADL) should be referred for rehabilitation with a goal of helping them become independent in these two areas. The length of stay in an inpatient rehabilitation facility for patients with a brain tumor is generally shorter than for patients with traumatic brain injury and stroke.^{8,9} Simple instructions, training by therapists, and provision of assistive devices may help the patient to quickly regain greater or even total independence. When life expectancy appears to be good and deficits are more profound, a comprehensive inpatient rehabilitation program may be the best option. Strengthening of weak muscles, stretching of tight joints and muscles along with skills training can be very effective in order to restore mobility and self-care functions. Reduction of spasticity with thorough frequent stretching of all joints, appropriate medications, and targeted use of botulinum toxin injections can be very helpful. Impaired balance and abnormal gait may be related to muscle weakness, fatigue, spasticity, proprioceptive loss, as well as diminished vision and cognition. All of these increase the risk of falling. Such risk may be decreased by muscle strengthening and aerobic exercises, balance and gait training using proper mobility aids (canes, crutches, walkers), wearing proper shoes and orthoses, modification of the home and workplace environment, reducing use of sedating drugs, and so on. Control of pain is important as well as elimination of joint contractures. Various visual deficits, including double vision and field deficits, need to be addressed, often by the use of alternating eye patches or special prism glasses. Speech disorders, such as dysarthria and aphasia, with impaired communication skills need to be evaluated and properly managed, often by introducing alternative communication methods such writing, typing, sign language, and pictures.

Table 2 Rehabilitation problems associated with cancer of the brain

- Paralysis
- Spasticity
- Joint contractures
- Pain
- Sensory deficits
- Visual field deficits
- Diplopia
- Aphasia
- Dysarthria
- Dysphagia
- Ataxia
- Cognitive and behavioral deficits
- Visual perceptual deficits
- Psychosocial vocational deficits

Neuropsychological changes of varying degrees are associated with cancer affecting the cerebral

hemispheres and may include reduced memory, judgment, visual perception, and so on. Careful evaluation of such deficits, followed by education of the patient and the family of the impact of such changes, is fundamental. Neuropsychological remediation and compensation strategies, such as provision of a “memory book,” may be helpful as well.

Spinal cord dysfunction

Primary tumors of the spine are uncommon, the most frequent being multiple myeloma. Metastases are much more common and are found in 5% of all cancer patients at autopsy.¹⁰ The most common cause of SCD is metastatic epidural compression.¹¹ SCD may also be iatrogenic resulting from radiation, chemotherapy, or surgical intervention. The most common initial symptom of a spinal tumor is pain. Neurologic dysfunction of varying degree may develop either suddenly or gradually depending on the cancer's growth and location. The neurologic level refers to the most caudal segment with normal sensory and motor function bilaterally. Below that level, the neurologic deficits are classified by using the American Spinal Injury Association(ASIA) impairment scale.¹² The neurologic level and degree of complications caused by a lesion will help predict the functional prognosis. Prognosis for life varies with cancer type. The median survival for spinal metastases is 7.7 months, worse for those with colon and lung cancer, but better for those with sarcoma, prostate, kidney, and breast cancer.¹³

Most spinal metastases are managed nonsurgically. When neurologic deficits occur rapidly, surgical decompression and/or radiotherapy is generally indicated. Spinal metastases and primary tumors may result in spinal instability, which should be managed with surgical stabilization.¹⁴ The rehabilitation of cancer patients with SCD depends on assessment of their neurologic, oncologic, medical, pain, and social support status.¹¹ SCD with profound paralysis and sensory loss, along with bladder and bowel dysfunction, requires specialized medical and nursing care, followed by comprehensive rehabilitation addressing each of the associated conditions ([Table 3](#)). Prevention of urinary tract complications, pressure ulcers, deep vein thrombosis/pulmonary embolism, joint contractures, and other complications must be addressed immediately with implementation of intermittent bladder catheterizations, prophylactic anticoagulation, proper bed positioning, and turning at least every 2 h, range of motion exercises, bowel evacuation routine, and focused emotional support. Physical and occupational therapists aim to restore mobility and self-care skills. Ambulation with assistive devices may be possible for many patients with incomplete lower level SCD, but those with neurologically complete thoracic or cervical level SCD will require a manual or powered wheelchair. Persons with incomplete SCD may benefit from ambulation training, which includes body weight support, that is, overhead suspension. Those with complete thoracic level SCD will require orthoses to stabilize their knees and ankles. Many with low lumbar level SCD may benefit from ankle-foot orthoses to compensate for ankle muscle weakness, such as a foot drop, in addition to using crutches or walkers for ambulation.

Table 3 Conditions associated with spinal cord dysfunction

- Loss of motor power
- Loss of sensation
- Pressure sores
- Urinary dysfunction
- Bowel dysfunction
- Sexual dysfunction
- Pain
- Spasticity
- Autonomic dysreflexia
- Joint contractures
- Heterotopic ossification
- Circulatory disturbances
- Orthostatic hypotension
- Edema
- Deep vein thrombophlebitis
- Respiratory insufficiency
- Metabolic disturbances
- Hormone imbalance
- Psychological problems
- Social problems
- Vocational problems

Recent development of robotic exoskeleton electrically powered devices, with a variety of controlled mechanisms, holds promise to enable people with complete paraplegia to regain a degree of independent and functional ambulation.¹⁵ As soon as deemed medically and functionally appropriate, the patient with SCD is discharged with necessary assistive devices, nursing supplies, personal assistance, and instruction for subsequent medical care.

Cancer of the head and neck

Contemporary multimodal treatment of head and neck cancer (HNC) can involve surgery and/or intensity-modulated radiation therapy (IMRT) with or without platinum-based chemotherapy. Surgery often involves resection of the primary tumor as well as neck dissection historically classified as radical [removal of all lymph nodes, spinal accessory nerve (SAN), sternocleidomastoid (SCM) muscle, internal jugular vein (IJV)], modified radical (removes all lymph nodes but spares one or more of the SAN, SCM, IJV), or selective (preserves one or more lymph node level normally removed in a radical neck

dissection).¹⁶

In general, the more extensive neck dissections result in more severe shoulder dysfunction, pain, and reduced quality of life.¹⁷ Although resection or damage to the SAN is a major cause, this morbidity, damage to other key structures, including the cervical root branches and cervical plexus, also plays an important role.^{18–20} Perturbation of scapulothoracic motion from trapezius weakness (compromised SAN) and rotator cuff (RTC) weakness (compromised root branches) can lead to musculoskeletal shoulder disorders such as RTC tendonitis and adhesive capsulitis.²¹ Damage to the cervical plexus and its branches, as well as the cervical root branches, can cause neuropathic pain.²⁰

Radiation can damage any structure in the radiation field including nerve, muscle, tendon, ligament, blood vessel, lymphatic, and bone.²² Late effects of radiation in HNC include radiculopathy, cervical and/or brachial plexopathy, and mononeuropathies of the cranial and other nerves located within the radiation field. Late effects of radiation include dysphagia, dysarthria, xerostomia, trismus, dropped head syndrome, cervical dystonia, shoulder dysfunction, neck and/or shoulder pain, and multiple other adverse sequelae.^{23–26} The combination of surgery and radiation likely has additive morbidity.

The treatment of late effects in HNC survivors varies depending on the specific issues. Physical therapy is the primary modality for most disorders. In two prospective randomized trials, progressive resistance training (PRT) for HNC cancer patients with SAN neurapraxia/neurectomy and shoulder dysfunction was shown to be more effective than standard physical therapy in terms of improving shoulder pain, range of motion, and disability.^{27, 28} Nociceptive pain (RTC tendonitis, adhesive capsulitis) not responsive to physical therapy may require nonsteroidal anti-inflammatory drugs (NSAIDs) or opioid analgesics. Shoulder injection may be beneficial in some patients but generally only produces transient effect in the face of chronic neuromuscular dysfunction. Neuropathic pain and muscle spasm should initially be treated with nerve stabilizing agents (gabapentin, pregabalin, duloxetine, tricyclic antidepressants).²² HNC can cause dysphagia, if it affects the structure and function of the mouth, throat, and/or esophagus. Impaired swallowing can lead to complications, such as aspiration pneumonia and malnutrition. Rehabilitation first involves a comprehensive evaluation, which begins with bedside swallow tests using liquids and food of different consistencies, proceeding as needed to video fluorography and endoscopy of the pharynx, larynx, and esophagus. Training to improve swallowing involves strengthening exercises for weak muscles, identification of optimal head and neck positions for swallowing, careful feeding of liquids and foods of different viscosities, providing intraoral devices and adaptive bottles, cups, plates, and utensils and sometimes by undergoing specific surgical procedures.

Cancer of the breast

Treatment of breast cancer may include lumpectomy, mastectomy, sentinel lymph node biopsy, and axillary lymph node dissection with or without radiation and chemotherapy.²⁹ There are multiple potential complications of breast cancer and its treatment that benefit from rehabilitative intervention resulting primarily from effects of disease and surgery, radiotherapy, chemotherapy, and other agents used in its treatment.

The incidence of lymphedema varies from 6% to 28%.³⁰ Mastectomy, extent of axillary lymph node dissection, radiotherapy, and positive lymph nodes increase the risk of developing lymphedema.³¹ Treatment options for lymphedema include comprehensive physical therapy, low-level laser therapy (LLLT), pharmacotherapy, and surgery.³² Comprehensive physical therapy (including complete decongestive therapy) may include manual lymphatic drainage (MLD), progressive exercise, low-stretch

compression bandaging, fitting of appropriate gradient compression garments, and education regarding skin care and other aspects of lymphedema management.

Upper body pain and dysfunction in breast cancer survivors is caused by a variety of disorders ([Table 4](#)).³³ The rehabilitation of these disorders varies greatly, but often involves physical therapy and medications such as NSAIDs, opioids, nerve stabilizers, and occasionally injection (i.e., intra-articular corticosteroids for RTC tendonitis).³³ Women who choose mastectomy often request reconstructive breast surgery with filler implants made of materials, such as saline solution, silicone gel, or compound substances. Others prefer to use external breast prostheses, made either of silicone or light weight foam or fiber fill. These come in various sizes and consistencies, but all require wearing custom fit bras and garments for optimal cosmesis.

Cancer of the limbs

Primary malignant tumors of the limbs require surgical treatment. The exact type of surgery depends on the tumors location, size, type, grade, and stage as well as on the age and general health of the patient. The main goal is to remove the tumor by an excision with wide margins through a site well clear of any malignancy or by radical removal of the entire bone or the compartment afflicted by the tumor. A subsequent surgical goal is to reconstruct the resulting defect for optimal function and cosmesis. Although limb amputation has been practiced for centuries, in recent years, limb salvage by extended local or regional excision and reconstruction has become the principal goal and is now the chosen surgical intervention in approximately 90% of cases. The survival and disease-free survival after both types of surgical approaches are similar and have been greatly improved in recent years by consequent use of chemotherapy, radiation, or both.

Metastases to bones are more common than primary bone tumors, but usually metastases affect the spine rather than limbs. Bone tumors often present initially with localized pain or with a pathologic fracture. Pathologic fractures require internal fixation combined with the use of methyl methacrylate, which may

relieve pain, restore early mobility, ease nursing care, and provide psychological reassurance.

Regardless of whether amputation or limb sparing surgery is planned, preoperative rehabilitation should start immediately after the diagnosis of limb cancer is established. This will include discussing the surgery and the anticipated postoperative course, establishing realistic expectations, and offering peer counseling by a successfully rehabilitated amputee. Simultaneously, appropriate physical exercise program should begin with strengthening exercises for all four limbs and trunk, as well as ambulation training with nonweight bearing on the affected lower limb.

Local resection of the tumor with limb sparing reconstruction results in disease-free survival equal to that for amputation, but more important in better function, cosmesis, and emotional adjustment. The goal is to remove the active tumor, while saving adjacent nerves, tendons, and vessels. The cancerous bone may be replaced by transplanting a fresh frozen cadaveric bone allograft or an autograft or by installing a synthetic metallic prosthetic implant. Alternatively after removal of the bone tumor, the limb may be placed in an external fixation device which maintains distraction between the bone ends and allows new bone growth by periodically adjusting the pins and fixators frame. This method is often preferred for growing children and adolescents. It will ultimately fill the gap between bone ends and result in the appropriate bone length and solid healing. Rehabilitation following lower limb sparing surgery is lengthy, intense, and crucial for success. It involves strengthening exercises for the uninvolved limbs on the first postoperative day, but the intensity of strengthening exercises and the amount of weight bearing on the affected limb depend on the exact limb reconstruction and the postoperative course. For most, long-term outcomes are excellent with complete self-sufficiency and ability to ambulate without assistive devices.

Limb amputation for cancer may be the preferred surgical intervention for large tumors that involve nerve and vessels, and thus make limb salvage impossible. Although maximum preservation of limb length compatible with eradication of the cancer is desirable, certain amputation levels will make it easier to fit a prosthesis to the residual limb. Thus, amputations through the hind foot, distal tibia, or the femoral supracondylar region are best avoided. Optimally, 12–18 cm of the tibia should be preserved for below knee amputations and at least similar femoral length and above knee amputations. Postoperatively, physical and occupational therapy should begin within 2 days, for muscle strengthening, joint mobilization, and ambulation training with a walker, crutches, and ultimately with prosthesis and a cane. All the lower limb prostheses require a custom-molded plastic socket for the residual limb with an inside silicone liner for comfort and often layers of socks to accommodate a shrinking residual limb. Attached to the socket of a below knee prosthesis is a shank and ankle foot mechanism, but an above knee prosthesis would also have a knee joint mechanism. The prosthetic knee joint and ankle foot mechanisms vary greatly in design from the most basic to those with microprocessor control and battery power source. Accordingly, the function provided and cost differs significantly.

Cancer of an upper limb can be treated with limb salvage surgery, although a proximal location may involve nerves and vessels and require shoulder disarticulation or even interscapular-thoracic amputation. A variety of prostheses are available for cosmesis or functional use depending on the individual's condition, abilities, and desires.

Conclusion

Management of cancer appropriately focuses on prevention, early diagnosis, and cure, but following effective treatment, many cancer patients experience neuromuscular, musculoskeletal, pain, and functional disorders that result in physical disability or handicap. As the prognosis for cancer improves, it becomes more important to ensure that all cancer patients regain maximum function in the broadest sense to ensure

return to all former roles. Multidisciplinary rehabilitation, therefore, is an integral part of the total management of the cancer patient. The exact functional deficits need to be identified for each patient and proper rehabilitation interventions started promptly or at the same time as other treatments.

Chapter 49

Integrative oncology in cancer care

Gabriel Lopez, MD ■ Richard T. Lee, MD ■ Alejandro Chaoul, PhD ■ M. Kay Garcia, DrPH, MSN, LAc ■ Lorenzo Cohen, PhD

Overview

Integrative medicine seeks to merge conventional medicine and complementary therapies in a manner that is comprehensive, personalized, evidence based, and safe. Integrative oncology is the term used to describe the application of integrative medicine to cancer care. The field of integrative oncology is a constantly evolving set of disciplines. This chapter reviews the role of integrative medicine in cancer care with an emphasis on effective communication, an overview of the evidence, integrative-based resources to guide health care providers and patients, and presents a model of how to effectively incorporate integrative medicine within cancer care. Existing research suggests that the majority of cancer patients desire communication with their physicians about integrative medicine. It is the healthcare professional's responsibility to ask patients about their use of complementary medicines and to provide evidence-based advice to guide patients in this evolving area. Key findings in the areas of mind-body practices, massage, and acupuncture are presented. Mind-body practices help to improve mood, sleep quality, physical functioning, and overall well-being. Massage is helpful at relieving pain, anxiety, and increasing relaxation. Acupuncture has the greatest evidence to support its use in managing symptoms such as chemotherapy-induced nausea, vomiting, and pain; initial research suggests benefit in providing relief for radiation-induced xerostomia and other symptoms. Many authoritative resources now exist to help guide patients' appropriate use of complementary therapies, allowing the medical team to follow evidence-based guidelines.

Introduction

Integrative medicine seeks to combine conventional medicine with the safest and most effective complementary therapies. Although applying the concept of integrative medicine to cancer care is still relatively new, a number of comprehensive cancer centers in the United States are trying to put this concept into practice under the term *integrative oncology*. As a result of growing interest in integrative oncology, the National Cancer Institute formed the Office of Cancer Complementary and Alternative Medicine, the American Cancer Society dedicated a portion of its web site to assessment of complementary therapies, the Consortium of Academic Health Centers for Integrative Medicine (CAHCIM) formed an oncology working group, and the Society for Integrative Oncology (SIO) was formed. This chapter reviews the role of integrative medicine in cancer care with an emphasis on effective communication, an overview of the evidence, integrative-based resources to guide health care providers and patients, and an example of how to effectively incorporate integrative medicine within cancer care.

Definitions

Complementary and alternative medicine (CAM) has been defined by the National Center for Complementary and Integrative Health (NCCIH) (formerly the National Center for Complementary and Alternative Medicine) and major US surveys as “... diverse medical and healthcare systems, practices, and products that are not presently considered to be part of conventional medicine.”¹ Although evidence may exist for some of these modalities, it may not be sufficient to bring them into the realm of *conventional* medicine, and other CAM modalities may have no support for their use. *Alternative* medicine is the use of a nonconventional treatment modality in place of conventional medicine whether or not there is evidence for its efficacy. *Complementary* medicine, on the other hand, is making use of a CAM modality in combination with conventional medicine whether or not evidence exists for its efficacy. Several different types of specialty health care providers offer CAM therapies and these may include physicians, nurses, physical therapists, psychologists, acupuncturists, and massage therapists who are operating within the guidelines of their licenses or accrediting organizations. Practitioners of all disciplines should be knowledgeable and aware of all treatment options and open to communication with other types of practitioners.

Integrative medicine seeks to merge conventional medicine and complementary therapies in a manner that is comprehensive, personalized, evidence based, and safe. CAHCIM has defined integrative medicine as “the practice of medicine that reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, healthcare professionals and disciplines to achieve optimal health and healing.”² The application of integrative medicine to cancer care has come into practice under the term *integrative oncology*. The terms CAM and CIM are often used interchangeably; however, when the term CAM is used, it includes treatment that could be considered alternative and used in place of conventional care; the term CIM would not include alternative treatment approaches.

Utilization

The World Health Organization (WHO) estimates that up to 80% of people in developing countries rely on nonconventional traditional medicines for their primary health care.³ People in more developed countries also seek out complementary medicine and practices. A 2007 survey by the US Centers for Disease Control found that 38% of adults had used CAM therapies during the past 12 months⁴; results from the 2012 survey are upcoming.

Among patients and families touched by cancer, the use of CAM is higher than in the general population. An estimated 48–69% of US patients with cancer use CAM therapies and percentages increase if spiritual practices are included.⁵ CAM therapies are used by up to 69% of cancer patients, with increased use in those with advanced cancers.^{5, 6}

In most cases, people who use CAM are not disappointed or dissatisfied with conventional medicine but want to do everything possible to regain health and to improve quality of life (QOL), reduce side effects, stimulate immunity, or prevent new cancers or recurrences.^{5, 7} Whether or not patients use CAM therapies to treat cancer or its effects, they may use them to treat other chronic conditions such as arthritis, heart disease, diabetes, and chronic pain.

Communication

Research indicates that neither adult nor pediatric patients receive sufficient information or discuss CAM therapies with physicians, pharmacists, nurses, or CAM practitioners.⁸ It is estimated that 38–60% of patients with cancer are taking complementary medicines without informing any member of their healthcare team.^{6, 7} Most patients do not bring up the topic of CAM because no one asks; thus patients may believe that it is unimportant. This lack of discussion is of grave concern because herbs and supplements may have direct toxicity or interact with cancer treatments. Patients are commonly unaware of the differences between the United States Food and Drug Administration (FDA)-approved medications (which require evidence of efficacy, safety, and quality control manufacturing) and supplements, which are governed not by the FDA but by the Dietary Supplement Health and Education Act (DSHEA) of 1994. Supplements under this legislation are exempt from the same scrutiny the FDA imposes on medications; furthermore, these supplements are not intended to treat, prevent, or cure diseases. The common belief by patients is that “natural” means safe needs to be addressed with education as some herbs and supplements have been associated with multiple drug interactions, as well as increased cancer risk and organ toxicity.^{9, 10}

Existing research suggests that the majority of cancer patients desire communication with their physicians about CAM.¹¹ There is general agreement within the oncology community that in order to provide optimal patient care, oncologists must not only be aware of CAM use but also be willing and able to discuss all therapeutic approaches with their patients. It is the healthcare professional's responsibility to ask patients about their use of complementary medicines, and the discussion should ideally take place before the patient starts using a complementary treatment—whether it is a nutritional supplement, mind-body therapy, or other CAM approach.

A number of strategies can be used to increase the chance of a worthwhile dialogue. One approach is to include the topic of CAM as part of a new patient assessment. For example, when asking about medications, physicians should inquire about everything the patient ingests—including over-the-counter products, vitamins, minerals, herbs, and even the patient's diet. Physicians may consider having the patients bring in the actual bottles of herbs and supplements for evaluation. When asking about a patient's past medical history, physicians may ask about all other healthcare professionals involved in the patient's care to learn if the patients have visited with CAM practitioners such as naturopaths or chiropractors. If the issue of CAM arises, clinicians need to develop an empathic communication strategy that addresses the patient's needs while maintaining an understanding of the current state of the science.¹² In other words, this strategy needs to be balanced between clinical objectivity and bonding with the patient so that it can benefit both the patient and the healthcare provider. The physician who is receptive to patient inquiries is able to establish an environment in which a patient feels comfortable to bring up the topic of CAM therapies. Part of this strategy should be an open attitude combined with a willingness to review evidence-based references and consult with other health care professionals. Patients need reliable information on CAM from reliable resources, as well as adequate time to discuss this information with their oncologists.¹³

The evidence

The field of integrative oncology is a constantly evolving set of disciplines. There has been a dramatic increase in research in integrative oncology. In the following section, we list some of the key findings to date in integrative oncology in the main areas of CAM where there is sufficient evidence to recommend the therapies: mind-body practices, massage, and acupuncture. Although there is ongoing research in many other areas such as healing touch, homeopathy, natural products, and special diets, there is insufficient

evidence to recommend these at this point in time.

Mind-body practices

The belief that what we think and feel can influence our health and healing dates back thousands of years. The importance of the role of the mind, emotions, and behaviors in health and well-being is central to traditional Chinese, Tibetan, Greek, and Ayurvedic medicines and other medical traditions of the world.

The health-damaging effects of chronic stress are well documented in the medical literature. Research shows that chronic stress affects almost every biological system in our bodies.¹⁴ Unmanaged chronic stress can speed the aging process through telomere shortening,¹⁵ increasing the risk for heart disease,¹⁶ sleeping difficulties,¹⁷ digestive problems,¹⁸ and even depression.¹⁹ Research has shown that stress can also decrease compliance with health-screening behaviors and treatment.²⁰ Moreover, it can also cause patients to forego healthy eating and exercise habits that help prevent cancer and other disease.

With regard to cancer, there is little convincing evidence that chronic stress affects cancer initiation; however, there is extensive evidence that chronic stress can promote cancer growth and progression.^{21, 22} The underlying mechanisms for such effects are complex and involve chronic activation of the sympathetic nervous system (SNS) and the HPA axis.²³ Sustained elevations from these pathways (e.g., norepinephrine and cortisol) can result in diverse effects including stimulation of cancer invasion, angiogenesis, inflammation and immune dysregulation, reduced anoikis, and even reduced efficacy of chemotherapy drugs.²⁴ The underlying signaling pathways offer opportunities for designing new therapeutic approaches for disrupting the effects of stress biology on cancer biology and include both behavioral and pharmacological (e.g., beta-blockers) approaches.

The clinical significance of stress-related biological changes and the changes in the tumor micro-environment has not been widely studied. However, these changes may be significant enough to affect not only the immediate health of the patient but also the course of the disease and thus the future health of the patient. It is, therefore, prudent to suggest that patients engage in some type of practice to reduce stress in their lives.

Mind-body practices are defined as a variety of techniques designed to enhance the mind's capacity to affect bodily function and symptoms. Mind-body techniques include relaxation, hypnosis, visual imagery, meditation, biofeedback, yoga, tai chi, qigong, and other movement-based therapies, cognitive-behavioral therapies, group support, autogenic training, and spirituality as well as expressive arts therapies such as art, music, or dance. As research continues, the treatments that are found beneficial will hopefully become integrated into conventional medical care.

Research has shown that after being diagnosed with cancer, patients try to bring about positive changes in their lifestyles, indicating a tendency to take control of their health care.²⁵ Techniques of stress management that have proven helpful include progressive muscle relaxation, diaphragmatic breathing, guided imagery, and social support. Participating in stress management programs before treatment has enabled patients to tolerate therapy with fewer reported side effects. Supportive expressive group therapy has also been found to be useful for patients with cancer. Although there is some data to support the use of expressive art therapies such as music therapy,²⁶ art therapy,²⁷ and expressive writing²⁸ and journaling to improve QOL, the number of trials is limited and they typically have small sample sizes and often no control groups. Psychosocial interventions have been shown to specifically reduce anxiety, depression, and mood disturbance in cancer patients and assist their coping skills.²⁹

Newell et al.³⁰ reviewed psychological therapies for cancer patients and concluded that interventions

involving self-practice and hypnosis for managing nausea and vomiting could be recommended but that further research was suggested to examine the benefits of relaxation training and guided imagery. Ernst et al.³¹ examined the change in the state of the evidence for mind-body therapies for various medical conditions between 2000 and 2005 and found that there is now maximal evidence for the use of relaxation techniques for anxiety, hypertension, insomnia, and nausea due to chemotherapy. The beneficial effects of hypnosis, and especially self-hypnosis, is further supported by more recent research as hypnosis was found beneficial for reducing distress and discomfort during difficult medical procedures.³² An NIH Technology Assessment Panel found strong evidence for hypnosis in alleviating cancer-related pain.³³ Hypnosis effectively treats anticipatory nausea in pediatric and adult cancer patients, reduces postoperative nausea and vomiting, and improves adjustment to invasive medical procedures, and when combined with cognitive behavioral therapy (CBT), hypnosis leads to reduced fatigue in women with breast cancer at the end of radiotherapy and 1 and 6 months later.³⁴

Research examining yoga, tai chi, and meditation, including mindfulness-based stress reduction (MBSR), incorporated into cancer care suggests that these mind-body practices help to improve aspects of QOL including improved mood, sleep quality, physical functioning, and overall well-being of patients undergoing treatment and cancer survivors.³⁵

The meditation practice that has been researched the most is MBSR. The larger randomized controlled trials (RCTs) of meditation published in the past few years have used some form of MBSR for women with breast cancer. MBSR has been found to reduce self-reported levels of anxiety and depression and improve sleep quality; it has reduced the long-term emotional and physical adverse effects of medical treatments, including endocrine treatment; and resulted in a significant reduction in mood disturbance and symptoms of stress. A cancer-specific version of MBSR called mindfulness-based cancer recovery (MBCR) found that breast cancer survivors scoring 4 or greater in the distress thermometer had lower symptoms of stress and improved QOL.³⁶ In addition, both MBCR and a supportive expressive therapy group resulted in more normative diurnal cortisol profiles than a control group.

The more movement-based mind-body practices such as Indian-based yoga, Tibetan yoga, and Chinese tai chi/qigong typically combine physical postures or movements, breathing techniques, and meditation with the goal to enhance health and well-being. Indian-based yoga (“yoga” is Sanskrit for “to yoke” or “join”), one of the most widely practiced Eastern traditions in Western cultures, focuses on the union of mind and body or the harmonic synchronization of body, breath, and mind. Yoga has increasingly gained popularity in the cancer setting. In fact, several systematic reviews and meta-analyses indicate the QOL benefits associated with practicing yoga in cancer patients and survivors.^{37, 38} Research demonstrates that yoga is useful for treating sleep disturbances³⁹ and fatigue.⁴⁰ Yoga has also been found to reduce inflammatory signaling and stress hormone regulation,⁴¹ which plays a role in behavioral symptoms such as fatigue after breast cancer treatment.⁴² Thus, yoga may actually impact biological pathways beyond patients' perceptions of QOL and symptoms. Although most yoga research has been conducted in women with early-stage breast cancer, efforts are underway to extend these findings to women with advanced breast cancer and survivors of lung cancer and caregivers.⁴³

Less research has examined the effects of *tai chi/qigong* in oncology.⁴⁴ Encouraging advances are evident and *tai chi/qigong* has been found to reduce fatigue and distress, improve peripheral circulatory status and functional aerobic capacity, and lead to less postoperative humoral and cellular immunity dysregulation.

Massage

Massage has shown promise for relief of cancer and cancer treatment-related symptoms. As a manipulative touch-based therapy, massage can benefit cancer patients when performed by therapists who have an awareness of the special needs of cancer patients.⁴⁵ A massage therapist with special training in oncology massage is the best equipped to safely deliver the massage. Risk of bruising, bleeding, or injury can be minimized by careful application of pressure, avoiding massage into the deep tissue or bone in selected patients. Areas that have recently had surgery or radiation should be avoided. In patients with extremities subject to lymphedema, therapists will need to adjust their technique to maximize safety. Patients may benefit from formal lymphedema therapy as part of a physical therapy program.⁴⁶

Research to date suggests that massage is helpful at relieving pain, anxiety, fatigue, distress, and increasing relaxation.^{47, 48} Benefit on mood and pain relief is limited to the more immediate effect of massage, with no current studies demonstrating long-term relief.^{49, 50} Anecdotal and case report evidence has suggested benefit of massage for the relief of chemotherapy-induced peripheral neuropathy. A massage to the feet, hands, and head can provide therapeutic benefit as these areas are especially sensitive to tactile stimulation and can result in relaxation and increased well-being. Massage provided by caregivers may offer a unique opportunity for interaction between patient and caregiver that can help enhance well-being of both.⁵¹ In addition to symptomatic relief, studies have also demonstrated systemic effects of massage, with the decreases in cortisol levels resulting from a massage intervention.⁵² More research is needed to better understand massage mechanisms and treatment protocols (ideal massage-type, dosing) to better define the role of massage therapy in cancer symptom management.

Acupuncture

Acupuncture is a treatment modality that is part of traditional Chinese medicine (TCM). It has been practiced in China for thousands of years and is used in at least 78 countries throughout the world. According to TCM theory, the placement of acupuncture needles, heat, or pressure at specific body points can help regulate the flow of Qi (vital energy) within the body. The most common form of acupuncture involves the placement of solid, sterile, stainless steel needles into various sites on the body that are believed to have reduced bioelectrical resistance and increased conductance. The needles may be stimulated manually or a mild electrical current may be applied directly to the needles after insertion. Stainless steel or gold (semi-permanent) needles, or “studs,” are also sometimes placed at points on the ears and left in place for 3–5 days.

The strongest evidence supporting the use of acupuncture in cancer care is for symptom management. Studies have shown that acupuncture is helpful to control nausea and vomiting from multiple causes (i.e., chemotherapy-induced nausea and vomiting (CINV), postoperative nausea and vomiting, and pregnancy),^{53, 54} and although there is good evidence for the use of acupuncture to control pain, there is still limited research in a cancer setting. In a large individual patient-level data meta-analysis of 29 trials involving noncancer patients ($N = 14,597$) with chronic pain, significantly better pain control was found in favor of real acupuncture compared to no acupuncture (50% vs 30%, $P < 0.001$) as well as real acupuncture compared to sham acupuncture, though to a lesser degree (50% vs 42.5, $P < 0.001$).

For the management of other treatment- or cancer-related symptoms, the evidence is not as strong as that for pain and nausea; however, initial research suggests that acupuncture may help reduce the severity of radiation-induced xerostomia with a lasting benefit.^{55, 56} There is also some evidence to suggest that acupuncture may be useful in treating or helping to manage symptoms such as constipation, loss of appetite, peripheral neuropathy, hot flushes, fatigue, insomnia and sleep disorders, dyspnea, anxiety/depression, and leukopenia, but the quality of research for these indications remains weak and

further studies are needed.⁵⁷ When performed correctly, acupuncture has been shown to be a safe, minimally invasive procedure with very few side effects. The side effects most commonly reported are fainting, bruising, and mild discomfort. Infection is a potential risk, but very uncommon when treatment is provided by a qualified acupuncturist. Treatments should only be performed by a health care professional with an appropriate license and experience.

The mechanisms of acupuncture are not well understood, but for symptoms such as CINV and pain, there is clear evidence to support its use. Although data are still lacking for other symptom control, as a cost-effective treatment option with minimal associated risks, acupuncture may be a helpful addition to cancer care for patients suffering from uncontrolled treatment-related side effects or for those in whom conventional treatment approaches have failed.

Educational resources

Comprehensive reviews can quickly become outdated, and the ease of Internet publishing has fostered the growth of comprehensive scientific review organizations that provide electronic access to their reviews. We outline websites of organizations providing reliable information for providers and patients ([Table 1](#)).

Table 1 Recommended web sites for evidence-based resources

Organization/web site (alphabetical order)	Address/URL
Cochrane Review Organization	www.cochrane.org
Memorial Sloan-Kettering Cancer Center	www.mskcc.org/cancer-care/integrative-medicine/about-herbs
Natural Medicines Comprehensive Database	www.naturaldatabase.com/
Natural Standard	www.naturalstandard.com/
NCI Office of Cancer Complementary and Alternative Medicine (OCCAM)	www.cancer.gov/cam
University of Texas MD Anderson Cancer Center Integrative Medicine Program	www.mdanderson.org/integrativemed

The American Cancer Society (ACS) and National Cancer Institute (NCI) Office of Cancer Complementary and Alternative Medicine (OCCAM) provide valuable educational resources for patients and the general public on complementary therapies. Natural Medicines Comprehensive Database provides evidence-based reviews of complementary therapies. The Cochrane Review Organization, founded in 1993 as an international nonprofit independent organization, provides systematic reviews that include complementary therapies.

Natural Standard is part of a multidisciplinary, multi-institutional initiative dedicated to the review of complementary and alternative therapies. It follows a similar process to build in-depth evidence and consensus-based analysis of scientific data in addition to historic and folkloric perspectives. The integrative medicine service at the Memorial Sloan-Kettering Cancer Center provides evidence-based reviews as part of their “About Herbs, Botanicals & Other Products” Internet resource. The integrative medicine program at the University of Texas MD Anderson Cancer Center offers an Internet resource for patients and providers to learn more about the evidence-based role of Integrative Medicine in cancer care.

Integrative oncology in clinical practice

Integrative oncology has the ability to enhance the care provided for cancer patients by incorporating additional treatment options that lead to improved health, symptom management, and QOL. Most major medical centers now offer some complementary medicine treatment modalities alongside the conventional care.⁵⁸ In order to create comprehensive integrative cancer care, these types of therapies must be delivered in a manner that does not just avoid potential interactions but works to create synergy with ongoing treatment. To do so, the integrative oncology approach must incorporate principles of being evidence based, personalized, and safe.

The Integrative Medicine Center at MD Anderson Cancer Center is one example. The center utilizes a bio-psychosocial model of healthcare ([Figure 1](#)) as a clinical framework to guide the implementation of services to patients throughout the cancer continuum (prevention, treatment, and survivorship), and some services are also provided for caregivers. The clinical services are provided to address specific medical conditions such as pain or anxiety or the appropriate use of herbs and supplements and not available to patients as part of a spa service. The center provides patient care on an individual bases as well as in groups. Patients may receive inpatient and outpatient physician consultation, acupuncture, massage, mind-body therapy such as meditation, and music therapy. Physical therapy for exercise counseling, a dietitian for nutrition counseling, and a psychologist for mood management and behavioral counseling are also available for all patients. Patients may also attend free group classes such as meditation, yoga, tai chi/qigong, music therapy, exercise, and cooking classes. All staff members meet on weekly bases to discuss challenging new patients and to help coordinate care. Clinical notes are available in the electronic health record. As part of routine care, patients complete validated instruments on symptoms and QOL and are included as part of a broader clinical research initiative to understand the clinical impact of the clinical services provided. The integrative medicine center works collaboratively with similar supportive services such as palliative medicine, psychiatry, pain center, and rehabilitation services. Most referrals come from these service areas as well as from primary oncologists.

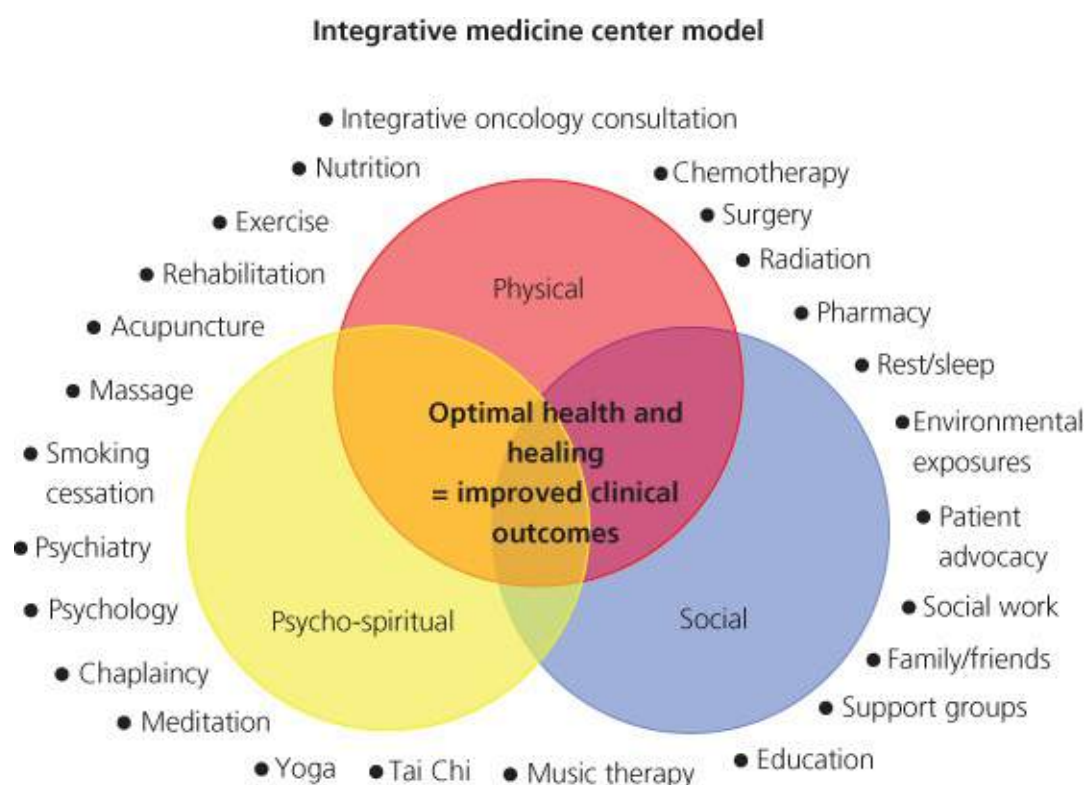

Figure 1 Integrative medicine center model. Based on the bio-psychosocial model of health care, our center functions within a framework of cancer care delivery.

Conclusion

Integrative oncology is a rapidly expanding discipline that holds tremendous promise for additional treatment options and more effective symptom control. An integrative approach also provides patients with a more personalized system of care for meeting their needs. The majority of patients either are using complementary medicines or want to know about them, so it is incumbent on the conventional medical system to provide appropriate education and clinical services. The clinical model for integrative care requires a patient-centered approach with attention to patient concerns and enhanced communication skills. In addition, it is essential that conventional and nonconventional practitioners work together in developing an integrative model. In this way, cancer patients will be receiving the best medical care making use of all appropriate treatment modalities.

Chapter 50

Health services research

Michaela A. Dinan PhD ■ Bradford R. Hirsch MD, MBA ■ Amy Abernethy MD, PhD

Overview

Health services research (HSR) describes a diverse group of research strategies and fields that seek to evaluate the impact of health care on patients and populations and has been a critical component of understanding the use, outcomes, and costs associated with oncology care since its inception over 100 years ago. In modern times, physicians and researchers often tout “bench to bedside” innovations as the goal of biomedical research. However, patients, physicians, and health care systems in the real world are subjected to a host of factors that impact patient care before, during, and after an intervention occurs at the bedside. Although HSR is a complex and evolving concept, a basic understanding of the key principles of HSR is needed to accurately assess, quantify, and optimize the real-world impact of progress in oncology today and in the future.

Introduction—what is health services research?

Health services research (HSR) comprises a diverse group of research strategies and fields that seek to evaluate the impact of health care on patients and populations. While the focus of the included disciplines may differ, there are similarities which allow us to group them together under the umbrella of HSR. In each case the same basic methodology applies: A treatment or intervention is examined in the context of an outcome of interest in order to better understand and guide clinical practice.

According to the Institute of Medicine (IOM), HSR focuses on the investigation of three major aspects of health care including (1) access to care, (2) the quality of care, and (3) the cost of health care in order to inform health care consumers about their best options for medical treatment and/or prevention.¹ The IOM has also developed a list of the major issues that health services researchers are studying today ([Table 1](#)).

Table 1 IOM list of major health services research topics

- Health services organization and financing
- Access to health care
- Behaviors of practitioners, patients, and health care consumers
- Quality of care
- Clinical outcomes research
- Health care decision-making and informatics
- Health professions workforce

HSR is truly a multidisciplinary field. Health services researchers, biostatisticians, economists, and

clinicians are all examples of critical and necessary players in the HSR arena. In oncology, the clinical expertise of medical, surgical, and radiation oncologists as well as pathologists and radiologists are all needed to develop clinically relevant questions that will lead to improvements in patient care. Close collaboration between methodologists and clinicians is essential to ensure both the scientific validity and clinical significance of HSR studies.

The goals of HSR in oncology are many. While some research focuses on the investigation of diagnostics and treatments to prolong survival, other seeks to improve quality of life (QOL), inform decision making, improve access to care, ensure guideline concordant care, or examine the economic impact of care for cancer patients. In addition to the wide range of these and other potential outcomes, HSR in oncology has several stakeholders with vested interests in the results including patients and their families, physicians and other medical staff, additional providers and payers of health care, industry, and policy makers that must be considered in any effort to make advances in oncology.

The significance of health services research in cancer

HSR in oncology is the principal means by which we frame the scope of cancer and attempt to improve cancer care delivery in the real world. Discoveries made in the controlled environments of laboratories and clinical trials may or may not translate when taken out of the context of a select group of trial participants and applied to the larger population of patients. That is to say, most clinical trials are focused on the *efficacy* of a specified intervention or the ability of an intervention to provide benefit under tightly controlled circumstances. In contrast, HSR focuses on the *effectiveness* of these interventions, which describes the ability of an intervention to provide benefit under real-world conditions. The goal of HSR is to improve the effectiveness of interventions as they are disseminated into broader, more diverse populations and promote the health of all members of the population.

HSR in oncology has been used to provide estimates of the scope of cancer on a national scale and as a prediction of how it will change in the future. For example, HSR using the population-based Surveillance, Epidemiology, and End Results (SEER) registry provides the estimate that in 2014, there were an estimated 1,665,540 patients newly diagnosed with cancer and 585,720 people who died from their cancer. As the U.S. population continues to age, this number is expected to increase. For example, in 2010, the total direct estimated cost of cancer care in the United States was \$124.5 billion. After only reflecting demographic changes, by 2020, this cost has been projected to increase to \$157.8 billion.² These costs will likely be much higher in reality due to the adoption of expensive innovative therapies, the widespread diffusion of advanced technologies without supporting evidence, inappropriate use (either over or under) of existing treatments, and patient demands and unrealistic expectations are additional areas of concern. HSR provides a framework to consider how to mitigate the impact of this surge in need on current medical resources and infrastructure.

Disciplines within health services research

In practice, HSR is often separated into multiple distinct fields of discipline—health economics, epidemiology, qualitative research, implementation research. The distinctions have developed over time based on the data requirements, methodologies, and expertise needed to answer questions meaningfully. Despite these potential differences, there is considerable overlap and a common goal of inferring causality and informing practice. Outcomes research revolves around the identification of a treatment or exposure of interest and a relevant outcome (i.e., the impact of a new treatment on survival). Health

economists focus on health care costs and resource utilization, epidemiologists on naturally occurring exposures and patterns, and health services researchers on questions that examine exposures or treatments within the health care system—either directly or indirectly.

An overview of health services research study designs

HSR can be conducted with a variety of different study designs. They may analyze primary data (collected prospectively as part of a clinical study) or secondary data (collected for some other purpose, such as for hospital billing, and are then repurposed). Clinical trial study designs are more familiar, where a specific intervention is imposed on a study group. Randomized Clinical Trials (RCTs) are considered the gold standard of clinical research because the intervention or exposure of interest is randomly designated across study participants. RCTs are often blinded, where the physician is not aware of a subjects assignment to a given study arm, or even double blinded, where neither the physician nor the subject is aware of the assignment. These design elements help to avoid any biases that may occur by ensuring the random distribution of interventions across subjects.

Observational analyses do not assign interventions among subjects and are most often retrospective in nature. Instead, researchers examine the relationship between exposures or events of interest that occurred and the associated effects or outcomes. The studies can be descriptive or analytic in their design. Descriptive studies include case reports or case series, ecologic studies, and cross-sectional studies, while analytic studies include longitudinal cohort and case–control studies. Descriptive analyses are used to generate hypotheses, whereas analytic analyses are used to test specific hypotheses about the association between a specific exposure and outcome.

Types of secondary data sources relevant to HSR in oncology

A common understanding among health services researchers is that the study is only as good as the data. There are limitations to every data source so health services researchers must use multiple approaches to be able to address a question of interest. Primary data quality will depend largely on the instrument design and any logistic constraints involved in data collection. Secondary data are often limited by the purpose for which they were originally collected. Billing data (aka claims data), are collected as documentation of services provided and payments received; studies using these data must account for the inherent limitations when designing an analytic plan.

There are a few commonly encountered types of oncology databases available for secondary analyses in HSR which include clinical registries, administrative datasets, clinical trial databases, and more recently an increasing body of data from aggregated electronic medical records (EMRs) (described later in the chapter). A thorough understanding of the strengths and limitations of the dataset is critical for one to conduct a valid analysis ([Table 2](#)). Clinical registries may collect relevant data on patients with an incident cancer diagnosis within a specific population, health care system, network, or region. Strengths of clinical registries include high-quality short-term exposure and outcome data, clinically rich data specific to a disease of interest, collection of potential confounders, and the potential for large sample sizes. The principal weakness of registry data are a lack of randomization to key exposures of interest, poor intermediate and long-term follow-up and outcomes, and lack of data regarding unrelated disease states such as cardiovascular disease.

Table 2 Strengths and weaknesses of commonly encountered large secondary databases

Data Source	Examples	Strengths	Weaknesses
Disease registries	SEER NCDB EMR data-generated	<ul style="list-style-type: none">• high-quality short-term exposure and outcome data• clinically rich• collection of potential confounders• large sample sizes across a broad population	<ul style="list-style-type: none">• lack of randomization to key exposure• poor long-term follow-up• lack of data for unrelated disease states
Administrative data	CMS (Medicare) VA (Veterans Affairs) Kaiser Permanente	<ul style="list-style-type: none">• broad coverage of the population• efficiency of data collection• long-term follow-up availability of patient-specific identifiers that can be linked to additional data sources	<ul style="list-style-type: none">• lack of randomization to key exposure• inaccurately recorded data• limited clinical details
Clinical trials	Collaborative group studies Industry trials Institutional trials	<ul style="list-style-type: none">• clinically rich data• random assignment of key exposures	<ul style="list-style-type: none">• pre-selected population and smaller sample sizes• loss to follow-up

Administrative datasets consist of information that is routinely collected within the operations of a given health care entity, such as an insurer (i.e, Medicare), integrated health care systems (i.e., Veterans Affairs Hospitals), or large health care organizations (i.e., Kaiser Permanente). The strength of administrative data lie in their broad coverage of tens or even hundreds of millions of lives, the efficiency of data availability, and the long-term follow-up available through the use of patient identifiers. In addition, administrative data are representative of the population at large, while data collected within a clinical trial are clinically rich but limited to a carefully pre-selected, smaller population because of cost and scientific considerations. The weaknesses of administrative data stem from their collection for purposes of billing and tracking health care resource utilization, often limiting the granularity of available information. Information such as dates of claims and types of procedures performed are highly accurate. However, information that is not critical to billing, such as cancer stage, are not always captured.

Different types of data can be linked together to help offset limitations of any single data set. For example, registry and clinical trial data, which often suffer from a lack of long-term follow-up and incompleteness can be supplemented with administrative claims data (such as Medicare) to augment the available follow-up and survival data.

Data is universally important across all study designs but the type of data is highly specific to the type of study being conducted. Further discussion of specific datasets and approaches will be presented

subsequently in the context of different methodologies. However, two cancer-specific registries, SEER and the National Cancer Data Base (NCDB) that are particularly important to know as they play central roles in HSR in oncology are worth describing in detail.

Surveillance, Epidemiology, and End Results

The SEER tumor registry program collects detailed clinical and pathological information on 28% of cancer patients in the United States, aggregating it from participating registries that are representative of the national patient population. Limitations of these data include a lack of detailed information on treatments, providers, and cost. To address these needs, linkages were pursued to generate a richer set of variables. This resulted in a collaboration between the National Cancer Institute (NCI) and the Centers for Medicare and Medicaid Services (CMS) to make a SEER-Medicare dataset available that adds Medicare administrative data and health care claims. As CMS provides health insurance to over 97% of Americans aged 65 and older, this allows a detailed assessment of health care utilization and costs among SEER patients. The SEER-Medicare data have been used to examine cancer care quality around issues of racial disparities, physician and hospital characteristics, screening, treatment choices (i.e, surgery, chemotherapy, radiation), complications, costs, and mortality.³ While powerful, a core limitation of the SEER-Medicare dataset is that it only includes those 65 years of age and older.

National Cancer Data Base (NCDB)

Another oncology-specific dataset which is widely used is the NCDB which is a joint project of the American Cancer Society and the American College of Surgeons' Commission on Cancer (CoC). The NCDB was established in 1989 as a nationwide, hospital-based, comprehensive clinical surveillance data set. The NCDB obtains data from more than 1,500 CoC-accredited facilities which captures 30 million patient records and 70% of all newly diagnosed cancer cases.⁴ The key strength of the NCDB is its sheer size and capture of the majority of cancers diagnosed within the United States. It is well posed to study nationwide patterns of care, adoption of novel surgical procedures, and the approach to rare cancers. As a surgical data set, it contains excellent data on the details of a patient's surgery and survival. However, some aspects of the data are not reliably coded; there are limited details regarding chemotherapy, radiation or noncancer related health; and there is no information on relapse, recurrence, or subsequent treatments.

Statistical analyses in health services research

An in depth review of statistics is well beyond the scope of this chapter, so we will focus on commonly used techniques that encompass the vast majority of HSR. In HSR, statistical analyses are used to analyze data from a population of interest in order to either describe or learn something (i.e., make an inference) about the general state of affairs in that population. Descriptive statistics simply describe or summarize a set of data, by providing means, frequencies, counts, plots, or other depictions. Inferential or analytic statistics use more complex methodologies to attempt to draw generalizable inferences from a set of data, such as whether or not two groups differ from one another by more than what would reasonably be expected by chance.

Multivariable versus univariate analyses

In HSR, one of the most common distinctions made in practice is the use of statistics to investigate single variables vs. multiple variables. Single variable or “univariate” analyses are used to summarize or

describe the properties of a single variable, such as what percent of a population has ever smoked. Multivariable or multivariate analyses (in practice these are used interchangeably) are more complex and seek to explain the relationship between a single variable of interest and multiple other variables at the same time.

Often univariate versus multivariable analyses are referred to as “unadjusted” and “adjusted,” as the multivariable approach “adjusts” for potential confounding by control variables. Such control variables might include clinically relevant variables associated with the outcome of interest such as age, stage, or grade and *must* include any variables that might be associated with both the exposure and outcome of interest in order to fully control for potential confounding. In a study that performs both “unadjusted” and “adjusted” analyses, the results from the adjusted (or multivariable) analyses are more likely to reflect the true relationship of interest, as these models have at least attempted to adjust for factors that might otherwise explain the observed relationship. Variables are often inter-related in HSR and a failure to account for these relationships can result in erroneous conclusions. The key question that HSR seeks to answer is often how a certain treatment, condition, or exposure impacts a specific outcome of interest after controlling for all other relevant factors.

Multivariable analyses

One of the most widely used methods in multivariable analysis in HSR is that of multivariable regression analysis. The term “regression” was originally coined in the late 1800s by Francis Galton to describe the tendency of tall or short pea plants (outliers) to produce offspring that were more similar to or “regressed” towards the overall population height.⁵ In its simplest form, this is essentially drawing a simple straight line through a plot of two variables that shows the mean or average of one variable as a function of the other. Significant mathematical and computational progress since has allowed for the routine use of far more complicated models that are able to predict the value of a so-called “dependent” variable whose value is predicted *depending* on the values of multiple “independent” variables. Such models come in many forms and have been refined and developed to be able to predict, model, or describe any combination of different variable types. Most often in HSR, continuous data are modeled using linear regression, dichotomous data using logistic regression (from its use of binary logic values, i.e., zero or one to describe the dependent variable), and survival data using cox proportional hazard models (survival variables include an event such as death or relapse vs. no death or relapse combined with the time to that event). Linear regressions will predict the mean value of the dependent variable as a function of each independent variable (i.e., average weight as a function of sex and height), logistic regressions will estimate odds ratios (OR) associated with a particular exposure, and cox proportional hazards models yield hazard ratios (HR). Other frequently used multivariable statistical analyses include variations of the χ^2 test (chi-squared), such as the Cochran–Mantel–Haenszel test,^{6,7} which essentially performs the χ^2 test for an association between two categorical variables while controlling for other potentially confounding variables.

One of the benefits of multivariable regression is the ability to capture “interaction effects,” or an interaction between two independent or explanatory variables on the dependent variable of interest. Interaction effects can capture cases where a variable might only impact the outcome of treatment within a subset of patients. For example, a meta-analysis of three randomized controlled trials in nonsmall cell lung cancer found a significant interaction between squamous tumor histology, receipt of pemetrexed, and a lack of treatment response.⁸ This meta-analysis confirmed that the drug pemetrexed is associated with improved outcomes, but only in patients with nonsquamous cell histology. As a result, pemetrexed is now the drug of choice in nonsquamous NSCLC.

Bias and confounders

Perhaps the single most important concept in HSR is the idea of bias or confounding. A confounder is anything that confuses, obscures, or otherwise mixes the effect of the characteristic of interest with others. The word “confound” comes from the latin for “pour together,”⁹ and so literally describes a situation where the observed association is mixed or confused by a confounder. An example of confounding can be demonstrated using a hypothetical retrospective study of patients with metastatic disease, in which patients who have less aggressive disease and receive surgery for their metastatic disease are observed to live longer. In this case, the observed association of surgery with prolonged survival is being confused with, or “confounded” by, the association of nonaggressive disease with both surgery and survival.

Bias is also used to describe confounding, but can be more descriptive by additionally specifying the direction of the observed erroneous association. Bias is a related term from the old French *biais*, meaning “slant,”⁹ and describes the situation where the observed association is biased, or unfairly slanted, to yield either a false positive (can bias the estimate of an association upward or downward) or false negative (biased towards the null hypothesis) association between two variables.

One specific example of bias in the HSR oncology literature comes from analyses of survival in patients with nonsmall cell lung cancer (NSCLC). Several studies had observed that receipt of PET scans are associated with improved survival, and erroneously concluded that receipt of PET *improves* survival. However, upon closer examination, we know that PET scans are generally administered to patients with early stage disease who are candidates for curative surgery and definitive treatment. The use of PET scans is not indicated for patients with obvious advanced or metastatic disease. In this case, one would say that the association of PET with survival is confounded by selection bias, or selective administration of PET scans to patients with less advanced disease. Another way to describe this would be to say that the association of PET with survival is being confounded by selective administration of PET to lower risk patients.^{10, 11}

There are several commonly encountered types of bias that are important in the accurate interpretation of observational HSR studies. *Omitted variable bias* is one of the principal forms of bias in observational studies and is nearly always present to some extent in HSR. It will occur in any situation where (1) a variable exists that is associated with both the outcome and exposure of interest and (2) is omitted as a control. For example, in the PET-NSCLC scenario, disease stage was correlated with both PET and survival, but was not included in the model.

Selection bias is used to describe when a group or exposure is not randomly applied to patients, or in the example case above, where PET scans were *selectively* applied to patients with less advanced disease. *Recall bias* refers to the situation where one population is more likely to recall an event than another. For example, patients with a rare form of cancer might be more likely to recall exposure to any number of environmental stimuli that have been forgotten or would have been overlooked by patients without cancer who had the identical exposure. Bias due to *loss to follow-up* can occur if patients who remain in the study are systematically different from those who do not. *Nonresponse bias* can be seen in self-reported surveys, where survey participants are often more likely to express stronger beliefs than that held by the overall target study population. *Misclassification bias* refers to the case where either the exposure or outcome of interest is misclassified. Lastly, *interviewer bias* can occur when the interviewer knows which exposure or treatment a patient has had, and probes more deeply than they otherwise would have in patients without that exposure.

Minimizing confounders and bias

There are several potential methods that can be used to minimize confounders. Several of these methods can only be implemented during the design phase of a study, and it is therefore key to involve a statistician or HSR methodologist early on in the design of any study, when the full set of all options are available. For example, RCTs will often stratify by key variables known to influence the outcome of interest in order to ensure that they will not wind up with an unbalanced treatment and control group in the final analysis. Multivariable regression analyses are commonly used to help adjust or control for potential confounders. However, a key limitation of such attempts is that variables that are not or cannot be observed cannot be controlled. There are nearly always such unobservable factors at play to some extent in most observational HSR studies, which is why any observed associations should not be reported as causal without further confirmation.

Commonly used methods that are used to mitigate the impact of bias include matching, stratification, subgroup analysis, and instrumental variable analysis.

Matching is the process whereby the characteristics between two groups are matched as closely as possible, in order to create populations that are similar in all respects. The quality of the match can be indirectly assessed by checking to make sure that observable variables that were not used to match patients appear to be similar between groups.

When there are many factors that may differ between two populations, exact matching on all factors is not possible. A calculated *propensity score* may be used to predict the likelihood (or propensity) to receive the treatment or exposure of interest.¹² Patients can then either be matched directly or stratified by their propensity to assess the exposure or treatment of interest, thereby mitigating important differences between study groups.

Related to matching approaches is the idea of *stratification or subgroup analysis*, which respectively control for, or limit analysis to, a specific subgroup of selected patients in which outcomes are predicted to be similar (i.e. stage, age, performance status).

The above approaches all have in common are that they identify potential confounders and attempt to correct or adjust for them. In contrast, an approach called *instrumental variable (IV)* analysis is meant to minimize bias by avoiding confounders all together. In the IV approach, researchers attempt to identify a so-called “instrument,” or proxy that is strongly associated with the exposure of interest, but that is not associated with the outcome of interest through confounding. For example, distance to the nearest facility with PET scanners might predict the likelihood of undergoing a PET scan (the exposure of interest), but should not otherwise be directly associated with stage or survival (outcomes) except through the exposure of interest (PET). Strong “instruments” can be difficult to identify and often are unavailable.

It is important to realize that none of the above methods will completely eliminate bias in real-world HSR analyses. As such, the ability to mitigate, and test for, residual bias is paramount in conducting accurately interpreting observational HSR.

Internal and external validity

Internal validity refers to whether or not observed findings are likely to be reflective of the examined population. In other words, internal validity describes whether the observed findings can be believed within the patients that were analyzed in the study. Any and all studies must have internal validity in order to allow for clinically meaningful interpretation. Common threats to internal validity include selection bias, differential follow-up, recall bias, confounding, misclassification, investigator or interviewer bias, or any systematic differences between control and treatment groups that are associated with the exposure of interest.

External validity refers to whether the associations observed within the confines of the population studied can be generalized to patients outside (external to) the study sample. Not all studies will be externally valid to the same extent. For example, many RCTs are limited to young patients with few comorbidities. The benefit seen in RCTs may not extend to older, sicker, or heavily pretreated patients who were not included in the study.

Different outcomes methods

Meta-analyses and systematic reviews

Systematic reviews are thorough, systematized reviews of the literature on a specific question in HSR and often take place as the preliminary step within a meta-analysis. Meta-analysis describes a statistical technique for combining data from multiple studies in order to try and provide a more precise estimate of the true impact of an intervention or exposure. In order for such studies to be valid, meta-analyses should first perform a quality systemic review of the existing literature, incorporate all relevant data, and check for evidence of heterogeneity in reported studies in order to assess whether or not there is evidence of a potential bias in the field to only publish positive associations. Major findings should be confirmed via the use of sensitivity analyses that ensure that observed estimates are robust to reasonable variations in the analysis. Systematic reviews and meta-analysis are often considered a principal component of the evidence development process, and are particularly important in supporting the generalizability and understanding of clinical effectiveness.

Randomized controlled trials

RCTs have long been considered to produce the highest level of evidence among individual trials. In an RCT, patients are randomly assigned to either a control (placebo or standard of care) arm or an experimental arm. Such trials have been used in countless assessments of therapeutic benefit of medications, behavioral interventions, screening studies, and chemoprevention studies. Although such trials represent the pinnacle of evidence development and have a number of strengths, it is critical for care providers and researchers to have a thorough understanding of both the benefits and limitations of such studies so that they are able to accurately interpret and incorporate their findings in guiding clinical practice and future HSR studies.

The key strength of the RCT is its ability to ensure that a treatment was assigned at random, which serves as the single most reliable method to remove potential sources of bias. This allows the closest ability we have to study what we truly want to understand—the “counterfactual condition.” Counterfactual means literally “against the facts” and describes a “what-if” situation. What we really want to know is “what if” the same patient was exposed to treatment A versus treatment B? If we could go back in time and administer a different treatment to the same patient, would it have changed their outcome? This is obviously not possible. However, through the use of RCTs, we are able to randomly assign treatment so that we can indirectly infer, on average, what would have been the impact had a patient received treatment A versus treatment B. Again, the potential for bias introduced by confounders in observational studies is the principal weakness of observational studies and the ability to avoid confounded treatment assignment is the fundamental strength of RCTs.

Potential limitations of randomized controlled trials

RCTs are not able to address many questions in HSR. Perhaps the most significant reason is that RCTs are

often impossible to conduct because of ethical concerns about a lack of equipoise, or equal validity of both proposed treatment strategies. Because of this, there is often only a limited period during which equipoise of two proposed management strategies exists. A classic example of this is the comparison of radical prostatectomy to radiation therapy in the definitive management of localized prostate cancer. In most cases, a patient's provider and the patient themselves are generally unwilling to randomly assign such substantially different treatments. Numerous RCTs attempting to compare the two strategies have resulted in limited accrual, leading to concerns about sample sizes and external validity.¹³ In the United Kingdom, only 1 of 20 patients enrolled on such a study consented to randomization.¹⁴

Even when adequate equipoise exists to enroll meaningful numbers of patients into RCTs, there are additional limitations. Caution should always be taken whenever interpreting a “negative study” to make sure that the study was adequately powered to answer the question being asked.

Another key limitation of RCTs is that such studies are often applied to a selected group of patients that lack external validity. Patients who are eligible for clinical trials are heavily screened and reflect a group of patients whose outcomes are often superior to those seen in the community. An example of difficulties with external validity comes from a high-quality and well-known meta-analysis of the benefit of chemotherapy in localized breast cancer.¹⁵ Despite the inclusion of 194 trials, few patients were over the age of 69, which leaves the benefit of chemotherapy unclear in women over 70.

The process of study design, enrollment, follow-up and analysis of RCTs can take decades or longer before results are known. The studies can be outdated before they are completed, particularly in areas of cancer care where practice is changing rapidly and the natural disease history is relatively indolent or protracted such as in localized breast or prostate cancer. RCTs cannot assess how the general population is treated, examine the extent to which risks and benefits seen in controlled settings match those observed in actual practice, or characterize adoption, utilization, costs, or factors associated with the use of an intervention in real-world practice. Although RCTs remain a critical component in creating high-level evidence of the efficacy of experimental treatments, observational studies must be used as a complement in order to provide a full and balanced perspective of the true impact and effectiveness of proposed treatment strategies.

Observational studies

Observational studies do not assign or alter any factor of interest as, by definition, they cannot control which patients receive a given exposure or treatment. They are performed on the various data sources described previously—administrative claims data, disease registries, data collected within large health organizations (i.e., Veterans Affairs), and as secondary analyses of clinical trial data. SEER, the population-based registry outlined earlier that now covers 28% of the US population, and the NCDB, the hospital-based registry of more than 1,500 CoC-accredited facilities that captures 70% of newly diagnosed cancer cases nationally, are excellent examples.⁴ The Nationwide Inpatient Sample (NIS) is another example, as it contains discharge data from 44 states since 2012, representing 20% of all community hospitals.¹⁶ Large administrative claims data bases, such as Medicare claims and those curated by large private insurers, are also routinely linked to provide additional data such as death, treatment, patient surveys, or other factors of interest. This results in large, comprehensive samples of current practice within the United States.

The potential for bias or confounding is the primary limitation of observational studies, and a host of advanced statistical methods discussed earlier have been developed to help combat and mitigate potential biases in order to avoid invalid conclusions. Despite this fundamental weakness, observational studies

continue to play an important and critical role in much of HSR that cannot be addressed by RCTs. Perhaps the single most important risk factor for developing cancer in the modern era, smoking, has never been examined within a RCT, but has been firmly established by countless observational studies across numerous cancer types.

There are several principal strengths of observational studies. They examine real-world practice in the community, as opposed to that limited to major academic or cancer trial centers, and provide a representation of the actual use and outcomes associated with an intervention as it is used in practice. Compared to interventional studies, observational studies have the additional benefits of significantly reduced costs, large sample sizes, the potential to observe extended follow-up, and often the statistical power necessary to detect heterogeneous treatment effects or risks among rare patient subgroups.

Types of observational studies

Observational studies can be primarily classified as descriptive or analytic. The focus of analytic studies is similar to that of randomized trials, where the goal is to assess whether or not a causal relationship exists between an exposure or treatment and the outcome of interest. Such studies seek to test a specific hypothesis, for example one might hypothesize that patients undergoing surgery at a high-volume center have superior outcomes compared to those treated at lower volume centers. In contrast, descriptive studies characterize a particular set of patient characteristics or outcomes and can be used to generate hypotheses to be tested in future studies.

The two most common examples of analytic observational studies are case–control and cohort studies. Case–control studies are often used in cancer HSR to assess the association between environmental exposures such as smoking, genotype, geography, drugs, diet, or toxins and the likelihood of developing cancer (the outcome). Such studies identify patients with the outcome of interests (cases, i.e., cancer) and match them to patients who did not experience the outcome (controls, i.e., no cancer). Interviews or surveys are then often conducted to obtain additional information from both sets of patients. The strength of such studies is that they can be used to analyze factors that might predispose people to rare cancers that would otherwise be difficult to evaluate. The primary challenge of these studies is often identifying controls that are otherwise similar to the cases except for the exposure of interest and ensuring that recall bias among controls does not over-report exposures compared to the control cases.

In contrast to case–control studies, cohort studies select a group of patients based on their exposure and then follow them forward over time. Cohort studies are called as such because they first define the specific cohorts of interest—that is exposure and nonexposure—before examining outcomes. There are numerous examples of cohort studies in HSR, which include analyses of clinical trials, registries, and other retrospective or prospective databases. These studies are often used to characterize the adoption and costs of emerging medical technology such as advanced imaging and PET scans¹⁷ or Intensity Modulated Radiation Therapy (IMRT) in the treatment of prostate cancer.¹⁸

Prospective analyses consist of data collected with the intention of analyzing it for a given purpose. In contrast, retrospective analyses utilize data that have already been collected for a different reason, often leveraging administrative claims used to bill insurance companies or general cancer registries that include treatment data. Although a distinction is often made between prospective and retrospective analyses, the methods and approaches used to analyze the data are similar. However, prospective analyses, especially those for which a detailed analysis plan is created prior to collecting and viewing the data, are less likely to lead to extensive subgroup analyses or other approaches that may identify spurious associations due to chance and extensive data manipulation. The strengths of observational cohort studies

include the ability to examine rare exposures over prolonged periods of time, such as the impact of atomic bomb radiation exposure on the risk of developing leukemia and other cancers decades later. In contemporary HSR, cohort studies are perhaps the most commonly used observational study approach and are used to compare the impact of a particular treatment on patient outcomes. For example, given the difficulties of conducting large RCTs of prostatectomy versus radiation in prostate cancer, many cohort studies have compared outcomes following treatment with these two modalities (Sun 2014).

Descriptive studies include ecologic studies, cross-sectional studies, and case reports or case series. Unlike analytic studies, such studies are not designed to test hypotheses, but rather to generate hypotheses that may be tested in later studies. Ecologic studies describe situations where the exposure and outcomes occur at the individual-level, but are measured at the population level.¹⁹ For example, ecologic studies of many cancers have been used to demonstrate changes in the risk of specific cancers such as breast or prostate between the US and other countries, presumably due to cultural, environmental, lifestyle, or dietary differences in exposures.²⁰ Such studies, while hypothesis generating, suffer from the primary weakness that they cannot confirm individual-level associations between exposures and outcomes.

In contrast to *ecologic studies*, cross-sectional studies are used to observe individuals at a single snapshot in time, and can characterize the association of exposures and outcomes among those patients. However, the primary limitation of these studies is that they cannot be used to draw causal inferences, as it is not possible to distinguish whether such an association represents the exposure causing the outcome or the outcome causing the exposure.

Lastly, *case reports or case series* describe detailed exposures and outcomes of a small number of patients. Such studies have often heralded the potential for extraordinary therapeutic efficacy of novel treatment strategies. A contemporary example of a high impact case report comes from the case of combining novel immune checkpoint inhibitors with radiation, where radiation to a single site of disease was observed to induce complete systemic resolution of all sites of disease in a patient with metastatic melanoma. The effect was attributed to a radiation-induced stimulation of a systemic immune response.²¹

Common limitations of most retrospectively performed analyses include a lack of personal risk factors, detailed performance status, and other factors that might influence or more accurately characterize the exposure or outcome of interest that would have been collected had the analysis plan been known at the time of data collection. The quality of analyses performed on any data set will vary widely depending on the quality of the data. Key to the internal validity of any study is the reliability of key exposures, outcomes, and potential confounders contained within the data. In administrative claims data, for example, claim dates and procedural codes are typically heavily audited and highly reliable, since this information is used to determine payment information. However, the reliability of a diagnosis of constipation or some other minor complication that does not impact payment might be missed in a large proportion of patients. Therefore, familiarity with the data being analyzed is paramount to performing a well-conducted study.

Modeling

Modeling studies in HSR refer to the creation of algorithms to describe complex associations and relationships between exposures, outcomes, and confounders.²² Modeling can play a particularly important role in guiding the design of policies, guidelines, treatment approaches, or reimbursement that would otherwise be too time consuming, costly, and complicated to analyze using direct interventional or conventional observational approaches. Modeling also provides a means of exploring relationships among data which cannot be directly observed or feasibly obtained in practice, such as those involving costs or long term outcomes. Models used in HSR often examine the impact of various decision

algorithms, new interventions, policies, or patient factors on associated outcomes or costs. The studies often use metrics such as health adjusted life-years (QUALYs) to objectively provide an indication of the balance between overall quantify and QOL for cancer patients. Cost-effectiveness analyses often report incremental cost effectiveness ratios (ICERs), which describe the relative cost and gains of alternative management strategies or exposures.

An example in the cancer literature comes from several analyses of the impact of Oncotype DX testing in breast cancer. Use of the Oncotype DX test, which predicts the benefit associated with receipt of chemotherapy, has been previously shown to change physician recommendations to prescribe less overall chemotherapy. Modeling studies of Oncotype DX testing have been used to perform cost-effectiveness analyses and have predicted that the use of the assay has the potential to be cost-saving.²³ The advantage of modeling is that various factors and their relative impact on outcomes of interest can be dissected—for example, one could adjust estimates of cost savings from Oncotype DX testing depending on the utilization strategy, the age of the population, and the cost of chemotherapy. The obvious disadvantage of modeling is that many assumptions must be made that may impact the findings.

Quality of care

The IOM has defined quality of care as “the degree to which health care services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge,” and then later extended the definition to encompass “care that incorporates respect for patients' values and preferences.”^{24, 25} It is underappreciated that, despite substantial improvements in available treatments and technology, the main determinants of patient health outcomes, quality of care, and overall costs are related to variability in clinical practice^{26, 27} and the failure of patients to receive basic care.²⁸

One such example comes from studies of surgery at high-volume centers. For over thirty years it has been consistently observed that centers with higher volume, or total number of cases performed, are often associated with improved outcomes.²⁹ Twenty years after this was initially observed, this was confirmed in a meta-analysis showing that in 123 of 128 studies included, lower hospital mortality was observed in high-volume centers across 40 different procedures.³⁰ The risk of receiving a procedure at a low-volume center was highest for complicated procedures such as esophagectomy and pancreatectomy, where differences in 30-day mortality approach 5–10%.³¹ However, it is important to note that such studies are observational in nature, vary in their definition of “high volume,” and may be significantly biased by case selection of patients willing to travel to higher volume centers. Quality of care may also vary by geographic region owing to differences in regional treatment patterns, patient populations, available oncology specialists, or other factors. For example, rates of laparoscopic colectomy³² and end of life care³³ vary widely by geography.

The quality metrics used to describe the structure, process, and outcomes of care were proposed by Dr. Donabedian in 1950 and continue to be used to this day.¹ Structure describes the context in which care is provided and its associated financial and personnel resources. Examples might include institutional characteristics such as provider expertise, accreditation, and case volume. Processes consist of patient and provider activities in the diagnosis and treatment of an illness and are often defined in terms of guidelines issued by national organizations such as the National Comprehensive Cancer Network (NCCN) or American Society of Clinical Oncology (ASCO). Outcomes describe the patient's health post treatment and are defined in terms such as overall survival, disease-specific survival, objective response

rates, time to progression, and toxicity. The use of outcomes in formal metrics is often debated in oncology due to variations in case-mix, disease-severity, and other potential confounders that might be outside an institution's control. Increasingly, methods are used to overcome this limitation.

Despite the potential for each of these to impact the quality of care, there are inherent challenges in using outcomes and structure-based endpoints to define quality in a way that can incentivize health care providers and systems to improve care. For example, outcomes may be significantly impacted by the case-mix seen by an institution. Efforts to “cherry-pick” or otherwise select patients may be effective at increasing profits, but not improve care. Structure-based endpoints may not be appropriate as a one size fits all solution depending on the total case volume, case mix, amount of resources, or rural versus urban location. As a result, assessments of health quality in both HSR and in practical use are dominated by procedural measures. As an example, the majority of Healthcare Effectiveness Data and Information Set (HEDIS) measures currently used to assess health care performance across a wide variety of settings relies almost entirely on procedure-based definitions of quality such as the use of cancer screening, immunizations, or specific treatments for disease.³⁴ Procedures can be underused, overused, or misused. In practice, underuse is often most easily studied in the setting where current guidelines recommend a specific procedure and whether or not patients received the recommended standard of care can be examined. Overuse and misuse, however, are challenging to prove, since guidelines tend to be less likely to describe situations where a specific test should not be performed under any circumstances. For example, although a PET scan may not be indicated for all patients with breast or colorectal cancer, a borderline CT scan or other equivocal study would be a reasonable indication to perform a PET. Such nuances can be difficult to describe systematically within many retrospective data sets. Lastly, misuse can be similarly difficult to confirm in the absence of detailed treatment records, which typically are not available in larger retrospective studies.

HSR 2.0

HSR has advanced quickly over the last two decades due in part to the rapid progress made in computational power and the ability to generate, store, link, analyze, and interpret large datasets. Until 1970, it would often take up to 24 hours to run a single regression analysis using the electromechanical desk calculators of the day.³⁵ Advances in personal computing, the internet, and now mobile devices, provide a previously unparalleled opportunity to fully capture and analyze health services from the patient, provider, and health system perspectives. The IOM has formally acknowledged the idea of a learning health system (LHS), defined as an organization in which “science, informatics, incentives, and culture are aligned for continuous improvement and innovation—with best practices seamlessly embedded in the delivery process and new knowledge captured as an integral by-product of the delivery experience.”³⁶ The idea behind the LHS is to provide rapid learning personalized health care, in which patient care naturally feeds back information on patient outcomes to help guide future management decisions.³⁷ Although the idea of the LHS is becoming increasingly more common, “use cases” describing their effective implementation to assess patient outcomes and recommend future areas for research are only beginning to emerge. For example, an LHS approach is being used to evaluate the role of biologics in pediatric crohn's patients.³⁸

EMRs are foundational to a learning health system, as they provide a digital footprint of each patient's story. Multiple patient cases are aggregated to generate streams of continuously updating information. To the effect that data in the EMR can be codified to a common standard, then EMR data can approximate registry data. In order to solve this, information in structured data feeds (e.g., laboratory data) needs to be

harmonized and normalized to a single common data model; information trapped in unstructured documents (e.g., PDFs of clinical notes, pathology reports) must be transferred to a codifiable digital standards. Multiple groups are focused on solving this problem in cancer.

The potential contributors to LHS and related efforts are broad, spanning organizations such as traditional health organizations, government entities, and genomics companies. HSR will benefit from real-world data obtained in real time through the linking of EMRs to numerous external databases. The potential to incorporate decisions support into routine care, leveraging patient specific data in areas such as genomics, treatment history, and predicted outcomes will require knowledge of how to manage such data from technical, medicolegal, ethical, and practical perspectives. In the face of rising health care costs and inefficiencies, oncology workshops focused on the delivery of affordable care have proposed the use of LHS to provide a potential solution to help economize health services and clinical research.³⁹

Outcomes and endpoints

Although HSR can encompass any outcome or endpoint associated with patient care, there are a number of types of outcomes and endpoints that form the bulk of current HSR including QOL, cost, quality, access, patterns of care, and CER.

Patient reported outcomes

Patient reported outcomes (PROs) are generated by questions posed to patients regarding their symptoms and other concerns, as opposed to being documented by physicians or other members of the health care team.

Widespread internet access and advances in computational technology now provide the opportunity to engage with patients and collect longitudinal PROs, which has grown dramatically over the past few years. As a result, the collection and utilization of PROs has emerged as a distinct area of study with networks of researchers dedicated to its implementation. In support of this, researchers with expertise in the collection and utilization of PROs often collaborate with QOL researchers to efficiently achieve their research goals. For the purpose of the discussion, we will only briefly mention QOL as a subset of PRO research, noting that it in fact composes a large portion of PRO research but will be described in more detail in the next section.

The use of PROs in HSR has several strengths including efficient collection, improved accuracy as to the patient's experience when compared to physician-reported measures, and the ability to use them to predict objective clinical outcomes such as survival, patient satisfaction, and general health.⁴⁰ PRO measures can be either generic or disease-specific, each of which have their respective advantages and weaknesses.⁴¹ Advantages of general PRO tools include wider generalizability across disease types and a larger body of literature to support both their validity and association with traditional objective endpoints.

Although a large number of PROs have been used in the literature, there are several PRO measures that have been specifically evaluated in oncology and are worth brief mention here and include the EORTC QOL Questionnaire (EORTC QLQ-C30), Functional Assessment of Cancer Therapy (FACT), MD Anderson Symptom Inventory (MDASI), PRO version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE), and PRO Measurement Information System (PROMIS).⁴⁰ Efforts to validate, standardize, and compare PROs have greatly improved the quality of PRO measures, which are now used routinely in clinical trial design and the approval of new drug applications submitted to the FDA.

A recent advance in the LHS field has been the incorporation of the patient's voice using PROs. In

particular, the capture of electronic PROs (ePROs) over conventional PROs are numerous, and include reduced cost, increased efficiency of delivery and completion for both patients and providers, and the ability to use computer adaptive testing (CAT) to further economize and personalize the data gathered from these interactions. Through this cycle, these data can then be used to help inform clinical care, provide decision support, and educate patients and clinicians in real-time at the point of care.

Quality of life

Measures of QOL are numerous and complex, each containing specific domains or areas of interest (i.e., fatigue, urinary symptoms, medical events), with each domain including multiple items. Key measures of the utility of specific QOL instruments include their reliability, internal consistency, reproducibility between interviewers, and validity (content and construct). The short form—36 item (SF-36) is an example of a questionnaire that has been used in hundreds of studies and disease types with a large body of literature supporting its reliability and applicability. Alternatively, disease-specific measures provide a more targeted assessment of key factors relevant to a particular patient population. For example, for patients with prostate cancer, urologic and sexual QOL metrics should be directly assessed through disease-specific tools such as the International Index of Erectile Function (IIEF) and American Urologic Association (AUA). Choosing the best measures of QOL requires a thorough understanding of the most relevant symptoms and outcomes to a specific patient population.⁴⁰ QOL research can also be used to derive utilities, or quantitative measures of QOL. Such utilities can be used to adjust survival analyses to represent both quantity and QOL.

QOL measures have a number of limitations, including the fact that they often contain a large number of domains and items, with many potential permutations of measures, dysfunctions and symptoms, impeding efforts at standardization, and validation. QOL measures may also not hold the same value for all patients. For example, elderly patients may not be as concerned with sexual function and previously disabled patients may have a different baseline level of functionality that precedes their diagnosis. Lastly, as with any data, missing data or failure of patients to complete questionnaires may occur due to fatigue, apathy, decline in mental function, or overall decline in health. Such declines are notorious in palliative care settings, where non-participation may be strongly associated with declining patient overall performance status and can result in reporting bias.

Costs

As described previously in this chapter, the cost of cancer in the US is increasing rapidly due to the aging of the population and the adoption, and increased use, of expensive emerging medical technologies. Efforts to accurately quantify current costs, understand factors driving costs, and model the impact of alternative strategies are a critical component of HSR. Such analyses may examine overall costs, cost-effectiveness, cost-utility, cost-benefits, and help provide a uniform framework and set universal thresholds to objectively and rationally inform policy, reimbursement, payer, provider, and patient decisions.

Even the most basic cost analyses are more complex and nuanced than one might initially expect. Patients undergoing the same treatment, at the same institution, for the same condition, may pay vastly different amounts for the same service (e.g., owing to different insurance). Because of the nature of health care and its perception as a right (i.e., emergency care), “customers” cannot be turned away for certain services. The means by which hospitals and medical facilities balance the costs of those who can pay versus those who cannot set the stage for a widely variable, often obscure, pricing system in which the physician often is not able to know the cost of the treatment they are prescribing. This is in stark contrast to other

consumer services in which charges are known in advance and discussed upfront by service providers such as is done by mechanics and veterinarians.

As a result, the method and perspective used to estimate costs of medical care must be carefully specified and can include payments made by the insurer (payer perspective), out of pocket payments by the patient (patient perspective), total payments, total charges, lost wages due to lost productivity, and the additional burden placed on family members or other caregivers (societal perspective). Many interventions may alter subsequent management strategies and outcomes, which may impact overall costs via these “indirect costs.” Of all these metrics, hospital listed charges vary the most widely, are the least reliable indicators of true cost, and are rarely used since most patients pay a lower price as negotiated by their insurance company. Marginal costs indicate the additional cost of a change in treatment strategies or additional services and are often used to examine the incremental impact of changes in treatment strategies. Because of the complexity of calculating health care costs, and the potential variation in the cost for a given service, close attention should be paid to the details and underlying assumptions of any cost estimates.

Bundled episodes of care

Many payers no longer operate using an a-la-carte, fee for service system where each service or good is associated with a payment. Inpatient costs are increasingly bundled and rates of reimbursements set by a Diagnosis Related Group (DRG) code which consists of a single lump sum that is paid to hospitals to cover all care administered during a hospitalization. These DRG codes are based on estimates of how much an admission should reasonably cost given the reason for the admission and potential complicating factors. Similarly, surgical procedures are often bundled, where a single reimbursement is expected to cover the surgery and all associated follow-up care, including complications within a predetermined timeframe. These systems are designed to incentivize providers and hospitals to provide efficient care and minimize complications.

Cost-effectiveness analysis

There are several types of cost analyses beyond simple summations that provide objective data with which patient, providers, payers, and policy makers can make informed decisions. Commonly analyses include cost-effectiveness analyses and modeling (described previously in this chapter). A cost-effectiveness analysis has been defined by the National Institute for Health and Clinical Excellence (NICE) as an economic study design in which consequences of different interventions are measured using a single outcome (i.e., life-years gained, deaths avoided, cases detected). Alternative interventions are then compared in terms of cost per unit of effectiveness.⁴² This key metric is referred to as the incremental cost-effectiveness ratio (ICER). Whether or not a specific intervention is considered “cost-effective” depends on the available resources and willingness to pay of the target population. A classic analysis of over 500 life-saving interventions suggested that the median cost per life year saved was approximately \$42,000 per life year saved⁴³ (in 1995 dollars), providing a rough benchmark of the relative willingness of the American public to pay. In contrast, global health initiatives, vaccinations, and the treatment of malaria are highly cost-effective at less than \$100 per life year saved. A screening colonoscopy every 10 years beginning at age 50 costs roughly \$11,000 per year of life saved.⁴⁴ The World Health Organization recommends considering cost-effectiveness in terms of gross domestic product (GDP) per capita.⁴⁵ Using this schema, interventions are considered highly cost-effective (less than GDP per capita); cost-effective (between one and three times GDP per capita); and not cost-effective (more than three times GDP per capita). For the United States (2012 GDP per capita) this would equate to <\$50,000, \$50,000–\$150,000, and >\$150,000, respectively. In the end, cost-effectiveness analyses are often phrased in terms of

currently accepted ICERs. For example, if a given health system is already paying for interventions that cost \$60,000 per QALY, it would make logical sense for them to cover a novel intervention with an ICER <\$60,000. In current US practice interventions, ICERs of <\$50,000 are generally considered cost-effective. Such analyses provide a detailed and objective framework with which patients, providers, and policy makers can make rational tradeoffs in costs, care, and outcomes.

Comparative effectiveness research

According to the Agency for Healthcare Research and Quality (AHRQ), CER is “designed to inform health care decisions by providing evidence on the effectiveness, benefits, and harms of different treatment options.”⁴⁶ The term “comparative effectiveness” was coined roughly 25 years ago and was originally used to describe research to “help patients, family, and caregivers make more informed decisions with providers.”⁴⁷ In practice, the use of CER is used to describe studies (often observational) that attempt to compare the benefits of two interventions or management strategies. The 2010 Patient Protection and Affordable Care Act (PPACA) established the Patient-Centered Outcomes Research Institute (PCORI) to fund and conduct research to determine the effectiveness of various medical services. PCORI explicitly emphasized the incorporation of costs and cost-effectiveness into studies.⁴⁸ As a result, the use of CER has evolved over recent years to include a greater focus on cost and cost-effectiveness.

CER is not a specific analysis technique or approach but a re-framing of existing observational study methodologies to focus on the comparison of potential treatment strategies. Most CER studies are simply cohort-based studies, described previously in this chapter, with an emphasis on attempting to simulate an RCT comparing two treatment arms with the goal of performing causal inference. At the end of the day, the key challenge in CER studies, much like other observational studies, is the mitigation of potential bias and confounding.

Part 7

Individualized Treatment

Chapter 51

Personalized medicine in oncology drug development

Nicholas C. Dracopoli, PhD ■ Iqbal Grewal, PhD, DSc, FRCPath ■ Chris H. Takimoto, MD, PhD, FACP ■ Peter F. Lebowitz, MD, PhD

Overview

The concept of personalized medicine in oncology drug development is no longer an aspiration; it is now, in large measure, the accepted paradigm of how oncology drugs should be developed. In modern oncology drug development, determining which molecularly characterized tumors will benefit the most from a drug is a critical part of the development plan. In addition, another important personalized medicine approach is emerging whereby a therapeutic is specific to an individual patient. Examples of this individualized therapeutic approach include engineering of autologous immune cells with reinfusion into the patient or cancer vaccines that are specific to an individual tumor.

A growing number of successful examples have demonstrated that the personalized medicine approach via biomarker selection can provide more benefit to patients and more rapid approval of drugs. The benefits of a personalized medicine strategy in oncology drug development are multiple and include an increased probability of overall success, smaller Phase 3 registration trials, and the potential for enhanced clinical benefits for patients. In a recent review, Falconi and colleagues examined the outcome of 676 Phase 1, 2, and 3 clinical trials of novel therapeutics for non-small cell lung cancer conducted from 1998 to 2012.¹ Overall, the cumulative success rate, as defined by the advancement to the next stage of clinical testing or to approval, was only 11%. However, when a biomarker was utilized for patient selection, the cumulative success rate increased by nearly sixfold to 62%. Thus, there is strong objective evidence for predictive biomarkers to enhance the probability of success in drug development. Using specific genetic and/or protein markers, a number of important drugs have been developed and approved in specific populations. This approach represents a paradigm shift that has proved so powerful that it is now a standard.

Introduction

The growing armamentarium of biomarker tools will allow a further expansion of the personalized drug development approach. It will also increase complexity across development and this will come with challenges. While precision medicine is now a reality, the successes have generally been where the companion diagnostic is the same as the target of the drug. As the science advances, efforts will need to be expanded in a few areas of personalized medicine to realize further gains. Some examples include

1. Multiplex biomarker panels as diagnostics. With few exceptions, most successful personalized medicine programs in oncology have measured a single gene or protein. As multiplexed approaches become mainstream with the analysis of thousands of datapoints, diagnostics using full panels will begin to emerge. This may require different clinical development strategies with the identification of a biomarker panel in early clinical trials and confirmation in registration studies.

Some successful examples of multiplex diagnostics include transcriptional profiling efforts. Using this approach, a gene expression pattern is identified for responders versus nonresponders. This profile is then prospectively applied to a validation set of samples to determine the predictive value, sensitivity, and specificity of the test. Of the profiles in clinical use, such as Oncotype Dx (Genomic Health, Redwood City, California), MammaPrint (Agendia BV, Amsterdam, the Netherlands), and H/I (AvariaDX, Carlsbad, California), these tests are better at identifying the patients unlikely to benefit from treatment than the potential responders.

2. Immuno-oncology personalized medicine. While analysis of cancer cells has formed the mainstay of personalized medicine, it is becoming increasingly clear that other components of a tumor, such as immune cells and stromal cells, are critical biologic mediators that can now be manipulated for therapeutic benefit. As new therapies target these microenvironment cells, new technologies for profiling are being developed. The complexity of measuring multiple markers in multiple cell types presents challenges in the development of novel immunotherapy.
3. Personalized therapeutics. These include engineered autologous cells and individual tumor antigen approaches and are discussed in detail below.

Thus, while personalized medicine has finally become a reality in oncology drug development, it is becoming a far more complex proposition as we address more complex mechanisms and biology. In this chapter, we try to cover some of the key issues that are critical to understand in order to achieve further successes.

Role of biomarkers and companion diagnostics in personalized medicine

Types of biomarkers

Biomarkers and their associated diagnostics are critical components of most personalized drug development efforts. Biomarkers can be classified into several types as shown in [Table 1](#). These include predictive, prognostic, and surrogate end points. All of these biomarker types contribute in critical ways to drug development, but we typically think of predictive biomarkers as being the driving force in personalized medicine. These are used to identify patients within a population who have a higher probability of responding to treatment than the “all-comer” population. The symbiotic development of molecular profiling technologies and the completion of the human genome sequence created new opportunities for the comprehensive discovery of markers to help predict drug efficacy or reduce risk of drug toxicity.

Table 1 Types of Biomarkers and Diagnostics

Marker	Function	Test
PD/MOA	<ul style="list-style-type: none"> Determine whether a drug hits the target and has impact on the biological pathway Evaluate mechanism of action (MOA) PK/PD correlations and determine dose and schedule Determine biologically effective dose 	<ul style="list-style-type: none"> Research test used during drug development Not developed as companion diagnostic
Predictive	<ul style="list-style-type: none"> Identify patients most likely to respond, or are least likely to suffer an adverse event when treated with a drug 	<ul style="list-style-type: none"> Companion diagnostic test (e.g., herceptin, EGFR)
Resistance	<ul style="list-style-type: none"> Identify mechanisms driving acquired drug resistance 	<ul style="list-style-type: none"> Mutation analyses (e.g., Bcr-Abl mutation in imatinib treated CML)
Prognostic	<ul style="list-style-type: none"> Predict course of disease independent of any specific treatment modality 	<ul style="list-style-type: none"> Approved tests (e.g., CellSearch, Mammaprint)
Surrogate	<ul style="list-style-type: none"> Approved registrational end points 	<ul style="list-style-type: none"> Commercial diagnostic tests (e.g., LDL, HbA1c, viral load, blood pressure)

Today, an enormous number of biomarkers have been described, but most lack sufficient characterization necessary for clinical application. In October 2014, the GOBIOM database (www.gvkbio.com) lists more than 45,000 biomarkers. In effect, this is the equivalent of two biomarkers for every gene in the human genome! This suggests that the term biomarker is being greatly overused as we simply do not have this many useful biomarkers to support all different research applications. The vast majority of these biomarkers are poorly characterized and cannot be used effectively in research or clinical applications without considerable efforts to develop analytically valid assays as well as correlative data to confirm their role as a biomarker of a biological process.

Biomarkers have diverse uses throughout the drug development process as readouts for mechanism of action (MOA), pharmacodynamics (PDs), prognosis, response prediction, drug resistance, and surrogate markers (Table 1). Perhaps the most common use is as MOA markers to confirm the drug is hitting the expected target and having the desired downstream effect, often by measuring protein phosphorylation in members of the downstream signaling pathway. PD biomarkers are widely employed with pharmacokinetic (PK) analyses to determine a biologically effective dose and define the dose for the first Phase 2 efficacy studies. Prognostic markers are developed to determine the likely course of disease in the absence of any specific pharmaceutical intervention and have been widely used in some oncology indications to predict the likelihood of disease recurrence after resection of the primary tumor (e.g., Mammaprint and Oncotype Dx). Predictive biomarker tests are used to predict response to a specific treatment and are discussed in detail below. Increasingly, biomarker strategies are being used to detect and follow emergent resistance to therapy and considerable success has been achieved for the class of

tyrosine kinase inhibitors to predict resistance to therapy.

Successes and challenges with companion diagnostics

As a testament to the successes of personalized drug development in oncology, as of January 2015, a total of 20 companion diagnostic tests have been approved by the FDA and are broadly used today in the treatment of cancer patients.² These 20 tests are described in [Table 2](#). Several important factors emerge upon close examination of the approved companion diagnostics in this table. Firstly, all the tests are simple and measure the status of the drug target or, for Kirsten-Ras (KRAS), a resistance pathway downstream of the drug target.^{3, 4} Each test is a single analyte test that measures the somatic genetic changes that activate the drug target including gene amplification (HER2, KIT), mutation (KRAS, epidermal growth factor receptor (EGFR), BRAF) or translocation (ALK). Secondly, all of the approved companion diagnostics in oncology are for signal transduction inhibitors with driver mutations in the target or downstream pathways. In contrast, there are no FDA-approved companion diagnostics for other drug mechanisms including cytotoxic drugs, epigenetic modulators, or immuno-oncology therapies. Why is it that we have been successful in developing companion diagnostics for signal transduction inhibitors but not for other important oncology drug targets? The answer is mainly that these driver mutations are the target (or closely related to the target) of the drugs being developed. Consequently, it is possible to quickly test the hypothesis that proliferation and metastasis of a tumor are driven by somatic abnormality detected in the drug target and that only those patients with such a somatic aberration will respond to inhibition of this target. This hypothesis can begin to be confirmed or refuted in clinical studies as soon as an efficacious dose is established in Phase 1 studies. In contrast, if samples have to be collected in Phase 2 for molecular profiling in order to develop a hypothesis, the development of a predictive marker becomes much more difficult. In this scenario, a stepwise approach must be taken which includes biomarker hypothesis generation, hypothesis testing and validation, and, finally, diagnostic development.

Table 2 List of approved FDA companion diagnostics in October 2014

TEST	Manufacturer	Drug(s)	Method	Analyte

One recent example of this complexity is seen with the development of immuno-oncology agents. Checkpoint inhibitors like anti-PD-1 antibodies have demonstrated significant survival benefits and are the vanguard of a new wave of immune modulators.⁵ These new drugs function by inhibiting immune checkpoints and preventing the tumor from evading the host immune system. However, early clinical data show that measuring the expression of the target checkpoints is quite complex as a predictive biomarker. While the response rate can be improved by—three to four times with high expression of PDL1 when using a PD1 inhibitor, it is also true that tumors without detectable expression respond to the drug. Consequently, simply testing for the expression of the checkpoint target may be insufficient as a predictive marker for this new type of drug and we may have to develop new molecular profiles to predict response to these important immune-modulating drugs.

In addition to the FDA-approved companion diagnostics for oncology drugs, there are many more tests being used for research and clinical applications in Clinical Laboratory Improvement Amendment (CLIA) and College of American Pathology (CAP) accredited laboratories. These tests vary from single-analyte tests to complex molecular profiles. Some have highly validated analytical performance and strong evidence of clinical utility, while other tests are much less well characterized. Recently, many

laboratories have developed sequencing panels to screen for canonical cancer mutations in 30–300 genes. These panels are mostly used for research purposes and increasingly for screening cancer patients for enrollment into targeted clinical studies. Perhaps the best known of these tests is FoundationOne, provided by Foundation Medicine Inc. This test sequences 230 cancer genes in formalin-fixed paraffin-embedded tissue (FFPET) to identify somatic mutations. This information is analyzed and may be used by physicians to direct patients to appropriate clinical trials with targeted agents or, sometimes, off-label treatment with approved agents.

Strategies for companion diagnostic development

Companion diagnostic (CDx) development—preclinical approach

The first step in the CDx development is the formulation of the predictive biomarker hypothesis. Ideally, this begins at the same time a new therapeutic agent or target is identified. The predictive biomarker hypothesis outlines a strategy for identifying and testing assays that can prospectively predict drug sensitivity or resistance. Beginning at the earliest stages of drug discovery, this hypothesis should incorporate a thorough understanding of target biology and the drug's proposed MOA. The resulting output is a series of candidate predictive biomarker assays that will undergo rigorous preclinical and clinical evaluation testing their value as CDx tests. Candidate biomarkers may predict either drug sensitivity or resistance. In either case, the CDx co-development strategy is similar.

As discussed above, in some programs, the predictive biomarker hypothesis is inherently defined by the drug target. For example, a program targeting a tumor resistance mutation might use the presence of that mutation as a predictive biomarker to select patients for early clinical trial evaluation to demonstrate rapid proof of concept. This approach has been utilized in the development of the second generation of EGFR inhibitors that target the T790M resistance mutation in NSCLC patients.⁶ In other situations, a predictive biomarker might simply be high expression of the drug target such as HER2/Neu expression in breast cancer patients optimally treated with trastuzumab.⁷ Most of the currently approved oncology CDx assays measure a single gene or protein directly related to the drug's molecular target.

The specific characteristics of the proposed predictive biomarker test can influence its clinical validation. For example, a biomarker with a binary readout, such as the presence or absence of a mutation, is the simplest to evaluate in clinical trials because of the lack of ambiguity about what constitutes a positive test. In contrast, a continuous variable, such as intensity of immunohistochemical staining or the degree of gene amplification or copy number, is more complex because of the need to establish a threshold for test positivity in actual clinical studies. Even more complicated are multivariate tests, such as microarray signatures or composite parameters derived from a variety of different tests. In general, as these predictive biomarkers grow more sophisticated, the burden to conduct more highly powered clinical trials for clinical validation also increases.

If the drug MOA is not well characterized, then the predictive biomarker hypothesis may be difficult to formulate and an exploratory approach may be warranted. For example, the potency of a new therapeutic across a panel of molecularly characterized tumor cell lines can be explored and used to identify molecular signatures, or, ideally, individual gene alterations, that strongly associate with drug sensitivity or resistance. To date, complex gene signatures associated with drug sensitivity have not been useful as companion diagnostics; however, this approach might still be valuable as a tool for biomarker discovery. The prevalence of any newly identified candidate predictive biomarkers can be ascertained in archived tumor tissues to explore potential clinical relevance. Ultimately, the exploratory predictive biomarker hypothesis should yield a series of promising candidate assays for further evaluation in the clinic.

Once a series of potential candidate predictive biomarkers are identified, the strength of the predictive biomarker hypothesis should be evaluated. The predictive potential of the associated candidate biomarkers can be explored in preclinical experiments conducted in relevant *in vitro* cell lines and *in vivo* tumor models. The presence of the predictive biomarker should strongly correlate with drug sensitivity over a series of tumor models. Confirmatory findings in patient-derived xenografts would further support the clinical relevance of the candidate predictive biomarker. The strength of the predictive biomarker hypothesis could substantially impact the choice of patient populations studied. If the predictive biomarker potential is highly compelling, then treatment in early trials might be restricted to biomarker-positive patients as a rapid proof-of-concept strategy. However, if the biomarker correlation is more tenuous, then treating both biomarker-positive and biomarker-negative patients early in clinical development is warranted.

A final preclinical step in CDx development is the preparation of qualified laboratory assays suitable for application to clinical trials. Ideal tests should be simple, robust, sensitive, and possess a rapid turnaround if used for patient screening. Analysis of circulating tumor cells, plasma proteins, or tests performed on formalin-fixed, paraffin-embedded tumor archival tissues are more advantageous than tests that require fresh tumor biopsies. Prototype assays for several different predictive biomarker candidates may be used for exploratory evaluation in preclinical experiments and for nonscreening studies in patients enrolled in early clinical studies.⁸ However, complete analytical validation will be required for full CDx testing, ideally prior to the initiation of pivotal later stage trials. Careful coordination between the clinical study team and the translational research personnel handling predictive biomarker logistics is essential to ensure consistent sample processing, shipping, and turnaround of test results.

CDx development in early clinical trials

The procedures required to develop a drug therapeutic are well characterized, but the steps required for CDx validation are often less well appreciated. In the past, predictive biomarkers were explored retrospectively by conducting *post hoc* analyses on clinical trial data for hypothesis generation.⁹ However, this slow, linear way of thinking is outdated and remains at odds with the requirement to develop CDx tests rapidly alongside new therapeutics. In the modern era, proactive co-development plans are essential.

Development of a CDx can strongly influence the design of traditional first-in-human Phase 1 oncology studies. These trials are traditionally performed in cancer patients and their classic endpoints include dose selection, PKs, toxicity profiles, and the determination of the maximum tolerated dose. Phase 1 trials also frequently incorporate PD biomarker endpoints such as receptor occupancy, or target inhibition, to assess target engagement and downstream pathway modulation. These PD assays can assist in the selection of a recommended Phase 2 dose; however, they are generally not used as companion diagnostics, and their use is limited to early development trials. A traditional solid tumor Phase 1 oncology study will accrue patients with a variety of advanced tumor types, independent of their biomarker status, to ensure rapid determination of toxicity profiles, collect PKs data, and establish firm dosing recommendations.

Increasingly, Phase 1 oncology trials are incorporating early assessment of drug activity in expansion cohorts opened immediately after dose selection. This attempt to establish rapid proof of concept in a defined population has diminished the role of standalone Phase 2a efficacy trials in many current drug development programs.^{10, 11} However, it has fueled a corresponding increase in Phase 1 trial size and complexity. A critical early decision is whether to limit enrollment in these expansion cohorts to biomarker-positive patients or to include an all-comer, biomarker agnostic approach. If the biomarker

hypothesis is compelling and biomarker-negative patients are not expected to benefit from treatment, there is good rationale to limit accrual to biomarker-positive patients. A popular Phase 1 strategy is to enroll unselected patients during dose escalation but to restrict expansion cohort accrual to biomarker-positive patients. This type of enrichment approach provides an early opportunity to observe an efficacy signal in the proof-of-concept population deemed most likely to respond to the investigational treatment. A disadvantage is that many patients will have to be screened if the prevalence of the predictive biomarker is low, and this can further increase the study complexity. Alternatively, if an all-comer or biomarker-stratified approach is used in the Phase 1 expansion, then the retrospective determination of the predictive biomarker status in all patients should be mandatory.

Even if a biomarker enrichment strategy is employed, the exploratory nature of these early trials should enforce a measure of clinical equipoise. Overly strict assumptions about the utility of the candidate predictive biomarkers must be avoided until sufficient supportive clinical data are collected. In CDx development, biomarker misspecification is not unusual, and the initial candidate predictive biomarker may be superseded by new markers identified in these exploratory clinical trials. For example, the first Phase 1 trials of the kinase inhibitor, crizotinib, initially focused on patients with tumors harboring cMET alterations because this was the major discovery target for the drug. However, crizotinib is also a potent ALK tyrosine kinase inhibitor; and in Phase 1 trials, the EML4/ALK translocation was identified as a definitive companion diagnostic for further lung cancer development.¹²

CDx development in later stage clinical trials

Prior to the initiation of pivotal registration trials, the predictive biomarker assay should undergo full analytical validation. Ideally, only one validated version of the assay conducted at a central laboratory should be employed in Phase 2b or Phase 3 trials.⁸ If two versions of the CDx assay are used in clinical validation, then a bridging diagnostic study will be necessary. Because later stage trials will require large numbers of patients and study centers, the uniform implementation of the CDx across a wide geographical area presents additional logistical challenges. These factors have to be carefully considered when the program transitions into later stages of development because of the shift in focus from biomarker exploration to validation of a full-fledged companion diagnostic.

The design of late-stage CDx development clinical trials will heavily depend on the clinical data collected to date regarding the proposed CDx. If the predictive biomarker test is unambiguous and little or no activity is still anticipated in biomarker negative patients, then a pure enrichment strategy can be pursued ([Figure 1](#)). This approach focuses solely on biomarker-positive patients and relatively conventional Phase 2b and Phase 3 study designs can be considered. However, if meaningful drug activity may still occur in biomarker-negative patients, then a biomarker-stratified study design that includes both biomarker-positive and biomarker-negative patients should be considered ([Figure 2](#)). The study design options for biomarker-stratified randomized trials are quite large and this is a rapidly growing area of clinical research. Some general illustrative examples of both enrichment and biomarker-stratified clinical trial designs are discussed in the following sections.

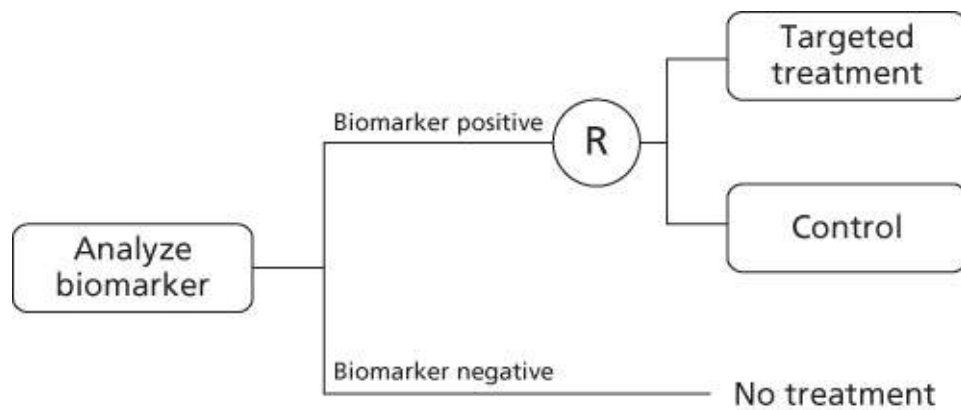

Figure 1 Targeted enrichment design.

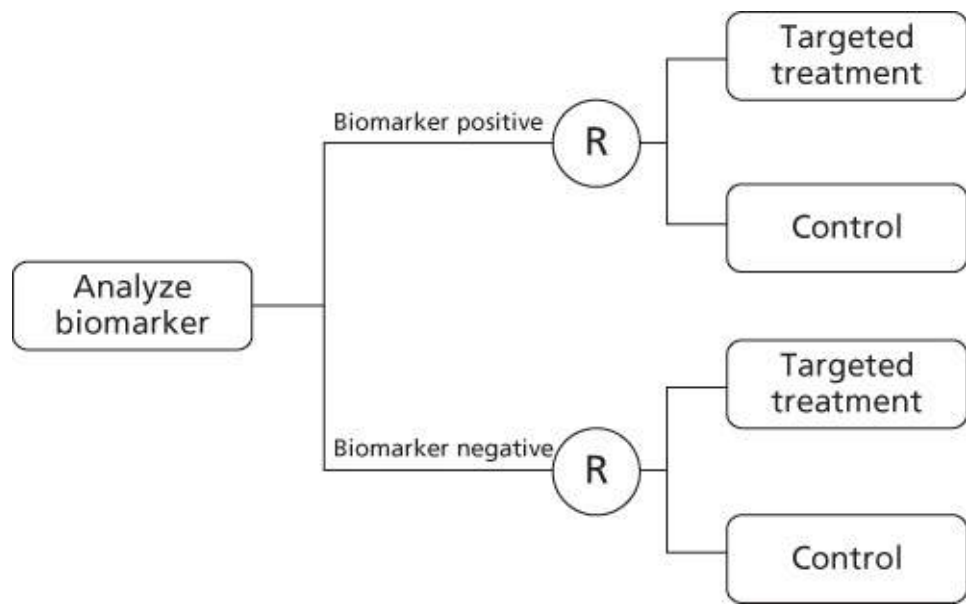

Figure 2 Biomarker stratification design. R = Randomized.

Enrichment study designs

In a pure enrichment strategy, randomized studies are conducted only in biomarker-positive patients and study designs remain relatively conventional (Figure 1).¹³ If the biomarker strongly predicts treatment effect, the resulting randomized trial will be smaller than a corresponding unselected patient trial due to the larger clinical benefit anticipated in patients with tumors with reduced molecular heterogeneity. The efficiency of an enrichment design over an all-comer treatment approach depends on the prevalence of the predictive biomarker and the effectiveness of the treatment in the biomarker-negative patients. When the biomarker is present in less than half of the potential patients and the treatment effect is minimal in the marker-negative population, the enrichment design will randomize substantially fewer patients than an unselected trial.^{9, 13} However, depending on the prevalence of the predictive biomarker, many patients may need to be screened to identify sufficient biomarker-positive patients.

A disadvantage of the pure enrichment strategy for CDx development is that the negative predictive value of the biomarker is unknown because these patients are excluded from the study. There is at least one example of a CDx approved with a novel therapeutic that later failed to demonstrate medical or clinical utility. The original approval of the anti-EGFR antibody, cetuximab, for patients with metastatic colorectal cancer, included a CDx test using immunohistochemistry to document EGFR expression. However, later trials demonstrated that cetuximab was equally as effective in EGFR-negative and EGFR-positive patients¹⁴ consistent with a lack of medical utility for the CDx. As a consequence, a successful enrichment strategy registration program may require additional testing in biomarker-negative patients as

a post-approval commitment. Nonetheless, the enrichment clinical trial designs remain popular and there are many successful oncology CDx co-development programs that have utilized this approach. Prominent recent examples include the approval of the registration of vemorafenib in melanoma patients with V600E BRAF mutations¹⁵ and crizotinib in NSCLC patients with EML4/ALK translocations.¹²

Biomarker-stratified designs

If the predictive biomarker test characteristics are unambiguous but the question of clinical validation remains, then a biomarker-stratified trial design that enrolls both biomarker-positive and biomarker-negative patients should be considered. In the simplest form, the treatment effect is examined by randomizing both biomarker groups to receive experimental or control treatment ([Figure 2](#)).⁹ The need for prestratification by biomarker status will depend on the prevalence of the biomarker in the study population. When appropriately powered, this study design provides the most information about the treatment effect and the biomarker's predictive and prognostic power. However, it is relatively inefficient because of the need to examine sufficient numbers of patients in the both biomarker subgroups. Numerous modifications of this approach have been proposed using different statistical analysis plans to enhance efficiency.^{9, 13} Some examples include the sequential accrual design that starts enrolling biomarker-positive patients with expansion to biomarker-negative patients only after an initial treatment effect is observed.⁹ Another alternative, called the “fall-back” design, starts by treating all comers followed by a narrower focus on biomarker-positive patients only if the overall results lack statistical significance.¹⁶ Detailed descriptions of these and other biomarker-stratified study designs are beyond the scope of this discussion but are described thoroughly by Simon and colleagues.^{9, 13, 16}

Because choice of biomarker study designs in later development may be difficult, Freidlin and colleagues proposed a novel Phase 2 strategy to guide decision making for further co-development trials.¹⁷ For situations where a well-defined predictive biomarker exists, the following strategy can help choose between enrichment and biomarker-stratified study designs. Briefly, the outcome of the Phase 2 trial is used to recommend one of four different options for the Phase 3 CDx trial. First is to perform a randomized Phase 3 study enrolling only biomarker-positive patients using an enrichment design because the drug is active and the diagnostic defines the sole treatment population. Second is to implement a randomized biomarker-stratified design, because the treatment is active in both marker-positive and marker-negative patients but the biomarker has some power to predict clinical outcomes. Third is to enroll all patients regardless of biomarker status because the drug is broadly active and the biomarker lacks clinical validity. Finally, the fourth option is to not proceed to Phase 3 and to halt all further development because the drug lacks efficacy in any population.

Using Freidlin's Phase 2 strategy, patients are randomly assigned to experimental and control treatments and the predictive biomarker status is determined.¹⁷ The treatment effect is assessed first in the biomarker-positive population and later, depending on the results, in the overall population or the biomarker-negative subgroup. The decision algorithm for this approach is outlined by Freidlin, with the resulting output being a recommended Phase 3 strategy. In this example, the hazard ratio for progression-free survival is used to assess the treatment effect, although it can adapt to a variety of Phase 2 endpoints. This approach nicely highlights the decisions that drug development scientists face when designing a CDx development program. However, a potential disadvantage of this biomarker Phase 2 trial is that it can be large and complex, and it may recommend an additional large and complex CDx Phase 3 trial.

If questions persist about the predictive biomarker at the end of Phase 2, it may still be possible to discover or refine an existing diagnostic during Phase 3 trials. Several innovative adaptive Phase 3 study designs have been proposed to explore and adjust new predictive biomarkers while simultaneously

evaluating therapeutic efficacy. For example, the biomarker-adaptive threshold design can select the optimal cut-point for test positivity for a continuous or graded predictive biomarker in Phase 3 trials.¹⁸ This has utility if the biomarker threshold for positivity has not been determined at the start of the pivotal trial, and it preserves statistical power to detect an overall broad treatment effect. A more generalized variation on this approach, called the adaptive biomarker design, can analyze the predictive power of several different predefined binary biomarkers simultaneously, allowing for the selection of one that has the greatest correlation with clinical outcome.^{13, 18}

If no candidate predictive biomarker exists at the end of Phase 2 but gene expression profiling can be conducted in Phase 3 patients, Freidlin and colleagues proposed a novel adaptive signature design that prospectively defines a predictive biomarker signature and validates its correlation with therapeutic efficacy in the same pivotal Phase 3 trial.¹⁹ In this study design, a predictive biomarker signature is developed in a training subset and validated in separate, mutually exclusive patient subgroup while preserving statistical power to evaluate the overall treatment effect. In simulation tests, the adaptive signature design reduced the chance of rejecting an active treatment when the fraction of sensitive patients is low; however, when the treatment is broadly active, it still detects an overall treatment effect similar to a conventional trial. Freidlin et al. recently published a more statistically robust version of this approach called the cross-validated adaptive signature design that utilizes the full patient population for signature development and validation.²⁰ One of the stated goals of the adaptive signature design is to allow pharmaceutical companies to invest in pharmacogenomic biomarkers for patient selection without compromising the opportunity for broader indications where supported by Phase 3 data.¹⁹ Performing biomarker discovery and validation in a single trial is an attractive concept, but, at present, no approved CDx has used this approach. Thus, this remains a promising but, at present, theoretical option for future CDx development.

Regulatory considerations in CDx development

In a dual drug-diagnostic co-development program, the goal is to validate a predictive biomarker as a CDx while at the same time demonstrating the safety and efficacy of a novel therapeutic in a unified series of clinical trials ([Figure 3](#)). The regulatory standards for approving a new therapeutic are well defined but the regulatory expectations for a CDx are evolving with the science.

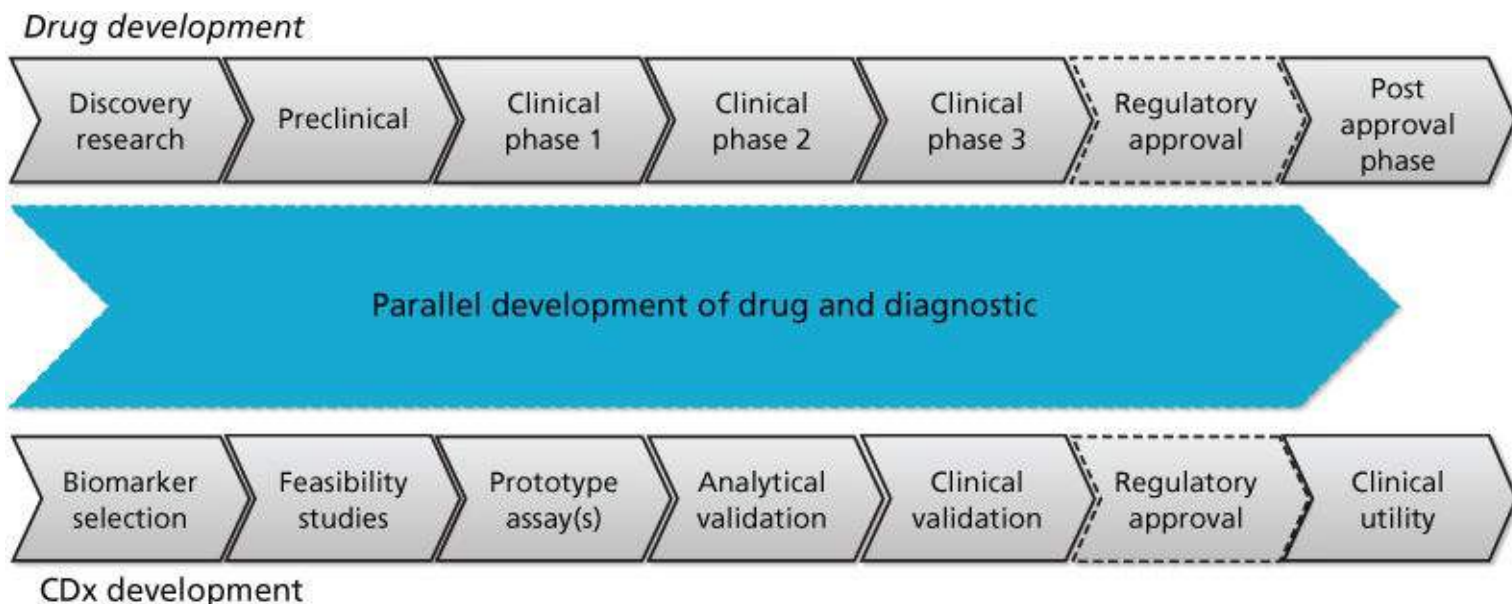

Figure 3 The drug-diagnostic co-development model showing the drug development process and the parallel companion (CDx) process striving for an aligned regulator co-approval at the end of Phase 3.

Companion diagnostic tests have been under increasing regulatory scrutiny because of the recognition that their misuse could potentially harm patients. For example, a false-positive diagnostic result might expose a cancer patient to a toxic treatment with minimal chance of benefit, while a false-negative test could deprive a patient of a possibly efficacious therapy. In order to be labeled a companion diagnostic, a predictive biomarker must demonstrate analytical validity, clinical validity, and medical utility. Analytical validity requires the technical demonstration of robustness and reproducibility under relevant laboratory conditions.^{13, 21, 22} If a gold standard reference test exists, then formal accuracy parameters, such as specificity and sensitivity, should also be determined. Analytical validation is predominantly a laboratory-based exercise that can be performed on clinical specimens from stored tissue banks; however, the demonstration of clinical validity and medical utility require appropriately designed clinical trials. Clinical validity is defined by the correlation of the predictive biomarker with a specific clinical end point or treatment effect.^{13, 21, 22} For example, a specific gene translocation might predict objective responses to a novel therapeutic. Finally, and most importantly, medical or clinical utility is achieved by showing that the use of the biomarker improves clinical outcomes.^{13, 21, 22}

In 2004, the FDA released a document entitled “Drug-Diagnostic Co-Development Concept Paper” that addressed the challenges of coordinated development of a therapeutic drug and diagnostic product.²¹ Further, FDA guidance on this and related topics has been released;²³ however, as described by Fridyland et al., many strategic dilemmas remain when designing and implementing CDx co-development programs.²²

Personalized immunotherapeutics

Recent advances in tumor immunology have offered strong scientific basis for advancing personalized immunotherapy. This is a rapidly expanding area of drug development where immune-based treatments can be tailored to a single patient or novel immune-based predictive biomarkers can be used to select patients who are most likely to benefit from specific treatments. The latter approach is very similar to the personalized medicine approaches discussed in previous sections. The former approach, personalized immunotherapeutics, involves the production of a specific therapeutic for a specific patient. The technical

and logistical hurdles for personalized immunotherapeutics are significant but the potential to dramatically impact disease outcomes is compelling.

Tumor immunology has burgeoned as a field thanks to many exciting discoveries that have uncovered how tumors evade the body's immune system and clinical studies which test new therapeutics that exploit the immune dynamics of tumors.²⁴ Approval of new immunotherapies such as cancer vaccines for prostate cancer and monoclonal antibodies targeting the immune checkpoints for melanoma has provided the human proof of concept that the immune system can successfully eliminate tumors and eradicate cancer.^{24–26} Investigations of complex interactions between the host immune response against tumors and tumor immune evasion mechanisms have now become an intensely studied area of research. However, tumors are also diverse in nature, displaying distinct characteristics in different patients, and they may use various methods to subvert the immune system. The complex nature of interactions of tumor cells with the host immune system and unique attributes of individual patients suggest that personalized methods to leverage the body's own immune system may offer the most promising therapy for patients.

Recently, the field of tumor immunology has been growing, with innovative therapeutic advances on many fronts. The most popular immunotherapy strategy is specific T-cell activation, which has been fairly successful in initial experiments. Other therapeutics like cancer vaccines have had mixed results, proving effective against some cancers but not against all others.²⁷ One new technology that has been receiving attention is T-cell reprogramming, which utilizes genetic modifications to program the body's own immune cells against tumors. This approach involves *ex vivo* modification of autologous T cells with reinfusion into the patient. Furthermore, new methods of molecular analytics such as immunophenotyping allow for the collection of patient data, which can be used and applied to make personalized immunotherapies. In this respect, intensive research in patient-specific genomic and molecular analyses and the application of this information to develop personalized immunotherapies to selectively treat patients' cancers are being aggressively pursued.²⁸

Identification of genetic alterations for finding unique antigens

Cancer cells undergo high rates of mutations and other epigenetic alterations that, in theory, should make them recognizable by the immune system. Understanding the nature of these alterations and translating this into useful information could be used to engineer personalized immunotherapies. Various technologies are now available for genome-wide DNA and RNA sequencing, deciphering epigenetic regulation, and identifying transcript variation within the tumor cells that can be used to profile the tumors within a given patient. Patient-specific T-cell epitope discovery and immunophenotyping of patient biopsies and other tumor samples could be used to identify protein mutations in cancer cells. By defining unique protein sequences that harbor epitopes recognizable to the immune system, researchers may be able to create a personalized vaccine to treat patients with recurrent cancers. Thus, identification of epitopes specific to individuals may help develop tailored therapies that maximize effectiveness based on the biology of a patient.

Genetic profiling of tumors is also applicable to T-cell reprogramming, since it allows for discovery of distinct T-cell-binding antigens and the development of personalized T-cell-based immunotherapies. Genetic methods can be applied to T-cell programming in two ways. First, genome sequencing of tumor cells may reveal mutations that occurred in cell-surface receptors, which would allow for the selection of a target antigen and reprogramming of the T cells against that antigen. Considering intratumor heterogeneity, it may be necessary to select multiple mutant antigens. Second, as tumor cells are known to change over time, they may lose initial antigens or gain new cell-surface mutations. Thus, tumors have to be carefully monitored for any changes in the selected antigens. The whole process would have to be

repeated over time to account for future mutations and to select new target antigens, in the case that the therapy does not wipe out all of the cancer cells. Monitoring cancer cells as well as antitumor immune response is a key to the success of T-cell programming against specific antigens.

To validate the therapeutic utility of unique tumor-specific antigens and develop methods for monitoring specific antitumor T-cell response, studies in animals that have yielded useful information have been conducted and these could be applied to develop human therapeutics.²⁹ An approach combining whole-exome and transcriptome sequencing analysis with mass spectrometry was used to identify neo-epitope-containing peptides in murine tumor models. Vaccination of mice with these peptides generated strong antitumor T-cell responses, confirming the therapeutic potential of this approach. These studies open the door for developing personalized vaccines and PD monitoring of antitumor T-cell responses in cancer patients.

Personalized vaccines using individualized tumor specific antigens

Cancer vaccines that activate the immune system have shown some promise in animal models, but they have not been as successful in human trials.³⁰ Cancer vaccines should theoretically work by activating host-adaptive immune response against tumor-associated antigens that are contained within the vaccines. In order for this to happen, a given antigen must be taken up by antigen-presenting cells such as dendritic cells (DCs). The DC then must process the antigen, display the processed antigen on its surface in the form of a complex with the human leukocyte antigen (HLA) molecule, and migrate to the lymph node where it can present the antigen/HLA complex to T cells. This process activates the T cells which may then enter the circulation and migrate to the tumor, orchestrating an immune response to kill tumor cells. One key feature of a successful vaccine is an antigen that can be processed with a peptide fragment so that it can bind appropriately to HLA molecules.

New research methods are now being employed to discover which tumor-derived antigens may serve as good tumor antigens for efficient recognition by the immune system. Sophisticated tools that predict binding of a given peptide to a number of different HLA alleles, such as NetMHC, could be used to determine how strongly the immune system recognizes a change in the cancer.³¹ In this method, each peptide is assigned a score based on the affinity to HLAs to determine if the host immune system has the potential to recognize changes in the cancer. However, high recognition does not necessarily correlate to strong vaccine potential. To further improve the chances of generating a strong immune response, experiments could be conducted to determine which epitopes are involved in the host antitumor response. By comparing NetMHC scores of different peptides, those with the strongest immunogenic activity could be selected. This method can be used to select peptides using patient data to create personalized vaccines.³¹

Idiotypic-based vaccines

Tumor-specific immunity can also be induced by immunizing patients with unique antigenic determinants that are displayed on hematological malignancies. For example, in the case of B-cell malignancies, tumors usually arise from a single clone that expresses an immunoglobulin (Ig) molecule with a unique amino acid sequence in the variable regions of Ig called the idiotype (Id). Thus, for a given patient, the Id can be considered as tumor-associated antigens and could serve as very specific target antigens for vaccination.³² Tumor-specific Id containing Ig from B-cell lymphomas have been successfully prepared by creating a cell line that secretes the tumor-derived Igs. These Igs can then be purified and used for vaccine preparation.³³

Although, vaccination with Id-based vaccines has shown success in the clinic, progress in this area is very limited.³⁴ The biggest challenge is that tumor cells from each patient express unique Ids, and a vaccine needs to be patient specific and catered for an individual patient. In addition, there are the logistical issues of sequencing patients' Ids and then preparing vaccines for each individual patient and the Id. Nevertheless, clinical trials with custom-made monoclonal antibodies against tumor-associated Ids have been conducted and have shown remarkable efficacy, leading to long-term remission in many patients.³⁴ Some patients treated with this approach have become refractory to the treatment due to mutations in the Id that prevent anti-Id antibody binding.

Since the Ids are derived from self-proteins, many of the Id-based vaccines do not induce a good immune response. Because of this, studies have been conducted to improve the immunogenicity of vaccines by combining these antigens with DCs to promote the uptake and presentation of the antigen to the immune system. This approach has shown some promise by inducing both humoral and cellular responses. For example, a clinical trial using Id-pulsed DCs was conducted in B-cell lymphoma patients, where 8/10 patients showed efficacy as measured by T-cell proliferative anti-Id responses.³⁵

Use of patient-specific tumor-infiltrating lymphocytes (TILs)

As discussed earlier, tumor cells harbor many genetic mutations and other alterations that give rise to neo-epitopes that may serve as novel antigens to induce an antitumor T-cell response.³⁶ It has been found that many immunogenic tumors have high rates of mutation and are often infiltrated by T lymphocytes that possess the ability to recognize antigens expressed by the tumor cells.³⁷ The presence of tumor-infiltrating lymphocytes (TILs) is thought to mediate a critical role in the efficacy of adoptive cell therapy and other forms of immunotherapies in melanoma patients.^{38–40} Based on this notion, adoptive cell therapy using patient's own TILs has been tried in melanoma patients. In this therapeutic approach, TILs are collected from patients, expanded in the laboratory, and produced in large quantities in order to infuse back into the patient. While this type of personalized therapy has shown success in melanoma patients, it remains to be seen if similar successes can be achieved against epithelial cancers.⁴¹ Epithelial cancers usually contain fewer mutations than melanoma, which may make them less immunogenic.⁴² Some progress in this field is being made, such as the mapping of the mutant antigens in human epithelial tumors, but strategies to exploit this newfound information for developing effective therapies still remains an open question despite some promising case reports with TILs in epithelial tumors.⁴³

DC-based personalized immunotherapy by using tumor cells as an immunogen

Despite the identification of unique tumor-associated mutant peptides, a relatively small number of these critical mutations are actually seen by the immune system because they may not be presented by DCs. In order to be presented by DCs, the specific epitope must bind HLA and this does not occur for all peptides. This limitation usually restricts the induction of a broad repertoire of tumor-specific T-cell clones, thereby leading to potential tumor escape. Thus, personalized tumor-derived vaccines that overcome this limitation are desirable. In this respect, whole dead tumor preparations that may contain large numbers of known and unknown antigens can be used to facilitate the induction of a polyclonal T-cell response against tumor cells.^{44, 45} Thus, loading of DCs with whole tumors could offer the distinct advantage of presenting all of the antigenic components of the tumor to T cells, compared with loading the DCs with just a few peptides. In addition, this approach offers a truly personalized therapy as it would be specific to a patient's own tumors. The general approach of this immune therapy is clearly appealing;

however, many questions still remain unanswered. For example, it is not clear whether dead tumor cells in the form of apoptotic cells, necrotic cells, or whole lysates are better sources of antigens for pulsing DCs.^{46–48} Another approach is to use amplified tumor-derived RNA to generate tumor antigens.⁴⁹ Clinical trials using whole-tumor cell preparations to pulse DCs have resulted in efficient antitumor immunity as well as clinical responses. Durable complete responses have been reported in advanced melanoma patients after treatment with autologous tumor cell-pulsed DC vaccine.⁴⁵ Clinical benefits have also been observed with tumor cell lysate-pulsed DC vaccination in renal cell carcinoma patients as well as in clinical trials using DC-based therapy in prostate cancer patients.⁵⁰

Conclusions

Cancers are highly heterogeneous and vary from patient to patient, which makes personalized therapeutics a highly compelling approach. It is thus anticipated that personalized immunotherapy will play a critical role in harnessing the power and precision of the immune system to mount antitumor immune responses. However, this approach will require novel technologies and extensive research. Although considerable progress has been made, many questions still remain unanswered: How do we identify and prioritize antigens? How can we selectively activate the immune response and avoid toxicity? What are the best approaches to immune profiling? What is the feasibility of autologous therapeutics requiring processing of cells and antigens for each patient? There is no doubt that the future research in personalized therapy will take the center stage to answer these questions in the coming years and offer personalized immunotherapy for improving outcomes for the cancer patients.

Chemotherapy

Chapter 52

Preclinical and early clinical development of chemotherapeutic drugs, mechanism-based agents and biologics

Axel-R. Hanauske, MD, PhD, MBA ■ Daniel D. Von Hoff, MD, FACP

Overview

Over the past 10 years, the approach to drug development has changed considerably. Owing to the enormous increase in insights into the molecular biology of cancer cells, a largely empirical approach has been mostly abandoned and replaced with a biology-driven, hypothesis-based, and translational approach. Notwithstanding this dramatic development, the hierarchical sequence of clinical drug-development trials basically remained unchanged and is divided into three phases. This chapter provides an overview of the various steps of early clinical development with milestones of the drug-development process, the role of the National Cancer Institute, and the switch to mechanism-based drug development. It outlines challenges in the clinical development of these new agents and provides a fundamental understanding of the complexity involved in early clinical drug development.

While the overall age-adjusted cancer death rates have been declining in most countries over the past decade, there remains a great need for development of new agents for treatment of patients with advanced cancer. There is also a perceived need for developing new agents that will be used to treat patients with “early cancer” (either before evidence of metastatic disease or at the state referred to as intraepithelial neoplasia).^{1, 2} This latter approach for treating early cancer, referred to in the past as chemoprevention, represents a new concept that could have an enormous impact on the disease.

In this chapter, we describe the fundamentals of development of new agents from discovery through the initial safety (Phase I) clinical trials. Along the way, we discuss a few studies that illustrate new methodologies introduced into drug development in recent years. This chapter largely concentrates on the development of new chemical entities and not on the development of biologic agents, although some of the principles outlined here also apply to the development of those agents.

As an overview, [Figure 1](#) describes the classic stages in the development of a new agent. Using this basic process, there have been well over 150 new agents developed for treatment of patients with a variety of malignancies as well as for treatment of early cancer. Although this is an impressive list of agents available to treat patients with a variety of cancers, it is—in light of the biological diversity of the various types of cancer—obvious that we still need major additions to our armamentarium. Table A1 details all of the anticancer agents that are approved by the Federal Drug Administration and their official approved indications. We provide that table because, as noted below, as new strategies are being developed for the proper testing of new agents, one has to be cognizant of the agents that are already approved for a specific indication. One must also be aware as to whether a new agent should be developed alone or in combination in a “front-line” setting or in a salvage or palliative setting. Table A1, together with [Figures 1](#) and [2](#), helps to understand how to design pivotal clinical trials that will lead to

approval by regulatory agencies and, most importantly, make an active and safe new drug available for patients.

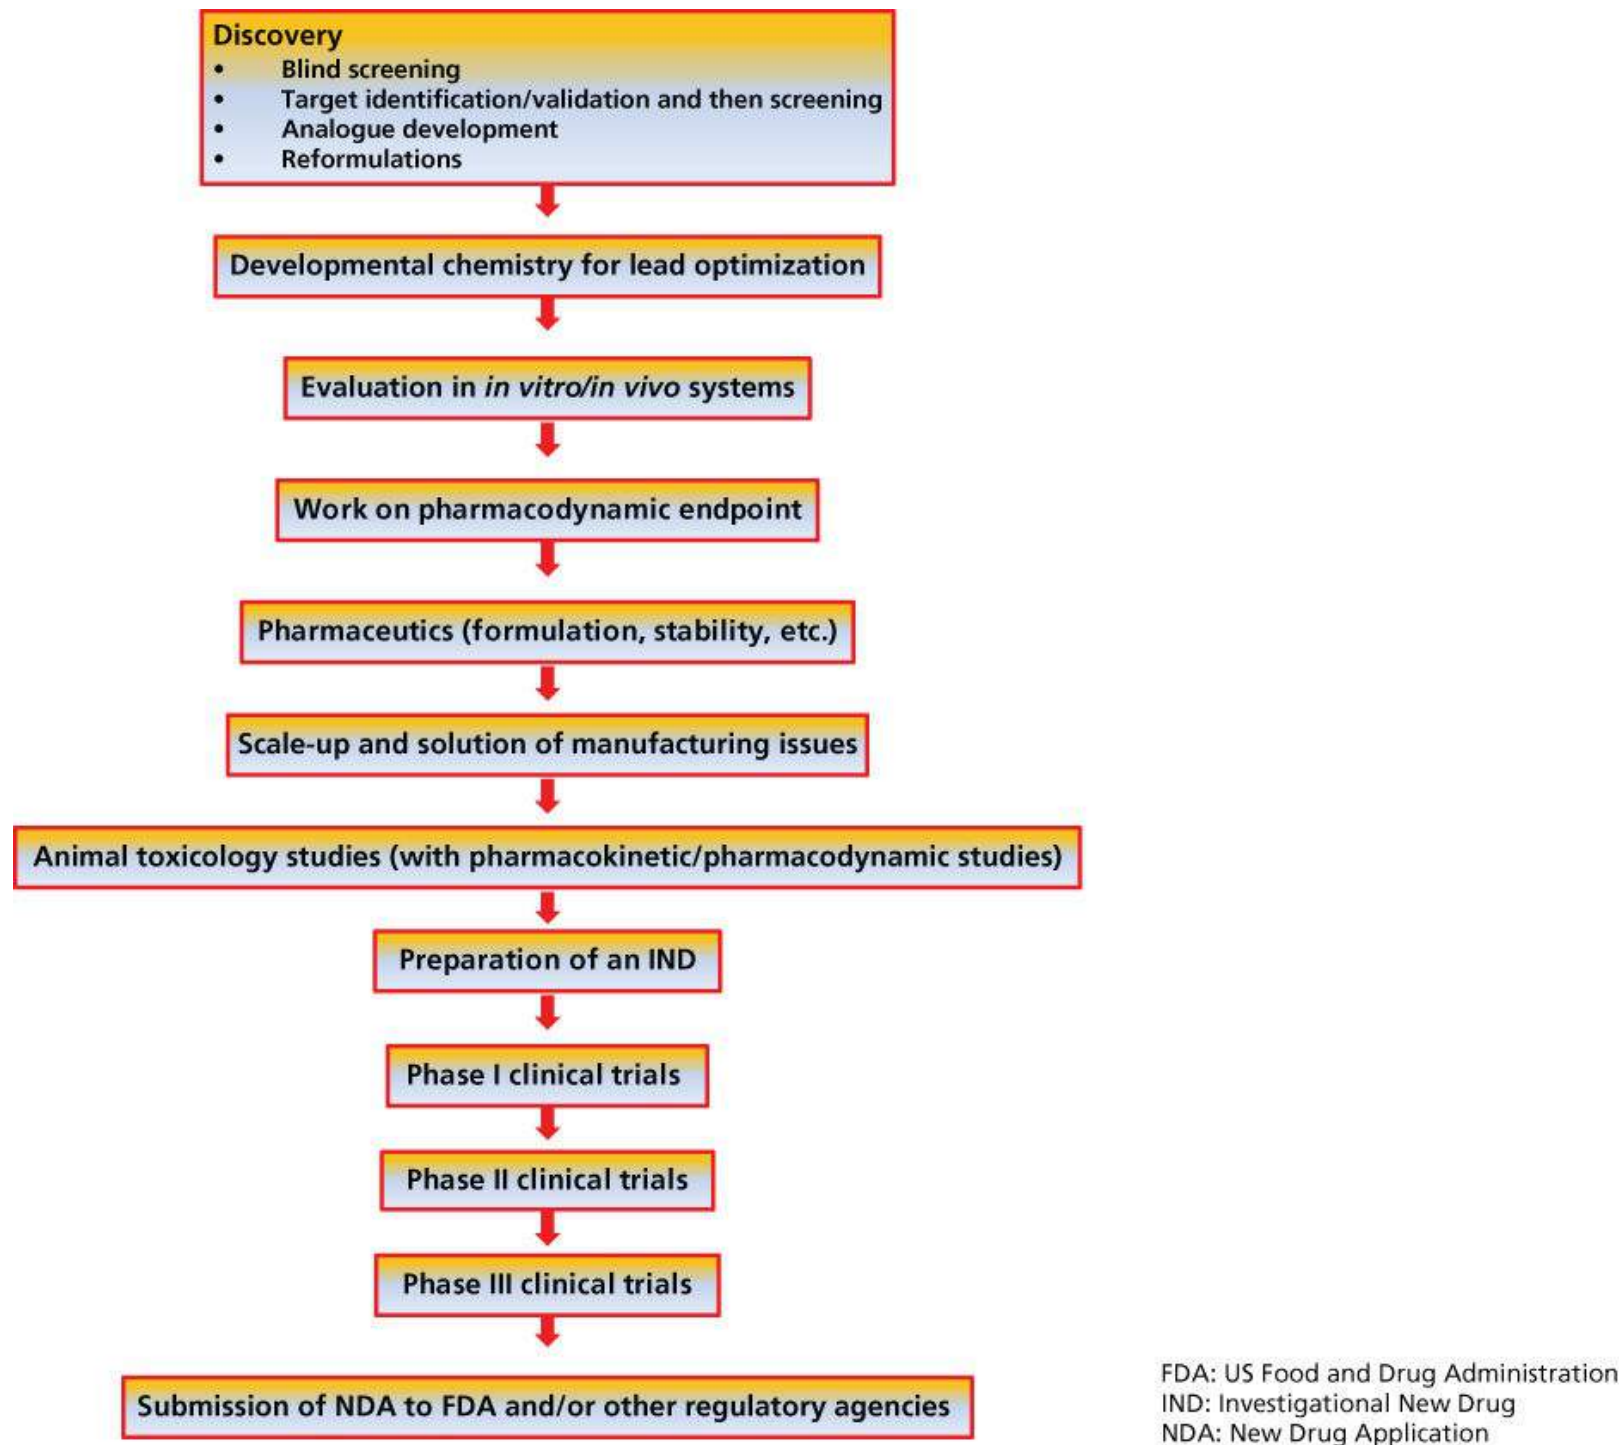

Figure 1 The stages in development of a new anticancer agent.

Evolution of the discovery process

Clinical observation in the discovery process

As this chapter is being written, the process for discovery is changing rapidly. Initial anticancer drug discovery was based on important observations by clinicians and preclinical scientists. An example of such observations, where many feel the field of chemotherapy of cancer began, was the observation by Adair and Bogg in 1931 that troops in World War I exposed to sulfur mustard developed lymphoid and bone marrow hypoplasia.³ They then used this very toxic agent to treat a number of patients with cancer

with sulfur mustard. The agent had a limited effect. Further studies of the related nitrogen mustard (of World War II) demonstrated more substantial antitumor effects, particularly in patients with lymphoma.^{4, 5} Another classic example of an astute observation by clinicians was when Farber and colleagues noticed that young patients with leukemia who were treated with liver extracts or folic acid had worsening of their leukemia.⁶ They then treated the patients with folic acid antagonists and described the antileukemic activity of these antagonists.

Histocytotoxic effects and physiologic observations

Just like the observation that mustard gases cause hypoplasia of lymph nodes, spleen, and bone marrow (with subsequent clinical activity of nitrogen mustard and other alkylating agents in patients with lymphoma), there have been a number of other correlations between specific histocytotoxicity (toxicity to a particular type of tissue) and clinical activity of an agent. One of the best examples is the finding that the agent streptozocin caused destruction of the islet cells in animals (leading to diabetes).⁷ Streptozocin was tried and found to have clinical activity in patients with insulinomas (a histocytotoxic effect).⁸

In early animal toxicology studies, cisplatin caused hypoplasia of the testes and ovaries in animals and was subsequently found to have substantial activity in patients with testicular or ovarian cancer.^{9–11}

As an example of a physiologic observation leading to the development of a series of new anticancer agents, the physiologic observation that rat hepatomas incorporated more uracil than the surrounding normal liver led to the Heidelberger group synthesizing the 5-fluoropyrimidines.^{12, 13} The observations by Elion and Hitchings, who surmised (based on the presumption that nucleic acids were in control of cell growth) that purine and pyrimidine analogs would be useful in treatment of cancers, certainly led to the development of 6-mercaptopurine, 6-thioguanine, and many other useful anticancer agents.^{14–16} Although there is still clearly room for important clinical, toxicological, and physiologic observation, these observations will probably not dominate future drug discovery. However, readers are encouraged to keep their eyes open to clinical, histocytotoxic, and physiologic observations as described above as serendipity has been historically pivotal in successful drug development.

Early and continuing role of the National Cancer Institute drug-discovery program in the drug-discovery process

In the early 1960s, the US National Cancer Institute (NCI) began a major leadership role in the discovery and development of new anticancer agents. This was critical at that time because industry felt that investment in this area would not be feasible financially and that the risks were high. The NCI began its leadership by establishing the National Service Center (NSC), which served as a clearinghouse (and a bank of compounds) for all compounds for all chemists, biologists, and other interested investigators. Compounds could be submitted to the NSC, assigned an NSC number (e.g., NSC 3101139 for mitoxantrone), and tested in a series of *in vitro* and *in vivo* preclinical models. Agents that passed certain hurdles of *in vitro* and *in vivo* antitumor activity were considered by a body at the NCI called the “Decision Network” for bringing them into toxicology studies and eventually into clinical trials.

The very early efforts of the NCI used the KB squamous cancer cell line, originally obtained from a patient with a carcinoma of the mouth, to screen a large numbers of compounds. Compounds that were active against that cell line were further evaluated *in vivo* in the two murine leukemias called P388 and L1210.^{17, 18} These *in vitro* and *in vivo* screens did lead to compounds with clinical activity against leukemia and lymphoma (e.g., vinca alkaloids and nitrosoureas). Finding agents with antitumor activity

against solid tumors was much less successful.¹⁸ In 1975, the NCI revisited their evaluation process to include *in vivo* evaluation of compounds against solid tumors (both autologous animal tumors and human tumors growing as xenografts in nude mice). A very important retrospective analysis of that big experiment was conducted by Staquet and colleagues.¹⁹ The results of their analyses are detailed in [Table 1](#).

Table 1 The most predictive animal models: The National Cancer Institute Experience 1978–1982

Reasonably predictive ^a	Not predictive at all
P388 leukemia (mouse)	Lewis lung
L1210 leukemia (mouse)	CD8 (breast)
B16 melanoma (mouse)	Co38 (colon)
MX-1 mammary ^b	LXI ^b (lung)
	CX1 ^b (colon)

^a Especially with regression of established tumors.

^b Xenografts.

Source: Adapted from Staquet 1983.

As can be seen in the table, the P388 and L1210 mouse leukemias continued to be predictive for activity of new agents in the clinic, as did the B16 mouse melanoma solid tumor autologous model growing in immunocompetent mice. The only human tumor xenograft that appeared to be predictive for clinical antitumor activity was the MX I mammary tumor xenograft growing in nude mice. The predictivity of these models was not tumor specific but rather *in vivo* activity in those systems predicted, in general, for clinical activity.¹⁸ Also of importance in the report by Staquet and colleagues was the finding that actual regression of established tumors in these models and the percentage of animals surviving for ≥ 45 days were even stronger predictors of eventual clinical efficacy of the agents.¹⁹

In 2001, Johnson et al.²⁰ reported on the relationship between drug activity in NCI preclinical *in vitro* and *in vivo* models and clinical activity of a new agent. It is of interest that of 39 agents for which there were both xenograft and Phase II clinical data available, clinical activity in at least some Phase II trials was observed if there was activity in at least one-third of the xenograft models tested. Of particular note was that if there was preclinical activity in one-third or more of the xenografts tested, there was a 45% chance that the compound would have clinical activity. In that same study, only nonsmall-cell lung cancer (NSCLC) xenografts were predictive for the clinical activity against the same histology (e.g., nonsmall-cell lung cancer). Thus, although these *in vivo* evaluations systems are often maligned, when a systematic large-scale evaluation of them was examined, some models appeared to be reasonable predictors (although not tumor-specific predictors) for activity in the clinic.

Of additional note in [Table 1](#) is the finding that several models were judged as not predictive at all for clinical activity. Some of the models, such as the Lewis lung model, continue to be used to justify bringing many new agents into clinical trials (particularly new agents, such as angiogenesis inhibitors). It is important that investigators who are contemplating bringing new agents into the clinic based on preclinical activity only in the Lewis lung, CD8, Co38, LXI, or CX1 models are mindful of the extensive prior experience demonstrating them not to be predictive for clinical activity.

To be most successful, however, it is important to remember the parameter Staquet and colleagues used for evidence of activity in the clinic (to make the correlation with the preclinical models): tumor

shrinkage. Thus, their findings might not be applicable to the newer generations of more cytostatic agents (rather than the cytotoxic agents being evaluated in the 1960s–1980s).

The NCI made a further revision in their evaluation strategy in 1985 when they placed a large series of 60 human tumor cell lines in place for screening purposes.^{18, 21–25} They have attempted to make this a more tumor-type-oriented approval with inclusion of breast, lung, colon, kidney, brain, ovary, prostate, and melanoma human tumor lines.^{18, 22, 23} At the time of introduction of this concept into the drug evaluation process, there was a great deal of discussion in the research community on how these cell lines were selected. Many investigators felt that cell lines with too rapid a doubling time were selected and did not represent the more slowly dividing solid tumors. However, this 60-cell-line screening panel is the system that is currently in place. More can be learned about the 60-cell-line success by visiting the website of the NCI at <http://dtp.nci.nih.gov/branches/btb/ivclsp.html>. Agents that are deemed active in the cell-line screens (based on criteria outlined in Refs 18 and 23 and based on other criteria, such as disease-specific activity) are then evaluated in the traditional *in vivo* models to determine their therapeutic index. If they are found active, they are moved forward into preclinical toxicology studies (see below).^{24, 25}

The true predictivity of the NCI-60-cell-line panel is as yet unknown as there are no published analyses as to the true predictivity of this approach for antitumor activity in the clinic. However, many excellent analyses of the results from the NCI-60-cell lines have led to some very provocative and useful research tools.

As an initial example of a unique use of results from the 60-cell-line screening, Paull and colleagues described a method (which they dubbed the COMPARE program) in which a compound evaluated in the 60-cell-line screen is used as a seed and the COMPARE program is used to detect the compounds that have similar patterns (or fingerprints) of activity against the 60-cell lines.²⁶ A correlation coefficient is then calculated to describe the closeness of other agents to the pattern of activity of the seed compound. It appears that if two compounds have similar correlation coefficients, this will predict for comparable mechanisms of action of the compounds or even the existence of a similar intracellular target, as described by Weinstein and colleagues.²⁷ If the correlation coefficient of a new, active compound is low compared with the compounds evaluated in the NCI screen, it might substantially increase interest in the new compound as it is very likely to have a new (unique) mechanism of action.

Of additional importance and of great interest to the cancer research community is that the NCI-60-cell lines continue to be characterized for presence or absence of specific targets (kinases, telomerase, mismatch repair proteins, and receptors).^{28–30} Most recently, this cell-line panel underwent complete whole exome sequencing, and genetic alterations that may affect protein function were identified in 6% of all genes.³¹ The precise molecular characterization of these lines is certain to help the evaluation not only of novel compounds but has also been reported to identify gene signatures that are indicative of radiation responsiveness.³²

Historically, other preclinical models explored by the NCI for evaluating compounds that deserve mention were models put in place to evaluate agents against tumors taken directly from patients. There were two systems including the *in vitro* human tumor cloning assay (HTCA) and the *in vivo* subrenal capsule system (SRC). Although initial correlations were promising between agents detected as active in these assays and having subsequent antitumor activity in the clinic, the assays were deemed logistically too difficult to use as an up-front screen to evaluate the vast array of compounds.^{33–36}

More recently, methods have been established to grow tumor tissue that is directly taken from patients or is taken from adequately stored tumor banks directly in diabetic and severely immune-compromised mice

(NOD-SCID mice). This results in patient-derived xenografts (PDX, also termed “xenopatients”) that more accurately reflect the pathologic and molecular characteristics of the original patients' tumors.^{37–41} While these models may still not be feasible for routine clinical use in personalized medicine, they do provide another progress in the early drug-development process and may help identify sensitive tumor types and molecular patterns of resistance. They are specifically useful in the development of mechanism-based therapeutics.⁴² With the advent of immunotherapeutic therapies (e.g., anti-CTLA-4, anti-PD1, and anti-PD-L1 monoclonal antibodies), preclinical mouse models using allografts into immunocompetent mice will be more often used.⁴³

As whole exome sequencing of patients' tumors becomes affordable, attempts have been published to generate mouse models that resemble the same combination of abnormalities as detected in the individual patient. These “avatar” models are then treated with anticancer agents, and the patient would receive the drug that is active in the model.⁴⁴

Mechanistically based (“targeted”) drug discovery and evaluation

With the explosion of molecular techniques and knowledge of cell biology, there is now an incredible array of new methods for discovery of potential targets present in tumor cells versus normal cells.

One spectacular example of a mechanistically based approach to therapy was the development of imatinib, which has substantial activity against chronic myelogenous leukemia and against gastrointestinal stromal sarcomas. To put the timeline for development of imatinib into perspective, the basic biology ground work for the discovery and development of imatinib actually began with the discovery of the Philadelphia chromosome in chronic myeloid leukemias (CMLs) in 1960.⁴⁵ This was actually the first consistent chromosomal abnormality discovered in any type of cancer. The abnormality is a translocation involving chromosomes 9 and 22.⁴⁶ Work done in 1990–1993 documented that the translocation caused the *ABL* gene on the chromosome 9 (a nonreceptor tyrosine kinase) to move next to the *BCR* (breakpoint cluster region) gene on 22. This translocation codes the BCR-ABL protein, which is a 210-kDa transforming tyrosine kinase constitutively expressed and responsible for about 95% of patients with CML.^{47, 48} This abnormal tyrosine kinase does not exist in normal cells of the patients; therefore, it was an excellent target for development of an agent with activity against CML.

Screening was conducted to find compounds with specific activity against the BCR-ABL tyrosine kinase, and the agent (CGP57148, aka STI 571, imatinib) was found to be the most selective inhibitor of the kinase by targeting the adenosine triphosphate-binding site (ATP-pocket) of the enzyme.⁴⁹ The agent was tested *in vitro* and *in vivo* and found to be selectively toxic to BCR-ABL-positive cells.^{49–51} Phase I and II trials in 1999 and 2000 documented that dramatic activity of imatinib against CML, particularly in the chronic phase of the disease.^{52, 53} As noted above, this impressive example of drug development really spanned nearly 40 years from identification of the target until documentation of clinical activity of a compound against the disease (only 10 years if one starts counting from the time of discovery of the target, the p210 BCR-ABL tyrosine kinase). Of note is that additional work has shown that imatinib also has substantial activity against several other neoplastic diseases such as gastrointestinal stromal sarcomas, which possess abnormalities in the KIT oncogene and has received regulatory approvals for a total of nine different indications (Table A1).

Although not in the scope of this chapter, a variety of other targeted therapeutics has also demonstrated substantial clinical antitumor activities (antiestrogens, antiandrogens, aromatase inhibitors, and monoclonal antibodies to CD20, CD52, HER-2/*neu*, etc.). However, at the time of the writing of this chapter, there were also some disappointments in the area of targeting. For example, the farnesyl

transferase inhibitors that have been developed to target tumors with mutations in *ras* have not shown activity against pancreatic cancer, even though they have clear clinical activity against breast cancer and acute leukemias, where *ras* mutations are not thought to be critical to the development or progression of either disease.^{54–56} Another example of difficulties with targeting is the finding that despite the upregulation of the epidermal growth factor receptor (EGFR) in a number of malignancies, the activities of small-molecule inhibitors of the EGFR kinase or monoclonal antibodies to the EGFR do not appear to correlate with the increased expression of EGFR (at least by currently available methods of measuring the receptor or its kinase).⁵⁷ These findings, however, should not discourage the search for useful applications either within hematology/oncology or outside of malignant diseases. As an example, recent publications indicate a beneficial effect of farnesyl transferase inhibitors in Hutchinson–Gilford progeria.^{58, 59}

Clearly, there is a great deal of work to do if targeted therapy is to succeed in major tumor types. In a recent piece of work, Druker and Lydon⁶⁰ outlined the lessons learned for the development of imatinib. These lessons provide guidelines for thinking about improved mechanism-based approaches, including the following:

1. Identification of an appropriate target molecule for drug development. The identification of the BCR-ABL tyrosine kinase as the kinase to cause CML (i.e., a single molecular defect as a target) was important. The kinase was a “disease gene.” For success, one probably should have a target that is critical to the disease process.
2. Availability of a validated surrogate endpoint that can be easily measured in patients to ensure that the new agent is indeed interfering with the desired target and has the desired effects. For CML, this is the Philadelphia chromosome, which is monitored in blood cells (and by blood counts).
3. Improvements in techniques important for drug designs (e.g., crystallography and molecular modeling) to optimize the selectivity (specificity) of compounds.

There is no question that with improvements in our understanding of the wiring of the cell there will be continuing efforts at developing mechanism-based agents.^{60–65} However, given the terrific amount of work and substantial resources necessary to clinically develop a new agent, it is very critical that targets are selected wisely.⁶⁶ In addition, it has become clear that the biologic role of a target identified may not be static throughout the clinical course of a patient. Thus, early drug development has led to the insight that repeat biopsies are necessary to understand sensitivity and resistance mechanisms. Conducting pre- and post-treatment biopsies remains a challenge in the clinic and may not be possible in all tumor types.

In addition to targeting the tumor cells, it is now clear that targeting the environment of tumor cells is taking on a whole new importance. The exciting area of angiogenesis has given all clinicians a sense of optimism, given the finding that the monoclonal antibody bevacizumab, directed against VEGF-A, has substantially improved the survival (when combined with chemotherapy) of patients with colorectal cancer, non-small-cell lung cancer, and possibly breast cancer.^{67–69} It is clear that the agent also has single-agent activity against renal cell and ovarian cancers.^{70, 71} While bevacizumab is neutralizing the ligand to the VEGF receptor 2, recently ramucirumab—another monoclonal antibody—has created much interest because it binds to the extracellular domain and blocks the VEGF receptor 2 directly.

Conceptually, this would impede binding of all ligands and not only of VEGF-A to the receptor.^{72, 73} Small molecules that target VEGF and PDGF pathways (to alter the angiogenic process) such as sunitinib (SU 1248) or regorafenib (BAY 73-4506) are also demonstrating substantial clinical antitumor activity. Research inspired by the successful development of antiangiogenic compounds has also led to the very

important insight that not only is tumor angiogenesis induced and sustained through a network of signaling pathways, but that autocrine and paracrine loops of angiogenic factors may also play a pivotal role in determining the cancer stem cell pool size.⁷⁴ Despite these impressive advances and the new mechanism of action, the new agents affecting the tumor environment still require the steps of drug development as outlined in this chapter. One of the biggest challenges for antiangiogenic compounds is the identification of a predictive biomarker, which is sufficiently robust to select patients for treatment decisions.

As early clinical trial designs move toward molecularly characterized tumors, the development of biomarkers remains a challenge for several reasons⁷⁵:

- Lack of comprehensive understanding of the tumor biology or the mechanism of action of the candidate drug;
- Lack of a reliable, reproducible, sufficiently sensitive, or specific methods to measure the candidate biomarker molecule(s);
- Lack of statistical power that the observation made in early-phase studies can be carried over into larger studies (Phase II or Phase III).

For an example see Refs .

Because of these complexities, drugs that reach Phase I often lack relevant, clinically meaningful pharmacodynamic markers. The validation of biomarkers in Phase I would require a conceptual redesign of Phase I trials with enrichment of target-carrying patients during the dose-escalation phase or at least during subsequent expansion cohorts that need to be large enough to allow for sound biostatistics in patient populations specifically expressing the candidate biomarker or biomarker profile, adaptive trial designs that allow learning during ongoing trials, and randomized dose-refining Phase II trials ([Figure 2](#)).^{78, 79} Even in the presence of a robust and predictive PD marker, it may be wise to continue dose escalation until a maximally tolerated dose (MTD) is reached so that a good understanding of the dose range can be generated in consideration of both acute and delayed toxicities. On the basis of statistical simulations, Hoering and colleagues have proposed a Phase I/II hybrid trial design that includes an initial traditional dose escalation, which is subsequently followed by a modified, single arm Phase II part that includes both dose and schedule optimization and efficacy testing. The authors hypothesize that this will be helpful in determining the best dose to move into large, randomized studies.⁸⁰

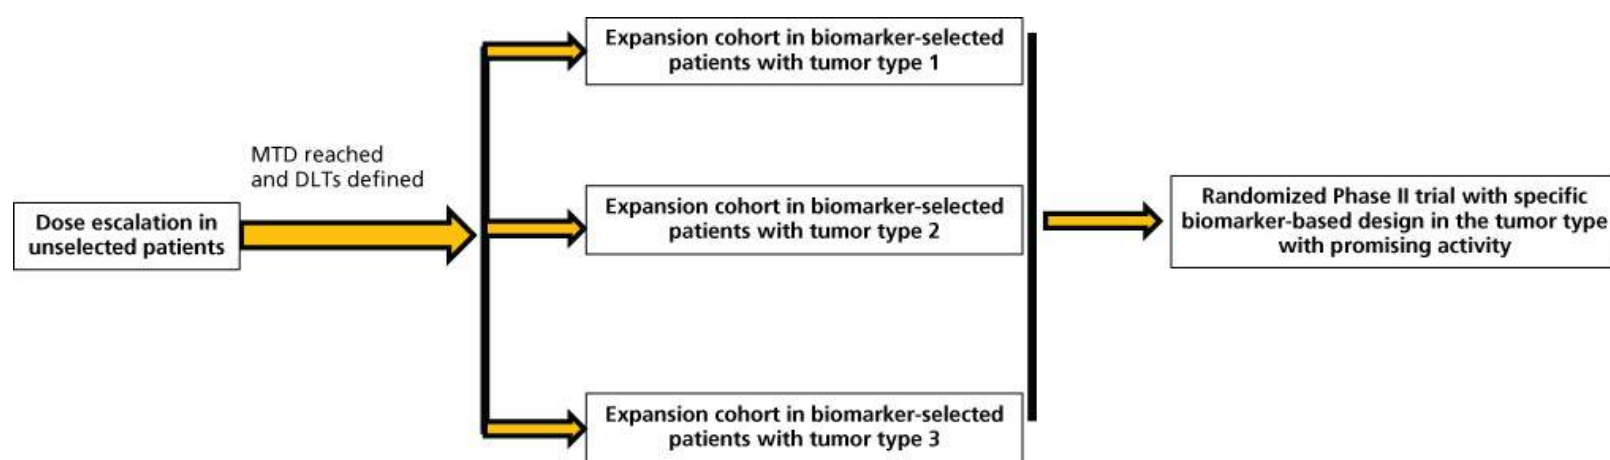

Figure 2 An example of an early phase trial design with targeted agents and patient enrichment.

Special aspects developing protein-engineered compounds

Protein-engineered compounds like monoclonal antibodies, peptides, peptibodies, or fusion proteins are developed against soluble peptide ligands or membrane-bound receptors. During Phase I studies, these compounds may not deliver DLTs or MTDs. Absolute doses exceeding 20 mg/kg may also raise the concern of nonspecific, protein-related toxicities when treatment is to be administered over a long time. As the production of monoclonal antibodies may occur in virally transformed cells, the residual viral load—despite all efforts to remove the viruses—may also be a concern if very high protein doses are administered for long periods. For these reasons, the choice of doses and schedules for later development in Phase II or Phase III studies often rests on a “biologically effective dose (BED)” or “biologically active dose (BAD).” This dose schedule may be derived from PK observations in animal models. As an example, the minimum plasma concentration of the monoclonal antibody that resulted in xenograft responses in mice may be used, and doses in Phase I trials that result in the respective or higher plasma concentrations may be carried forward into later Phase II or Phase III trials. However, this approach carries a significant risk for a dose and schedule in patients that have suboptimal efficacy and require subsequent refinement after Phase III trials have been completed and analyzed. The reasons are that animal models may not be predictive and may require species-specific antibodies/engineered proteins, which are different from those used in human trials. The development of protein-engineered drugs like monoclonal antibodies thus will profoundly benefit from robust and *predictive* PK/PD modeling and the application of a reliable biomarker as early in the process of preclinical and clinical studies as possible. Without a PK/PD model, a biomarker, an MTD, and unequivocally drug-related DLTs, the choice of a dose and schedule for subsequent trials means flying blindly even if the compound has encouraging early clinical activity. It carries the risk for losing a potentially active compound and for very late dose/schedule optimization studies that impact on life-cycle management. Encore studies in tumor types, which had shown a negative or marginally positive result in completed Phase III trials, may be ethically debatable. This creates the challenge to use the Phase I setting and add expansion cohorts to optimize dosing and scheduling in order to achieve maximum target blockade and provide an early proof of concept in humans. Such an approach may also include inpatient dose escalations although these should be considered in individual cases and with appropriate care.

Of specific interest is the development of immunotherapeutic antibodies. In general, compounds in clinical use and development have a negative effect on cells, for example, by shutting down metabolic or reproductive pathways or blocking receptors or downstream phosphorylation events. In contrast, the blockage of immune checkpoint receptors/ligands by immunotherapeutic antibodies *reactivates* the immune system. Thus, the activity of these new compounds is not directly on the tumor but on the immune system. Early-phase trials of this type of agents need to involve assays to determine the cellular immune response, awareness of delayed tumor shrinkage including the potential for initial increase in tumor lesions, and awareness of novel toxicities (e.g., hypophysitis, thyroiditis, and autoimmune-like states due to overactivation of the immune system), which may require immunosuppressive therapies.^{81–83}

Sources of compounds to evaluate against targets

There is no question that the most rational way to develop a new agent against a target is to understand the crystal structure of that target (at least for nonbiologic agents) and rationally design an agent to interact with that target.^{60, 61, 66} However, for a vast majority of these targets, there is not a crystal structure identified. Fortunately, there can usually be a method developed to aid in identifying inhibitors of targets using molecular screening.⁸⁴ Therefore, it is necessary for a drug-development team to have access to major libraries of compounds to use against their target with a high-throughput system. The NCI has always been a key resource for libraries of compounds, including natural products.⁸⁵ The NCI has made

the NCI Diversity Library (http://dtp.nci.nih.gov/branches/dscb/diversity_explanation.html) available to investigators. In addition, there are a number of additional libraries available for investigator use (e.g., <http://htbc.stanford.edu/compounds.html>; <http://www.chemdiv.com>, etc.)

Preparation of agents for clinical trials

Formulation

Pharmaceutics or the formulation of a compound for preclinical pharmacology, toxicology, and clinical trials is an often overlooked but very important aspect of drug development. It is very desirable to have the best formulation in place that one plans to use in clinical trials before proceeding with animal pharmacology and toxicology.⁸⁶

Difficult formulations have often led to prolonged development programs that have occasionally caused such difficulties that development of the compound was nearly discontinued. This was certainly the case with paclitaxel, which requires for solubilization a difficult cremaphor-containing combination that may result in idiosyncratic reactions in some patients.⁸⁷ A multitude of other anticancer agents (in addition to paclitaxel) have had significant formulation problems, including etoposide (solved by a formulation using 20 mg etoposide, 2 mg citric acid, 30 mg benzyl alcohol, 80 mg modified polysorbate 80/Tween 80, 650 mg polyethylene glycol 300, and 30.5% (V/V) alcohol), CPT-11 (topoisomerase I inhibitor) (solved using a prodrug that is broken down by carboxylesterase in patients' serum and tumors), docetaxel (solved using a formulation of polysorbate 80), and several others. If one requires an exotic formulation for intravenous use, there may be a major delay in the start of clinical trials. In general, only formulations that have already been used in patients should be used to formulate a new agent. Recently, there have been some important advances in the area of formulation. As an example, the packaging of paclitaxel into specially prepared albumin particles (called “nab-technology”) has changed the characteristics of paclitaxel and has led to impressive activity of nab-paclitaxel in breast, non-small-cell lung cancer, and pancreas cancer.^{88–90}

Another major question that frequently arises in the formulation process is whether an oral route of administration would be preferable over an intravenous route. In general, for cytotoxic agents, there is a worry that there is a much greater chance for wide variability in the gastrointestinal absorption of agents. This variability could lead to unpredictable and potentially serious side effects in some patients and not in others. In addition, patient compliance with oral drug intake has been questioned, particularly if these drugs can cause nausea or vomiting. Therefore, in general, if an agent can be formulated for both intravenous and oral use, it is deemed preferable to develop the intravenous formulation first. This allows one to carefully determine the pharmacology of the compound in a situation in which absorption is not an issue. An exception to this is when the compound has great schedule dependency in its preclinical activity work-up. In that situation, an oral formulation may be more desirable.⁹¹ Moreover, if the drug is predicted to be taken repeatedly (e.g., daily) for a prolonged period of time, development of an oral application may be advantageous.

Development of an assay for a pharmacodynamic endpoint (surrogate marker)

The development of anticancer agents had been for the most part empiric. More specifically, there had not been a prior emphasis on ensuring that the new agent actually affected the target it was designed to hit. With more mechanism-based drug design, it has been recommended to try to have some assay in place to

determine whether the agent is having the desired effect on the target (i.e., a pharmacodynamic endpoint). As it is plausible to assume that any compound exerts a variety of biological effects, such an assay—of course—may not reflect the totality of a drug's biochemical or clinical effects.

This area is becoming critically important. As an example, Hidalgo and colleagues have measured phosphorylation of the EGFR in skin biopsies in patients receiving EGFR antagonists.⁹² Moreover, the likelihood to respond to pemetrexed has been linked to the expression level of thymidylate synthase and mrp-4, and the antitumor activity of the serine-threonine kinase inhibitor enzastaurin has been correlated with the expression of GSK-3 β .^{93, 94} It is extremely important that these surrogate markers accompany mechanism-based drug development. Without these markers, their development will be confusing, and it will not be known whether it was an inappropriate target or whether the new agent just did not affect the target (for pharmacokinetic and a variety of other possible reasons) if the compound failed.

Animal pharmacology

Animal pharmacology studies have rarely been a major part of the development of a new anticancer agent [at least in the preparation of an investigational new drug (IND) application]. The exception to this is, of course, with oral anticancer agents for which bioavailability studies are required. Other important pieces of information that can be learned from pharmacology studies in animals can include (1) organ distribution of the agent including penetration and dwell time in tumors (particularly useful for compounds that are formulated in liposomes or are new compounds formulated in nanoparticles encapsulated in albumin) and (2) penetration into the central nervous system or other sanctuaries.^{95, 96}

One other very powerful piece of information that can be gleaned from animal pharmacology was described by Collins and colleagues.⁹⁷ This often forgotten piece of work demonstrated that there was a direct relationship between the concentration \times time ($C \times T$) product at the LD₁₀ in mice and the $C \times T$ product at the MTD in patients.⁹⁷ Essentially (based on a milligram per square meter basis), the $C \times T$ in mouse is equal to $C \times T$ in humans. This important relationship appears to hold up across most animal species and can be used as a target for dose escalation in Phase I trials with a new agent in patients (see below). Work by others has confirmed the relationship and has documented how that relationship can be used to determine which serum concentrations of agents will be achieved in patients (and should therefore be used in *in vitro* model systems).^{98, 99}

Animal toxicology

These studies are a critical part of any drug-development program. In general, the models used for toxicology studies to date (mouse, rat, or beagle dog, used because of a biliary system closer to human) have given an excellent safety record for the development of new anticancer agents (e.g., there essentially have been no catastrophes in the initial Phase I clinical trials in patients). One area in which one must be a bit more careful is in the area of nucleosides and antimetabolites. As an example, the starting dose for fludarabine phosphate was too high and substantial bone marrow toxicity was noted in the first dose level in patients presumably owing to the fact that fludarabine requires activation by deoxycytidine kinase and the levels of this enzyme are much higher in human cancer cells than they are in mouse and canine marrow cells.^{100, 101} Pemetrexed (MTA, LY231514), a multitargeted enzyme inhibitor approved for the treatment of patients with mesothelioma and non-small-cell lung cancer, had a similar problem, but with worse toxicities in animals than in patients.¹⁰² Therefore, investigators should be alert about the possibility of discordance between animals and humans when examining results of animal toxicity studies with nucleoside analogs or other antimetabolites. This is particularly important when anticancer agents are

studied in very innovative formulations like nanoparticles.¹⁰³

As noted above, the usual animal species required for formal toxicology studies is either a mouse or a rat plus the beagle dog.¹⁰⁴ For monoclonal antibodies and other biologics, a primate model is frequently required. An excellent review of toxicity requirements by the US Food and Drug Administration (FDA) has been published by DeGeorge et al.¹⁰⁴ In Europe, there is a movement to use only two murine species (mouse and rat) as a toxicology package necessary to begin a Phase I trial in patients.¹⁰⁵ However, if the tolerable doses in those species (based on a milligram per square meter basis) are widely divergent, additional toxicology studies in the dog are a necessity before beginning the Phase I clinical trial in patients.

In general, the animal models used are reliable in predicting certain types of organ toxicities (such as myelosuppression).^{106, 107} However, the dog has been noted to be somewhat overpredictive for renal, hepatic, and gastrointestinal toxicities.¹⁰⁸ Neurologic, pancreatic, dermatologic, and pulmonary toxicities are generally not well predicted by the murine and canine models. The models are imperfect in predicting other organ toxicities, and, occasionally, toxicities are noted in one species (e.g., a murine species) but do not occur in another (e.g., the dog). This is often attributable to a difference in metabolism of the agent between the species. If unacceptable toxicities are noted in mice, one should still strongly consider going into dogs or primates as they may not exhibit toxicities reported in murine models. This has been done for a few compounds that were cardiotoxic in the mouse toxicology program, but the dog correctly predicted that no serious cardiac toxicity would be noted in patients.¹⁰⁹

As will be outlined below, the animal toxicology package is most critical to help define the starting doses in patients beginning with the Phase I trial of the agent.

Preparation of an IND (investigational new drug) application

Before a clinical trial can begin in the United States and most other countries, it is necessary to prepare an IND application and to submit this document to a regulatory agency (e.g., the FDA). The necessary components of the IND are outlined in [Table 2](#).

Table 2 Investigational New Drug (IND) application

1. Cover sheet—Form 1571
 - a. Name, address, and telephone number of sponsor, etc.
 - b. Phase of clinical investigation
 - c. Commitment not to begin clinical investigation until an IND is in effect
 - d. IRB commitment
 - e. Commitment to follow all regulation requirements
 - f. Name and title of person responsible for monitoring
 - g. Name and title of person responsible for safety
 - h. Any transfer obligations, e.g., Clinical Research Organization
 - i. Signature of sponsor
2. Table of contents
3. Introductory statement and general investigational plan
4. Reserved for FDA
5. Investigator's brochure
6. Protocols
7. CMC information
8. Pharmacology and toxicology information
9. Previous human experience with the investigational drug
10. Additional information

CMC, chemistry, manufacturing, and control; FDA, US Food and Drug Administration; IND, investigational new drug.

More details can be found at the FDA website:

<http://www.fda.gov/drugs/developmentapprovalprocess/howdrugsaredevelopedandapproved/approvalapplications/investigationalnewdrugindappl>

The clinical trial can proceed with a new agent if 30 days go by after filing the IND package and there is no comment by the FDA. Of course, if the FDA requires additional information before the 30-day waiting period expires, that information must be supplied and approved before the first Phase I trial can proceed.

Early clinical trials

Phase 0 clinical trials

Phase 0 trials are designed to be conducted before regular Phase I trials. Conceptually, they have been proposed to inform later Phase I trials regarding pharmacokinetic/pharmacodynamic relationships, starting dose, and other parameters. Phase 0 trials have short durations (usually just one course), and use doses far below the subsequent starting dose for Phase I. The regulatory requirements have been laid out in an FDA guidance paper on an abbreviated IND published in January 2006 and are considerably easier than requirements for a full IND document. Owing to ethical considerations (no therapeutic benefit),

failure to accelerate drug development and increase in resource consumption, this trial design has been largely abandoned.^{110–115}

Phase I clinical trials

This is the first trial of a new agent in patients (or in normal volunteers). Several excellent reviews have been written on Phase I trial methodologies.^{116–118} The objectives of the first Phase I trial in humans differ as to whether the agent is first given to patients or is first given to normal volunteers.

Phase I trial in normal volunteers versus patients

There is always some interest in conducting initial Phase I clinical trials of new anticancer agents in normal volunteers rather than in patients. The number one reason cited for this approach is that the normal volunteers have normal organ function not impaired by malignancy and by prior treatment of their malignancy as in the case in patients. In addition, normal volunteers would not normally be on other concomitant medications (usually an average of 10 for patients on a Phase I trial), which could complicate the pharmacokinetics and the side effect profile of a new agent.¹¹⁹ However, clinicians caring for patients with cancer often view the conduct of the initial Phase I trial in normal volunteers as a waste of precious time and a step that delays the administration of a promising agent to the very people who need it: patients with advanced cancer. Nevertheless, with the development of many new cytostatic rather than cytotoxic agents that are noncarcinogenic, there is more and more interest in first trying the new agents in normal volunteers—just as is done in other areas of drug development such as cardiology.

For a new agent to even be considered for administration to a normal volunteer, it, of course, must be demonstrated to be noncarcinogenic and nonmutagenic in the appropriate preclinical systems. Then an initial trial in normal volunteers can begin.

The objectives of the initial clinical trial of a new anticancer agent performed in normal volunteers are more limited than if the initial clinical trial is performed in patients with advanced cancer. The objectives include the following:

1. To determine the clinical pharmacology of a *single dose* of the agent when given at the starting dose (and perhaps at one additional dose level, to ensure linear kinetics for the agent). This clinical pharmacology information would include peak plasma levels, half-lives of the agent, and the area under the curve (AUC) for the agent. In addition, some pharmacodynamic data could be collected, for example, whether the agent hits a target in a particular normal tissue (such as white blood cells).
2. To determine the clinical pharmacology of multiple daily doses (usually not to exceed 5–7 days) of the new agent at the starting dose (and perhaps at one additional dose level) to ensure that no accumulation of the agent occurs. The clinical pharmacology of the agent would include peak plasma levels, trough levels, half-lives of the agent, AUC for the agent, and steady-state plasma levels. In addition, some pharmacodynamic data could also be collected, for example, whether the agent was hitting a target in a particular normal tissue (such as white blood cells, buccal mucosal cells, saliva, hair, and fingernails).
3. To determine if there are any *side effects* noted for these low doses of the agent in these volunteers. This is usually done by having placebo controls. This can be done by either a balanced randomization (one normal volunteer receives placebo for every one normal volunteer receiving the new agent) or by an unbalanced randomization (one normal volunteer receiving the placebo for every two or more normal volunteers receiving the new agent).

The thought using the normal volunteer approach for the initial trials of a new agent is that the pharmacokinetic data obtained will provide clean, important information with less variability (vs the variability in patients with advanced cancer). It is felt that this solid information might actually shorten the Phase I clinical trials for the new agent in patients and indeed allow patients with advanced cancer to receive more effective doses and schedules of the new agent, which would give them a better chance of benefitting from treatment. There can, however, be problems with taking a new cytostatic agent—even at low doses—into a normal volunteer population. There has been a recent instance in which a cytostatic agent was taken into normal volunteers and at low doses of daily administration caused a very severe cutaneous reaction (which had not been seen with the single dose). Although not life threatening, it was cosmetically severe and actually delayed the administration of the agent to patients. In summary, the administration of new anticancer agents to normal volunteers remains somewhat controversial in oncology drug-development circles.

The objectives for a Phase I trial in patients with advanced malignancies include the following:

1. To determine the maximum tolerated dose (MTD) of the drug. The MTD is the dose recommended for subsequent Phase II trials of the new agent.
2. To define the qualitative and quantitative toxicities of the new agent. In traditional Phase I trials this is described by grading of toxicities according to internationally accepted tables and by observing dose-limiting toxicities (DLTs). These tables are regularly updated and are published under http://ctep.cancer.gov/protocolDevelopment/electronic_applications/ctc.htm. The dose at which DLTs are seen has recently been referred to as “NTD” or nontolerated dose.
3. To obtain robust information on the clinical pharmacology of the new agent. The need for this important aspect has been recently re-emphasized.¹²⁰
4. To obtain pharmacodynamic information on the new agent (e.g., does a specific plasma concentration of the new agent interact with/modulate a particular target). These studies can be done using tissue samples (normal and tumor), peripheral blood cells, skin biopsies, effusions, serum proteins, buccal mucosal cells, or new imaging techniques.
5. To document early evidence of antitumor activity (e.g., objective responses, tumor marker decline, and clinical benefit).

Selection of schedule and route for a Phase I trial

The schedules most commonly explored in Phase I trials include (1) single dose repeated every 3 or 4 weeks, (2) daily \times 5 administration repeated every 3 or 4 weeks, (3) weekly \times 4 repeated every 6 weeks, (4) weekly \times 3 repeated every 4 weeks, (5) 120 h continuous infusion, and (6) daily \times 21 every 28 days. Of course, as more information (e.g., pharmacokinetic/pharmacodynamic information) becomes available on the new agent, it may become necessary to explore other schedules. The choice of what schedule to use (e.g., the choice between a bolus vs a more frequent, e.g., daily \times 5 or daily \times 21 schedule) is most frequently based on (1) the schedule-dependency for antitumor activity in the preclinical models, (2) the pharmacokinetics of the agent in the preclinical model (and eventually from data in patients), and (3) very importantly, the mechanism of action and preclinical data regarding the mechanism of action (e.g., dwell time for a drug to be “on target” to have an effect). The reader is cautioned that decisions on schedule based on the most active schedule in the preclinical animal models need to take into account the fact that animal tumors have a more rapid doubling time and a much higher growth fraction than do most types of human cancers (other than leukemias or aggressive lymphomas).

As far as the route is concerned, the tried and true method for development of new agents (even if an oral route is possible with the new agent) was to proceed with the first Phase I trial by the intravenous route. This intravenous trial could then be followed by the oral Phase I trial. This has classically been done because (1) there is certainty of delivery of the agent with the intravenous route (many patients with cancer may have abnormalities of their gastrointestinal tracts, they may have low-grade nausea from other medications (e.g., pain medication), or swallowing might be difficult for them and compliance may be an issue); (2) with the intravenous route, there is no question that the drug is delivered with a chance for the greatest peak plasma levels of the agent; and (3) having the correct intravenous dose first and then proceeding with the oral Phase I trial of the agent allows one to assess the bioavailability of the oral form of the agent.

With the introduction of new cytostatic agents, which tend to have more schedule dependence, it is becoming more and more common to only develop the oral form of the agent (e.g., tamoxifen, capecitabine, imatinib, and vemurafenib). With the oral form of the agent, there is more room for creativity in schedules (e.g., daily \times 5, 2 days off; daily \times 5; and daily \times 42). However, one must remember that the schedules used for the Phase I trial cannot be greatly different than the schedules used in the animal toxicology package and should be manageable in a more uncontrolled clinical setting after approval of the new agent. With better diagnostic tools, pharmacogenetic variability of patients is garnering increasing awareness. Pharmacogenetic variability may be important for differences in clinical activity and toxicities and thus may need to be considered when dose and schedule of a mechanistically based agent are chosen.¹²¹

Calculation of the starting dose for a Phase I trial

The criteria for calculation of a starting dose include using either one-tenth the LD10 (or MTD) in the mouse or rat or one-third or one-sixth of the toxic dose low (TDL) in the dog. The TDL is defined as the lowest dose that produces a toxic effect and usually a dose that, if doubled, causes no lethality. The decision to use the murine model or the dog to guide the starting dose considers which dose will give the lower or more conservative starting dose on the schedule planned for later use.¹²²

Because animal toxicology studies frequently give data on a milligram per kilogram basis, it is critical to scale all doses between animals and humans using a milligram per square meter basis.^{123, 124} [Table 3](#) details the conversion factor suggested by Freireich et al.¹²³ for milligram per kilogram in an animal species to a milligram per square meter scale.

Table 3 Conversion factor for changing milligram per kilogram to milligram per square meter for starting dose in humans

Animal model	Appropriate conversion factor for converting mg/kg mg/m ²
Mouse	3
Rat	6
Monkey	12
Dog	20
Human	37

Source: Adapted from Freireich 1966.

To demonstrate of how one would calculate the starting dose for a new agent, we could use the example

of the development of the topoisomerase I inhibitor CPT-11.¹²⁵ In animal toxicology studies with CPT-11, the most sensitive animal species was the mouse using a weekly schedule. For CPT-11, the MTD in the mouse given CPT-11 on the weekly schedule was 70 mg/kg. Using the conversion factor of 3 ([Table 3](#)), the MTD in the mouse on a milligram per square meter level would be $70 \text{ mg/kg} \times 3 = 210 \text{ mg/m}^2$. Then, the starting dose in humans using the mouse information would be one-tenth of the MTD in mouse or one-tenth of 210 or 21 mg/m² given weekly. If the dog had been the most sensitive animal species to CPT-1 I, we would have used that dog toxicology information to determine our starting dose for CPT-11.

Methods for dose escalation

Dose-escalation methodologies are used to determine the DLTs, which in turn define the MTD. Side effects are used to titrate further dose increases and it is assumed that there is a monotone relationship among dose, toxicity, and activity.

The method used for dose escalation in Phase I trials has classically been the *modified Fibonacci* search scheme.^{118, 126} However, as can be seen in [Table 4](#), there are now several methods for escalation of dose in Phase I trials that can be used.^{127–133} Most of these other methods of dose escalation were developed to try to minimize the number of patients receiving very low, ineffective doses of a new agent and to try to improve the ethics of the situation.^{134, 136, 137} The modified Fibonacci search scheme is the most often used method of dose escalation. However, it can result in the highest number of patients receiving ineffective doses, largely because while the initial dose escalations are substantial, there is eventually a tapering off of the percent dose escalation to just 33% escalations at each subsequent dose level. [Table 5](#) details a classic modified Fibonacci dose-escalation scheme. The real benefit of starting a Phase I clinical trial with a new agent using the modified Fibonacci scheme is that it has a superb record of safety. It is particularly the preferred method when one has an agent that has a steep dose–toxicity curve in the animal toxicology studies with the new agent.

Table 4 Methods for dose escalation in Phase I trials

Method	Proposed by
Modified Fibonacci	Hansen ¹²⁶
Doubling method	Gottlieb ¹²⁷
	Freireich (personal communication)
Pharmacologically guided	Collins ⁹⁷
2 × AUC method	Evans ¹²⁸
Geometric mean + extended factor of 2	Erlichmann ¹²⁹
Continual reassessment	O'Quigley ^{130, 131}
(and modified continual reassessment)	Faries ¹³²
Accelerated titration design	Simon ¹³³
Selection by patient method	Freedman ^{134, 135}

Table 5 Modified Fibonacci dose-escalation scheme in Phase I trials

Dose level	Dose	Increase above preceding dose (%)
1	N	Starting dose
2	2 N	100
3	3,3 N	67
4	5 N	50
5	7 N	40
6	12 N	33
7	16 N	33
And so on	—	—

Along with the modified Fibonacci method cohort sizing usually follows a 3 + 3 design for each dose level. This must be done carefully. In general, the first patient (patient 1) at a new dose level is entered into the study and observed for 3 weeks. If no toxicities are noted in patient 1, patient 2 on the same dose level is then entered and observed for at least 2 weeks (note that, by that time, patient 1 will be well into his/her second course). If no toxicities are noted in patient 2, patient 3 can be entered after patient 2 is observed for 2 weeks. Although there is always pressure from many quarters to enter patients more quickly into a Phase I trial, following this methodology provides the highest degree of safety possible and provides added protection in cases in which the new agent (or its metabolites) has a particularly long half-life or a new agent has nonlinear kinetics. One must also be careful and probably use the modified Fibonacci method when one is dealing with an agent that is a prodrug (as is CPT-11), and limited information is available on the active metabolite.

If no DLT (see definition below) is reached at a dose level, the dose is escalated for the next cohort of patients. If only one of the three patients at a particular dose level is noted to have a DLT, then up to three more patients can be entered onto that dose level. If two or more patients of three or six patients are noted to have DLTs, then one has exceeded the MTD of the drug. Then, additional patients are entered on the preceding dose level to ensure that one has a correct MTD—the dose to be taken into Phase II trials with the new agent. It is very important to note that there is no real scientific basis for the three patients per dose level used in standard Phase I trials.¹³⁸ The major rationale for the 3 + 3 cohort size design per dose level is that, to date, it has provided a good safety record for Phase I trials, allows for a more thorough pharmacokinetic and possibly also pharmacodynamic evaluation at lower dose levels, is straightforward to use, is generally accepted by Institutional Review Boards, and comes at no model-related additional cost. In a recent literature review, which retrospectively analyzed 1235 Phase I trials, the 3 + 3 cohort size approach has been found to be by far the most frequently used approach despite concerns that the 3 + 3 cohort sizing may be inferior compared to more complicated model-based cohort sizing.^{139, 140}

The next dose-escalation method outlined in [Table 4](#) is the *doubling method*. This was proposed to try to minimize the number of patients entered at ineffective dose levels. This method provides a more rapid dose escalation. Theoretically, it could lead to overshooting the dose with attendant severe toxicities (although one cannot find any examples of problems in the literature). This doubling method of dose escalation ($n, 2n, 4n, 8n, 16n \dots$) is probably now one of the most commonly used methods of dose escalation in Phase I trials at least at low doses of the agent that do not cause toxicities.

Another method for dose escalation introduced by Simon et al.¹³³ that also uses one patient per dose level

is the *accelerated titration* design. They introduced two designs (design I and II). With design I, cohorts of one patient per dose level are treated with 40% escalations between dose levels. With the first DLT, there is an expansion of the cohort to a total of three new patients. With design II, there is only one patient per dose level, but there are dose escalations of 100% between levels, and with the first DLT, the level is also expanded to three new patients. Then, escalation proceeds by 40% increments. On both designs I and II, inpatient dose escalation is allowed if patients had grade 0 or 1 toxicity on the prior course.

Another Phase I dose-escalation methodology that is now used very infrequently is the method proposed in 1990 by Collins et al.⁹⁷ This method is also known as the *pharmacologically guided dose-escalation* method. The method is based on an important piece of work showing that the area under the $C \times T$ plasma disappearance curve (AUC) at the LD 10 (or MTD) in the mouse is equal to the AUC at the MTD in humans. Basically, that finding provides the investigators with a target AUC. In practice, at each dose level, an AUC is determined for patients receiving that dose of the new agent. The AUC at that level is then used to determine what the next dose escalation will be (if the agent has linear kinetics). Use of this method for pharmacologically guided dose escalation requires real-time pharmacokinetics, which is sometimes problematic in a clinical situation. However, it can lead to more aggressive dose escalations. There have been some suggested improvements in the methodology, which have been implemented by some Phase I clinical trials groups.^{141, 142}

The most aggressive concept introduced to try to minimize the number of patients receiving ineffective doses of a new agent is the *continual reassessment method* proposed by O'Quigley and colleagues in 1990. This model has been repeatedly commented on and has been modified by other authors.^{130–132, 143–145} In this modified continual reassessment method (MCRM), a group of clinicians estimates the lower and upper dose limits where clinical toxicities might be noted (based on animal toxicology data). A Bayesian approach is then used to construct a dose–toxicity curve. The Phase I trial is started at one-tenth of the LD 10 or MTD in the mouse or at one-third or one-sixth of the TDL in the dog. However, the difference is that only one patient is entered at the first dose level. After the appropriate amount of follow-up (usually 2–3 weeks), it is judged whether the patient had toxicities (\geq grade 1). If not, then the dose–toxicities curve is consulted to determine the next dose escalation. Dose escalation usually can proceed by doubling the dose as long as the dose is below the estimated MTD (on the dose–toxicity curve). The CRM/MCRM methods have now been in use for some time. There have been a few reviews of the results of trials conducted using modifications of the continual reassessment method.^{141, 146, 147} In general, the MCRM does not seem to decrease the time it takes to complete a Phase I trial, nor does it actually substantially decrease the number of patients entered into the Phase I trial. It does require quick and complete availability of toxicity information before the next patient is treated. It does shorten the time it takes to get to a dose that is close to the MTD for the study, and the MCRM helps decrease the number of patients who receive a potentially ineffective ($<80\%$ of the MTD) dose in the context of a Phase I study (see response rate information below) but consequently may also increase the number of patients treated at toxic doses. One potential issue with the CRM approach also is when toxicities occur late and thus cannot be captured during the dose-determining process. This is important as a recent review on early studies with mechanism-based compounds found that 57% of grade ≥ 3 toxicities occurred after the completion of the first course of treatment.¹⁴⁸ This observation together with the observation that long-lasting, low-grade toxicities after treatment with mechanism-based agents may also define a “DLT” has been corroborated by international retrospective analyses.^{149, 150} Modifications of the CRM may be helpful taking these important aspects in consideration, but it is unclear whether they are generally useful.¹⁵¹ Iasonos and O'Quigley have recently analyzed the published performance of adaptive dose-finding studies including various modifications of the originally proposed continual reassessment

method.¹⁵² The authors concluded that adaptive designs in Phase I trials are at least safe and can be adjusted to various clinical situations in Phase I.

Bayesian Phase I trial designs have been developed for combination Phase I studies with mechanism-based novel compounds but have not yet been broadly used clinically for this purpose. These mathematical methods also pay attention to the time-to-onset of toxicities.^{153, 154}

Another frequent issue in selection of patients for a Phase I trial is whether only patients with a certain disease should be entered into the study (e.g., only patients with prostate cancer). Interestingly, this is not frequently done, but will probably be done more frequently as more targeted disease-specific agents are brought into Phase I trials. Until that is done, it is likely that most Phase I trials, particularly with cytotoxic agents, will continue to allow entry of patients with a variety of malignancies.

Definitions of MTD and DLTs

The classic definition of an *MTD* is the highest dose that causes one or less of six patients to have DLT. This MTD is the dose that is generally recommended as the dose to be used in single-agent Phase II trials. However, there have been different definitions of the MTD used by the European research groups and it is important to carefully review the MTD definition before working with a new agent.

The definition of a *DLT* is grade ≥ 3 nonhematologic or grade 4 hematologic (e.g., absolute neutrophil count $< 500/\mu\text{L}$) toxicities according to the NCI Common Toxicity Criteria for Adverse Events (NCI CTCAE) found at the following website:

http://ctep.cancer.gov/protocolDevelopment/electronic_applications/ctc.htm.

There are frequent discussions as to whether Phase I trials should always seek to define the MTD and DLTs. This question is becoming increasingly asked in clinical trials with agents that are mechanism based (e.g., monoclonal antibodies and kinase inhibitors). Rather than defining an MTD, there is an increasing emphasis (using pharmacodynamic measurements) on defining a BED. Of note is that often the BED and the MTD are actually quite close to each other. In addition, caution is urged at stopping the Phase I trial at the BED. The Phase I trials with imatinib may have stopped too early if only the BED was used. There is new evidence that one mechanism of resistance of CML cells to imatinib may be attributable to low-dose exposure. It would be nice to know whether higher doses of imatinib could be used to kill these clones of tumor cells.

Selection criteria for patients for Phase I trials

[Table 6](#) details the traditionally used selection criteria for inclusion in a Phase I trial. These are offered as guidelines only. As Phase I clinical trials theoretically could pose a risk to patients, efforts have been made to generate additional scoring systems or measurements that could predict the prognosis of patients who are candidates for Phase I inclusion more precisely than traditional eligibility criteria.^{155–158} These systems are refined with new information on cancer biology and, as an example, a study by Olmos and colleagues concluded that the number of circulating tumor cells—together with albumin, lactate dehydrogenase, and the number of metastatic sites—could be used to better predict the prognosis of Phase I candidate patients.¹⁵⁹ Similar efforts have been undertaken to predict which patients may develop serious drug-related toxicities, and these patients may be excluded from entering a Phase I trial.^{160, 161} These efforts are directed to detect which patient may have benefit from study participation but also ensure that the agent receives adequate evaluation in a patient population with adequate life expectancy. On the flip side of this approach there is discussion whether Phase I trials are biased to include patients who are not representative of the population treated after marketing authorization has occurred. In fact,

even if the final recommended Phase II dose is used in and confirmed by subsequent Phase III trials, “real world” use after approval shows that dose and schedule modifications are frequent.¹⁶² These modifications are usually driven by concerns about toxicities, but one must keep in mind that a reduced dose may also lead to reduced clinical benefit.

Table 6 Common selection criteria for entry of patients into a Phase I trial

1.	Age ≥18 years
2.	Pathologically confirmed diagnosis of any malignant solid tumor
3.	Measurable disease not required
4.	Life expectancy ≥12 weeks
5.	Karnofsky Performance Status of ≥70% (ECOG ≤ 2)
6.	<div>Adequate organ function:</div> <div> <div>a. Neutrophils ≥ 1500/μL, hemoglobin ≥ 9 g/dL</div> <div>b. Platelets ≥ 100,000/μL</div> <div>c. Serum bilirubin with normal limits</div> <div>d. SGOT ≤ 3 × ULN (except if owing to disease, then ≤ 5 × ULN is acceptable)</div> <div>e. Serum creatinine within normal limits and calculated creatinine clearance ≥ 60 mL/min</div> <div>f. No atrial or ventricular arrhythmias requiring control by medication; no ischemic event experienced within the preceding 6 months</div> <div>g. No history of seizure disorder requiring active therapy; no clinical evidence of malignancy of the central nervous system</div> </div>
7.	Must have exhausted all therapy, which has a better chance of working for the patients (including investigational therapy) or must be in a situation for which there is no standard therapy
8.	Must not have received any chemotherapy within 4 weeks before entry (6 weeks for mitomycin-C or nitrosoureas) with complete recovery from toxic effects of that therapy
9.	Patients must not be receiving any concomitant radiation therapy
10.	Patients must have recovered from the reversible toxicities of prior therapy
11.	Female patients must be of nonchild-bearing potential or nonlactating and using adequate contraception with a negative pregnancy test at study entry and before each course of therapy
12.	Male patients must also be using adequate contraception
13.	No other serious concurrent medical illness or active infection should be present that would jeopardize the ability of the patient to receive (with reasonable safety) the chemotherapy outlined in the protocol
14.	An effort must be made to minimize concomitant medications to those necessary for pain control, patient comfort, or life-threatening problems
15.	Patients must sign an informed consent form. The patient must be aware of the neoplastic nature of his/her disease and willingly consent after being informed of the procedure to be followed, the experimental nature of the therapy, alternatives, potential benefits, side effects, risks, and discomforts

A few points of the traditional exclusion criteria are also worthy a discussion. First, an important question is whether older patients should participate in Phase I trials. Of note is the study by Bowen et al.,¹⁶³ which indicated that a patient's chronologic age did not impact on the toxicities experienced in Phase I trials of a new agent. In contrast to these findings, Schwandt et al.¹⁶⁴ found in their retrospective analysis of more than 500 patients older than 70 years in fact a slightly increased likelihood for toxicities, but the authors concluded that this risk remained within the acceptable range in Phase I trials. Both studies concluded that age alone is no criterion to exclude a patient from participating in a Phase I trial.

Second, one of the most interesting new questions that is arising in the Phase I trial arena (because of the development of more targeted agents) is whether only patients whose tumors exhibit the particular target should be entered into the Phase I trial. This would seem to make sense because if the patient's tumor has the target (e.g., estrogen receptor or *HER2/neu*, CD20 or CD52 positivity, or the BCR-ABL rearrangement or mutated c-kit), the patients should be more likely to respond to the new agent. A strong plea has been made to only include target-carrying patients at least in Phase II trials.¹⁶⁵ It is fairly clear that the presence of the target in the patient's tumor should be a criterion for entry into the study if the agent is *certain* to work only on tumors that possess the target and if one is certain that the mechanism of action for the new agent is only against that particular target. In addition, one must be certain that the assay used to measure that particular target is accurate and reproducible. In this context, archival tissues or blood samples are unlikely to yield relevant information at later stages of the tumor evolution as tumors change their molecular characteristics during the clinical course.¹⁶⁶ When these criteria are met, the limitation of the patient population to those expressing the target can be very effective as has been shown by a Phase I trial with ceritinib in non-small-cell lung cancer patients carrying the EML-ALK translocation.¹⁶⁷ The selection of patients for entry on a new agent trial based on the presence of the target in their tumors thus is a strategy that will become more a standard as we can better pinpoint the precise mechanism(s) of action of new agents. Until then, the need to select patients based on the presence of a specific target either in peripheral tissues or tumor biopsies is a bit uncertain for many compounds in the area of Phase I trials.

Third, a frequent issue in selection of patients for a Phase I trial is whether only patients with a certain disease should be entered into the study (e.g., only patients with prostate cancer). Interestingly, this is not frequently done but will probably be done more frequently as more targeted disease-specific agents are brought into Phase I trials.

While traditionally Phase I studies only served as lead-ins for larger randomized trials, the recent progress in the development of mechanistically based agents has allowed a new—though still experimental—regulatory approach to drug approval. In 2012, FDA has issued a new guidance that one can obtain “Breakthrough Designation” based on limited data with a mechanism-based compound ([http://www.fda.gov/downloads/drugs/guidancecomplianceregulatoryinformation/guidances/ucm358301.p](http://www.fda.gov/downloads/drugs/guidancecomplianceregulatoryinformation/guidances/ucm358301.pdf)¹⁶⁹ This is a promising new model for drug development and has been used for two anticancer drugs (obinutuzumab and ibrutinib) and one noncancer agent in 2013 and, at the writing of this chapter, for five anticancer compounds (ofatumumab, ceritinib, idelalisib, ibrutinib, and pembrolizumab) and one noncancer agent in 2014 (Table A1). Ceritinib was approved through this process based on Phase I data only.^{120, 167} Approvals based on Breakthrough Designation are, however, preliminary approvals, and follow-up trials will be mandated by the FDA to confirm the benefit-risk ratio for patients.

Combination of agents in Phase I trials

Ethics are more straightforward in the conduct of Phase I trials, which combine a new agent with an already approved agent. In this setting, the patient will at least receive one agent with proven clinical activity (usually an approved small molecule). Novel anticancer agents may also be combined with traditional radiation therapy in a Phase I setting.¹⁷⁰ There is an increasing amount of clinical trial activity in this area with initial experience at least with monoclonal antibodies (e.g., trastuzumab, rituximab, and cetuximab) demonstrating increased clinical activity when used in combination with standard chemotherapeutic agents. On the other hand, there are also examples with small molecules in which the add-on strategy has not validated the initial enthusiasm at least in unselected patient populations.¹⁷¹ Nevertheless, this remains an area of active exploration with the recent addition of mechanism-based agents such as signal transduction inhibitors used in combination with standard chemotherapeutic agents. General guidelines include the fact that the standard agent should generally be administered at the dose and schedule that are usually used (e.g., used at their approved dose and schedule) if at all possible. This improves acceptance by investigators and patients of the study design. Sequencing of the agents should be worked out in preclinical models (if at all possible), although the predictive value of these models is not established. By starting with the recommended/acceptable dose of the standard agent, one can then start escalation of the new agent with a fixed dose of the standard agent. In general, the starting dose for the new agent would be 25% of the MTD (or BED where applicable) for the new agent alone (if there are no overlapping toxicities with the standard agent). Depending on what is seen at that initial level, the next dose levels of the new agent would be 50% of its MTD, 75% of its MTD, and then 100% of its MTD (if possible). There are also some sophisticated models that have been reported to provide additional rationales for the dose escalations used in combination Phase I studies.¹⁷²

With specific focus on early studies involving mechanism-based agents, Yap et al.¹⁷³ have recently nicely summarized a number of trial designs based on the basic concepts of reversal of resistance, sequencing of drugs, addition of a novel drug to a backbone treatment, alternating drugs, and pulsed schedules. There is thus a multitude of combination opportunities to address vertical resistance or horizontal resistance by alternative pathways and the decision which combination to use for drug development must be made on sound understanding of tumor biology.¹⁷⁴ Independent of which approach is ultimately applied, one should always be mindful that mechanism-based agents may have unexpected toxicities when combined, but one should never allow to compromise on dose in such a way that both agents are administered at suboptimal doses or target inhibition.^{175, 176} Most recently, the Clinical Trial Design Task Force of the NCI Investigational Drug Steering Committee has published the following set of recommendations: how to rationally choose combinations for Phase I testing¹⁷⁷:

- the new combination should have a clear pharmacologic or biologic rationale and hypotheses explained in the protocol
- it should be described in the protocol how the combination will translate into clinical benefit and what the next steps in development of the combination will be beyond Phase I
- the design of the study should address DLT, potential for PK interactions contributing to toxicities, and a hypothesis for the mechanistic basis of such interaction.

Are Phase I clinical trials therapeutic?

Phase I trials have sometime been considered as nontherapeutic, that is, without therapeutic intent or benefit to the patient. This connotation needs to be corrected because several studies have been documenting that, indeed, conventional responses (complete and partial responses) can be seen in patients

with advanced malignancies who are participating in single-agent Phase I trials of a new agent.^{178–182} The reported response rates range from 5% to 7% (with about 1% complete response rate). However, there are also examples of considerably higher response rates, particularly in Phase I combination trials.^{52, 183–186} Most responses are noted in a range of 80–120% of the MTD for the agent. Roberts and colleagues reviewed 213 studies (6474 cancer patients) published in peer-reviewed journals.¹⁸⁷ They noted an overall response rate of 3.8%. Of note is that they found that response rates have decreased over the 12-year study period (6.2% in 1991–1994 vs 2.5% 1999–2002). During the observation period, toxic death rates also declined from 1.1% (1991–1994) to 0.06% (1999–2002). From these data, the authors concluded that the ratio of risk to benefit probably has improved. In an analysis of 24 Phase I studies, Jain et al. found a correlation between RECIST-based response and overall survival of patients.¹⁸⁸ This finding also supports the value of using response as an outcome measure in Phase I trials. For head and neck cancer, a study by Garrido-Laguna suggested that the progression-free survival of patients entered in Phase I studies is similar to the progression-free survival of their last treatment with an FDA-approved agent.¹⁵⁷ Of interest is whether the category of stable disease will become an increasingly used measure of interest (particularly stable disease lasting ≥ 4 months). There is interest in this category of nonprogressing patients, and it is likely to be increasingly used as a criterion used to determine whether a new agent exhibits some antitumor effect in a Phase I setting.¹⁸⁹ However, the use of WHO or RECIST criteria practically dichotomizes patient response (no response vs response) based on more or less arbitrary thresholds. Even if a more granular categoric grouping is used (CR, PR, SD, and PD), this approach may miss beneficial effects of smaller than threshold tumor shrinkage. Using tumor shrinkage as a continuous variable instead provides more granular information on antitumor activity, and thus is increasingly used alone or in combination with functional imaging procedures to assess biologic activity of novel compounds studied in early clinical trials.^{165, 186, 188, 190} Many other attempts to detect early signs of anticancer activity have been published. They include immune elements of tumor response, functional imaging procedures that measure tumor metabolism or perfusion, and tumor growth rate calculations.^{167, 191–195} A yet experimental approach is to measure time to tumor growth (TTG) as a relatively fast endpoint to determine clinical activity. This endpoint has been proposed based on a modeling of two large randomized Phase III studies in colorectal cancer by Claret and colleagues, and while it is still experimental and not validated for the Phase I setting, it is a potentially valuable additional tool to identify drug activity in early clinical development phases.^{196, 197}

Another method that is gaining interest to determine whether a new agent is having some antitumor activity is the concept of using patients as their own controls.¹⁹⁸ In this method, one uses the time a patient who is about to enter a new agent Phase I trial has been on their prior therapeutic regimen as a comparator to the time the patient is on trial without progressive disease. If the patient remains on the new Phase I agent for a period of time (period B) longer than he/she was on a prior therapy, the agent is judged to have had some impact on the natural history of the patient's tumor. If 30% of patients on the Phase I trial (who are at or near the MTD) have a period B that is longer than period A, the agent may be a promising one. This method is becoming increasingly used by clinicians in the Phase I trial arena.

Issues regarding Phase I trials in general

There is more and more being written about the ethics of patient participation in Phase I trials.^{134, 199–203} In recent publications it was noted that instead of the often-quoted perception by many that patients were motivated by altruism, the motivation for patients participating in Phase I trials included the following^{186, 203–206}.

1. Hope for improvement in their condition (high motivation)
2. Pressure exerted by relatives and friends (high motivation)
3. They felt they had no choice (high motivation)
4. Advice or trust of physicians (low motivation)
5. Altruism (low motivation)

These findings again emphasize how important it is for the patient to have all of the facts from the clinical development team so that they can take an informed decision as to whether to participate in a Phase I trial.²⁰⁷ Several studies have found, however, that quite often important information on prognosis, supportive care, and the experimental nature of early clinical studies are either missed by clinicians or misunderstood by patients, and thus “therapeutic misconceptions” are a real risk for the physician–patient interaction.^{208–210} In this context, a study by Berger et al. is of interest, which reports that the length of the consent documents in Oncology trials in Norway has doubled between 1987 and 2007.²¹¹ This observation is certainly also directionally true for the United States. It is not necessarily a reflection of biologic complexity, but rather the result of an increasingly complex legal and administrative bureaucratic environment. For studies that include additional biopsies or biomarkers, often several separate informed consent forms need to be signed by the patient. Despite these complex formalities, several studies demonstrated that participation of a patient in a Phase I trial increased a patient's level of hope and appetite, which are both measures for quality of life.^{212, 213} Particularly, younger patients may also be interested to understand whether there could be a potential conflict of interest by the physician/institution offering participation in clinical trials.²¹⁴

Learning from failures is an important part of early-phase drug development. A salient example at the writing of this chapter is the tremendous effort that went into the development of agents that disrupt the insulin-like growth factor pathway (IGF-receptor inhibitors). This concept has been taken back to the drawing board, and some of the following aspects may have contributed to the clinical failure of monoclonal antibodies to the IGF receptor: suboptimal PK and PD behavior, patient selection, absence of predictive and robust biomarkers, tumor choice based on nonpredictive cell-line data, lack of clear driver mutations in cancer, IGF copy number retrieved from biobase data, and misinterpretation of elevated IGF serum concentrations, which may have been bystander effects related to tumor hypoxia. In this context, an interesting analysis by Camaccho and colleagues found that only about two-thirds of Phase I trials presented at an annual meeting of the American Society of Clinical Oncology were subsequently actually published as article.²¹⁵ This is unfortunate as patients dedicate their time, health, and hope to these trials and it should thus be expected that the results of the treatment will be shared with the medical community in an appropriately detailed manner.

As already stated at the beginning of this chapter, the change in the types of compounds coming up for early-phase studies is remarkable. Several types of compounds can be identified: (1) chemotherapeutic agents with no “off-target” effects, (2) mechanism-based agents that—at high doses—may have significant and usually toxic “off-target” effects, (3) mechanism-based biologic compounds that have no further effect beyond a maximum, and (4) immunotherapy compounds for which not only toxicity but also traditional efficacy endpoints in early-phase studies may not be adequate. In today's Phase I era, it has become important to tailor the methodology of early-phase clinical evaluations to the type of compound or otherwise risk misleading results.

Future technologies likely to impact on Phase I trials

Over the past 10 years, the development of new agents has shifted from classic cytotoxic agents to molecularly mechanism-based compounds. However, the initial hopes of a faster and more efficient drug-development process have not been consistently met, and the early phase as well late phase development has often been slow, more complicated, and more expensive. New trial designs that incorporate predictive and robust biomarkers, pharmacokinetics, and pharmacodynamics are needed. In some cases of multitargeted agents, a biomarker signature may be necessary.²¹⁶

In addition, the rapid advances in functional imaging (e.g. dynamic magnetic resonance imaging, positron emission tomography, and single-photon emission computed tomography) are likely to dramatically impact on the Phase I clinical trial both by helping investigators assess pharmacodynamic endpoints and perhaps assess early evidence of an antitumor effect.

Recent reports on the use of proteomics on serum (with distinct patterns of proteins predicting for presence of disease) represent new patterns of tumor markers that will certainly become useful for detecting early effects of new agents.^{217, 218}

The above and other new technologies should help the Phase I investigator determine early whether a particular new agent is helping that particular patient and improve the prospect for gain for patients who are willing to participate in Phase I trials with new agents.

Summary

Since the early beginnings of systematic anticancer therapy in the 1930s, more than 150 drugs have been identified to be active against cancer and have been approved by the US Food and Drug Administration. Despite this tremendous effort, cancer remains one of the biggest health care burdens, and only a minority of metastatic cancers can be cured. Along with the development of anticancer agents, methods have been established to standardize the development process itself and to provide objective assessments of the benefit a new drug may deliver. The past 10 years have seen a particularly dramatic acceleration of our understanding of the molecular biology and wiring of cancer cells, and this has greatly impacted on the understanding of how new drugs that target specific molecular processes should be developed. At the writing of this chapter, the efforts to develop such mechanism-based agents has largely replaced the more traditional development of chemotherapy directed against general features of cell growth. Nevertheless, it must not be forgotten, how important the initial, serendipity-based observations were and that these observations have led to the National Cancer Institute's extensive efforts to identify potential candidates for clinical drug discovery and preclinical assays to predict clinical activity. This was the beginning of what is now called “personalized” medicine—yet at that time without fundamental understanding of the complexity of mutational events. The identification of imatinib as active agent against chronic myelogenous leukemia provided a milestone in the new era of drug development and has inspired an intensive search for more drugable targets and subsequent drug development. Despite the tremendous progress in the early development of mechanism-based drugs, the clinical methodology has been largely unchanged and is divided into three phases based on different endpoints (Phase I, Phase II, and Phase III). The increasing understanding of how to best develop mechanism-based agents is in the process of mending some of the clinical development phases with new Phase I designs based on Bayesian approaches becoming more popular. Mechanism-based drugs also have toxicities that may differ from those caused by traditional chemotherapy, and this needs to be considered. Their use would also only make sense if the tumor expresses the targeted

molecular abnormality. Given the biologic drift a tumor may undergo during initial treatment, repetitive biopsies may become mandatory for treatment decisions/decisions to include a patient into a specific trial. As we are heading into this new and exciting era of anticancer therapy, new technologies like imaging techniques, proteinomics, and metabolomics will add to our understanding how it will be possible to develop more active and tolerable drugs.

Appendix

See Table A1 *FDA-approved anticancer agents, their primary mechanisms of action, and their indications* can be found on Vital Source version of this title, see inside front cover.

Appendix Table A1 should appear in online only not for print.

Chapter 53

Tumor growth kinetics

Elizabeth Comen, MD ■ Teresa A. Gilewski, MD ■ Larry Norton, MD

Overview

Kinetics is the study of movement and changes in magnitude over time. Kinetics is a central concept in oncology; cancer progression reflects changes in cancer cell numbers, metastatic sites, and tumor mass as a function of time. It is the purpose of this chapter to illustrate both the practical applications and theoretical implications of one aspect of kinetics—tumor growth kinetics. Just as time and space are inextricably linked so too are growth kinetics and the tumor's microenvironment. Here we review the kinetics of cellular proliferation and population growth, finding a theoretical basis for improved practices in cancer chemotherapy.

Introduction

Kinetics is the study of movement or, more generally, changes in magnitude—size, shape, distance, velocity, or indeed anything quantifiable—over time. As a science, therefore, kinetics should be considered central to oncology. Cancer is, after all, all about changes in cancer cell numbers, sites of involvement, and tumor mass sizes as a function of time. Morbidity and mortality from cancer is a consequence of such changes, as measured by recurrence-free, progression-free, and overall survival (OS) times. Moreover, at the molecular level, cancer is not a static process, but involves aberrations in gene integrity, copy number and expression, post-translational modification, and RNA and protein production and degradation that are time dependent. Failure to analyze and interpret cancer biology with regard to changes over time, therefore, may miss the essences of phenomena and thereby lead to misinterpretations, both conceptual and clinical.

The purpose of this chapter is to use recent results in cancer research to illustrate both the practical applications and theoretical implications of one aspect of kinetics—tumor growth kinetics, the study of changes in cell number and over time tumor mass—for cancer medicine. In evaluating carcinogenesis within a time-dependent fashion, it is critical to understand the relevance of the space in which cancer cells change over time. Specifically, cancer–stromal interactions uniquely influence cancer growth. Just as time and space are inextricably linked so are growth kinetics and the tumor's microenvironment. Here, we offer novel insights into how a multitude of cancer processes are best understood by evaluating not simply a kinetic framework but also how the stroma mediates cancer growth.

Some mysteries in cancer medicine

The study of cancer reveals many enigmas, sets of observations that are both true and seemingly incompatible. Identifying enigmas thereby indicates weakness in theories, creating opportunities for progress by hypothesis-testing experimentation. We will examine some of these and then seek their elucidation using kinetic science.

Polygenetic etiology of cancer

As our first example, let us consider the observation that cancer cells manifest myriad changes in gene morphology and copy numbers. This is consistent with the theory that malignancy results from accumulated abnormalities in diverse, somewhat independent genomic processes, the *polygenetic* concept of cancer. The functionalities associated with such changes include self-sufficiency in growth signals, insensitivity to antigrowth and pro-apoptotic signals, and the abilities to invade, to form metastases, to induce angiogenesis, and to replicate without limit. Yet how is this theory compatible with the equally well-documented observation that carcinomas *in situ*, which are clinically benign in that they do not metastasize and rarely grow to large sizes, are usually as aberrant genetically as the malignancies they spawn?

The concept of a polygenetic etiology of malignancy presents another mystery, which concerns the strong statistical association of histologic grade, tumor size, and propensity for traveling to regional (largely nodal) and distant sites. These traits are so commonly grouped together that we may forget that they are manifestations of distinct biologic processes: morphogenesis, regulation of mitosis apoptosis, and metastasis, respectively. Indeed, metastatic behavior presents many thought-provoking enigmas. Toward the end of the nineteenth century, Halsted used the prevailing mechanics of his time to hypothesize that the malignant spread of primary breast cancer could be halted by the meticulous removal of a whole breast containing the tumor in contiguity with the ipsilateral axillary contents. The idea behind the radical mastectomy was that cancer cells gain access to the rest of the body by invading lymphatic channels in the breast, channels that then traverse the axilla before connecting with the systemic circulation.

Many observations would seem to support Halsted's contention. Radical mastectomies did indeed cure some individuals, almost all of whom would have died of metastatic cancer had their breast cancers been left intact—a fact proven by observational studies in the nineteenth century. Also, lymphatic invasion is a powerful prognostic variable. Most compelling is the modern observation that sentinel lymph node mapping confirms a common flow pattern from the breast for lymph and cancer cells. Yet how would one invoke Halsted's theory to explain how some patients with uninvolved axillary lymph nodes at the time of radical local surgery still develop distant metastases?

Molecular classification versus cancer stem cell concept

Another enigma concerns the classification of tumors by RNA expression profiling. It is unquestionably true that tumors differ in their patterns of gene expression, and that these differences correlate with clinically meaningful endpoints such as disease-free and OS and benefit from chemotherapy.¹ Hence, testing a small anatomic sample of a cancerous mass is informative regarding the behavior of the whole cancer, as if all of the cells in the cancer carry the critical information. Yet how can we reconcile this observation with the popular, experimentally derived hypothesis that it is only a tiny minority of cancer cells—“cancer stem cells” or tumor-initiating cells—within the mass that have the capacity to form new tumors?

Cancer as a local versus systemic disease

It is well known that breast cancer is often a systemic disease early in its life-history; this is underscored by the fact that systemic adjuvant therapies like hormonal treatments and chemotherapy improve cancer-free and OS. But how is this compatible with the equally venerable observation that better local control,

as by radiation therapy to the remaining breast tissue following breast-conserving surgery, improves survival? Indeed, it seems that for every four cases of local recurrence prevented by radiation therapy, one patient is saved from distant metastases and subsequent death. If the disease is metastatic early, why should local control make any difference at all? Part of the answer may be found in the observation that on detailed histopathological analysis, breast cancer cells are commonly found centimeters away from the clear margins of excised primary tumors. But this raises new questions. How did these cells get there, and what is the relationship between such cells and distant metastases?

Gompertzian growth

Another enigma concerns growth patterns. It has been shown that the growth pattern of breast cancer cannot be explained by simple exponential or linear kinetics, but must follow an S-shaped curve intermediate between these two extremes ([Figure 1](#)).² The evidence is not only from direct clinical observations but also from logical inferences based on clinical observations. For example, based on retrospective analyses of preexisting mammograms after the clinical diagnosis of breast cancer, it has been estimated that an average tumor may take 2 years to grow in size from one cell to 10^9 or 10^{10} cells. This number of cells corresponds to a tumor volume of 1–10 cm³ if all of the cells were packed tightly together, which for the sake of this argument is a rational size range for the diagnosis of a primary mass.

Figure 1 (a,b) Gompertzian growth on two scales.

Now let us consider what would happen should cancers grow in a linear pattern. This means that growth would be from one cell to two cells, then three cells, the four cells, and so on in equal units of time. By this pattern, if it took a tumor 2 years to grow from one cell to this size range (10^9 or 10^{10} cells), it would take another 2 years for it to double in size to 2–20 cm³ and yet another 2 years to triple in size to 3–30 cm³. This is clearly an unrealistically slow growth for an untreated primary cancer. Hence, it is extremely unlikely that cancers grow linearly.

Nor is exponential kinetics applicable to real-life examples. An exponential growth pattern involves constant doubling times. That is, if it takes a week for one cell to divide into two cells, by exponential kinetics, it would take another week for those two cells to become four, an additional week for those four to divide into eight, and so on. Many decades ago, Howard Skipper and colleagues used exponential kinetics to explain the growth and response to therapy of a murine leukemia, laying the groundwork for much of the experimental and clinical chemotherapy to follow. But does exponential kinetics apply to human disease? Let us turn again to the case of a primary breast cancer growing from one cell to 10^9 or

10^{10} cells over 2 years. Were it to have grown exponentially to this point and continue to grow exponentially thereafter the mass would double in size every 22–24 days, which means that it would reach a size of 4–40 cm³ in <7 weeks from diagnosis. This is an explosive growth rate that is just incompatible with general medical experience. Hence, exponential kinetics cannot apply. Yet, mitosis does produce two cells from one, so early malignant growth at the few-cell stage must be approximately exponential. This is truly an enigma.

The only way to resolve this mystery is to hypothesize that although growth may start in an exponential fashion, there is a progressive deviation toward slower growth as the tumor becomes larger. Of the infinite number of possible decremented exponential curves, one type has been shown to accurately fit actual tumor growth curves.³ This type was defined by Benjamin Gompertz in 1825 and has since been one of the most utilized mathematical formulas in all of biomathematics. It is illustrated in [Figure 1](#) on two different scales of size: arithmetic and logarithmic. The “S” shape is apparent on the arithmetic scale, but on the logarithmic scales, the relative growth rate is seen to be continuously decreasing as the mass grows larger. As will be discussed in depth later, Gompertzian kinetics have proven very useful in designing improved regimens of anticancer chemotherapy, not only in breast cancer—where it was first explored—but also in malignant lymphoma, childhood sarcoma, and other malignant diseases. But if Gompertzian growth kinetics is ubiquitous in nature, what is its (necessarily ubiquitous) etiology?

In this chapter, we will explore these issues—carcinogenesis, the behavior of tumor-initiating cells, pathohistologic grading, and patterns of metastatic spread—using the framework provided by the science of kinetics. We will examine the fundamentals of cell proliferation as a cause of tumor growth and the development of cellular heterogeneity. We will seek in modern molecular science an etiology of Gompertzian growth. We will also illustrate the clinical relevance of growth kinetics in practical cancer medicine with a focus on the therapeutic implications of Gompertzian growth on the dose scheduling of anticancer drugs. We will identify new areas for kinetic research that have implications for prognostication, choice of therapies, the discovery of new therapeutic targets, and the design of prevention strategies.

The kinetics of cellular proliferation

The study of how cancer cells divide provides some insight into these enigmas, but presents mysteries of its own, the contemplation of which may provide further illumination. As tumors are comprised of cancer cells with their supporting stroma, it is reasonable to start a discussion of tumor kinetics by considering the proliferative kinetics of cancer cells.

Assessing growth parameters

Mitosis, or cell division, is the basic biologic process that results in an increase in somatic cell numbers over time. The term *growth* applies to the increasing volume of a cellular population and is measured in units of volume (cubic centimeters) or weight (milligrams). Growth is largely the consequence of increasing numbers of cells but also can be influenced by the increasing size of the individual cells, edema, and changes in the context of the extracellular matrix, hemorrhage, and infiltration by host cells, such as leukocytes. The term *proliferation*, in contrast, applies specifically to an increase in the number of cells, which is measured as cell number as a function of time. Cells divide by progressing through a sequence of steps that are collectively called the mitotic or “cell” cycle.

It is important for the student of cell kinetics to understand the methods for assessing cell cycle phases

because—as in all areas of science—concepts are inextricably confounded with their means of quantification.⁴ At the simplest level, metaphase cells may be counted on a microscope slide. This *mitotic index* is a rough estimate of the percent of cells in M phase. Experimentally, the mitotic index can be improved by a now seldom used method called the stathmokinetic technique, in which a mitotic poison is applied at a known time before counting. The proliferative activity of a tissue may also be estimated by examining microscopic slides after immunohistologic staining for the Ki-67 protein, present in all proliferating cells and absent in nonproliferating cells. Although Ki-67 staining is now mostly used, historically the most productive technique is the thymidine labeling index (TLI). Here, viable cells are exposed briefly *in vitro* to a radiolabeled precursor of DNA. The most common thymidine label is tritium, but carbon 14 has also been used. The percentage of tumor cells with autoradiographic grains over their nuclei estimates the fraction of cells that were in S phase during the period of thymidine exposure.

Except for the stathmokinetic technique, all of the above are static assays, providing a snapshot rather than a movie of proliferation.⁵ Nevertheless, the snapshot is of a concept called the *growth fraction*, the proportion of the cancerous mass that is actually involved in proliferation. Previously, the growth fraction of human leukemias was assessed by the use of the TLI *in vivo*, now no longer permissible.

A kinetic extension of the TLI is the percentage of labeled mitoses curve. This technique counts, as a function of time after exposure, the number of M phases that contain radioactive label. This measures the cells currently in M phase that had been in S phase during the exposure to radioisotope. Hence, it is the only technique that actually measures cell cycle durations. Kinetic autoradiographic techniques of this type were used decades ago to divide the cell cycle into four phases: the synthesis of DNA occurs mostly in the S phase and the actual division of the parent cell into two daughters during the M phase; the time gap between cell division and DNA synthesis is gap number 1, or G1, and the time gap between DNA synthesis and cell division is gap number 2, or G2. Although the term *mitosis* is often used to refer to the M phase, the adjective *mitotic* properly refers to all cells that are engaged in any portion of the whole process of self-replication: G1, S, G2, and M phases. This distinguishes mitotic cells from cells that do not divide within a defined period of observation, called G0 cells. The M phase is the least variable in length, lasting about 1 h in most mammalian cells. The G2 phase is usually 3 h in length. The total duration of the cell cycle varies considerably, but the average in human cancer is between 2 and 4 days. Most of this variability is accounted for by variability in the length of the G1 phase. The long mitotic cycle in adult humans is in marked contrast with the cell cycle duration in *Drosophila*, which may take minutes, or with that of mammalian embryos, which may take only hours.

In G1 phase, a normal mammalian somatic cell contains a diploid number of chromosomes and hence diploid (2N) DNA content. During the S phase, a cell's DNA content should increase from 2N to 4N. (A very small number of so-called S0 cells may stop synthesizing DNA before completing the S phase, and rarely a cell can rest in the G2 phase and not proceed into M phase.) G0 cells tend to be smaller than G1 phase cells and have lower RNA and protein contents. The variations in cellular DNA content during the proliferative cycle can be exploited analytically by a collection of automated methods called *flow cytometry*. In fluorescence-activated cell sorting, a suspension of individual cells is automatically counted by being allocated into bins by DNA content, RNA content, cell size, antibody (such as Ki-67) label, uptake of bromodeoxyuridine and/or tritiated thymidine during the S phase, or combinations of such markers. This can be performed on fresh tissue—leukemias, tumor cells in effusions or ascites, enzymatically dispersed solid tumors—or on cells recovered from paraffin-embedded specimens. By measuring DNA content per cell, flow cytometry can also identify cells with abnormal amounts of DNA in the G0–G1 peak, termed *aneuploid*. The S-phase fraction may be impossible to measure in the presence

of marked aneuploidy, one limitation of this method.

Growth fraction, death fraction, tumor size, and therapeutic response

Using the previous techniques, it has been determined that 2–20% of cells in a typical cancer are in the S phase at any point in time. Because the S phase occupies one-quarter to one-half of the cell cycle, the growth fraction is usually 4–80%, with an average of <20%. For a given tissue, malignant or benign, the length of the cell cycle *in vivo* is fairly constant in spite of variations in the number of cycling cells in that population. However, subtle changes in cycle kinetics have been seen in cancers in laboratory animals that are allowed to grow large and phase lengths can shift significantly as cells are cultured *in vitro*. This is in addition to changes in the growth fraction itself during tumor growth: one of the most robust, and mysterious, observations in tumor growth kinetics is that the growth fraction decreases with increasing tumor size. Is this the etiology or the consequence of Gompertzian growth? We will further discuss this later.

It is relevant in this regard that the rate of decrease in the growth fraction as the mass gets larger is slower for malignant than for benign tissues. But this is one of the few quantitative differences between malignant and benign tissues in cytokinetic terms. Some normal tissues, such as bone marrow and alimentary mucosa, have larger growth fractions and shorter mitotic cycle times than many cancers, even cancers of those tissues. This is the second major enigma presented by cytokinetic data. Although the growth fraction of a malignancy may be no greater than that of normal tissues from which it sprang, within a given histologic type of cancer, both a high S-phase fraction and the presence of aneuploidy are frequently associated with a growth rate that is relatively more rapid. This rapid growth suggests a malignant behavior that is relatively more aggressive, and often portends a poorer therapeutic response. These observations amplify rather than solve the enigma mentioned earlier of the association between histologic grade, tumor size, and metastatic behavior.

A partial answer may perhaps be found in the important companion concept to the concept of the growth fraction: the *death fraction* or *cell-loss fraction*. This is simply the proportion of the cellular mass that is lost by cell death per unit of time. The cell-loss fraction is hard to estimate from actual measurements since apoptosis—a common path of cell death—can leave few anatomic traces. It is usually inferred by comparing the expected growth rate (calculated from the measured growth fraction) with the actual growth rate. The impact of a high cell-loss fraction can be considerable. For example, basal cell epitheliomas of the skin grow slowly in spite of demonstrating a large number of metaphase figures. The importance of cell loss, however, goes beyond its impact on growth rate. Each mitotic cycle carries with it a finite probability of mutation. A tumor with a higher cell loss rate takes more mitotic cycles to double in size than a tumor with a lower cell loss rate. Thus, the rate of cell loss relates directly to the rate of mutations toward biologic properties of clinical importance.

Indeed, high rates of cell turnover are implicated in carcinogenesis itself. Elevated levels of thyroid-stimulating hormone predispose to thyroid cancer. Chronic thermal injury with compensatory hyperplasia and hyperplasia secondary to solar damage lead to skin cancer. Hyperproliferation of the bone marrow in dysmyelopoiesis and in chronic granulocytic leukemia is a likely contributor to the development of acute leukemia. Hyperproliferation of benign colonic and breast epithelium is clearly associated with neoplastic transformation. Indeed, chemical carcinogenesis requires a growth promoter. It is even possible—based on studies of Hodgkin's lymphoma and gastrointestinal cancer—that the hyperproliferation of residual cancer cells in compensation for cell death secondary to antineoplastic

drug treatment may predispose to the development of drug resistance.

But the concept of the cell-loss fraction is not free of its own enigmas. Chemotherapy is thought to shrink cancers by damaging cancer cells and thus inducing them to undergo apoptosis. Mitotic cells, especially those in S phase, are thought to be especially vulnerable to this process, and indeed a great deal of experimental evidence supports this hypothesis. However, if the growth fraction of a typical tumor is <20%, meaning that the S phase fraction is 5–10%, and if the spontaneous cell-loss fraction is already greater than zero even in the absence of chemotherapy, how does chemotherapy increase the cell-loss fraction further so that cytoreductions of more than 90% are routine? Furthermore, attempts to increase chemotherapy effects by recruiting breast cancer cells into S phase by the use of estradiol have not yielded the expected large therapeutic benefits.

Another enigma concerns the effect of chemotherapy on normal host tissues. Chemotherapy is certainly toxic to rapidly dividing bone marrow, alimentary mucosa, and hair follicles. Yet, these tissues usually recover from the impact of chemotherapy. Some cancers, however, that are growing no more rapidly than these normal tissues may experience cytoreductions from which they never recover, that is, acute leukemias, malignant lymphomas, choriocarcinomas, and germ cell cancers may be cured by chemotherapy regimens that do not eradicate the patient's normal tissues that have comparable growth kinetics.

Hence, the study of cellular proliferation raises as many questions as answers. Why does the growth fraction decrease with population size, but less so in cancer than in normal tissues? How are the growth and cell-loss fractions related to histologic grade, tumor size, and metastatic potential? How does chemotherapy work given that so few cells, even in virulent cancers, are mitotic at the time of treatment? To approach an answer to these enigmas, we need to expand our focus from the kinetic behavior of cells to the kinetic behavior of cellular populations.

The kinetics of chemotherapy response

We have already critically examined tumor growth and have concluded that the Gompertzian curve or patterns of growth closely approximating Gompertzian curves are the only tenable ways to explain clinical observations. Nevertheless, some concepts derived from non-Gompertzian laboratory models are useful and merit discussion. Foremost in this regard is the body of work associated with Howard Skipper and colleagues at the Southern Research Institute.⁶ The experimental leukemia they studied grows exponentially and regresses exponentially in response to effective treatment. This means that the percentage of cells killed is always the same regardless of the tumor size at the time of treatment. When graphed on a logarithmic scale of cell number versus an arithmetic scale of time, it would appear that the amount of cell death caused by the treatment is always the same in terms of logarithmic displacement: a log-kill of one means that 90% of the cells were killed, a log-kill of two means that 99% of the cells were killed, and so on. If a given dose of a given drug reduces 10^6 cells to 10^5 cells, the same therapy applied against 10^4 cells will result in 10^3 survivors.

The second seminal observation associated with these scientists is that for many drugs, the log-kill increases with increasing dose. Hence, it requires higher drug dosages to eradicate larger-sized transplanted tumors. Moreover, if two or more drugs are used, the log-kills are multiplicative: if drug A at a certain dose level causes a log-kill of one and drug B at a certain dose level also causes a log-kill of one, then the combination of A plus B, each given at the same dose levels as when they were used as single agents, would cause a log-kill of two.

The third observation recalled the Nobel Prize winning work of Max Delbrück and Salvador Luria concerning mutations toward resistance to destruction.⁷ Although Delbrück and Luria worked on bacterial resistance to viral infection, Skipper and colleagues evaluated resistance to chemotherapy, based on Lloyd Law's demonstration of the applicability of the Delbrück–Luria model to this setting.⁸ The concept is that genetic alterations for survival traits arise in the absence of selection pressure, rather than being in response to selection pressure. In fact, the concept is similar to Darwin's evolutionary theory of natural selection, but applied at the cellular rather than the organism level. A new way of stating this observation is as follows: if in one mitosis a bacterium or mammalian cell mutates toward a given property with small probability x , the probability of the unit not developing that property in one mitosis is $1 - x$. In y mitoses, the probability of no mutations occurring is $(1 - x)^y$. If each mitosis produces two viable cells (no cell loss), it takes $N - 1$ mitoses for one cell to grow into N cells. Hence, the probability of not finding any one unit with that property in N cells is $\exp[(N - 1) \ln(1 - x)]$, which is a very small number. Adding cell loss into the model, which increases the number of mitoses necessary to reach N cells, would make the probability of no mutations occurring even smaller. Hence, mutations toward drug resistance must be common in a clinical cancer, which has been shown in many experiments over many decades. The same mathematics would explain why aneuploidy, as a manifestation of genetic change, is so strongly associated with high cell turnover. It might also explain the positive association of primary tumor size with the probability of metastatic spread due to cells that mutated toward that property.

On the basis of this evolutionary model, some theoreticians suggested that when two equally active chemotherapy regimens were available, if they could not be given together at full dose levels, they should be strictly alternated so as to kill cells as quickly as possible before they had a chance to mutate toward drug resistance.⁹ Others argued that mutations had more likely occurred before diagnosis, so it was more important to achieve as high cell-kill as possible in each of the subpopulations of cells already present at the time of diagnosis.^{10–12} Although the former model argues that adjuvant treatment must be instituted as early as possible in the growth history of a cancer to be effective, many trials have failed to find an advantage to preoperative chemotherapy for primary breast cancer, which is more consistent with the latter model. Indeed, both points of view may be argued convincingly on theoretical grounds, but experimental evidence including large prospective clinical trials has strongly favored the latter. The latter model is also concordant with the observation that many cancers—malignant lymphomas, acute leukemias, and breast cancers specifically—that are not cured by chemotherapy often still retain sensitivity to the same chemotherapy when it is applied at a later time.¹³ Hence, all chemotherapeutic failure cannot be attributed to permanent drug resistance, but rather the persistence of cells that were not eradicated. A tumor may relapse because some of its cells, relatively but not absolutely insensitive to the agents applied, are not exposed to enough drug for a long time to be eradicated.¹⁴ This is analogous to a bacterial infection relapsing because an insufficient dose intensity of an antibiotic is applied, even though the microorganisms are sensitive *in vitro*. In both infection and neoplasia, however, prolonged or repeated episodes of low-dose therapy can give rise to absolute resistance by the selection of cells that are biochemically resistant to treatment.

Can manipulations of dose level or schedule overcome this problem? As mentioned earlier, the strict alternation of agents or combinations of agents has not proven useful in this regard. Dose level escalations of a moderate degree have improved results in many common cancers including primary and metastatic breast cancer, childhood acute lymphoblastic leukemia, and adult germ cell tumors. Yet, results do not indicate a strictly rising dose–response relationship. For example, doses of cyclophosphamide over 600 mg/m² do not improve results in the adjuvant chemotherapy of breast cancer, nor do doses of doxorubicin over 60 mg/m². Neither has massive dose level escalation requiring autologous bone marrow rescue

proven to be an advantageous strategy.

Yet, schedule alterations are feasible and have provided some improvement in results. The principles established by Skipper and colleagues in the exponentially growing murine leukemia have been translated into the Gompertzian setting.¹⁵ The implications are illustrated in [Figures 2](#) and [3](#), which are computer simulations of the mathematical model produced by this translation. In [Figure 2a](#), a tumor comprised of cells sensitive to therapy is shown to be growing in a Gompertzian fashion. In response to each administration of treatment, indicated by the arrows, the tumor volume shrinks because of the induced log-kill and then regrows partially before the next administration for the first three cycles of treatment. After the fourth dose of chemotherapy, the cancer is left untreated, eventually reaching 10^{10} cells, a clinically appreciable number, at the time indicated (dashed line) and continuing to grow thereafter. [Figure 2b](#) illustrates what would happen if the same tumor were treated with the same four cycles of chemotherapy, but with a shorter intertreatment interval. As there is less time for the tumor to regrow between cycles, the cancer cell number is smaller for each successive treatment after the first. It has been determined empirically that for Gompertzian populations, the log-kill is proportional to the relative rate of growth at the time of treatment. Clearly, this may be because a greater percentage of the cells may be in S phase and hence vulnerable. Because—in Gompertzian growth—the relative rate of growth is more rapid for smaller populations compared with larger populations, the log-kill is greater for smaller populations as well. When, after the fourth dose of chemotherapy, the tumor grows in an unimpeded fashion, it is shown to take longer to reach 10^{10} cells (having started its regrowth at a smaller size), which translates to improved prognosis for the patient. Indeed, prospective, randomized clinical trials in primary breast cancer, then malignant lymphoma, then childhood Ewing's-family sarcoma have confirmed that the more frequent administration of chemotherapy improves OS time as predicted by this simulation.^{16–19} The administration of CHOP chemotherapy for lymphoma each 14 days (as permitted by the use of granulocyte colony stimulating factor, G-CSF) rather than each 21 days, as was the old standard, is now widely used.¹⁸

Figure 2 (a,b) Impact of dose density.

Figure 3 (a–c) Impact of sequential dose density.

Figure 3 extends this analysis to the case of a tumor that has developed heterogeneity in drug sensitivity before the time of initiation of therapy. This is illustrated by two growth curves, one black and one red, but the total tumor volume would be the sum of the two as the “black” cells and the “red” cells would be admixed in the tumor mass. The “black” cells are sensitive to the therapy symbolized by the black arrows, but are resistant to the therapy symbolized by the red arrows. In a parallel fashion, the “red” cells are sensitive to the therapy symbolized by the red arrows, but are resistant to the therapy symbolized by the black arrows. In **Figure 3a**, the black and red therapies are given in an alternating manner. In **Figure 3b**, the same therapies are given in sequence. It is clear that the log-kill from the sequential approach is greater in the “black” cancer cell population and not inferior in the “red” cells. Hence, the overall cytoreduction is greater—which results in a better prognosis for the patient—shown by increased time to 10^{10} cells. The reason for the greater log-kill is the increased density of the black treatment, as in **Figure 2b**. In the adjuvant chemotherapy of breast cancer, the first use of doxorubicin—now a standard drug in this setting—was in such a sequential fashion.²⁰ The advantages of this approach have been shown in a prospective, randomized adjuvant chemotherapy trial conducted by the National Cancer Institute in Milan, Italy.²¹ The administration of four cycles of doxorubicin followed by eight cycles of the three-drug combination CMF (cyclophosphamide, methotrexate, and 5-fluorouracil) was superior in disease-free and OS to a regimen giving the same drugs for the same number of cycles but in an alternating fashion. Similarly, the Breast International Group (Study 02-98) has published that taxane added benefit to doxorubicin only when used sequentially, not when used simultaneously at somewhat reduced dose levels.²² (Both arms were followed by identical courses of CMF, which does not impact the conclusion that sequential therapy was superior to combination therapy.)

Figure 3c takes this concept further by reducing the intertreatment time for both the black and red therapies. Here, the log-kill is much greater that regrowth may be precluded. This is the treatment plan tested in the breast cancer adjuvant setting by the North American Breast Intergroup in a trial (c9741) coordinated by the Cancer and Leukemia Group B. The use of G-CSF allowed for 14-day cycles of doxorubicin plus cyclophosphamide for four cycles followed sequentially by four 14-day cycles of paclitaxel. Compared with the same chemotherapy given each 21 days, the dose-denser regimen not only improved disease-free and OS, but was less toxic by virtue of preserved granulocyte counts and perhaps other effects.¹⁶ More recently, in a systematic review and meta-analysis of 10 randomized controlled trials, dose-dense chemotherapy demonstrated improved overall and disease-free survival, particularly in hormone-receptor-negative breast cancers.¹⁷ Specifically, in three of trials (3337 patients in total), dose-dense chemotherapy was compared to standard chemotherapy with similar chemotherapy agents. In these three studies, dose-dense chemotherapy led to an improved OS [hazard ratio (HR) of death = 0.84, 95% confidence interval (CI) = 0.72–0.98, $P = 0.03$] and as well as disease-free survival (HR of recurrence or death = 0.83, 95% CI = 0.73–0.94, $P = 0.005$) when compared to alternative schedules. In seven other

trials (8652 patients in total), dose-dense chemotherapy was compared to standard regimens with a variety of different chemotherapy agents and dosages. In this mixed group, dose-dense chemotherapy continued to demonstrate improved OS and disease-free survival (HR of death = 0.85, 95% CI = 0.75 to 0.96, $P = 0.01$ and HR of recurrence or death = 0.81, 95% CI = 0.73 to 0.88, $P < 0.001$, respectively).¹⁷ [Figure 4](#) compares HRs for patients who received dose-dense chemotherapy versus those who received conventional chemotherapy.¹⁷

Figure 4 Forest plot of HR comparing OS in patients who received dose-dense versus conventional chemotherapy.

The concepts illustrated in [Figure 3b](#) are relevant to modern combinations of chemotherapy with biological agents. The use of a prolonged, continuous treatment that inhibits cancer growth but does not interfere with the ability of [Figure 5](#) simulates chemotherapy to kill cancer cells. In [Figure 5a](#), the growth-inhibitory treatment (cross-hatched box) is started after the chemotherapy is completed. In [Figure 5b](#), the treatment is given simultaneously with the red chemotherapy. It is clear that the plan in [Figure 5b](#) is superior in time-to-10¹⁰-cells for two reasons. The first is that the “black” cells, which are not sensitive to the red therapy, are inhibited earlier in their regrowth. The second is that because the growth of the “red” cells is inhibited by the growth-inhibitory therapy, there is less regrowth between cycles of therapy, so fewer cells are present with each cycle after the first, meaning greater log-kill (as in [Figure 3c](#)). This may explain the efficacy of the HER2-modulating drug trastuzumab in adjuvant chemotherapy of HER2 over-expressing mode-positive primary breast cancer. In this trial (9831), coordinated for the North American Breast Intergroup by the North-Central Cancer Treatment Group, all patients received doxorubicin plus cyclophosphamide followed by weekly paclitaxel. The patients wh o received a year of

continuous trastuzumab starting with the paclitaxel experienced fewer recurrences of breast cancer than those who started their trastuzumab after the paclitaxel was completed.²³ To build on these results, investigators at Memorial Sloan-Kettering Cancer Center have completed a phase II study proving the tolerability of a dose-dense chemotherapy regimen, following the concept in [Figure 3c](#), with a year of trastuzumab starting simultaneously with the paclitaxel portion of the treatment.

Figure 5 (a,b) Impact of growth-inhibitory therapy (that does not inhibit chemotherapy).

However, it must not be assumed that growth-inhibitory therapy must always be given with chemotherapy. [Figure 6](#) illustrates the impact of a growth-inhibitory treatment (cross-hatched box) that interferes with the action of chemotherapy. In [Figure 6a](#), this is given after the chemotherapy is completed and because it has no chemotherapy to disrupt, it yields identical results to [Figure 5a](#). However, in [Figure 6b](#), it is seen that the impact of the treatment on the “red” cells is complex. Because the growth-inhibitory treatment is started earlier on the “red” cells than in [Figure 5a](#), there is a greater effect. But also the impact of the chemotherapy, symbolized by the red arrows, is reduced, which is disadvantageous. The net effect—as measured by the time to 10^{10} cells—is neutral in this simulation. Should the growth-inhibitory drug be better at slowing growth or less interfering with chemotherapy, the net effect would be beneficial to the patient as concerns the “red” cancer cells. But if the drug is less growth-inhibitory or more potent at interfering with chemotherapy, then the net effect would not be beneficial. The other factor in this complex equation is the effect of earlier institution of the growth-inhibitory drug on the “black” cells. Hence, when one is dealing with a drug that might not only slow growth but also interfere with the action of chemotherapy, it would be difficult to predict if it would be better to use the drug during or after chemotherapy. This may explain why when the Southwest Oncology Group tested tamoxifen starting during or after chemotherapy for the adjuvant therapy of hormone-receptor positive primary breast cancer, it found that the sequential plan was superior.²⁴

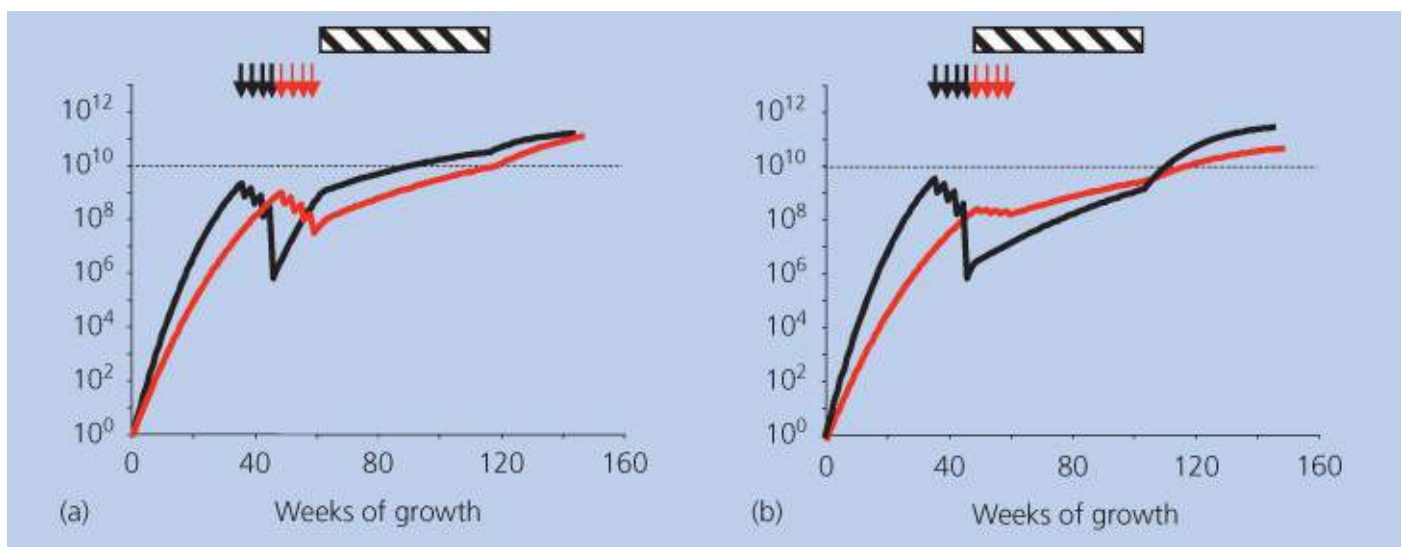

Figure 6 (a,b) Impact of growth-inhibitory therapy (that inhibits chemotherapy).

The etiology of Gompertzian growth

That malignant cellular populations follow Gompertzian growth curves and that such curves are useful in predicting or explaining therapeutic response to anticancer therapy are established by the examples previously. But what is the etiology of this pattern of growth and how does that relate to the other enigmas cited throughout this chapter? An emerging body of work concerning the molecular biology of metastases may provide insight in this regard.

One of the cardinal features of cancer cells is their abnormal mobility. This is manifested on both the phenotypic and molecular levels. Oncogenes often co-deregulate both cell adhesion and mitosis. There exist several sets of gene expression signatures that predict poor prognosis in breast cancer and other diseases, and many of the implicated gene products concern alteration of the microenvironment. These include matrix metalloproteinases, stimulators of angiogenesis, and molecules that influence cell adhesion, shape, and spatial orientation. Laboratory models of metastasis frequently involve genes of these functional classes. Indeed, a poor-prognosis signature in human breast cancer has been created that totally excludes genes associated with proliferation. Yet, in both the laboratory and clinic, tumors with high levels of expression of environment-modifying genes tend to grow rapidly. This raises the question: how do environment-modifying genes, and genes associated with cell mobility, contribute to growth rate *independent* of aberrations in mitosis and apoptosis?

A working hypothesis that has recently proposed this question is illustrated in [Figure 7](#).²⁵ In [Figure 7a](#), we visualize a primary tumor as a collection of cohesive cells in the organ of origin. Some of these cells have the capacity, by virtue of the functions listed earlier, to move, either by direct extension into surrounding tissue (path A) or into blood vessels in their vicinity (paths B and C). We understand that these cells can extravasate in sites of potential metastases (path B), but why cannot they also travel back to the primary site (path C), with preference for locations close to the primary mass where growth factors secreted by cancer and stromal cells should be in abundance? We may term path C *self-seeding* as contrasted with the distant seeding via path B. A later evolution of this process is shown in [Figure 7b](#). Here, the cells spread by paths A, B, and C above have grown by mitosis into masses. In addition, new paths of seeding are now possible: path D, direct extension into the tissue surrounding the metastasis; path E, a self-seed from the metastasis to the metastasis; path F, a seed from the metastasis back to the organ of origin; path G, an exchange of cells within the primary tumor location; and path H, a systemic seed (which may locate in a distant site or return to the primary organ) from a satellite lesion in the primary organ.

Figure 7 (a) Patterns of seeding—early. (b) Patterns of seeding—later.

Although data confirming the existence of these pathways are still accumulating, the implications regarding tumor growth kinetics are so compelling as to merit careful consideration. In [Figure 7b](#), it is apparent that the tumor mass is not a discrete, organized entity but rather a collection or conglomerate of smaller masses. Each, being independent, may induce its own blood supply, perhaps by attraction of marrow-derived circulating endothelial cell precursors as well as cytokine-rich leukocytes. This would explain not only the abundance of vessels in many cancers but the architectural disorganization characteristic of malignant anaplasia. Furthermore, as each of the component nodules of the conglomerate

is relatively small, it is not unreasonable to expect that it would be relatively fast-growing, accounting for the rapid growth of neoplasia in spite of a growth fraction that—as we saw earlier—is not especially large compared with the tissue of origin.

The presence of self-seeded masses in the organ of origin (the progeny of path C in [Figure 7a](#)) that can then send seeds back into circulation (path H, [Figure 7b](#)) would explain why it is necessary to irradiate residual “normal” tissue in organs after the “clean” excision of primary lesions from those organs. The exchange of seeds between sites in the primary lesion (path G) would explain how tumor-initiating or stem cells may become disseminated throughout a tumor mass, rendering sampling for expression profiling practical.

Moreover, growth of a primary mass from the outside-in (self-seeding) as well as the inside-out (mitosis) provides a ready explanation for Gompertzian growth. In the simplest case, a sphere, the surface area is proportional to the square of its diameter while the volume is proportional to the cube of its diameter. As the mass and hence its diameter (d) grow larger, the ratio of surface area to volume drops proportional to $1/d$. As growth from outside-in happens at the surface, the growth fraction would be expected to fall proportional to $1/d$. That is, the relative growth rate would fall as the mass grew large, which is exactly what is seen in Gompertzian growth. Now cancerous masses are not perfect spheres, so the surface area would not be proportional to the diameter raised to a power of two (i.e., squared), but rather a power between two and three. The more aggressive the process of seeding, the more irregular would be the surface of the mass, and the closer the power would be to three. For example, if the self-seeding is very prominent, the surface area may be proportional to $d^{2.9}$, so the growth fraction would fall proportional to $d^{2.9}/d^3$, which is very slowly compared with $1/d$. This would account for the enigma, cited earlier, that the growth fraction falls more slowly with increasing population size than normal tissues with surface areas closer to a proportion of d^2 .

This model would explain the association between anaplasia, growth rate, tumor size, and metastatic potential as follows: many of the same gene functions that permit the movement of a cell into and out of the bloodstream to form a self-seed should be involved in the formation of distant metastases. Hence, cancers that are more likely to involve regional lymph nodes are more likely to metastasize to distant sites because the genetic tool kits for both processes are similar, but not identical, accounting for discrepancies as well. Indeed, the genetic tool kit for preneoplasia may differ only slightly from that of invasive cancer, explaining the enigma of similar polygenetic abnormalities in both types of lesions. Ductal carcinoma *in situ* of the breast, for example, may be a frank neoplasia that is just not very efficient at self-seeding, lacking, for example, the ability to enter or exit the circulation, alter the microenvironment in seeded locations, or attract marrow-derived stromal cells. This line of reasoning would also explain the earlier observation that cell cycle phase lengths are similar in cancer and normal tissues. The cells that seed the component masses of the primary-site conglomerate may be quite normal except for the fact that they are abnormally re-located because of their abnormal mobility. In this regard, a primary breast cancer could be thought of as a contiguous collection of dozens to thousands of embryonic breasts, each within itself close to normal.

The growth by seeding depends to such a large degree on supporting stroma, including or particularly marrow-derived cells that contribute to angiogenesis and matrix formation, would seem to make cancers vulnerable to interventions that attack these component in addition to the cancer cells themselves. This might explain how chemotherapy—which has profound effects on bone marrow—can be so effective against tumor in which five or fewer percent of the cells are in S phase. How the self-seeding model relates to the very controversial but provocative concept of tumor dormancy and the impact of surgical debulking on such dormancy is a topic of active interest.²⁶

The interrelationship of tumor self-seeding and tumor microenvironment

The self-seeding model, as described previously, depends not only on the inherent mobility of cancer cells, but equally on the noncancerous cells, which allow circulating tumor cells to migrate to and survive in distant sites. Ultimately, the tumor microenvironment or “soil” inextricably influences the capacity of cancer cells to grow and thrive. The tumor microenvironment is a complex mix of stromal cells, extracellular matrix, vasculature, and other supportive cells. Each of these factors may uniquely mediate tumor growth and metastasis. Most notably, the recognition that some of these noncancerous cells include the immune system has sparked increasing interest in developing immunotherapies for cancer patients.

Since the late nineteenth century, when Rudolf Virchow first recognized the presence of leukocytes within tumors, immunotherapy has remained largely an elusive strategy to treat cancer. More recently, burgeoning evidence across multiple solid tumors points toward a critical interplay between solid tumors and immune regulating cells. Experimental models suggest that the innate immune system is essential to primary tumor growth and routing metastasis, working in concert to either inhibit or promote growth, invasion, and spread.²⁷ Indeed, tumor-infiltrating lymphocytes, peritumor lymphoid structures, and their associated molecular signatures may have prognostic relevance. Three recent studies noted a potential relationship between levels of tumor-infiltrating lymphocytes and breast cancer prognosis.^{28–30} It also appears that tumor-infiltrating stromal and immune cells may function quite differently than those in the circulation or in the noncancerous tissue.^{31, 32} For example, disseminated tumor cells found in the bone marrow of newly diagnosed breast cancer patients predict an overall poor prognosis, but not all of the patients with cancer cells found in their bone marrow will develop fulminant bone metastasis.³³ More recently, two unique studies suggest a novel role that leukocytes may play in mediating tumor growth and spread. These studies suggest that improving cancer outcomes will come from treating not only the cancer cells but key immune regulator both within the stroma and circulation.

First, the evolving evidence that tumor-infiltrating leukocytes may influence tumor behavior led to the application of genomic profiling techniques, commonly used to identify mutations within tumor cells, to tumor-infiltrating leukocytes in breast cancers. Mutations found in the tumor-infiltrating leukocytes were compared to the mutations found in circulating leukocytes, epithelial cells (buccal swab), as well as those found in the breast cancer cells themselves. In 20 patients, tumor-infiltrating leukocytes from breast cancer samples were matched to 20 peripheral blood/buccal swab samples. In 8 of the 20 patients, within their tumor-infiltrating lymphocytes only, mutations in known cancer genes were identified. These mutations were not found within the tumor cells themselves or the peripheral blood/buccal swab samples. Importantly, somatic mutations in tumor-infiltrating leukocytes occurred in known leukemia genes, including *BCOR*, *TET2*, and *EZH2*.³⁴ Thus, for the first time, somatic oncogenic mutations were identified only among tumor-infiltrating leukocytes in breast cancer samples and not in germline epithelial samples or peripheral circulating leukocytes. Notably, from a morphologic standpoint, these tumor-infiltrating leukocytes appeared entirely “normal.” Investigations are underway to assess the functional role these mutated tumor-infiltrating leukocytes may have in tumor growth and progression.

Second, neutrophils, most often associated with their role against infections, appear to have a polarizing function in response to cancer. Specifically, neutrophils can act either in a protumorigenic³⁵ or in an antimetastatic³⁶ manner depending on relative concentrations of select cytokines. In murine mammary tumor models, for example, it has been demonstrated that neutrophils can be activated by a primary tumor and that these activated neutrophils can inhibit metastatic seeding to the lung.³⁶ In metastatic sites, varying

cytokine levels appear to mediate neutrophil function, and in turn either growth inhibition or progression. In this respect, the tumor microenvironment appears to modulate immune function depending on the relative milieu. In newly diagnosed breast cancer patients with no evidence of metastasis, neutrophil function was explored. Women with newly diagnosed primary breast tumors who were undergoing either a lumpectomy or mastectomy had peripheral neutrophils purified from their circulation at the time of their surgery. These neutrophils were compared to neutrophils purified from the circulation of healthy volunteers with no evidence of cancer. *In vitro* assays demonstrated that the neutrophils from breast cancer patients were cytotoxic to select breast cancer cell lines as opposed to neutrophils obtained from healthy women.³⁶ These experiments suggest that women with intact primary breast tumors activated neutrophils are capable of killing cancer cells in laboratory models. Neutrophils from women with no history of cancer did not share this capacity. Ongoing research will assess whether efforts to stimulate neutrophils in breast cancer patients will improve outcomes. Increasingly, research points to the impact of interactions between cancer cells and hematopoietic cells, both infiltrating and in the circulation, on cancer pathogenesis and therapeutic response. Modeling cancer growth patterns will undoubtedly need to incorporate the integral role of the tumor microenvironment in order to improve clinical outcomes.

Conclusion

In this chapter, we have reviewed the kinetics of cellular proliferation and population growth, finding a theoretical basis for improved practices in cancer chemotherapy. Moreover, we have examined various clinical and laboratory-derived enigmas from a kinetic point of view, finding connections between molecular oncology and the behavior of malignancies on the macroscopic scale. Lastly, it is clear that the kinetics of tumor growth may be connected to the tumor microenvironment and that this microenvironment can evolve both within a primary tumor as well as metastatic sites. This latter science, particularly immuno-oncology, is young but emergent, reinvigorating a mature field that has demonstrated practical worth at the same time as it promises future advances.

Chapter 54

Principles of dose, schedule, and combination therapy

William N. Hait, MD, PhD ■ Joseph P. Eder, MD

Overview

The discovery and development of oncology drugs are complex and associated with a high failure rate. For example, the chance of a new drug that enters clinical trial has an approximately ten percent chance of achieving regulatory approval and ultimately becoming available for patients. Determining the proper dose and schedule of a drug are arguably the two most important determinants of both safety and efficacy, the primary determinants of regulatory approval. Understanding how to best estimate the proper dose and schedule for the many types of therapeutic agents now widely available and in development is a critical skill for those in the drug discovery and development field. This area of expertise has been made more complex with the addition of biological agents such as monoclonal antibodies, alternative protein scaffolds, and vaccines to that of hormones and small molecule platforms. In this chapter, we review the basic principles that underlie the appropriate selection of dose and schedule with a major focus on cytotoxic chemotherapy. In addition, we discuss the many variables that can underlie the dose-response relationship including characteristics of the tumor, the tumor microenvironment, the host including enzymes of drug metabolism and mechanisms of drug clearance. Finally, we review the clinical trial designs that have been successfully used to properly select dose and schedule for oncology drugs.

Introduction

The identification of novel, clinically active agents has been central to progress in cancer chemotherapy. [Table 1](#) presents examples of new agents and of cellular pathways and targets being explored for new therapeutic targets. Dose is a significant determinant of the antitumor activity and toxicology for the established, “classical” cytotoxic chemotherapeutic agents.¹ These agents are DNA damaging agents, directly or indirectly, or inhibitors of cell division, and a quantitative relationship between target interaction and cell lethality is unknown. High-dose chemotherapy (4–10 times the baseline dose), made possible by hematopoietic stem cell transplantation, has proved curative for selected hematologic neoplasms. The FDA is quite explicit in the centrality of the dose–response relationship of any agent for any purpose “Exposure-response information is at the heart of any determination of the safety and effectiveness of drugs. That is, a drug can be determined to be safe and effective only when the relationship of beneficial and adverse effects to a defined exposure is known.”²

Table 1 Molecular targets for cancer treatment

The cell cycle
<ul style="list-style-type: none">• Cyclin-dependent kinases, cyclins, cyclin-dependent kinase inhibitors, and mitotic tubule-associated proteins
Differentiation

The effect of dose for biologically therapeutic agents such as the interferons, interleukins, monoclonal antibodies, hormones, and for molecularly targeted tyrosine kinase inhibitors is complicated, and there is not the same unequivocal evidence for a dose–response effect with these agents. Contemporary targeted agents have a much more specific relationship to the extent of target interaction, such as receptor occupancy (RO) for monoclonal antibodies or extent of phosphorylation inhibition for kinase inhibitors (proof of mechanism) and a measured pharmacodynamics effect (proof of principle), such as phosphorylation inhibition expected to correlate with clinical efficacy in the proper molecularly selected patient segment (proof of concept) than dose alone implies, although in clinical medicine this is the

surrogate used.

The schedule of drug administration may be important to the therapeutic index independent of dose. Cytokinetic studies related to drug schedule have led to the improved use of agents such as cytosine arabinoside (cytarabine, ara-C) in both experimental and clinical leukemia (see the section titled “Cytokinetics of bone marrow”).^{3, 4} Most of the molecularly targeted agents, whether small molecules or monoclonal antibodies, are dosed to provide a continuous effect, which markedly changes the clinical toxicity profile.

Combination chemotherapy has been crucial in the development of curative regimens for hematologic malignancies, pediatric solid tumors, testicular cancer, and ovarian cancer and for the adjuvant regimens for breast, lung, and bowel cancer, and for osteosarcomas.^{5, 6} The rationale for combination chemotherapy is discussed under the various topical headlines. The principal rationales include (1) the empiric: almost all therapy that has proven curative in the clinic involves the use of agents in combination (Table 2); (2) the fact that genetic instability results in tumor cell heterogeneity, which manifests as drug resistance in cancer therapy^{6–8}; and (3) signal transduction inhibitors molecularly targeted to specific cancer driver mutations, with the possible exception of imatinib in some patients with chronic myelogenous leukemia (CML),⁹ invariably induce resistance that can be circumvented by either combining a second agent (dabrafenib and trametinib in melanoma)¹⁰ or using second-generation agent with a broader spectrum of targets specific for the mutations conferring resistance which develop (ceritinib in EML4/ALK mutant NSCLC)^{11, 12} to have significant therapeutic benefit. Although dose and combination chemotherapy are generally considered separately, they have an important and complex relationship.^{13, 14} There is an impressive increase in the number of putative molecular targets for cancer treatment in development (Table 1). A major clinical research challenge will be not only to maximize the effectiveness of individual agents but also to integrate drugs into optimal combination strategies.

Table 2 Number of agents and curative treatment for childhood acute lymphoblastic leukemia (ALL)

Dose

In controlled experimental systems, such as established tumor cell lines in culture, the relationship between dose and tumor cytotoxicity may be close to linear-log (i.e., exponential).¹⁵ For example, a linear increase in the dose of selected chemotherapeutic agents causes a log reduction of MCF7 human breast cancer cells in culture.¹⁶ When the dose is expressed as multiples of the IC₉₀ (i.e., the dose or concentration that reduces the number of tumor cells by 90%), a very good response in terms of tumor regression in a patient is obtained. The estimated total tumor burden for patients with clinically evident

cancer is $5 \times 10^{11} \pm 10^1$ (11 ± 1 logs). Thus, a dose that produces a good partial remission (e.g., 50–90% tumor regression) produces at most a 1-log reduction, which is <10% of the “exponential iceberg.” Numerous factors influence the dose effect. They are presented in the subsections that follow.^{17, 18}

Factors influencing the dose effect

Class of antineoplastic agent

The ideal therapeutic agent would maintain a linear relationship between dose and log tumor cell reduction (log-TCR) down through multiple logs of tumor cell death. Ionizing radiation comes closest to this ideal. As a group, alkylating agents maintained dose/log-TCR superior to the other chemotherapeutic agents. DNA damaging alkylating agents exhibit major activity during the S and M periods of the cell cycle, but unlike other chemotherapeutic agents, they maintain activity throughout the cell cycle. Although comparative studies demonstrate a dose effect in chemotherapy-sensitive tumors such as the leukemias and lymphomas, the effect of dose is less evident in solid tumors, particularly those tumors of epithelial origin.^{19, 20} Purine- and pyrimidine-targeted antimetabolites are active mainly in proliferating cells, and therefore pharmacokinetic resistance occurs that is overcome less by increasing dose than by increasing the duration of exposure, allowing more cells to enter the proliferative compartment. This also applies to the DNA-damaging topoisomerase I and II directed agents and microtubule-interacting agents, where the target must be encountered in the setting of DNA synthesis or mitotic spindle assembly to produce antineoplastic cytotoxicity.^{21, 22}

Agents directed at hormone receptors, growth factor receptors and intracellular kinase signaling targets have a different relationship as once receptor/kinase interactions are saturated, further dose increases will produce no further effect.²³ Hence, these agents are analogous to antimetabolites in that dose escalation once saturation levels of drug are achieved produces no further benefit. Higher doses of imatinib in chronic phase or accelerated phase CML with a suboptimal response to standard dose can benefit a subgroup of patients, but the percentage is low and the duration of response brief.^{24, 25}

Tumor factors

Intrinsic tumor cell sensitivity

The more sensitive the tumor is to a given agent, the steeper the dose effect. Thus, if a unit dose produces a 0.5 log-TCR, then doubling that dose may produce up to a 1.0 log tumor cell kill—which clinically represents only a partial remission. In a chemotherapy-sensitive tumor, where a unit dose produces a 3 log-TCR, doubling the dose may produce up to a 6 log-TCR, depending on the degree of tumor cell heterogeneity and drug resistance (see the section titled “Drug resistance”). A 6 log-TCR would produce a major clinical achievement in terms of complete response, duration of complete response, and, most important, an approach to tumor cure or eradication. Thus, for patients with a metastatic common epithelial tumor, such as breast cancer, the most that can be achieved with standard single-agent chemotherapy is a partial response (<1 log-TCR) in about 30% of patients. Combinations result in higher partial response rates and a low (10–20%) complete response rate. Alternatively, combination chemotherapy regimens in patients with chemotherapy-sensitive tumors (e.g., non-Hodgkin's lymphoma, Hodgkin's disease, and germ cell tumors) may achieve multi-log-TCR as a result of combination chemotherapy.²⁶

Tumor burden

Tumor burden is a consistent adverse prognostic factor for response to chemotherapy. This finding was first demonstrated for transplanted tumors in mice; in these animals, macroscopic (i.e., palpable) tumors often respond minimally to chemotherapy. The same tumor, at a microscopic tumor burden size, may be much more responsive and potentially curable.^{26, 27}

These observations in mice are consistent with the parallel observation that adjuvant cancer treatment can be curative for patients with breast cancer but not for those with overt metastatic breast cancer. Postulates for the delay in growth of microscopic metastases include a balanced rate of cell loss (i.e., apoptosis) and cell production and inability to support tumor neovascularization (angiogenesis). Resistant microscopic tumor may persist in most long-term survivors, an observation that has major implications for therapeutic strategy (see the section titled “Cytokinetics of the tumor—The growth fraction”).

The study of microscopic metastases in patients may become increasingly possible with molecular techniques for detection and characterization of minimal residual tumor.²⁶ The kinetics of microscopic disease can be inferred from adjuvant chemotherapy studies (see the section titled “Adjuvant chemotherapy”).

Drug resistance

In the laboratory, drug resistance is usually produced by “selection pressure”—that is, by exposing target cells to progressively increasing concentrations of the selecting agent. Drug resistance is usually expressed as the concentration of drug that is required to produce 50% inhibition in a colony or growth assay (IC_{50}) for the resistant cell line, divided by the concentration required (IC_{50}) for the parent sensitive cell line. For a detailed presentation of drug resistance, see the section titled “Combination chemotherapy” and 63.

Cytokinetics of the tumor—The growth fraction

The growth fraction (GF) of the tumor and the dose of cell cycle-specific agents have a major effect on the log-TCR of tumor cells. The generation time of cycling (i.e., mitotically active) cells is much shorter than the volume doubling time.^{28–32} Thus, many cells within tumors are dying or “noncycling”—that is, in G_0/G_1 . The GF of a tumor is the ratio of the cycling cells to the total number of tumor cells.

For the common epithelial solid tumors, the GF is often <5%.^{33, 34} A solid tumor with a GF of 5% would be minimally responsive to cell cycle-specific agents and variably sensitive to other chemotherapeutic agents. Repetitive treatments, however, might “recruit” cells into cycle by allowing dormant, noncycling cells access to necessary growth conditions and thus enabling them to be more effective. Prolonged exposure to cell cycle-specific agents might be effective in low-GF tumors. In contrast, a high-GF tumor such as Burkitt's lymphoma might have a multilog response with the same treatment or even the same dose over a shorter period.¹ A recent challenge to the long-standing clonal evolution model of cancer evokes specific cancer progenitor cells (CPCs) as responsible for the continued proliferation of a tumor. By this model, self-renewing CPCs give rise to all progenitor and differentiated cells within a tumor but remain a small proportion of all tumor cells.³⁵ CPCs, as with normal tissue stem cells, are extremely resistant to chemotherapy and radiotherapy.³⁶ The difference between curative therapeutic regimens and those that are only palliative may be attributable to the relative sensitivities of CPCs and the progenitor and differentiated cancer cells incapable of self-renewal. Identification of therapeutic targets within the CPC population should offer significant opportunities for more effective therapies.

Tumor hypoxia

Hypoxia commonly occurs in both experimental and clinical solid tumors, a condition presumably resulting from inadequate angiogenesis and high metabolic activity (oxygen consumption). Oxygen distribution within tumors is heterogeneous and even a small fraction of hypoxic cells can profoundly affect chemotherapy responsiveness. The farther cells are from blood vessels, the lower the concentration of chemotherapeutic agents in those cells. Cellular proliferation decreases as a function of distance from blood vessels, with a significant fraction of nonproliferating cells conferring kinetic resistance to cell cycle-specific agents. Certain cancer chemotherapy agents require oxygen as an intermediate in toxicity or metabolism.³⁷ Finally, hypoxia produces altered gene expression. Hypoxia-inducible factor 1 (*HIF1*) stops proliferation and prevents apoptosis in the hypoxic fraction of cells by increasing angiogenesis. Hypoxia increases the production of hepatocytes growth factor (*HGF*) and its receptor *MET*, with a further increase in angiogenesis, and increased incidence of metastasis and drug resistance.^{38, 39} There may be increased expression of adenosine triphosphate-binding cassette (ABC) proteins such as p-glycoprotein (PgP) that may confer resistance to chemotherapeutic agents. Hypoxia also selects for *TP53* mutants with a reduced apoptotic response to DNA damage or cell cycle arrest targeted agents.⁴⁰ Exploiting hypoxia as a target in cancer therapy with bioreductive alkylating agents such as mitomycin C and the nitroimidazoles, which can serve as electron acceptors in lieu of oxygen, has been tried in numerous clinical circumstances with no or minimal benefit.^{41, 42} Impaired chemosensitivity is not universal, and in selected cell lines (i.e., renal), some drugs appear even less effective in normoxia than hypoxia.⁴³ Radiotherapy in particular requires molecular oxygen for cytotoxicity.⁴⁴

Oncogene addiction-growth factor signaling

The maintenance of the transformed state results in significant metabolic and genetic stress on cancer cells. Maintaining viability under these conditions requires positive anti-apoptotic signaling factors and interfering with these survival pathways can result in tumor cell lethality. In particular, mutant oncogenes such as *BCR-ABL* in CML, or mutant growth factor receptors such as *EGFR* (*ERBB1*) in lung cancer, *BRAF* in melanoma, and *CKIT* in gastrointestinal stromal tumors (GIST) provide essential survival signals and interruption of these pathways produces significant clinical benefit in affected patient. The emergence of diagnostic molecular testing enables identification of patients and permits selection of appropriate therapy.

Host factors

Cytokinetics of bone marrow

Because of the bone marrow's proliferative activity and relative lack of DNA repair capacity, myelosuppression is dose limiting for many chemotherapeutic agents. Exploiting the cytokinetic difference between marrow and tumor has been a basis for the construction of selected clinical strategies.^{4, 28}

Normal marrow recovers within 1–2 weeks after cytarabine, with little cumulative myelosuppression. For many patients, recovery of acute myelogenous leukemia (AML) cells as compared with normal marrow cells between courses of cytarabine is incomplete. AML cells *in vitro* are less susceptible to growth factors such as G- and GM-CSF than are the cells of the normal marrow.⁴⁵ Thus, when marrow CSFs increase in homeostatic response to cytarabine-induced myelosuppression, the interval recovery of normal marrow may be more rapid than that demonstrated by the AML cells, a factor that should, with successive dosing, result in a cumulative effect—the therapeutic advantage.

Similar changes occur in other proliferative tissues, including the gastrointestinal tract, where drugs cause mitotic arrest with loss of epithelial surface cells, including cells involved in the adsorption of fluids. This requires a recovery period just as the marrow does.⁴⁶

Pharmacokinetics

Pharmacokinetic factors commonly affect the dose–response curve. If an inactivating enzyme for the drug becomes saturated, both toxicity and antitumor effect may increase disproportionately, an effect observed with certain dose schedules of 5-fluorouracil (5-FU) for example.^{47, 48}

The opposite effect may occur if a drug activation system becomes saturated. Ifosfamide, a prodrug, is activated by the cytochrome P450, oxygen-dependent, drug-metabolizing enzymes in the liver to the biologically active 4-hydroxyl derivative. The 3-day conventional dose of ifosfamide is higher (1200 to 2400 mg/m² daily) than that for cyclophosphamide (600 mg/m²) because the rate of P450 activation of ifosfamide is relatively slow. With increasing doses of cyclophosphamide, a constant fractional conversion to active 4-hydroxyl cyclophosphamide occurs. However, for ifosfamide, once the P450 enzyme system becomes saturated, a decreasing proportion of ifosfamide is converted into the active form, with a consequent loss of antitumor effect at higher doses.³⁷

Clinical trials and the dose effect

Dose selection in patients

Clearance determines the total drug exposure (area under the curve of concentration multiplied by time [AUC]), and AUC in mice correlates with toxicity in that species. This relationship of AUC with drug exposure and toxicity also holds true in humans and can be predicted from mouse data.⁴⁹ The process for initial dose selection in phase I clinical trials is detailed in 45. In most circumstances, the dose is determined in phase I trials and in other situations is individualized to the body surface area (BSA), weight or exposure (AUC) of the patient.

The Dubois BSA formula is useful in allometric scaling of drug-dose selection between species. The expectation was that similar adjustments would reduce the variability in clearance between patients and is often used in determining the initial dose in first time in human (FTIH) trials. BSA may be helpful in selecting the dose of cytotoxic agents in childhood leukemia and was subsequently incorporated into standard usage.^{50, 51} Recent reviews of the literature and individual institutional experience can find no significant correlation between BSA and clearance variability with investigational or commonly used anticancer drugs except for paclitaxel, oral busulfan, and possibly temozolomide.^{52, 53}

BSA may correlate with glomerular filtration rate, blood volume, and basal metabolic rate.⁵² However, the variability in drug clearance introduced by these factors is small (<25%) compared with that induced by hepatic metabolic enzymes, and there is no correlation between BSA and metabolic activity.⁵²

Cytochrome P450 3A4 (family 3, subfamily A, and polypeptide 4) is the most prevalent metabolic enzyme in humans and is responsible for more than 55% of drug metabolic clearance.⁵⁴ Recent studies utilizing noncancer drugs as indicators of *CYP3A4* metabolic activity, such as midazolam clearance,⁵⁵ suggest potential clinical utility with agents that are metabolized by this pathway—for example, docetaxel.⁵⁶ Enzymatic pathways are responsible for the clearance of 5-FU and 6-mercaptopurine (6-MP) and for glucuronidation via *UGT1A1* for clearance of SN-38, the active product of irinotecan (see individual chapters). Each of these enzymes has a significant incidence of polymorphisms that affect drug disposition

and correlate with toxicity. Persons with the UGT1A1*28 homozygous 7/7 genotype have a reduced capacity for glucuronidation as the major metabolic pathway of SN-38 and higher drug exposure (AUC). Several studies have confirmed a significant correlation among the SN-38 exposure, 1A1*28 genotype, and severe neutropenia and diarrhea.⁵⁷ Pharmacogenetic profiling offers the prospect of individualized dose selection in the future and is a frequent component in early clinical drug development. These DNA-based tests are not commercially available yet and have no clinical role at the present time.

Glomerular filtration rate as estimated from serum creatinine does correlate with toxicity for topotecan, etoposide, and carboplatin. Indeed, calculated AUC from serum creatinine (Calvert formula) is now used to dose carboplatin.⁵¹ At present, these alternatives (except for carboplatin AUC dosing) remain under investigation, and BSA-based dosing remains the standard of clinical practice for classical chemotherapy agents.

All the molecularly targeted tyrosine kinase inhibitors approved for clinical use as well as the many more in clinical development are administered as a flat dose with no adjustment for weight or BSA. Dose selection of monoclonal antibodies used in cancer medicine also does not follow a classical dose escalation to toxicity. RO of a surface glycoprotein target is a quantitative measure of an appropriate dose of agents directed at surface proteins (i.e., anti PD 1 immune checkpoint agents) or depletion of a circulating protein (VEGF (vascular endothelial growth factor) and bevacizumab).

Real-time pharmacokinetics and patient safety

Pharmacokinetic studies provide important information regarding the dose effect. Such studies indicate substantial variation in serum drug levels and in the AUC per given dose. For methotrexate and 6-MP in acute leukemia and for high-dose busulfan and carmustine bis-chloroethylnitrosourea (BCNU) in the transplant setting, the AUC level of drug or its active metabolites (or both) correlates with toxicity and therapeutic effect.^{58–61}

Plasma levels of methotrexate used in high doses ($>1 \text{ gm/m}^2$) in selected settings of ALL or DLBCL are clinically tested and are used to determine the duration and dose of leucovorin rescue in these patients.⁶² Substantial variation in the AUC per given dose of paclitaxel was also observed in patients with solid tumors. Real-time adjustment of dose on subsequent days significantly reduced mucositis requiring morphine administration and decreased the duration of hospital stay.⁶³

Dose effect in sensitive tumors

Few clinical studies have included dose intensity as an independent, randomized variable. In a Cancer and Leukemia Group B (CALGB) study, 596 patients with AML were randomized to receive four 5-day courses of cytarabine at one of three dose schedules: (1) 100 mg/m^2 daily (standard arm), (2) 400 mg/m^2 by continuous infusion, or (3) 3 g/m^2 in a 3-h infusion every 12 h (twice daily) on days 1, 3, and 5.³ For patients 60 years of age or younger, the probability of remaining in continuous complete remission after 4 years was 24% in the 100 mg/m^2 group; 29% in the 400 mg/m^2 group; and 44% in the 3 g/m^2 group ($p = 0.002$), indicating a better response with increased dose. Elderly patients were less responsive. In acute lymphocytic leukemia (ALL), the dose rate of maintenance chemotherapy had a major impact on the duration of response.⁶⁴ Similarly, in studies of combination chemotherapy in small cell lung cancer, the dose effect was significant, albeit with outmoded therapy.⁶⁵

Increased doses of anthracycline combined with standard dose cytarabine in the initial therapy of patients with AML resulted in an increase in CR rate and PFS (progression free survival) in both young and

elderly patients.⁶⁶

Dose–response effects are less well studied in the new kinase inhibitors, which tend to be dosed at the maximum tolerated daily dose, leaving little opportunity for significant increases. Increasing doses of imatinib in patients with chronic phase or accelerated phase CML and in GIST show an increase in response rate in a subgroup of patients. In cases where resistance to imatinib is due to increased metabolic clearance, increased activity of PgP or amplification of the *BCR-ABL* gene, this might be expected although responses were seen even in patients with mutations in the *BCR-ABL* kinase itself.^{24, 25, 67, 68}

In treating individual patients, dose is a key factor if cure is possible. Thus, for leukemias, lymphomas, testicular cancer, childhood solid tumors, and conventional-dose adjuvant treatment of breast cancer, dose should not be compromised even at the risk of significant toxicity. For more resistant tumors, where palliation is the goal, dose should be adjusted primarily on the basis of toxicity.

Peripheral blood stem cell and marrow transplantation

Allogeneic bone marrow transplantation produces disease-free survival plateaus (i.e., cures) in patients with acute and chronic leukemias and lymphomas, but because of the effect of graft versus leukemia, the component contributed by dose cannot be independently evaluated.

The most compelling evidence regarding dose–response is in high-dose, autologous stem cell rescue studies in patients with relapsed lymphoma.^{69, 70} Alkylating agents and total body radiotherapy-based regimens are commonly used because their dose-limiting toxicity is myelosuppression. Depending on the agent, dose can be escalated between 3 and 20 times baseline before nonmyelosuppressive toxicity becomes dose limiting. Given the considerable overlap of AUCs for serum levels of drugs at dose escalations of 2–4 times baseline, the escalations possible with stem cell support allow better comparisons of the effect of dose. High-dose therapy with autologous stem cell rescue produces high complete response rates and cures in non-Hodgkin's lymphoma and testicular cancer.^{70, 71} However, because toxicity can be lethal, high-dose therapy should be limited to specialized centers.⁷²

Adjuvant chemotherapy

Randomized studies

Cytokinetics provides an experimental basis for many therapeutic designs. A brief review of the related history follows.

Skipper et al.¹⁵ established the fundamental exponential relationship between drug treatment and surviving tumor fractions. It is the fractional TCR that is constant for a given dose and drug. Although this exponential relationship is modified by other factors, such as drug resistance and microenvironment, it remains the fundamental tenet of cytokinetics and chemotherapy. Norton and Simon⁷³ applied Gompertzian theory and analysis to treatment during remission and demonstrated the potentially greater effectiveness of late intensification. Goldie and Coldman⁷⁴ introduced the mutation-to-resistance theory, relating tumor burden and inherent mutation rate to potential for cure. Hryniuk and colleagues found a significant dose–response effect not only in the leukemias and lymphomas but also in the relatively less chemosensitive tumors, such as breast cancer.^{75–77}

The adjuvant setting, where the tumor burden is microscopic, should be ideal for demonstrating a dose effect. There, many factors that could reduce tumor cytotoxicity (tumor size, decreased and abnormal

vascularity, low GF, hypoxia, and increased tumor heterogeneity) and contribute to chemotherapy resistance are less evident in the microscopic tumor (adjuvant) setting. Combination chemotherapy with cyclophosphamide, methotrexate, and 5-FU (CMF) or with cyclophosphamide, doxorubicin (Adriamycin), and 5-FU (CAF), which produces only transient partial and a few complete responses in metastatic breast cancer, reduces relapse and mortality rates by 20–30% in the adjuvant breast cancer setting.⁷⁸ Similar effects are seen in colon cancer.⁷⁹

Attempts to improve disease-free survival by increasing the adjuvant chemotherapy dose in breast cancer have produced mixed results. The first statistically robust positive study was conducted by the CALGB.¹⁹ Patients with node-positive breast cancer were randomized to one of three CAF regimens. The high-dose arm involved four courses of CAF at doses of 600 cyclophosphamide, 60 doxorubicin, and 600 mg/m² 5-FU every 3–4 weeks; in the low-dose arm, the doses were 300, 30, and 300 mg/m², respectively. A 10% difference in the relapse-free curve developed by 2 years and persisted through 10 years. That result represents an approximately 20% reduction in mortality. The dose effect was seen most prominently in the 20% of patients whose tumors overexpressed *ERBB2* (*HER2/neu*). For tumors without *ERBB2* overexpression, no significant dose effect was seen.^{20, 80, 81} This subset effect would not have been identified in the absence of the molecular marker.

Two other studies conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP) failed to show that a 2 or 4 times increase in the dose of cyclophosphamide alone affected response in terms of relapse or survival in adjuvant breast cancer.^{80, 81} Thus, in the comparative study of CAF, the dose of doxorubicin was probably important; however, in another study of adjuvant breast cancer, patients randomized to three doses of doxorubicin⁸² (60, 75, and 90 mg/m², all given with the standard dose of cyclophosphamide) showed no difference in disease-free or overall survival (OS). The 60 mg/m² is probably a threshold dose, above which no further benefit accrues.

The basis for the seemingly discordant results of dose in major clinical trials has been the subject of preclinical and mechanism-of-action studies, but it remains unexplained. It can be speculated how often in the analysis of large comparative studies an important effect has been missed within a subset not known to exist at the time. That possibility is an important limitation in the interpretation of negative studies.

Dose-dense chemotherapy

The concept behind dose-dense chemotherapy is to increase the intensity of drug administration by shortening the interval between treatments without increasing the total dose of drug administered. This increase is accomplished by escalating the dose or the number of cycles in a given period of time. The use of neutrophil-colony-stimulating factors is an essential requirement for dose-dense therapy. Interim reports on the CALGB 9741 study, the use of dose-dense therapy with cyclophosphamide, doxorubicin, and paclitaxel in adjuvant breast cancer, either concurrently or sequentially in 2-week as opposed to the standard 3-week cycles significantly reduced the annual risk of recurrence or death. The DFS (risk ratio [RR] = 0.74, *P* = 0.10) and OS (RR = 0.69, *P* = 0.013) were prolonged in the dose-dense arms. There was no difference in either DFS or OS between sequential and concurrent therapy. There was no interaction between dose-density and sequence. This preliminary report supported the concept of dose-dense intensification as a means to enhance chemotherapy efficacy, albeit at a cost of increased toxicity.⁸² Definitive randomized trials have not confirmed these initial reports, although not all the studies are completed.⁸³

Summary

In the clinic, the effect of dose correlates generally with the basic chemosensitivity of the tumor. Thus, Burkitt's lymphoma, ALL, and testicular cancer are all highly sensitive and highly responsive to dose intensity, including achievement of cure. On the other hand, relatively insensitive tumors such as gastrointestinal and lung cancers respond poorly to chemotherapy and are not significantly affected by dose. There are clearly unknown factors at work in the human cancer patient, which continue to defy simple explanation, among them the complex milieu of the inherent genetic background in the particular cell type and patient in which cancer arises, the effect of somatic and nontransformed stromal cells, the emerging role of cancer stem cells and other unappreciated factors not accounted for by the reductionist *in vitro* and *in vivo* models on which cancer researchers depend.

Schedule of drug administration

Schedule effects of individual agents

Cytarabine

Skipper and colleagues performed elegant, quantitative studies of L1210 mouse leukemia using the prototype cell-cycle phase-specific agent cytarabine.^{4, 15} Cytarabine was shown to produce optimal therapeutic effects when given in courses of appropriate duration and with intervals that allowed for recovery of normal bone marrow. Extrapolating their work to human AML, the investigators gave patients repeated courses of a continuous infusion for 5–7 days separated by 2–3 weeks for recovery. In patients with AML, this schedule produced a 30–40% complete response rate as compared with 10% for other schedules, such as daily intravenous administration.^{4, 84, 85} The addition of daunorubicin to cytarabine further increased the complete response rate and has become the backbone for remission induction therapy for the treatment of AML in adults for more than four decades (for details, see the section titled “Cytokinetics of bone marrow”).

Gemcitabine

The dose-limiting toxicity of gemcitabine, a nucleoside analog structurally related to cytarabine, is myelosuppression.^{86, 87} Unlike cytarabine, gemcitabine has activity in solid tumors, particularly in pancreatic, breast, and non-small-cell lung cancer. Weekly or biweekly bolus treatments are well tolerated, with toxicity largely limited to the marrow. Clinically and in experimental animals, gemcitabine given by continuous infusion necessitates a marked reduction in dose, particularly because of myelosuppression but also because of gastrointestinal toxicity and, in some circumstances, hypotension.⁸⁷

Methotrexate

Intermittent methotrexate (5-day bolus courses every 3–4 weeks), developed by Li and colleagues for gestational choriocarcinoma, proved to be curative.⁸⁸ Goldin et al.⁸⁹ demonstrated in L1210 mouse leukemia that intermittent methotrexate was superior to continuous (daily) methotrexate. In a randomized, comparative study of patients with ALL in complete remission, intermittent methotrexate was significantly superior to daily therapy.⁹⁰ This empiric observation is consistent with subsequent findings by Schimke et al.,⁹¹ indicating that continuous exposure to methotrexate *in vitro* produces drug resistance more consistently than does intermittent methotrexate. Moreover, with continuous administration, resistance results from gene amplification as compared with a transport defect following intermittent methotrexate.^{91, 92} The kinetics of bone marrow recovery and mucosal cell replacement, important in cytarabine

scheduling, may be important clinical determinants of scheduling with methotrexate as well.

Fluoropyrimidines

In clinical studies, 5-FU is commonly administered in daily pulse doses of 350–450 mg/m² for 5 days. Using that schedule, myelosuppression is dose limiting. Twice that dose can be delivered by continuous infusion over 5 days, in which case mucositis and diarrhea become dose limiting.⁹³

Fluorodeoxyuridine (FUDR) is much more toxic when delivered by continuous infusion than by intermittent bolus dosing. For example, daily doses in the range 30–50 mg/m² produce toxicity. The biochemical basis for the schedule difference is speculative. Continuous-infusion FUDR may have a greater effect on DNA synthesis; other schedules have a relatively greater effect on host tissue ribonucleic acid (RNA) and RNA synthesis.⁹³ Data regarding the effect of these differences in schedule on the therapeutic index are few. (Modulation with leucovorin is discussed later in this chapter.) Longer durations of systemic administration currently are under study.⁹⁴

Capecitabine is an oral prodrug of 5-FU. It has allowed protracted administration with opportunities for increased effectiveness and simplicity of administration. It has not fully supplanted intravenous 5-FU in all indications, as in the FOLFOX regimen for colorectal and gastric cancer.⁹⁵

Thus, mechanisms of action, resistance, and cross-resistance for 5-FU appear to differ depending on the analog chosen and the schedule of administration, among other factors.⁹⁶

Alkylating agents

The alkylating agents are a heterogeneous group of compounds that have in common interaction with DNA. That interaction leads to malignant transformation of mammalian cells in culture and to carcinogenesis in patients. The cytotoxic action of these agents is produced by the addition of an alkyl (CH₃) group and/or intra- and interstrand linkages that impair or prevent DNA replication directly or produce lethal double-stranded breaks if not fully repaired by DNA damage repair mechanisms, which are frequently defective in transformed cells. This mutagenic interaction also explains its teratogenic and carcinogenic potential.

The alkylating agents are of equal potency in terms of antitumor effect. The difference is primarily host toxicity. This variation in toxicity is particularly true for the dichloroplatinum group of compounds, which closely resemble X-radiation in terms of antitumor effect. They are substantially different in toxicity depending on the nature of the trans-adducts. Most experimental data regarding alkylating agents suggest that they are schedule independent: that is, the antitumor and host effects are dose-related, independent of schedule.⁹⁷ (See the sections titled “Pharmacokinetics” and “Adjuvant chemotherapy” for discussions of specific aspects of cyclophosphamide and ifosfamide.)

Anthracyclines

Cardiotoxicity is an important delayed toxicity of anthracyclines. In experimental studies, peak concentrations produced more cardiotoxicity for an equivalent dose than did lower concentrations achieved by continuous-infusion schedules. Weiss and Manthel⁹⁸ first demonstrated that weekly doxorubicin administration produced less cardiotoxicity per total dose administered than did standard triweekly regimens. Legha and colleagues demonstrated that a 4-day, continuous infusion of doxorubicin every 3 weeks is less cardiotoxic than bolus injections, an observation confirmed in randomized studies.^{99–101} Infusion approaches allow a 30–50% increase in total cumulative dose before

cardiotoxicity develops. In experimental and preliminary clinical studies, liposomal doxorubicin may be less cardiotoxic than doxorubicin.^{102, 103} The use of the cardioprotective agent dexrazoxane is current clinical practice in selected settings.¹⁰⁴

Etoposide

An inhibitor of topoisomerase II that produces DNA double-strand breaks, etoposide is selectively active against cells in cycle. Etoposide is commonly used in combination chemotherapy of solid tumors, particularly with cisplatin. Preclinical studies showed that etoposide must be present both during and immediately following cisplatin to achieve optimal effect, consistent with a possible interaction with cisplatin involving inhibition of DNA repair. In small cell lung cancer, the optimal etoposide dose schedule of five daily doses every 3–4 weeks is consistent with the discussion earlier in this chapter of marrow and tumor cytokinetics and response to cell cycle-specific agents.¹⁰⁵

Tubulin binders

Although the *Vinca* alkaloids vincristine and vinblastine are cell cycle-specific, no schedule appears superior to standard weekly dosing.¹⁰⁶ On the basis of limited data, the same is true for vinorelbine. Paclitaxel schedule considerations have been dominated by acute histamine-like toxicity, probably related to the vehicle (Cremophor EL); this toxicity is relieved by antihistamines and corticosteroids. Practical and economic considerations favoring outpatient use have resulted in 1- to 3-h intravenous infusions, although some randomized trials suggest an advantage for infusions that are even longer.¹⁰⁷

Weekly infusions are superior to intermittent administration in breast and ovarian cancer.^{108, 109} Myelosuppression correlates with the duration of plasma concentrations of paclitaxel above the threshold of 0.1 mol/L.¹⁰⁷ Neutropenia appears to be related more to schedule than to dose, although neuropathy appears dose related.¹¹⁰

General use of intermittent dosing

For most chemotherapeutic agents that directly or indirectly target DNA or the mitotic spindle used alone or in combination, intermittent courses (e.g., four 5-day courses every 3–4 weeks) are generally superior to other schedules such as continuous (i.e., daily) dosing. Such is the case for cyclophosphamide and methotrexate in Burkitt's lymphoma, methotrexate and actinomycin D in choriocarcinoma, melphalan in myeloma, cytarabine in AML, and methotrexate in ALL.¹¹¹ It is also true for combination regimens for Hodgkin's disease, ALL, and childhood solid tumors.^{106, 111, 112} In experimental and clinical studies alike, intermittent intensive treatment for rapidly proliferating tumors is superior. The reason may be recruitment of resting G_0/G_1 cells into active cycle. Continuous treatment may be superior for more indolent, low-GF tumors, but more definitive studies are needed.¹¹³

Advances in supportive care now allow a novel approach to intermittent intensive chemotherapy. Neutrophil colony stimulating factors in dose-dense adjuvant breast cancer therapy¹¹⁴ or leukapheresis following marrow recovery from chemotherapy and treatment with G-CSF allow the harvest of sufficient peripheral blood circulating stem cells to rescue as many as four courses of moderately intensive chemotherapy.¹¹⁵

Continuous administration

Protracted infusions (6 weeks) of 5-FU combined with local radiotherapy in adjuvant rectal cancer

demonstrated both a lower local recurrence rate in the irradiated field and a reduced incidence of metastatic relapse.¹¹⁶ Capecitabine is an orally absorbable agent that undergoes biotransformation to 5-FU. Prolonged administration over 14 days of capecitabine as a single agent, repeated at 21-day intervals, shows a response rate that is superior to that of intravenous 5-FU and leucovorin, although no survival benefit accrues.^{117, 118} Capecitabine is also active in refractory breast cancer as monotherapy or in combination. The role of continuous fluoropyrimidine administration with capecitabine is being explored in combination chemotherapy and with radiation. The treatment interruption every 3 weeks does seem to significantly reduce dose-limiting hand-foot syndrome toxicity with capecitabine.

Targeted kinase inhibitors

For reasons related to the mechanism of action, continuous oral administration of many new targeted therapies such as imatinib in CML and GIST is the current clinical schedule.^{113, 119} The continued suppression of proliferative growth factor signals and interruption of survival pathway signals in tumor cells or the tumor vascular network appears necessary in the clinic and in preclinical models. One clinical trial of a randomized discontinuation of the multitargeted tyrosine kinase inhibitor sorafenib in renal cell cancer patients with stable disease demonstrated a significant PFS advantage at 6 months for patients who continued to receive sorafenib versus placebo, which supports the preclinical modeling in the clinic.¹²⁰ For other agents such as the multi-kinase inhibitor sunitinib, intermittent schedules are used because of better tolerance, similar to the DNA damaging agents and mitotic spindle inhibitors.¹²¹

Combination chemotherapy

Rationale

The most compelling rationales for combination chemotherapy are (1) tumor cell heterogeneity and its implication for drug resistance and (2) the success of combination chemotherapy in the clinic. In practical clinical terms, the selection of specific combinations in particular types of cancer depends on the individual activity of the agents in the target cancer type and the absence of overlapping toxicities. The agents with the highest single-agent activity are preferred, particularly agents that produce complete responses (if any such agents exist), with different mechanisms of action to address the theoretical heterogeneity issue.

Combination chemotherapy in the clinic

Ample clinical precedent exists for using multiple agents. An example is the treatment of ALL in children, where multiple active agents have been identified. A direct correlation is seen between the number of agents used and the cure rate ([Table 1](#)). In fact, essentially all curative chemotherapy involves combinations of two and usually three or more agents ([Table 3](#)). Curative combinations need not incorporate each agent at each dosing encounter; for example, the sequential use of taxanes after doxorubicin and cyclophosphamide in breast cancer or in pediatric soft tissue cancers, but within a patient's total treatment course. Normal tissue tolerance often limits the number of agents that can be administered at one time).

Table 3 Cancer chemotherapy—number of agents required for cure by tumor type

Tumor	Number of agents required for cure	Adjuvant or neoadjuvant	Number of agents required for cure
Acute lymphoblastic leukemia (children)	4–7	Wilms tumor	2–3
Gestational choriocarcinoma ^a		Embryonal rhabdomyosarcoma	2–3
Early	1–3	Osteogenic sarcoma	3
Advanced	2–4	Soft tissue sarcoma	3
Acute myeloid leukemia	3+	Ovarian cancer	3–4
Testicular cancer	3	Breast cancer	2–4
Burkitt lymphoma ^b	1–4	Colorectal cancer	2
Hodgkin disease	4–5	Non-small-cell lung carcinoma, stage IIIA	2
Diffuse histiocytic lymphoma	4–5	Small-cell lung carcinoma, limited	2–4

^a One agent is curative, but a higher cure rate results with two or more agents.

^b One agent cures state 1 African Burkitt lymphoma, but two or more agents are better.

Current studies have demonstrated evidence for synergy or an additive effect between established DNA/mitotic spindle targeted chemotherapeutic agents and agents representing other classes. Molecularly targeted agents, whether monoclonal antibodies or small molecules, have been combined with cytotoxic agents as well as other targeted agents. Trastuzumab, a monoclonal antibody to *ERBB2*, is synergistic with doxorubicin and paclitaxel. *ERBB2* is present on the cancer cell surface in 25% of patients with breast cancer, and benefit is restricted to only those patients with amplification of the *ERBB2* gene.¹²² Toxicities may be substantial, however. Trastuzumab in combination with doxorubicin increased cardiac toxicity. A lesser risk of cardiac toxicity exists when trastuzumab is included in paclitaxel combinations. The addition of a complement-fixing monoclonal antibody, rituximab, to cyclophosphamide, hydroxydaunomycin/doxorubicin, vincristine sulfate, and prednisone chemotherapy in non-Hodgkin's lymphoma increases response without an increase in toxicity. The addition of the mTOR inhibitor everolimus to an aromatase inhibitor (AI) markedly prolongs the PFS in estrogen receptor-dependent metastatic breast cancer.¹²³ The addition of the CDK 4/6 inhibitor palbociclib to an AI increases the PFS in ER positive breast cancer.¹²⁴ This compatibility of new and old is not to be assumed, as combinations of cytotoxic chemotherapy with both erlotinib and gefitinib fail to produce significant benefit in lung cancer.¹²⁵

The combination of multiple targets in a single molecule can be incorporated into novel molecularly targeted agents. Certainly, multiple targets within a single small molecule, such as VEGFR and PDGFR, in the angiogenesis pathways produce greater clinical benefit than targeting either alone, as the success, limited as it may be, of single agent sorafenib and sunitinib demonstrates *viz-a-viz* single agent, including bevacizumab and many failed compounds limited to VEGFR2 alone.¹²

Multiple agents can be directed at a single target protein or to sequential proteins in a single pathway essential to the neoplastic process. Combining the monoclonal antibodies trastuzumab and pertuzumab,

which bind to different epitopes of the ERBB2 receptor, produces unprecedented OS in ERBB2-expressing metastatic breast cancer.¹²⁶ Sequential inhibition of BRAF and MEK in BRAF^{V600E} melanoma produces greater response rates, PFS and OS.¹⁰ All-trans-retinoic acid and arsenic trioxide interact with the PML protein in acute promyelocytic leukemia cells with resultant differentiation and durable remission.¹²⁷

Technology has reached a point where a monoclonal antibody can be conjugated to a small molecule to deliver therapy in a highly selective manner, such as the T-DMI conjugate of trastuzumab and auristatin in breast cancer or radioactive yttrium to anti CD30 in Hodgkin's lymphoma.^{128, 129}

Tumor cell heterogeneity and drug resistance

Tumors are clonal in origin, but the increasing DNA instability that accompanies the onset of neoplasia leads to increased variation in the daughter cells, called “clonal evolution” to tumor cell heterogeneity. This evolution is associated with selection for progeny with greater survival capacity, which is evident as higher proliferative capacity, resistance to apoptosis, greater metastatic or invasive potential, reduced dependence on normal cellular growth factors, and angiogenesis.¹³⁰ Heterogeneity among tumor cells increases the number and diversity of potential target sites for chemotherapy and the need to combine therapeutic agents.

Initially, resistance was thought to be limited to the selecting agent (mono-drug resistance). The recognition of multidrug resistance required a reexamination of this rationale for combination chemotherapy.¹³¹ The ABC family of transport proteins such as (*ABCB1*, PgP), the multidrug resistance proteins (*ABCC1*), and the breast cancer-related protein (*ABCG2*) confer multidrug resistance that relates almost exclusively to natural products. Prolonged exposure to low doses of substrate drugs such as doxorubicin may overcome resistance mediated by these transport proteins.¹³² However, glutathione transferase, DNA repair capacity, and topoisomerase II alterations also may be associated with multidrug resistance.¹³³

Recent studies of multicellular drug resistance indicate an altered set point for apoptosis.¹³⁴ Differences between *in vitro* and *in vivo* drug resistance are modifying the approach to combination chemotherapy.¹³⁵ Although prolonged drug exposure results in stable, resistant cell lines, acute exposure may induce short-term, reversible resistance. How the short-term resistance relates mechanistically to the long-term, presumably genetic, resistance is under study.

The advent of molecular profiling of patient tumors as a clinical means of treatment selection continues to emphasize the heterogeneity that exists within a single tumor at a single point in time and also the variability that occurs over time in a single tumor and the heterogeneity that exists in a single point in time in different metastases in the same patient. New treatment algorithms are being developed to address this complex problem (see 42 for a more detailed discussion).

Cytokinetics

The discovery that solid tumors contain a large number of potentially clonogenic cells in G₁ or G₀—presumably because of tumor hypoxia and a low GF—provided a basis for combination chemotherapy.^{27, 28, 33} Thus, cell cycle-specific agents were employed to kill mitotically active cells, and non-cell cycle-specific agents (e.g., alkylating agents) were added to damage the noncycling tumor cells. The use of repeated cycles allows normal tissues to recover, so that dose need not be compromised, and G₀/G₁ tumor cells can be recruited into the proliferating fraction by increased availability of nutrients, oxygen, and

vascular access.

Synchronization

Synchronization of tumor or normal cells *in vitro* and *in vivo* with drugs that inhibit DNA synthesis or that arrest cells in mitosis can be achieved. Experimentally, the most impressive synchronization has been achieved with hormonal agents that affect tumor but not essential normal cells.

Some degree of tumor-cell synchrony follows this hormonal manipulation in experimental studies but the heterogeneity of human tumors with regard to the time course of recruitment and synchronization has limited this approach, and it remains investigational.^{136, 137}

Modulation

Agents that are nontoxic may still improve the therapeutic index of an established chemotherapeutic agent, either by reducing normal-tissue toxicity—as leucovorin does for methotrexate, for example—or by preferentially enhancing antitumor efficacy—as 5-FU and leucovorin do in metastatic and adjuvant colon cancer studies.^{138–144}

Biochemically, the product of 5-FU, fluorodeoxyuridine monophosphate (FdUMP), binds to the substrate site of thymidylate synthase (TS), thus inhibiting DNA synthesis and, therefore, cellular replication. The stability and duration of this inhibition directly relate to a third agent, 5, 10-methylenetetrahydrofolate, which is a metabolic product of leucovorin that also binds to TS, producing the so-called ternary complex (FdUMP—TS—5,10-methylenetetrahydrofolate). In preclinical systems, *in vitro* and *in vivo* alike, leucovorin favorably modulated the therapeutic index of 5-FU. A number of clinical trials comparing 5-FU to 5-FU with leucovorin indicated an advantage for 5-FU/leucovorin in patients with metastatic colorectal cancer at a cost of only moderately increased mucositis and diarrhea. The combination of 5-FU with leucovorin improved survival rates in two separate studies in metastatic and adjuvant colon cancers.^{143, 144}

Bevacizumab (Avastin) is a monoclonal antibody that depletes serum VEGF. VEGF is an essential mitogenic and antiapoptotic factor for endothelial cells (*see* 11). Signaling through the VEGF receptor 2 (KDR) and platelet-derived growth factor receptor beta (PDGFRB) acts to increase endothelial cell permeability, which results in increased interstitial fluid pressure (IFP) within tumors. In colon, breast, lung, head and neck, cervix, and skin carcinomas, the IFP is significantly higher than in normal tissues.^{145–}

¹⁴⁸ Increased tumor IFP acts as a barrier for tumor transvascular transport; reduction of tumor IFP, or modulation of microvascular pressure, increases the transvascular transport of tumor-targeting antibodies or low-molecular-weight tracer compounds.^{149, 150} Growing evidence indicates that the PDGFRB and KDR tyrosine kinases play a crucial role in increased tumor IFP. That makes them candidate targets for pharmacologic intervention for tumor interstitial hypertension^{151–154} and for a novel, possibly general, combination strategy that will enhance the therapeutic effects of standard chemotherapeutics.

Bevacizumab reduces the IFP in patients with advanced colorectal cancer and increases the uptake of gadolinium in the tumors. Combined with irinotecan, 5-FU, and leucovorin, bevacizumab produces a significant prolongation of survival in patients with metastatic colorectal cancer.¹⁵⁵ This modulation of IFP occurs only within tumors and provides a selective increase in drug levels to the tumor without increasing host toxicity, as was noted in both of the latter two studies. Those findings offer a general treatment strategy for solid tumors of any type.

Bevacizumab (and similar agents) combined with cytotoxic chemotherapy has shown improvements in PFS and OS in many—though not all—types of cancer. Given the many mechanisms of VEGF action, it is

uncertain which mechanism(s) mediates this effect. That VEGF-targeted therapy is more effective in combination, concurrent or sequential, than as a single agent denotes it as a modulator in most clinical circumstances.

Implications of drug resistance

Tumor cell heterogeneity in response to the potentially cytotoxic and antiproliferative effects of cancer chemotherapeutic agents has been the stimulus for a current novel approach to combination chemotherapy. Avoiding therapeutic resistance has been from the beginning a major rationale for combination chemotherapy.

Initial observations about resistance involved reduced drug levels at the site of action because of increased efflux, alteration or amplification of the target, and cellular inactivation. Recent investigations have focused on mechanisms of drug sensitivity or resistance operative after interaction of the drug and its target receptor, including apoptosis (programmed cell death). The cell damage caused by various chemotherapeutic agents has the common property of triggering the apoptosis cascade in an active process that requires energy, enzymes, and cytostructure for completion.¹⁵⁶ In addition to apoptosis, under certain circumstances, cells undergo necrotic cell death owing to drug-induced depletion of ATP.¹⁵⁷ Finally, autophagy, a highly conserved process of cell survival under conditions of nutrient and or oxygen deprivation can lead to a previously unappreciated form of drug resistance following treatment with cytotoxic drugs, hormonal agents, and radiation.¹⁵⁸ Drug resistance must always be viewed in the context of therapeutic index. Resistance fundamentally means that there exists no selective cancer cytotoxicity in relation to toxicity in the cancer-bearing host. This may be present at the outset or become apparent only during therapy. This narrow or lack of therapeutic index is present in most cancer therapeutic agents.

Reversal of drug resistance

Another approach to modulation involves reversal of drug resistance, the most studied of which is multidrug resistance mediated by PgP. Verapamil and several other lipid-soluble heterocyclic drugs, including cyclosporine analogs, can inhibit PgP and thus reduce the efflux of a number of natural antitumor products (doxorubicin, vincristine, taxanes, and others) from the cell, thereby increasing cytotoxicity. PgP is increased in B-cell tumors, AML, sarcoma, and tumors previously treated with drugs that led to multidrug resistance.¹⁵⁹ This approach has not yet produced significant clinical benefit in clinical trials or practice.

Molecular biology/targeted therapy

Implications for dose and schedule

The level of optimism among researchers has increased substantially as a result of recent “proof of concept” regarding the clinical effectiveness of more-targeted therapies. Evidence for unique molecular targets in cancer cells (e.g., fusion genes, mutations, and recombinations) and on their surfaces has led to synthesis of small molecules and monoclonal antibodies with a target specificity achieved only rarely in cancer therapeutics.^{160–162}

[Table 2](#) presents a sampling of combinations of molecules and biochemical pathways that are currently being evaluated as targets for selective antitumor agents. The magnitude of such activity and the number of active agents in preclinical systems offer remarkable opportunities for the use of agents in combination.

The cumulative effect of these agents on a molecular level suggests an interaction that may result from the diversity of target interaction and a sequential or simultaneous attack on critical cell behavior.

Another important area of diversity relates to anticipated toxicity. Thus, as compared with classical chemotherapy agents, where dose-delineating toxicity usually relates to proliferating tissues and is relatively uniform, the molecular biologic agents will almost certainly express toxicity that varies from agent to agent and that largely differs from the classical antitumor agents. Molecular agents are under extensive study not only for their antitumor properties but also most particularly for their interaction with each other and other established antitumor agents.

Experimental models of combination therapy

The classical antitumor agents are limited largely to those that directly or indirectly produce DNA damage; the products of the molecular biology era markedly extend the diversity of target mechanisms. Indeed, using experimental models, a number of interesting preclinical experiments have demonstrated an additive or synergistic effect. The literature on preclinical models and computer analysis has been reviewed by Rideout and Chou.¹⁶³

The future of combination chemotherapy will be influenced substantially by the number of these compounds and their interactions. The strategy of combining drugs whose mechanisms of action vary has been successful, even in the curative treatment of hematologic, childhood, and embryonal neoplasms.

The terms “additive” and “synergistic” are commonly used in the clinic but are not well defined. In considering these terms, selectivity for the tumor as compared to the host—the *therapeutic index*—is key. If two agents with additive therapeutic effect have a differing dose-limiting toxicity, so that the toxicity is nonadditive, the overall antitumor effect should be described as additive. When the effects are greater than “additive,” the term “synergism” may be appropriate.

[Table 4](#) presents the properties and comparisons of combination chemotherapy and combined modality therapy. Incorporation of many more classes of agents will force more efficient experimental designs. Such designs may include, for example, a rolling phase II/phase III study design. Increasingly, quantitative molecular markers and “real-time” pharmacology will be integrated operationally into clinical studies. The effectiveness of such related approaches should improve the efficiency and effectiveness of clinical trials.

Table 4 Combination chemotherapy versus holotherapy

Combination	Chemotherapy	Holotherapy
Diversity of agents	Drawn from one class, antiproliferative	Drawn from all classes ^a
Number of agents	2–5	4–12+
Toxicity	Bone marrow and gastrointestinal (steep dose), cardiac, neuralgic, and pulmonary	Major diversity, including that relative to dose and toxicity; toxicity commonly nonadditive; limited, greater selection
Experimental design of clinical trials	Rigid, establishment	Flexible, innovative, semi-Bayesian; patient participation
Endpoints	Classical; R, dR, DFS, OS	MRT
Integration with basic science	Limited	Extensive, operational; PK, PD; targets

^a Chemotherapy, immunotherapy, endocrinology, antiangiogenesis, antimatrix, gene therapy, and control of cell cycle (anticyclins [*CDK* family], transcriptional control, and antisense).

Abbreviations: DFS, disease-free survival; dR, duration of response; MRT, microbeam radiation therapy; OS, overall survival; PD, pharmacodynamics; PK, pharmacokinetics; R, response (partial or complete).

Oncogenes and tumor-suppressor genes may operate by modifying or exploiting abnormalities in the cell cycle, by interfering with growth factors, angiogenesis, and DNA repair. Identification of the specific genes or gene pathways in a particular patient by tumor profiling will allow identification of the precise agents most likely to be effective in that patient, with the goal of personalizing cancer therapy.

An integrated approach to cancer chemotherapy

More than a half-century has elapsed since cancer chemotherapy began. The chemotherapy agents now in use originated as biologically targeted therapy. Hitchings and Elion developed specific inhibitors of purine synthesis such as 6-MP and 6-TG; Heidelberger targeted RNA synthesis with 5-FU; and Farber targeted the reduced folate pathway with aminopterin. These innovations not only provided the groundwork for cancer treatment but also became tools for discovery of the basic workings of transformed cancer cells.

Natural products such as the *Vinca* alkaloids, anthracyclines, and taxanes were selected specifically for activity against cancer proliferation. These agents were combined with other classes of agents—for example, hormones, alkylating agents, and irradiation—which are active against proliferating cells. The optimal use of the new agents requires their integration into increasingly complex combinations so that a greater therapeutic index results. The same is true for the current classical chemotherapeutic agents, which largely inhibit proliferation.

Abbreviations: ATRA, all-*trans*-retinoic acid; IFL, irinotecan/5-fluorouracil/leucovorin; MRT, microbeam radiation therapy.

Molecular biology particularly has expanded the number of classes. Thus, hormones, immunotoxins, and inhibitors of invasion and metastasis are available in addition to the classical antiproliferation and DNA damaging compounds. Receptors and kinases of unique structure and quantity, capable of targeting with specific molecular agents, continue to be discovered and the pathways activated in cancer further

elucidated.

It has become readily apparent that the vast majority of cancers will be treated successfully only with combinations of agents chosen for the highest possible individual activity against a specific type of cancer. Ideally, such drugs will have different dose-limiting toxicities. Empiricism was an essential component in the development of contemporary cancer therapy, but rational drug discovery, analog development, preclinical modeling, precise pathologic diagnosis, careful staging of disease, and clinical trial design are the foundation for the measure of success known today.

The breakthroughs in molecular biology have presented the cancer therapist with enormous opportunities and challenges. On the basis of these breakthroughs, a molecular diagnosis will be able to not only determine where and how cancer originates but also the processes that are essential to its survival. The specific processes that initiate and propagate cancer have become the targets of unprecedented rational drug development ([Table 2](#)). Pharmaceutical technology provides not only small molecules but also monoclonal antibodies, immunoconjugates, ribozymes, antisense RNA, and recombinant viruses.

The therapy of cancer now has the potential to combine agents with even more mechanisms of action to confront the heterogeneity of cancer with a wider array of therapeutics. Some of these combinations are now the standard of care, as improvements in response and survival demonstrate ([Table 4](#)). The challenges to be overcome include (1) clinical development of cytostatic agents without the expectation of significant acute toxicity; (2) combining of classes of targeted agents ([Table 5](#)) both molecular and biologic, with regard to dose and schedule; and (3) selection of the appropriate types of cancer and individual patients for a specific therapy.

Table 5 Therapeutic interaction between agents of different classes

Agent	Cancer acted on
Chemotherapy + other systemic agent	
Chemo + immunotherapy	
Cisplatin + herceptin	Breast cancer
Taxol + herceptin	Breast cancer
CHOP + rituximab	Lymphoma
Chemotherapy → MRT → recovery of immunity → vaccine	
Minitransplant chemotherapy followed by allogeneic armed lymphocyte	
Chemotherapy + hormonal therapy	
Vincristine + prednisone	Acute lymphocytic leukemia
Chemotherapy + tamoxifen	Breast cancer
Chemotherapy + differentiation agent	
Daunorubicin + ATRA	Acute progranulocytic leukemia
Chemotherapy + antiangiogenesis	
IFL + bevacizumab	Colorectal cancer

With molecular biology playing an increasing role, the clinical and laboratory sciences that address the therapy of cancer will continue to accelerate toward cancer control.

Chapter 55

Pharmacology

Manish R. Sharma, MD ■ Mark J. Ratain, MD

Overview

The biology and clinical indications relevant to systemic anticancer therapies are covered extensively in other chapters in this book. In this chapter, we will focus on the principles of clinical pharmacology as they apply to systemic anticancer therapies and will attempt to illustrate how an understanding of clinical pharmacokinetics and pharmacodynamics can optimize the therapeutic index of these agents. The United States Food and Drug Administration (FDA) conducts a question-based clinical pharmacology and biopharmaceutics review for each approved drug (<http://www.fda.gov/downloads/AboutFDA/ReportsManualsForms/StaffPoliciesandProcedures/ucm07>). Their reviews are publicly available on the FDA website (<http://www.accessdata.fda.gov/scripts/cder/drugsatfda/>) by searching for the drug name, and often include details that are not included in the product label. We will use their standard questions to introduce the principles of clinical pharmacology and will highlight examples that illustrate these principles.

General attributes of the drug

What are the highlights of the chemistry and physical-chemical properties of the drug substance and the formulation of the drug product as they relate to clinical pharmacology and biopharmaceutics review?

The FDA introduced the biopharmaceutics classification system (BCS) in 2000 (<http://www.fda.gov/downloads/Drugs/Guidances/ucm070246.pdf>) to establish the criteria that could be used to qualify a new molecular entity for a waiver of *in vivo* bioequivalence studies. The concept, initially developed by Amidon et al.,¹ was that *in vivo* performance could be predicted from *in vitro* measurements of permeability and solubility. BCS class 1 drugs (high permeability/high solubility) are eligible for a waiver of *in vivo* bioequivalence studies. The Biopharmaceutics Drug Disposition Classification System (BDDCS) was subsequently proposed by Wu and Benet² and based on the hypothesis that high permeability-rate compounds are readily reabsorbed from the potential unchanged excretion routes (urine and bile) and therefore are primarily eliminated through metabolism. Many oral kinase inhibitors that have been developed as anticancer therapies are high permeability/low solubility compounds that are BCS and BDDCS class 2. These drugs are susceptible to food effects on intestinal absorption; drug–drug interactions related to efflux transporters in the gut, uptake/efflux transporters in the liver, or metabolism; and pharmacogenetic variants that impact transporters or metabolism.³

What are the proposed mechanism(s) of action and therapeutic indication(s)?

There are three major types of anticancer therapies: cytotoxics, biologics, and small molecule non-cytotoxics. Classes of each type of therapy, examples of drugs within each class, and their presumed mechanisms of action are shown in [Table 1](#) and covered extensively in other chapters. It is noteworthy that the mechanism of action of a kinase inhibitor may be unclear even after a drug has demonstrated efficacy in a therapeutic indication. For example, regorafenib inhibits multiple tyrosine kinases with relatively high affinity, but the mechanism by which it prolongs survival in chemotherapy-refractory metastatic colorectal cancer (presumed to be related to inhibition of angiogenesis) remains elusive.⁴

Table 1 Anticancer therapies and their mechanisms of action

(a) Cytotoxics		
Class of drugs	Example drug(s)	Target/mechanism of action
Alkylating agents	Cyclophosphamide	Cross-linking of DNA
Platinum agents	Cisplatin, carboplatin, oxaliplatin	Cross-linking of DNA
Antibiotics	Doxorubicin	Inhibits topoisomerase II; stabilizes topoisomerase II-DNA complex
Antimetabolites	Antifolates: methotrexate Pyrimidine analogs: 5-fluorouracil Purine analogs: 6-mercaptopurine	Interference with the incorporation of nucleotides into DNA
Tubulin-binding agents	Taxanes: paclitaxel Vinca alkaloids: vincristine, eribulin, ixabepilone	Enhance or inhibit tubulin polymerization
Camptothecins	Irinotecan	Stabilizes topoisomerase I DNA to induce DNA strand breaks
(b) Biologics		
Class of drugs	Example drug(s)	Target/mechanism of action
Monoclonal antibodies	Anti-CD20: rituximab Anti-HER2: trastuzumab Anti-EGFR: cetuximab, panitumumab Anti-PD-1: pembrolizumab, nivolumab Anti-VEGF: bevacizumab	Binding to cell surface receptor or ligand to block signal transduction and enhance antibody-dependent cellular cytotoxicity

Antibody-drug conjugates	Trastuzumab emtansine	Binds to HER2 to deliver a tubulin-binding agent to cells
Protein-based	Ziv-aflibercept	Binds to VEGF-A, -B, -C
Cytokines	IL-2, interferon-alpha	Immune system activation
Autologous cellular immunotherapy	Sipuleucel-T	Sensitizes the immune system to prostate cancer antigens

(c) Small molecule non-cyotoxics

Target/mechanism of action	Example drug(s)	
EGFR inhibitor	Erlotinib, afatinib	
HER2 inhibitor	Lapatinib	
ALK inhibitor	Crizotinib, ceritinib	
VEGFR2 inhibitor	Sorafenib, sunitinib, pazopanib	
BRAF inhibitor	Vemurafenib, dabrafenib	
MEK inhibitor	Trametinib	
mTOR inhibitor	Everolimus, temsirolimus	
BCR-ABL inhibitor	Imatinib, nilotinib	
KIT inhibitor	Imatinib, sunitinib, regorafenib	
PARP inhibitor	Olaparib	
ER antagonist	Tamoxifen, fulvestrant	
Aromatase inhibitor	Anastrozole, letrozole, exemestane	
AR antagonist	Flutamide, bicalutamide, enzalutamide	
CYP17A1 inhibitor	Abiraterone	
Proteasome inhibitor	Bortezomib, carfilzomib	
Bruton's tyrosine kinase inhibitor	Ibrutinib	

This is intended to be an illustrative rather than a comprehensive list.

What are the proposed dosage(s) and route(s) of administration?

Potential routes of administration for cancer therapies are intravenous, oral, intravascular, intracavitary, subcutaneous, or intramuscular. The optimal route of administration depends on a number of factors. By definition, drugs administered by the intravenous route are 100% available in the blood. For oral drugs,

the fraction of an administered dose of drug that reaches systemic circulation is referred to as its bioavailability. Alternatively, it is the ratio of the plasma area under the concentration–time curve (AUC) after oral administration to the plasma AUC after intravenous administration of the same dose. Bioavailability is influenced by both absorption and the first-pass effect, which is the reduction in available drug due to metabolism in the gastrointestinal tract and liver before an orally administered dose reaches systemic circulation. Oral drugs are convenient and theoretically should be less expensive, but are plagued by inconsistent bioavailability both within and between patients.⁵ Factors influencing the bioavailability of oral drugs include adherence, release of the drug from its formulation, stability in the gastrointestinal tract, factors influencing dissolution and rate of absorption (including coadministration with food), metabolism in the intestinal wall or liver before systemic circulation, and concurrent medications (impacting absorption or metabolism).⁶ Intravascular or intracavitary administration of drugs may be employed to achieve a higher drug concentration in the vicinity of the tumor.^{7–9} Finally, subcutaneous formulations often deliver comparable exposure to intravenous administration, as demonstrated with trastuzumab in breast cancer.¹⁰

General clinical pharmacology

What are the design features of the clinical pharmacology and clinical studies used to support dosing or claims?

The optimal dosing strategy for an anticancer therapy is the one that maximizes efficacy, minimizes severe toxicity, and minimizes pharmacokinetic variability between patients. With few exceptions, cytotoxic therapies are typically dosed by body surface area for historical reasons, even though height and weight are only two of the many variables that influence pharmacokinetic variability.¹¹ Biologics have typically been dosed by weight, while small molecule non-cytotoxics have typically been assigned a fixed dose for all patients. Because it was assumed that a higher dose of a drug would lead to greater efficacy, traditional phase I trials sought to determine the maximum tolerated dose (MTD), defined as the dose immediately below that which caused a prespecified rate of dose-limiting toxicity in a dose-escalation design.¹²

It is increasingly recognized that the conventional paradigm for dosing of anticancer therapy is suboptimal for two reasons. First, it does not evaluate the sources of interpatient variability in response and/or toxicity, and as such does not facilitate individualized dosing. Second, many biologics and small molecule non-cytotoxics may achieve maximum efficacy at a dose lower than the MTD because of either saturable bioavailability or a saturable effect on the targeted signaling pathway.^{13, 14} A number of recently approved anticancer therapies have required evaluation of alternative doses in postmarketing trials, whereas the ideal approach would be to conduct randomized dose-comparison studies with pharmacokinetic sampling and exposure-response analyses in the premarketing setting.¹⁵

What is the basis for selecting the response endpoints (i.e., clinical or surrogate endpoints) or biomarkers (collectively called pharmacodynamics) and how are they measured in clinical pharmacology and clinical studies?

The conventional response endpoints in trials of anticancer therapy are overall survival (OS), progression-free survival (PFS; defined as time to death or disease progression, whichever comes first), or objective response rate, with response defined as $\geq 30\%$ reduction in the sum of the longest diameters of target lesions as defined by the response evaluation criteria in solid tumors (RECIST).¹⁶ Although

there are a number of limitations to RECIST as a method for evaluating drug effect, it remains the most commonly used approach.¹⁷ Recommendations from the National Cancer Institute's Investigational Drug Steering Committee (IDSC) exist regarding the selection of endpoints for phase II trials of anticancer therapies and regarding the use of biomarkers in early clinical trials of novel anticancer therapies.^{18, 19}

Are the active moieties in the plasma (or other biological fluid) appropriately identified and measured to assess pharmacokinetic parameters and exposure–response relationships?

Many anticancer therapies require activation before they are able to have their anticancer effect, with an activation process involving chemical or enzymatic reactions in normal or tumor tissues. In most cases, the activation process happens intracellularly, such that the active moieties cannot be measured in the plasma. Cisplatin, for example, undergoes a chemical reaction with water molecules intracellularly, resulting in the generation of a positively charged aquated species that attacks nucleophilic sites on DNA.²⁰ Antimetabolites such as gemcitabine, 5-fluorouracil, and methotrexate undergo intracellular phosphorylation, phosphoribosylation, and polyglutamylation, respectively, to have and/or maximize their effects.^{21–23} On the other hand, some anticancer therapies are activated primarily in the liver, such that active moieties can and should be measured in the plasma in order to explore valid exposure–response relationships. One example is the topoisomerase-interacting agent irinotecan, which is converted by liver carboxylesterase into SN-38, an active moiety that is released into the systemic circulation and exposure to which predicts severe toxicity from irinotecan.²⁴

Exposure–response

What are the characteristics of the exposure–response relationships for efficacy?

The results of treatment with an anticancer therapy depend on both pharmacokinetics and pharmacodynamics. Pharmacokinetics refers to the relationship between dose and concentration, whereas pharmacodynamics refers to the relationship between concentration (or exposure) and “response,” with response broadly defined as any measurable effect of the drug related to efficacy, toxicity, or neither. Exposure–response relationships help to define the target exposure range at which the drug is effective without causing severe toxicity (often referred to as the therapeutic index). Many anticancer therapies have a narrow therapeutic index.

In general, any drug may be considered to have a maximal effect and a median dose (the dose required for 50% of the maximal effect). Wagner proposed a generalized sigmoidal model of drug effect ([Figure 1](#)), based on the hypothesis that all drug effects require an initial interaction with a receptor.²⁵ Pharmacodynamic models are generally different for agents that only work during certain phases of the cell cycle (phase-specific agents) compared with agents that work during any phase of the cell cycle (nonphase-specific agents). For nonphase-specific agents, such as cyclophosphamide and other alkylating agents, a simple log-linear model can be used as follows:

$$\text{Survival fraction} = \text{No. of treated cells} / \text{No. of control cells} = e^{-KC}$$

Figure 1 Example of E_{\max} model as proposed by Wagner. The maximum effect is 100%, and a concentration of six results in 50% effect. The exponent H , also known as the Hill constant, determines the shape of the curve and is usually between 1 and 2.

This model has a steep exposure–response curve, as the effect continues to increase proportionally as the concentration (C) increases. For any K (in Equation 1), an increase in C by $2.3/K$ will result in a 1-log increase in antitumor effect (Figure 2a).^{26, 27}

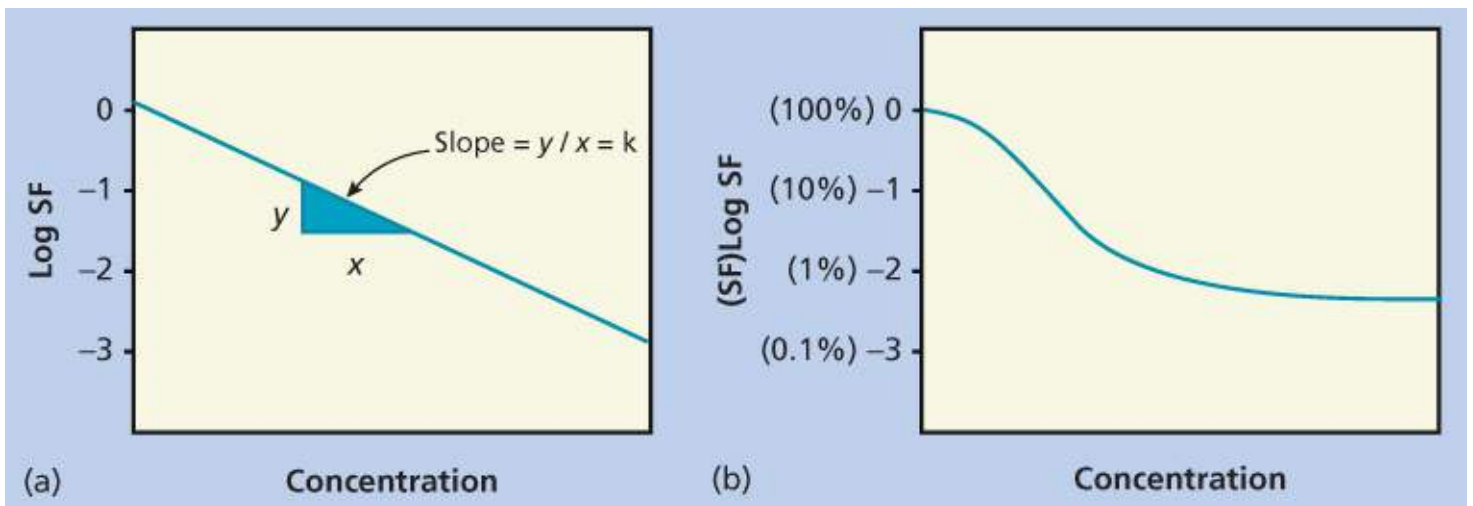

Figure 2 Pharmacodynamic plots for drugs with (a) nonsaturable and (b) saturable effects. In the simplest pharmacodynamic model (a), there is a linear relationship between dose and log kill. In (b) there is a maximal effect, resulting in a plateau in the dose–response curve. *Abbreviation:* SF, survival fraction.

Table 2 Anticancer therapies (in alphabetical order) for which a relationship between exposure and efficacy has been established, including the disease context and reference

Drug	Disease	References
Axitinib	Renal cell carcinoma	Rini <i>et al.</i> ³¹
Busulfan	Allogeneic bone marrow transplantation	Bleyzac <i>et al.</i> ³²
Carboplatin	Ovarian cancer	Jodrell <i>et al.</i> ³³
Dasatinib	Chronic myeloid leukemia	Wang <i>et al.</i> ³⁴
Erlotinib	Non-small cell lung cancer	Tiseo <i>et al.</i> ³⁵
5-Fluorouracil	Head and neck cancer	Milano <i>et al.</i> ³⁶
Imatinib	Chronic myeloid leukemia gastrointestinal stromal tumor (GIST)	Larson <i>et al.</i> ³⁷ Demetri <i>et al.</i> ³⁸
Methotrexate	Acute lymphoblastic leukemia	Evans <i>et al.</i> ³⁹

^b http://www.accessdata.fda.gov/drugsatfda_docs/nda/2011/202429Orig1s000ClinPharmR.pdf

For phase-specific agents, such as the antimetabolites, the exposure–response relationships are much more complicated. By definition, some cells are out of phase and therefore not sensitive (or relatively insensitive) to the effects of the drug during the period of drug exposure. This cannot be overcome by increasing the dose, but can potentially be overcome by increasing the duration of drug exposure.²⁸ The result is the appearance of a plateau in the exposure–response curve (Figure 2b). To further complicate matters, plasma concentrations may be an inadequate predictor of clinical effect for those agents that undergo intracellular anabolism to active metabolites, as is the case for cytarabine and many other antimetabolites.²⁹

Trastuzumab emtansine (T-DM1), an antibody-drug conjugate consisting of a recombinant humanized monoclonal antibody targeting the extracellular domain of HER2 linked to a microtubule-stabilizing agent, is a recent example of a drug for which the exposure–response relationship for efficacy has been well studied. In the case of T-DM1 for the treatment of HER2-positive metastatic breast cancer, higher trough concentrations on day 21 of cycle 1 are associated with improved OS and PFS after adjusting for baseline risk factors. In fact, patients with exposures below the median level had OS and PFS comparable to the active control arm of lapatinib plus capecitabine, suggesting that dose escalation might improve efficacy for this subset of patients.³⁰ Relationships between exposure and efficacy have also been found for a

number of other anticancer therapies that are summarized with references in [Table 2](#). Although still controversial, therapeutic drug monitoring has been suggested for many kinase inhibitors on the basis of these exposure–efficacy relationships.⁴³

What are the characteristics of the exposure–response relationships for safety?

Exposure–response relationships for safety are analogous to those for efficacy, except that the phenotypes of interest are potentially severe toxicities of the drug rather than efficacy measures. Many historical examples with cytotoxic therapies highlight the value of elucidating such relationships. The relationship between toxicity subsequent to high-dose methotrexate and that of delayed methotrexate clearance has led to the routine use of therapeutic drug monitoring of plasma methotrexate concentrations to guide leucovorin dosing.⁴⁴ The relationship between paclitaxel and neutropenia (generalizable to other cytotoxic therapies) is best described using nonlinear models that allow for an indirect effect of plasma concentration on bone marrow suppression, and these types of models have informed the optimization of the dose and schedule for many drugs.^{45, 46} Another example of a drug with a very well-characterized exposure–response relationship for safety is carboplatin, an analogue of cisplatin. Unlike cisplatin, the dose-limiting toxicity of carboplatin is thrombocytopenia, which is a function of drug dose, renal function, pretreatment platelet count, and prior therapy.⁴⁷ The platelet nadir produced by a dose of carboplatin is related to the carboplatin clearance, which is directly proportional to creatinine clearance. Thus, patients at high risk of severe thrombocytopenia following carboplatin therapy can be identified prospectively, and the drug doses can be modified by monitoring creatinine clearance. Although many attempts have been made to avoid severe toxicities of cytotoxic therapies by monitoring plasma drug concentrations during treatment, these attempts have generally not led to changes in clinical practice.

Vemurafenib, an oral small molecule inhibitor of the BRAF kinase harboring the V600E or V600K mutations in patients with metastatic melanoma, provides a more recent example of a drug with a well-established exposure–response relationship for safety in addition to an exposure–response relationship for efficacy. (Of note, although the FDA label indicates that the drug may be administered with or without food, exposure is increased when the drug is taken with food.) When exposure is measured by trough concentration at steady state, there is an increased probability of squamous cell carcinoma (SCC; a well-known, treatment-related adverse effect) with increasing exposure in a logistic regression model ($p < 0.0001$) (http://www.accessdata.fda.gov/drugsatfda_docs/nda/2011/202429Orig1s000ClinPharmR.pdf). Despite this clear relationship, dose reductions for SCC events are not recommended because the survival benefits outweigh this safety risk.

Does this drug prolong the QT or QTc interval?

Many drugs prolong the QT interval by delaying depolarization and repolarization of the ventricles in the heart. The QT interval is corrected for the heart rate by one of two accepted formulas to calculate the heart-rate corrected QT (QTc) interval. QTc prolongation is associated with a higher incidence of ventricular tachyarrhythmias (particularly torsade de pointes) that can potentially lead to sudden cardiac death. As an increased risk of sudden cardiac death is a major safety issue, FDA and other regulatory authorities require that sponsors adequately assess this risk during clinical development of a new drug. In 2005, international guidelines were developed to guide the design and data interpretation of thorough QT studies, and these guidelines were circulated by FDA in a Guidance to Industry (Guidance for Industry: E14 Clinical Evaluation of QT/QTc Interval Prolongation and Proarrhythmic Potential for Non-Antiarrhythmic Drugs. FDA, October 2005). In this guidance document, FDA recommends that the $\Delta\Delta\text{QTc}$ (change in QTc compared to baseline, corrected for placebo effect) be used as the endpoint for thorough

QT studies, and that the upper bound of the one-sided 95% CI (identical to the upper bound of a two-sided 90% CI) of the largest time-matched mean effect of the drug on the QTc interval should exclude 10 ms in order to conclude that there is no significant safety risk related to QTc prolongation.

Nilotinib is an oral small molecule inhibitor of BCR-ABL and other kinases that is used in the treatment of chronic myeloid leukemia (CML). A thorough QT study in healthy volunteers, in accordance with the E14 guidance, was conducted and demonstrated a clear relationship between steady-state concentration and $\Delta\Delta\text{QTc}$, while concentrations in that study were lower than concentrations that can be expected with the approved therapeutic dose in cancer patients

(http://www.accessdata.fda.gov/drugsatfda_docs/nda/2007/022068s000_ClinPharmR.pdf). As a result, it is recommended that the drug not be used in patients with hypokalemia, hypomagnesemia, or long QT syndrome who would be at especially high risk for QTc prolongation leading to sudden cardiac death.

Furthermore, the FDA required that the sponsor initiate a Risk Evaluation and Mitigation Strategy (REMS) to “minimize the risk of QT prolongation and its potential cardiac sequelae”

(http://www.accessdata.fda.gov/drugsatfda_docs/label/2010/022068s001rems.pdf). As part of the REMS and also in a “black box” warning on the drug label, prescribers and patients are cautioned to avoid concomitant use of drugs known to prolong the QT interval as well as CYP3A4 inhibitors and food, both of which are expected to substantially increase exposure to the drug. ECG (electrocardiogram) monitoring is recommended at baseline, 1 week after starting therapy, and periodically thereafter, including after any dose adjustments (Tasigna prescribing information, http://www.accessdata.fda.gov/drugsatfda_docs/label/2007/022068lbl.pdf).

Is the dose and dosing regimen selected by the sponsor consistent with the known relationship among dose, concentration, and response, and are there any unresolved dosing or administration issues?

While the dose and schedule for most anticancer therapies are selected on the basis of dose–concentration–response relationship, there are some for which there are unresolved dosing issues. One example is omacetaxine, a protein synthesis inhibitor that is approved for use in CML after resistance and/or intolerance of two or more tyrosine kinase inhibitors. Although the drug is labeled to be prescribed at an induction and maintenance dose of 1.25 mg/m² because this is the dose that was used in the pivotal study, the reviewers found no evidence of a correlation between clearance of the drug and BSA. As a result, BSA-based dosing results in lower concentrations in patients with smaller body size, such as women, which was associated with a decrease in efficacy

(http://www.accessdata.fda.gov/drugsatfda_docs/nda/2012/203585Orig1s000ClinPharmR.pdf). Another example is cabazitaxel, a microtubule-stabilizing agent that is approved for use in hormone-refractory metastatic prostate cancer after previous therapy with docetaxel. In a phase II trial in advanced breast cancer, the initial dose was 20 mg/m² every 3 weeks, and dose escalation to 25 mg/m² was allowed if no grade > 2 toxicity was observed in cycle 1. Even though only 21 of 71 patients could be escalated in cycle 2, the sponsor chose 25 mg/m² every 3 weeks as the dose for the pivotal phase III trial in prostate cancer. On the basis of the available data, there is no clear exposure–response relationship for efficacy but there is a relationship between AUC and probability of grade 3+ neutropenia, suggesting that some patients could avoid the need for dose reduction and growth factor support by starting at a lower initial dose (http://www.accessdata.fda.gov/drugsatfda_docs/nda/2010/201023s000ClinPharmR.pdf). Finally, correct dosing can often be an issue when a drug is studied in a new disease and gets approved for a new indication. In the case of trastuzumab, the approved dose for breast cancer was used in the randomized phase III trial that demonstrated the efficacy of trastuzumab in combination with chemotherapy compared to chemotherapy alone for metastatic HER2-positive gastric/gastroesophageal junction (GEJ) cancer.⁴⁸

Subsequently, a case report and review of pharmacokinetic data from the sponsor have suggested that clearance of the drug is ~70% higher in patients with gastric cancer than in those with breast cancer.⁴⁹ One possible explanation is that patients with metastatic gastric cancer have higher tumor burden and higher levels of circulating HER2 extracellular domains, resulting in higher clearance of the drug. Another possibility is that patients with gastric cancer may have lower albumin concentrations, leading to higher clearance of the drug. Standard dose versus higher dose trastuzumab is currently being explored in a randomized phase III trial in patients with HER2-positive metastatic gastric/GEJ cancer (HELOISE study; NCT01450696).

What are the pharmacokinetic characteristics of the drug and its major metabolite?

What are the single-dose and multiple-dose pharmacokinetic parameters?

Pharmacokinetics is the study of drug absorption, distribution, metabolism, and excretion. A fundamental concept in pharmacokinetics is drug clearance, that is, elimination of the drug from the body, analogous to the concept of creatinine clearance. In clinical practice, clearance of a drug is rarely measured directly but is calculated as either of the following:

$$\text{Clearance} = \text{Dose}/\text{AUC} \quad 2$$

$$\text{Clearance} = \text{Infusion rate}/C_{ss} \quad 3$$

The AUC represents the total drug exposure integrated over time and is an important parameter for both pharmacokinetic and pharmacodynamic analyses. As indicated in Equation (2), the clearance is simply the ratio of the dose to the AUC, so that the higher the AUC for a given dose is, the lower will be the clearance. If a drug is administered by continuous infusion and a steady state is achieved, the clearance can be estimated from a single measurement of the plasma drug concentration (C_{ss}) as in Equation (3).

Clearance can conceptually be considered to be a function of both distribution and elimination. In the simplest pharmacokinetic model,

$$\text{Clearance} = VK \quad 4$$

where V is the volume of distribution and K is the elimination constant. V is the volume of fluid in which the dose is initially diluted, and thus the higher the V is, the lower will be the initial concentration. K is the elimination constant, which is inversely proportional to the half-life, the period of time that must elapse to reach a 50% decrease in plasma concentration. When the half-life is short, K is high and plasma concentrations decline rapidly. Thus, both a high V and a high K result in high clearance and relatively low plasma concentrations.

In most phase I trials of anticancer therapy, pharmacokinetic sampling is done at multiple time points after the first dose of drug administration and is repeated again after multiple doses of drug administration, the latter of which may or may not correspond to steady state. For single-dose sampling, parameters that are presented typically include the maximum concentration observed (C_{max}), the time at maximum concentration (T_{max}), AUC, V , clearance, and the half-life. For multiple-dose sampling, parameters are generally the same except for the potential addition of the minimum concentration (C_{min}) before a dose. Pharmacokinetic parameters can be described by one of two methods. The first is noncompartmental analysis, a two-step process in which parameters such as C_{max} and AUC are estimated for each patient

and summary statistics are calculated for the population. Noncompartmental analysis can be done quickly and does not require special software. The second is population pharmacokinetic modeling, a one-step process in which parameters are estimated for the population of patients by developing a nonlinear mixed effects model with one or more compartments. Population pharmacokinetic modeling has several advantages: (1) it can be done with sparse (fewer time points) sampling data; (2) it is less susceptible to missing data; and (3) it can easily include covariates that minimize the between patient variability. A disadvantage is that it requires special software and training.⁵⁰ The interested reader is likely to benefit from hands on experience with such software. Several caveats need to be emphasized for the casual reader. The validity of pharmacokinetic modeling depends to a large extent on the quality of the data that are used to develop the model. Thus, drug infusions must be precisely timed, a sufficient number of plasma samples must be drawn, the samples must be obtained on schedule, and analytic methods must be sensitive and specific. The data must be properly weighted to avoid bias due to the increased probability of analytic errors at drug concentrations near the detection limit of the assay. Results obtained using a specific model should be compared with those using noncompartmental analysis. Extrapolation of models outside the known time points must be done with great caution.

What are the characteristics of drug absorption?

Variability in absorption is a major source of interpatient variability in pharmacokinetics. The rate and extent of drug absorption depends on its solubility and permeability across the mucosal lining of the intestine. In pharmacokinetic models, absorption is typically estimated by a first-order rate constant, K_a . Absorption may be saturable, meaning that higher doses do not lead to higher exposure above a certain threshold dose. BCS class 1 drugs with high permeability/high solubility are absorbed quickly and extensively, whereas drugs in BCS classes 2–4 have variable absorption and may be influenced by a number of factors. For example, many small molecule tyrosine kinase inhibitors have their absorption limited by membrane efflux transporters such as P-glycoprotein (also known as ABCB1), breast cancer resistance protein (ABCG2), and members of the multi-drug resistance protein family (ABCC family), the same transporters that may be overexpressed in cancer cells as a resistance mechanism.⁵¹ Prandial conditions are also very important, as a number of oral anticancer therapies have enhanced absorption leading to increased exposure (and potentially increased toxicity) when coadministered with food, particularly a high-fat meal. Examples include erlotinib, lapatinib, nilotinib, pazopanib, vemurafenib, and abiraterone, the last of which can have a 10-fold increase in AUC with a high fat meal (compared to an overnight fast).^{52–54} These oral anticancer therapies are generally labeled to be taken fasting despite the fact that exposure is increased with food, in contrast to the typical approach for noncancer therapies; theoretically increasing the risks of the drug if patient adherence to labeling is suboptimal.^{53, 55} Finally, a number of oral anticancer therapies are weak bases that have pH-dependent solubility and may have their absorption decreased by concomitant use of proton-pump inhibitors or other acid-reducing agents that are frequently prescribed and/or used over-the-counter. Examples of therapies with clinically significant decreases in exposure when coadministered with acid-reducing agents include dasatinib, erlotinib, gefitinib, and nilotinib.⁵⁶ When these kinase inhibitors are prescribed, patients should be instructed to abstain from the use of acid-reducing agents that might compromise the efficacy of these drugs.

What are the characteristics of drug distribution?

In pharmacokinetic models, there is a volume of distribution for each compartment in the model. Distribution is impacted by a number of factors, most notably water solubility and protein binding. Hydrophilic compounds, such as methotrexate, can distribute into fluid collections (such as pleural effusions or ascites) and significantly delay clearance of the drug from the central (plasma)

compartment.⁵⁷ On the other hand, pegylated liposomal doxorubicin is an example of a drug that has been engineered to be hydrophobic. Compared to free doxorubicin, its volume of distribution is very small and is mostly restricted to the intravascular compartment because the tight junctions of endothelial cells in blood vessels prevent extravasation of the liposomes, a fact that likely explains its reduced cardiotoxicity.⁵⁸ Protein binding is very important because only unbound drug can reach the target site and be eliminated. Vismodegib is an example of a drug that has high-affinity reversible binding to alpha-1-acid glycoprotein (AAG) and albumin, resulting in plasma levels of unbound drug that are <1% of total drug levels and contributing to low clearance of the drug. AAG levels account for approximately 70% of the pharmacokinetic variability between patients, suggesting that this is the single most important factor influencing the pharmacokinetics of the drug.⁵⁹ Concomitant drugs or disease states (e.g., hypoproteinemia) might increase the fraction of unbound drug but the clinical significance of this remains unclear for vismodegib and most other drugs.⁶⁰

Does the mass balance study suggest renal or hepatic as the major route of elimination?

Mass balance studies involve the administration of radiolabeled drug to humans. Radioactivity is measured at different time points in the blood, urine, and feces, in order to understand to what extent hepatic metabolism, biliary excretion, and urinary excretion are contributing to elimination. The biological specimens are also used to identify and quantify the parent drug and its metabolites.⁶¹ FDA guidance recommends that any metabolite whose exposure exceeds 10% of the parent AUC at steady state should be evaluated in a preclinical animal model for toxicology (<http://www.fda.gov/OHRMS/DOCKETS/98fr/FDA-2008-D-0065-GDL.pdf>).

There are many examples of anticancer therapies that are eliminated primarily by renal or hepatic routes. Carboplatin and methotrexate are examples of drugs that are predominantly excreted unchanged in the kidney. This is relevant to carboplatin dosing, which is calculated by a simple formula based on renal function, as shown in Equation (5).⁶²

$$\text{Dose(mg)} = (\text{Target AUC}) \times (\text{GFR} + 25)$$

5

As for methotrexate, its urinary excretion can result in precipitation in renal tubules and resulting nephrotoxicity. It has been shown that nephrotoxicity and other toxicities can be prevented after the administration of high-dose methotrexate by urinary alkalization, as the drug is significantly more soluble at a higher pH.^{63, 64} On the other hand, all of the taxanes (including paclitaxel, nab-paclitaxel, docetaxel, and cabazitaxel) undergo extensive hepatic metabolism and biliary excretion, resulting in the need for dose adjustment in patients with hepatic dysfunction.⁶⁵ Well-conducted organ dysfunction studies are necessary to guide selection of the most appropriate dose/schedule of anticancer therapies in patients with compromised renal and/or hepatic function. Ideally, these would be done before marketing the drug, but imatinib and sorafenib are examples for which these studies were done in the post-marketing setting.^{66, 67}

What are the characteristics of drug metabolism?

If it is determined by a mass balance study that a drug undergoes significant metabolism, then a number of follow-up questions need to be addressed. The hepatic extraction ratio, which varies between 0 and 1, is roughly a measure of the liver's efficiency for eliminating drug from the systemic circulation during a single pass through the liver. Drugs with a low (<0.3) extraction ratio will not have their clearance influenced by hepatic blood flow but will have their clearance correlated with plasma protein binding.

On the other hand, drugs with a high (>0.7) extraction ratio will have their clearance correlated with hepatic blood flow but will not have their clearance influenced by plasma protein binding. The concept of using floxuridine rather than 5-FU for the hepatic arterial infusion of chemotherapy for liver metastases is based on the fact that floxuridine has a higher hepatic extraction ratio, allowing high doses to be administered locally to the tumors without excessive systemic toxicity.⁶⁸ The enzymes responsible for metabolism fall into one of three phases of metabolism: modification (phase I), conjugation (phase II), or excretion (phase III). Phase I reactions include oxidation, reduction, and hydrolysis, and are typically catalyzed by cytochrome P450 enzymes that are abundant in liver microsomes. In phase II reactions, the activated metabolites of phase I reactions are conjugated with charged species to make them more hydrophilic. Finally, in phase III reactions, members of the ATP-binding cassette (ABC) family of transporters remove phase II products to the extracellular medium. For example, irinotecan is first activated by carboxylesterase (phase I) to its active metabolite SN-38 and by CYP3A4 to the inactive metabolite aminopentane carboxylic (APC) acid. SN-38 is then glucuronidated by UDP glucuronosyltransferase 1 polypeptide A1 (UGT1A1; phase II) to SN-38-glucuronide (SN-38-G). SN-38-G is excreted into bile by the ABCC2 transporter (phase III).⁶⁹ In the case of irinotecan, the parent drug and these three metabolites (APC, SN-38, and SN-38-G) accounted for 93% of the mean radiochemical AUC in the mass balance study, indicating that these are the metabolic enzymes of interest.⁷⁰ Enzymes responsible for drug metabolism are often first identified using *in vitro* studies in human liver microsomes or human hepatocytes, followed by *in vivo* studies in animals and finally *in vivo* studies in humans. Liquid chromatography-mass spectrometry (LC-MS) technology is now widely used to identify and measure metabolites in drug metabolism studies.⁷¹

What are the characteristics of drug excretion?

The characteristics of drug excretion include not only whether the drug is eliminated primarily by biliary or renal excretion but the specific metabolites that are eliminated and the transporters that are involved in their excretion. While excretion is straightforward in some cases, in other cases, it can be quite complicated. Irinotecan again serves as an instructive example. After SN-38-G is excreted in bile, intestinal bacteria such as *Escherichia coli* can convert the compound back to the active metabolite SN-38 by producing the enzyme β -glucuronidase, and this SN-38 can be reabsorbed and returned to the liver in a phenomenon known as enterohepatic recirculation.⁶⁹ In fact, a pharmacokinetic model for SN-38 after irinotecan dosing required inclusion of enterohepatic recirculation in order to accurately describe the observed data.⁷² Cisplatin provides another example of complicated excretion, as it is known to be both actively secreted and reabsorbed in the renal tubules.^{73, 74}

On the basis of pharmacokinetic parameters, what is the degree of linearity or nonlinearity in the dose–concentration relationship?

The key feature of a linear pharmacokinetic model is that

$$dC/dt = -KC$$

6

This indicates that the instantaneous rate of change in drug concentration depends only on the current concentration. The clearance and half-life will remain constant no matter how high the concentration is. One implication of this principle is that the AUC is not affected by changes in drug schedule. For example, the AUC after a 60 mg/m² bolus dose of doxorubicin equals the total AUC for 3 daily (or weekly) bolus doses of 20 mg/m², which equals the AUC for the same dose administered as a 96-h infusion. A second implication is that the AUC is proportional to the dose. Thus, if one measures the AUC

for a 60 mg/m² dose, one can estimate the AUC for a 90 mg/m² dose in the same patient as being 50% greater. A simple graph of dose versus AUC in a dose-ranging study can be used to determine whether or not a drug has linear pharmacokinetics.

The simplest linear pharmacokinetic model, shown graphically in [Figure 3](#), is

$$C(t) = \frac{\text{Dose}}{V}(e^{-kt})$$

7

Figure 3 Concentration-time plot for 1-compartment linear pharmacokinetic model. C_0 represents the initial concentration, assuming instantaneous administration and distribution. The half-life is $\log_e(2)/k$. *Abbreviation:* V , volume of distribution.

This model assumes that the drug is administered as an instantaneous bolus and that complete distribution of the drug is also instantaneous. These assumptions are often not valid. If the drug is administered as a slow bolus or infusion, the model must be corrected for the infusion duration (T). During the administration of the drug, the concentration is increasing:

$$C(t) = \frac{\text{Dose}}{VKT}(1 - e^{-kt})$$

8

After the infusion is terminated, the drug concentration decays at the same rate as if it had been administered as an instantaneous bolus. Thus, if T represents the infusion time, then the post-infusion drug concentrations can be represented as

$$C'(t) = C(T)e^{-k(t-T)}$$

9

Often, the pharmacokinetic data are more complex than those shown in [Figure 3](#) and may be optimally fitted to a multi-compartment model, usually two or three compartments ([Figure 4](#)). It must be emphasized that the compartments are theoretical and do not necessarily correlate with any anatomic space or physiologic process.

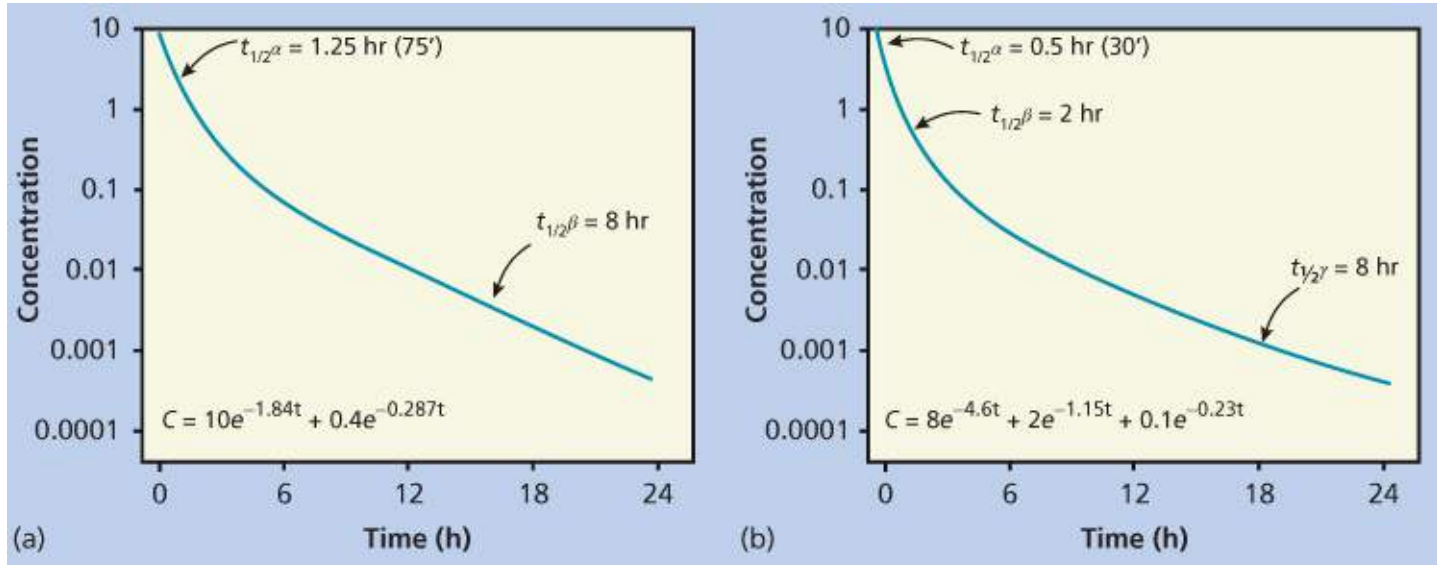

Figure 4 Concentration-time plots for representative 2-compartment (a) and 3-compartment (b) linear pharmacokinetic models. The two curves are very similar, with $C_0 \sim 10$ for both models. Note that for each “compartment” there is one term, and the corresponding half-life equals $t_{1/2} \log_e(2)/k^n$, where k^n is the n th term.

The presence of nonlinear pharmacokinetics implies that some aspect of the pharmacokinetic behavior of the drug is saturable. The mathematics of nonlinear models is beyond the scope of this chapter, but the principles are very relevant to several anticancer agents.^{75, 76} In contrast to the administration schedule of drugs with linear pharmacokinetics, alteration of the administration schedule of drugs that display nonlinear kinetics may markedly affect the AUC and potentially alter clinical effects.

Nonlinear pharmacokinetic behavior commonly occurs when there is saturation of a major metabolic or transport pathway. This results in decreased clearance at higher doses, with a greater than proportional increase in the AUC. The AUC will also increase if the infusion duration is shortened because of slower clearance at the higher peak plasma concentrations. This is clearly the case for 5-FU, probably because of saturation of its conversion to dihydrofluorouracil by the enzyme dihydropyrimidine dehydrogenase.^{77–79} As 5-FU is used on a variety of schedules, its nonlinear pharmacokinetic behavior may be one factor in its highly schedule-dependent effects. Paclitaxel has also been demonstrated to have nonlinear pharmacokinetics, owing to its formulation.^{80–82} Thus, the AUC is higher, for a fixed dose, when administered by a shorter (3-h vs 24-h) infusion schedule, although this does not result in enhanced toxicity.⁸³

The opposite situation arises when a drug's absorption from the gastrointestinal tract (or renal tubular reabsorption) is saturable. In this case, an increase in dose results in a less than proportional increase in the AUC. Gastrointestinal absorption of drugs that resemble natural compounds is frequently mediated by active transport processes that display saturable kinetics. Folate analogues such as methotrexate or leucovorin and amino acid analogues such as melphalan are examples of drugs with saturable absorption.^{84–86} Cisplatin appears to have nonlinear pharmacokinetics owing to the saturation of its renal tubular reabsorption.^{74, 87} Free plasma platinum is increased by 42% when the drug is given as a 24-h continuous infusion, rather than as a 20-min infusion.⁸⁷

How do the pharmacokinetic parameters change with time following chronic dosing?

Steady state occurs when the rate of drug administration is equal to the rate of drug elimination. The

accumulation ratio relates the exposure (measured by C_{\max} , AUC, or C_{\min}) at steady state to the exposure after a single dose, and is inversely related to the dosing interval. Although this ratio can be predicted using single-dose pharmacokinetic parameters, it is more accurate to measure the ratio directly using observed data. For drugs with one compartment pharmacokinetics, the time to steady state is directly proportional to the half-life and is independent of the dose and dosing interval. In practice, steady state is generally assumed to be reached in 4–5 half lives. The plasma concentration at steady state (C_p^{ss}) can be estimated as,

$$C_p^{ss} = S \times F \times D / CL \times \tau \quad 10$$

where S is the salt factor, F is the bioavailability, D is the dose, CL is clearance, and τ is the dosing interval. Nonadherence to medication can decrease the C_p^{ss} over time, whereas drug–drug interactions and prandial conditions can either increase or decrease the C_p^{ss} over time. There are specific examples of anticancer therapies that are susceptible to changes in C_p^{ss} over time. For example, cyclophosphamide autoinduction of CYP450 enzymes involved in its metabolism resulted in an approximate doubling of CL by the end of a 96-h infusion.⁸⁸ Although the mechanism remains unclear, a prospective study in patients with gastrointestinal stromal tumors demonstrated that imatinib exposure decreased by approximately 30% over the first 90 days of therapy before stabilizing.⁸⁹ Therapeutic drug monitoring is a consideration in the case of drugs such as imatinib with an established exposure–response relationship and changes in exposure over time with chronic dosing.

What is the inter- and intra-subject variability of pharmacokinetic parameters in volunteers and patients, and what are the major causes of variability?

Interpatient variability of pharmacokinetic parameters is potentially of great importance for optimizing anticancer therapy. The extent of variability in a parameter is usually presented as a coefficient of variation (ratio of standard deviation to the mean). It can be estimated by noncompartmental methods or by a population pharmacokinetic model. Owing to variability in bioavailability, oral agents generally have higher pharmacokinetic variability than intravenous agents. For example, in a study of etoposide, the coefficient of variation of the AUC for oral versus intravenous drug was 58% and 28%, respectively.⁹⁰

[Table 3](#) lists the potential sources of interpatient pharmacokinetic variability in cancer patients, many of which are also potential sources of inpatient pharmacokinetic variability. In a population pharmacokinetic model, the variables in [Table 3](#) can be explored as covariates and included in the model if their inclusion significantly reduces interpatient variability and improves the overall model fit to the observed data. Concomitant medications can explain variability by affecting absorption, elimination, and protein binding. Symptoms that are more commonly encountered in patients than in volunteers, such as nausea/vomiting and weight loss, can contribute to variability in the therapeutic setting. Hypoalbuminemia is commonly encountered in cancer patients and can potentially lead to higher clearance of biologics. For example, a population pharmacokinetic model of trastuzumab in patients with advanced gastric or GEJ cancer found that decreasing serum albumin levels were associated with increased clearance of the drug.⁴² Similarly, estimates of bevacizumab clearance in patients with advanced gastric cancer using a previously established population pharmacokinetic model (developed using data from patients with other cancers) were used to demonstrate that clearance of the drug is faster in patients with lower albumin.⁹¹ Prandial state can have a significant impact on both interpatient and inpatient pharmacokinetic variability. A population pharmacokinetic model of abiraterone demonstrated that higher fat content of food taken with abiraterone decreased its bioavailability, while patients with metastatic castrate-resistant

prostate cancer (compared with healthy subjects) had lower clearance of the drug.⁹²

Table 3 Potential sources of interpatient pharmacokinetic variability in cancer patients

<i>Factors affecting absorption</i>
Nausea/vomiting ^a
Prior surgery, radiotherapy, and/or chemotherapy
Concurrent antiemetics affecting gut motility (e.g., metoclopramide) ^a
Patient adherence ^a
Genetic differences in intestinal drug metabolizing and/or drug transport enzymes
Concomitant medications ^a
Prandial state (for drugs with a significant food effect) ^a
<i>Factors affecting distribution</i>
Weight loss ^a
Obesity
Decreased body fat (lipophilic drugs) ^a
Pleural effusions or ascites (methotrexate) ^a
<i>Factors affecting elimination (metabolism and/or excretion)</i>
Hepatic dysfunction ^a
Renal dysfunction ^a
Genetic differences in drug metabolizing and/or drug transport enzymes
Hypoalbuminemia (for biologics) ^a
Concomitant medications ^a
<i>Factors affecting protein binding</i>
Hypoalbuminemia ^a
Concomitant medications ^a

^a Potential source of inpatient pharmacokinetic variability.

Inpatient pharmacokinetic variability is much more difficult to estimate because it requires repeated pharmacokinetic sampling in the same subjects at later time points. For example, oncologists are commonly faced with the clinical situation of increasing myelosuppression after repetitive dosing. This is generally assumed to be due to the cumulative effects of chemotherapy, making the patient more sensitive to subsequent doses. However, it is also possible that the patient's clearance of the drug(s) may have decreased, resulting in increased drug exposure. Changes in organ function are a major source of intrasubject pharmacokinetic variability. Renal function may change because of progressive disease (ureteral obstruction), complications of therapy (volume depletion), or as a direct toxic effect of therapy (cisplatin). Similarly, renal function may improve over time, reducing the actual drug exposure. Hepatic function may also change, producing changes in drug clearance that may result in the appearance of increased toxicity over time.

Intrinsic factors

What intrinsic factors (age, gender, race, weight, height, disease, genetic polymorphism, pregnancy, and organ dysfunction) influence exposure and/or response, and what is the impact of any differences in exposure on efficacy or safety responses? On the basis of what is known about exposure–response relationships and their variability and the groups studied, healthy volunteers versus patients versus specific populations, what dosage regimen adjustments, if any, are recommended for each of these groups?

As intrinsic patient factors can influence exposure to an anticancer therapy, dose adjustments and/or recommendations to avoid using the drug in certain populations may be necessary if the impact on exposure is significant enough to also impact efficacy or safety responses. For example, 6-mercaptopurine is a drug that is commonly used in the treatment of pediatric acute lymphoblastic leukemia. 6-mercaptopurine, along with its prodrug azathioprine and the purine analog 6-thioguanine, is metabolized primarily by thiopurine S-methyltransferase (TMPT). The *TPMT* gene is subject to a number of polymorphisms that decrease the activity of TMPT, the first of which was identified in 1995.⁹³ Other polymorphisms have been identified since and there are substantial ethnic differences in the frequencies of these rare variants, but three polymorphisms account for more than 90% of inactivating alleles. As individuals who inherit two inactive *TPMT* alleles (<1% of the population) universally experience severe myelosuppression and a high proportion of those who inherit one inactive allele (~3–14% of the population) experience moderate to severe myelosuppression; the Clinical Pharmacogenetics Implementation Consortium has published guidelines that recommend dose reductions in these patients.⁹⁴ Similarly, patients treated with irinotecan who are homozygous for the *UGT1A1**28 polymorphism have higher exposure to SN-38 and are at higher risk for severe neutropenia, suggesting that a dose reduction is necessary in these patients.²⁴

In other cases, dose adjustments and/or recommendations to avoid use of the drug may be unnecessary even when such recommendations have made it into the drug label. This is illustrated by the recommended dose reduction for capecitabine in the setting of renal impairment (Xeloda prescribing information, http://www.accessdata.fda.gov/drugsatfda_docs/label/2005/020896s016lbl.pdf). In an editorial regarding this recommendation,⁹⁵ Ratain noted that the recommended 25% reduction was for patients with a creatinine clearance of 31–50 mL/min as estimated by the Cockcroft–Gault formula, which has been criticized as inaccurate.⁹⁶ This formula estimates a lower creatinine clearance for women and individuals with increased serum creatinine, low weight, and increased age. Furthermore, this definition of renal impairment is not adjusted for BSA. As a result, it is possible that a small woman would receive a dose reduction and a large man would not, even though their BSA-normalized creatinine clearances were the same.

Extrinsic factors

What extrinsic factors (drugs, herbal products, diet, smoking, and alcohol use) influence dose–exposure and/or—response and what is the impact of any differences in exposure on response? On the basis of what is known about exposure–response relationships and their variability, what dosage regimen adjustments, if any, do you recommend for each of these factors?

Drug–drug interactions can compromise efficacy or safety by decreasing or increasing exposure to a drug, respectively, with impact on the associated response. Prescription and over-the-counter drugs are often used concomitantly with anticancer therapy, sometimes without the oncologist being aware of such use. Common mechanisms for drug–drug interactions are induction or inhibition of CYP450 enzymes, and inhibition of the P-glycoprotein transporter. For example, a drug–drug interaction with potential therapeutic implications is that of tamoxifen and selective serotonin reuptake inhibitor (SSRI) antidepressants. Paroxetine, an SSRI that is commonly prescribed for depression or for hot flashes associated with tamoxifen therapy, is a strong inhibitor of the CYP2D6 enzyme that converts tamoxifen into its active metabolite endoxifen.⁹⁷ In a prospective clinical trial, 12 women with breast cancer who were taking adjuvant tamoxifen underwent pharmacokinetic sampling before and after 4 weeks of paroxetine coadministration. Endoxifen concentrations decreased by 64% in subjects who were homozygous for the wild-type CYP2D6 allele, but only by 24% in women with a variant CYP2D6 genotype.⁹⁸ Similar results were reported in a prospective study of 80 women taking tamoxifen, approximately 30% of whom were taking various SSRIs, after a period of 4 months.⁹⁹ Although the precise clinical implications of a decrease in endoxifen concentrations are still under investigation,¹⁰⁰ these data have resulted in recommendations to avoid SSRIs that are potent CYP2D6 inhibitors (such as paroxetine and fluoxetine) in patients treated with tamoxifen owing to concerns about compromising efficacy.¹⁰¹ The drug label warns prescribers to weigh the benefits for treating vasomotor symptoms against the potential risk of reduced effectiveness of tamoxifen (Brisdelle prescribing information, http://www.accessdata.fda.gov/drugsatfda_docs/label/2013/204516s000lbl.pdf).

Although anticancer drugs are often administered in combination, there have been relatively few studies to explore the potential pharmacokinetic and/or pharmacodynamic interactions between drugs. For example, with the combination of paclitaxel and cisplatin, an important regimen for ovarian cancer, cisplatin reduces paclitaxel clearance if given first.¹⁰² On the other hand, paclitaxel and carboplatin do not have a pharmacokinetic interaction, but it has been observed that paclitaxel mitigates the thrombocytopenia caused by carboplatin,¹⁰³ and a mechanism has been proposed that explains this phenomenon at the level of the megakaryocyte.¹⁰⁴ Another issue with combination therapy is that drugs may be labeled to be coadministered without considering whether they are matched with regard to prandial conditions. For example, capecitabine and lapatinib are used together in the treatment of metastatic breast cancer. Capecitabine is labeled to be taken twice daily with food, whereas lapatinib (which has a significant increase in exposure with food) is labeled to be taken once daily fasting.¹⁰⁵ When possible, it makes sense to match prandial conditions for colabeled drugs, in order to maximize patient adherence to the prescribed dose and schedule for both drugs.

Besides drugs, many other extrinsic factors can influence exposure and response to anticancer therapies. An excellent example is the induction of CYP1A1/1A2 by cigarette smoking and the impact of this factor on exposure to erlotinib in patients with lung cancer. A dose-escalation study of erlotinib in current smokers demonstrated that the MTD was 300 mg daily, and that steady-state trough plasma concentrations and incidence of rash and diarrhea in patients treated at this dose were similar to those in former or never smokers receiving 150 mg daily in previous studies.¹⁰⁶ St. John's wort (*Hypericum perforatum*), a herbal

antidepressant commonly used by cancer patients, is a known ligand for the pregnane X receptor (PXR) that can induce the transcription of PXR-regulated genes such as CYP3A and UGTs.^{107–110} Concomitant administration of St. John's wort has been demonstrated to significantly decrease exposure to irinotecan, imatinib, and docetaxel.^{111–113} The opposite is true for grapefruit juice, which is a potent inhibitor of CYP3A4 and has been demonstrated to increase exposure to sirolimus with the implication that it would likely do the same for other anticancer therapies that are CYP3A4 substrates.¹¹⁴

General biopharmaceutics

On the basis of the biopharmaceutics classification system (BCS) principles, in what class is this drug and formulation? What solubility, permeability, and dissolution data support this classification?

As discussed at the beginning of this chapter, the BCS predicts the *in vivo* performance of drugs on the basis of *in vitro* measurements of permeability and solubility, whereas the BDDCS predicts drug disposition and drug–drug interactions in the intestine and liver.³ BCS class 1 drugs have high solubility and high permeability with rapid dissolution, suggesting that an *in vivo* bioequivalence study is not necessary because they will be absorbed quickly and completely. BCS class 2 drugs have low solubility and high permeability, and many kinase inhibitors fall into this class. BCS class 3 drugs have high solubility and low permeability, whereas BCS class 4 drugs have low solubility and low permeability. BDDCS class 1 drugs have high solubility with transporter effects that are minimal in the gut and liver, implying that they are predominantly eliminated by metabolism. As P-glycoprotein efflux is not a major method of elimination for BDDCS class 1 drugs, these drugs tend to overcome the blood–brain barrier and have good distribution into the brain. BDDCS class 2 drugs have low solubility with efflux transporter effects predominating in the gut and both uptake and efflux transporters affecting the liver. BDDCS class 3 drugs have high solubility with absorptive transporter effects predominating.

What is the effect of food on the bioavailability (BA) of the drug from the dosage form? What dosing recommendation should be made, if any, regarding administration of the product in relation to meals or meal types?

In general, high-fat meals have little to no effect on the extent of absorption of BDDCS class 1 drugs, increase exposure to BDDCS class 2 drugs (such as many kinase inhibitors), and decrease exposure for BDDCS class 3 drugs.³ Food may affect pharmacokinetics by any number of mechanisms, including delaying gastric emptying, stimulating bile flow, changing the pH of the gastrointestinal tract, increasing splanchnic blood flow, changing intestinal metabolism of a drug, and physically/chemically interacting with the drug or dosage form.⁹⁰ In food effect studies, the FDA recommends reporting the ratio of geometric means between groups for exposure parameters such as C_{\max} and AUC, along with 90% confidence intervals. Bioequivalence in the fed state is successfully demonstrated if the 90% CI is contained within the range 80–125% while ratios outside of that range would establish a significant food effect (FDA Guidance for Industry entitled “Food Effect Bioavailability and Fed Bioequivalence Studies,” 2002).

Small molecule non-cytotoxics that have been demonstrated to have an increase in exposure with food include erlotinib, lapatinib, nilotinib, pazopanib, vemurafenib, and abiraterone.^{52–54} A recent example of another FDA-approved drug with a significant food effect is ceritinib, the second-generation ALK

inhibitor that has demonstrated efficacy in ALK-rearranged non-small cell lung cancer.¹¹⁵ Ceritinib is a BCS class 4 compound that is a substrate for the apical efflux transporter, P-glycoprotein. In the FDA New Drug Application leading to accelerated approval, the sponsor relied upon pharmacokinetic data for a single 500 mg dose in healthy subjects under fasting, low-fat, or high-fat prandial conditions. The FDA used a pharmacokinetic model to predict the effect of food after multiple doses of ceritinib 750 mg daily and 600 mg daily. At steady state, the model predicted that food increases ceritinib C_{\max} and AUC by 68% and 67%, respectively, and that 600 mg daily with food yields comparable exposure to 750 mg daily fasting (http://www.accessdata.fda.gov/drugsatfda_docs/nda/2014/205755Orig1s000ClinPharmR.pdf). The drug was labeled to be taken fasting at a dose of 750 mg daily because this is the dose that was used in the pivotal trial. FDA has issued a post-marketing requirement to evaluate 450 mg daily with food versus 750 mg daily fasting in patients, and one can presume that evidence of noninferiority of the lower dose would result in a label change.

Conclusions

As illustrated earlier, there are examples from all classes of anticancer therapies that illustrate how an understanding of clinical pharmacology can enhance the therapeutic use of these agents. As the goal is to maximize efficacy while maintaining tolerability, the oncologist needs to understand the basic relationship between dose and exposure (pharmacokinetics), as well as exposure and response (pharmacodynamics) for the population as a whole. The oncologist also needs to understand how and why a certain patient might have a different response than an average patient, and why drug effects may vary over time (interpatient and inpatient variability). When questions arise, the drug label is a reasonable place to start, but the question-based FDA clinical pharmacology and biopharmaceutics review provides more detailed answers that may be missing from the label. As many new observations about the clinical pharmacology of anticancer therapies are made after drugs are marketed, a current review of the literature is always recommended as well.

Acknowledgments

The authors would like to thank William K. Plunkett Jr., PhD for his contributions to this chapter in previous editions of this book. Some of the key concepts and content from the last edition were carried forward into the current version.

Chapter 56

Folate antagonists

Peter D. Cole, MD ■ Lisa Figueiredo, MD ■ Joseph R. Bertino, MD

Overview

Folic acid antagonists (antifols) are cytotoxic drugs used as antineoplastic, antimicrobial, anti-inflammatory, and immune-suppressive agents. While several folate antagonists have been developed, methotrexate (4-amino-4-deoxy-10-*N*-methyl-pteroylglutamic acid; MTX) is the antifol with the most extensive history and widest spectrum of use. MTX remains an essential drug in curative chemotherapy regimens used to treat patients with acute lymphoblastic leukemia, osteosarcoma, and choriocarcinoma and is an important agent in the therapy of patients with lymphoma, breast cancer, bladder cancer, and head and neck cancer. In addition, it is used for patients with nonmalignant diseases such as rheumatoid arthritis, psoriasis, autoimmune diseases, and graft versus host disease. This chapter will review the clinical use of and the metabolism of MTX and discuss structurally related folate antagonists that have been developed to overcome resistance or have alternate intracellular targets.

Historical overview

In the early 1940s, the combined observations that patients with acute leukemia often have serum folate deficiency and that the bone marrow megaloblasts of folate-deficient patients morphologically resemble leukemic blasts prompted some investigators to postulate that leukemia might be a result of a deficiency of this B vitamin. However, it rapidly became apparent that administration of folic acid to patients with leukemia was not only ineffective but often accelerated the course of the disease.¹ Thus, efforts to treat these leukemias turned to pharmacologically mimicking folate deficiency using folate analogs with effects antagonistic to those of the vitamin. Aminopterin (4-amino-4-deoxy PGA; AMT; [Figure 1](#)) was the first of these analogs to produce temporary remissions in 5 of 16 patients with acute leukemia.² This report was a landmark in cancer chemotherapy, as the first successful example of the power of rational drug design leading to an effective antineoplastic agent.

Since the initial study indicating the usefulness of AMT in the treatment of acute leukemia of childhood, there has been sustained interest in folate antagonists. Although known to be less potent, 4-amino-4-deoxy-10-*N*-methyl-pteroylglutamic acid (MTX) supplanted AMT in the clinic in the early 1950s because the toxicity caused by AMT was greater and less predictable.^{3–5} Newer antifols, rationally designed analogs of folate or MTX, have been synthesized either in an effort to overcome cellular resistance to MTX or to target alternative folate-dependent processes. This chapter will discuss two, pralatrexate and pemetrexed, which recently received FDA approval for oncologic indications.

Mechanisms of action of MTX

Folate antagonists function in several ways: by competing with folates for uptake into cells, by inhibiting

the formation of folate coenzymes, or by inhibiting one or more reactions that are mediated by folate coenzymes. Thus far, the clinically important anti-neoplastic folate analogs appear to work primarily by inhibiting dihydrofolate reductase (DHFR) or thymidylate synthase (TS). The prototypic DHFR inhibitor is a 4-amino-substituted pterin compound, such as MTX or AMT ([Figure 1](#)). Substitution of an amino group for the 4-hydroxy moiety results in a folate analog with a several thousand-fold increase in affinity for DHFR. The K_i of MTX for DHFR is below 10^{-10} M, well below the micromolar K_m of the natural substrate, dihydrofolate. By stoichiometrically inhibiting DHFR at slightly acidic pH, MTX blocks the cell's ability to replenish a supply of reduced folates necessary for *de novo* thymidylate synthesis ([Figure 2](#)).⁶ In rapidly dividing cells, the inhibition of thymidylate biosynthesis leads to a decrease in thymidine triphosphate pools, a decrease in DNA synthesis, and eventually cell death.⁷

Intracellular metabolism of classical antifolates such as MTX to polyglutamate species significantly impacts their function and mechanisms of cytotoxicity.⁸ Folylpolyglutamate synthetase (FPGS) adds glutamate residues in γ -carboxyl linkage to both folate coenzymes and classical folate antagonists (those with a glutamate moiety). This addition of up to seven or eight additional glutamate molecules serves to add mass and negative charge, markedly reducing efflux and increasing total intracellular accumulation at steady state.⁹ Both quantitative differences in FPGS expression and qualitative differences in FPGS function¹⁰ exist between neoplastic and non-neoplastic tissues, which may explain some of the selectivity of antifolates for neoplastic cells.¹¹ A relative lack of FPGS may explain the observation that a cell population with a large number of G_0 cells would be less affected by the same concentration and time of exposure to MTX than a population with more actively dividing cells.

Figure 1 Structure of folic acid and structurally related classical antifolates, AMT and MTX. (a) Folic acid (pteroylglutamic acid; PGA). (b) Aminopterin (4-amino-PGA). (c) Methotrexate (4-amino-N-10-methyl PGA).

Figure 2 Primary site of action of MTX and MTX(glu)_n. MTX enters cells by either the reduced folate carrier (1) or the membrane folate-binding protein (2). MTX is then metabolized by the cytosolic enzyme folylpolyglutamate synthetase (3) to MTX(glu)_n, a potent inhibitor of dihydrofolate reductase (DHFR) (4). MTX(glu)_n can be hydrolyzed to MTX by the lysosomal enzyme γ-glutamyl hydrolase (GGH) (5). *Abbreviations:* CH₂FH₄, N₅, N10-methylene tetrahydrofolate; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate/deoxyuridylate; FH₂, dihydrofolate; FH₄, tetrahydrofolate; MTX, methotrexate; MTX(glu)_n, MTX polyglutamates.

MTX polyglutamates are more potent inhibitors of DHFR than the parent compound because they bind as tightly to DHFR as MTX but dissociate less rapidly.¹² In addition, MTX polyglutamates are potent inhibitors of other folate-requiring enzymes, including TS¹³ and two of the rate-limiting steps of *de novo* purine synthesis: glycinamide ribonucleotide (GAR) and aminoimidazole carboxamide ribonucleotide (AICAR) transformylases.¹⁴ These two enzymes are potently inhibited by DHF-polyglutamates and 10-formyl-DHF polyglutamates, which increase after MTX inhibits DHFR.¹⁵ As a result, inhibition of *de novo* purine synthesis may be at least as relevant as DHFR inhibition to the cytotoxic effects of MTX in cancer cells¹⁶ and for the anti-inflammatory action of MTX in patients with rheumatologic diseases.^{17, 18}

Other possible mechanisms by which MTX exerts antineoplastic or anti-inflammatory action are worth mentioning. First, by inhibiting folate-dependent methionine biosynthesis, MTX causes intracellular concentrations of homocysteine (Hcy) to increase, resulting in a secondary increase in S-adenosyl-homocysteine (SAH), a potent inhibitor of many folate-dependent methylation reactions. MTX exposure, therefore, can block membrane localization of ras,¹⁹ a member of a family of critical signal transduction proteins constitutively activated in a number of human cancers. Second, the anti-inflammatory effects of MTX and some component of its antineoplastic activity may be due to its ability to inhibit endothelial cell proliferation at low concentrations.²⁰ Preclinical data confirm that low-dose methotrexate can inhibit the growth of microscopic metastatic disease through its antiangiogenic properties.²¹ In addition to the mechanisms mentioned earlier, rapidly proliferating cancer cells overexpress enzymes of the mitochondrial and glycine-serine pathway, and this phenotype is a recently appreciated determinant of methotrexate sensitivity.²²

Pharmacokinetics of MTX

MTX is one of few anticancer agents for which pharmacokinetic data are routinely used in clinical practice to modulate the balance between efficacy and toxicity.²³ Retrospective analysis of children with acute lymphoblastic leukemia (ALL) shows that lower MTX clearance²⁴ and higher MTX concentrations²⁵ are associated with lower risk of relapse. Even more intriguing are data from a prospective randomized trial in patients with ALL comparing dosing by body surface area with individualized dosing based on pharmacokinetic data, which showed significantly improved complete continuous remission rates in the individualized therapy arm.²⁶ It is possible, however, that these results are protocol specific, as others have found that pharmacologically guided treatment intensification led to inferior outcomes for some subpopulations.²⁷

Absorption

Following oral administration, peak plasma concentrations occur 1–5 h after a dose of 15–30 mg/m². Absorption can be relatively poor and unpredictable,^{28, 29} affected by food, nonabsorbable antibiotics, bile salts, and a shortened intestine transit time. Thus, it is suggested that the drug be taken on an empty stomach with clear liquids. Nevertheless, at a dose and schedule of 25 mg/m², given orally every 6 h for four doses, plasma MTX concentration >0.5 μM was seen in more than 85% of pediatric patients with ALL, indicating the reliability of this oral regimen.³⁰

Distribution

After intravenous (IV) administration of MTX, the initial volume of distribution (V_d) is approximately 0.18 L/kg of body weight. The initial distribution phase has a $t_{1/2}$ of 30–45 min; the beta $t_{1/2}$ is 3–4 h. Steady-state V_d is between 0.4 and 0.8 L/kg.³¹

After high doses of MTX (>3 g/m²), peak serum concentrations in the range 10⁻⁴ to 10⁻³ M are achieved.³² At these concentrations, transmembrane transport is saturated, limiting further influx of MTX to passive diffusion. Uptake of reduced folates, including leucovorin (LV), is inhibited as well. Studies of MTX metabolism in lymphoblasts *in vitro* have also shown that too high an extracellular concentration of drug can impede metabolism of MTX to a polyglutamate.³³

MTX binding to plasma proteins, especially to albumin, is approximately 50%.^{34, 35} The 7-hydroxy metabolite of MTX is 90% bound to plasma proteins, but apparently does not interfere with MTX binding to plasma proteins at clinically observed concentrations. The highest tissue-to-plasma concentrations found in humans are in the liver and kidney, followed by the gastrointestinal tract. Prolonged plasma levels after high-dose MTX infusions in humans have been attributed to decreased transit rate secondary to gastrointestinal obstruction.

Because of the blood–brain barrier and efflux mechanisms that actively remove MTX from the CNS,³⁶ cerebrospinal fluid (CSF) MTX concentrations are approximately 1% of those in the plasma; therefore, cytotoxic concentrations are not obtained in the CSF after conventional doses but only with doses of 500 mg/m² and higher.³⁷ After high-dose systemic MTX administration, lumbar CSF and ventricular CSF concentrations were similar. HDMTX may be able to replace intrathecal drug for the treatment of patients with nonleukemic leptomeningeal disease.³⁸ However, a recent meta-analysis of CNS-directed therapy for children with ALL concluded that efforts to increase CSF penetration using HDMTX have not produced the desired result of lowering the rate of CNS relapse in this population.³⁹

As MTX is accumulated poorly into the CSF, even small doses of LV given orally can increase CSF

folates significantly. This systemic rescue, especially if given too early after MTX, may rescue leukemic cells in the CSF compartment.⁴⁰

When injected into an indwelling ventricular catheter, MTX reaches reproducible therapeutic drug concentrations ($>10^{-6}$ M) for at least 48 h.⁴¹ In contrast, when MTX is given by the lumbar route into the CSF, it distributes unreliably into the ventricles. An improved dose schedule utilizing the administration of multiple small doses of intrathecal MTX has been suggested.⁴² Following intrathecal administration, MTX slowly exits into the systemic circulation with a $t_{1/2}$ of 8–10 h.³⁶ Systemic toxicity can be observed if multiple doses of intrathecal MTX are administered without LV rescue. The pharmacology of intrathecal MTX and the amount of intraventricular MTX may be altered by overt meningeal leukemia and the position of the patient at the time of lumbar puncture.⁴³ The clinical observation that irradiation followed by MTX treatment may predispose patients to neurotoxicity may be a consequence of the effect of radiation therapy on the blood–brain barrier.⁴⁴

Patients with pleural or peritoneal effusions may be at increased risk for developing toxicity to HD-MTX as a result of “third spacing” or MTX trapping in the infusion and slow release leading to sustained MTX concentrations in serum.⁴⁵ In these circumstances, higher LV doses and prolonged LV rescue may be necessary, until the serum level of MTX decreases to $<0.05 \times 10^{-6}$ M.

Metabolism

The major metabolite of MTX, produced by the action of hepatic aldehyde oxidase, is 7-hydroxy MTX (7-OH MTX) (Figure 3), which is only 1% as potent an inhibitor of DHFR as MTX.⁴⁶ It is also less water soluble than MTX and may contribute to renal toxicity after high doses.⁴⁷

Figure 3 Catabolism of MTX. MTX (a) can be converted in the liver to 7-OH MTX (b). In addition, enteric bacteria will cleave the molecule to dAMPA plus glutamate (c).

A second, less important pathway of metabolism of MTX occurs in the intestine. MTX is hydrolyzed by bacteria to the pteroate (4-deoxy-4-amino-N¹⁰-methyl pteronic acid; dAMPA) and glutamic acid ([Figure 3](#)).⁴⁸ dAMPA, like 7-OH MTX, is also a relatively inactive metabolite with approximately 1/200th the affinity of MTX for DHFR. dAMPA excretion in the urine accounts for <5% of the dose administered.

The third metabolic product of MTX is MTX polyglutamate. As discussed earlier, MTX polyglutamates are at least as potent inhibitors of DHFR as is MTX and have a slower rate of disassociation from DHFR.¹² MTX polyglutamates are not found in plasma or urine because of the abundant activity of γ -glutamyl hydrolase(s) (GGH) in plasma that convert folyl- and MTX-polyglutamates to monoglutamates. Similar to MTX, 7-OH MTX is also polyglutamylated intracellularly, and retention of these polyglutamate forms could contribute to MTX cytotoxicity.⁴⁹

Compliance with oral MTX regimens can be monitored by measuring MTX-polyglutamate concentrations within circulating erythrocytes red blood cells (RBCs).^{50–52} Nucleated RBC precursors within the bone marrow will accumulate and metabolize circulating MTX. The resulting MTX polyglutamates will remain within the mature RBC throughout its lifespan,⁵³ while unmetabolized MTX will gradually efflux.⁵⁴

Excretion

The majority of administered MTX (and its metabolites 7-OH MTX and DAMPA) is excreted unchanged in the urine.^{55, 56} Because of active secretion in the proximal tubules, renal clearance of MTX can exceed creatinine clearance.⁵⁷ There is wide inter-patient variability in MTX clearance, which does not correlate perfectly with renal function.⁵⁸ MTX excretion is reported to be inversely related to age as plasma clearance of renal eliminated drugs is closely correlated with maturation of kidney function. Children tend to exhibit more rapid MTX clearance than adults, and a general trend toward decreasing clearance with increasing age has been observed.⁵⁹ MTX excretion through organic acid transporters can be inhibited by probenecid or competitively blocked by other weak organic acids, such as aspirin or penicillin G. MTX elimination is increased by drugs that block distal tubular reabsorption, such as folic acid, some cephalosporins, and sulfamethoxazole.

Less than 10% of MTX is typically recovered in the feces.⁶⁰ Following IV administration of doses of 30–80 mg/m², 0.4–20% of the administered dose is excreted through the canalicular multiorganic acid transporter (cMOAT; ABCC2; MRP2) into the bile. Using a knock-out mouse model (ABCC2^{-/-}; ABCG2^{-/-}), it was shown that both transporters play overlapping roles in the elimination of MTX and 7-OH-MTX. Many polymorphisms and mutations of these transporters have been identified, leading to differences in expression and activity, affecting systemic MTX exposure. Consequently, patients with mutations or heterozygous polymorphisms in ABCC2 and/or ABCG2 might be at increased risk for MTX toxicity.⁶¹

Drug interactions

Several drugs used in cancer patients, including antibiotics, may alter the renal excretion of MTX, increasing toxicity or decreasing efficacy. Deleterious and even fatal reactions have been reported between MTX and nonsteroidal anti-inflammatory drugs, in particular with naproxen and ketoprofen.^{62, 63} This increased toxicity may be due to decreased renal elimination, possibly as a result of competition for renal secretion.⁵⁷ Other commonly used organic drugs may also potentiate MTX toxicity, such as phenylbutazone, salicylate, and probenecid.^{64, 65} Probenecid increased the efficacy of MTX in tumor-bearing mice, but it has not been used clinically with this goal in mind.⁶⁶

Increased toxicity was also reported when trimethoprim, the antibacterial agent, was used together with MTX. Presumably, this antifolate, with only weak binding affinity to mammalian DHFR, lowers folate stores, especially in patients with subclinical folate deficiency, making marrow cells more susceptible to MTX-induced toxicity.⁶⁷ Alcohol should also be avoided in patients receiving MTX because of the risk of hepatic fibrosis and cirrhosis.

Pharmacogenomics

A growing body of data implicates inherited variation in genes for enzymes responsible for folate metabolism in interpatient variability in antifolate response or toxicity. A more detailed discussion of these data is beyond the scope of this chapter but has been the subject of comprehensive reviews.^{68–71} Briefly, functional polymorphisms have been described in either the promoter or coding regions of the genes for DHFR, methylenetetrahydrofolate reductase (MTHFR), aminoimidazole carboxamide ribonucleotide transformylase (ATIC), the reduced folate carrier (RFC), GGH, methionine synthase (MTR), methionine synthase reductase (MTRR), methylenetetrahydrofolate dehydrogenase (MTHFD), serine hydroxymethyltransferase (SHMT), TS, and solute carrier organic anion transporter gene 1B1 (SLCO1B1). Many of these polymorphisms are present at significant frequency among the population and some have been linked to higher rates of relapse or toxicity among patients with acute lymphoblastic leukemia^{72–77} or rheumatoid arthritis.⁷⁸ If replicated in larger populations, these data suggest the potential for individualizing MTX therapy, based on each patient's genotype.

Gene–environment interactions may also modulate the effects of genotypic variation on toxicity. To focus on one relevant example, some of the observed variation in serum homocysteine (a marker of functional folate deficiency) is explained by two common functional polymorphisms in the MTHFR gene, C677T and A1298C, but only under conditions of decreased intake of dietary folate.^{79, 80} Adequate dietary folate in countries with mandated folate supplementation could erase the effects of genetic polymorphisms.

Clinical application

Clinical dosage schedules

MTX has been administered on a variety of dosage schedules since its introduction into the clinic more than six decades ago ([Table 1](#)). In a trial of MTX in patients with head and neck cancer treated with 50, 500, or 5000 mg/m² with LV “rescue,” a trend of dose responsiveness was seen (5 of 24, 5 of 16, 9 of 18, respectively). Some responses were noted with the 5000 mg/m² dose regimen in patients who did not respond at lower doses.⁸¹ The importance of dose scheduling was emphasized by an experimental study showing that resistance to high-dose pulse MTX may not extend to continuous low-dose exposure.⁸² Determining the optimum dose schedule of MTX is complicated by the use of the drug in combination therapy ([Table 2](#)). Sequencing appears to be important when MTX is used with 5-fluorouracil (5-FU), with L-asparaginase, and probably with cytosine arabinoside and 6-mercaptopurine or 6-thioguanine. Table 2 summarizes the use of some common drug combinations that include MTX, along with sequence specificity.

Table 1 Dosage schedules commonly used for methotrexate (MTX)

Schedule and dose	Use/comments
<i>Oral</i>	
Weekly or biweekly (15–25 mg in single or divided doses)	Mainly for nonmalignant conditions, such as psoriasis or rheumatoid arthritis
Weekly or biweekly (20–30 mg/m ²)	Maintenance therapy for ALL
<i>Parenteral</i>	
Pulse weekly (30–60 mg/m ²)	Choriocarcinoma, ALL
Intermediate dose (120–500 mg/m ² weekly)	ALL, NHL; requires LV rescue, 10–15 mg/m ² q 6 h × 6–8 doses
High dose (500–12,000 mg/m ² weekly or every other week)	Osteosarcoma, ALL, neoplastic meningitis; requires LV rescue

Abbreviations: ALL, acute lymphoblastic leukemia; LV, leucovorin; NHL, non-Hodgkin lymphoma.

Table 2 Combination chemotherapy with methotrexate (MTX)

Used with	Schedule notes	Result	Comments
5-FU	MTX must precede 5-FU by 24 h	Synergistic	
Anthracyclines		Additive	
Bleomycin		Additive	Mucosal toxicity is increased
Corticosteroids	Used together	Synergistic	Used in ALL
Cyclophosphamide	Used together	Additive	
Cytarabine	Used together	Additive or synergistic	
L-asparaginase	If MTX precedes l-asparaginase by 24 h If used simultaneously	Synergistic Antagonistic	Used in ALL, AML
Vinca alkaloids		Additive	

Abbreviations: ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; 5-FU, 5-fl uorouracil.

Current uses for MTX in the treatment of neoplastic disease

Acute lymphoblastic leukemia

MTX is a component of nearly all multiagent therapeutic regimens for patients with acute lymphoblastic leukemia post-remission, and some protocols include MTX in remission induction. In addition to systemic use, MTX is administered intrathecally for the treatment of meningeal leukemia and for prophylaxis against CNS relapse.

During the intensive, early post-remission phases, MTX can be administered orally or parenterally. Parenteral administration at intermediate dose (100–500 mg/m²/dose) or high dose (≥1000 mg/m²) has

been incorporated in some protocols to increase accumulation of MTX-polyglutamates by blast cells,⁸³ to overcome mechanisms of resistance and to increase penetration into protected sites including the CNS and testes.⁸⁴ While the ability of HD-MTX to prevent CNS relapse is not clearly proven,³⁹ the rate of isolated testicular relapse does appear to have decreased with the addition of intermediate or HD-MTX.⁸⁵ Randomized trials comparing escalating IV doses with oral MTX showed a significant improvement in 5-year event-free survival (EFS) in those patients randomly assigned to the IV MTX-based interim maintenance compared with the oral MTX-based arm.^{86–89} However, in some studies, the increase in EFS came at the expense of increased hematologic and neurologic toxicity.^{90–93}

During later maintenance phases, most current protocols rely on prolonged weekly administration of MTX at low doses (20–50 mg/m²/dose) in combination with daily mercaptopurine. Early studies showed that twice-weekly therapy (20 mg/m²) was superior to continuous daily oral administration for treatment during remission.⁹⁴ The effectiveness of an oral divided dose (25–30 mg/m² given every 6 h for 4–6 doses weekly) has also been shown.³⁰

Acute myelogenous leukemia

MTX has limited value in the current treatment of patients with acute nonlymphocytic leukemia. Complete remissions can be seen in approximately one quarter of adults with AML treated with MTX-containing regimens: prednisone, Oncovin, methotrexate, and Purinethol (POMP)⁹⁵ or MTX with L-asparaginase (the “Capizzi Regimen”).^{96, 97} High-dose regimens with LV rescue have a transient but rapid effect on the peripheral blood count without producing marrow remissions in the large majority of these patients.⁹⁸ The lack of efficacy of MTX in this disease has been attributed to poor intracellular retention of the drug caused by a lack of polyglutamylation and an increase of the target enzyme DHFR following treatment.⁹⁹

Lymphoma

On the basis of the phase II studies that indicated that moderate to high doses of MTX (200 mg/m² to 3 gm/m²) with LV rescue could produce transient regressions in patients with large cell lymphoma, MTX with LV rescue has been added to combination regimens for intermediate- and high-grade lymphomas. In some regimens (e.g., M-BACOD), MTX is used with LV during the leukopenic phase of drug treatment, as the MTX/LV combination has little marrow toxicity.¹⁰⁰ On the basis of the experimental studies showing that MTX and cytosine arabinoside produce additive and possibly synergistic effects,¹⁰¹ this combination has also been utilized in regimens to treat this disease (e.g., COMLA; cyclophosphamide, vincristine, MTX, cytosine arabinoside, and LV). Similarly, following documentation of responses to therapy including MTX,^{102, 103} among patients with Burkitt's lymphoma, high-dose MTX with LV rescue has been added to CVAD, cytarabine and intrathecal therapy as well as to other combination chemotherapy regimens^{104–106} for patients with Burkitt's lymphoma.

Most treatment regimens for patients with primary CNS lymphoma include high-dose MTX, as conventional radiation doses may lead to neurotoxicity. In a retrospective review of 226 patients with primary CNS lymphoma, those patients treated with regimens that included HDMTX followed by radiotherapy had an improved survival, with no higher risk of late neurotoxicity.¹⁰⁷

Choriocarcinoma

Choriocarcinoma is unique in that single-drug treatment with either MTX or actinomycin D produces a substantial number of cures.¹⁰⁸ The basis for the unusual sensitivity of this tumor to MTX is not entirely

clear, but choriocarcinoma cells may accumulate and retain this drug effectively by synthesizing long-chain polyglutamates. The JAR (human choriocarcinoma) cell line was shown to have active-receptor coupled uptake (potocytosis) of folates and antifolates.¹⁰⁹ Current programs for the treatment of this malignancy utilize MTX in combination with other drugs, especially for “poor risk” or relapsed patients.¹¹⁰

Breast cancer

MTX as a single agent causes regressions of breast cancer in approximately 30% of patients. When used with fluorouracil, sequential use of MTX followed by 5-FU improved response rates to 50% and improves disease-free survival when used as adjuvant therapy.¹¹¹ The adjuvant use of cyclophosphamide, MTX and 5-FU cyclophosphamide methotrexate fluorouracil (CMF) also significantly reduces the risk of relapse,¹¹² may allow more conservative surgery among women with localized disease when used as neoadjuvant therapy,¹¹³ and has a role in the treatment of patients with inoperable, advanced disease.¹¹⁴ The combination of MTX, 5-FU with vinorelbine (VMF) instead of cyclophosphamide, has also shown activity among women with advanced breast cancer.¹¹⁵ An additional advantage of this combination is the diminution of long-term toxicity (infertility, carcinogenesis) compared to regimens containing alkylating agents. Finally, it is interesting to note that low-dose oral MTX (2.5 mg BID \times 2 days/week) with daily oral cyclophosphamide has shown activity among heavily pretreated women with advanced metastatic breast cancer.¹¹⁶

Gastrointestinal cancer

Antifolates have limited effectiveness in the treatment of gastrointestinal malignancies. The role of MTX in the treatment of these diseases is mainly to modulate, and possibly improve, the effectiveness of 5-FU. By inhibiting purine synthesis, MTX pretreatment increases phosphoribosyl pyrophosphate, a precursor necessary for 5-FU nucleotide formation.¹¹⁷ Data from recent trials using high-dose MTX followed by LV/5-FU in patients with colon cancer highlight the need for a 7- to 24-h interval between MTX and 5-FU administration.¹¹⁸ However, a randomized phase III study comparing 5-FU plus MTX to standard, continuous infusion of 5-FU demonstrated increased toxicity among those treated with MTX, and no difference in overall survival between the two arms. On the basis of these findings, 5-FU remains the standard of care for advanced gastric cancer.^{119–121}

Genitourinary cancer

MTX alone (100 mg/m²), or in high doses (\geq 500 mg/m²) with LV rescue, is active in the treatment of advanced bladder cancer. The response rate reported (approximately 30%) is similar to the response rate of the other most active single drug, cisplatin. Combinations of drugs including MTX with cisplatin, vinblastine, and doxorubicin (M-VAC) have resulted in a substantial number of long-term clinical remissions.¹²² A meta-analysis of randomized trials found that neoadjuvant treatment with MTX-containing regimens conferred a survival advantage.¹²³

Head and neck cancer

MTX is an active agent for the treatment of patients with advanced carcinoma of the head and neck region. High-dose MTX regimens with LV rescue appear to improve response rates from 30% to 50%, but remission duration and survival are not improved.¹²⁴ MTX has also been used with 5-FU in this disease, with response rates as high as 60%.^{125, 126} The sequence and timing of drug administration have not been

shown to affect the response rate, although different patterns of toxicity were observed.

Lung cancer

MTX as a single agent in conventional doses, or in high doses with LV rescue, has only marginal activity in non-small-cell lung cancer (NSCLC). This drug does have limited activity in small cell lung cancer and has been used in combination regimens to treat that disease. Pralatrexate, a nonclassical antifolate discussed later in further detail, has been shown to have activity for patients with previously treated NSCLC.¹²⁷

Osteogenic sarcoma

Osteosarcoma responds poorly to conventional doses of methotrexate. However, high-dose methotrexate has been one of the mainstays of treatment since its introduction in the 1970s.¹²⁸ Randomized trials of pre- and post-definitive treatment demonstrated the beneficial effect of chemotherapy that includes high-dose MTX with LV rescue.¹²⁹ Different studies investigated whether MTX peak concentration and area under concentration–time curve (AUC) are significant prognostic factors of osteosarcoma.¹³⁰ Controversy remains as to whether there is correlation between MTX exposure and outcome.¹³¹ A recent study analyzed the relation between MTX pharmacokinetics, toxicity and survival in children with osteosarcoma. Although there was no correlation between survival and peak concentration or AUC, the 48-h MTX concentration had significant correlation to survival, confirming that systemic MTX exposure was a significant prognostic factor of treatment outcome.¹³²

Neoplastic meningitis

Intrathecal MTX is often a component of therapy for patients with solid-tumor neoplastic meningitis. High-dose IV MTX (8 g/m²) given as the sole treatment with LV rescue may be a reasonable alternative,³⁸ as therapeutic antineoplastic concentrations of MTX can be achieved more easily in the presence of neoplastic meningitis.¹³³

Adverse effects

Hematologic toxicity

Expression of many folate-dependent enzymes targeted by MTX are cell-cycle specific, consistent with their role in DNA synthesis. Tissues that are self-renewing, with a higher S-phase fraction, are therefore at highest risk for damage by the folate antagonists. Bone marrow progenitor cells of all lineages are affected by MTX, but neutropenia usually predominates, with a nadir 10 days after drug administration and recovery typically between days 14 and 21. The effects on the marrow are dose related, but there is considerable variability among patients. Genetic variants,^{71, 134, 135} subclinical folate deficiency, impaired renal function, a damaged marrow owing to previous radiation therapy, chemotherapy, or infection, and the use of trimethoprim-sulfamethoxazole for *Pneumocystis carinii* prophylaxis may predispose patients to hematologic (and gastrointestinal) toxicity. Young patients usually tolerate MTX better than older individuals, a fact presumably related to clearance of the drug by the kidneys. The administration of LV can prevent or lessen MTX toxicity and allows larger doses of the antifolate to be administered.

Gastrointestinal toxicity

Nausea and vomiting, even with high doses of MTX, are usually mild to moderate. In contrast, mucositis is a common side effect of MTX treatment. Mucositis usually manifests 3–5 days following exposure to the drug. This is an early sign of MTX toxicity and the drug should be discontinued when it occurs. More severe gastrointestinal toxicity is manifest by diarrhea, which may progress to severe bloody diarrhea. When this occurs in association with neutropenia, patients are at high risk of typhlitis, sepsis, and death. These severe side effects generally occur in a setting of renal damage, usually a consequence of high doses of MTX ($\geq 500 \text{ mg/m}^2/\text{dose}$), but may also occur in patients treated with conventional doses. MTX blood levels and serum creatinine levels should be followed, and appropriate doses of LV administered, along with supportive measures (see the following discussion).

Renal toxicity

Renal toxicity occurs occasionally following high-dose regimens of MTX and is rare during treatment with lower doses. When it occurs, renal toxicity leads to delayed MTX clearance and subsequently to severe marrow and gastrointestinal toxicity, which can be fatal, especially in adults.¹³⁶ This toxicity is believed to be due to precipitation of MTX and its less soluble metabolite 7-OH MTX ([Figure 3](#)) in the tubules, as well as to a possible direct effect of this drug on the renal tubule.⁴⁷ The use of vigorous hydration, often with osmotic diuresis and alkalinization of urine to increase solubility of MTX and 7-OH MTX, has markedly ameliorated this problem. Occasional patients, even with this regimen ([Table 3](#)), exhibit renal impairment; therefore, careful monitoring of MTX and creatinine serum levels is essential. For those patients who have markedly delayed clearance of MTX secondary to acute renal dysfunction, increasing the dose and rate of LV administration has been the routine therapeutic maneuver to counteract the consequences of prolonged exposure to high MTX levels.¹³⁷

Table 3 Supportive care for high-dose methotrexate (MTX) treatment

Pretreatment hydration and alkalinization
8–12 h before treatment, patients should receive 1.5 L/m^2 of saline or 5% glucose with 100 mEq HCO_3 and 20 mEq KCl/L. Continue hydration until urine pH is 7.0 or greater before MTX administration
Monitoring
MTX levels should be monitored at 24 h after completion of MTX infusion. Serum creatinine should be measured pretreatment, at 24, and at 48 h
Additional LV rescue
Required for an MTX level $>10^{-6} \text{ M}$ at 24 h. Increase LV dose to $100 \text{ mg/m}^2 \text{ q } 6 \text{ h}$ for levels above 10^{-6} M and $200 \text{ mg/m}^2 \text{ q } 6 \text{ h}$ for levels above $5 \times 10^{-6} \text{ M}$. Monitor MTX levels daily and continue LV until plasma MTX concentration is $<10^{-8} \text{ M}$

Abbreviation: LV, leucovorin.

Methylxanthines, such as caffeine or aminophylline, may be useful in the setting of delayed MTX clearance. MTX administration has been shown to increase serum adenosine concentrations, which will decrease glomerular filtration rate.¹⁷ Adenosine receptor competitive antagonists, such as the methylxanthines, may therefore act as a specific diuretic to increase MTX elimination.¹³⁸

Extremely high levels of MTX ($>10^{-3} \text{ M}$) are difficult to rescue, even with high doses of LV.¹³⁹ Removal of MTX by peritoneal dialysis or hemodialysis is ineffective because the drug is extensively protein bound. Charcoal hemoperfusion columns have been used successfully in a small number of patients, but its efficacy is limited by rebounds in MTX levels.¹⁴⁰ Extracorporeal methods of methotrexate removal

such as high-flux hemodialysis and hemodiafiltration have had variable efficacy, but both are highly invasive procedures that have resulted in only transient and small decreases in MTX levels, necessitating their combined or repeated daily use to lower MTX concentration effectively.^{141, 142} Oral charcoal and cholestyramine have also been used to bind MTX in the gut, thus limiting enterohepatic recirculation and toxicity.¹⁴³ Thymidine (1–3 g/m²/day) is also capable of rescuing patients from MTX toxicity, but this metabolite is not generally available.¹⁴⁴ A recombinant form of bacterial carboxypeptidase, glucarpidase [carboxypeptidase-G₂ (CPDG₂)], an enzyme that hydrolytically cleaves the peptide bond in MTX resulting in glutamate and dAMPA ([Figure 3](#)), has been reported to reduce systemic MTX concentrations rapidly by >95% within 1 h of administration^{145, 146} When given in combination within 96 h after the start of the MTX infusion in addition to LV, carboxypeptidase G2 is highly effective in patients at high risk for developing life-threatening MTX toxicity after IV^{146–148} or intrathecal administration.¹⁴⁹ While most studies are reported in the adult population, a recent retrospective review in pediatric patients showed similar results.¹⁵⁰

Hepatotoxicity

Chronic low-dose weekly MTX treatment for patients with psoriasis, rheumatoid arthritis, or ALL has been associated with portal fibrosis, and in some patients, with frank cirrhosis.¹⁵¹ Among cancer patients, acute elevations of liver enzymes commonly occur within days after treatment with MTX, but rapidly return to normal, and do not appear to predict chronic liver toxicity, even when elevated to 10–20 times the upper limit of normal.^{152, 153} Concurrent administration of dexamethasone may increase MTX-induced hepatotoxicity.¹⁵⁴ Alcohol and other hepatotoxic drugs should be avoided in these patient populations.

Central nervous system toxicity

Intrathecal MTX and IV administration of high-dose MTX have been associated with acute neurotoxicity, ranging from mild to severe. In cases of inadvertent overdosing (>100 mg intrathecally), fatalities have been reported. Greater understanding of the pathophysiology of MTX-induced neurotoxicity is now beginning to lead to therapeutic interventions to prevent or treat this complication of therapy.

The most common immediate side effect of intrathecal MTX administration, manifest by severe headache, fever, meningismus, vomiting, and CSF pleocytosis, is thought to be caused by a chemical arachnoiditis, or perhaps by the release of adenosine, which is a potent autotoxin in the CNS.¹⁵⁵ This effect of adenosine has been ameliorated by systemic administration of low doses of methylxanthines, such as aminophylline and theophylline, which act as competitive antagonists at adenosine receptors.¹³⁸ Dosage adjustment or switching to cytosine arabinoside may be required if these symptoms persist. Acute toxicity occurring several days after high-dose systemic MTX treatment manifests with headache, paresis, aphasia, or seizures. It is usually transient, resolving within 2–3 days.¹⁵⁶

Subacute neurotoxicity (7–14 days after administration) has been observed in 5–18% of patients receiving intrathecal MTX and/or IV high-dose MTX. At its most severe, it presents with motor paralysis of the extremities, cranial nerve palsies, seizures, and even coma. While the pathogenesis of subacute antifolate-induced neurotoxicity is likely multifactorial, disruption to homocysteine homeostasis may play a pivotal role. By inhibiting remethylation to methionine, MTX leads to increased amounts of homocysteine in the plasma and CSF of patients.¹⁵⁷ Homocysteine may cause neurotoxicity through induction of oxidative damage to neuronal tissue and vascular endothelium.^{158, 159} In addition, homocysteine and its metabolites are excitotoxic amino acids (glutamate analog) that activate the *N*-methyl-D-aspartate (NMDA) class of glutamate receptors. Subacute neurotoxicity of MTX may be

ameliorated by an antagonist of the NMDA receptor, such as dextromethorphan or memantine.^{160–162}

Delayed MTX-induced neurotoxicity may be associated with chronic demyelinating encephalopathy in as many as 80% of children with acute lymphoblastic leukemia, and the magnitude of the radiographic changes seems to correlate with dose and number of doses of IV MTX.^{92, 93} Computed tomography scans show cortical thinning, ventricular enlargement, and diffuse intracerebral calcifications. Although most commonly attributed to the combination of cranial radiation with intrathecal MTX, encephalopathy has been reported in patients treated only with high-dose IV MTX. The pathogenesis of delayed neurotoxicity may be a result of impairing folate-dependent methylation of components of the myelin sheath.¹⁶³

In patients who receive an MTX overdose intrathecally (>100 mg), immediate CSF removal with ventriculolumbar perfusion is indicated.¹⁶⁴ Intrathecal use of carboxypeptidase G2 was shown to decrease mortality in animals given a lethal dose of MTX intrathecally and may be the preferred treatment for this complication.¹⁶⁵ Intrathecal or systemic LV is not indicated in these cases, as it is unlikely that this toxicity is attributable to inhibition of DHFR.

Pulmonary toxicity

Although uncommon, pulmonary toxicity due to MTX has been noted in patients treated chronically with low-dose oral MTX.¹⁶⁶ The clinical picture usually consists of cough, dyspnea, fever, and hypoxemia. Chest radiograph findings are nonspecific but may show patchy interstitial infiltrates. *P. carinii* must be ruled out, especially in patients also receiving steroids. Histologic examinations show diffuse interstitial lymphocytic infiltrates, giant cells, and noncaseating granulomas. In some patients, a peripheral eosinophilia is observed, raising the possibility that this is an allergic pneumonitis. The process may progress to fibrosis and discontinuing MTX while the pulmonary toxicity is reversible is important. Some patients have been retreated without recurrence of the problem.

Skin toxicity

Skin toxicity to MTX occurs in 5–10% of patients. It manifests as an erythematous rash, characteristically noted on the neck and upper trunk. The rash may be pruritic and relatively insignificant and usually lasts for several days. A cutaneous vasculitis after intermediate-dose MTX has also been reported.¹⁶⁷ In the setting of severe systemic MTX toxicity following HD-MTX or overdose, the skin manifestations may progress to severe bullous formation and desquamation.¹⁶⁸

Teratogenic and mutagenic effects

Folate deficiency alters gene expression by causing hypomethylation of DNA and increases DNA strand breaks by causing mis-incorporation of uracil instead of thymine. Consequently, folate deficiency can directly influence carcinogenesis.¹⁶⁹ MTX is known to be a potent abortifacient, especially if administered during the first trimester of pregnancy. Nevertheless, there is no direct evidence that MTX has any mutagenic or carcinogenic effects.

Miscellaneous toxicity

Osteoporosis has been reported with chronic low-dose MTX administration¹⁷⁰ and may result from direct inhibition of osteoblastic differentiation.¹⁷¹ Fever, seizures, radiation recall, phototoxicity, and anaphylactoid reactions have been reported with high-dose administration. Pleuritic and left-upper-quadrant pain, presumably attributable to splenic capsule inflammation, has been reported with a

moderately high-dose regimen. An acute hemolytic anemia due to an IgG-3 antibody that reacts with erythrocytes only in the presence of MTX has been described.¹⁷²

Resistance to antifolates

Although the development of effective chemotherapeutic regimens including MTX has improved significantly the therapy of a number of different malignancies, achieving prolonged disease-free survival is still difficult even in chemotherapy-sensitive diseases. The efficacy of MTX, as with other antineoplastic agents, is limited ultimately by either inherent resistance or resistance acquired during the course of therapy. Distinct categories of resistance mechanisms have been described: (1) decreased accumulation due to impaired transport into the cell, (2) decreased accumulation of polyglutamate forms, owing to either decreased polyglutamate formation or increased removal of glutamate residues, (3) an increase in DHFR, (4) altered or mutated DHFR that binds MTX less avidly than the normal enzyme. In addition, because both DHFR and FPGS activities fluctuate with cell cycle, dysregulation of cell cycle genes may have a profound effect on antimetabolite resistance.

Intrinsic resistance to MTX

Intrinsic sensitivity to antifolates has been shown to relate to expression of mitochondrial enzymes.²² Driven by *myc* activation, enzymes related to the cellular metabolism of serine, folate, and glycine are upregulated in many tumor types. This differential expression leads to selective sensitivity to folate antagonists relative to normal tissues.

Impaired ability to transport MTX into cells through the RFC results in intrinsic resistance in many tumor types. The vast majority of mechanisms of impaired antifolate transport involve quantitative and/or qualitative alterations at the RFC level. This includes mutations in RFC that alter its transport activity, RFC silencing via promoter methylation and 3'-UTR alterations, RFC silencing via loss of function of transcriptional regulators, and alterations in gene copy number of RFC in antifolate-resistant cells.¹⁷³ Decreased expression of RFC mRNA has been documented by quantitative reverse transcription polymerase chain reaction (RT-PCR) in osteosarcoma samples at initial biopsy.¹⁷⁴ In other tumors, decreased expression can result from aberrant methylation in the promoter region.^{175, 176}

Mutations in the RFC gene corresponding to altered transport function have been documented both in resistant cell lines¹⁷⁷ and in leukemic blasts at diagnosis.¹⁷⁸ Single nucleotide polymorphisms (SNPs) in the gene for RFC can result in proteins with a decreased affinity for antifolates, while maintaining sufficient affinity for folate to allow continued cell growth. Other known polymorphisms selectively increase affinity for folates and increase the intracellular folate pool. However, in one analysis of 246 pediatric leukemia patient samples, only three were found to have potentially functional RFC polymorphisms, suggesting that they do not appear to play a major role in intrinsic MTX resistance in this population.¹⁷⁹

Polyglutamylation enhances cellular retention of classical antifolates. Therefore, loss of FPGS activity can confer relative resistance. Differing ability to form long-chain MTX polyglutamates to some degree explains the relative intrinsic resistance of AML to MTX, compared with ALL.^{180, 181} Similarly, tumor cells from patients with soft tissue sarcomas intrinsically resistant to MTX have a low capacity to form long-chain MTX polyglutamates.^{182, 183} Higher MTX-polyglutamate accumulation in B-lineage ALL blasts as compared to T-lineage blasts may be explained by the finding of higher FPGS activity in B-lineage blasts.^{184, 185} The possibility that different isoforms (splice variants) of FPGS are expressed in different

tissues is supported by the finding of differences in FPGS affinity for MTX between AML and ALL cell lines and blast samples,¹⁸⁶ between resistant and sensitive sarcoma cell lines,¹⁸⁷ and by differences between FPGS isolated from L1210 cells and murine liver in degree of inhibition by long-chain folylpolyglutamates.¹⁰

Increased expression of the target enzyme DHFR, a well-described mechanism of acquired MTX resistance, may also confer intrinsic resistance. A polymorphism in the 3' untranslated region that decreases binding of an inhibitory micro-RNA species (miR-24) leads to increased DHFR expression without prior MTX exposure.¹⁸⁸ Although this SNP was initially described as existing in 11–16% of a Japanese cohort,¹⁸⁹ the prevalence of this SNP may be much lower in other populations.¹⁹⁰

Lack of the retinoblastoma protein, frequently deleted or altered in many tumor types, may play a role in intrinsic MTX resistance. In the absence of retinoblastoma protein, levels of the transcription factor E2F increase, resulting in an increase in transcription of several genes involved in DNA replication, including DHFR.¹⁹¹

Overexpression of *p*-glycoprotein does not confer resistance to MTX. However, MTX is a substrate for the related proteins, multidrug resistance proteins 1–5 (ABCC1–5)^{192, 193} and the breast cancer resistance protein (ABCG2).¹⁹⁴ ABCC5¹⁹³ and ABCG2¹⁹⁵ are able to transport both MTX and MTX-diglutamate. Overexpression of these proteins produces MTX resistance *in vitro*^{193, 196, 197} and may affect the response to therapy among patients with leukemia.^{198, 199} To what degree these proteins contribute to clinically relevant intrinsic resistance to MTX in other diseases is not clear.

Acquired resistance to MTX

Four predominant mechanisms of acquired resistance to MTX have been described in experimental tumors and clinical samples: an increase in DHFR activity due to amplification of this gene; altered binding of MTX to DHFR due to DHFR mutations; decreased influx of MTX through the RFC; or to a decrease of long-chain polyglutamate formation.

At the point of entry into the cell, either mutations or deletions in the RFC could result in decreased uptake of MTX and MTX resistance. Although polymorphisms in the gene for RFC do not seem to be a common mechanism of intrinsic resistance among patients with leukemia,¹⁷⁹ decreased transport of MTX through the RFC has been shown to be a common mechanism of acquired resistance to MTX in leukemic blasts from patients with relapsed ALL.²⁰⁰

Exposure to MTX leads to a rapid increase in DHFR protein, as DHFR bound to MTX will not bind to its own mRNA and inhibit further translation.²⁰¹ Unstable or reversible resistance due to gene amplification has also been associated with the presence of “double minute” chromosomes containing the DHFR amplicon,²⁰² while high-level stable resistance has been associated with an abnormal banding region, often referred to as a homogeneously staining region.^{203–207} Point mutations in DHFR in several cell lines, including human cells, have been detected that cause a change in the binding of MTX to the enzyme and have usually involved amino acids that bind to the inhibitor by hydrophobic interaction.²⁰⁸

Although defects in polyglutamylation have been described in several MTX-resistant cell lines,²⁰⁹ the resistance of these cells has usually been found to be attributable to a combination of mechanisms. Increased hydrolysis of MTX polyglutamates can result from increased transport of MTX-polyglutamates into the lysosome²¹⁰ or increased levels of GGH activity.^{183, 211} Recent studies have provided ample evidence that epigenetic regulation and SNPs in the promoter and coding region of GGH can affect GGH

expression and, therefore, responsiveness to antifolate therapy.^{212–214} However, forced overexpression of GGH in cancer cell lines does not confer resistance to short exposure to MTX.²¹⁵

Strategies to overcome resistance to MTX using new (or older) antifols

The rational design of new folate antagonists is driven by an increasing understanding of the molecular basis of normal folate physiology, of MTX cytotoxicity and MTX resistance, and is guided by crystallographic data from the target enzymes.²⁰⁸ Newer antifolates have been designed to have one or more of the following properties: increased transport into the cell by either increased affinity for the RFC or independence of the RFC, independence of polyglutamylation or increased polyglutamylation by virtue of increased affinity for FPGS, increased inhibition of DHFR or TS, or increased inhibition of enzymes responsible for purine synthesis.

Aminopterin (AMT), an older antifol

Preclinical and clinical data support reevaluating an antifol older than MTX, 4-amino-pteroyl-glutamic acid (AMT; [Figure 1](#)), the first antifolate to produce remissions among patients with leukemia.² AMT has several advantages over MTX, including 20–40 times greater clinical potency,²¹⁶ more efficient conversion (higher $V_{\max} : K_m$ ratio) by FPGS to polyglutamates²¹⁷ leading to greater accumulation by patients' leukemic blasts *in vitro*,²¹⁸ and complete oral bioavailability.²¹⁹ Twenty-seven percent of children with refractory ALL had clinically significant responses to oral AMT in a phase II trial,²²⁰ and a phase IIb trial demonstrated that AMT can be substituted safely for MTX without excessive toxicity¹³⁴ in multiagent therapy for children with newly diagnosed ALL at high risk of relapse. Recent preclinical data suggest that AMT may benefit patients with atopic dermatitis.²²¹

Pralatrexate, a second-generation DHFR inhibitor

Similar to MTX, pralatrexate (10-propargyl-10-deazaaminopterin; PDX; [Figure 4](#)) competitively inhibits DHFR, limiting thymidine synthesis and cell division. PDX was designed to have high affinity for the RFC and FPGS, leading to enhanced and selective intracellular internalization and retention in tumor cells.²²² Consequently, PDX exhibits a 14-fold greater rate of influx²²³ and more potent inhibition of tumor growth when compared to MTX.²²⁴

Figure 4 Novel folate antagonists of clinical interest.

Pralatrexate is given via IV administration. The total systemic exposure (AUC) and maximum plasma concentration (C_{\max}) increase proportionally with dose. The terminal elimination $t_{1/2}$ of PDX is 12–18 h. Approximately one-third of an IV dose is excreted unchanged in urine, and clearance decreases with decreasing creatinine clearance. The PK of PDX does not change significantly over multiple treatment

cycles.²²⁵

Preclinical studies of PDX in combination with gemcitabine²²⁶ and bortezomib²²⁷ led to clinical trials of these combinations for patients with lymphoma. The overall response rate among those with T-cell lymphomas was significantly higher than those with B-cell lymphoma, suggesting a possible selectivity of the T-cell malignancies.²²⁸ PROPEL (pralatrexate in relapsed or refractory peripheral T-cell lymphoma) was a prospective study looking at relapsed or refractory PTCL. It included 115 patients, most of whom had been heavily pretreated. An overall response rate of 29% was reported, and based on this finding, the FDA approved the use of PDX for treatment of relapsed and refractory T-cell lymphoma.²²⁹ PDX has also been shown to have high activity with acceptable toxicity in patients with NSCLC¹²⁷ and relapsed or refractory cutaneous T-cell lymphoma.²³⁰ A recent study using both *in vitro* and *in vivo* models demonstrated the protective effect of LV on PDX toxicity.²³¹

Pemetrexed, an inhibitor of multiple folate-dependent enzymes, primarily TS

Pemetrexed (*N*-[4-[2-(2-amino-3,4-dihydro-4-oxo-7H-pyrrolo[2,3-d]pyrimidin-5-yl)ethyl] benzoyl]-L-glutamic acid; [Figure 4](#)) inhibits TS, DHFR, and glycinamide ribonucleotide formyltransferase (GARFT). Although promoted initially as a “multitargeted” antifolate, it is primarily a TS inhibitor, as indicated by its greater affinity for this enzyme and by end-product inhibition experiments.^{232, 233} Pemetrexed is transported into cells via the RFC, as well as the proton-coupled folate transporter. Pemetrexed is rapidly polyglutamated by FPGS, with a K_m for the enzyme two orders of magnitude below that of MTX. Similar to pralatrexate, pemetrexed is administered intravenously. The AUC and C_{max} increase proportionally with dose. The elimination $t_{1/2}$ of pemetrexed is 3.5 h in patients with normal renal function. The PK of pemetrexed did not change significantly over multiple treatment cycles.²³⁴ Clinically, pemetrexed toxicity is increased with a high concentration of plasma homocysteine, which in turn has been associated with nutritional folate deficiency or low concentrations of 5-methyl tetrahydrofolate required for methionine synthesis, secondary to mutations in methylene tetrahydrofolate reductase. Supplementation with these vitamins in all subsequent regimens reduced toxicity and allowed delivery of a greater number of courses, increasing response rates.²³⁵

Pemetrexed has broad-spectrum activity in multiple tumor types.²³⁶ On the basis of the results from a phase III clinical trial, pemetrexed in combination with cisplatin is considered first-line therapy for advanced NSCLC.²³⁷ The use of pemetrexed as maintenance therapy in NSCLC was evaluated in the PARAMOUNT phase III study. This study proved pemetrexed to be effective with an improvement in progression free and overall survival.²³⁸ It is also used as monotherapy for relapsed or refractory NSCLC and in combination with cisplatin for the treatment of pleural mesothelioma.^{235, 239} There have been several preclinical and phase I studies looking at pemetrexed in patients with advanced solid malignancies such as breast cancer, colorectal cancer, and medulloblastoma.^{240–242} As a consequence of these studies, multiple phase II studies are underway.

Acknowledgments

Barton A. Kamen, MD, PhD, an author of previous versions of this chapter, died in 2012 after a battle with cancer. Bart was a respected clinician, clinical researcher, teacher, and basic scientist with a legacy of many significant contributions to the (anti)folate field, including the identification of the folate-binding

protein and description of its defining characteristics.

Chapter 57

Pyrimidine and purine antimetabolites

Robert B. Diasio, MD

Overview

The development of pyrimidine and purine antimetabolite drugs has been based on the rationale that nucleic acids are critical to cell replication and, therefore, the pyrimidine and purine bases (and their nucleosides) that are the “building blocks” necessary to synthesize nucleic acids are themselves potential sites for designing drugs that could be effective in inhibiting nucleic acid synthesis, whether that be in bacteria, viruses, or tumor cells. In this chapter, the various antimetabolites or analogs of uracil/thymine, cytidine/deoxycytidine, hypoxanthine/guanine, and adenosine that are currently used in the management of cancer are presented and reviewed with regard to metabolism, mechanism of action, clinical pharmacology, clinical activity, and toxicity.

The development of pyrimidine and purine antimetabolite drugs has been based on the rationale that nucleic acids are critical to cell replication and, therefore, the pyrimidine and purine bases (and their nucleosides) that are the “building blocks” necessary to synthesize nucleic acids are themselves potential sites for designing drugs that could be effective in inhibiting nucleic acid synthesis, whether that be in bacteria, viruses, or tumor cells. Recognizing that neoplastic cells (e.g., leukemic cells) often reproduce rapidly compared to their normal counterparts (e.g., lymphocytes or granulocytes), there is further logic for designing drugs similar to the pyrimidine or purine base or nucleoside precursors in the hope that they might disrupt nucleic acid synthesis. The term “antimetabolite” refers to the ability of synthetic pyrimidines and purines to mimic the structure of the naturally occurring pyrimidine and purine bases (or nucleoside metabolites) and, therefore, to enter biochemical pathways similar to their natural counterparts. However, the slight molecular differences in the antimetabolite analogs can result in interference with the synthesis of DNA and RNA. The resultant disruption in naturally occurring nucleic acid synthesis may occur in several ways. Thus, the pyrimidine or purine antimetabolites might compete with the naturally occurring counterpart for an enzyme that is critical in the nucleic acid synthesis pathway, thereby disturbing the pools of natural pyrimidine and purine nucleotides needed to synthesize DNA or RNA. Alternatively, the pyrimidine or purine may be incorporated directly into DNA or RNA resulting in the formation of a dysfunctional nucleic acid or possibly resulting in nucleic acid fragmentation as the DNA or RNA seeks to correct the abnormality.¹

Pyrimidine antimetabolites

Potential pyrimidine antimetabolite cancer chemotherapy drugs might include structural modifications of the naturally occurring pyrimidine bases uracil, cytosine, or thymine or their ribose or deoxyribose nucleosides ([Figure 1a](#)). While thymine antimetabolites, such as azidothymidine (AZT), are effective in the treatment of viral infections, they are not as useful as uracil and cytosine antimetabolites in the treatment of cancer.

Uracil antimetabolites

Over the years, there have been several uracil antimetabolites that have shown potential activity in the treatment of various malignancies. The only uracil antimetabolites that remain actively used today in the United States are the 5-fluorouracil (5-FU) drugs ([Figure 1](#)), including the parent drug 5-FU, its deoxyribose nucleoside, 5-fluorodeoxyuridine (Floxuridine, FdUR or FdUrd) that is used occasionally today with hepatic arterial infusion, and the prodrug of 5-FU, capecitabine. In other parts of the world, particularly Asia, there has been widespread use of other 5-FU prodrugs (e.g., UFT, S-1), but in the United States, capecitabine is the only one presently approved.²

5-Fluorouracil (5-FU)

5-FU is one of the first rationally synthesized antineoplastic agents.³ The stimulus for developing this antimetabolite derives from the observation that rapidly growing tumor cells require an exogenous source of uracil for growth (beyond what can be provided by the endogenous natural synthetic pathway forming uracil from orotic acid). Exogenously formed uracil can be converted into deoxyuridyate (dUMP), which in turn, in the presence of 5,10 methylene tetrahydrofolate, can form thymidylate required for DNA synthesis, from donation of a methyl group to the fifth position of the uracil ([Figures 1](#) and [2](#)). 5-FU is a close analog of uracil with fluorine effectively substituting for hydrogen at the fifth position of uracil due to similar conformation, including a similar van der Waals radius. As can be seen in [Figure 2](#), this allows 5-FU to enter the biochemical pathways used naturally by uracil.

Figure 1 Uracil/thymine antimetabolites. (a) Natural occurring pyrimidine bases uracil and thymine together with the uracil deoxyribonucleoside (2'-deoxyuridine). (b) Antimetabolites 5-fluorouracil and 5-fluoro-2'-deoxyuridine developed from structural modifications of uracil and 2'-deoxyuridine.

the cell, any enzymatic limitation of conversion of 5-FU to the nucleoside and then to the nucleotide. Thus, reduced uridine phosphorylase/kinase or orotate phosphoribosyltransferase could result in decreased levels of 5-FU nucleotides.

One aspect of 5-FU metabolism and pharmacology that is somewhat different from other agents is the concept of “biochemical modulation,” in which the activity of 5-FU at an important enzymatic step or a critical site of action is influenced by the addition of an important chemical or precursor to a critical metabolite.⁶ The best example of this is the use of leucovorin (folinic acid) that is often administered with 5-FU to increase the likelihood of adequate amounts of 5,10-methylene tetrahydrofolate being available to insure combination with FdUMP and thymidylate synthase (TS) to form a ternary complex capable of inhibiting DNA synthesis.

Mechanism of action

5-FU is thought to derive its anticancer activity from the effect of its nucleotide metabolites at three different sites ([Figure 2](#)). Inhibition of the enzyme TS by FdUMP (which actually has an affinity for TS greater than that of the natural substrate dUMP) in the presence of 5,10-methylene tetrahydrofolate inhibits the formation of thymidylate (TMP), which is critical for DNA synthesis. This has long been thought to be the primary mechanism by which fluoropyrimidine drugs work.⁵ A second possible mechanism is the incorporation of the 5-FU ribonucleotide fluoro uridylate triphosphate (FUTP) into RNA in place of the natural uracil ribonucleotide UTP. This form of RNA may also be important owing to its effect on small RNAs.² The third mechanism is somewhat similar to the second with incorporation of the 5-FU deoxyribonucleotide FdUTP into DNA in place of the natural thymidylate nucleotide TTP. In this latter setting, however, it is the excision and repair of DNA containing FdUTP by uracil glycosylase resulting in DNA fragmentation that is thought to contribute to cytotoxicity.³

Clinical pharmacology

5-FU is typically administered as either an intravenous bolus or an intravenous infusion. Following administration as an intravenous bolus, 5-FU is rapidly cleared following first pass through the liver where it is rapidly catabolized with more than 85% of the administered dose being inactivated by initial degradation to dihydrofluorouracil (FUH₂).³ The half-life of 5-FU in this setting is typically approximately 13 ± 7 min with the clearance being approximately 600 ± 200 mL/min/m².⁴ Administering 5-FU by continuous infusion over 5 days or as a protracted multiday infusion by ambulatory pump, leads to a predicted, relatively constant but low level of 5-FU.²

Variability in the efficiency of catabolism exists with the main determinant being DPD, the rate-limiting step in 5-FU catabolism. In a small (<5%) but significant part of the population, genetic variants in the gene coding for DPD (*DPYD*) can result in decreased DPD activity that can shift more 5-FU into the anabolic pathway and in turn result in increased toxicity.^{7, 8}

Clinical use and indications

5-FU continues to be widely used to treat several common malignancies, including colorectal cancer and certain forms of skin cancer and breast cancer. It remains the major component of both adjuvant and advanced colorectal cancer regimens typically being administered with other drugs.²

Toxicities

Toxicities from 5-FU vary depending on dose and schedule of administration. Acute toxicities associated

with intravenous bolus administration include myelosuppression, mucositis, and diarrhea. Prolonged exposure to 5-FU from continuous infusion may result in palmar-plantar erythrodysesthesia (hand-foot syndrome).^{2, 3}

Other 5-FU drugs

Over the past 60 years, there have been many additional 5-FU analogs synthesized. Most of these have been prodrugs of 5-FU.

5-Fluorodeoxyuridine

Background

5-Fluorodeoxyuridine (FdUrd, FUDR), the deoxyuridine of 5-FU, was synthesized about the same time as 5-FU in the late 1950s. Today it has relatively limited use. Its structure is shown in [Figure 1](#).

Metabolism

FdUrd can function as a prodrug of 5-FU, being converted by deoxyuridine or thymidine phosphorylase into 5-FU. However, because it is a very good substrate for deoxyuridine or thymidine kinase, it is more likely rapidly directly converted into FdUMP, one of the primary active metabolites of 5-FU.

Mechanism of action

Formation of FdUMP can, in the presence of 5,10 methylene tetrahydrofolate, form an irreversible ternary complex with TS thereby blocking DNA synthesis. As most administered FdUrd will be metabolized directly to FdUMP, FdUrd is a relatively pure S-phase inhibitor.⁹

Clinical pharmacology

Today, when FdUrd is used, it is mainly as a continuous hepatic arterial infusion through an implantable pump.¹⁰

Clinical activity

FdUrd is utilized mainly in the treatment of hepatocellular cancer and colorectal cancer metastases to the liver.

Toxicities

With prolonged hepatic arterial infusion, the major toxicities are hepatic and include biliary sclerosis and occasional elevation of transaminases.^{2, 3}

Capecitabine

Background

There have been many attempts to develop an oral 5-FU drug that could not only provide a more convenient way of receiving 5-FU but also mimic the desirable effects of a 5-FU infusion.¹¹ Capecitabine is the only oral 5-FU prodrug FDA approved in the United States, although other oral forms of 5-FU are available in Asia and Europe.

Metabolism

Capecitabine is converted into 5-FU by the sequential action of three enzymes: (1) hepatic carboxylesterase, which initially hydrolyzes the drug to 5'-deoxy-5-fluorocytidine; (2) cytidine deaminase, which in turn deaminates this derivative to 5'-deoxy-5-fluorouridine (5'-dFUrd); and (3) finally, thymidine phosphorylase, which converts 5'-dFUrd into 5-FU ([Figure 3](#)). Because tumor tissue often has a higher activity of thymidine phosphorylase compared to most normal tissues, there is a potential selective benefit and in turn an improved therapeutic index.

Figure 3 Structure and activation of capecitabine. The prodrug capecitabine is converted into 5-FU by three enzymatic steps carboxylesterase, cytidine deaminase, and uridine (or thymidine) phosphorylase. Intermediate metabolites include 5'-deoxyfluorocytidine (5'dFCR) and 5'-deoxyfluorouridine (5'dFUR).

Mechanism of action

Following conversion into 5-FU, the mechanism of action is identical with that of 5-FU (see above).

Clinical pharmacology

Capecitabine provides an alternative, more patient-friendly way of administering 5-FU to produce the effects of a 5-FU protracted infusion.

Clinical activity

Capecitabine has a similar spectrum of activity as 5-FU and is typically used in the treatment of colorectal and breast cancer.

Toxicities

The toxicities of Capecitabine are similar to those of 5-FU infusion with palmar-plantar erythrodysesthesia being the major toxicity seen with continuous Capecitabine use. Of interest has been a difference in the dose tolerance of Capecitabine in European versus American populations. It remains unclear what the basis for this is although external factors such as folate levels may contribute.¹²

Cytosine antimetabolites

Cytosine antimetabolites with clinical anticancer activity have been mainly nucleosides, where the major structural modification has been in the sugar part of the molecule and not the base. Currently, there are four cytosine antimetabolites used clinically. These include cytosine arabinoside (ara-C), 5-azacytidine (and the related decitabine), and gemcitabine ([Figure 4](#)).

Figure 4 Cytidine/deoxycytidine antimetabolites. (a) Natural occurring cytosine nucleosides cytidine and deoxycytidine. (b) Antimetabolites cytosine arabinoside, 5-azacytidine, decitabine, and gemcitabine developed from structural modifications of the sugar of the cytosine nucleosides.

Cytosine arabinoside

Background

Ara-C was identified as a natural product following isolation from *Cryptotethya crypta*. The arabinoside

sugar differentiates this compound from the cytosine deoxyribonucleoside that is normally a component of DNA in that the 2'-OH group is in the *cis* configuration relative to the *N*-glycosyl bond between the cytosine and the sugar ([Figure 4](#)).¹³ Today, ara-C is prepared synthetically for commercial use. Its effectiveness in cancer chemotherapy led to the synthesis of other arabinoside compounds, such as the purine antimetabolites 2-fluoro-ara-adenosine monophosphate and nelarabine (see the following discussion).

Metabolism

Following uptake into cells through nucleoside transporters, ara-C must first be converted into ara-C monophosphate (ara-CMP) by the action of deoxycytidine kinase and then further phosphorylated to the diphosphate (ara-CDP) and triphosphate (ara-CTP), the latter which is critical for cytostatic activity¹⁴ ([Figure 5](#)).

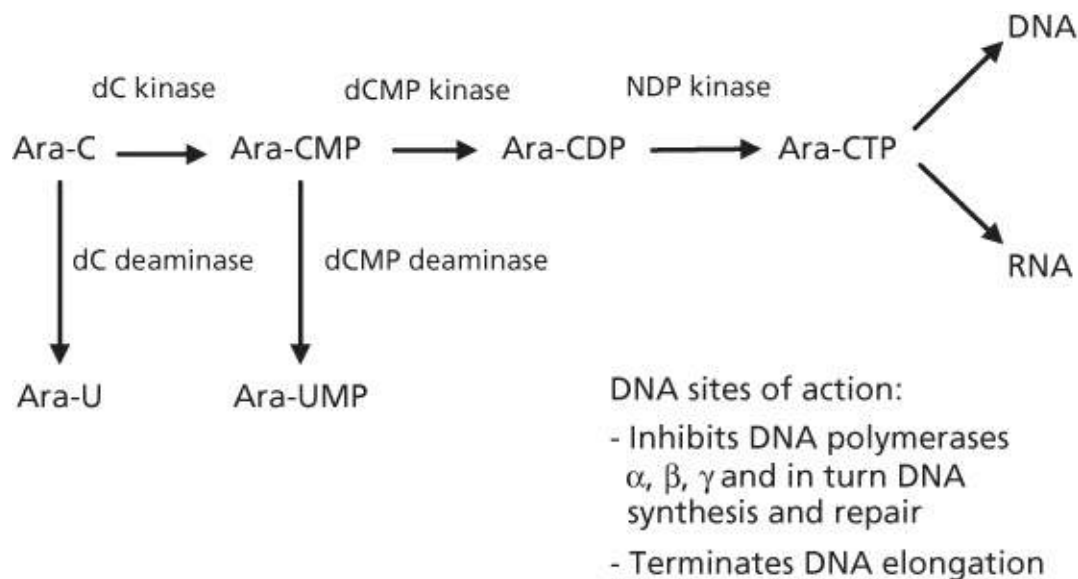

Figure 5 Metabolism and sites of action of ara-C. The metabolic pathway used by ara-C. Ara-C is activated to ara-CTP by the sequential action of three kinases: deoxycytidine kinase (*dC kinase*), deoxycytidine monophosphate kinase (*dCMP kinase*), and nucleotide diphosphate kinase (*NDP kinase*). Ara-C is inactivated by both cytidine deaminase (*CdR deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also listed are the sites of action of ara-C.

Catabolism or degradation of ara-C can occur through the action of either cytidine deaminase, converting ara-C to ara-U, which is inactive, or deoxycytidylate deaminase, converting ara-CMP to ara-UMP, which is also inactive. Increased deamination is a basis for increased resistance as is decreased transport into the cell or any other potential mechanism for decreased anabolism to the active metabolite ara-CTP.

Mechanism of action

The mechanism of action of ara-C is thought to occur at several potential sites. Thus, ara-CTP is a potent inhibitor of DNA polymerases α , β , γ resulting in inhibition of DNA synthesis, elongation, and repair. An alternative mechanism of action occurs following incorporation of ara-CTP into DNA where it can terminate DNA elongation acting as a DNA chain terminator.¹⁵

Clinical pharmacology

The bioavailability of ara-C is poor with extensive deamination occurring in the gastrointestinal tract. This has necessitated intravenous administration typically by continuous infusion. Ara-C undergoes

metabolism to ara-U within the plasma, liver, and various peripheral tissues with >80% excreted into the urine as ara-U. Ara-C can also cross the blood–brain barrier and enter the cerebrospinal fluid.

Clinical activity

Ara-C is an effective anti-leukemic agent, often used as the standard induction regimen for acute myelogenous leukemia (AML). It also has activity in acute lymphocytic leukemia (ALL) and chronic myelogenous leukemia, as well as other hematologic malignancies such as non-Hodgkin's lymphoma. Of interest, the drug has essentially no activity in nonhematologic solid tumors.

Toxicities

Toxicities vary depending on both dose and schedule. As one might predict, one of the most prominent toxicities is myelosuppression. This is seen with standard 7-day regimens with peak myelosuppression at 7–14 days and is particularly prominent with the use of high doses (2–3 g/m²). Accompanying the myelosuppression are other hematologic toxicities in particular thrombocytopenia. Other toxicities include gastrointestinal manifestations such as nausea, anorexia, and vomiting as well as diarrhea, mucositis, and abdominal pain at times with pancreatitis and finally cerebellar toxicities at high doses.

5-Azacytidine and decitabine

Background

5-Azacytidine represents an attempt to improve on the success of ara-C in treating leukemias. Of particular interest was identifying cytidine analogs that did not require activation by deoxycytidine kinase, the enzyme with decreased or absent activity in many ara-C-resistant tumors. A number of analogs were synthesized, in particular ribonucleosides, where structural changes had been made in the pyrimidine ring that still allowed the compound to be anabolized by uridine–cytidine kinase.¹³ The most active of these was 5-azacytidine, which was also later identified occurring naturally in fungal cultures ([Figure 4](#)). 5-Azacytidine was shown to be toxic to both bacterial and mammalian cells. A related drug is decitabine ([Figure 4](#)).

Cellular uptake and metabolism

5-Azacytidine utilizes the equilibrative nucleoside transporter to enter human cells. Once within the cell, it is anabolized by utilizing the uridine–cytidine pathway to form 5-azacytidine monophosphate. This is converted into 5-azacytidine triphosphate by the sequential action of deoxycytidine monophosphate kinase and deoxycytidine diphosphate kinase ([Figure 6](#)). Decitabine's cellular uptake and metabolism are similar.

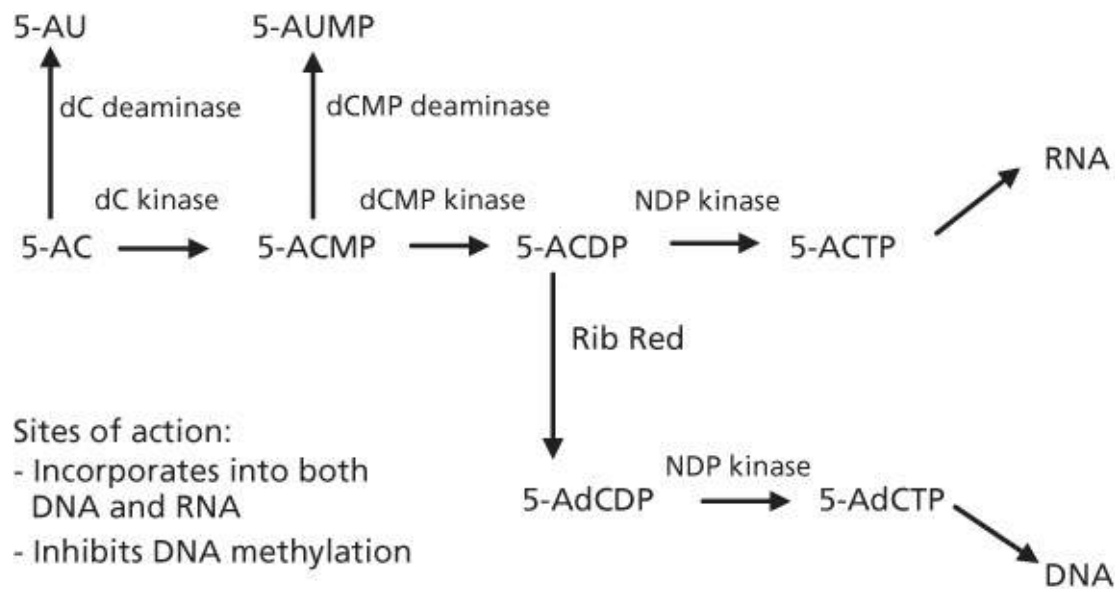

Figure 6 Metabolism and sites of action of 5-azacytidine. The metabolic pathway used by 5-AC. 5-AC is initially activated by the sequential action of deoxycytidine kinase (*dC kinase*) and deoxycytidine monophosphate kinase (*dCMP kinase*) to 5-ACDP. This can then be converted into 5-ACTP by nucleotide diphosphate kinase (*NDP kinase*) or into 5-AdCDP by the action of ribonucleotide reductase (*Rib Red*). 5-AdCDP can then be converted into 5-AdCTP by *NDP kinase*. 5-AC is inactivated by both cytidine deaminase (*dC deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also listed are the sites of action of 5-AC.

Resistance to 5-azacytidine might occur through several mechanisms. Thus, a deficient or altered nucleoside transporter on the cell surface could inhibit cellular uptake and in turn result in relative resistance. Endogenous levels of uridine and/or cytidine can compete with 5-azacytidine for phosphorylation resulting in less activity. Similarly decreased or absent expression of uridine–cytidine kinase could produce resistance. The presence of increased activity of catabolizing enzymes (e.g., cytidine deaminase) could result in the formation of 5-azauridine, which lacks cell toxicity.¹³

Mechanism of action

5-Azacytidine triphosphate is the critical metabolite. There are several suggested sites of action. The 5-azacytidine triphosphate first competes with naturally occurring CTP for incorporation into RNA. 5-Azacytidine triphosphate that gets incorporated into RNA can produce several detrimental effects on RNA processing and function including inhibition of ribosomal 32S and 18S formation, alteration of acceptor function of transfer RNA, disruption of polyribosomal assembly, and resultant inhibition of protein synthesis.⁹ In addition, 5-azacytidine triphosphate can be incorporated into DNA, leading to the inhibition of DNA methylation following replication of DNA.¹³ It is the latter effect that makes this drug particularly interesting to the study of epigenetic effects secondary to methylation. Decitabine has a similar mechanism of action. This includes demethylation or interference with the methylation of DNA. As a result, normal function to the tumor suppressor genes is restored, enabling control over cell growth. As a typical antimetabolite decitabine can also be incorporated into nucleic acid, interacting with a number of potential targets to produce a direct cytotoxic effect that causes death of rapidly dividing cancer cells.

Clinical pharmacology

5-Azacytidine is administered via intravenous infusion and undergoes rapid deamination to 5-azauridine. Plasma clearance is often lower in women and the elderly, and caution should therefore be used in these groups.

Clinical activity

With both 5-azacytidine and decitabine, clinical activity has been observed in both AML and myelodysplasia.¹⁶ As noted earlier, 5-azacytidine's inhibitory effect on DNA methylation is of particular interest in that it enables a mechanism clinically and experimentally to increase expression of epigenetically suppressed genes.

Toxicities

Similar to other members of this antimetabolite group, the major dose-limiting toxic manifestation for both 5-azacytidine and decitabine is myelosuppression in particular neutropenia as well as thrombocytopenia. Nausea and vomiting occur particularly with bolus administration. Other toxicities observed particularly with high dose 5-azacytidine include hepatocellular abnormalities, hyperbilirubinemia, muscle tenderness and weakness, CNS toxicity with lethargy, confusion, and even coma.¹⁷ Because of these latter toxicities, one should use caution in administering these drugs in the presence of hepatic failure or altered mental status.

Gemcitabine

Background

Gemcitabine is a synthetic nucleoside analog in which two fluorines have been substituted for the hydrogens in deoxycytidine.¹³ The structure of gemcitabine is shown in [Figure 4](#).

Cellular uptake and metabolism

Similar to other antimetabolites, gemcitabine utilizes the cell's nucleoside transporter to enter human cells. Once within the cell, it must be anabolized utilizing the cell's natural deoxycytidine pathways to form the gemcitabine triphosphate to achieve activity; it is inactive as the parent drug ([Figure 7](#)).¹⁸

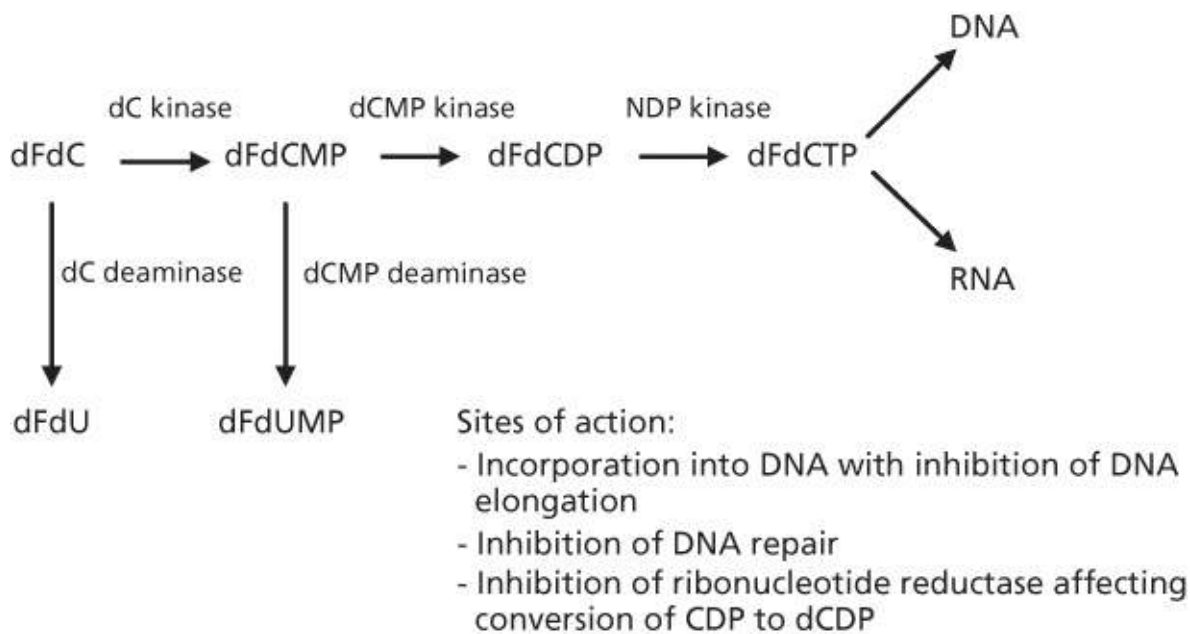

Figure 7 Metabolism and sites of action of gemcitabine (dFdC). The metabolic pathway used by gemcitabine (dFdC). Initially, dFdC must be activated to dFdCTP by the sequential action of three kinases: deoxycytidine kinase (*dC kinase*), deoxycytidine monophosphate kinase (*dCMP kinase*), and nucleotide diphosphate kinase (*NDP kinase*). Similar to ara-C, dFdC is inactivated by both cytidine deaminase (*dC deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also shown are the sites of action of dFdC.

There are several theoretical sites of resistance to gemcitabine. Thus, a deficient or altered nucleoside transporter can inhibit the cellular uptake of gemcitabine and result in relative resistance.¹³ Metabolically, resistance can occur through both decreased activity of critical anabolizing enzymes (e.g., deoxycytidine kinase) or increased activity of catabolizing enzymes (e.g., cytidine deaminase or deoxycytidylate deaminase).

Mechanism of action

Gemcitabine triphosphate is the critical metabolite. There are several suggested sites of action. The most important is thought to be chain termination and inhibition of DNA synthesis and function following incorporation into DNA.¹⁹ Gemcitabine triphosphate is also thought to directly inhibit DNA polymerases α , β , γ and can result in chain termination and inhibition of DNA synthesis and also DNA repair. Lastly, gemcitabine triphosphate is capable of inhibiting ribonucleotide reductase, further contributing to inhibition of DNA synthesis by depleting critically needed deoxyribonucleotide pools.

Clinical pharmacology

Gemcitabine is typically administered via intravenous infusion because of rapid deamination to 2',2'-difluoro-2'-deoxyuridine (dFdU). Plasma clearance is often lower in women and the elderly, and caution should therefore be used in these groups.

Clinical activity

Although it has structural similarity and shares an identical site of action with ara-C, gemcitabine has a much broader spectrum of clinical activity including several solid tumors for example, pancreatic, lung (small cell and non-small cell), ovarian, bladder, and breast cancers as well as in hematologic malignancies, for example, both Hodgkin's and non-Hodgkin's lymphoma.

Toxicities

The major dose-limiting toxicity is myelosuppression with both neutropenia and to a somewhat lesser extent thrombocytopenia. When infusions are increased beyond 30 min, hematologic toxicity tends to be more severe. Other frequently observed toxicities include flu-like symptoms including fever, headaches, myalgias, and arthralgias.

Purine antimetabolites

Purine antimetabolite cancer chemotherapy drugs include structural modifications of the naturally occurring purine bases, guanine and adenine, or their ribose or deoxyribose nucleosides. As with the pyrimidine antimetabolites, the structural changes can be in either the base or the sugar.²⁰

Guanine antimetabolites

Two guanine antimetabolites, 6-mercaptopurine (6-MP) and 6-thioguanine (6-TG), have shown potential anticancer activity. Both were synthesized more than six decades ago but continue to be used today. While not having significant anticancer activity (and therefore not discussed here), azathioprine, a pro-drug of 6-MP that results in slow release of 6-MP is an effective immunosuppressant that has been widely used in organ transplantation, inflammatory bowel disease (e.g., Crohn's), and rheumatologic diseases.

6-Mercaptopurine

Background

The structure of 6-MP is closely related to the naturally occurring purine base hypoxanthine ([Figure 8a](#)); a thiol group substituting for the hydroxyl group at the sixth position. As is characteristic of other antimetabolites, 6-MP can enter the anabolic and catabolic pathways used by the natural occurring metabolites, in this case hypoxanthine.

Figure 8 Hypoxanthine/guanine antimetabolites. (a) Natural occurring purine bases hypoxanthine and guanine. (b) Antimetabolites 6-mercaptopurine and 6-thioguanine developed from structural modifications of hypoxanthine and guanine as well as nelarabine a pro-drug of the deoxyguanosine antimetabolite 9- β -D-arabinofuranosylguanine (ara-G).

Metabolism

Following uptake into cells, 6-MP can be immediately anabolized by hypoxanthine guanine phosphoribosyltransferase (HGPRT) to 6-thioinosine monophosphate (TIMP). TIMP can be further anabolized to the triphosphate and then be incorporated into DNA. The metabolism of 6-MP is shown in [Figure 9](#).

Inhibition of *de novo* purine biosynthesis

Figure 9 Metabolism and sites of action of 6-mercaptopurine (6-MP) and 6-thioguanine (6-TG). 6-MP is converted into 6-thioinosine monophosphate (TIMP) and 6-TG is converted into 6-thioguanine ribonucleotide monophosphate (6-TGMP) by hypoxanthine guanine phosphoribosyltransferase (*HGPRT*) in the presence of PRPP. TIMP is active by inhibiting *de novo* purine biosynthesis at three steps: (1) inhibiting formation of inosine monophosphate (IMP) from glutamine and PRPP, (2) inhibiting conversion of IMP into AMP, and (3) inhibiting conversion of GMP into AMP. Through the sequential activation of nucleotide kinases, 6-TGMP can be eventually converted into the ribonucleotide diphosphate (6-TGDP) and then ribonucleotide triphosphate (6-TGTP). 6-TGTP is active following incorporation into both RNA and DNA, resulting in a disturbance of nucleic acid function.

Resistance can result from decreased availability of TIMP from either decreased anabolism or increased catabolism primarily mediated by phosphatases.

Mechanism of action

TIMP is thought to be the active metabolite deriving its mechanism of action through inhibiting *de novo* purine biosynthesis leading to a disturbance in the size of the natural purine nucleotide pools needed for nucleic acid synthesis ([Figure 9](#)).

Clinical pharmacology

6-MP is administered orally (typically 90 mg/m²), although its absorption can be erratic with variation in peak concentrations and peak times. 6-MP has minimal binding to serum proteins with the half-life of free drug being in 20–45 min range.²¹

6-MP is metabolized by xanthine oxidase. Because other drugs used in the oncologic setting such as allopurinol also utilize this same enzyme in its metabolism, this can lead to a potential serious drug interaction accompanied by increased toxicity (in effect more active 6-MP metabolite present). Therefore, with concomitant use, the dose of 6-MP is typically reduced 50–75%.²²

Another important clinical pharmacologic finding with 6-MP use is pharmacogenetic. Thus, because there

is variability in the expression of thiopurine methyltransferase (TPMT) in the general population owing to variants within the TPMT gene, the metabolism and hence the availability of active drug may vary. It is possible now to screen for these TPMT variants before 6-MP administration and thereby avoid toxicity.²³

Clinical activity

Although introduced clinically more than 50 years ago, 6-MP continues to have a clinical role in the management of ALL, particularly in children. 6-MP lacks efficacy in solid tumors. Because of its immunosuppressive effects, it has also been used for nononcologic diseases (e.g., Crohn's disease).

Toxicities

The primary toxicity with 6-MP is myelosuppression. Other toxicities include gastrointestinal, in particular anorexia, nausea, vomiting, and diarrhea. Hepatotoxicity may also be seen. For this reason, concomitant use of hepatotoxic agents should be avoided. Finally, 6-MP, like its prodrug azathioprine, can produce immunosuppression, and with this an increased risk of infections.

6-Thioguanine

Background

6-TG, like 6-MP, is one of the original purine antimetabolites, first synthesized in the 1950s. It too belongs to the family of guanine antimetabolites. Its structure is shown in [Figure 8](#).

Metabolism

Following uptake into cells, 6-TG is anabolized utilizing the endogenous enzymes in the guanine pathway as shown in [Figure 9](#). 6-TG differs from 6-MP in that it is converted directly into 6-TG nucleotide monophosphate and then subsequently to the nucleotide diphosphate and nucleotide triphosphate, which can then be incorporated into RNA and DNA.

Similar to other antimetabolites, resistance may occur from either decreased activity of anabolic enzymes or increased activity of catabolic enzymes.²⁰

Mechanism of action

The mechanism of action of 6-TG is thought to be secondary to its incorporation into both RNA and DNA where it interferes with nucleic acid synthesis and function.²⁴

Clinical pharmacology

6-TG is typically administered orally. Its oral bioavailability is variable with peak levels occurring 2–4 h after dosing. Its metabolism differs from that of 6-MP in that it is not metabolized by xanthine oxidase. Therefore, no drug interactions occur with concomitant administration of allopurinol, and unlike 6-MP, the dose of 6-TG need not be reduced to avoid toxicity.

6-TG, however like 6-MP, is a substrate for TPMT and therefore in the presence of decreased expression secondary to genetic variability in the TPMT gene expression, one must be adjust for dose in affected individuals. TPMT deficiency is common enough (approximately 10% of all patients) that TPMT screening is recommended before drug administration.²³

Clinical activity

6-TG is active in AML, where it is sometimes used for remission induction and maintenance therapy. 6-TG is also used in ALL.

Toxicities

Myelosuppression is the major toxicity. Other toxicities include stomatitis and gastrointestinal toxicities in particular anorexia, nausea/vomiting, and diarrhea. Hepatotoxicity may also be seen in a significant percentage of patients, in particular cholestatic jaundice and occasionally transaminase elevations. For this reason, concomitant use of hepatotoxic agents should be avoided. Finally, like 6-MP, 6-TG is also associated with immunosuppression with an increased risk of infections.

Nelarabine

Background

Nelarabine is a prodrug of the deoxyguanosine antimetabolite 9- β -D-arabinofuranosylguanine (ara-G), which is cytotoxic. It is one of the newer purine antimetabolites that was developed for use in patients resistant to fludarabine (see the following discussion). Its structure is shown in [Figure 8](#).

Metabolism

As a prodrug, Nelarabine must first be converted into ara-G²⁵ by adenosine deaminase (ADA)-mediated demethylation. Once transported into the tumor cells by nucleoside transporters, ara-G is anabolized to the ribonucleotide triphosphate (ara-GTP), which is the active metabolite. It utilizes the same enzymes used by naturally occurring purines in the purine anabolic pathway ([Figure 10](#)). Similar to other antimetabolites, the activity of catabolic enzymes may contribute to relative resistance.

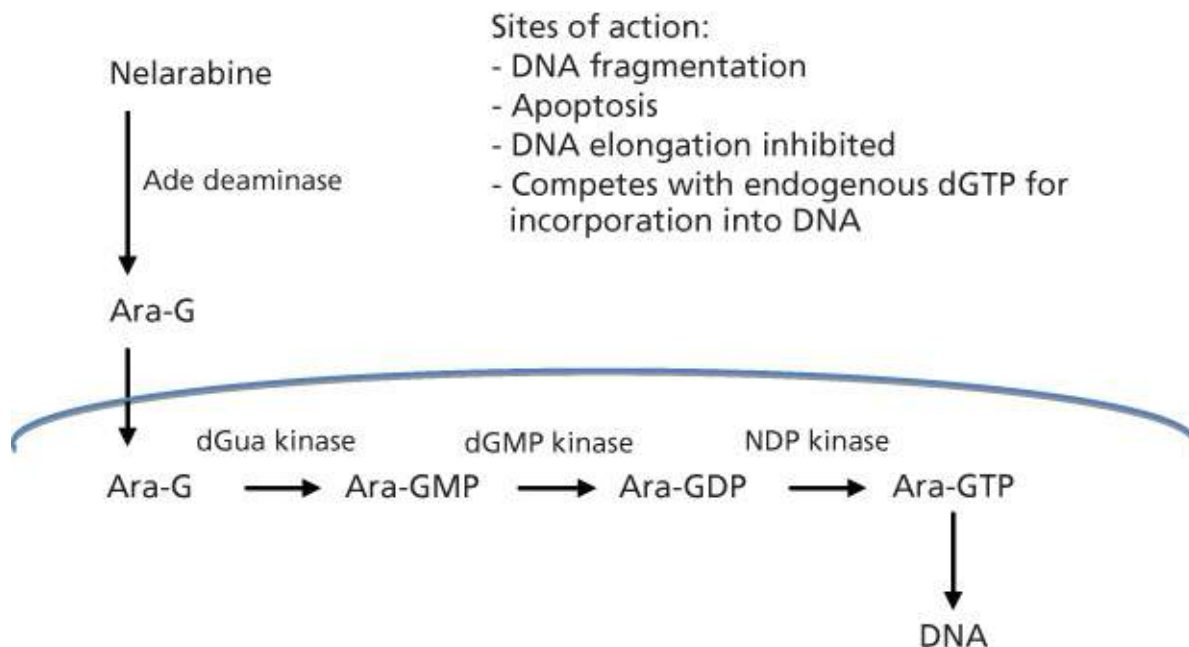

Figure 10 Metabolism and sites of action of nelarabine. Nelarabine is a prodrug that following intravenous administration is undergoes O-demethylation in the blood by adenosine deaminase (*Ade deaminase*) to Ara-G. Ara-G then transported into cells by nucleoside transporters where it is converted by deoxyguanosine kinases (*dGua kinase*) into the monophosphate, ara-GMP, and then through the sequential action of nucleotide kinases, dGMP kinase and NDP kinase, to the active metabolite ara-GTP. Also shown are the sites of action ara-GTP.

Mechanism of action

Ara-GTP is active following incorporation into DNA where it can result in DNA fragmentation and apoptosis. Similar to other antimetabolites, ara-GTP competes with the naturally occurring deoxyguanosine triphosphate (dGTP) for incorporation into DNA. Following incorporation at the 3' end of the elongating DNA, further incorporation into DNA is inhibited resulting in apoptosis and cellular death. Other mechanisms of action cannot be ruled out but remain unclear at present.²⁶

Clinical pharmacology

Nelarabine is a soluble prodrug typically administered by 2–3 h intravenous infusion. Neither nelarabine nor ara-G is significantly bound by plasma proteins and is eliminated through the kidney.²⁷

Clinical activity

Nelarabine was approved by FDA in 2005 for use in patients with T-cell acute leukemia or T-cell lymphoblastic lymphoma, who were unresponsive to previous chemotherapy or relapsed after at least two chemotherapy regimens.²⁸

Toxicities

Common toxicities include malaise, fever, nausea, and myelosuppression. Serious (Grades 3 and 4) neurologic toxicities occur in 10–15% of patients and may include both central nervous system side effects, for example, obtundation, seizures, and encephalopathy, and peripheral neuropathy.

Adenosine antimetabolites

The adenosine analogs represent the other major class of purine antimetabolites. In contrast to the guanine antimetabolites that depend on structural modification within the purine base, the adenosine antimetabolites rely on changes within the sugar portion of the molecule. This structural change results in decreased effectiveness of ADA. Halogen substitution at the second position of the deoxyadenosine with fluorine in fludarabine and chlorine in cladribine also contributes to the desired effect. Currently, there are several adenosine antimetabolites approved for clinical use ([Figure 11](#)). These include fludarabine, cladribine, and clofarabine. A fourth adenosine-like analog, pentostatin (Deoxycoformycin), is a naturally occurring purine analog that was first identified in fermentation broths of *Streptomyces antibioticus*. Its structure is similar to the transitional form of adenosine in the ADA reaction. It is one of the most effective inhibitors of ADA and more details are covered elsewhere.²⁰

Figure 11 Adenosine antimetabolites. (a) The natural occurring purine base adenosine. (b) The antimetabolites fludarabine monophosphate, cladribine, and clofarabine developed from structural modifications of adenosine. In addition (although not discussed in this chapter), pentostatin, an adenosine analog first isolated from fermentation broths of *Streptomyces antibioticus*, is shown for comparison as it corresponds to the transitional form of adenosine in the adenosine deaminase reaction.

Fludarabine

Background

Fludarabine, also known as 9-β-D-arabinosyl-2-fluoroadenine monophosphate or F-ara-AMP, has a structure that is shown in [Figure 11](#).

Metabolism

Following intravenous administration, it is rapidly dephosphorylated to F-ara A ([Figure 12](#)). This can then cross into cells using the nucleoside transporters. Within the cells in the presence of ATP and deoxycytidine kinase, it is converted back into a nucleotide monophosphate and then sequentially converted into F-ara-ATP.²⁹

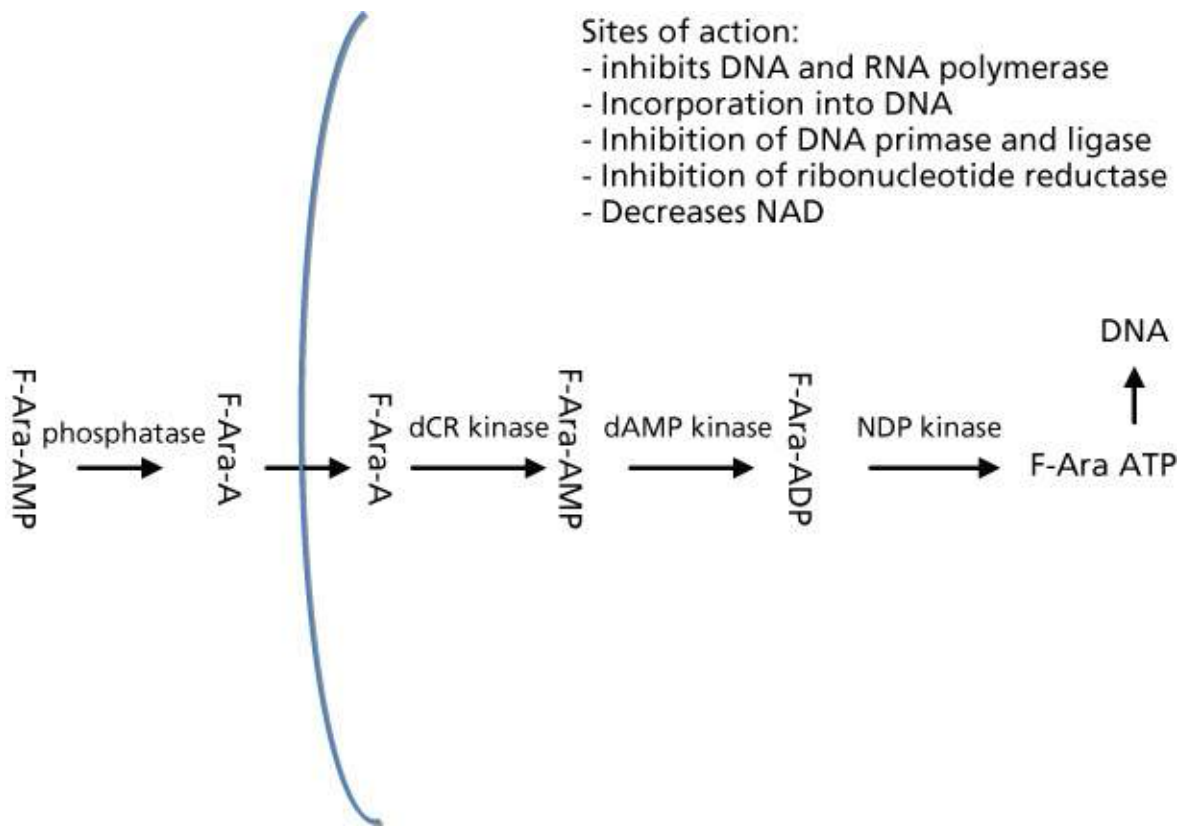

Figure 12 Metabolism and sites of action of fludarabine (F-Ara-AMP). Following intravenous administration, F-Ara-AMP is dephosphorylated in the blood by ubiquitous phosphatases to F-Ara-A. F-Ara-A is then transported into cells by nucleoside transporters where it is reconverted by deoxycytidine kinase (*dCR kinase*) into the monophosphate, F-Ara-AMP, and then through the action of nucleotide kinases (*dAMP kinase* and *NDP kinase*) converted into the active metabolite F-Ara-ATP. Listed are the sites of action for F-Ara-ATP.

Mechanism of action

F-ara-ATP is the active metabolite responsible for the mechanism of action. This results from competition with the natural metabolite deoxyadenosine triphosphate (dATP).

Clinical pharmacology

F-ara-AMP must be administered by the intravenous route. Peak concentrations are observed after 3–4 h. It is excreted into the urine with almost 25% of the administered drug being eliminated unchanged.

Clinical activity

This purine antimetabolite is active in chronic lymphocytic leukemia where it was first approved. It also has activity in several other hematologic malignancies including prolymphocytic leukemia, indolent non-Hodgkin's lymphoma, cutaneous T-cell lymphoma, mantle cell lymphoma, and Waldenstrom macroglobulinemia. Fludarabine has essentially no activity in nonhematologic solid tumors.³⁰

Toxicities

The two major side effects limiting F-ara-AMP in the clinic are myelosuppression and immunosuppression. The myelosuppression is often lymphocytopenia and thrombocytopenia. Fever is often seen with myelosuppression. Immunosuppression is primarily T-cell mediated with much less effect on B-cells. Lymphocyte counts, in particular CD4 cells, are often depressed after F-ara-MP and may take

more than a year to recover. The combined effect of myelosuppression and immunosuppression may result in an increased risk for opportunistic infections such as *Candida albicans*, *Pneumocystis carinii*, or viral infections with varicella-zoster. Prophylactic antibiotic coverage for *P. carinii* is often recommended with trimethoprim sulfamethoxazole the drug of choice to be coadministered with F-ara-AMP. Other less frequent toxicities include anorexia, nausea, vomiting, diarrhea, abdominal pain and at times increased salivation, and parageusia (metallic taste), skin rash, and stomatitis.²⁰ Laboratory abnormalities include transient elevations of hepatic enzymes as well as evidence of renal dysfunction.

Cladribine

Background

Cladribine is a purine deoxyadenosine analog. Its structure is shown in [Figure 11](#).

Metabolism

Following entry into the cell using the cell's nucleoside transporters, cladribine is anabolized via deoxycytidine kinase (dC kinase) to cladribine monophosphate eventually being converted into cladribine triphosphate, the active metabolite^{31, 32} ([Figure 13](#)).

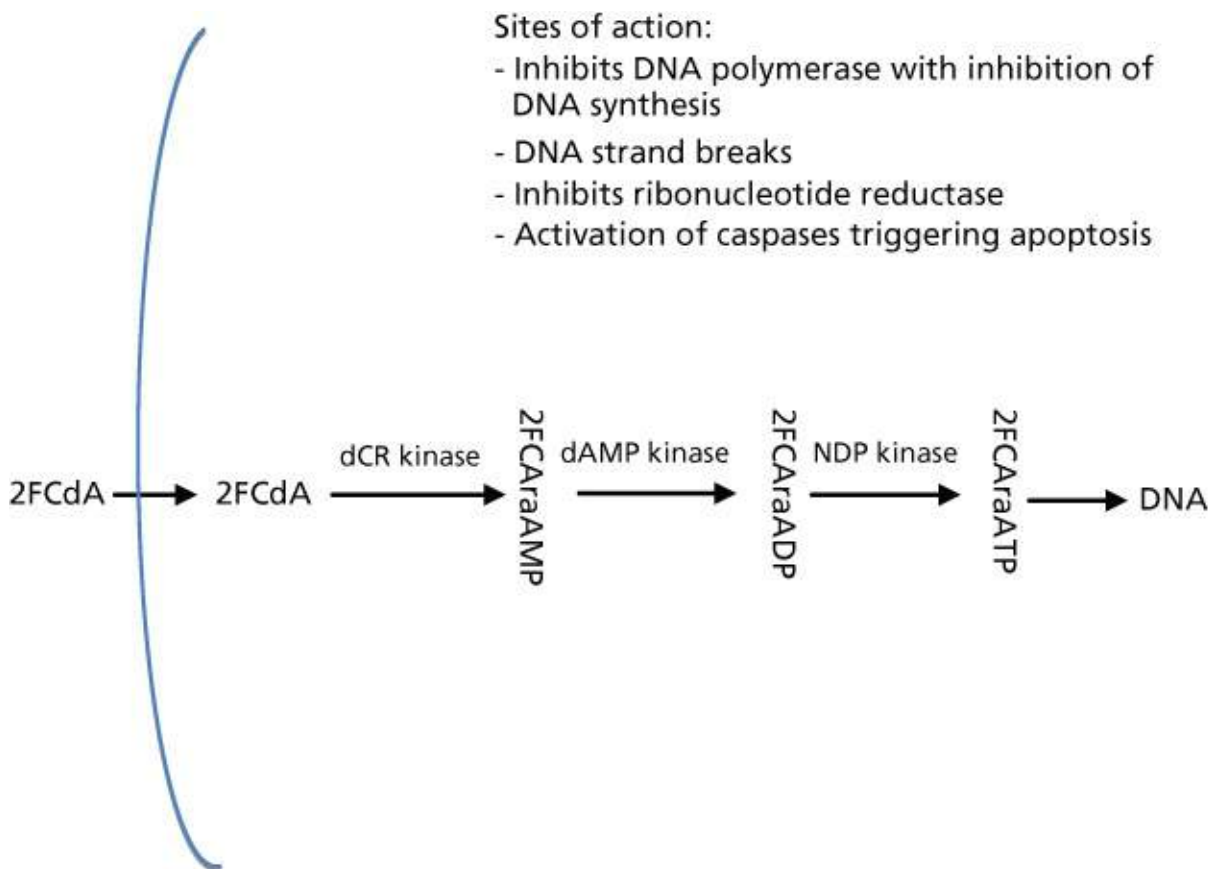

Figure 13 Metabolism and sites of action of cladribine. Following intravenous administration, cladribine is transported into cells by nucleoside transporters where it is reconverted by deoxycytidine kinase (*dCR kinase*) into the monophosphate, 2CFara-AMP, and then through the action of nucleotide kinases (*dAMP kinase* and *NDP kinase*) to the active metabolite 2CFara-ATP. Also listed are the sites of action ara-2CFara-ATP.

Altered metabolism of cladribine can contribute to resistance, in particular decreased activity of dC kinase, a critical step in the anabolism of this drug. Similarly, increased expression of catabolic enzymes, in particular 5'-nucleotidase, may contribute to resistance.

Mechanism of action

The active metabolite cladribine triphosphate competes with naturally occurring dATP for incorporation into DNA where it can cause termination of chain elongation. There can also be inhibition of DNA synthesis and repair due to an imbalance in critical deoxyribonucleotide pools as well as inhibition of ribonucleotide reductase.

Clinical pharmacology

Cladribine can be administered orally. The drug is primarily excreted via the kidney with approximately 50% cleared into the urine, with as much as 25% unchanged. The drug can cross the blood–brain barrier into the cerebrospinal fluid.

Clinical activity

Cladribine was initially approved by the FDA for treatment of hairy cell leukemia and remains the drug of choice for that disease. Its response rate is 60% or greater for treatment of hairy cell leukemia with both primary and relapsed disease. The drug also has activity in low-grade lymphoproliferative diseases. It has potential activity for patients with CLL and non-Hodgkin's lymphoma.^{33, 34}

Toxicities

Myelosuppression is the primary dose-limiting toxicity at standard doses with both thrombocytopenia and neutropenia. Other toxicities include nausea, vomiting and diarrhea, and neurotoxicity. Cladribine can also cause immunosuppression with decreased lymphocyte counts particularly CD-4 positive cells. These depressed counts may take years to recover after finishing treatment. The decreased CD-4 counts predispose patients to developing opportunistic infections.

Clofarabine

Background

Clofarabine was synthesized to develop a potentially more effective adenine analog than fludarabine and cladribine ([Figure 11](#)). This 2-halo-2'-halodeoxyarabinofuranosyl adenine analog has the 2-chloroadenine aglycone that conveys resistance to inactivation by ADA. It also is thought to benefit from the fluorine in the 2' position of the sugar in the arabinosyl configuration that potentially contributes to its DNA inhibition. The fluorine substituted at the C-2' position is thought to inhibit the effect of purine nucleoside phosphorylase (PNP) (phosphorolysis) in contrast to what typically occurs with fludarabine and cladribine.²⁰

Metabolism

Following uptake into tumor cells, clofarabine must be anabolized to a triphosphate, which is the active metabolite. Its chemistry potentially contributes to decreased catabolism and hence increased effectiveness. Clofarabine is actually a better substrate for deoxycytidine kinase than fludarabine or cladribine.³⁵

Resistance can result from perturbation of metabolism due to either decreased anabolism or increased catabolism.

Mechanism of action

Several possible sites of action include inhibition of DNA synthesis due to chain termination following incorporation into DNA; inhibition of DNA synthesis by inhibiting DNA polymerases α , β , and γ , which in turn interferes with DNA chain elongation and synthesis and repair of DNA. DNA synthesis is further inhibited by depletion of intracellular deoxyribonucleotide pools through inhibition of ribonucleotide reductase.^{36, 37}

Clinical pharmacology

Clofarabine is typically administered as an intravenous infusion at doses between 2 and 40 mg/m² over 5 days. Half-life is approximately 5 h with plasma concentrations as high as 2.5 μ M being achievable, although there is interpatient variability. It is estimated that 50–60% of the administered drug may be excreted unchanged into the urine. Currently, there is no data to guide use of this drug in individuals with renal or hepatic insufficiency.

Clinical activity

FDA approved clofarabine in 2004 for use in refractory pediatric ALL. It has also been used in adult AML and myelodysplastic syndrome. Of particular clinical interest is the combined use of clofarabine with ara-C with increased response being reported without increased toxicity. This is thought to be a result of potentiation by increasing ara-C concentrations.^{38–40}

Toxicities

The major toxic manifestation is myelosuppression, which results in an increased risk for infection. Hepatic transaminase elevation has also been noted in as many as 25% of patients. Other side effects include anorexia, nausea, and skin rash particularly in children.

Chapter 58

Alkylating agents and platinum antitumor compounds

Zahid H. Siddik, PhD

Overview

Alkylating agents and platinum-based compounds are highly potent antitumor drugs used in the treatment of a variety of cancers. These drugs target DNA (deoxyribonucleic acid) but require activation by spontaneous or metabolic transformation to induce formation of DNA monofunctional adducts and interstrand and intrastrand crosslinks. As a result of this damage, the DNA unwinds and/or bends, and such distortions are then recognized by specialized DNA damage recognition proteins to activate checkpoints, which arrest the cell cycle to allow cells time to repair the damage and survive. If the DNA damage is extensive and repair cannot be completed, then cells activate p53-dependent or independent apoptosis (programmed cell death) to affect antitumor drug response. As activated species from alkylating agents and platinum compounds are not tumor-selective, they will also interact with DNA and other endogenous macromolecules in normal cells to induce severe side effects; at times the toxicity can be irreversible and cumulative and, thereby, presents a dose-limiting barrier. Another limitation is that genetic changes in tumors that are either intrinsic or acquired can inhibit apoptosis and induce resistance to alkylating and platinating drugs. Resistance mechanisms may be observed in the form of reduced drug accumulation, increased drug inactivation, increased DNA repair, failure of DNA damage recognition system to recognize the damage, and aberrant apoptotic signal transduction pathways. Rational strategies to circumvent resistance mechanisms are, therefore, needed desperately to enhance patient care.

Introduction

Hallmarks of cancer include sustained proliferative signaling and replicative immortality as biological features that contribute to uncontrolled increase in tumor mass.^{1, 2} These characteristics are consistent with absence of feedback or inhibitory control on DNA (deoxyribonucleic acid) replication and the cell cycle that is commonly found in tumor cells. It is not surprising, therefore, that therapeutics targeting or covalently interacting with DNA to inhibit DNA replication and, thereby, cellular proliferation, have been the mainstay for clinically managing patients with cancer. Such therapeutics are broadly known as DNA alkylating agents and include platinum-based antitumor compounds. These agents form monofunctional and/or bifunctional adducts, with bifunctional adducts existing in several forms, including interstrand and intrastrand DNA crosslinks ([Figure 1](#)).

Figure 1 Monofunctional DNA adducts and interstrand and intrastrand crosslinks induced by DNA damaging agents (X = alkyl or platinum species).

The foundation for alkylating agents as therapeutics dates back to the 1914–1918 Great War when poison gases, such as chlorine or the fatally vesicant sulfur mustard gas, were used indiscriminately against enemy soldiers in chemical warfare. The sulfur mustard ([Figure 2](#)) was first used by the Germany military in 1917 against British, Canadian, and French soldiers near the town of Ypres, Belgium. During autopsy of dead soldiers, it was noted that mustard gas was highly myelosuppressive and produced lymphoid aplasia.³ Thus, the notion that such agents could combat uncontrolled growth of cancers was conceptualized, but the high toxicity and reactivity of mustard gas precluded its clinical application. Efforts in early 1940s at Yale University by Goodman and Gilman^{4, 5} eventually resulted in the less-reactive and less-toxic nitrogen mustard, mechlorethamine or mustine ([Figure 2](#)), as the first agent to be tested in antitumor clinical trials in lymphoma patients, and its demonstrated activity firmly laid the foundation for modern cancer chemotherapy. Its activity also spawned the development of more effective and less-toxic alkylating agents, and some of these remain part of the present-day clinical anticancer armamentarium. Apart from the nitrogen mustards, several structural classes of alkylating agents are also of considerable interest, including the aziridines, hexitol epoxides, alkyl sulfonates, nitrosoureas, and the triazines/hydrazines, and these, together with the platinum-containing antitumor drugs, form the basis of this article.

Figure 2 Structures of sulfur and nitrogen mustards.

General mechanisms of cytotoxicity

Alkylating agents and platinum antitumor compounds can transform to highly reactive species that indiscriminately form strong chemical bonds with endogenous macromolecules having electron-rich (nucleophilic) centers, such as nitrogen and sulfur atoms. The macromolecules can be peptides, proteins, or nucleic acids, but the interaction with DNA is the basis for their potent cytotoxic effects. Interactions with DNA can be monofunctional, when only a single alkylating or platinating reaction is permissible, or bifunctional, when covalent bonds are formed at nucleophilic centers of two different bases on DNA to induce crosslinks or adducts. Moreover, such crosslinks, formed predominantly through the N7 position of guanine, can be interstrand (between opposite DNA strands; induced preferentially by alkylating agents) or intrastrand (on the same DNA strand; induced preferentially by platinum drugs) ([Figure 1](#)).

Although the chance interaction between alkylating agents and DNA can be influenced by a number of factors, such as formation, detoxification, and nuclear access of the active alkylating moiety, the actual interaction with DNA is site specific. The N7 site of guanine, for instance, is electron rich and facilitates preferential covalent interaction with the positively charged alkylating species. The interaction is further facilitated by the nucleotide sequence, that is, interstrand GG crosslinks with nitrogen mustards are favored when guanine is in the 5'-GC-3' or 5'-GXC-3' sequence (where X = any nucleotide) in both DNA strands.^{6, 7} On the other hand, N2-guanine in the 5'-CG-3' sequence (cytosine preceded by guanine) is

preferred for crosslinking by mitomycin C owing to its orientation in the minor groove of DNA.⁸ Alkylation at O6-guanine and N3-cytosine can also occur.

The critical nature of N7-diguanyl crosslinks in the cytotoxicity of alkylating agents was established in early 1960s.^{6,9} Although interstrand crosslinks may be envisioned as preventing separation of DNA strands during replication of the genome to induce cytotoxicity, this is by no means certain; it is clear that monofunctional, interstrand, and intrastrand adducts all have cellular effects, including inhibition of DNA synthesis, cell cycle arrest and apoptosis; however, the bifunctional drugs have greater potency than monofunctional agents. These cellular effects are the net result of specific distortions and unwinding in DNA induced by the alkylating or platinating drug and resultant coordinated assembly of distinct proteins at the DNA damage site to activate a number of signal transduction pathways. The final cellular effect is dependent on the concentration of the drug and, thereby, the extent of DNA damage; low level of DNA damage induces cell cycle arrest to permit DNA repair and cell survival, whereas extensive DNA damage overwhelms the capacity of the repair machinery and activates apoptosis. These events occur in both tumor and normal cells, and the small difference in relative tolerance to DNA damage between normal and tumor cells makes side effects of therapy inevitable that prevent administration of larger doses.

Alkylating agents

Bifunctional alkylating agents

Nitrogen mustards

Soon after the initial report of clinical activity of mechlorethamine in 1946,^{4,5} many nitrogen mustards were evaluated for their antitumor potential through structure–activity relationships. Of the handful that advanced to clinical trials, a few were approved by the FDA and are still in use today. In addition to mechlorethamine, these include cyclophosphamide, ifosfamide, melphalan, chlorambucil, and bendamustine, which are shown in [Figure 2](#). Also shown in this figure is 4-hydroperoxycyclophosphamide, which is the prodrug form of active 4-hydroxycyclophosphamide.

The sequence of events and specificity of the reaction between nitrogen mustards and DNA have been well described by Colvin et al.¹⁰ The bis-chloroethyl group of these agents is critically important for the predominant alkylation of N7-guanine in DNA, although alkylation can occur but infrequently at O6-guanine and at N3- and N7-adenine. The alkylation is sequence specific and requires guanine in the 5'-GXC-3' sequence (where X = any nucleotide). For interaction, the chloroethyl moiety cyclizes to form the highly reactive aziridinium ion intermediate that reacts readily with electron-rich sites, as shown with N7-guanine in [Figure 3](#). It is possible that the aziridinium ion may first rearrange to the reactive carbonium ion intermediate for the alkylation reaction, but this remains uncertain. As there are two chloroethyl groups present, this results in sequential bifunctional alkylation to crosslink DNA. As indicated above, interstrand crosslinks are preferred by nitrogen mustards, with 1,3-crosslinks being the favored interaction. However, DNA–DNA intrastrand, DNA–protein, and DNA–glutathione crosslinks are also formed, but lack cytotoxic potential. Interstrand DNA crosslinks are the critical lesions, and according to Roberts et al.,¹¹ bifunctional interstrand DNA crosslinks are about 100-fold more effective at killing cells than monofunctional DNA adducts.

Figure 3 DNA alkylation by nitrogen mustard to form interstrand crosslink.

All nitrogen mustards are neutral and must be activated to interact with DNA target sites. Mechlorethamine, for instance, is activated spontaneously at physiological pH, but the rapid rate of activation is a major cause of much of the unwanted side effects. Chemical modification of the molecule, however, has played a crucial role not only to stabilize nitrogen mustard congeners, but also to influence their physicochemical properties that regulate transport, distribution, and reactivity of the molecule in order to enhance clinical utility.¹² Cyclophosphamide, which has an oxazaphosphorine ring, was selected from over a 1000 oxazaphosphorine candidates, and its chemical inertness and dependence on metabolic activation were considered as desirable characteristics.^{13, 14} The primary site for this activation is the liver, where the P450-mediated mixed function oxidase reaction initiates a complex series of chemical transformation events^{15–18} that is depicted in part in [Figure 4](#). The 4-hydroxycyclophosphamide is the most significant metabolite, which is relatively nonpolar and can readily distribute throughout the body, including tumor cells. This metabolite can be formed directly from the prodrug 4-hydroperoxycyclophosphamide ([Figure 1](#)), which has demonstrated utility in purging tumor cells in bone marrow aspirates of patients undergoing autologous bone marrow transplant.¹⁹ At physiologic pH, a small amount of the 4-hydroxycyclophosphamide exists in equilibrium with aldophosphamide, which is relatively unstable and spontaneously decomposes to form the highly reactive phosphoramidate mustard and then nornitrogen mustard.

Figure 4 Metabolic activation and inactivation of cyclophosphamide.

An important by-product of the metabolism of cyclophosphamide, resulting from the conversion of aldophosphamide to phosphoramidate mustard (Figure 4), is acrolein,¹⁸ which induces hemorrhagic cystitis as a serious side effect,²⁰ but whether it has antitumor activity is of interest. Although a study with the model compound didechloro-4-hydroperoxycyclophosphamide indicated that the spontaneously released acrolein lacked cytotoxicity,²¹ other studies have demonstrated that acrolein indeed has antitumor and carcinogenic activities but is inactivated by O6-alkylguanine-alkyltransferase.^{22–24} Aldehyde dehydrogenase can also play a significant role in moderating activity by converting aldophosphamide to the inactive carboxyphosphamide metabolite, which accounts for about 80% of the cyclophosphamide dose excreted in the urine. Not surprisingly, this enzyme can confer resistance to cyclophosphamide in tumor cells when ectopically overexpressed.²⁵ Thus, high levels of aldehyde dehydrogenase in the liver, early hematopoietic cells, and intestinal stem and mucosal absorptive cells are consistent with reduced hepatic, gastrointestinal (GI), and hematopoietic toxicities associated with cyclophosphamide as compared to other alkylating agents. Urinary excretion of metabolites can be compromised at high doses of cyclophosphamide by an antidiuretic effect owing to sodium loss and water reabsorption by renal tubules, with resultant edema.²⁶ The electrolyte imbalance may also contribute to the reported dose-

limiting and fatal cardiotoxicity of high-dose chemotherapy.²⁷ This limitation has been recognized and doses are now monitored clinically to prevent this lesion from becoming serious.

Ifosfamide ([Figure 2](#)) is a structural isomer of cyclophosphamide that is important in the treatment of testicular cancer and sarcomas. Like cyclophosphamide, it also requires activation by hepatic mixed function oxidase,¹³ but the low rate of metabolic activation by 4-hydroxylation and conversion to the corresponding active isophosphoramide mustard decreases its potency approximately fourfold.^{28, 29} On the other hand, increase in the dose to compensate for the lower potency leads to a greater cumulative production of acrolein, which increases the incidence of urothelial toxicity that requires concurrent administration of the thiol-based mesna to inactivate the toxic by-product. Renal and bladder toxicity, as well as neurotoxicity, of ifosfamide have also been ascribed to the formation of chloroacetaldehyde,³⁰ the product of oxidation of the chloroethyl side chain ([Figure 4](#)) that is generated in greater quantities with ifosfamide than with cyclophosphamide (~50% vs ~10% of the dose). The primary metabolite of ifosfamide, aldoifosfamide, is also a substrate for aldehyde dehydrogenase, and this is consistent with low toxicity of the drug to the bone marrow and the GI tract due, as mentioned previously with cyclophosphamide, to the presence of high levels of the enzyme in these organs.

Melphalan, chlorambucil, and bendamustine do not have the oxazaphosphorine ring of cyclophosphamide and ifosfamide in their structure, and so do not require metabolic activation, although metabolism of these agents does occur in the liver, but only for its disposition. These agents instead have an unsaturated electron-withdrawing aromatic ring ([Figure 2](#)) that moderates activation of the bis-chloroethyl group and formation of the aziridinium ion in order to minimize side effects. Owing to its phenylalanine-based structure, melphalan can be transported actively into cells and across the blood–brain barrier.^{31–33} These nitrogen mustards have found important applications against several cancers: melphalan against multiple myeloma, breast cancer, and ovarian carcinoma³⁴; chlorambucil against ovarian cancer, chronic lymphocytic leukemia (CLL), and Hodgkin's and non-Hodgkin's lymphoma^{35–37}; and bendamustine against CLL and lymphomas.³⁸ Owing to its improved tolerance, bendamustine is reported to be more cost-effective as a therapeutic drug than the structurally similar chlorambucil.³⁹

Aziridines

Also known as ethyleneimines, the aziridines alkylate through the three-membered heterocyclic aziridine ring. Aziridine family of drugs includes thiotepa (*N,N',N''*-triethylenethiophosphoramide), mitomycin C, and triethylenemelamine, which are shown in [Figure 5](#). Also shown is hexamethylmelamine, which is similar to triethylenemelamine, but lacks the classical aziridine ring. Of these, thiotepa and mitomycin C are of clinical interest for a number of diseases, including refractory osteosarcoma and bladder cancer, respectively.^{40, 41} High-dose thiotepa has also been used in drug combination regimens with⁴² or without⁴³ autologous stem cell support for breast cancer. Hexamethylmelamine, on the other hand, has found application in salvage therapy for recurrent ovarian cancer.⁴⁴

Figure 5 Chemical structures of aziridines and hexamethylmelamine.

The aziridine ring in the chemical structure of thiotepa is not charged, which makes it less reactive with electron-rich centers in RNA (ribonucleic acid), DNA, protein, and thiols (such as glutathione) than the structurally similar aziridinium ring formed with nitrogen mustards. In DNA, thiotepa alkylates sites in all four nucleotides, particularly at O2-cytosine, N1-thymine, N1-, N2-, and N7-adenine, and N1-, N7-, and O6-guanine.⁴⁵ However, N7-guanine remains the preferential target, as with other alkylating agents, and results in guanine–guanine (GG) and adenine–guanine (AG) interstrand crosslinks, primarily 1,2-crosslinks.⁴⁶ These crosslinks are formed sequentially; the first reaction at N7-guanine leads to the monofunctional adduct, and the second reaction with a nearby guanine results in the crosslink, as shown by pathway A in [Figure 6](#). Crosslinking may also proceed via metabolism of thiotepa to tepa (sulfur replaced by oxygen), followed by opening of the aziridine ring and conversion to the chloroethyl-containing crosslinking species, as found in nitrogen mustards.⁴⁷ Alternatively, the aziridine ring is cleaved to mediate alkylation of N7-guanine and forms a monofunctional DNA adduct ([Figure 6](#), pathway B), which induces DNA single-strand breaks and then cell death.^{48, 49}

Figure 6 Metabolism and interaction of thiotepa with DNA to form interstrand crosslinks (pathway A) or monofunctional adducts (pathway B).

Unlike thiotepa, interaction of mitomycin C with DNA requires metabolic reduction to leucoaziridinomitosenes for the formation of the monofunctional adduct.⁵⁰ Spontaneous intramolecular rearrangement and elimination of the carbamate group at C10 of mitomycin C results in a second alkylation reaction with the opposite strand of DNA to induce cytotoxic 1,2-GG interstrand crosslink lesions (Figure 7). Interestingly, alkylation at the N2-guanine site of DNA is preferred by mitomycin C, particularly if guanine is present in the 5'-purine-CG-pyridine-3' sequence in both strands of the duplex.⁸

Figure 7 DNA interstrand crosslinks induced by mitomycin C.

On the basis of the presence of the aziridine ring in the triethylenemelamine structure, alkylation by this agent likely occurs in the same manner as that described for thiotepa. However, with hexamethylmelamine, metabolic activation in the liver is required.^{51, 52} The metabolism generates a

carbinolamine intermediate, *N*-methylol-pentamethylmelamine, which rearranges to the reactive iminium ion as the species responsible for alkylation of guanine in DNA (Figure 8). As hexamethylmelamine metabolism can also result in the dicarbinolamine product *N,N'*-dimethylol-tetramethylmelamine,⁵³ bifunctional interstrand DNA crosslink is the likely outcome, particularly as the tricarbinolamine-based prodrug of hexamethylmelamine, trimelamol, readily forms such crosslinks.⁵⁴ It is noteworthy that trimelamol has been investigated in clinical trials,⁵⁵ but the development did not continue, owing likely to limited clinical activity⁵⁶ and/or drug formulation/stability issues.⁵⁷

Figure 8 Activation of hexamethylmelamine to form DNA adducts.

Hexitol epoxides

The di-epoxide 1,2:5,6-dianhydrogalactitol (DAG) and its prodrug 1,2-dibromodulcitol (DBD), like the aziridines, also alkylate via a strained tricyclic ring (Figure 9). Chemical interaction between DAG and DNA results in alkylation at N7-guanine,⁵⁸ a site commonly preferred by several other alkylating agents. In cell-free, cellular, and *in vivo* rodent systems, N7-monoguanyl and N7-diguanyl derivatives are detected as two major products that represent monofunctional and interstrand crosslinked DNA adducts, respectively.^{58–61}

Figure 9 Conversion of dibromodulcitol to dianhydrogalactitol to form interstrand crosslinks.

Both DBD and DAG have shown antitumor properties that were similar to alkylating agents in some experimental antitumor models, but different in others. Lack of cross-resistance with DAG, for instance, was observed in a nitrosourea (BCNU)-resistant L1210 leukemia model.⁶² Of the two hexitols, DAG has greater chemical stability and better preclinical antitumor activity profile.^{63, 64} Nevertheless, both DBD and DAG entered clinical trials in 1970s and demonstrated some activity in GI and lung cancer.^{65, 66} Interestingly, these hexitols cross the blood–brain barrier in patients,^{67–69} and follow-up clinical trials found a 44% response rate with DAG in brain cancer.⁶⁶ DAG was recently granted orphan designation in the United States and Europe for brain cancer, and clinical trials are currently underway in the United States (ClinicalTrials.gov Identifier: NCT01478178). In China, however, it has been marketed for the treatment of chronic myelogenous leukemia (CML) and lung cancer for over 20 years.

Alkyl sulfonates

Busulfan and the analog hepsulfam are the best known alkyl sulfonates, which are symmetrical and have either two sulfonates (busulfan) or sulfamates (hepsulfam) separated by a linear alkyl chain. Busulfan was approved in 1999 as a standard of care for CML, but its clinical application subsequently diminished by first the introduction of the less-toxic hydroxyurea and then by the targeted therapeutic Gleevec. However, busulfan is still used in the allogeneic stem cell or bone marrow transplantation setting.^{70, 71} Although hepsulfam was more potent than busulfan in human tumor model systems,^{72, 73} it has not been effective in clinical trials.

The sulfonate or the sulfamate is the critical group responsible for the alkylation reaction at N7-guanine to form GG interstrand crosslink,^{74, 75} as shown with busulfan in [Figure 10](#). However, this crosslink formation by busulfan has been disputed⁷⁶ and the alternative GA intrastrand crosslink has been proposed.⁷⁷ Significantly, where any crosslinking has been reported, this has been correlated to cytotoxicity.

Figure 10 Busulfan-induced DNA interstrand crosslinks.

Nitrosoureas

Much of the structure–activity understanding, and the basis for clinical development of 2-chloroethylnitrosoureas (CENUs) as derivatives of urea, came from the work of Montgomery and his colleagues.^{78–80} With the ability to cross the blood–brain barrier, four analogs entered the clinic,^{81, 82} and these are shown in [Figure 11](#). BCNU (Carmustine) and CCNU (Lomustine) are effective against several types of cancers, including glioma, glioblastoma multiforme, GI tumors, breast, and multiple myeloma, with streptozotocin (Zanosar) effective against cancers of the pancreatic islet cell, owing primarily to its uptake via the glucose transport protein GLUT2 that is present at relatively high levels in these cells.⁸³ Absence of any advantage over other nitrosoureas has halted the use of methyl-CCNU (Semustine). The limitation in clinical utility of nitrosoureas is ascribed to their severe side effects, including hematopoietic and renal toxicities, with streptozotocin in particular demonstrating substantial toxicity to β cells of the normal pancreatic islets owing to the GLUT2 transporter.⁸⁴ The development of novel nitrosoureas, therefore, continues, and a third generation analog, fotemustine (Muphoran) ([Figure 11](#)), has shown activity in brain cancer and metastatic melanoma, with or without brain involvement, and has received approval in Australia, Brazil, China, and Europe, but not as yet in the United States.^{85, 86}

Figure 11 Chemical structures of urea and selected chloroethylnitrosourea derivatives.

It is widely acknowledged that CENUs as bifunctional DNA interstrand crosslinkers are unstable, as exemplified by a short half-life of about 50 min for BCNU⁸²; the several products of decomposition are shown in [Figure 12](#). An unusual feature of some CENUs is that they can generate isocyanate, which carbonylates the ϵ -amino group of lysine in proteins, including histone and other nuclear proteins, but there is disagreement whether the carbonylated-protein contributes to cytotoxicity.^{79, 87, 88} A second unusual feature is that CENUs can alkylate at O6-guanine in DNA, likely through formation of the 2-chloroethyl diazene hydroxide and the analogous 2-hydroxyethyl diazene hydroxide species ([Figure 12](#)).^{81, 82} Rearrangement of these species to carbonium ions leads to alkylation at the O6-site of guanine to form monoadducts.⁸⁹ The O6-alkylation reaction is considered important as upregulation of O6-alkylguanine-DNA alkyltransferase, which repairs the O6-adduct, increases resistance and, conversely, inhibition of this enzyme with O6-benzylguanine sensitizes tumor cells to nitrosoureas.^{89–91} However, adducts from N7-alkylation of guanine ([Figure 12](#)) are normally the predominant species, particularly where this purine is in the middle of a GGG sequence.⁹² These DNA monoadducts form rapidly (often within an hour), but then slowly convert to the cytotoxic N7-diguanyl interstrand crosslink that may take up to 8 h.⁸² It is noteworthy that N3-cytosine–N1-guanyl crosslinks are also formed through cyclization of the O6-chloroethyl-guanine monoadduct to the O6,N1-ethanoguanine pentacyclic intermediate, which reacts with N3-site of cytosine and becomes crosslinked to the N1-site of guanine following opening and rearrangement of the ethanoguanine ring.^{82, 93, 94} There is also a proposal from steric considerations that only the CG crosslink of CENUs is interstrand, with the similarly cytotoxic GG adduct being intrastrand.⁸⁹

Figure 12 Activation of chloroethylnitrosourea (CENU) and reaction with DNA.

Monofunctional alkylating agents

Structures of some monoalkylators discussed below are shown in [Figure 13](#).

Figure 13 Structures of monofunctional alkylating agents.

Hydrazines

More than 400 hydrazine compounds have been tested preclinically, but only procarbazine has received clinical approval for the treatment of cancers, specifically Hodgkin's lymphoma, lung cancer, and melanoma. Its activation is poorly understood, but metabolic oxidation to azoxy-procarbazine is an important step. This metabolite rearranges to a reactive methyl diazonium intermediate that forms O6- and predominantly N7-methyl-guanine adducts, which then spontaneously depurinate to induce single-strand breaks.^{95–97} DNA–DNA or DNA–protein crosslinks have not been reported. Another hydrazine that had been studied since the early 1970s was hydrazine sulfate, but the clinical activity was equivocal, and the compound never received approval in the United States.

Triazines

The most recognizable triazines are hexamethylmelamine (Altretamine), dacarbazine (DTIC-Dome), and temozolomide (Temodar). Of these, hexamethylmelamine is likely a bifunctional alkylator and, therefore, has been grouped above with its closely resembling trimethylmelamine under “aziridines.” Dacarbazine has been used against a variety of cancers, including Hodgkin's lymphoma, sarcoma, malignant melanoma, and pancreatic islet cell carcinoma. Temozolomide is an imidazotetrazine derivative of dacarbazine that is particularly active against astrocytoma, as well as melanoma. Triazines methylate O6- and N7-guanine,⁹⁸ but, like the hydrazines, require metabolic activation for cytotoxic alkylation and DNA single-strand breaks. For dacarbazine, hepatic activation to [methyl-triazenyl]-imidazole-carboxamide (MTIC)

generates the reactive DNA-methylating methyl diazonium ion.⁹⁹ Temozolomide, in contrast, functions as a prodrug of MTIC and spontaneously generates the reactive species.¹⁰⁰

Isoquinoline alkaloids

The two naturally occurring tetrahydroisoquinoline alkaloids of interest are trabectedin (ecteinascidin-743, Yondelis) and Zalypsis. Trabectedin is the first marine-derived antitumor agent to be approved in Europe, Russia, and South Korea for cancer treatment, specifically advanced soft tissue sarcoma and platinum-resistant ovarian cancer.¹⁰¹ Its approval in the United States, however, is pending. The drug initially binds noncovalently to TCG, CGG, AGC, or GGC sequence of one strand in the DNA minor groove, where dehydration of the carbinolamine group generates the iminium intermediate that then alkylates the unusual N2-site of guanine in the opposite strand.¹⁰² Trabectedin-induced monofunctional adducts then recruit the transcriptionally coupled nuclear excision repair (TC-NER) protein Rad13/ERCC5 to the DNA damage site and induce strand breaks and cell death. An additional unusual feature of trabectedin, not found in several bifunctional alkylating agents, is that absence of the p53 tumor suppressor activity increases antitumor activity about threefold.¹⁰³ Zalypsis is essentially a synthetic derivative of trabectedin that has an identical mode of action as the parent molecule.^{104, 105} It is presently undergoing clinical trials.

Decomposition and metabolism

For therapeutic formulation and medical handling, alkylating agents must initially be in an inactive state to preserve maximal potency of the molecule until administered to patients. As discussed above for alkylating agents, such as temozolomide and cyclophosphamide, this potency is realized through spontaneous decomposition in the biological milieu or through metabolic activation, respectively. The resultant active species are strong electrophiles and key to inhibiting tumor growth, but are themselves also prone to decomposition by hydrolytic reactions with water or by direct inactivating interactions with the abundance of nucleophilic targets in the cell. Thiols, such as the tripeptide glutathione or cysteine-rich metallothionein protein, are major targets of interaction; in some cases, the inactivation by glutathione is facilitated by glutathione S-transferase. Consequently, depletion of glutathione by inhibiting its synthesis can enhance antitumor activity of these agents.¹⁰⁶ In contrast, presence of glutathione is important for bifunctional activation of mitomycin C.¹⁰⁷ Metabolism of alkylating agents in the liver and extrahepatic tissues also plays a major role in drug disposition. Apart from hydroxylation, other reactions are also important, and this includes dechlorination and denitrosation, as observed with nitrosoureas.⁸⁷ As noted earlier, high levels of aldehyde dehydrogenase in the GI and hematopoietic cells can protect cells by detoxifying metabolites of cyclophosphamide. Moreover, metabolism can be influenced by other agents, such as phenobarbital,^{108, 109} which can increase microsomal enzymatic activity and the rate at which the active species and the inactive metabolites are generated and disposed of.

Resistance to alkylating agents

A major clinical limitation of alkylating agents is resistance of tumor cells. This resistance can be intrinsic that arises during tumor development or it can be acquired by tumor cells via drug selection pressures. In many tumors, presence of a single resistance mechanism is rare, but multiple mechanisms abound, as has been reported for melphalan¹¹⁰ and temozolomide.¹¹¹ Thus, any effort to induce antitumor response in refractory cancers will require circumventing multiple mechanisms of resistance, and this makes the task more challenging. However, knowledge of individual mechanisms may allow identification of weakness in the signaling network within tumor cells that may be exploited for synthetic

lethality approaches.¹¹² Alternatively, identifying a resistance mechanism that, if circumvented, will provide a dominant trigger for apoptosis and over-ride remaining resistance mechanisms may have potential also.

In general terms, resistance of tumor cells can be due to (1) reduced intracellular drug concentration, (2) increased cellular inactivation, (3) enhanced DNA repair, and (4) downregulation of apoptotic signaling. Reduced uptake in resistant cells has been observed with melphalan owing to downregulation of the L-type amino acid transporter.^{110, 113} However, most alkylating agents rely on diffusion for cell entry and are not affected by transporters. Resistance to alkylating agents can occur from increased inactivation due to elevated levels of thiol-containing compounds or thiol-related enzymes, such as glutathione, metallothionein, γ -glutamylcysteine synthase (involved in glutathione synthesis), and glutathione S-transferase (increases drug conjugation with glutathione).^{114–118} Increased inactivation can also occur by elevated levels of aldehyde dehydrogenase, which readily detoxicates cyclophosphamide and related alkylating agents.^{119, 120}

Alkylating agents target DNA, and persistence of DNA adducts correlates with cytotoxicity. In resistant tumor cells, these adducts are repaired efficiently. As discussed above, one repair mechanism involves the enzyme O6-alkylguanine-alkyltransferase, which reverses the initial alkylation of O6-guanine in DNA and prevents the formation of interstrand crosslinks. Thus, upregulation of this alkyltransferase increases resistance in cancers, as observed in human glioma cells resistant to BCNU.¹²¹ In contrast, the cytotoxic effects of O6-alkylguanine adducts (O6-methyl O6-ethyl) are facilitated by the mismatch repair (MMR) pathway¹²² and, conversely, resistance to the methyl-alkylator temozolomide arises when defects in the MMR pathway are present.¹²³ Repair of crosslinks also occurs by the nucleotide excision repair (NER) and the alternative nonhomologous end-joining (NHEJ) pathways. Thus, increased repair by the NER and NHEJ system in human tumor cells induces resistance to cyclophosphamide, melphalan, and chlorambucil.^{124–127} In contrast, and as noted above, the activity of the monofunctional alkylating agent trabectedin is in fact enhanced by the participation of NER protein Rad13/ERCC5.¹⁰²

Adduct formation and interstrand crosslinks kill cells by apoptosis, which has been demonstrated for a number of alkylating agents, including cyclophosphamide and temozolomide.^{128, 129} DNA damage activates a complex set of signal transduction pathways that converge on the apoptotic machinery to induce cell death. Specifically, alkylation of nucleotide bases induces unwinding and bending of DNA, and the resultant conformational changes in DNA are sensed by specialized recognition proteins that transduce DNA damage signals. This results in transcriptional activation of specific genes that finally activate caspases, which carry out the apoptotic cell death program. As a large number of proteins are involved, such as ATR, Chk1, Chk2, p53, Bak, and Bax, apoptosis can be inhibited if any critical step of the apoptotic cell death program becomes disrupted, and this leads to resistance to alkylating agents. As an example, loss of p53 function through mutation or other means leads to temozolomide resistance.^{111, 130} Resistance to this agent has also been noted in stem-like glioblastoma cells by overexpression of Mdm2 protein, which inhibits p53 by increasing its proteosomal degradation.¹³¹ On the other hand, overexpressed Bcl-2 protein in some cancers binds to Bax and, thereby, blocks the caspase-9/caspase-3 cascade to inhibit cyclophosphamide-induced apoptosis.¹²⁸ Alternatively, resistance to cyclophosphamide, chlorambucil, and temozolomide in human B cell CLL and U87MG glioblastoma cells can occur when Bax expression is low.^{132, 133}

Although drug resistance to alkylating agents in tumor cells can often be observed in both tissue culture and in rodent models, this is not always the case. In a classical example, EMT-6 murine mammary tumors that developed resistance to cyclophosphamide by directly injecting tumor-bearing mice with the drug did

not display this resistance when cells from these tumors were exposed to this agent *in vitro*.¹³⁴ This demonstrates that some mechanisms of resistance to alkylating agents, such as the influence of TGF- β (transforming growth factor-beta) growth factor, poor tumor perfusion, changes in intracellular pH, and the tumor microenvironment, may only operate *in vivo*.^{135–137}

Clinical pharmacology

The pharmacokinetics (PK) of a drug dictates its pharmacodynamics (PD), and this PK–PD relationship is integral to understanding the basis for drug activity and toxicity and designing regimens that maximize activity against cancer and minimize side effects. The pharmacology of alkylating agents has been studied for over six decades, but it was clear as early as 1952 that an ideal alkylating agent should be administered in an inactive form and converted into an active form in patient's tumor.^{12, 138} The essential knowledge on the clinical pharmacology of these agents of interest is summarized below.

Cyclophosphamide

A systemic dose of 50–75 mg/kg cyclophosphamide produces plasma levels of up to 400 $\mu\text{mol/L}$ of the intact drug, which then decays with a half-life of 3–10 h.^{139–141} Peak plasma concentration of 50–100 $\mu\text{mol/L}$ phosphoramidate mustard metabolite was also observed at about 3 h. Interestingly, the AUC of this and the 4-hydroxy-cyclophosphamide metabolite were similar after intravenous and oral administration, and this indicated both routes to be therapeutically effective. However, there is considerable variation in the PK of the drug among patients, but this is likely due to a prior dose of cyclophosphamide autoinducing its own metabolism or to administration of metabolism-inducing drugs, such as phenobarbital.^{109, 142, 143} At conventional doses, however, variations in PK do not significantly affect its toxicity or therapeutic effects.¹⁴⁴ One explanation for this is that the final AUC for the active metabolites is unaffected, which is supported by the demonstration that cyclophosphamide given iv over 90 min yields 4-hydroxycyclophosphamide AUC of 105–110 $\mu\text{mol/L}$ that is similar to an AUC when the dose is infused over 4 days.¹⁴⁵ Although high-dose therapy is an attractive approach in bone marrow transplantation regimens, the benefits can be limited by saturable PK.¹⁴⁶ Urinary excretion of cyclophosphamide, predominantly as inactive metabolites, is the main route of excretion and accounts for about 60–70% of the dose.^{147, 148} Renal function does not appear to correlate with the toxicity of cyclophosphamide, and this supports drug clearance of active metabolites being determined by spontaneous decomposition, and not renal excretion.

Ifosfamide

The clinical PK data on ifosfamide is limited, but appears to be similar to that of cyclophosphamide. However, levels of the active 4-hydroxy metabolite from ifosfamide are lower than from cyclophosphamide.^{149–151} As with cyclophosphamide, ifosfamide is orally bioavailable and can autoinduce its own metabolism.^{141, 152} Although such similarities may make the choice between these two agents difficult, the potential for larger interpatient variation in metabolism of the side chain and the impact of concomitantly administered drugs altering the metabolic pathway may limit the utility of ifosfamide more than that of cyclophosphamide.^{153–155}

Melphalan

An iv dose of 0.6 mg/kg results in peak melphalan plasma levels of 4–13 $\mu\text{mol/L}$, which then decays biexponentially, with a rapid α -phase half-life ($T_{1/2\alpha}$) of 8 min and a relatively slower β -phase half-life

($T_{1/2\beta}$) of 1.8 h.^{156, 157} At this dose, the mean AUC of 8 $\mu\text{mol h/L}$ of melphalan was achieved and 24-h urinary excretion of melphalan was about 13% of the dose. Similar plasma PK has been observed following high-dose iv melphalan, and as spontaneous degradation of melphalan plays a major role in drug elimination, renal insufficiency was reported not to impact drug clearance.¹⁵⁸ Another study, however, has demonstrated that renal insufficiency reduces drug clearance and increases myelosuppression, which disappears with dose reduction.¹⁵⁹ Melphalan has good oral bioavailability, and conventional doses of 0.15–0.25 mg/kg melphalan given orally resulted in peak plasma levels of up to 0.2–0.6 $\mu\text{mol/L}$ by 1–2 h, which decayed with a half-life of 0.6–3 h.¹⁶⁰ However, absorption after oral dosing can vary, with food reducing drug absorption and high doses subject to saturable absorption kinetics.^{161–163}

Chlorambucil

An oral dose of 0.6 mg/kg chlorambucil produced peak plasma levels of 2–6 $\mu\text{mol/L}$ of the intact drug an hour later and 2–4 $\mu\text{mol/L}$ of the metabolite phenylacetic acid mustard by 2–4 h.¹⁵⁷ The β -phase half-life of the parent compound was 92 min, with that of the metabolite being 145 min. In another study, PK analysis of an oral daily dose of 0.8–0.9 mg/kg over 4 days indicated that the AUC of about 10 $\mu\text{mol h/L}$ of chlorambucil on day 1 decreased 17% by day 4, with further progressive decreases noted with each 4-week treatment cycle.¹⁶⁴ This suggests that chlorambucil, as with cyclophosphamide and ifosfamide, may also be subject to autoinduction of its metabolism and excretion, although an alternative possibility is that repeat dosing reduces absorption from the gut. A two- to fourfold inter- and intraindividual variation in the PK of oral chlorambucil has also been reported.¹⁶⁵ Interestingly, plasma AUC of the drug or its metabolite phenylacetic acid mustard was unaffected by food intake.¹⁶⁶

Bendamustine

A bolus iv dose of 5 mg/kg bendamustine was eliminated rapidly from the plasma, with $T_{1/2\alpha}$ of about 10 min and $T_{1/2\beta}$ of 36 min, and a resultant AUC of about 28 $\mu\text{mol h/L}$.¹⁶⁷ The oral bioavailability is good and in the range 0.25–0.94 (mean, 0.57). The drug is metabolized by hepatic mixed function oxidases to N-demethyl- and γ -hydroxy-bendamustine as major metabolites.¹⁶⁸ Glutathione conjugates of the metabolites are also known, and an additional metabolite, dihydroxy-bendamustine, has been observed in patients plasma after an iv dose.¹⁶⁹ Total excretion of the drug accounts for 76% of the iv dose, with similar amounts appearing in the urine and the feces. Only about 5% of the dose was recovered as unchanged parent drug, and this indicates that bendamustine is extensively metabolized.

Thiotepa

Administration of thiotepa at 12 mg/m^2 iv resulted in peak plasma levels of about 5 $\mu\text{mol/L}$ for the parent drug, which then decayed biphasically with a $T_{1/2\alpha}$ of 8 min and a $T_{1/2\beta}$ of 2 h, and resulting in an AUC of about 9 $\mu\text{mol h/L}$.¹⁷⁰ The peak concentration of the metabolite tepa of about 1 $\mu\text{mol/L}$ was reached 2 h after drug administration and persisted in the plasma longer than thiotepa. Urinary excretion accounted for about 30% of the dose in 24 h, with 1.5% as unchanged drug and the majority (~24% of dose) representing unknown, but reactive, species. Thus, the biotransformation of thiotepa is extensive. In a 4-day continuous iv infusion study using high doses (up to 900 mg/m^2), peak plasma levels of thiotepa were reached during the first day, but then declined progressively by about 30% over the next 3 days.¹⁷¹ The high dose also produced corresponding high plasma AUC values of up to 600 $\mu\text{mol h/L}$. Thiotepa has also been given intraperitoneally, with absorption occurring rapidly and resulting in plasma levels that were

similar to those observed after iv administration.¹⁷² However, the AUC of the drug in the peritoneum was over fourfold higher than in the plasma, and provides a strong rationale for intraperitoneal drug administration to increase drug exposure to cancers confined to this region.

Nitrosoureas

The PK of BCNU has been studied after iv infusion of 60–170 mg/m², which produced peak plasma concentrations of about 5 µmol/L that then decayed biphasically with a $T_{1/2\alpha}$ of 6 min and a $T_{1/2\beta}$ of 68 min.¹⁷³ PK of high-dose BCNU (300–750 mg/m²), when normalized to a constant dose of 1 g/m², demonstrated a peak plasma level as ultrafilterable BCNU of 7.8 µmol/L and a mean AUC of 9 µmol h/L.¹⁷⁴ This represents only 23% of the total plasma BCNU that is bioavailable for alkylation function. The PK study of CCNU given orally at a dose of 130 mg/m² to patients failed to detect the parent compound in the plasma, likely due to rapid conversion to trans-4-hydroxy CCNU and cis-4-hydroxy CCNU.¹⁷⁵ These two metabolites reached peak levels of 3 µmol/L by 2–4 h after administration. The half-life for the plasma clearance of hydroxy-CCNU metabolites was about 1–3 h.

Busulfan

The insolubility of busulfan in aqueous solutions requires the drug to be used largely as an oral preparation. At an oral dose of 1 mg/kg, absorption is highly variable, as seen in the wide range for peak plasma levels of 1–10 µmol/L, AUC of 10–85 µmol h/L, and plasma elimination half-lives of 1–7 h.¹⁷⁶ However, in young children (2 months to 3.6 years), the peak plasma concentrations are lower (1–5 µmol/L), the mean elimination time was 34% faster than in adults, and the AUC consistently about threefold lower than in adults.¹⁷⁷ Since 2002, busulfan has been available as an iv-formulated Busulfex, which is now widely used, particularly as it is well tolerated and provides more consistent dose-dependent linear PK.¹⁷⁸ Thus, at 0.8 mg/kg busulfan given iv as Busulfex, peak plasma concentration of about 15 µmol/L is achieved, that then declines with a half-life of about 3 h, resulting in a mean AUC of about 80 µmol h/L.

Temozolomide

An oral dose of 150 mg/m² temozolomide was absorbed rapidly, with peak plasma levels of 40 µmol/L observed within an hour and an AUC of 116 µmol h/L.^{179, 180} Elimination from the plasma was rapid, with a half-life of about 1.8 h. Food intake reduced absorption and, thereby, peak concentration by 32% and AUC by 9%, and delayed time to reach peak concentration to 2.3 h. Temozolomide infused iv over 90 min gave peak drug levels of 38 µmol/L and an AUC of 127 µmol h/L, which are similar to those after oral administration and consistent with rapid and complete absorption of the drug from the gut. About 38–39% of temozolomide dose is excreted over 7 days, with the majority (37.7%) in the urine and the remainder (0.8%) in the feces. Of the dose in the urine, only about 6% is unchanged temozolomide.

Trabectedin

The maximally tolerated dose (MTD) of trabectedin when administered either as a 1 or 3 h iv infusion for 3 consecutive weeks every 4 weeks was about 0.6 mg/m²,¹⁸¹ which indicates that this agent has high potency. The plasma concentrations and AUC of trabectedin increase linearly with dose. At the MTD, the 1-h infusion resulted in a mean peak concentration of 15 nmol/L, mean AUC of 43 nmol h/L, and terminal phase plasma $T_{1/2}$ of about 4 days. In comparison, the 3-h infusion gave corresponding values of 8 nmol/L, 31 nmol h/L, and 2 days, respectively. As a 24-h infusion every 21 days, the MTD was 1.5 mg/m², but a

significant increase in total body clearance was noted between the first and fifth course of treatment.¹⁸² The MTD on course one gave a peak concentration of 2.4 nmol/L, AUC of 74 nmol h/L, and terminal plasma $T_{1/2}$ of about 4 days. This AUC value when adjusted for dose is consistent with that obtained with the shorter 1 or 3 h infusion. Biotransformation of trabectedin occurs in the liver, and several metabolites are excreted in the urine and feces of patients.¹⁸³

Adverse effects

Given that alkylating agents target DNA, normal tissues have the potential to be impacted by treatment with these drugs, particularly those having a high proliferation rate. However, unwanted toxicities may arise in any tissue owing to several reasons, including tissue-specific increases in accumulation of active drug and/or toxic metabolite. Owing to their narrow therapeutic index, each alkylating agent will likely induce several side effects, some that are mild but others that become dose-limiting and attenuate clinical utility.

Hematopoietic toxicity, particularly affecting granulocytes and platelets, is the most common dose-limiting toxicity associated with alkylating agents. However, this is reversible, as has been demonstrated with temozolomide.¹⁸⁰ Interestingly, cyclophosphamide and ifosfamide are less myelosuppressive, and this is likely due to the presence of aldehyde dehydrogenase, which inactivates the aldophosphamide metabolite in hematopoietic stem cells and early granulocytes. In cases of severe hematopoietic toxicities with other alkylating agents, counter measures available to stimulate recovery include granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF). These protective measures also allow dose intensification for increased antitumor response. However, use of these protective agents is not without additional complications.¹⁸⁴ As DNA alkylation of normal hematopoietic cells is also increased in high-dose therapy, secondary leukemia is a serious side effect in up to 10% of the patients. Similarly, with DNA as a target, alkylating agents are high-risk teratogens, particularly in the first trimester of pregnancy.¹⁸⁵

The GI tract expresses aldehyde dehydrogenase to protect itself from toxic effects of cyclophosphamide and ifosfamide. However, other alkylating agents target the rapidly proliferating cells in the GI tract to induce side effects, particularly in high-dose regimens. For instance, high doses of melphalan and thiotepa induce stomatitis, esophagitis, and diarrhea. Nausea and vomiting, which involve the GI tract, are mediated in part by a CNS (central nervous system) effect, which may be due to the high lipophilicity of the drugs and their ability to cross the blood–brain barrier. Fortunately, nausea and vomiting can be controlled with antiemetics, including dopamine and serotonin antagonists¹⁸⁶ in conjunction with improved guidelines.^{187, 188}

The use of busulfan, and to a limited extent melphalan, cyclophosphamide, and chlorambucil, has been associated with pulmonary damage,¹⁸⁹ which may manifest as nonproductive cough and dyspnea, possibly progressing to pulmonary insufficiency and eventual death. Busulfan-induced pulmonary toxicity can occur rapidly, as early as 6 weeks after initiating therapy, and impacting 3–43% of the patients, depending on the therapeutic protocol and inclusion of high-dose therapy. Hepatotoxicity also can be induced by high-dose therapy, and fatal veno-occlusive disease syndrome following bone marrow transplantation, characterized in part by hepatomegaly, has been observed in up to 25% of patients receiving cyclophosphamide and busulfan.^{190, 191} Mild and transient hepatotoxicity has been reported at standard doses of melphalan, busulfan, chlorambucil, and trabectedin. The more serious cirrhosis, fibrosis, and cholestasis have also been implicated. Nitrosoureas are also hepatotoxins, with BCNU in particular associated with liver abnormalities in up to 26% of patients that are usually reversible, but have proved

to be fatal in a few cases.¹⁹⁰

Gonadal damage is a serious side effect of alkylating agents, such as cyclophosphamide, chlorambucil, melphalan, busulfan, mechlorethamine, CCNU, and BCNU, but reverses in most cases over a period of a few years.¹⁹² Procarbazine-containing regimens, on the other hand, render permanent infertility in the majority of men being treated for lymphomas. In women, procarbazine and cyclophosphamide induce ovarian failure and transient amenorrhea.¹⁹³ Significantly, women older than 25 years are at a higher risk of ovarian failure, and those older than 30 years have a 12-fold greater risk of menstrual irregularities.

Although hematopoietic and GI toxicities are mild with cyclophosphamide and ifosfamide, hemorrhagic cystitis of the bladder is serious.¹⁹⁴ Busulfan, thiotepea, and temozolomide have also been implicated in this side effect. However, use of thiols, such as mesna to inactivate metabolites, and adequate hydration, to force their urinary excretion, have provided some protection. Toxicity to the kidney is also a serious side effect of therapy, particularly with nitrosoureas. In a study using six courses of therapy with 200 mg/m² BCNU or methyl-CCNU, renal impairment was common, as evidenced by elevation in blood urea nitrogen or serum creatinine.¹⁹⁵ In some patients, renal damage manifested as tubular atrophy, interstitial fibrosis, and glomerular sclerosis.

Cardiotoxicity can also be a serious side effect induced by cyclophosphamide, ifosfamide, and busulfan, and has known to be fatal in the case of high-dose cyclophosphamide.^{196–198} Pathological findings indicated endothelial injury and hemorrhagic myopericarditis as specific drug-induced cardiotoxic effects. In contrast, neurotoxicity as a serious complication is not common at standard doses of busulfan or BCNU, but becomes severe only at high iv doses or when administered at a standard dose by the intracarotid route.^{199–201}

Alkylating agents can induce severe alopecia as a side effect, and this is seen particularly with cyclophosphamide, ifosfamide, and busulfan.²⁰² This side effect is exacerbated by inclusion of vincristine or doxorubicin in drug-combination protocols. The toxicity may be due to the penetration of lipophilic metabolites into the hair follicles,²⁰³ but it is usually reversible. Other minor toxicities associated with alkylating agents and observed on rare occasions include allergic reactions and transient antidiuretic effects.

Platinum antitumor compounds

The most recognizable platinum antitumor compound is cisplatin (cis-diamminedichloroplatinum(II)), which is a neutral, square planar inorganic complex with two labile chloro and two stable ammine ligands in a cis-configuration. This chemical geometry is important, as the analogous trans-geometry in transplatin ([Figure 14](#)) renders the molecule about 20-fold less cytotoxic. However, there are some exceptions to the low potency associated with the trans-geometry.²⁰⁴ Cisplatin was first described in 1844 as Peyrone's salt, but its cytotoxic activity was not discovered until 1969 when a serendipitous observation was made by the Rosenberg group that passing direct current via platinum electrodes immersed in a culture of *Escherichia coli* prevented cell division, but the bacteria continued to grow as filaments. Detailed examination led to the discovery that the electrodes had reacted with nutrients in the culture medium to form several products, including cisplatin, that potently arrested cell division in *E. coli*. Cisplatin was selected for eventual development as an antitumor agent, and it received approval for clinical use in 1978 by the US Food and Drug Administration (FDA).²⁰⁵

Figure 14 Structures of cisplatin and selected analogs.

Basis for cisplatin analog development

Since its FDA approval, cisplatin has been extensively used in the treatment of several cancers, including testicular, ovarian, head and neck, bladder, and cervical cancers.²⁰⁶ The cure rate for testicular cancer, in particular, increased from 10% to 85% with inclusion of cisplatin as part of the therapeutic regimen. Although cisplatin is stable and easy to handle, it demonstrated some major clinical limitations. For this reason, hundreds of platinum molecules were synthesized to identify alternative platinum congeners with improved toxicity profiles and a broader spectrum of activity. In the 20 year span between 1979 and 1999, 23 platinum drugs entered clinical trials, but none since, with a majority failing to demonstrate clinical activity.²⁰⁷ Some of these molecules are shown in [Figure 14](#), which includes carboplatin and oxaliplatin as the only other platinum compounds to have received FDA approval. Cisplatin and similar square planar analogs have the central platinum(II) in a divalent state, but others, such as the octahedral ormaplatin, have the tetravalent platinum(IV) atom.

A major drawback of cisplatin that was apparent early was its irreversible and cumulative toxicities to the kidneys and the peripheral nerves. The dose-limiting nephrotoxicity, however, became the driver of a search for a safer platinum analog. An examination of some 300 analogs by the Harrap group led to the selection of carboplatin for clinical trials in early 1980s.²⁰⁸ This analog has a bidentate cyclobutanedicarboxylate ligand that replaces the two chloro-atoms ([Figure 14](#)), and this was sufficient to obviate not only nephrotoxicity, but also peripheral neuropathy. On the basis of the clinical activity, however, carboplatin is similar to cisplatin and, therefore, cancers refractory to cisplatin are fully cross-resistant to carboplatin.^{209, 210} This renewed an interest in identifying an analog that lacked the cross-resistance characteristic, and required modification of the ammine ligand. Several such analogs entered clinical trials, including ormaplatin and oxaliplatin, which have the bidentate 1,2-diaminocyclohexane (DACH) moiety, and picoplatin, which has one ammine group substituted by methylpyridine ([Figure 14](#)),

but only oxaliplatin has demonstrated significant activity in specific refractory cancers.²⁰⁸ In contrast to others, satraplatin, which also has one ammine substituted with a monoaminocyclohexane group, was tested clinically as an oral formulation, and although it has demonstrated some activity,²¹¹ its future, like that of picoplatin, remains unclear.²⁰⁷

Basis for activity of platinum compounds

Although cisplatin, carboplatin, and oxaliplatin are considered chemically inert, they are, nevertheless, clinically active. For activity, the neutral platinum molecules are transformed spontaneously to reactive species in an aqueous or biological environment. This entails displacement of the chloro (in cisplatin) or the dicarboxylato ligand (in carboplatin and oxaliplatin) with water molecules, as exemplified in [Figure 15](#) with cisplatin.^{212, 213} The resulting species exist in equilibrium in an aqueous solution, but in a biological environment, the equilibrium is not established as the chloro-monoaquo species reacts immediately with nucleophilic sites in biomolecules. In carboplatin, the bidentate cyclobutane-dicarboxylic acid (CBDCA) ligand slows the aquation reaction and this in turn reduces drug potency that requires the clinical dose to be fourfold greater than that of cisplatin.²¹⁴ The bidentate oxalate group of oxaliplatin, on the other hand, is relatively more labile, and its potency is comparable to that of cisplatin. The platinum(IV) compounds, such as satraplatin, are stable in an aqueous environment, and their reduction to platinum(II) species is a prerequisite for aquation reactions. Surprisingly, ormaplatin is highly reactive and binds rapidly to plasma proteins,²¹⁵ and this indicates that the nature of the equatorial ligands in Pt(IV) compounds dictates the rate of reduction and activation of the molecule (Cl⁻ acetate).

Figure 15 Aquation of cisplatin to active platinating species.

Interaction of platinum drugs with DNA

Several studies have established that DNA is the primary cytotoxic target of platinum drugs.²¹⁶ As platinum drugs react immediately with endogenous macromolecules upon activation, it is likely that the drug enters the nucleus in an intact neutral form and becomes aquated in situ for interaction with DNA, primarily at N7-site of guanine. Platinum drugs form both interstrand and intrastrand crosslinks in various configurations ([Figure 2](#)). As with nitrogen mustards, interstrand crosslinks are readily formed when guanine is in the 5'-GC-3' sequence.²¹⁷

Cisplatin-induced interstrand crosslinks have biological effects, such as cytotoxicity and inhibition of transcriptional activity of DNA-dependent RNA polymerases,^{218, 219} but available evidence suggests that intrastrand adducts are the more potent cytotoxic lesions. This is consistent with the inability of weakly

active transplatin to form intrastrand adducts.²¹⁹ Moreover, 85–90% of adducts formed by cisplatin are 1,2-intrastrand AG and GG crosslinks, with 1,3-intrastrand GXG crosslinks (where X = any nucleotide), interstrand GG-crosslinks, and monofunctional adducts, each representing 2–6%. The low level of interstrand crosslinks may also be due to their unstable nature, and they slowly convert to the stable intrastrand adduct.^{217, 220} DNA–protein crosslinks and monofunctional adducts are also formed but are not considered cytotoxic based on the fact that they are formed extensively by transplatin²²¹ or they fail to inhibit DNA-dependent RNA polymerases.^{222, 223}

The ability of DACH-containing platinum compounds, such as oxaliplatin, to circumvent cisplatin resistance has drawn considerable attention.²²⁴ Interestingly, the profile of monoadducts and interstrand and intrastrand diadducts formed by the analogous model drug DACH-sulfato-platinum(II) was essentially similar to those found with cisplatin.²²⁵ Thus, circumvention of cisplatin resistance must be due to the subtle chemical difference in the DNA adduct formed between oxaliplatin versus cisplatin ([Figure 16](#)). As cisplatin and carboplatin form identical bifunctional adducts, this explains why their cytotoxic profiles are similar.

Figure 16 DNA crosslinks of oxaliplatin, cisplatin, and carboplatin. Cisplatin and carboplatin form identical crosslinks; crosslink of oxaliplatin is structurally different by virtue of the diaminocyclohexane ligand tethered to the platinum atom.

DNA-damage signals and cell death

Only a few crosslinks by cisplatin are sufficient to inhibit DNA replication, and this conveys the high potency of the drug.²²⁶ Thus, crosslinks provide the basic understanding for cell death with platinum drugs. However, differences in activity between cisplatin and oxaliplatin in cisplatin-resistant cells warrant additional discussion. Both intrastrand and interstrand adducts induce the DNA to unwind and bend at the site of DNA damage. For instance, cisplatin intrastrand crosslink unwinds DNA by 13°–23° and bends it by 32°–34°;²²⁷ whereas interstrand crosslinks unwind the double helix by 79°, with bends of 45°.^{217, 228} Interstrand crosslinks formed by oxaliplatin, on the other hand, induce unwinding by 82° and

bending by 61°. Such differences in DNA conformation induced by distinct platinum drugs are recognized differentially by DNA damage sensor proteins; for instance, the nonhistone chromosomal protein HMGB1 and MMR proteins hMLH1, hMSH2, and hMSH6 recognize GG crosslinks of cisplatin but not those of satraplatin or the clinically active oxaliplatin.^{228–230} In this respect, loss of MMR proteins leads to cisplatin resistance but not oxaliplatin resistance.^{230, 231} Similarly, HMGB1 fails to recognize interstrand crosslinks of the poorly active transplatin.²³² Thus, recognition by independent proteins of oxaliplatin-induced local DNA distortions results in propagation of distinct signaling that bypasses the block in cisplatin-induced signaling and enables oxaliplatin to activate DNA damage checkpoints and circumvent cisplatin resistance. However, identity of proteins that specifically recognize oxaliplatin adducts is not known.

DNA damage checkpoints activate several kinases, such as ATR, Chk1, and Chk2, which function in an orchestrated manner to activate target proteins for cellular effects. A critical target protein in this regard is the tumor suppressor p53, which is a transcription factor that is essential for facilitating cisplatin-induced cytotoxicity.²³³ The process is complex, but essentially involves stabilization and activation of p53 via post-translation phosphorylation by checkpoint kinases at key p53 sites, such as Serine-15 and Serine-20. The activated p53 can then transcriptionally upregulate gene targets, including p21 and Bax. The p21 protein is pivotal in inhibiting cyclin-dependent kinases to induce cell cycle arrest by cisplatin.²³⁴ Increase in the proapoptotic Bax protein, on the hand, eventually leads to formation of the apoptosome complex, which activates the caspase-9/caspase-3 cascade to affect apoptotic cell death.²³⁵ The p53 protein can also activate apoptosis in a transcription-independent manner by directly interacting with pro- and antiapoptotic proteins in the mitochondria to tilt the balance in favor of apoptosis.²³³

Mechanism of resistance to platinum drugs

As discussed earlier, the mode of action of platinum compounds involves intracellular transport of the drug, its activation, formation of DNA adducts, recognition of DNA damage, checkpoint activation, and induction of apoptosis. Disruption of any single step in this coordinated process will inhibit cell death and lead to resistance, which may be intrinsic or acquired, but the mechanism is invariably multifactorial.²³⁶ The level of cisplatin resistance in the clinic is difficult to define, but it is at least twofold as doubling the cisplatin dose induces antitumor response in otherwise refractory patients.^{237, 238} It is likely that in some tumor cells the resistance may be substantially greater.^{233, 236}

Resistance can occur at the biochemical level from reduced drug accumulation, increased thiol levels, and/or increased DNA adduct repair in tumor cells that individually or collectively reduce the level or persistence of cytotoxic DNA crosslinks.^{239, 240} Reduced accumulation of cisplatin by 20–70% has been documented and these can be due to altered levels of transporter proteins involved in influx (e.g., lower Ctr1 expression) or efflux (e.g., increased ATP7A, ATP7B, or ATP11B expression).^{236, 241, 242} Resistance due to thiols can occur following elevation in levels of metallothionein and/or glutathione, or in expression of enzymes involved in their biosynthesis, such as glutathione-associated γ -glutamylcysteine synthetase, or in catalyzing their inactivating conjugation with the platinum drug, such as glutathione S-transferase that has been observed in head and neck cancer patients.^{236, 243} Enhanced removal of adducts by DNA repair to affect resistance by a factor of up to twofold is frequently encountered, and this has been correlated to increased expression of repair genes, such as the NER gene ERCC1 in ovarian cancer patients.²⁴⁴

Before repair of crosslink adducts can be initiated, the DNA lesion has to be first recognized. Thus, downregulation of MMR proteins can prevent recognition of DNA damage; specifically, hMLH1, hMSH2,

and hMSH6 can become mutated or silenced by promoter hypermethylation.²³⁶ Molecular mechanisms of resistance can also occur through defects in checkpoint proteins, as exemplified by mutation or silencing of Chk2 in nonsmall cell lung cancer patients that likely impedes stabilization and activation of p53 and, thereby, apoptosis.²⁴⁵ This p53-dependent apoptosis can also be inhibited by other factors, including upregulation of Bcl-2 protein, inhibitors of apoptosis protein, and Her-2/neu, PI3K/Akt, and Ras/MAPK pathways.²³⁶ The p53 itself can become mutated, and this probably has the greatest impact in inducing cisplatin resistance.^{233, 246}

Clinical pharmacology

The PK of cisplatin or oxaliplatin as the intact molecule is complicated by its rapid and spontaneous transformation to active species, which are then inactivated through irreversible binding to proteins. Thus, analysis of “total” platinum does not reveal the fraction that is “free” (bioavailable parent drug and active species) from the inactive protein-bound fraction. Therefore, PK in plasma has involved estimating total platinum in the plasma and low molecular weight free platinum in plasma ultrafiltrates, usually by flameless atomic absorption spectrophotometry (FAAS).^{215, 247} However, the more stable carboplatin is amenable to high-performance liquid chromatography (HPLC) analysis of parent drug in the ultrafiltrate fraction, but the difference in PK of carboplatin using HPLC and FAAS is minimal.^{248, 249}

Cisplatin

The plasma PK has been investigated at a standard dose of 100 mg/m² cisplatin using a bolus (4–15 min infusion) or a 3- and 24-h infusion schedule, which, respectively, gave peak levels as free platinum species of 44, 10, and 1.4 μmol/L and corresponding AUC of 24.7, 27.4, and 27.8 μmol h/L.²⁵⁰ Similarity in these AUC values explains why clinical activity is independent of schedule. However, toxicity is usually lower with longer infusions, and this may be considered for optimizing the therapeutic schedule. After bolus administration, free platinum levels decline biphasically, with $T_{1/2\alpha}$ of 6–10 min and $T_{1/2\beta}$ of 36–40 min.^{215, 251} Total plasma platinum declined in a triphasic manner, with half-lives of 13 min for $T_{1/2\alpha}$, 43 min for $T_{1/2\beta}$, and 5.4 days for terminal $T_{1/2\gamma}$. This long $T_{1/2\gamma}$ and the corresponding high AUC of 908 μmol h/L for total platinum²⁴⁷ indicate the prolonged retention of covalently bound platinum in plasma. Thus, urinary excretion is low, accounting for only 28–33% of the dose in 24 h.^{215, 252}

Oxaliplatin

As with cisplatin, covalent interaction with plasma proteins and urinary excretion of 37% in 24 h of a standard 130 mg/m² dose given as a 2-h infusion also contribute to the rapid clearance of oxaliplatin.²¹⁵ Peak plasma concentration at this schedule was 6.2 μmol/L for free platinum and 18.5 μmol/L for total platinum on cycle 5. The threefold difference between free and total peak concentration may be due to accumulation of protein-bound platinum from previous cycles of treatment. Nevertheless, the AUC values of 61 and 1062 μmol h/L for free and total platinum compare reasonably with those with cisplatin.^{215, 247} The free plasma platinum decays triexponentially, with a $T_{1/2\alpha}$ of 17 min, a $T_{1/2\beta}$ of 16 h, and a $T_{1/2\gamma}$ of about 270 h.

Carboplatin

The low reactivity of carboplatin results in high urinary excretion of about 77% of the dose in 24 h, with most (41%) as intact carboplatin drug.^{215, 249} Peak total platinum concentration of 251 μmol/L was observed after a dose of 550 mg/m², and this likely represents intact drug based on slow reaction kinetics

of carboplatin with plasma proteins²⁴⁷ and similar $T_{1/2\alpha}$ and/or $T_{1/2\beta}$ values for total and free platinum and for intact drug.^{215, 247} As free platinum, the drug decays biphasically, with $T_{1/2\alpha}$ of 23 min and $T_{1/2\beta}$ of 2 h. Total platinum, however, decayed triphasically, with a similar $T_{1/2\alpha}$ of 22 min and $T_{1/2\beta}$ of 1.9 h, and a prolonged $T_{1/2\gamma}$ of 5.8 days. The AUC for total and free platinum and for intact carboplatin were 1385, 506, and 456 $\mu\text{mol h/L}$, respectively, and this supports intact carboplatin as the major component of the plasma “free” drug fraction.

Adverse effects

The dose-limiting complication with cisplatin is the cumulative and irreversible nephrotoxicity, which manifests as a decrease in the glomerular filtration rate and is characterized by focal acute tubular necrosis, dilatation of convoluted tubules, and formation of casts.^{253, 254} Serum electrolyte imbalance also occurs, including hypomagnesemia, in over 50% of the patients.²⁵⁵ The cause may be due to active tubular transport of cisplatin that increases tubular drug concentration.²⁵⁶ However, hydration and forced diuresis may reduce the severity and/or incidence of kidney damage. Nephrotoxicity is rare with oxaliplatin and carboplatin, which are cleared by glomerular filtration only.^{215, 257} On the basis of this, the Calvert formula was devised to individualize carboplatin dosing based on renal function and this is now in standard use.²⁵⁷

Cumulative ototoxicity has also been a significant problem with cisplatin, usually in the form of tinnitus and hearing loss, with young children being more susceptible.²⁵⁸ High-frequency hearing loss is often the first sign, progressing to involve the middle frequencies at doses in excess of 100 mg/m^2 , and finally resulting in total loss of hearing in about 50% of patients receiving cumulative doses greater than 400 mg/m^2 .²⁵⁹ Radiation treatment in combination therapy exacerbates the toxicity. The incidence of ototoxicity with carboplatin or oxaliplatin, however, is low and this may be due to reduced cochlear drug accumulation in contrast to cisplatin.^{260–262}

Peripheral neuropathy has been described for all three drugs.²⁶¹ With cisplatin, it is more frequent, cumulative, and irreversible, involving mainly sensory neuropathy in up to 50% of the patients receiving cumulative doses in excess of 300 mg/m^2 . Tingling paresthesia, weakness, tremors, and loss of taste are usually encountered, and seizures have also been described. Neurotoxicity is particularly severe following intra-arterial administration of cisplatin in head and neck patients. Peripheral neuropathy with oxaliplatin is dose limiting and can be acute or chronic, but symptoms of the chronic form improve after treatment stops and resolves completely over a period of 6–8 months in 40% of the cases. Carboplatin is the least neurotoxic, affecting only 4–6% of the patients. For chemoprotection of peripheral neuropathy, several strategies have been devised, including the use of thiol compounds and vitamin E.²⁶¹

Cisplatin is considered one of the most emetic antitumor agents. This drug at doses $>50 \text{ mg/m}^2$ has a 90% risk of inducing emesis, with lower doses associated with reduced risk (30–90%).²⁶³ In comparison, carboplatin and oxaliplatin pose only moderate risks at therapeutic doses. Antiemetics have been developed to provide relief from this side effect, and include the dopamine antagonist metoclopramide and the serotonin receptor antagonists, such as ondansetron, granisetron, and dolasetron.

Myelosuppression is associated with the use of the platinum drugs, but the effects are usually reversible. Cisplatin-induced hematological toxicity is manifested as leucopenia, whereas carboplatin induces thrombocytopenia as its dose-limiting toxicity, which may be severe enough to cause internal bleeding. Neutropenia and thrombocytopenia have been reported with oxaliplatin. Pulmonary toxicity, hepatotoxicity, alopecia, and/or allergic reactions are among several other side effects that may also be

observed with these platinum drugs.

Chapter 59

DNA topoisomerase targeting drugs

Anish Thomas, MBBS, MD ■ Susan Bates, MD ■ William D. Figg Sr, Pharm D ■ Yves Pommier, MD, PhD

Overview

DNA topoisomerase targeting drugs are widely used in the treatment of multiple cancers. These drugs act by generating topoisomerase-linked DNA breaks and by blocking the religation of the cleavage complexes. Although topoisomerase targeting drugs have a wide spectrum of activity, structural, pharmacokinetic, and pharmacodynamic characteristics somewhat limit their efficacy and safety. To circumvent these limitations and to further exploit its activity, newer inhibitors- including novel formulations and those that achieve targeted delivery- are being developed. Recently described mechanisms that underlie cellular sensitivity to these agents will enable us to predict the activity of topoisomerase targeting drugs and to precisely select patients who are most likely to benefit. Understanding the genetic variants in drug metabolizing enzymes, transporters, and other proteins that influence the pharmacology of these drugs will allow for further individualizing the use of these drugs.

Introduction

The human genome consists of long double-stranded and helical DNA polymers (46 chromosomes) densely packaged in the cell nucleus (~1.8 m of DNA squeezed in a nucleus almost 1 million times smaller in diameter). Relaxing DNA supercoiling by topoisomerases is obligatory when the two genomic strands separate for transcription and replication, because the nucleosomal structure of chromatin constrains and generates DNA supercoiling. Moreover, Type II topoisomerases are required at mitosis for the even distribution of the genome between daughter cells following replication. Thus, topoisomerases are ubiquitous and essential for all organisms as they prevent and resolve DNA and RNA entanglements and resolve DNA supercoiling during transcription and replication.

Topoisomerases were named historically with the first topoisomerase being Topo I in *Escherichia coli*¹ and Top1 in mouse.² Notably, most of the anticancer and antibacterial agents, which are highly specific for their topoisomerase targets, are integral to the anticancer chemotherapeutic armamentarium and were discovered independently and before the term topoisomerase was even coined.

Topoisomerase biology

Human cells contain six topoisomerase genes, with three of the encoded enzymes targeted by anticancer drugs: Top1, Top2 α , and Top2 β ([Table 1](#)).^{3–5}

Table 1 Characteristics of topoisomerases

Genes	Chromosome	Proteins	Drugs	Mechanism	Polarity ^a	Main functions
<i>TOP1</i>	20q12-q13.1	Top1 100 kDa monomer	Camptothecins Indenos	Swivelling Rotation	3'-Y	Nuclear supercoiling relaxation
<i>TOP1MT</i>	8q24.3	Top1mt 70 kDa monomer	None			Mitochondrial supercoiling relaxation
<i>TOP2A</i>	17q21-q22	Top2α 170 kDa dimer	Anthracyclines, Anthracediones Epipodophyllotoxins	Strand passage ATPase	5'-PY	Decatenation/replication
<i>TOP2B</i>	3p24	Top2β 180 kDa dimer				Transcription

^a Covalent linkage between the catalytic tyrosine and the end of the broken DNA.

^b Bloom syndrome, RecQ helicase.

The type of topoisomerase-mediated DNA break is specific of each topoisomerase ([Figure 1](#); [Table 1](#)). These catalytic intermediates are referred to as cleavage complexes ([Figure 1](#)b, e). The reverse religation reaction is carried out by the attack of the ribose hydroxyl ends toward the tyrosyl-DNA bond.

Figure 1 Topoisomerase molecular mechanisms. (a–c) Topoisomerases I (Top1 for nuclear DNA and Top1mt for mitochondrial DNA) relax supercoiled DNA (a) by reversibly cleaving one DNA strand, forming a covalent bond between the enzyme catalytic tyrosine and the 3'-end of the nicked DNA (the Top1 cleavage complex: Top1cc; b). This reaction allows the swiveling of the broken strand around the intact strand. Rapid religation allows the dissociation of Top1 (c). (d–f) Topoisomerases II act on two DNA duplexes. They act as homodimers, cleaving both strands by forming a covalent bond between their catalytic tyrosine and the 5'-end of the DNA break (Top2cc; e). This reaction allows the passage of the intact duplex through the Top2 homodimer (red dotted arrow; e). Top2 inhibitors trap the Top2cc and prevent the normal religation (f). Topoisomerase cleavage complexes (b and d) are the targets of topoisomerase inhibitors.

Top1 (and Top1mt) covalently attaches to the 3'-end of the break, whereas the other topoisomerases (Top2α and β and Top3α and β) attach to the 5'-end of the break. Topoisomerases act by cutting and religating the DNA backbone without assistance of nucleases and ligases. Top1 and Top1mt cleave and religate one strand of DNA duplex, whereas Top2α and β cleave and religate both strands with a four base-pair staggered cut (Figure 1). The DNA cutting-religation mechanism is common to all topoisomerases and utilizes an enzyme catalytic tyrosine residue acting as nucleophile and becoming covalently attached to the end of the broken DNA. The polarity of the attachment to the 3'- versus the 5'-ends of the DNA Top3α and β has the opposite polarity, with covalent attachment to the 5'-end of the breaks (Table 1; Figure 1b, e). Topoisomerases are biochemically distinct. Top1 and Top1mt act as monomers in the absence of nucleotide or metal cofactors, whereas Top2α and β act as dimers, requiring ATP and Mg²⁺ for catalysis. Top3α and β also require Mg²⁺ but function as monomers without ATP. Notably, the DNA substrates differ for Top3 enzymes. Both Top1 and Top2 process double-stranded DNA, whereas the Top3 substrates need to be single-stranded nucleic acids (DNA for Top3α and RNA for Top3β).

Mechanisms of action

Common mechanism of action and molecular pharmacology of topoisomerase inhibitors: trapping the topoisomerase cleavage complexes by interfacial inhibition

Topoisomerase cleavage complexes are normally highly reversible and therefore transient and hardly detectable in the absence of the topoisomerase inhibitor. This is because the religation of the cleavage complexes is driven by the realignment of the broken ends, which itself is determined by two basic structural features of double-stranded DNA: (1) the stacking of adjacent bases by π - π interactions within each strand, and (2) the pairing of bases across the opposite strands by hydrogen bond interactions (duplex DNA can be viewed as a “powerful molecular zipper”).

The clinical topoisomerase inhibitors act by generating topoisomerase-linked DNA breaks as they block the religation of the cleavage complexes when a single drug molecule tightly binds at the interface of the topoisomerase-DNA cleavage complex. The selectivity and strength of the drug binding is established by (1) the stacking of the drug with the bases flanking the cleavage site and (2) a network of hydrogen bonds with the topoisomerase ([Figure 2](#)). As the drug is bound within the cleavage site, it prevents DNA religation by misaligning the DNA end, which is normally required to attack the phosphotyrosyl bond. This mode of binding led to the concept of “interfacial inhibition,” which applies not only to protein–DNA interfaces but also to protein–protein interfaces, as in the case of tubulin and mTOR inhibitors.⁶ Crystal structures of drug-bound cleavage complexes have firmly established this mechanism for both Top1- and Top2-targeted drugs.⁶ The structural characteristics of each drug (differences in chemical scaffold and arrangement of hydrogen-bond donors and acceptors) ([Figure 3](#)) accounts for the selectivity of each drug for Top1 versus Top2 cleavage complexes, and for the differential DNA sequence selectivity and genomic targeting for different topoisomerase inhibitors within each class.^{5, 7}

Figure 2 Trapping of topoisomerase cleavage complexes by interfacial inhibition. (a) Binding of camptothecin and non-camptothecin Top1 inhibitors (green rectangle) at the cleavage site generated by the Top1. A single-drug molecule binds reversibly to the Top1cc by stacking against the bases flanking the cleavage site (intercalation) and by a network of hydrogen bonds with Top1 (orange circles and dashed green lines). (b) Same for etoposide with a single-drug molecule (green) intercalated in the cleavage site formed by each Top2 monomer. Hydrogen bonds with Top2 are shown as orange circles and dashed green lines.

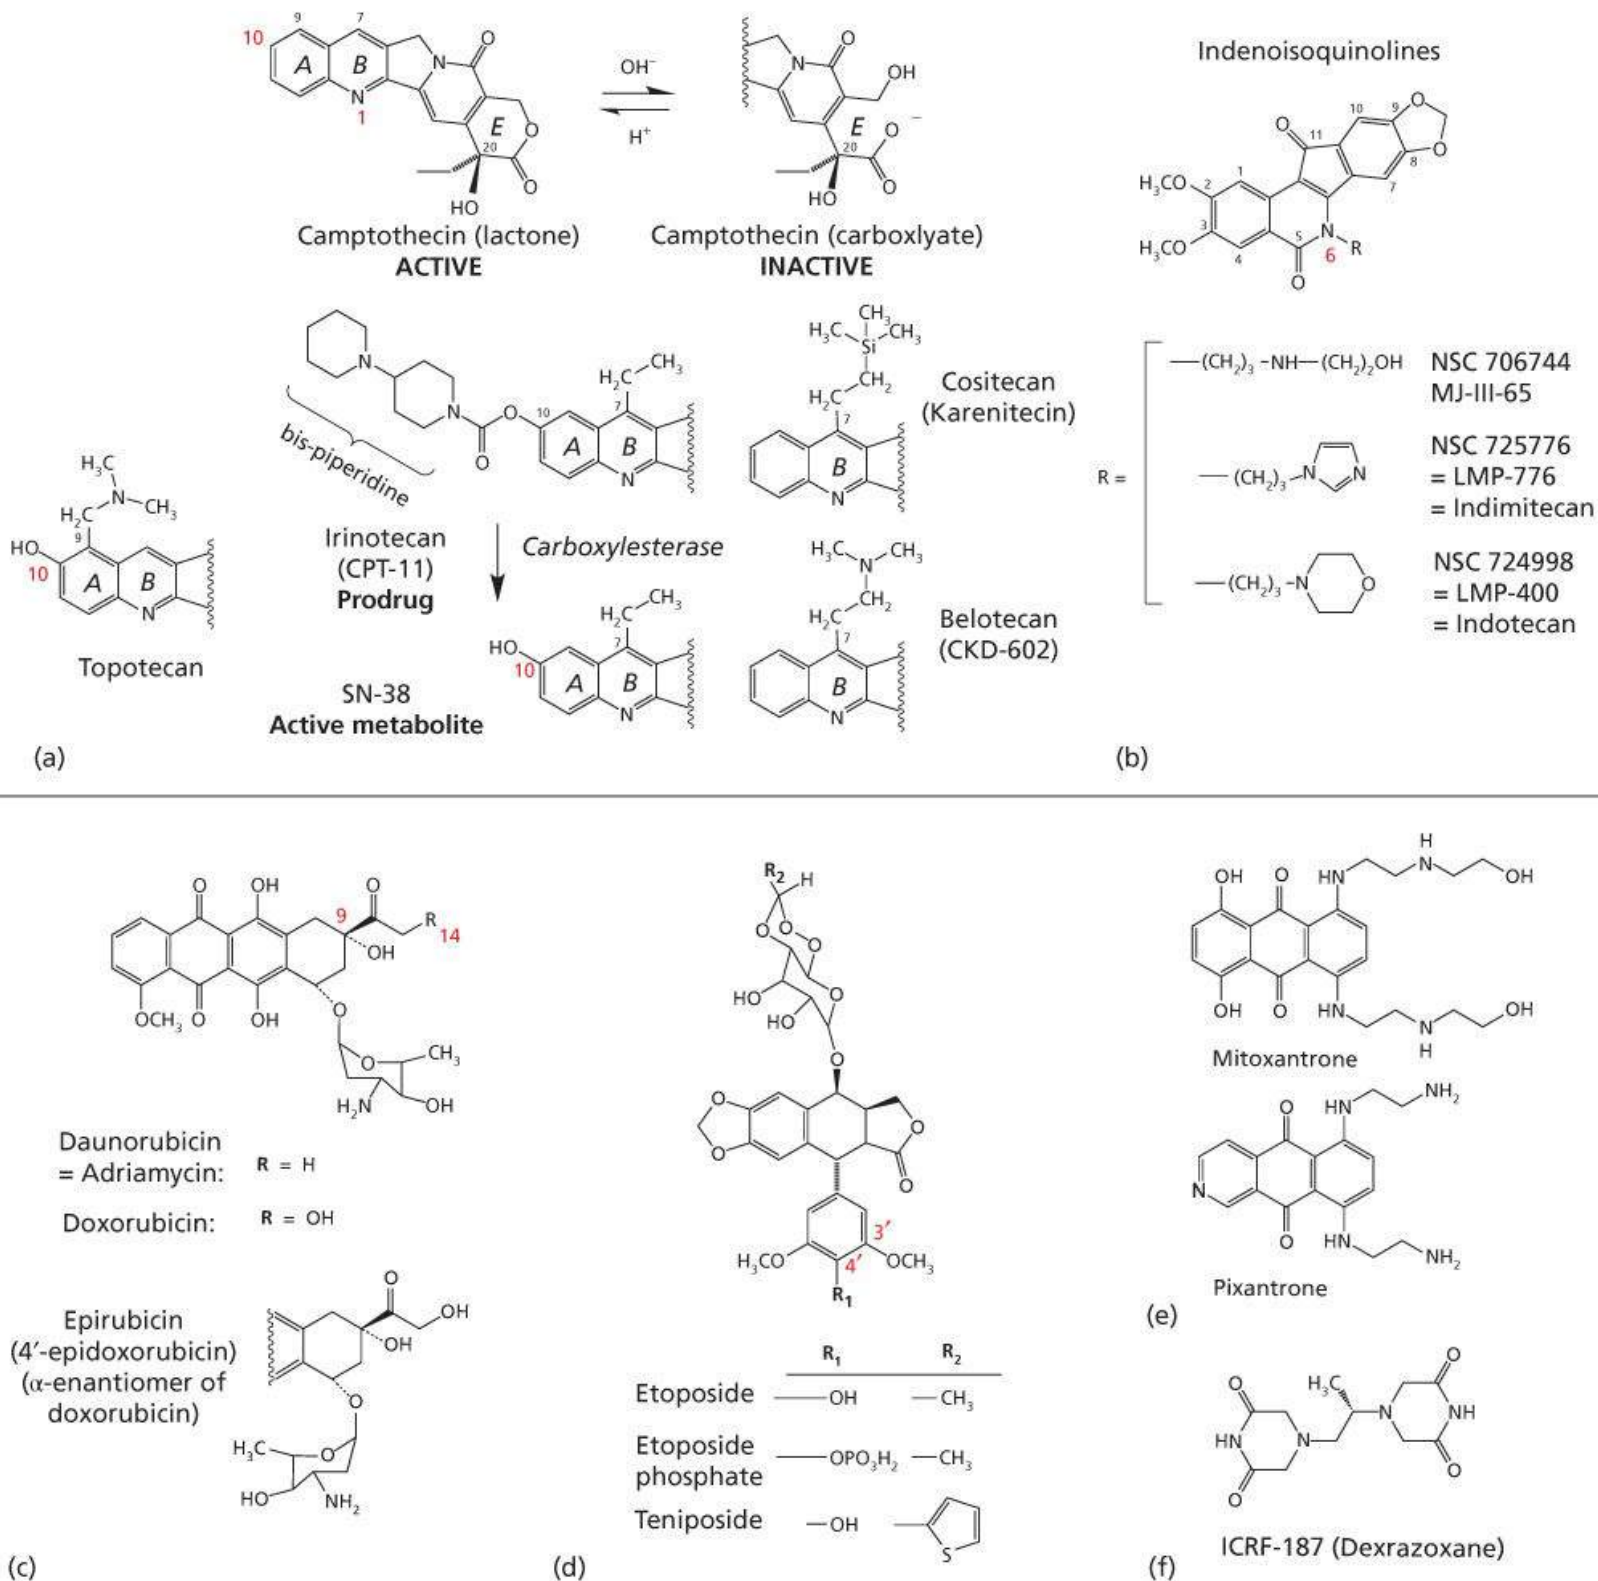

Figure 3 Clinical topoisomerase inhibitors. (a) Camptothecin derivatives are unstable at physiological pH, with formation of a carboxylate derivative within minutes. Irinotecan is a prodrug, which needs to be converted to SN-38 to trap Top1cc. (b) Non-camptothecin indenoisoquinoline derivatives in clinical trials. (c) Anthracycline derivatives. (d) Demethylepipodophyllotoxin derivatives. (e) Mitoxantrone. (f) Dexrazoxane, which acts as a catalytic inhibitor of Top2.

It is key to understand that the cytotoxicity of topoisomerase inhibitors is due to the trapping of topoisomerase cleavage complexes as separate from the associated topoisomerase catalytic inhibition. Except in molecularly defined settings, it is the topoisomerase cleavage complexes (the DNA breaks and associated topoisomerase-DNA covalent complexes) that kill cancer cells. This sets apart topoisomerase inhibitors from classical enzyme inhibitors such as antifolates. Indeed, knocking out Top1 renders yeast

cells totally immune to camptothecin⁸ and reduction of enzyme levels renders cancer cells drug resistant.^{3, 5} Also, mutations of TOP1 and TOP2 that render cells insensitive to the trapping of topoisomerase cleavage complexes confer high resistance to Top1 or Top2 inhibitors. Conversely, amplification of TOP2A, which is on the same locus as HER2, contributes to the selectivity and activity of doxorubicin in breast cancers with amplification at this locus.

The outcome of topoisomerase trapping is determined first by the ability of the cell to repair the cleavage complexes, and then by two common pathways: the apoptotic and the cell cycle checkpoint pathways. Topoisomerase repair pathways are specific to Top1 or Top2 and are discussed in the paragraphs that follow. Defects in pro-apoptotic molecules and excess of anti-apoptotic molecules, which are commonly associated with cancers, confer global resistance to topoisomerase inhibitors, as well as to other anticancer agents. Systematic analyses of cell lines with specific DNA repair alterations revealed that cells deficient in DNA double-strand break repair may be selectively sensitive to topoisomerase inhibitors.⁹ Genomic analyses recently uncovered a previously unsuspected common pathway that determines cellular sensitivity to both Top1 and Top2 inhibitors (and also other DNA damaging agents, including cisplatin and carboplatin). This novel pathway is centered on the gene SLFN11 (Schlafen 11).^{10, 11} This finding could be viewed as a paradigm for discovering genomic determinants and signatures to predict response to topoisomerase inhibitors and staging of patients who are most likely to respond to topoisomerase inhibitors.

Molecular pathways specific for cancer cell killing and DNA repair by Top1 inhibitors

Top1cc-targeted drugs (topotecan, irinotecan, and indenoisoquinoline derivatives) kill cancer cells primarily by replication collisions. Indeed, Top1cc's by themselves are not cytotoxic as they remain reversible even in the presence of drugs that increase their persistence.¹² Top1cc's damage DNA by replication and transcription fork collisions. This explains why cytotoxicity is directly related to drug exposure and why arresting DNA replication protects cells from camptothecin.⁴ Collisions arise from the fact that the drugs, by slowing down the nicking-closing activity of Top1, uncouple the Top1 from the polymerases and helicases, leading polymerases to collide into Top1cc. Such collisions have two consequences. They generate double-strand breaks (replication and transcription run-off) and irreversible Top1-DNA adducts, known as cleavage complexes. The replication double-strand breaks are repaired by homologous recombination, which explains the hypersensitivity of BRCA-deficient cancer cells to Top1cc-targeted drugs.⁹ The Top1-covalent complexes can be removed by two pathways, the excision pathway involving tyrosyl-DNA-phosphodiesterase 1 (TDP1) and the endonuclease pathway involving 3'-flap endonucleases such as XPF-ERCC1.¹³ It is also possible that drug-trapped Top1cc directly generate DNA double-strand breaks when they are within 10 base pairs on opposite strands of the DNA duplex or when they occur next to a preexisting single-strand break on the opposite strand.¹⁴ Finally, it is not excluded that topological defects contribute to the cytotoxicity of Top1cc-targeted drugs (accumulation of supercoils¹⁵) and formation of alternative structures such as R-loops¹⁶ and reversed replication forks.¹⁷

Molecular pathways specific for cancer cell killing and DNA repair by Top2 inhibitors

Contrary to Top1 inhibitors, Top2 inhibitors can kill cancer cells independently of DNA replication fork collisions. The collision mechanism in the case of Top2cc-targeted drugs involves transcription and

proteolysis of both Top2 and RNA polymerase II, leading to DNA double-strand breaks by disruption of the Top2 dimer. Alternatively, the Top2 homodimer interface could be disjoined by mechanical tension. It is important to note that 90% of Top2cc trapped by etoposide are not concerted and therefore consist in single-strand breaks, which is different from doxorubicin, which produces a majority of Top2-mediated DNA double-strand breaks.^{4, 5} Finally, it is not excluded that topological defects resulting from Top2 sequestration by the drug-induced cleavage complexes could contribute to the cytotoxicity of Top2cc-targeted drugs. Such topological defects would include persistent DNA knots and catenanes, potentially leading to chromosome breaks during mitosis. Top2 covalent complexes are removed by TDP2¹³ in conjunction with the end-joining pathway [Ku, DNA-dependent protein kinase (DNA-PK), ligase IV, and XRCC4].^{9, 18}

The anticancer activity of intercalating Top2 inhibitors (anthracyclines and anthracenediones) extends beyond the trapping of Top2 cleavage complexes

Some Top2 inhibitors are also potent DNA intercalating agents; this is the case of the anthracyclines ([Figure 3c](#)) and mitoxantrone ([Figure 3e](#)). Consequently, anthracyclines and mitoxantrone affect Top2cc in two ways: at low drug concentrations, they trap Top2cc, whereas at higher concentrations (>5 μ M), high levels of intercalation outside of the Top2cc suppress the binding of Top2 to DNA and thereby inhibit the formation of Top2cc. As a result, the concentration-response curve of doxorubicin is “bell-shaped.”^{4, 19} Intercalation of anthracyclines also destabilizes chromatin structure with nucleosome eviction.²⁰ Another property of the anthracyclines is the generation of oxygen radicals due to their quinone structure.²¹

Topoisomerase I inhibitors

Topotecan

Camptothecin and its derivatives were found to have a high degree of *in vitro* antitumor activity in the 1960s, which was then confirmed in early clinical trials.^{22–24} Clinical development was limited by unpredictable toxicities, including severe myelosuppression and diarrhea, and an incomplete understanding of the mechanism of antitumor activity. Topotecan has since been shown to be a specific inhibitor of the nuclear enzyme Top1²⁵ Following this, topotecan has been developed for a number of clinical indications ([Table 2](#)).

Table 2 DNA topoisomerase targeting drugs

Drug class	Drugs	Year of FDA approval	Approved indication
Camptothecin	Irinotecan	1996	Colorectal cancer
	Topotecan	1996	Cervical cancer, ovarian cancer, small cell lung cancer
Anthracycline	Doxorubicin	1974	Breast cancer, acute lymphoblastic leukemia, acute myeloid leukemia, Wilms tumor, neuroblastoma, soft tissue and bone sarcomas, ovarian cancer, transitional cell bladder carcinoma, thyroid carcinoma, gastric carcinoma, Hodgkin lymphoma, non-Hodgkin lymphoma, bronchogenic carcinoma
	Pegylated liposomal doxorubicin	1999	AIDS-related Kaposi sarcoma, multiple myeloma, ovarian cancer
	Daunorubicin	1979	Acute lymphocytic leukemia, acute myeloid leukemia
	Idarubicin	1990	Acute myeloid leukemia
Anthraquinone	Mitoxantrone	1987	Acute nonlymphocytic leukemias, advanced hormone-refractory prostate cancer
Podophyllotoxin	Etoposide	1984	Small cell lung cancer, testicular cancer
	Teniposide	1992	Acute lymphoblastic leukemia

Clinical pharmacology

Topotecan (9-dimethylaminomethyl-10-hydroxycamptothecin) ([Figure 3a](#)) is a semisynthetic analog of camptothecin, an alkaloid derived from the oriental tree *Camptotheca acuminata*. The side chain at the 9-position of the A-ring ([Figure 3a](#)), provides water solubility. Lactone topotecan, the active form of the drug, is unstable as it is rapidly and reversibly converted to the open-ring carboxylate in a pH-dependent reaction¹² ([Figure 3a](#)). At neutral pH, the open-ring form predominates.²⁶

Topotecan pharmacokinetics fit a two-compartment model with a terminal half-life of 2–3 h. The plasma concentrations increase linearly with increasing doses, but do not show evidence of accumulation on the 30-min infusion X 5-day schedule.²⁷ Binding of topotecan to plasma proteins is about 35%.²⁷

Topotecan lactone is widely distributed, with a steady-state mean volume of distribution of 75 L/m². Topotecan is predominantly eliminated in the urine after its conversion to the carboxylate species. Although large interindividual variability exists, about 30% of the administered dose is excreted unchanged in urine.²⁷

Renal dysfunction decreases topotecan plasma clearance, such that mild dysfunction (creatinine clearance 40–60 mL/min) and moderate dysfunction (creatinine clearance 20–39 mL/min), lead to reductions to 67% and 34% of normal values, respectively.²⁸ Dose adjustments are therefore recommended in case of renal impairment. Liver impairment does not influence topotecan clearance and doses do not need to be adjusted for patients with hepatic dysfunction.²⁹

Although the typical route of administration is IV, an oral formulation is available. The oral formulation of topotecan was aimed at maintaining sufficiently prolonged drug exposures, which are known to produce

highest antitumor efficacy *in vitro* and *in vivo*,¹² without the need for infusion pumps.³⁰ The approved oral dose is 2.3 mg/m² once daily for 5 consecutive days repeated every 21 days. The oral bioavailability of topotecan is approximately 35%.²⁷ The low bioavailability may be caused by hydrolysis of topotecan lactone in the gut, yielding the poorly absorbed open-ring form. Oral topotecan has shown clinical activity comparable to the IV dose in small cell lung cancer (SCLC).³¹

Clinical use

Topotecan monotherapy is approved in the United States and Europe for patients with metastatic ovarian cancer patients after failure of initial or subsequent chemotherapy, and in patients with relapsed SCLC. It is also approved in combination with cisplatin for recurrent or resistant (stage IVB) cervical cancer.³²

Topotecan has shown clinical activity in other tumor types, including pediatric medulloblastoma,³³ non-SCLC,³⁴ myelodysplastic syndrome, chronic myelomonocytic leukemia,³⁵ Ewing's sarcoma,³⁶ rhabdomyosarcoma,³⁷ and multiple myeloma.³⁸ In addition to the combination with cisplatin approved in cervical cancer, combinations of Top1 inhibitors with other antitumor agents have been pursued. Synergistic and additive combinations have been observed in preclinical models, including with histone deacetylase inhibitors and PARP inhibitors, and a number of drug combination strategies have been investigated in patients.^{39, 40} Topotecan diffuses to the spinal fluid and can be considered for treating brain metastases.⁴¹

Schedule of administration

Various schedules of topotecan have been evaluated in phase I studies. The FDA (Food and Drug Administration)-recommended dose of topotecan in recurrent ovarian cancer and SCLC is 1.5 mg/m² by IV infusion over 30 min on days 1 to 5 of a 21-day cycle.

Despite the high incidence of grade 3 or 4 myelosuppression associated with this dose and schedule of topotecan, it remains the standard of care. To mitigate this toxicity, multiple dose and schedule variations have been evaluated in phase I and II trials.^{42, 43} In ovarian cancer, weekly topotecan (4 mg/m²/week administered on days 1, 8, and 15) has been reported to have efficacy comparable to the standard schedule, but with less toxicity.⁴³ The weekly schedule has not been directly compared with the 5-day schedule in SCLC.³¹ In cervical cancer, topotecan is approved in combination with cisplatin. In this setting, the recommended dose of topotecan is 0.75 mg/m² IV over 30 min on days 1, 2, and 3 with cisplatin 50 mg/m² IV on day 1 repeated every 21 days.⁴⁴

Toxicity

The dose-limiting toxicity of topotecan is bone marrow suppression, primarily neutropenia, but thrombocytopenia and anemia may also occur. At a dose of 1.5 mg/m²/day for 5 days, topotecan produces an 80% to 90% decrease in white blood cell count at nadir after the first cycle of therapy. The degree of neutropenia has been correlated with the area under the curve (AUC) of the intact lactone or total drug concentrations.⁴⁵ Topotecan should not be administered to patients with baseline neutrophils <1500/mm³ or platelets <100,000/mm³.

As discussed above, renal dysfunction decreases topotecan clearance and increases toxicity. Additional factors associated with greater hematologic toxicity include advance age and prior therapy, including platinum administration (especially carboplatin), radiation therapy.⁴⁶ In high-risk patients receiving topotecan for 5 consecutive days, the incidence of severe myelosuppression may be mitigated by

reduction of the topotecan dose to 1.0 or 1.25 mg/m²/day. Hematopoietic growth factors, transfusions, and schedule adjustments may also help manage myelosuppression. Alternative schedules of 3-day, weekly dosing or oral administration are associated with less myelosuppression.⁴⁷

Other toxicities of topotecan less common than bone marrow suppression include rash, fever, fatigue, nausea and vomiting, mucositis, and elevated serum transaminases.⁴⁸ Most nonhematological side effects are generally manageable. Diarrhea is uncommon with IV administration, but has been reported with oral topotecan. Rare, but life-threatening nonhematologic toxicities includes interstitial lung disease and neutropenic colitis.

Irinotecan

Irinotecan is a potent water-soluble camptothecin derivative.

Clinical pharmacology

Irinotecan (CPT-11) is the prodrug of the potent 7-ethyl-10-hydroxy analog of camptothecin (SN-38) ([Figure 3a](#)).⁴⁵ It contains a bispiperidine substituent at C-10, to confer water solubility for parenteral administration. Irinotecan undergoes extensive metabolic conversion by esterases to its active metabolite SN-38 ([Figure 3a](#)). Irinotecan prodrug is activated by carboxylesterases to SN-38, the biologically active compound. This explains why irinotecan is orders of magnitude less active than SN-38 in *in vitro* cytotoxicity assays.^{49, 50}

Irinotecan peak plasma concentration and AUC increase proportionally with the administered dose, suggestive of linear pharmacokinetics. The plasma AUC of SN-38 is only 2% to 8% of irinotecan, indicating that only a small fraction of irinotecan is converted to SN-38, its active form. Both irinotecan and SN-38 exist in the active lactone form and the inactive carboxylate form. Similar to topotecan, both forms are in a pH-dependent equilibrium.¹²

Irinotecan plasma concentrations decline in a multiexponential manner after IV infusion. The mean terminal elimination half-life of irinotecan is 6 to 12 h and that of SN-38 10 to 20 h, both much longer than that of topotecan. The relatively large percentage of the lactone form of both irinotecan and SN-38, which persists in plasma after drug administration, is attributable to the preferential binding of the lactone forms to albumin.²⁶ SN-38 is 95% bound to plasma proteins compared to approximately 50% for irinotecan.⁴⁵

Unlike topotecan, irinotecan elimination occurs predominantly by biliary excretion.⁴⁵ Renal excretion of SN-38 and irinotecan represents only a fraction of the administered dose. The 1A1 isoform of uridine 5'-diphospho-glucuronosyl transferase (UGT1A1; encoded by the *UGT1A1* gene) mediates glucuronidation of SN-38 to the inactive metabolite SN-38G (see section titled "Pharmacogenomics"). There is wide interpatient variability in UGT1A1 enzyme activity related to UGT1A1 gene polymorphisms.^{51, 52} In addition, polymorphisms of this enzyme are associated with conditions causing familial hyperbilirubinemia such as Crigler–Najjar syndromes and Gilbert's disease.⁵³ UGT1A1 polymorphisms can significantly alter the metabolism of irinotecan and thereby impact its toxicity in individual patients, and dose reduction is recommended for patients bearing particular variants of UGT1A1. Irinotecan is also inactivated by CYP3A4-mediated oxidative metabolism.⁵⁴ The impact of polymorphic variants is discussed in more detail in the subsequent sections.

Clinical use

Irinotecan is approved in the United States and Europe for first-line therapy in combination with 5-

fluorouracil and leucovorin for metastatic colorectal cancers. It is also approved for metastatic colorectal cancer in patients whose disease has recurred or progressed following fluorouracil-based therapy.^{49, 55}

Irinotecan monotherapy or combinations with other agents have shown clinical activity in diverse tumor types, including extensive-stage SCLC,⁵⁶ squamous cell carcinoma of the cervix,⁵⁷ recurrent glioblastoma,⁵⁸ gastric cancer, esophageal cancer,⁵⁹ non-SCLC,⁶⁰ pancreatic cancer,⁶¹ rhabdomyosarcoma,⁶² and ovarian cancer.⁶³

Schedule of administration

Monotherapy with irinotecan is usually administered at 125 mg/m² IV infusion over 90 min on days 1, 8, 15, and 22 followed by 2-week rest (6-week treatment cycles). An alternative dosing regimen is 350 mg/m² given as a 60-min IV infusion once every 3 weeks. In patients with 5-fluorouracil-refractory, metastatic colorectal cancer, the weekly and once every 3-week schedule demonstrated similar efficacy and quality of life. The regimen of once every 3 weeks was associated with a significantly lower incidence of severe diarrhea.⁶⁴

In combination with 5-fluorouracil and leucovorin, irinotecan is used at 125 mg/m² IV infusion over 90 min on days 1, 8, 15, and 22 (6-week treatment cycles). An alternative dosing regimen is 180 mg/m² over 90 min on days 1, 15, and 29 (6-week treatment cycles).

Toxicity

Diarrhea and myelosuppression are the most concerning toxicities of irinotecan. Late-onset diarrhea occurs more than 24 h after irinotecan. When prolonged, it can lead to life-threatening dehydration and electrolyte imbalance.⁶⁵ Grade 3 or 4 late-onset diarrhea occurs in about a third of patients receiving weekly dosing. The median time to the onset of late diarrhea was 5 days with 3-week dosing and 11 days with weekly dosing.^{49, 55} Free intestinal luminal SN-38, either from bile or SN-38G deconjugation is responsible for late-onset diarrhea. SN-38 induces direct mucosal damage with resultant water and electrolyte malabsorption and mucous hypersecretion.⁶⁶ Late diarrhea should be treated without delay with loperamide, and fluid and electrolytes as needed. Antibiotic therapy is warranted if the patient develops ileus, fever, or severe neutropenia. Predisposing factors for late-onset diarrhea include increasing age, poor performance status, and prior abdominopelvic radiotherapy.⁶⁷ A reduced starting dose should be considered in patients with risk factors. Treatment-related diarrhea should have fully resolved before initiating the next course of treatment. Dose reductions are recommended for grades 3 and 4 diarrhea. Various measures to reduce its severity have been studied, but none have an established role in practice.⁶⁸ In 2005, the FDA approved a diagnostic test for the UGT1A1 variant allele *28, which has been associated with reduced expression leading to impaired clearance and increased toxicity.⁶⁹ However, other variant alleles that impair expression of the enzyme are also known and impact clearance of drugs requiring glucuronidation (discussed in greater detail below).

Less commonly, irinotecan can also cause early-onset diarrhea during or within 24 h of the infusion. It is usually transient and only infrequently severe. It is attributed to a cholinergic syndrome mediated by anticholinesterase activity of irinotecan.⁷⁰ This cholinergic syndrome tends to occur at higher irinotecan dose levels at peak irinotecan plasma levels. Other cholinergic symptoms including abdominal cramping, rhinitis, tearing, and increased salivation may occur. The mean duration of symptoms is 30 min and usually responds rapidly to atropine.

Table 3 Investigational Top1 inhibitors in clinical development

	Drugs/drug class	Comments
Camptothecin analogs	Belotecan	Water-soluble camptothecin analog
	Cositecan	Lipophilic, semisynthetic camptothecin
	Lipotecan	Lactone ring modified to increase antitumor potency
	Simmitecan	Ester prodrug of the Top1 inhibitor chimmitecan
Targeted camptothecin delivery	<i>Liposomal/nanoparticle/PEGylated formulations</i>	
	MM-398 Onivyde	Nanoliposomal formulation of irinotecan
	CPX-1	Liposome-encapsulated formulation of Irinotecan and floxuridine
	Firtecان pegol	Pegylated formulation of SN-38
	CRLX101	Cyclodextrin-based polymer conjugate of camptothecin
	<i>Antibody-drug conjugates</i>	
	Sacituzumab govitecan	Antibody drug conjugate [antibody that binds to trophoblast cell-surface antigen (TROP-2) and SN-38]
	<i>Camptothecin conjugates</i>	
	HA-irinotecan	Irinotecan complexed with hyaluronic acid
	Etirinotecan pegol (NKTR-102)	Irinotecan bound to polyethylene glycol core by a biodegradable linker
Non-camptothecin Top1 inhibitors	Indenoisoquinoline derivatives	Chemical stability, stable DNA-TOP1 trapping, no affected by drug efflux pumps

Other common toxicities observed with irinotecan are nausea, vomiting, abdominal pain, constipation, anorexia, asthenia, fever, decrease in body weight, and alopecia. Rare, but life-threatening nonhematological toxicities include interstitial lung disease and hypersensitivity reactions. Risk factors for pulmonary toxicity include preexisting lung disease, use of pulmonary toxic medications, radiation, and use of colony-stimulating factors. Patients with risk factors should be monitored for respiratory symptoms while on irinotecan and for several weeks after treatment.⁷¹

Camptothecin analogs and non-camptothecin Top1 inhibitors

As discussed above, camptothecin derivatives have several well-established limitations. They are inactivated within minutes at physiological pH by lactone E ring opening (Figure 3a). This results in a loss of antitumor activity since the lactone form is essential for antitumor activity. Other limitations include fast reversal of the trapped DNA-Top1 cleavage complex following drug removal and drug resistance mediated by ATP-binding cassette (ABC) transporters.¹²

Several newer derivatives of camptothecin currently in clinical development aim to mitigate some of the shortcomings of camptothecins and their derivatives (Table 3). Camptothecin analogs, derived from modifications to the parent drug, have been an area of active research.⁷² Belotecan hydrochloride, a water-soluble camptothecin analog is in clinical development for SCLC and ovarian cancer.⁷³ Cositecan (Karenitecin) (Figure 3a) is an orally active, highly lipophilic, semisynthetic camptothecin, under development for ovarian cancer. Due to its lipophilicity, cositecan exhibits enhanced tissue penetration

and bioavailability compared to water-soluble camptothecins and are less sensitive to drug resistance.

Several approaches have been taken to stabilize the lactone ring of camptothecins without interfering with their antitumor activity.¹⁹ Indenoisoquinolines are non-camptothecin inhibitors of Top1, but with better chemical stability, producing stable DNA-Top1 cleavage complexes. They also have a preference for unique DNA cleavage sites, compared with their camptothecin counterparts and have demonstrated activity against camptothecin-resistant cell lines and produce DNA protein cross-links, which are resistant to reversal. They also show less or no resistance to cells overexpressing the ABC transporters, ATP-binding cassette subfamily G member 2 (ABCG2), and multidrug resistance (MDR)-1.⁷⁴ Other approaches to address E-ring instability include the conversion of the E ring to a five-membered ring, which completely stabilizes the drug.⁷⁵

Targeted delivery of Top1 inhibitors

Several approaches are being explored to improve the targeted delivery, and tumor localization of camptothecins. Broadly they involve (1) liposomal or nanoparticle formulation to increase plasma half-life and tumor localization, (2) antibody conjugation for targeted delivery, and (3) conjugation to agents to improve pharmacokinetic properties and exposure.

Liposomal/nanoparticle formulations

Liposomes are microscopic phospholipid spheres with an aqueous core.⁷⁶ Due to their biphasic character, they can act as carriers for both lipophilic and hydrophilic drugs; hydrophilic drugs tend to be entrapped in the core, whereas the hydrophobic ones are entrapped within the lipid bilayers. Stable liposomal encapsulation of camptothecin minimizes its conversion to the inactive carboxylate form by reducing the direct exposure of the drug to physiologic pH and prolonging the residence time of the lactone active drug. PEGylation increases the size and molecular weight of conjugated biomolecules.⁷⁷ PEGylated molecules show increased half-life, decreased plasma clearance, and different biodistribution compared with non-PEGylated counterparts. PEGylation of liposomes further improves the stability and circulation time. Polymeric nanoparticles are drug carriers that are designed to have defined size and surface properties to favor drug deposition and retention in tumors.⁷⁸ These formulations are thought to improve the “passive” targeting of tumors, through a process known as the enhanced permeation retention effect, wherein macromolecules penetrate and are trapped in tumor tissue due to the abnormally leaky vasculature of tumors.⁷⁹

MM-398 (nal-IRI) is a nanoliposomal encapsulation of irinotecan sucrosfate. In preclinical studies, MM-398 improved the pharmacokinetics and tumor biodistribution of both irinotecan and SN-38 when compared with the free form of the drug, with less accumulation in organs responsible for dose-limiting toxicities.⁸⁰ MM-398 has shown clinical activity in combination with 5-fluorouracil and leucovorin in metastatic pancreatic cancer patients who have previously received gemcitabine-based therapy.⁸¹

CRLX101 is a nanoparticle therapeutic comprised of camptothecin covalently conjugated to a linear, cyclodextrin-polyethylene glycol copolymer.⁷² CRLX101 self-assembles in solution into nanoparticles with solubility increases of over 1000-fold compared with the parent drug camptothecin. CRLX101 is currently being evaluated in patients with renal, ovarian, and rectal cancers.

Antibody drug conjugates

Antibody drug conjugates (ADCs) generated by conjugating camptothecins to monoclonal antibodies are being investigated to facilitate targeted drug delivery to tumors. Sacituzumab govitecan is a humanized

antibody against trophoblast cell-surface antigen (TROP-2) conjugated by a pH-sensitive linker to SN-38.⁸² TROP-2 is a type I transmembrane, calcium-transducing, protein expressed by many epithelial cancers, but with limited normal tissue expression. The antibody internalizes selectively into cancer cells following binding to TROP-2 encoded by the *TACSTD2* gene. Sacituzumab govitecan is being investigated in triple-negative breast cancer and SCLC.

Camptothecin conjugates

Etirinotecan pegol is a long-acting topoisomerase-I inhibitor that consists of irinotecan conjugated to a polyethylene glycol core by a biodegradable linker. The linker slowly hydrolyses *in vivo* to form SN38, the active moiety. The drug is designed to provide prolonged continuous exposure to SN38 while reducing the toxicities associated with excessively high irinotecan and SN38 plasma concentrations. Etirinotecan pegol at a dose of 145 mg/m² administered IV every 21 days is being studied in a phase III trial in women with advanced breast cancer.⁸³ Hyaluronic acid-irinotecan is an IV formulation of irinotecan conjugated with hyaluronic acid.⁸⁴ Hyaluronic acid selectively binds cancer cells via CD44, thereby enhancing membrane fluidity and potentially reducing side effects.

Top2 inhibitors

Top2 targeting drugs used in clinic can be divided into intercalating and non-intercalating poisons. The intercalators are chemically diverse, and include doxorubicin and other anthracyclines, and anthracenediones ([Figure 3c](#), e). Non-intercalating Top2 poisons include the epipodophyllotoxins, etoposide and teniposide ([Figure 3d](#); [Table 2](#)).

Anthracyclines

Anthracycline antibiotics, originally isolated from fermentation products of *Streptomyces peucetius*, were shown to have antineoplastic activity decades ago, before topoisomerase enzymes were identified. It was not until 1984 that the anthracyclines were found to inhibit Top2.⁸⁵ Doxorubicin, also known as adriamycin and daunorubicin, represent first-generation anthracyclines; epirubicin and idarubicin are second-generation compounds aimed at reducing cardiotoxicity and drug efflux by ABC transporters. Anthracyclines have wide-ranging activity against human cancers and are used extensively in the curative, adjuvant, and palliative settings, both as single agents and in combination regimens.

Doxorubicin is the most commonly used anthracycline ([Figure 3c](#)). The anthracycline ring is lipophilic, but the presence of abundant hydroxyl groups adjacent to the amino sugar produces an amphoteric molecule. Doxorubicin binds to cell membranes, including cardiolipin as well as plasma proteins. Daunomycin differs from doxorubicin by a single hydroxyl group on carbon-14 ([Figure 3c](#)), but has a distinct spectrum of antitumor activity. Idarubicin is a semisynthetic derivative of daunomycin (4-demethoxy daunorubicin) without the 4-methoxy group ([Figure 3c](#)). Epirubicin is an epimer of doxorubicin: the C4' hydroxyl group on the amino sugar is in the equatorial rather than in the axial position which increases its lipophilicity. None of these analogs have stronger antitumor efficacy than the original two anthracyclines, but they tend to limit the toxicity of doxorubicin and daunorubicin.⁸⁶

Clinical pharmacology

Doxorubicin displays linear pharmacokinetics and exhibits a triphasic disposition after IV injection. The initial half-life is very short, approximately 5 min, suggesting rapid tissue uptake. The second phase of approximately 10 h represents its metabolism and the slow final phase of 24 to 48 h, the gradual release

of doxorubicin from multiple sites of binding including the DNA.⁸⁷ Doxorubicin and its major metabolite, doxorubicinol, are substantially bound to plasma proteins, about 50% to 90%.⁸⁸ Doxorubicin does not cross the blood-brain barrier.

Plasma clearance of doxorubicin is predominantly by metabolism and biliary excretion. The drug is extensively metabolized in the liver by aldo-keto reductase, to yield the dihydrodiol derivative doxorubicinol, which retains antitumor activity, and by the NADPH-dependent cytochrome P450 reductase to cleave the glycosidic bond and release aglycone metabolites.⁸⁹ The clearance of doxorubicin and doxorubicinol are reduced in patients with impaired hepatic function.⁹⁰ Renal clearance is quantitatively unimportant, and dose modification is not required in renal failure.

Liposome encapsulation of doxorubicin has been successfully used as a strategy to reduce toxicity without losing efficacy.⁹¹ Pegylated liposomal doxorubicin is a liposomal formulation of doxorubicin, which compared with unencapsulated doxorubicin has a long half-life and delayed uptake by the reticuloendothelial system due to the attachment of polyethylene glycol polymers to a lipid anchor and stable retention of the drug as a result of liposomal entrapment via an ammonium sulfate chemical gradient.⁹² The pharmacokinetic profile of this drug is characterized by an extended circulation time and a reduced volume of distribution, which promotes tumor uptake.

Clinical use

Doxorubicin is utilized in multiple human cancer types. It is FDA approved for adjuvant chemotherapy following resection of primary breast cancer for patients with axillary lymph node invasion. Doxorubicin is also used for the treatment of acute lymphoblastic and myeloblastic leukemias, and in combination regimens for non-Hodgkin's and Hodgkin's lymphoma. Doxorubicin has activity in many solid tumors including breast, ovarian, bladder, thyroid, gastric and lung cancers, soft tissue and bone sarcomas. Pegylated liposomal doxorubicin is used in treatment of AIDS-related Kaposi sarcoma after failure of or intolerance to prior systemic therapy and in multiple myeloma as a component of combination therapy.⁹³⁹⁴ It is also used in the treatment of progressive or recurrent ovarian cancer after platinum-based treatment.⁹⁵

Epirubicin has a spectrum of activity very similar to doxorubicin, but with lower toxicity.⁹⁶ Epirubicin is used as a component of adjuvant therapy for primary breast cancer and for esophageal and gastric cancers, and soft tissue and uterine sarcomas.⁹⁷

Daunomycin ([Figure 3c](#)) is used mostly as part of an induction regimen in acute lymphocytic leukemia and acute myeloid leukemia. It is also active in pediatric solid tumors, but has little activity against adult solid tumors. Idarubicin is used predominantly in the treatment of acute myeloid and lymphoid leukemia.⁹⁸

Schedule of administration

Single-agent doxorubicin is administered IV at 60 to 75 mg/m² every 21 days. In combination therapy, it is administered at 40 to 75 mg/m² every 21 to 28 days. Daunorubicin is given IV at 30 to 60 mg/m² daily for 3 days. Idarubicin is given IV at 12 mg/m² daily for 3 days. Epirubicin is given IV at 100 to 120 mg/m² by bolus injection every 3 weeks. Pegylated liposomal doxorubicin is administered IV at 20 mg/m² every 21 days for AIDS-related Kaposi sarcoma and 50 mg/m² once every 28 days in ovarian cancer.

Toxicity

All anthracyclines produce cardiac damage that can result in serious and even life-threatening

complications.^{99, 100} It is the major dose-limiting toxicity of prolonged treatment with doxorubicin. Cardiac toxicity is more common with doxorubicin and daunorubicin than with epirubicin or idarubicin.⁹⁶ Cardiac toxicity manifests acutely with electrocardiographic abnormalities, including ST-T elevations and arrhythmias and can occur at any time from initiation of treatment to several weeks afterward. Cardiomyopathy, a manifestation of chronic cardiotoxicity, may also occur early, within 1 year of termination of the treatment, or be delayed beyond 1 year after treatment.

Doxorubicin-associated cardiomyopathy and congestive heart failure are dose dependent. Risk increases proportionally to the total accumulated dose in a nonlinear fashion (1–5% up to 550 mg/m², 30% at 600 mg/m², and 50% at 1 g/m² or higher) with marked interindividual variation.¹⁰¹ The frequency of these complications is unacceptably high when the cumulative dose of the drug exceeds 550 mg/m² of body-surface area.¹⁰² The mode of administration plays an important role in cumulative cardiotoxicity and bolus administration appears to be involved.¹⁰³ Continuous infusion regimens have been studied in an effort to reduce cardiotoxicity. Infusion over 48 or 96 h has been studied, demonstrating a shift in the side effect profile, with less nausea and vomiting and cardiotoxicity to enhanced mucositis,¹⁰⁴ but allowing dosing above conventional limits. Despite evident advantages, the difficulty of administering a continuous infusion schedule meant that this approach has not had significant uptake in the community.

The cardiotoxicity of doxorubicin had been attributed to redox cycling and reactive oxygen species (ROS) generation; however, ROS scavengers have failed to prevent this toxicity.^{102, 105} More recent data implicate Top2 β ¹⁰⁶ Top2 α is overexpressed in tumors and represents the molecular basis of doxorubicin antitumor activity, whereas Top2 β is expressed by cardiomyocytes and nonreplicating cells.^{13, 107} Multiple lines of evidence indicate the role of Top2 β in contributing to the development of doxorubicin-induced cardiomyopathy. Top2 β -doxorubicin-DNA ternary cleavage complex can induce DNA double-strand breaks leading to cell death in cardiomyocytes. TOP2 β -deleted mouse embryonic fibroblasts have been shown to be resistant to doxorubicin-induced cell death.¹⁰⁸ Recent studies also indicate that the mitochondrial topoisomerase, Top1mt, counteracts the cytotoxicity of doxorubicin by enabling mitochondrial DNA replication and maintaining functional oxidative phosphorylation.¹⁰⁷

Several factors increase the risk for anthracycline cardiotoxicity. The strongest predictor is cumulative drug dose.¹⁰⁹ Age at the time of drug exposure, concomitant administration of other cardiotoxic drugs, radiation to the chest, and preexisting cardiovascular disease are other risk factors. A number of approaches have been taken to decrease the risk of cardiotoxicity while maintaining efficacy. These include alternate schedules of drug administration, modifications of the anthracycline molecule, and adjunctive treatment with beta-adrenergic blockers or dexrazoxane.¹⁰⁸ Recent evidence implicates Top1mt mutations, which exist as normal SNPs (single nucleotide polymorphisms), as potential determinants of the cardiotoxicity of doxorubicin.¹⁰⁷

Dexrazoxane ([Figure 3f](#)) is an ethylenediaminetetraacetic acid (EDTA)-like chelator that prevents anthracycline damage by binding to iron released from intracellular storage secondary to lipid peroxidation.¹¹⁰ Breast cancer patients treated with dexrazoxane experienced fewer cardiac events compared with those treated with anthracycline only.¹¹¹ Dexrazoxane is approved in the United States and Europe for patients with advanced or metastatic breast cancer who have already received 300 mg/m² of doxorubicin or 540 mg/m² of epirubicin. However, concerns exist regarding the possibility of lower response to chemotherapy and more myelosuppression with dexrazoxane use.¹¹² Dexrazoxane is therefore not recommended for routine use in breast cancer with doxorubicin-based chemotherapy. Continued cardiac monitoring is recommended in patients receiving doxorubicin.¹¹³

Other toxicities of anthracyclines include myelosuppression, mucositis, and alopecia, nausea, vomiting, diarrhea, and increased skin pigmentation. Myelosuppression is the acute dose-limiting toxicity. After bolus dose, the white blood cell count begins to fall in 7 days. The count reaches a nadir at 10 to 14 days and recovers 1 to 2 weeks later. Thrombocytopenia and anemia are less severe. Erythema at the injection site (flare reaction) is benign, in contrast to extravasation, which can lead to serious local complications such as severe necrosis of surrounding tissues. Inflammation at sites of previous radiation (radiation recall) can lead to unanticipated complications, including pericarditis, pleural effusion, and skin rash. The incidence of nausea and vomiting, and alopecia, are less with epirubicin than with doxorubicin.⁹⁶

The toxicity profile of pegylated liposomal doxorubicin is characterized by mucosal and cutaneous toxicities, mild myelosuppression, and decreased cardiotoxicity compared with doxorubicin and minimal alopecia. Palmar-plantar erythrodysesthesia is the most common grade 3 or 4 toxicity observed, frequently at the second or third cycle, and occurs at a higher frequency than with patients receiving conventional doxorubicin.¹¹⁴ The mucocutaneous toxicities are dose limiting. The pathophysiology of palmar-plantar erythrodysesthesia is not well understood. It has been hypothesized that following the local trauma, pegylated liposomal doxorubicin may extravasate via the eccrine glands from the deeper microcapillaries in the hands and feet where its accumulation is facilitated by the hydrophilic coating of the liposomes.¹¹⁵ Reduced cardiotoxicity of pegylated liposomal doxorubicin allows a larger cumulative dose than that of doxorubicin. Acute hypersensitivity reaction may occur usually with the first infusion.¹¹⁶

Newer anthracyclines

Although anthracyclines have wide spectrum of activity, structural, pharmacokinetic, and pharmacodynamic characteristics somewhat limit their efficacy and safety. To circumvent these limitations and to further exploit its activity, newer anthracyclines and anthracycline conjugates have been developed.

Amrubicin is a completely synthetic anthracycline with a structure similar to doxorubicin and potent Top2 inhibitory activity that is available only in Japan, where it is approved for use in non-SCLC and SCLC.¹¹⁷ Amrubicin itself has a weak antitumor effect and needs to be converted to its active form, amrubicinol, to be effective.¹¹⁸ In preclinical studies, amrubicin caused almost no cardiotoxicity. The lower cardiotoxicity of amrubicin has been attributed to lower levels of accumulation and metabolic advantages over doxorubicin.¹¹⁹ In second-line treatment of SCLC, although it was associated with better response rates, amrubicin did not improve survival compared with topotecan.¹²⁰ In first-line SCLC, amrubicin plus cisplatin was inferior to irinotecan plus amrubicin.¹²¹

Anthracenediones

Mitoxantrone ([Figure 3e](#)) is a potent inhibitor of Top2 derived in part from an early hypothesis that the cardiotoxicity of the anthracyclines might depend on the presence of an amino sugar.¹²² Since the aglycones of the cardiac glycosides have less cardiotoxic potency than the parent compounds, it was thought that a polycyclic aromatic molecule that intercalates with DNA, but which does not have an amino sugar might be an effective antitumor agent without cardiotoxicity. The antitumor spectrum of mitoxantrone is limited compared to that of doxorubicin. Mitoxantrone is used in the initial treatment of acute nonlymphocytic leukemias and is active in advanced castrate-resistant prostate cancer and breast cancer. The dose-limiting toxicity of mitoxantrone is leucopenia in patients with solid tumors, whereas stomatitis may be dose limiting in patients with leukemia. Other adverse effects are usually of mild or moderate severity. Cardiac effects, particularly congestive heart failure, may be of concern, especially in

patients previously treated with anthracyclines, mediastinal irradiation or patients with cardiovascular disease.

Pixantrone ([Figure 3e](#)) is an aza-anthracenedione with structural similarity to mitoxantrone. In preclinical models, compared with doxorubicin, pixantrone showed enhanced activity and decreased cardiotoxicity with decreased free radical formation.¹²³ Single-agent salvage therapy with pixantrone has received conditional marketing authorization in the European Union for the treatment of patients with multiply relapsed or refractory aggressive non-Hodgkin's B-cell lymphoma.¹²⁴ The recommended dose of pixantrone is 50 mg/m² administered on days 1, 8, and 15 of each 28-day cycle for up to six cycles. The most common side effects with pixantrone are bone marrow suppression (particularly of the neutrophil lineage) nausea, vomiting, and asthenia. It is not approved for use in the United States.

Epipodophyllotoxins

Podophyllotoxin is a natural product isolated from *Podophyllum peltatum* and *Podophyllum emodi*.¹²⁵ Although the anticancer activity of podophyllotoxin and selected derivatives were known in the 1940s, the prohibitive toxicity of podophyllin precluded further development. Demethylepipodophyllotoxin Top2 inhibitors are podophyllotoxin derivatives, which resulted from efforts to identify agents that retained antineoplastic activity, but had less toxicity.

Etoposide

Etoposide (VP-16) ([Figure 3d](#)) was the first agent to be recognized as a Top2 inhibiting anticancer drug.¹²⁶ As with several other topoisomerase inhibitors, the appreciation of its clinical activity and approval preceded the understanding of its mechanism of action and pharmacology.

Clinical pharmacology

Etoposide is not water soluble, which presents difficulties for rapid administration and drug hypersensitivity reactions related to the vehicles utilized as solubilisers. Etoposide phosphate, a water-soluble ester of etoposide at concentrations up to 20 mg/mL, is a result of efforts to overcome this issue and has been approved for IV use by the FDA.¹²⁷ The water solubility of etoposide phosphate also alleviates the risk of drug precipitation during IV administration. *In vivo* etoposide phosphate is rapidly converted to the active moiety, etoposide, by dephosphorylation. The pharmacokinetic profile, toxicity, and clinical activity of etoposide phosphate are similar to that of etoposide.

Etoposide exhibits a biphasic pharmacokinetics with a distribution half-life of about 1.5 h and terminal elimination half-life ranging from 4 to 11 h. There is a linear relationship between the AUC and peak plasma concentrations achieved following IV administration.¹²⁸ cerebrospinal fluid (CSF) concentrations of etoposide, albeit lower than in extracerebral tumors and in plasma, may exceed minimum cytotoxic levels and may be useful in central nervous system (CNS)-directed therapy.¹²⁹

Etoposide is highly bound to plasma proteins with an average free plasma fraction of 6%. Since free drug is biologically active, conditions that decrease protein binding increase the pharmacological effect of the drug.¹³⁰ Etoposide clearance is modestly decreased in patients with renal failure, and dose modification is recommended in patients with moderate renal impairment. Biliary excretion represents a minor route of elimination and clearance is not affected in patients with hepatic obstruction.¹³¹

Although the typical route of administration is IV, an oral formulation of etoposide is available.¹³² Bioavailability of oral etoposide is widely variable both within and between patients as compared to the

IV route and ranges from 40% to 75%. Oral bioavailability also varies with drug dose and is better at lower doses.¹³³ Despite its limitations, oral etoposide allows long-term drug administration and is approved by the FDA.

Clinical use

Etoposide is approved for use in combination with other agents in refractory testicular tumors and in first-line treatment of SCLC. Etoposide has also shown clinical activity in other tumor types, including non-Hodgkin's lymphomas, leukemias, Kaposi sarcoma, neuroblastoma, and soft-tissue sarcomas. It is also an important component of preparatory regimens given prior to bone marrow and peripheral stem-cell rescue.

Schedule of administration

Etoposide is administered in combination with other agents at a dose of 80–120 mg/m² IV on days 1–3 every 21 to 28 days in SCLC. The typical doses for testicular cancer are 50 to 100 mg/m²/day for days 1 to 5 or 100 mg/m²/day on days 1, 3, and 5 repeated every 21 to 28 days.

The duration of exposure to etoposide is an important determinant of activity, with many studies indicating that prolonged administration maximizes activity.^{134, 135} In SCLC, the 3–5 day schedule has greater efficacy than single-day administration.^{135, 136} To determine whether administration schedules longer than a standard 3- to 5-day treatment might further improve the therapeutic index of etoposide, prolonged oral dose regimens were developed. However, in phase III trials, patients with SCLC who were treated with 21 days of oral etoposide did not have any improvement in response rates or survival over those receiving the drug for 3–5 days.¹³⁷

Toxicity

Myelosuppression is the major dose-limiting toxicity of etoposide, IV or orally. Granulocyte and platelet nadirs occur 7 to 14 days and 9 to 16 days, respectively, after drug administration. Bone marrow recovery is usually complete by day 20. Other possible toxicities include allergic or other infusion reactions, which manifests as fever, bronchospasm, and hypotension. Toxicities associated with oral etoposide include nausea, vomiting, and mucositis.

Teniposide

Teniposide (VM-16) ([Figure 3d](#)) an etoposide analog is a semisynthetic derivative of podophyllotoxin. Teniposide differs from etoposide by its sugar ring. Although it was isolated and evaluated in patients before etoposide, early concerns about hypersensitivity reactions and use at low doses led to slower development of this drug.¹³² *In vitro*, teniposide is more potent than etoposide in killing cancer cells possibly related to its better cellular uptake.^{138–140} A greater fraction of teniposide is protein bound relative to etoposide,¹⁴¹ and renal function is less relevant to teniposide clearance.¹⁴² Myelosuppression is the dose-limiting toxicity for teniposide. It can also produce hypersensitivity reactions. Teniposide is approved for the treatment of refractory childhood acute lymphocytic leukemia. Few studies have directly the activity of these two agents.

Therapy-related secondary acute leukemia (t-AML)

One of the major complications of Top2 inhibitors, especially etoposide and mitoxanthrone, is acute secondary leukemia, occurring in approximately 5% of patients. Therapy-related acute myelocytic

leukemias (t-AML) are characterized by their relatively rapid onset (they can occur only a few months after therapy) and the presence of recurrent balanced translocations involving the mixed lineage leukemia (MLL) locus on 11q23 and over 50 partner genes.¹⁴³ The proposed molecular mechanism is by the disjoining of two drug-trapped Top2 cleavage complexes on different chromosomes in relationship with transcription collisions and illegitimate religation.¹⁴⁴ Top2 β has been implicated in the generation of these disjoined cleavage complexes.^{144, 145}

Pharmacogenomics

Genetic variants in drug metabolizing enzymes, transporters, and other proteins have been shown to influence the pharmacology of topoisomerase inhibitors including irinotecan and doxorubicin. An understanding of these genetic variants will allow for individualized dosing of each drug, with the aim of increasing therapeutic efficacy and minimizing toxicity.

Irinotecan

UDP-glucuronosyl transferase 1A

Several enzymes and drug transporters are involved in the elimination of irinotecan. Variations in irinotecan dosing are affected by genetic polymorphisms in the *UGT1A*, *CYP3A*, and *ABC* gene families. Several allelic variants of these genes alter functional activity, thereby contributing to interindividual differences in irinotecan metabolism and predisposing patients to variable toxicity.

SNPs have been described in the promoter and coding regions of the *UGT1A1* gene, which significantly impact irinotecan metabolism and toxicity.^{146, 147} The variants are described as alleles denoted by the * symbol followed by a number. While there are over 113 gene variants, only several variants have been described to influence irinotecan pharmacodynamics (*6, *27, *28, *36, *37, *60, *93). This chapter focuses on *28 and *6 variants, which are clinically relevant with supporting studies. Clearance of SN-38 via this pathway contributes to interindividual variability in irinotecan-induced toxicity that is associated with a variant allele in the proximal promoter region of *UGT1A1* (*UGT1A1**28). The *UGT1A1**28 (rs8175347, also referred to as the *UGT1A1* 7/7 genotype) allele has a seventh dinucleotide repeat in the TATA box of the promoter region, while the wildtype *UGT1A1**1 allele has six repeats, resulting in reduced rates of transcription, protein expression, and enzyme activity. The frequency of *UGT1A1**28 in the Caucasian and African American populations is 0.26–0.31 and 0.42–0.56, respectively.^{148, 149} Patients with the *UGT1A1**28 homozygous variant have significantly higher systemic exposure to SN-38 and lower plasma SN-38G/SN-38 ratio than *1/*1 patients and commonly develop dose limiting severe diarrhea or neutropenia.^{52, 150–153} The *UGT1A1**6 polymorphism is characterized by a single-nucleotide substitution in exon 1 of *UGT1A1*, resulting in decreased expression and increased toxicity similar to *UGT1A1**28. The *UGT1A1**6 (rs4148323) variant occurs at a higher frequency in Asians (frequency of 0.13–0.25)¹⁵⁴ and was associated with irinotecan-related diarrhea and neutropenia in Asians.^{150, 155, 156}

The concept of *UGT1A1* genotype-directed dosing of irinotecan has been evaluated in patients receiving single-agent irinotecan in an every-2-week regimen¹⁵⁷ or an every-3-week regimen¹⁵⁸ or in combination therapy involving irinotecan with fluorouracil,^{159, 160} capecitabine,¹⁶¹ or capecitabine and oxaliplatin.¹⁶² Despite differences in patient population and regimens, the general consensus with these studies is that patients with the *28/*28 genotype are at the highest risk of irinotecan-related toxicity and require a dose reduction of up to 40%. Since 2005, the US Food and Drug Administration has recommended a reduction of the initial irinotecan dose (by at least one level) for individuals who are *UGT1A1**28 homozygous

variant because they are at increased risk for neutropenia.

Numerous meta-analyses have evaluated the association of **28/*28* genotype to the risk of toxicity as a function of irinotecan dose. Hoskins et al.⁵¹ ($n = 821$) showed that severe hematotoxicity was significantly higher in **28/*28* patients for both high/intermediate doses. Hu et al.¹⁶³ ($n = 1998$) demonstrated the risk of grade 3–4 neutropenia is significantly increased in **28/*28* patients, and the risk is higher for high doses compared to intermediate or low doses. A recent meta-analysis of 16 colorectal cancer studies ($n = 2328$), revealed that regardless of irinotecan dose neutropenia grade 3–4 occurred more frequently in patients with **28/*28* as compared to **1/*1* (OR = 4.79, 95% CI = 3.28 to 7.01, $p < 0.00001$) or **1/*28* (OR = 3.44, 95% CI = 2.45 to 4.82, $p < 0.00001$).¹⁶⁴

Studies of irinotecan pharmacogenetics have mainly focused on the association of *UGT1A1*28* allele to irinotecan-related toxicity. The clinical utility of *UGT1A1*28* genotyping for preemptive dose reductions depends on whether *UGT1A1*28* also affects treatment efficacy and studies to date have been contradictory. A recent meta-analysis found no difference between the *UGT1A1*28* genotypes (homozygous, heterozygous, or wild type) and patient survival related to irinotecan therapy and included data for overall ($n = 1524$ patients) and progression-free survival ($n = 1494$ patients).¹⁶⁵ Therefore, while genotyping for **28* was shown to be cost-effective, clinical utility was classified as unclear.^{166, 167} Clinical implementation remains to be determined since studies to date on whether **28* affects treatment efficacy have been contradictory and since most episodes of severe toxicity (neutropenia or diarrhea) are managed by dose reduction in subsequent cycles.

In addition to *UGT1A1*, variants in the *UGT1A7* and *UGT1A9* genes are also involved in interpatient irinotecan-related toxicity differences. *UGT1A7* is primarily involved in extrahepatic metabolism (located in the intestine) and is responsible for detoxifying SN-38, whereas *UGT1A9* is necessary for conjugation of SN-38 to SN-38G in the liver.¹⁶⁸ *UGT1A7*2*, *UGT1A7*3*, or *UGT1A7*4*, polymorphisms may result in altered irinotecan metabolism and related toxicity.^{169–172} Patients homozygous for *UGT1A9*1* have been reported to have more severe diarrhea than *UGT1A9*9* or *UGT1A9*22* carriers.^{172, 173}

Together, these studies suggest that clinical outcome is likely the result of complex combined signature of the haplotypes involving key genomic variations in UGT metabolic detoxification (*UGT1A1*, *UGT1A7*, and *UGT1A9*) pathways.^{168, 171}

CYP3A and drug transporters

The *CYP3A4* and *CYP3A5* genes are crucial for oxidative metabolism of irinotecan to inactive metabolites APC and NPC. *In vitro* studies have shown variants (*CYP3A4*16* or *CYP3A4*18* or *CYP3A5*3*) with decreased activity, resulting in reduced rates of oxidative metabolism and hence less APC and NPC metabolite production.^{173, 174} However, correlations between these genetic variants with irinotecan treatment outcome remain to be elucidated.

Elimination of irinotecan is also dependent on the ABC drug transporters, present on the bile canalicular membrane that facilitates the secretion of irinotecan and its metabolites.¹⁷⁵ Specific polymorphisms of *ABCB1* and *ABCC2* can influence irinotecan drug disposition and tumor response.¹⁷⁶ While the *ABCC2*2* haplotype is associated with lower rates of irinotecan-induced diarrhea,¹⁷⁷ patients with *ABCC2* (rs3740066) and *ABCG2* (rs2231137) variants experience greater rates of grade 3 diarrhea.^{173, 178, 179} A pharmacogenomic profile of irinotecan-induced gastrointestinal toxicity using the novel drug-metabolizing enzyme and transporter (DMET) microarray genotyping platform identified three additional

SNPs mapping to the *ABCG1*, *ABCC5*, and *OATP1B1/SLCO1B1* transporter genes in colorectal cancer patients.¹⁸⁰ Moreover, a recent study demonstrated that *OATP1B1* and tumor *OATP1B3* modulated exposure, toxicity, and survival after irinotecan-based chemotherapy.¹⁸¹

Doxorubicin

Genetic polymorphisms exist in genes that mediate the metabolism, transport, and pharmacological actions of doxorubicin, but the clinical significance of these variants and their impact on doxorubicin efficacy and toxicity has only been evaluated in recent years. Doxorubicin is characterized by substantial interindividual variations in pharmacokinetic parameters¹⁸² and cumulative dose is the most significant risk factor for doxorubicin-induced cardiotoxicity.

The major metabolite of doxorubicin is 13-C alcohol, doxorubicinol; metabolized by enzymes carbonyl reductase 1 (CBR1), CBR3 and aldo-keto reductase 1C3 (AKR1C3). Functional SNPs have been characterized in CBR1, CBR3, and AKR1C3. Two SNPs (rs1143663 and rs9024) in *CBR1* that have a functional impact on CBR1 activity¹⁸³ or expression have been described.¹⁸⁴ To date, there are limited studies investigating the influence of genetic polymorphisms in the *CBR1* gene and no association was seen in a population of patients with breast cancer.¹⁸⁵ However, patients who were heterozygous for rs9024 and another *CBR1* variant with which it is in linkage disequilibrium (LD) had a lower clearance of doxorubicin.¹⁸⁶

Two common SNPs in *CBR3* G730A (rs1056892) and G11A (rs8133052) in LD were shown to have reduced catalytic efficiency compared with wild type *in vitro*.¹⁸⁷ It has been suggested that the wild-type *CBR3* G730A allele, which exhibits higher activity and increased expression, is associated with the risk of anthracycline-related congestive heart failure among childhood cancer survivors.¹⁸⁸ Higher CBR3 expression was found in tumor tissues from Asian patients with breast cancer, with the variant being associated with higher doxorubicinol AUC.¹⁸⁵ In the same cohort, the G11A minor allele was associated with greater hematotoxicity and efficacy in addition to an influence on doxorubicin pharmacokinetics (PK) and CBR expression.¹⁸⁵ Voon et al.¹⁸⁹ also showed that the G11A minor allele correlated with lower doxorubicinol AUC and longer overall survival. However, other studies in breast cancer patients showed no effect of these variants on doxorubicin PK¹⁸⁶ or survival.¹⁹⁰

An *in vitro* study has demonstrated that two nonsynonymous SNPs in exon 5 of the aldo-keto reductase 1C3 (AKR1C3) gene 508 C>T (rs35575889) and 538 C>T (rs34186955) encode enzymes that significantly reduced doxorubicin metabolism compared with wild type.¹⁹¹ In a clinical study of Asian patients with breast cancer, the above 2 SNPs were not identified; however, two intronic variants IVS4-212 C>G (rs1937840) and IVS4+218 G>A (rs1937841) were detected. The AKR1C3 IVS4-212 GG allele was associated with greater hematological toxicity and longer overall and progression-free survival after doxorubicin-based therapy.¹⁸⁹

Several transporters have been shown to be involved in transporting doxorubicin including ABCB1, ABCC1, ABCC2, ABCG2, RALBP1, and SLC22A16. Doxorubicin is a substrate for ABCB1 and doxorubicin efflux mediated by ABCB1 can lead to decreased efficacy in laboratory and animal models. Inhibition of ABCB1 may lead to increased doxorubicin-induced toxicity. Three high-frequency *ABCB1* polymorphisms, 1236C>T (rs1128503), 2677G>A/T (rs2032582), and 3435C>T (rs1045642) have been proposed to alter pharmacokinetics of substrate drugs, but there has been some controversy in the literature, with both positive and negative studies. This is likely due to different patient populations, other covariants, and individual substrate drug. One small study in Asian patients noted impaired doxorubicin

pharmacokinetics, resulting in significantly increased exposure levels and reduced clearance; however, the study involved only a small number of patients.¹⁹² Moreover, while the 2677A allele was associated with a shorter overall and progression-free survival in breast cancer patients treated with adjuvant doxorubicin and cyclophosphamide, the C1236T, G2677T, and C3435T SNPs had no effect on survival.¹⁹³ In Asian patients with breast cancer on a doxorubicin-based regimen, *ABCB1* G2677T/A was associated with drug clearance and platelet toxicity, and *ABCB1* IVS26+59 T>G was associated with overall survival.¹⁸⁹ The 3435T allele was significantly correlated with a prolonged progression-free survival in multiple myeloma patients treated with doxorubicin and bortezomib, consistent with the hypothesized loss of function or expression.¹⁹⁴ Other studies have found no impact of *ABCB1* genotypes in response to doxorubicin.¹⁹⁵ An additional *ABCB1* G1199T/A (rs2229109) variant found in European populations, not in LD with the other three, is less well studied clinically, but has been shown to have a functional impact on doxorubicin efflux and toxicity.¹⁹⁶ Given the inconsistencies in studies across populations, the functional significance of *ABCB1* SNPs on the disposition of doxorubicin remains controversial.

ABCG2-mediated resistance to doxorubicin is dependent on an acquired mutation (R482T/G).¹⁹⁷ In a clinical study of breast cancer patients, no significant influences on doxorubicin pharmacokinetic parameters were observed in relation to the *ABCG2* 421C>A polymorphism,¹⁹² which has been previously demonstrated to have less ATPase activity than wildtype.¹⁹⁸ Expression of other ABC family members, including *ABCB5*, *ABCB8*, *ABCC5*, and *RALBP1*, also confers resistance to doxorubicin; however, the clinical implications remain unknown.

The organic cation exporter *SLC22A16* transports doxorubicin into the cell. Homozygotes of the *SLC22A16* A146G (rs714368) may have a higher AUC for doxorubicin¹⁹⁹ and carriers of the same minor allele, and other *SLC22A16* SNPs (T312C and T755C variants) in LD, are less likely to have a dose delay during adjuvant doxorubicin and cyclophosphamide therapy for breast cancer.¹⁹³ A higher incidence of dose delay, indicative of increased toxicity, was seen in *SLC22A16* T1226C (rs12210538) carriers.¹⁹³

In a study of pharmacogenomic predictors of anthracycline-induced cardiotoxicity involving SNPs of 82 genes from 1697 patients, 3.2% of whom developed the toxicity acutely or chronically, five significant associations were identified and the polymorphisms were located in genes of the NAD(P)H oxidase complex (*CYBA* rs4673, *NCF4* rs1883112, and *RAC2* rs13058338), and doxorubicin transporters (*ABCC1* rs45511401, *ABCC2* rs8187694 and rs8187710).²⁰⁰ Rossi et al.²⁰¹ also showed *CYBA* rs4673 and *NCF4* rs1883112 being associated with toxicity in lymphoma patients treated with doxorubicin-containing chemotherapy. Polymorphisms in genes that reduce ROS may result in increased efficacy or toxicity following doxorubicin treatment and may include variants of superoxide dismutase II (*SOD2*), glutathione S-transferases (*GSTs*), or NAD(P)H:quinone oxidoreductase 1 (*NQO1*). Furthermore, pharmacogenetic studies have evaluated gene copy number for *ERBB2* and *TOP2A* as predictors of response to doxorubicin with contradictory results.^{202–204}

Daunorubicin, epirubicin, etoposide

Limited data are available on pharmacogenomics of daunorubicin, epirubicin, or etoposide. A pharmacogenomics study of daunorubicin in children using the DMET platform found associations between *FMO3* and *GSTP1* haplotypes with daunorubicin PK that could potentially affect efficacy and toxicity.²⁰⁵ The major inactivation pathway for epirubicin and epirubicinol is glucuronidation catalyzed by uridine diphosphate-glucuronosyltransferase 2B7 (*UGT2B7*). Breast cancer patients with the *UGT2B7* 802 C>T homozygous minor allele may benefit most from adjuvant epirubicin-based chemotherapy.²⁰⁶ In

a pharmacogenetic study of adjuvant breast cancer treatment with cyclophosphamide, epirubicin, and 5-fluorouracil, an NQO2 exonic SNP was associated with a higher exposure to epirubicinol relative to epirubicin. Other polymorphic variants of NQO1, CBR, UGT enzymes, and transporters had no influence on epirubicin or its metabolite.²⁰⁷ Finally, 63 genetic variants that contribute to etoposide-induced cytotoxicity were identified through a whole-genome association study using data generated on the HapMap cell lines.²⁰⁸

Perspectives

Topoisomerase inhibitors represent a basic component of the anticancer armamentarium. Four points are relevant to their future use: (1) novel formulations and targeted delivery approaches (exemplified by liposomes and antibody conjugates) may enable the selective targeting of tumors while limiting dose-limiting toxicities; (2) detailed understanding of the chemical limitation of the drugs (chemical instability of the camptothecins and redox reactions of the anthracyclines) and molecular mechanism of toxicities should enable the design of novel topoisomerase inhibitors, such as the non-camptothecin Top1 inhibitors (indenoisoquinoline LMP derivatives) and Top2 α -specific inhibitors that would avoid serious toxicities related to Top2 β inhibition (cardiac toxicity of the anthracyclines and secondary leukemia induced by the epipodophyllotoxins); (3) better understanding of the molecular basis of sensitivity will allow better choice of combinations of anticancer agents.^{10, 11} To date, combinations have been developed empirically, but going forward a better understanding of genomics and epigenomics will allow development of rational combination therapies. (4) Finally, it remains critically important to predict the activity of topoisomerase inhibitors and precisely select patients based on modern technology such as tumor genomic signatures.^{10, 11, 209} These agents, while identified before the era of personalized medicine, do have specific cellular targets, and it is important to understand them as such. It is important to identify the molecular basis of sensitivity and resistance so that in the future, strategies can be developed for making optimal therapeutic choices.

Chapter 60

Agents targeting microtubules and mitotic processes

Eric K. Rowinsky, MD

Overview

The treatment of many diseases owes much to the importance of medicines derived from natural sources, and the treatment of malignant disease is no exception. Billions of years of evolutionary pressure have resulted in the natural selection of plants, fungi, and microorganisms capable of producing potent and specific toxins. After several plant-derived compounds and other natural products, many of which targeted the mitotic processes, demonstrated prominent anticancer activity in the 1950s and 1960s, the microtubule was recognized as a subcellular target of major strategic importance.

The first widely used class of antimicrotubule agents, the plant-derived vinca alkaloids, had been the mainstay of both palliative and curative regimens for treating malignancies for several decades. The addition of the plant-derived taxanes, which possess a unique mechanism of action and anticancer spectra, to our therapeutic arsenal several decades later resulted in renewed interest in the microtubule and mitotic processes as targets for which to develop cancer therapeutics, as well as in the identification of other natural products to treat cancers. More recently, several plant- and marine-derived compounds as well as synthetic agents with yet even more distinctive disruptive actions on microtubules and other mitotic constituents have been identified. These include the analogs of the epothilones and halichondrin B, which were isolated from soil-dwelling myxobacterium and marine sponges, respectively. They also include potent antimicrotubule agents, such as analogs of maytansine and dolastatin, which are components of antibody-drug conjugates. This chapter focuses on the microtubule as a target for therapeutic development and antimicrotubule agents that comprise our therapeutic armamentarium.

Introduction

The treatment of many diseases owes much to the importance of medicines that have been derived from natural sources, and the treatment of malignant disease is no exception. In essence, billions of years of evolutionary pressure have resulted in the natural selection of plants, fungi, and microorganisms that are capable of producing highly potent and specific toxins. After several plant-derived compounds and other natural products, many of which were noted to suspend cell division in mitosis by affecting the mitotic spindle, demonstrated prominent anticancer activity in patients with advanced malignancies in the 1950s and 1960s, the microtubule was recognized as a subcellular target of major strategic importance.

The first widely used class of antimicrotubule agents, the plant-derived vinca alkaloids, had been the mainstay of both palliative and curative regimens for treating malignancies for several decades. The addition of the plant-derived taxanes, which possess a unique mechanism of action and anticancer spectra, to our therapeutic arsenal several decades later resulted in renewed interest in the microtubule and mitotic processes as targets for which to develop cancer therapeutics, as well as in the identification of

other natural products to treat cancers. More recently, several plant- and marine-derived compounds as well as synthetic agents with yet even more distinctive disruptive actions on microtubules and other mitotic constituents (e.g., mitotic kinesins and kinases) have been identified and added to our therapeutic arsenal. These include the analogs of the epothilones (e.g., ixabepilone) and halichondrin B (e.g., eribulin), which were isolated from soil-dwelling myxobacterium and marine sponges, respectively. They also include the highly potent antimicrotubule agents, such as analogs of maytansine and dolastatin, which are components of antibody-drug conjugates (ADCs) that utilize monoclonal antibodies (mAbs) to deliver them selectively cancer cells that express the mAb targets. This chapter focuses on the microtubule as a target for therapeutic development and antimicrotubule agents that comprise our therapeutic armamentarium, particularly the vinca alkaloids and taxanes, as well as several classes of promising antimicrotubule agents undergoing clinical evaluation.

Microtubules as strategic targets against cancer

Microtubules are highly regulated and integral components of the cellular cytoskeleton that can be disrupted by various natural products (e.g., vinca alkaloids, taxanes, epothilones, halichondrins, others), as well as an increasingly number of synthetic compounds.^{1–6} Microtubules, together with microfilaments and intermediate filaments, form the cytoskeleton and maintain cell structure. Although the most important functions of microtubules in proliferative cells are through their actions as components of the cytoskeleton and mitotic spindle apparatus, which pulls apart chromosomes and is vital to cell division, they are involved in many other critical functions throughout the cell cycle, including intracellular transport of vesicles and organelles, trafficking of proteins including many oncoproteins, locomotion, adhesion, and anchorage of subcellular organelles and receptors.^{1–8} The cytoskeleton, particularly microtubules, also influences gene expression and signal transduction, and vice versa; however, the mechanisms involved in these interactions are not well understood. The specific expression of transcription factors in concert with drug-mediated depolymerization of microtubules has been well described and such has provided information on the differential expression of specific genes.⁹ Lastly, the state of the cytoskeleton mediates cellular response via the action of various growth factors.⁹ Antimicrotubule agents disrupt these functions.^{1–9}

Microtubule structure and dynamics

Microtubules are dimeric structures made up of two globular subunits, α -tubulin and β -tubulin monomers, each of which consists of approximately 450 amino acids with a molecular weight of 50 kD.¹⁰ The α/β -tubulin dimers assemble into microtubules by forming linear protofilaments. Typically, microtubules are formed by the parallel association of 13 protofilaments, although microtubules composed of fewer or more protofilaments have been observed *in vitro*. Microtubules have distinct polarity, which is conferred by the unique alignment of the protofilaments. The protofilaments form a cylindrical wall around a hollow core; tubulin polymerizes end to end, with the α -tubulin subunit of one dimer in contact with the β -tubulin subunit of the next, as shown in [Figure 1](#). Therefore, one end of a protofilament will have the α -tubulin subunits exposed, while the other end will have the β -tubulin subunits exposed. These ends are designated the minus and plus ends, respectively. The protofilaments align parallel to one another with the same polarity, so, in a microtubule, there is one end, the plus end, with only β -tubulin subunits exposed, while the other end, the minus end, has only α -tubulin subunits exposed. At the plus end, there is guanosine triphosphate (GTP) binding, rapid assembly, and net elongation, whereas assembly is slow and net shortening occurs at the minus end. The unique functions of microtubules are related to their

polymerization dynamics, involving a dynamic equilibrium between an intracellular pool of α/β -tubulin dimers and microtubule polymers, and simultaneous release of the α/β -tubulin dimers into the soluble tubulin pool. Tubulin polymerization occurs by a nucleation–elongation mechanism, in which the slow formation of a short microtubule “nucleus” is followed by rapid elongation of the microtubule at its ends by the reversible, noncovalent addition of α/β -tubulin dimers. The dynamic equilibrium between free α/β -tubulin dimers and the microtubule occurs simultaneously at both ends of the microtubule.^{1–7} Each tubulin molecule is associated with two molecules of GTP. The nucleoside bound to α -tubulin, at the N site, is nonexchangeable, whereas the one bound to β -tubulin, at the E site, can be exchanged with free guanosine diphosphate (GDP). The assembly process utilizes energy provided by the hydrolysis of GTP.

Figure 1 Schematic model of the α/β -tubulin dimer with the monomers represented by shades of gray and white. The dimers associate linearly to form protofilaments that then in turn associate laterally to form the hollow cylindrical wall of the microtubule. Protofilaments can twist slowly around the microtubule axis, although these shown here are in parallel as in microtubules containing 13 protofilaments. Throughout most of the microtubule, lateral contacts involve α – α and β – β monomer interactions. Monomers of each type thus are in contact along a shallow spiral path around the microtubule.

Tubulin binds GTP with high affinity, and as tubulin-GTP is added to the ends of growing microtubules, GTP is gradually hydrolyzed to GDP and P_i .¹¹ The P_i ultimately dissociates, leaving a microtubule core that consists of tubulin bound to GDP. The GDP nucleotide remains nonexchangeable until the tubulin subunit dissociates from the microtubule. Although tubulin polymerization and dissociation, and consequently microtubule elongation and shortening, occur simultaneously at each end of the microtubule, the net changes in length at the more kinetically dynamic plus end are much larger over time than those at the minus end. If the polymerization reaction is followed *in vitro*, an initial lag phase is noted, after which microtubules form rapidly until a plateau phase is reached. In the intact cell, the minus ends of the microtubule are anchored at each of the two microtubule-organizing centers (MTOCs), whereas the plus end is free in the cytoplasm radiating toward the cell periphery. The centrosome, the principal MTOC of most cells, is the nidus for mitotic spindles; however, the Golgi apparatus can also serve as a platform for the nucleation of microtubules.¹² Because nucleation from the centrosome is inherently symmetrical, Golgi-associated microtubule nucleation permits formation of an asymmetrical microtubule network. In interphase, the MTOC organizes the microtubules that provides polarity to the cytoplasm and is involved

in the trafficking of proteins, including several oncoproteins.⁸

Treadmilling and dynamic instability

Two principal processes govern microtubule dynamics in live cells.^{1–15} The first, known as *treadmilling*, is the net growth at one end of the microtubule and the net shortening at the opposite end.⁸

Mitotic spindle formation and chromosomal segregation during the anaphase stage of mitosis, among other microtubule processes, occur by treadmilling. The second dynamic process, termed *dynamic instability*, occurs when the plus ends of microtubules switch spontaneously between states of slow sustained growth and rapid shortening.^{11, 13–15} Dynamic instability is dependent on a cycle of GTP hydrolysis and exchange. Mechanistically, the GTP cap model, in which a cap on the ends of the microtubule, consisting of GTP or GDP with associated nonexchangeable Pi, stabilizes the microtubule, thus allowing growth at the plus end, likely explains the process of dynamic instability. In essence, the switch between growth and shortening depends on the end conformation of the microtubule where growing ends are stabilized by a layer of GTP-tubulin subunits (GTP cap), whereas shortening ends have lost their GTP, allowing terminal GDP-tubulin dimers to dissociate from the microtubule lattice.¹⁶

Microtubules and mitosis

At the onset of mitosis, the interphase array of microtubules, which are attached to the MTOC, disassemble and are replaced by a new population of spindle microtubules that are much more dynamic.^{2, 13, 17, 18} Contained within the MTOC is another type of tubulin, γ -tubulin, which associates with other proteins to form a lock washer-like structure called the γ -tubulin ring complex. This complex acts as a template for α/β -tubulin dimers to begin polymerization; it caps the negative end, while microtubule growth occurs at the free positive end.¹⁹ A recently identified protein complex called augmin is critical for MTOC-dependent, spindle-based microtubule generation as it interacts with the γ -tubulin ring complex to increase microtubule density around the mitotic spindle origin.²⁰ As the spindle-shaped array of newly assembled microtubules is organized, the nuclear envelope breaks down and releases the newly condensed chromosomes, and the centrosomes, which were duplicated before mitosis, separate into the poles of the forming mitotic spindle. The rate of dynamic instability is accelerated during mitosis, resulting in the formation and attachment of the mitotic spindles to the chromosomes. In most cells, mitosis progresses rapidly, and the highly dynamic microtubules that comprise the mitotic spindle render them sensitive to antimicrotubule agents that disrupt polymerization dynamics.^{3, 13}

Dynamic instability and treadmilling are vital to the assembly and function of the mitotic spindle, and the high dynamicity of the microtubules that comprise the mitotic spindle is required for the precise alignment of the chromosomes and their attachment to the mitotic spindle during metaphase, as well as chromosome separation during anaphase. Dynamic instability and treadmilling enable the microtubules of the mitotic spindle to make vast growing and shortening excursions, often termed search and capture, essentially probing the cytoplasm, until their positive ends become attached to a chromosome at its kinetochore. If even a single chromosome is unable to achieve a bipolar attachment to the spindle, perhaps because of drug-induced suppression of microtubule dynamics, the cell will not traverse beyond a prometaphase/metaphase-like state and instead will undergo apoptosis due to a complex series of processes involving the spindle assembly checkpoint.^{21, 22} Although mitotic spindles can assemble even in the presence of low concentrations of antimicrotubule agents, mitosis cannot progress beyond the mitotic

checkpoint at the metaphase/anaphase transition.^{13, 17, 22} Such perturbations in mitotic spindle dynamics may delay cell-cycle progression at critical mitotic checkpoints, ultimately triggering apoptosis through a complicated interplay of checkpoint and mitotic kinases.^{7, 13, 17, 22} In the unperturbed normal state, oscillations of the duplicated chromosomes, dynamic instability, and treadmilling, in which there is addition of tubulin to the spindle at the kinetochore and loss of tubulin at the spindle poles, exert considerable tension on the chromosomes in metaphase and facilitate progression to anaphase. In anaphase, microtubules attached to the chromosomes undergo shortening, while another subpopulation of microtubules, called interpolar microtubules, lengthen, resulting in polar movement of the chromosomes. Suppression of spindle-microtubule treadmilling and dynamic instability by antimicrotubule agents reduce spindle tension and impede progression from metaphase to anaphase, thereby triggering cell death.^{3–5, 13, 17, 18, 23, 24} A similar process of positive-end capping activity for interphase microtubules, which is mediated by formins, the adenomatous polyposis coli protein, and EB1, has also been described.

Regulating microtubule dynamics and functional diversity

The net direction of the dynamic equilibrium between the intracellular pool of tubulin and the microtubule polymer is influenced by several factors that regulate the critical concentration of tubulin required for polymerization, including the GTP/GDP ratio, the ionic microenvironment, cell-cycle modulators, and various microtubule-associated proteins (MAPs) and regulatory proteins.^{1, 4, 5, 25, 26} MAPs are partly responsible for the functional diversity of microtubules in different tissues and are directly and indirectly being targeted for therapeutic development against cancer.²⁶ The major classes of MAPs include those that favor microtubule polymerization such as the tau proteins (molecular weights, 40–60 kD) and the high molecular weight (200–300 kD) proteins MAP1, MAPc (an adenosine triphosphatase [ATPase]), MAP2, MAP4, and XMAP215.^{4, 25–27} Other regulatory proteins include stathmin, XKCM1, XKIF2, and katanin, all of which favor depolymerization.²⁷ MAPs generally possess two binding domains, one of which binds to microtubules and facilitates the initial nucleation step of tubulin polymerization and a second that links microtubules to other cellular constituents. Still, other MAPs, such as the dyneins (GTPases) and kinesins (ATPases), function as microtubule motor proteins, transmitting chemical energy to mechanical force and moving various solutes and subcellular organelles along the microtubule.^{1, 4, 5, 25–27} Motor proteins play key roles in mitosis, premeiotic events, and organelle transport and are being evaluated as targets for anticancer therapeutic development (see section titled “Targeting Mitotic Motor Proteins and Kinases”).^{28, 29}

In addition to MAPs, the functional diversity of microtubules in various tissues is, in part, conferred by differences in tubulin isotypes and posttranslational modifications. There are at least six isotypes of α -tubulin and β -tubulin each in human cells, which are distinguished by different C-terminal amino acid sequences and encoded by a large multigene family that has been highly conserved throughout evolution.^{4, 30–33} Analysis of tubulin isotype expression in various tissues has demonstrated a complex, albeit highly conserved, pattern of isotype distribution, suggesting functional specificity.^{1, 4, 5, 25–27} Both forms of tubulin also undergo various posttranslational modifications, including phosphorylation, dephosphorylation, polyglycylation, delta 2 tubulin formation, acetylation, and polyglutamylation, by microtubule-bound enzymes.^{34, 35} Posttranslational modifications confer stability to the microtubule polymer, as well as structural and functional diversity.^{34, 35} Most modifications are rapidly reversed by soluble enzymes when microtubule depolymerization occurs. Posttranslational modifications generally occur on the C-terminal region of α -tubulin. This region, which is rich in negatively charged glutamate, forms relatively unstructured tails that project out from the microtubule and contact motor proteins. Therefore,

posttranslational modifications appear to regulate the interactions of motor proteins with microtubules.

Vinca alkaloids: Introduction and indications

The vinca alkaloids are naturally occurring or semisynthetic nitrogenous bases extracted from the pink periwinkle plant *Catharanthus roseus* G. Don. The early medicinal uses of this plant led to screening these compounds for their hypoglycemic activity, which was ultimately of minor importance compared to their cytotoxic effects. Many vinca alkaloids have been extensively evaluated, but only vincristine (VCR), vinblastine (VBL), and vinorelbine (VRL) are approved for use in the United States and elsewhere, whereas vinflunine (VFL) and vindesine (VDS) are approved for use in some regions. VCR sulfate liposomal injection is also available for use in the United States and elsewhere.

The vinca alkaloids have dimeric structures composed of two basic multiringed units ([Figure 2](#)), an indole nucleus (catharanthine), and a dihydroindole nucleus (vindoline), joined together with other complex systems.^{36–38} Structurally, VCR and VBL are identical except for a single substitution on the vindoline nucleus, where VCR and VBL possess formyl and methyl groups, respectively. Although this minor difference does not fundamentally alter the mechanisms and tubulin-binding properties of these agents, the anticancer and toxicologic profiles of VCR and VBL differ significantly.^{4, 36–41}

Figure 2 Chemical structures of the vinca alkaloids. Structural modifications with vinblastine as the reference are circled.

VCR is used more commonly to treat pediatric malignancies, which is due, in part, to a generally greater

level of intrinsic sensitivity of pediatric malignancies to VCR and better tolerance of therapeutic VCR doses in children. In both children and adults, however, VCR is an essential component of the chemotherapy regimens used to treat acute lymphocytic leukemia (ALL), lymphoid blast crisis of chronic myeloid leukemia (CML), and both Hodgkin and non-Hodgkin lymphoma. VCR also plays a role in some multimodality therapies of Wilms' tumor, Ewing's sarcoma, neuroblastoma, and rhabdomyosarcoma and is occasionally used in treating multiple myeloma, particularly as a component of the VAD (VCR, doxorubicin, and doxorubicin) regimen, recurrent small cell lung cancer, and sarcoma of both soft tissue and bone. The agent has also been used as a component of a combination regimen, known as PCV (procarbazine, lomustine, and VCR), which is used in early and advanced settings of anaplastic oligoastrocytoma and oligodendroglioma.⁴² More for a historical sense, indicating a wide range of utility, VCR and VCR-laden platelet transfusions have been effective in refractory autoimmune thrombocytopenia; VCR has been effective in treating both nonmalignant and immunologically mediated disorders such as autoimmune hemolytic anemia, hemolytic uremic syndrome, thrombotic thrombocytopenia purpura, and steroid-dependent nephritic syndrome.^{38–40, 43}

VBL has been a mainstay component of chemotherapy for germ cell malignancies and some types of advanced lymphoma.³⁸ For many years, a regimen termed PVB, consisting of cisplatin, VBL, and bleomycin, was a standard therapy for germ cell carcinoma; however, VBL has largely been replaced by etoposide in this setting because of the more favorable toxicity profile of the cisplatin–etoposide regimen. For Hodgkin's lymphoma, VBL is often used in combination with doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD).³⁸ This regimen has been either administered alone, alternated with nitrogen mustard, VCR, procarbazine, and prednisone (MOPP), which is noncross-resistant to ABVD, or used as a hybrid (MOPP/ABV) that includes both VCR and VBL, which has also been extensively studied. Anticancer activity has been observed with VBL as a single agent or in combination with other anticancer drugs in patients with advanced and/or relapsed carcinoma of the breast, bladder, and lung, as well as Kaposi's sarcoma, choriocarcinoma, terminal phase of CML, cutaneous T-cell lymphoma, and histiocytosis X.³⁸ Infusions of VBL or VBL-laden platelets have been effective in some cases of refractory autoimmune thrombocytopenia because of its avidity to platelets.^{38, 43} VBL has also been used alone or in combination with other agents to treat Kaposi's sarcoma and bladder, breast, and some types of malignancies of the central nervous system.^{38, 44–48}

The semisynthetic VBL derivative vinorelbine (5'-norhydro-VBL; VRL), which is structurally modified on its catharanthine nucleus, resulting in much greater lipophilicity as compared with the other vinca alkaloids, is approved in the United States for treating nonsmall cell lung cancer as either a single agent or in combination with cisplatin and has been registered elsewhere to treat patients with advanced breast cancer. The agent has also demonstrated clinical activity in advanced ovarian carcinoma and lymphoma, but a unique role in treatment of these cancers has not been defined. VRL has also been shown to confer favorable therapeutic indices to patients with advanced breast and lung cancers who are elderly and/or have diminished performance abilities.^{4, 38, 44–48}

Several other vinca alkaloids or reformulated versions of older vinca alkaloids are available for treating relevant malignancies worldwide. One widely studied vinca alkaloid, vindesine (desacetyl-VBL carboxamide), a semisynthetic derivative and human metabolite of VBL, was introduced in the 1970s and several regions outside the United States. In some reports, response rates in nonsmall cell lung cancer with combinations of VDS and cisplatin or mitomycin appear to be superior to those achieved with standard combinations or with either agent alone.^{38, 40, 41} In addition, anticancer activity has been seen in ALL, blast crisis of CML, malignant melanoma, various pediatric solid neoplasm, and advanced renal, breast, and esophageal carcinoma. In addition, VFL, which is a bifluorinated vinca alkaloid, has shown

notable clinical activity in bladder, breast, lung, and other cancers.^{4, 38, 44–52} In Europe, VFL is approved as a treatment option for patients with advanced urothelial cancer who have failed a prior platinum-containing regimen.⁵² Lastly, a sphingomyelin- and cholesterol-based liposomal nanoparticle formulation of VCR (vinCRISTine sulfate LIPOSOME injection (VSLI)) is registered in the United States for the treatment of adult patients with Philadelphia chromosome-negative ALL whose disease has progressed following at least two prior therapies.^{53, 54} Although the liposomal formulation permits delivery of higher VCR doses, has a longer circulatory time, and delivers greater amounts of active VCR to target tissues compared to standard VCR, the overall clinical benefits of the new formulation of VCR over standard VCR are not known.

Mechanism of action

The vinca alkaloids principally induce cytotoxicity by disrupting microtubule function, particularly that of microtubules that comprise the mitotic spindle apparatus, leading to metaphase arrest and cell death.^{2–7, 36–38, 55–59} However, they are capable of many other biochemical activities that may or may not be related to their effects on microtubules, including inhibiting synthesis of proteins and nucleic acids, elevating oxidized glutathione, altering lipid metabolism and membrane lipids, elevating cyclic adenosine monophosphate (cAMP), and inhibiting calcium–calmodulin-regulated cAMP phosphodiesterase.³⁸ Many effects that do not involve microtubule disruption occur only after treatment with superphysiological concentrations that are not readily attained *in vivo*, whereas nanomolar concentrations, which are readily achievable in following drug administration in clinical practice, induce typical antimicrotubule effects. The vinca alkaloids also disrupt the structural integrity of platelets and other cells, which are rich in tubulin. In addition to mitotic disruption, the vinca alkaloids and other antimicrotubule agents perturb cells in nonmitotic cell-cycle phases, which is not surprising because microtubules are involved in many nonmitotic functions.^{38, 57–59} The vinca alkaloids bind rapidly and reversibly to sites on tubulin (called the vinca domain), which are distinct from those of the taxanes, colchicine, podophyllotoxin, and GTP but similar to those of maytansine and several other plant alkaloids.

The vinca alkaloids appear to bind to two binding sites with different affinities.^{2, 4, 6, 7, 10, 37, 38, 51, 55–57, 60, 65} Binding of the vinca alkaloids to high-affinity sites (K_d , 1–2 μmol), which are at the ends of microtubules, is responsible for the potent suppression of tubulin exchange at low concentrations (<1 μmol). At low vinca alkaloid concentrations, processes dependent on microtubule dynamics (treadmilling and dynamic instability) are disrupted, but microtubule mass is not affected. The overall result is a potent mitotic block at the metaphase/anaphase boundary. Binding of vinca alkaloids to low-affinity sites (K_d , 0.25–3.0 mmol) along the sides of microtubules appears to result in reduced microtubule mass due to tubulin depolymerization and the splaying of microtubules into spiral aggregates or spiral protofilaments that form paracrystals, ultimately leading to microtubule disintegration. These effects occur at high drug concentrations (>1 –2 μmol) by a self-propagated mechanism, initially involving drug binding to a limited number of sites, which progressively weakens the lateral interactions between the protofilaments, thereby exposing new sites and augmentation of the process.

The vinca alkaloids induce a potent block in mitosis at the metaphase/anaphase transition.^{2, 4, 66} Following nuclear envelop breakdown, the vinca alkaloids block mitotic spindle formation and reduce the tension at the kinetochores of the chromosomes. Although chromosomes may condense, they remain scattered in the cells. The chromosomes separate along their lengths but still remain attached at their centromeres.^{2, 4, 9, 13, 18, 24, 58, 59, 67} Mitotic progress is delayed in a metaphase-like state, with chromosomes “stuck” at the spindle poles, unable to move to the spindle equator. The cell-cycle signal to the anaphase-promoting

complex, which is required for the cell to transition from metaphase to anaphase, is blocked, and apoptotic cell death ensues. Cell-cycle progression in the absence of anaphase or cytokinesis may occur, resulting in chromatin decondensation and formation of multilobed nuclei.^{2, 4, 13, 24} Disruption of dynamics without depolymerization of the microtubules that constitute the mitotic spindle ultimately induces apoptosis that involves expression of proapoptotic genes and both activation and inactivation of proapoptotic and antiapoptotic proteins, respectively (see section titled “Vinca Alkaloids, Mechanism of Action” and “Vinca Alkaloids, Mechanisms of Resistance” and “Taxanes, Mechanisms of Action, and Resistance”).^{2, 4, 9, 13, 18, 21, 23, 51, 67–72} Induction of apoptosis, however, is not dependent on the presence of an intact TP53 checkpoint. The loss of p21, a protein that controls entry into mitosis at the G₂/M checkpoint, sensitizes tumor cells to both vinca alkaloids and taxanes, possibly by hastening entry of drug-damaged cells into mitosis.^{23, 68–70}

The relationships between microtubule depolymerization caused by the vinca alkaloids and their resultant effects on cell proliferation, mitotic arrest, and mitotic spindle disruption have been characterized in a series of studies whose results indicate that cell growth inhibition is directly related to metaphase arrest.¹⁸ The inhibition of proliferation and blockage of cells in metaphase at the lowest effective drug concentration occur with little or no microtubule depolymerization or disorganization of the mitotic spindle apparatus. With increasing drug concentrations, the organization of microtubules and chromosomes in arrested mitotic spindles breaks down in a manner similar to most antimicrotubule drugs, regardless of the underlying mechanism.^{2–4, 13, 14}

In addition to their direct cytotoxic effects on tumor cells, the vinca alkaloids as well as the maytansinoids, taxanes, and various other antimicrotubule agents confer anticancer effects by inhibiting processes associated with malignant angiogenesis with surprising potency.⁷³ These antiangiogenic effects are most likely caused by drug-induced microtubule perturbations in vascular endothelial cells; however, the relative contribution of these effects to the clinical anticancer activity is unclear.

The reasons for the disparate sensitivity of various tissues and tumors to the vinca alkaloids are multifactorial. One possible explanation is the differential sensitivity of tissues with varying tubulin isotype composition, which may affect intracellular drug accumulation and drug binding to tubulin.^{4, 33, 74, 75} In addition, differences in the type and concentration of MAPs and posttranslational tubulin modifications, which may influence drug interactions with tubulin, as well as variability in cellular permeability and retention, may affect the formation and stability of complexes formed between the vinca alkaloids and tubulin. Palmitoylation, a posttranslational tubulin modification, is directly inhibited by the vinca alkaloids, and depalmitoylation of tubulin may not only be a mechanism of action, but may also relate to drug sensitivity.⁷⁶ Other putative factors include differences in tubulin isotypes (see sections titled “Vinca Alkaloids, Mechanisms of Resistance” and “Taxanes, Mechanisms of Resistance”), GTP content, rates of GTP hydrolysis, and cellular permeability.^{74, 77–81}

Mechanisms of resistance

In most preclinical models, resistance to the vinca alkaloids develops rapidly and is associated with decreased drug accumulation and retention. At least two types of mechanisms of resistance have been characterized. The first typifies the “classic” pleiotropic or multidrug-resistant (MDR) phenotype that can be either primary or acquired. Although many proteins that mediate MDR have been characterized, the most well known are the ATP-binding cassette (ABC) transporters that belong to the largest known transporter gene family and translocate a wide range of substrates across cellular compartments.^{82, 83}

These intracellular and extracellular membrane-spanning proteins, which transport both endobiotics and xenobiotics, confer resistance to the vinca alkaloids and other structurally bulky natural products. The best characterized ABC transporters are the permeability glycoproteins (Pgp) or the MDR-encoded gene product MDR1 (ABC subfamily B1) and the multidrug resistance protein (MRP; ABC subfamily C2).⁸²

MDR1 is a 170-kDa Pgp energy-dependent transmembrane pump that regulates the efflux of a wide range of bulky hydrophobic substances.⁸² The protein is constitutively overexpressed in various normal tissues, which include renal tubule epithelium, colonic mucosa, and adrenal medulla, as well as tumors derived from tissues that constitutively overexpress Pgp. Pgp, an ATPase, functions to bind and extrude the vinca alkaloids from the tumor cell in a process that requires energy in the form of ATP. The MDR phenotype also confers varying degrees of cross-resistance to other structurally bulky natural products such as the taxanes, anthracyclines, epipodophyllotoxins, and colchicine. The specific Pgp associated with vinca alkaloid resistance shows slight antigenic and amino acid sequence differences and a different amino acid map after digestion than does Pgp from cells selected for resistance to colchicines or taxanes.^{84–87} In fact, two forms of the protein have been demonstrated to be produced by a single clone of VCR-resistant cells, and these forms undergo posttranslational *N*-glycosylation and phosphorylation, which lead to further structural diversity and may explain the greater degree of resistance for the specific agent used compared with the resistance of other drugs conferred by MDR and may also account for the variable patterns of resistance among MDR cells. The composition of membrane gangliosides in cancer cells resistant to the vinca alkaloids has also been shown to differ from that of wild-type cells. The clinical ramifications of these resistance mechanisms are not known. In one study in childhood ALL, however, VCR resistance measured *in vitro* did not correlate with Pgp overexpression.⁸⁸

MRP1, a 190-kD membrane-spanning protein that shares 15% amino acid homology with MDR1, also confers resistance to the vinca alkaloids *in vitro*.^{39, 82, 83, 89–92} MRP1 expression is found in many tumors and has been associated with the MDR phenotype in cancers of the lung, colon, breast, bladder, and prostate, as well as leukemia. MRP1 transports glutathione conjugates of alkylating agents and several xenobiotics such as etoposide and doxorubicin but confers resistance only to the latter agents. MRP1 confers resistance to the vinca alkaloids and methotrexate.^{39, 82, 83, 89–92} Although other ABC transporters have been identified and several confer cellular resistance to the vinca alkaloids *in vitro*, their roles in conferring inherent or acquired drug resistance in the clinic are less clear than those of MDR1 and MRP1.

Drug resistance conferred by MDR1 and MRP *in vitro* is reversible after treatment with agents that have distinctly different structural and functional characteristics, such as the calcium channel blockers, calmodulin inhibitors, detergents, progestational and antiestrogenic agents, antibiotics, antihypertensives, antiarrhythmics, antimalarials, and immunosuppressives, which has been a source of clinical interest.^{39, 82, 93, 94} Those reversal agents bind directly to Pgp, thereby blocking the efflux of the cytotoxic drugs and increasing intracellular drug concentrations. However, clinical studies of resistance modulation have been confounded by the fact that MDR modulators, particularly MDR1 reversal agents, also enhance drug uptake in normal cells, decrease biliary elimination and drug clearance, and lead to enhanced toxicity.^{39, 82, 93, 94} Overall, clinical strategies aimed at reversing resistance to the vinca alkaloids with pharmacologic modulators of both MDR1 and MRP have been disappointing, most likely owing to the fact that the MDR1 expression is associated with overexpression of a large number of resistance proteins.⁸²

Structural and functional alterations in α - and β -tubulins due to either genetic mutations, posttranslational modifications, or differential expression of tubulin isoforms, particularly the β III-tubulin isoform, have been identified in tumor cells with resistance to the vinca alkaloids and taxanes in both preclinical and clinical studies.^{95–106} These studies suggest that the β III-tubulin isoform could be both a prognostic and a

predictive determinant of clinical benefit. Expression of β II-tubulin, which appears to depend on TP53 suppressor function, may also relate to vinca alkaloid resistance.¹⁰⁷

Increased expression of MAPs, particularly MAP4, has also been associated with vinca alkaloid resistance.⁷⁵ This alteration, as well as alterations in α - and β -tubulin, promotes resistance to agents that inhibit microtubule assembly by enhancing microtubule stability, possibly by promoting longitudinal inter- and intradimer interactions and/or lateral interactions between protofilaments. Furthermore, these “hyperstable” microtubules are collaterally sensitive to the taxanes (see sections titled “Taxanes, Mechanisms of Resistance”). Although such tubulin modifications have been demonstrated repeatedly in tumor cells that are continuously exposed to the vinca alkaloids *in vitro*, the relevance of “hyperstable tubulin” caused by alterations in tubulins or MAPs is not known.

Variability in cellular permeation and retention may also influence the formation and stability of vinca alkaloid-tubulin complexes.^{51, 79, 108–114} The vinca alkaloids are rapidly taken up into cells and then accumulate intracellularly, with intracellular to extracellular concentration ratios as high as 5- to 500-fold, depending on the cell type.^{80, 81} In murine leukemia cells, the intracellular concentrations of VCR are 5- to 20-fold higher than the extracellular concentrations, and ratios ranging from 150- to 500-fold have been reported with other vinca alkaloids.^{81, 108, 115} There are also marked differences in cellular uptake and retention between the vinca alkaloids, the latter of which may relate to potency and the duration of drug action. For example, VRL is more rapidly taken up and metabolized than other vinca alkaloids in isolated human hepatocytes,¹¹⁶ and the greater potency of VCR during exposures of short duration compared with VBL was related to the greater cellular retention of VCR in another model system. A key determinant of drug accumulation and retention is lipophilicity. The differences in the catharanthine ring of VRL render it a more lipophilic agent and increase its retention in tissues, which may explain why it is more effective at disrupting the microtubules of the mitotic spindles compared with axonal microtubules.¹¹⁴ The differential effects of the vinca alkaloids on axonal microtubules due to variable cellular retention and lipophilicity may explain why VRL treatment results in less neurotoxicity than other vinca alkaloids. The mechanisms responsible for the intracellular accumulation of the vinca alkaloids and other agents that bind to tubulin are not fully known, but may relate to their tubulin-binding properties and several other factors. Differential drug uptake among different tumor types may also relate to tubulin isotype expression, differential uptake and efflux, and intracellular reservoirs for drug accumulation. Lastly, pharmacokinetic differences related to the formulation vehicle appear to influence tissue uptake. For VSLI, liposomal entrapment appears to be associated with increased circulating time and tumor permeability in preclinical studies.⁵³ Increased tumor uptake of VCR following administration of VSLI may be due, in part, to the enhanced permeability and retention effect conferred by the liposomal formulation.

Pharmacology

Cellular pharmacology

Temperature-independent nonsaturable mechanisms, analogous to simple diffusion, are responsible for most transport of the vinca alkaloids, and temperature-dependent saturable processes are less important.¹¹⁷ Although drug concentration and duration of treatment are determinants of drug accumulation and cytotoxicity, the duration of drug exposure above a critical threshold concentration is perhaps the most important pharmacologic determinant of cytotoxicity.⁸⁰ Cytotoxicity is directly related to the extracellular concentration of drug when the duration of treatment is kept constant; for prolonged exposure

to VCR, the concentration yielding 50% inhibition lies in the range of 1–5 nmol/L.¹¹⁸

Clinical pharmacology

The clinical pharmacology of the vinca alkaloids, which were largely studied decades ago, largely reflects the fact that sensitive, specific, and reliable analytic assays capable of measuring the minute plasma concentrations resulting from the administration of milligram quantity doses were not available. Early results may have been confounded by the use of radiolabeled drugs and assay methods. The vinca alkaloids, particularly VCR and VBL, undergo spontaneous degradation, forming degradative products that can be separated using high-pressure liquid chromatography (HPLC). Radiolabeled compounds coupled to HPLC improved separation of the various chemical moieties. Radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) methods can measure drug concentrations in the picomolar range; however, these methods cannot distinguish between the parent compounds and related derivatives and, therefore, may not provide sufficient quantitative information about degradation products and metabolites. To meet the challenge, more refined RIA and ELISA methods using mAbs with considerably greater sensitivity and specificity have been developed. Furthermore, recent technical advances in extraction and detection methodologies have increased the sensitivity and specificity of chromatographic methods, particularly tandem mass spectroscopy in conjunction with HPLC. [Table 1](#) summarizes the pharmacokinetic characteristics of the vinca alkaloids, which generally exhibit triphasic clearance in human plasma following intravenous administration as a brief infusion. Except for VSLI, the pharmacokinetic behavior of these agents is typified by large volumes of distribution (V_d), high early clearance rates, long terminal half-lives, extensive hepatic metabolism, and biliary/fecal elimination. The relatively short α and β phases, which are likely a result of rapid distribution and uptake and binding to tubulin in peripheral tissues and formed blood elements, are similar for all vinca alkaloids. However, the terminal (γ) phase, which is relatively long because of the avid tissue sequestration and slow release of drug, has been reported to vary by approximately fourfold.

Table 1 Vinca alkaloids: comparative pharmacokinetic and toxicologic characteristics

	Vincristine	Vinblastine	Vindesine	Vinorelbine	Vinflunine	Vincristine sulfate liposome injection
Standard adult dose range (mg/m ²)	1–2 (weekly)	6–8 (weekly)	3–4 (weekly)	15–30 (weekly)	320 (every 3 weeks)	2.25 (week
Pharmacokinetic behavior	Triphasic	Triphasic	Triphasic	Triphasic	Multiphasic	Biphasic
Plasma half-lives						
α(min)	<5	<5	<5	<5	—	—
β(min)	50–155	53–99	55–99	49–168	—	—
γ(h)	23–85	20–64	20–24	18–49	40	7.66 ^a
Clearance (L/h/kg)	0.16	0.74	0.25	0.4–1.29	0.64	0.35 (L/h)
Primary route	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination (≈66%); renal (≈33%)	Hepatic metabolism biliary elimination
Principal toxicity	Neurotoxicity	Neutropenia	Neutropenia	Neutropenia	Neutropenia	Neutropeni
Other common toxicities	Constipation, SIADH	Alopecia neurotoxicity, mucositis	Alopecia, neurotoxicity	Neurotoxicity vomiting, constipation, mucositis	Neurotoxicity, myalgia, fatigue, anorexia, constipation, nausea/vomiting, anemia, injection site, thrombocytopenia, hyponatremia	Neurotoxic thrombocyt anemia

^a Represents noncompartmental half-live value.
SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Vincristine (VCR)

VCR is rapidly distributed to from the circulatory to the peripheral compartment following administration. There is extensive binding to both plasma proteins and formed blood elements, particularly platelets, which contain large quantities of tubulin. This served as the rationale for using VCR-laden platelets to treat disorders of platelet consumption such as refractory thrombocytopenia.^{38, 43}

In contrast, penetration of VCR and all other vinca alkaloids across the blood–brain barrier is poor, probably because of the molecule's large size and high substrate affinity for ABC transporter pumps that maintain the integrity of the blood–brain barrier. Following administration of conventional doses (1.4 mg/m²), given as a brief intravenous infusion, peak plasma levels approach 0.4 µmol.^{38, 117, 119–124} Total VCR clearance is slow, which reflects avid tissue binding and slow release, and terminal half-life ($t_{1/2}$) values in the range of 23–85 h have been reported.^{38, 117, 119–124} VCR is metabolized and excreted primarily by the hepatobiliary system. Seventy-two hours after the administration of radiolabeled VCR, approximately 12% and 70% of the radioactivity are recovered in the urine (50% of which consists of metabolites) and feces (40% of which consists of metabolites), respectively.^{38, 117, 119–126} As many as 11 metabolites have been detected in humans and other species.¹¹³ The nature of the VCR metabolites identified to date, such as 4-deacetyl-VCR and *N*-deformyl-VCR, which have been isolated from human bile, and 4'-deoxy-3'-hydroxyVCR and 3', 4'-epoxy-VCR *N*-oxide following incubation of VCR with bile, indicates that the agent is principally metabolized by hepatic cytochrome P450 CYP3A.^{38, 117, 119–127} There has been conflicting, albeit sparse, evidence that peak plasma concentration and systemic exposure are the principal pharmacologic determinants of neurotoxicity.¹²⁷

Vinblastine (VBL)

The pharmacologic behavior of VBL is similar to that of VCR. Following rapid intravenous injection of VBL at standard doses, peak plasma drug concentrations are approximately 0.4 µmol/L.^{38, 117, 128} Tissue distribution is also extensive. Like VCR, binding of VBL to plasma proteins and formed elements of blood is considerable. Furthermore, distribution is rapid with $t_{1/2}$ values of approximately 4 min and 1.6 h for α and β phases, respectively. Terminal half-life values ranging from 20 to 24 h have been reported. Like VCR, VBL disposition is principally through the hepatobiliary system. The principal mode of VBL disposition is hepatic metabolism and biliary excretion. Fecal excretion of the parent compound is low, indicating that metabolism is substantial. The cytochrome P450 CYP3A isoform appears to be principally responsible for its biotransformation.¹¹⁶ At least one metabolite, 4-deacetyl-VBL, or VDS, which appears to be as active as the parent compound, has been identified in humans, and small quantities have been detected in both urine and feces.

Vinorelbine (VRL)

The pharmacologic behavior of VRL is similar to those of the other vinca alkaloids, and plasma concentrations decline in a biexponential or triexponential manner. Immediately after intravenous administration, plasma concentrations decline rapidly followed by much slower elimination phases ($t_{1/2}$, 18–49 h).^{38, 46, 47, 129, 130} Plasma protein binding has been reported to range from 80% to 91%, with binding primarily to α_1 -acid glycoprotein, albumin, and lipoproteins. VRL is widely distributed with extensive sequestration in virtually all tissues, except the brain and testes. The drug is also extensively bound to platelets. The wide distribution of VRL may reflect the agent's lipophilicity, which is among the highest of the vinca alkaloids. Tissue to plasma ratios range from 20 to 80, although VRL concentrations in human lung have been reported to be 300-fold greater than plasma concentrations and 3.4–13.8-fold higher than lung concentrations achieved with VDS and VCR, respectively. Hepatic metabolism and biliary excretion of metabolites and VRL are the principal modes of drug disposition.^{38, 46, 47, 129–132} Approximately 33–80% of the administered dose of VRL is excreted into the feces, whereas urinary excretion represents only 16–30% of total drug disposition, the majority of which is metabolized. Cytochrome P450 isoform CYP3A is principally involved in biotransformation in humans.^{46–48, 132–137} The principal metabolites appear to be 4-*O*-deacetyl-VRL, 3,6-epoxy-VRL, and several hydroxy-VRL

isomers. Most metabolites are inactive. Although 4-*O*-deacetyl-VRL may be as active as VRL, this finding is of minor importance since concentrations are minute.

The total body clearance of VRL (1.2 L/h/kg) and mean $t_{1/2}$ values of approximately 26 h were found to be the same in elderly and younger patients with normal hepatic function in one study. Clearance has been found to be adversely affected in patients who have liver metastases that involve more than 75% of the organ; clearance can be predicted in such patients by the monoethylglycinexylidide clearance test, which assesses CYP3A4 function.¹³⁷ Dexamethasone has also been used as a probe of CYP3A metabolism in the assessment of VRL pharmacokinetics.¹³¹ Although VRL clearance is not accurately predicted by bilirubin concentrations in serum, markedly elevated levels have been associated with significant reductions in clearance in the few patients studied. VRL is active when given orally. In animals, 100% of radioactivity is absorbed after the ingestion of tritium-labeled VRL. The bioavailability of the parent compound in human studies is 43% and 27% for the powder-filled and liquid-filled capsules, respectively; the bioavailability of the gel-filled capsule was negligibly affected by food.^{129, 138, 139} C_{\max} values are achieved within 1–2 h after ingestion, and interindividual variability is moderate.

Vinflunine (VFL)

The pharmacokinetics of VFL have been demonstrated to be linear at clinically relevant doses (30 mg/m² to 400 mg/m²).^{49, 50} VFL undergoes multiexponential decay following intravenous administration, with a rapid initial distribution phase. Similar to other vinca alkaloids, the V_d of its terminal phase is large (2.42 L or 35 L/kg), indicating wide distribution to a large tubulin-rich tissue compartment.^{49, 50} Total clearance is large (43.9 L/h, 0.640 L/h/kg), reflecting its initial rapid distribution and binding to tubulin-rich tissues. Its terminal $t_{1/2}$ is approximately 40 h, reflecting its slow clearance from the peripheral compartment. VFL is moderately bound to human plasma proteins (67.2%). Protein binding is nonsaturable in the range of clinically achievable VFL concentrations and mainly involves high-density lipoproteins and serum albumin; binding to α_1 -acid glycoprotein and to platelets is negligible (<5%). Two-thirds of VFL is disposed of via hepatic metabolism and biliary excretion, whereas renal excretion accounts for one-third of administered drug.^{140, 141} Except for the principal metabolite, 4-*O*-deacetyl-VFL (DVFL) that is formed via multiple esterases, hepatic metabolism is mediated through CYP3A4. DVFL has comparable activity to the parent compound and a terminal $t_{1/2}$ of about 120 days. VFL has not been demonstrated to inhibit nor induce CYP3A4 nor other CYP metabolism enzymes in *in vitro* studies; however, coadministration of ketoconazole resulted in 30% and 50% increases in exposures to VFL and DVFL, respectively. Despite VFL's extensive liver metabolism and excretion, the pharmacokinetics of both VFL and DVFL were similar among 25 patients with varying degrees of liver dysfunction in one study. Nevertheless, dose adjustments for hepatic dysfunction are recommended (see section titled “Administration, Dose, and Schedule”).¹⁴² Since VFL clearance has been shown to be significantly decreased in patients ≥ 80 years old as compared to a control group of younger patients <70 years, dose reductions are recommended for elderly patients (≥ 75 years (see section titled “Administration, Dose and Schedule”).

Vincristine sulfate liposome injection (VSLI)

The pharmacokinetics of VCR following administration of VSLI are typified by much slower clearance rates from the central compartment compared to VCR administered in a conventional nonliposomal formulation.⁵³ The lipid composition and the approximate 100 nm mean particle size of the VSLI liposome contribute to low protein binding that result in a longer circulation time for the nanoparticle.⁵³

In vitro protein binding assays demonstrated negligible levels of human plasma proteins absorbed to VSLI. Approximately 18–39% of encapsulated VCR was released at 24 h *in vitro* using human plasma. These characteristics are likely responsible for preferential accumulation of VSLI accumulation in tumors and tissues of the macrophage phagocytic system (e.g., lymph nodes, bone marrow, spleen, and liver), possibly due to the larger microvascular fenestrations in those tissues, as well as enhanced permeability and retention.¹⁴³ In studies of mice with implanted human tumor xenografts, significantly faster accumulation of drug occurred in tumors than in nontumor tissues after a single dose of VSLI.¹⁴⁴ The interstitial amounts of drug were approximately 70-fold higher in tumor tissues compared to nontumor tissues at 1 h and remained higher at 48 h. Combined, these distribution data are consistent with VSLI exiting the systemic circulation, accumulating at the site of tumors where they act as a reservoir for the release of localized VCR to enhance the anticancer activity.

In human subjects receiving treated with VSLI 2.25 mg/m², mean plasma clearance was determined to be 345 mL/h.⁵³ Peak plasma concentration (C_{\max}) values averaged 1220 ng/mL, whereas values for the elimination $t_{1/2}$ averaged 7.66 h, and mean values for total and steady-state Vd were 3.57 and 2.91 L, respectively. Following intravenous administration of VSLI, fecal and urinary excretion over 96 h accounted for 69% and <8% of administered drug.

Drug interactions

The vinca alkaloids, particularly VCR and VBL, enhance methotrexate accumulation in tumor cells *in vitro*, an effect mediated by a vinca alkaloid-induced blockade of drug efflux; however, the minimal VCR concentrations required to achieve this effect (0.1 $\mu\text{mol/L}$) are attained transiently *in vivo*.^{145–147} The vinca alkaloids also inhibit the cellular influx and cytotoxicity of the epipodophyllotoxins *in vitro*, but the clinical ramifications of this effect are unknown.¹⁴⁸ L-Asparaginase may reduce the hepatic clearance of the vinca alkaloids, particularly VCR, which may result in increased toxicity. To minimize the possibility of this interaction, it is recommended that VCR be given 12–24 h before L-asparaginase. A pharmacokinetic interaction between VFL and pegylated liposomal doxorubicin was observed, resulting in a 15–30% apparent increase and a two to threefold decrease in VFL and doxorubicin exposure, respectively, whereas for doxorubicinol, the concentrations of the metabolite were not affected. According to an *in vitro* study, such changes could be related to adsorption of VFL on the liposomes and a modified blood distribution of both compounds. Therefore, caution should be exercised when this type of combination is used. A possible interaction between VFL and the taxanes, paclitaxel and docetaxel, which are CYP3A substrates, has been suggested based on the results of an *in vitro* study.

Treatment with the vinca alkaloids has precipitated seizures associated with subtherapeutic plasma phenytoin concentrations, most likely due to the induction of CYP3A-mediated clearance of phenytoin.^{149–152} Reduced plasma phenytoin levels have been noted from 1 to 10 days after treatment with both VCR and VBL. Administration of the any of the vinca alkaloids with erythromycin, itraconazole, ketoconazole, ritonavir, ketoconazole, grapefruit juice, and other pharmacologic inhibitors of CYP3A may lead to severe toxicity due to reduced hepatic metabolism.^{41, 152, 153} Drugs that induce CYP3A4, such as rifampin, and *Hypericum perforatum* (St. John's wort) should be avoided since they may accelerate the clearance of vinca alkaloids and increase drug exposure.⁵⁰ Concomitantly administered drugs, such as pentobarbital and H₂-histamine antagonists, may also influence VCR clearance by modulating hepatic cytochrome P450 metabolic processes.^{152, 154} It is important to be cognizant that concurrent use of the 3'-azido-3'-deoxythymidine (AZT) and the vinca alkaloids, such as in patients with Kaposi's sarcoma and acquired

immune deficiency syndrome, may result in reduced metabolism of AZT since the vinca alkaloids inhibit glucuronidation of AZT to its 5'-O-glucuronide metabolite.¹⁵⁵ Based on a report of a constellation of severe toxicities, including syndrome of inappropriate antidiuretic hormone secretion (SIADH), bilateral cranial nerve palsies, peripheral neuropathy, cranial nerve palsies, heart failure, and cardiovascular effects following VCR treatment in children with ALL who had been receiving treatment with nifedipine and itraconazole, it is possible that these medications may enhance the neurologic and cardiovascular effects of the vinca alkaloids.¹⁵⁴ Lastly, the significant interindividual and intraindividual variability of VCR pharmacokinetics in children has been attributed to the variable induction of P450 metabolism due to concurrent use of P450-inducing corticosteroids.^{150, 151}

Mitomycin C combined with the vinca alkaloids has been associated with pulmonary toxicity (see sections titled “Toxicity, Miscellaneous”).

Toxicity

The principal toxicities of the vinca alkaloids differ despite their structural and pharmacologic similarities. Neurotoxicity is the predominant toxicity of VCR, whereas myelosuppression predominates with VBL, VDS, VRL, VFL, and VSLI. However, peripheral neurotoxicity is noted after cumulative treatment with VBL, VDS, VRL, VFL, and VSL and in patients who are inherently susceptible.

Neurotoxicity

Although the vinca alkaloids are similar from a structural standpoint, their toxicologic profiles differ significantly. All of the vinca alkaloids induce a characteristic peripheral neurotoxicity, but VCR is most potent in this regard. The neurotoxicity is principally characterized by a peripheral, symmetric mixed sensory motor and autonomic polyneuropathy.^{37, 38, 41, 48, 156–160} The primary pathologic effects are axonal degeneration and decreased axonal transport, most likely caused by a drug-induced perturbation of microtubule function. At onset, only symmetric sensory impairment and paresthesia in a length-dependent manner, initially in the distal extremities, are often encountered. Neuritic pain and loss of deep tendon reflexes may develop with continued treatment, which may be followed by foot drop, wrist drop, motor dysfunction, ataxia, and paralysis. Back, bone, and limb pains may occur. Electrophysiologic studies typically reveal normal nerve conduction velocities; however, diminished amplitude of sensory and motor nerve action potentials and prolonged distal latencies, resembling axonal degeneration, may be noted.^{156–160} Rarely, cranial nerves are affected, resulting in hoarseness, diplopia, jaw pain, facial palsies, and laryngeal paralysis.^{38, 161, 162} The uptake of VCR into the brain is low, and the central nervous system effects, such as confusion, mental status changes, depression, hallucinations, agitation, insomnia, seizures, coma, SIADH, and visual disturbances, may occur in rare situations.^{38, 48, 163–165} Auditory effects, possibly secondary to disruption of the medial olivocochlear bundle, have also been reported. Acute, severe autonomic neurotoxicity is uncommon but may arise as a consequence of high-dose therapy (>2 mg/m²) or in patients with diminished drug clearance because of altered hepatic function.^{38, 158–160, 164–169} Toxic manifestations of autonomic neurotoxicity include constipation, abdominal cramps, paralytic ileus, urinary retention, orthostatic hypotension, and hypertension.^{38, 156–159, 166–169} Acute neurotoxic manifestations resembling Guillain-Barré syndrome have also been reported.¹⁶⁰ In adults treated with VCR, the neurotoxic effects may begin with cumulative doses as little as 5–6 mg, and manifestations may be cumulative doses of 15–20 mg. Neurotoxic manifestations are generally cumulative and resolve slowly after treatment, often requiring many years. Neurotoxicity occasionally worsens for a short time following treatment.¹⁷⁰ Although it has been remarked that children are less susceptible to neurotoxicity than adults

and that the elderly are particularly prone, these apparent age-related differences may, in fact, be caused by previously inaccurate dose calculation using body weight in children and adults and using body surface area in infants. In infants, VCR doses are calculated now according to body weight, which may be more accurate from a pharmacologic standpoint because of ubiquitous tissue distribution. Patients with antecedent neurologic disorders, such as Charcot–Marie–Tooth disease, hereditary and sensory neuropathy type 1, Guillain–Barré syndrome, and childhood poliomyelitis, are highly predisposed to neurotoxicity.^{171–173} VCR treatment in patients with hepatic dysfunction or obstructive liver disease is associated with an increased risk of developing neuropathy because of impaired drug metabolism and delayed biliary excretion.^{174, 175} An inherited polymorphism in the promoter region of CEP72, which encodes a centrosomal protein involved in microtubule formation, was associated with increased risk and severity of VCR-related peripheral neuropathy.¹⁷⁶ If replicated in additional populations, this finding may provide a basis for safer dosing of this widely prescribed anticancer agent.

The only known effective intervention for vinca alkaloid neurotoxicity is discontinuing treatment or reduction of the dose or frequency of drug administration.^{166, 176, 177} Although several antidotes, including thiamine, vitamin B12, folinic acid, pyridoxine, and neuroactive agents (e.g., sedatives, tranquilizers, anticonvulsants), have been used, these treatments have not been undoubtedly shown to be consistently effective.^{38, 127, 178–180} Folinic acid protects mice against otherwise lethal doses of the vinca alkaloids, and there are anecdotal reports of its successful use following VCR overdose in man; however, prospective studies have never been performed. Suggested dosages for folinic acid for the treatment of overdose are 15 mg every 3 h for 24 h and then every 6 h for at least 48 h.³⁸ There have been promising results with other neuroprotective agents. In one randomized double-blind trial, coadministration of glutamic acid and VCR appeared to reduce neurotoxicity.¹⁸⁰ An adrenocorticotropin analog (ORG 2766) also demonstrated protection against VCR-induced neuropathy in an animal model and in a double-blind, placebo-controlled pilot study in patients.³⁸ Several other agents, including nerve growth factor, insulin growth factor-1, and amifostine, appear to alter the course of neurotoxicity in experimental models, but there is no definitive evidence that these agents may be effective in the clinic. Severe neurotoxicity is observed less frequently with VBL, VDS, VRL, and VFL, as compared with VCR.^{114, 181} VRL has a lower affinity for axonal microtubules than either VCR or VBL, which seems to be confirmed by clinical observations.^{36, 38, 48, 114, 181} Characteristic vinca alkaloid neurotoxicity occurs with VSLI, but the agent has largely been evaluated in patients who have previously received VCR, and the relative neurotoxic effects of VCR and VSLI have not been studied.

Myelosuppression

Neutropenia is the principal dose-limiting toxicity of VBL, VDS, VRL, and VFL. It is also common with VSLI. Thrombocytopenia and anemia are usually less common and less severe. The onset of neutropenia is usually 7–11 days after treatment, and recovery is generally by days 14–21. Myelosuppression is not typically cumulative. Although VCR is rarely associated with hematologic toxicity, severe myelosuppression has been observed in situations, resulting in increased drug exposure, such as following inadvertent overdose, and hepatic insufficiency.

Gastrointestinal

Gastrointestinal toxicities, aside from those caused by autonomic dysfunction, may also occur.^{37, 38, 41, 48, 127, 182, 183} Gastrointestinal autonomic dysfunction, as manifested by bloating, constipation, and abdominal pain, occurs most commonly with VCR, high doses of the other vinca alkaloids, or settings associated

with high drug exposure (e.g., hepatic dysfunction, overdosages). An initial manifestation of autonomic dysfunction due to slow intestinal transit may be impaction of stool in the upper colon. An empty rectum may be noted on digital examination, or an abdominal radiograph may be useful in diagnosing this condition, which may be responsive to high enemas and laxatives. A routine prophylactic regimen to prevent constipation is therefore recommended for all patients receiving VCR. Severe autonomic toxicity may lead to paralytic ileus, intestinal necrosis, and even intestinal perforation. The ileus, which may mimic a “surgical abdomen,” usually resolves slowly with conservative measures after termination of treatment. Patients who receive high dosages of VCR or have hepatic dysfunction may be especially prone to develop severe gastrointestinal complications due to autonomic neurotoxicity. Although success with drugs used prophylactically to minimize toxicity, including lactulose, cerulein, metoclopramide, and a cholecystokin analog (sincalide), has been reported anecdotally, these agents also may alter the pharmacokinetic behavior of the vinca alkaloids by affecting biliary excretion and/or enterohepatic recirculation, which may ultimately result in increased drug clearance.³⁸

Mucositis, stomatitis, and pharyngitis occur more frequently with VBL than VCR, but not uncommon with VFL, VRL, and VDS. Nausea, vomiting, and diarrhea may also occur to a lesser extent. Asymptomatic and brief elevations in serum levels of hepatic transaminases and alkaline phosphatase have been noted. Pancreatitis has also been reported rarely with VRL.¹⁸²

Miscellaneous

All vinca alkaloids should be considered potent vesicants and may cause profound tissue damage if extravasation occurs. This warning should apply to VSLI as there is no evidence that the formulation protects against tissue damage if extravasation occurs. If extravasation is suspected, treatment should be discontinued immediately and aspiration of any residual drug remaining in the tissues should be attempted.^{38, 184–189} In experimental studies, cold packs have been shown to increase toxicity, while heat appears to limit damage. The application of local heat immediately for 1 h four times daily for 3–5 days and the injection of hyaluronidase, 150–1500 units (15 units/mL in 6 mL of 0.9% sodium chloride solution) subcutaneously, through 6 clockwise injections in a circumferential manner using a 25-gauge needle and changing the needle with each injection) into surrounding tissues are the treatment of choice in minimizing both discomfort and latent cellulitis.^{187–189} The use of leucovorin, diphenhydramine, hydrocortisone, isoproterenol, sodium bicarbonate, and vitamin A cream has been ineffective in animal models.¹⁸⁵ An immediate surgical consultation to consider early debridement is recommended. Discomfort and signs of phlebitis may also occur along the course of an injected vein, with resultant sclerosis, but phlebitis may be minimized if the vein is adequately flushed after treatment.

Mild and reversible alopecia occurs in approximately 10% and 20% of patients treated with VRL and VCR, respectively. Acute cardiac ischemia, chest pains without evidence of ischemia, fever without an obvious source, Raynaud's phenomenon, and palmar–plantar erythrodysesthesia (hand–foot syndrome) have also been reported.^{190–192} Respiratory reactions, characterized by dyspnea, is noted in approximately 5% of patients, particularly when the vinca alkaloids are combined with mitomycin C.^{193, 194} The onset of pulmonary toxicity may be acute, with bronchospasm and dyspnea as the predominant manifestations, resembling an allergic reaction. The second type of toxicity is a subacute reversible reaction associated with cough and dyspnea and occasionally with interstitial infiltrates. It typically occurs within 1 h of treatment. Corticosteroids may be beneficial in severe cases, and several patients have been re-treated without complications. There is no clear evidence that implicates VRL as a cause of chronic pulmonary toxicity.

All vinca alkaloids have been implicated in causing SIADH, and patients receiving vigorous hydration are particularly prone to severe hyponatremia due to SIADH.^{36–38, 48, 127} Plasma levels of antidiuretic hormone, which generally remit within 3 days' posttreatment, have been noted. Hyponatremia generally responds to fluid restriction. VBL may cause photosensitivity reactions, possibly due to corneal irritation, and muscular effects.¹⁹⁵ The inadvertent intrathecal administration of the vinca alkaloids causes an ascending myeloencephalopathy that is usually fatal. Reports of immediate cerebrospinal fluid withdrawal and lavage with Ringer's lactate solution supplemented with fresh frozen plasma (15 mL/L) at a rate of 55 mL/h for 24 h have provided encouraging results, with two affected patients surviving with paraplegia, albeit intact cerebral function.¹⁹⁶ To prevent this error, intrathecal methotrexate and intravenous VCR setting should not be administered in close temporal proximity, and the drugs should not be delivered together to staff.¹⁹⁷ Hepatic transaminase elevations have also been reported, particularly with VSLI.

Administration, dose, and schedule

It is recommended that the vinca alkaloids be administered by rapid intravenous injection. Inadequate flushing following treatment may increase the risk of phlebitis and injection site reactions, and, therefore, the catheter should not be removed before the vein is flushed. VCR is commonly administered to children weighing more than 10 kg as a bolus intravenous injection at a dosage of 1.5–2.0 mg/m² weekly, although 0.05–0.65 mg/kg weekly is commonly used in smaller children. For adults, the conventional weekly dose is 1.4–2.0 mg/m². A restriction of the absolute dose of VCR to 2.0–2.5 mg in children and 2.0 mg in adults, which is often referred to as “capping,” has been generally adopted based on early reports of gastrointestinal toxicity (autonomic neuropathy) in patients treated at higher doses. However, there is little factual evidence to support this practice, and available evidence suggests that it should be reconsidered, particularly in light of the wide interpatient variability in pharmacokinetic behavior and tolerance. There is significant interpatient variability in the clearance of VCR (up to 11-fold), and some patients are able to tolerate much higher doses with little or no toxicity. Moreover, the safety and efficacy of treatment regimens that do not employ capping at 2.0 mg have been documented in adults.¹⁹⁸ In any case, doses should not be reduced for mild peripheral neurotoxicity, particularly if VCR is being used in a potentially curative setting. Instead, doses should be modified for manifestations of more serious neurotoxicity, including severe symptomatic sensory changes, motor and cranial nerve deficits, and ileus, until toxicity resolves. In clearly palliative situations, dose reductions, lengthening dosing intervals, or selecting an alternative agent may be justified in the event of moderate neurotoxicity. A routine regimen to prevent serious consequences of severe autonomic toxicity, particularly constipation, is also recommended.

The recommended dose of VSLI is 2.25 mg/m² intravenously every 7 days. VSLI is prepared by mixing three components from a kit supplied by the manufacturer, which includes VCR sulfate, sodium phosphate, and sphingomyelin/cholesterol liposome injection. Following the manufacturer's procedure, VSLI should appear as a white to off-white, translucent suspension, essentially free of visible foreign matter and aggregates, comprised of sphingomyelin/cholesterol liposomes, with an approximate liposome mean diameter of 100 nm. Greater than 95% of the drug is encapsulated in the liposome. The procedure results in a solution that is diluted with either 5% dextrose injection or 0.9% sodium chloride injection to a final volume of 100 mL that is infused intravenously over 1 h.

The most common VBL schedule in chemotherapy regimens is a rapid intravenous injection at a dose of 6 mg/m² weekly. Approved weekly dosing recommendations are 2.5 and 3.7 mg/m² for children and adults, respectively, followed by gradual escalation in increments of 1.8 and 1.25 mg/m² weekly based on

hematologic tolerance. It is recommended that weekly VBL doses of 18.5 mg/m² in adults and 12.5 mg/m² in children not be exceeded as a single agent; however, these doses are much higher than most patients can tolerate because of myelosuppression, even on less frequent administration schedules. Because the severity of leukopenia that may occur with identical VBL doses varies widely, VBL should probably not be given more frequently than once each week. Five-day continuous infusions of VBL have been used at dosages ranging from 1.5 to 2.0 mg/m² per day, which achieves biologically relevant plasma concentrations of approximately 2.0 nmol/L, but the overall advantages of using protracted infusions for a drug that is widely distributed and avidly bound to peripheral tissues are unclear.

VRL is usually administered at a dosage of 30 mg/m² on a weekly or biweekly schedule as a 6–10-min intravenous injection through a side-arm port into a running infusion (alternatively, a slow bolus injection followed by flushing the vein with 5% dextrose or 0.9% sodium chloride solutions) or as a short infusion over 20 min. It appears that more rapid infusions are associated with less local venous toxicity. Oral dosages of 80–100 mg/m² given weekly are generally well tolerated, but an acceptable oral formulation has not been approved. Other dosing schedules that have been evaluated include chronic oral administration of low doses, intermittent high doses, and prolonged intravenous infusion schedules.

The recommended dose of VLF is 320 mg/m² as a 20-min intravenous infusion every 3 weeks. A reduced dose of 280 mg/m² is recommended for patients with World Health Organization or Eastern Cooperative Oncology Group performance status of 1 or 0 and a history of pelvic irradiation. In the absence of hematological toxicity in the first cycle causing treatment delay or dose reduction, the dose should be increased to 320 mg/m² for the subsequent cycles.

Because of their remarkable vesicant properties, the vinca alkaloids should not be administered intramuscularly, subcutaneously, intravesically, or intraperitoneally. Direct intrathecal injection of VCR and other vinca alkaloids inadvertently has induced a severe myeloencephalopathy characterized by ascending motor and sensory neuropathies, encephalopathy, and death (see sections titled “Toxicity, Neurotoxicity”).

Although specific dosing guidelines for patients with hepatic dysfunction have not been thoroughly formulated, the major role of the liver in the disposition of the vinca alkaloids implies that dose modifications should be considered for patients with hepatic dysfunction, particularly hepatic excretory dysfunction. For VCR, VRL, VDS, and VBL, a 50% dose reduction is often recommended for patients with total bilirubin levels between 1.5 and 3.0 mg/dL (50% dose reduction for bilirubin levels between 2.0 and 3.0 mg/dL is recommended for VRL), as well as at least a 75% dose reduction for plasma total bilirubin levels above 3.0 mg/dL. Dosing guidelines for patients with hepatic dysfunction have not been formulated, and therefore conservative measures, perhaps similar to the aforementioned guidelines for nonencapsulated vinca alkaloids, may be prudent since hepatic metabolism and biliary excretion are the principal processes involved with the disposition of VSLI. However, the pharmacokinetics of VSLI were evaluated in patients with moderate hepatic dysfunction (Child–Pugh B) and the dose-adjusted maximum plasma concentration and exposure were comparable to those with normal hepatic function.⁴⁹ The recommended doses of VFL are 250 and 200 mg/m² given once every 3 weeks for patients with mild (Child–Pugh grade A) and moderate (Child–Pugh grade B) liver impairment, respectively, as defined further in the prescribing information.

Dose reduction for renal impairment is not indicated for any of the vinca alkaloids except for VFL in which the recommended starting doses are 280 and 250 mg/m² every 3 weeks for patients with moderate (creatinine clearance rate between 40 and 60 mL/min) and severe (creatinine clearance rate between 20 and 40 mL/min) renal impairment, respectively.⁵³

VFL dose reductions are also recommended for elderly patients since drug clearance relates to age. In patients whose ages are between 75 and 80 years and for patients whose age exceeds 80 years, the recommended dose is 280 and 250 mg/m² every 3 weeks, respectively.⁵³

Taxanes: Introduction and indications

Although the taxanes affect microtubules, their principal mechanisms of action, pharmacology, clinical indications, and toxicities substantially differ from those of the vinca alkaloids. Interest in the taxanes began in 1963, when a crude extract of the bark of the Pacific yew tree, *Taxus brevifolia*, demonstrated notable anticancer activity in preclinical studies. In 1971, Wall and colleagues identified paclitaxel as the active constituent of the bark extract; however, the limited supply of its primary source that was exclusively derived from the Pacific yew tree, the difficulties inherent in large-scale isolation, extraction, and preparation of bulk compound, and its poor aqueous solubility delayed its development.¹⁹⁹ Interest was maintained after characterization of its novel mechanism of action and the availability of an adequate supply for requisite preclinical and limited clinical studies. The early search for taxanes derived from more abundant and renewable resources led to the semisynthesis of docetaxel by the addition of a side chain to 10-deacetylbaccatin III, an inactive taxane precursor found in the needles and other components of more abundant yew species.²⁰⁰ The supply of paclitaxel is no longer preclusive due to the development of commercially feasible semisynthetic processes. A wide variety of taxane analogs, as well as paclitaxel formulations, have been evaluated. The most recent to be broadly registered is protein-bound paclitaxel particles for injection (PBPPi), sometimes called “nab-paclitaxel” or nanoparticle albumin-bound paclitaxel, which is an albumin-bound formulation of paclitaxel.²⁰¹

[Figure 3](#) shows the structures of paclitaxel, docetaxel, and cabazitaxel, which are complex esters consisting of a 15-member taxane ring system linked to an unusual 4-member oxetane ring. The taxane rings of both paclitaxel and docetaxel, but not 10-deacetylbaccatin III, are linked to an ester side chain attached to the C-13 position of the ring, which is essential for antimicrotubule activity.²⁰² The structures of paclitaxel and docetaxel differ in substitutions at the C-10 taxane ring position and on the ester side chain attached at C-13, which render docetaxel slightly more water soluble and potent than paclitaxel. However, the clinical ramifications of these differences are not entirely clear. Another more recent addition to the therapeutic armamentarium is cabazitaxel, a dimethoxy derivative of docetaxel that is partially synthesized into a single diastereomer from 10-deacetylbaccatin III.²⁰³ Cabazitaxel is more potent and has lower substrate affinity for Pgp and other transmembrane drug efflux pumps than docetaxel, which, in part, explain its notable activity in docetaxel-resistant cancers.²⁰⁴

Clinical indications

Paclitaxel initially received regulatory approval in the United States and elsewhere for the treatment of patients with ovarian cancer after failure of first-line or subsequent chemotherapy. Its use in combination with a platinum compound as primary induction therapy in suboptimally debulked stages III or IV ovarian cancer has demonstrated a survival advantage over preexisting standard therapy in randomized phase III studies.²⁰⁵ In the United States, paclitaxel is also indicated for treatment of patients with metastatic breast cancer after failure of combination chemotherapy for metastatic disease or at relapse within 6 months of adjuvant chemotherapy, with prior therapy that includes an anthracycline.²⁰⁶ Paclitaxel is also indicated for the adjuvant treatment of node-positive breast cancer administered sequentially to standard doxorubicin-containing combination chemotherapy. In the clinical trial, there was an overall favorable effect on disease-free and overall survival in the total population of patients with both hormone receptor-positive and hormone receptor-negative tumors, but the benefit has been irrefutably demonstrated only in patients with hormone receptor-negative cancers.^{207–209} Compelling results have been noted following treatment of patients with both metastatic breast cancer and high-risk early-stage breast cancer with alternative taxane-containing regimens, particularly “dose-dense” and weekly regimens; however, these efficacy results should not be generalized to other indications and/or other taxanes.^{210, 211} Weekly administration schedules using paclitaxel and other taxanes have been associated with lower incidences of some adverse effects, particularly myelosuppression, compared to less frequent dosing schedules.

Various therapeutics received regulatory approval as components of paclitaxel-based combination regimens. The combination of gemcitabine and paclitaxel demonstrated superior survival to paclitaxel alone in the first-line treatment of metastatic breast cancer, and gemcitabine received regulatory approval for use with paclitaxel in this setting. Similarly, the combination of trastuzumab and paclitaxel is indicated in the first-line treatment of women with HER-2-amplified metastatic breast cancer.²¹² Paclitaxel is also indicated for adjuvant treatment of HER-2-amplified lymph node positive or negative (hormone receptor negative or with at least one high-risk feature) as part of a regimen consisting of doxorubicin, cyclophosphamide, and trastuzumab.^{213, 214} Paclitaxel has also received regulatory approval in the United States for second-line treatment of Kaposi's sarcoma associated with the acquired immunodeficiency syndrome and in combination with cisplatin as primary treatment advanced stage IIIB and stage IV nonsmall cell lung cancer patients who are not candidates for radiation therapy or potentially curative surgery.^{215, 216} Bevacizumab, in combination with paclitaxel and carboplatin, is approved for the treatment of stage IIIB and IV nonsquamous nonsmall cell lung cancer.²¹⁷

Docetaxel initially received regulatory approval in the United States and elsewhere for patients with metastatic or locally advanced breast cancer after failure of anthracycline-based chemotherapy, which was later broadened to a more general indication following chemotherapy failure.²⁰⁰ Subsequently, the combination of capecitabine and docetaxel demonstrated superior overall survival over docetaxel alone after failure of an anthracycline in patients with locally advanced or metastatic breast cancer, and capecitabine as a component of this doublet received regulatory approval.²¹⁸ Regulatory approval has also been granted for docetaxel combined with cyclophosphamide and doxorubicin as adjuvant treatment for locally advanced breast cancer.²¹⁹ In nonsmall cell lung cancer, docetaxel initially is approved for treatment of unresectable locally advanced or metastatic disease after demonstrating increased survival after failure of cisplatin-based therapy, and the combination of docetaxel and cisplatin was later granted

regulatory approval as first-line treatment of such patients.²²⁰ Regulatory approval was granted for docetaxel plus prednisone in patients with hormone-refractory prostate cancer as the regimen demonstrated superior overall survival compared to mitoxantrone plus prednisone.²²¹ Similarly, the taxanes have notable activity in the treatment of squamous cell carcinoma of the head and neck, and docetaxel combined with cisplatin and 5-fluorouracil has received regulatory approval in the neoadjuvant treatment of patients with locally advanced disease.²²² Docetaxel combined with cisplatin and 5-fluorouracil is approved for patients with untreated advanced gastric and gastroesophageal junction adenocarcinoma, whereas paclitaxel combined with ramucirumab is indicated for patients with relapsed or refractory disease.^{223, 224}

Cabazitaxel plus prednisone is indicated for treatment of patients with metastatic castrate-resistant prostate cancer previously treated with a docetaxel-containing regimen since the combination showed improved overall survival compared to mitoxantrone plus prednisone in this indication.²²⁵

PBPPI, the newest taxane to receive regulatory approval in the United States and elsewhere, is a formulation of paclitaxel in 3–4% human serum albumin, similar to the concentration of albumin in the blood.²⁰¹ PBPPI was initially approved in patients with metastatic breast cancer after failure of combination chemotherapy for metastatic disease or relapse within 6 months of adjuvant chemotherapy.²²⁶ PBPPI plus carboplatin is indicated in patients with locally advanced or metastatic nonsmall cell lung cancer based on a randomized trial demonstrating that the objective response rates were higher with the regimen compared to paclitaxel plus carboplatin; overall survival was similar.²²⁷ Additionally, PBPPI combined with gemcitabine is indicated in the first-line treatment of metastatic adenocarcinoma of the pancreas, as the regimen demonstrated increased overall survival compared to gemcitabine alone.²⁰¹

It is important to note that the anticancer spectra for paclitaxel, docetaxel, cabazitaxel, and PBPPI are identical, with modest activity noted in many other cancers including endometrial, bladder, small cell lung, and germ cell carcinoma, lymphoma, and melanoma. Differences in clinical efficacy endpoints and regulatory indications between these taxanes may reflect different regulatory strategies, study designs, and dose schedules and not necessarily the inherent superiority of any specific taxane. In contrast to the vinca alkaloids, the taxanes do not seem to have relevant activity in pediatric malignancies.

Mechanisms of action

The binding site for paclitaxel on microtubules is different from the binding sites for exchangeable GTP, colchicine, podophyllotoxin, and the vinca alkaloids. Paclitaxel binds to the N-terminal 31 amino acids of the β -tubulin subunit of tubulin polymers; however, other sites may be involved.^{199, 228–234} Paclitaxel binds in a pocket that is lined by several hydrophobic residues on the luminal side of the microtubule wall, roughly in the middle of the monomer along the protofilament direction.^{3–7, 199, 234, 235} Docetaxel, which most likely shares the same binding site as paclitaxel, appears to have a 1.9-fold higher affinity for the site, and the tubulin assembly process induced by docetaxel proceeds with a critical protein concentration that is 2.1-fold lower than that of paclitaxel.^{233, 236–240} However, it is not clear whether these differences translate into increased therapeutic indices for docetaxel in the clinic since higher potency may result in more severe toxicity at identical drug concentrations. Nevertheless, the results of both preclinical and clinical studies indicate that the taxanes may not be completely cross-resistant in individual tumors, but these results may reflect differences in delivered dose and schedule. Nevertheless, the anticancer spectra of paclitaxel, docetaxel, and other taxanes are nearly identical. Although both the vinca alkaloids and taxanes produce similar disruptive effects on the mitotic spindle apparatus, their

principal mechanisms of action differ. Following binding to the β -tubulin subunit, the taxanes stabilize lateral contacts between microtubule protofilaments by electrostatic interactions.⁷ In effect, this interaction alters the tubulin rate dissociation constants at both ends of the microtubules, reduces the critical tubulin concentration required for microtubule assembly, and promotes both nucleation and elongation of the polymerization reaction, thereby stabilizing microtubules against depolymerization and enhancing polymerization.^{2-7, 55, 239-245}

Binding of the taxanes to polymerized tubulin strengthens the microtubule. At substoichiometric concentrations, the taxanes suppress microtubule dynamics without appreciably increasing the rate of formation of polymerized tubulin.^{2-7, 55, 239-245} At much higher concentrations, which are achieved in the clinic, the taxanes induce both tubulin polymerization and increased microtubule mass. The microtubules of taxane-treated cells are extraordinarily stable, resisting depolymerization by cold, calcium, GTP, and depolymerizing agents like the vinca alkaloids and colchicine. These actions result in the suppression of treadmilling and dynamic instability, which are essential for normal microtubule dynamics during both the mitotic and nonmitotic phases of the cell cycle.^{2, 3, 13, 17, 20} Both stoichiometric and substoichiometric binding of the taxanes inhibit the proliferation of cells, principally by inducing a sustained mitotic block at the metaphase/anaphase boundary; however, morphologic changes, such as microtubule bundle formation during the nonmitotic phases of the cell cycle, suggest that the interphase microtubules are also affected. Nevertheless, perturbations in microtubule dynamics are most relevant during mitotic spindle formation, and therefore cells are most sensitive to the taxanes in mitosis.

Perturbations of mitotic processes and the induction of mitotic arrest by the taxanes trigger apoptosis; however, the precise mechanisms by which these perturbations result in cell death are not entirely clear. Nevertheless, the disruptive effects of the taxanes on the formation of functional mitotic spindle, which is responsible for chromosome segregation, ultimately activates the mitotic checkpoint, the principal cell-cycle control mechanism in mitosis that prevents missegregation of the chromosomes. The mitotic checkpoint delays separation of the chromosomes, which enter mitosis as replicated pairs of sister chromatids, until each pair has made stable attachments to both poles of the mitotic spindle. The taxanes impede attachment of the mitotic spindle to the kinetochores, which activate a signal transduction cascade that delays mitotic progression by inhibiting the anaphase-promoting complex.^{22, 246-248} Paclitaxel-treated cells ultimately enter anaphase and undergo mitosis, but the presence of unattached kinetochores result in the division of chromosomes in multiple directions; chromosome segregation is random due to multipolar division followed by partial cytokinesis failure. The resultant daughter cells are aneuploid, and a portion of these cells die, presumably due to loss of one or more essential chromosomes.

Microtubule perturbations induced by the taxanes trigger a delay in the mitotic checkpoint, which ultimately results in cell death via the intrinsic pathway of apoptosis.^{22, 75, 244-262} This process involves various regulatory constituents such as the tumor suppressor gene TP53, inhibitors of cyclin-dependent kinases (e.g., p21/Waf-1), and regulators of other protein kinases.^{244, 245, 262} As a consequence, cells are arrested in G₂/M, after which time they either undergo apoptosis or traverse through G₂/M and ultimately divide.^{248, 259} The apoptotic initiating events include activation of the proapoptotic molecules Bax and Bad, as well as inactivation of the antiapoptotic regulators Bcl-2 and Bcl_xL.^{248, 259-261} Various kinases have been implicated in the inactivation of Bcl-2 induced by the taxanes and other antimicrotubule agents, including Jun N-terminal kinase and its proapoptotic effectors (e.g., Bim, c-Raf, extracellular signal-regulated kinase 1 and 2, apoptosis signal-regulated kinase, cyclin-dependent kinase 1 (CDK-1), cAMP-dependent protein kinase A, and protein kinase C).^{69, 250, 260-264} Inactivation of Bcl-2 family members and activation of proapoptotic molecules stimulate the intrinsic pathway of apoptosis and downstream

effector caspases.^{257, 259} The taxanes may also induce cell death independent of caspase activation.^{241, 265}

The taxanes also perturb interphase microtubules in nonproliferating cells as manifested by the formation of microtubule bundles.²⁴⁸ Paclitaxel has been reported to induce transcription factors and enzymes that mediate proliferation, apoptosis, and inflammation.^{252, 262, 266, 267} The taxanes also enhance the effects of ionizing radiation *in vitro* and *in vivo*, most likely by inhibiting cell-cycle progression in G₂/M, which is the most radiosensitive phase of the cell cycle.^{268–272} In addition, the taxanes inhibit angiogenesis at concentrations below those that induce cytotoxicity, but the contribution of these antiangiogenic effects to the anticancer effects of the taxanes is not entirely clear.^{258, 273, 274}

Similar to the vinca alkaloids, the taxanes induce many other cellular effects that may or may not relate to their disruptive effects on microtubule dynamics. Although the taxanes primarily block cell-cycle traverse in the mitotic phases, the agents prevent G₀- to S-phase transition.^{260, 275} Explanations that have been proposed to account for the nonmitotic actions of the taxanes include disruptive effects on tubulin in the cell membrane, the interphase cytoskeleton, and microtubules that are involved in growth factor signaling and vascular endothelial growth factor expression through reactive oxygen species production and/or hypoxia inducible factor-1 α .^{38, 276, 277}

The taxanes perturb nonmalignant, as well as malignant, tissues. These effects are mediated, at least, in part, by disrupting microtubule dynamics. Paclitaxel inhibits relevant morphologic and biochemical processes in human neutrophils, including chemotaxis, migration, spreading, polarization, hydrogen peroxide generation, and killing of phagocytized microorganisms.³⁸ Paclitaxel also antagonizes the effects of microtubule-disrupting drugs on lymphocyte function and cAMP metabolism and inhibits the proliferation of stimulated human lymphocytes. Paclitaxel mimics the effects of endotoxic bacterial lipopolysaccharide on macrophages, which results in a rapid decrement in tumor necrosis factor- α (TNF- α) receptors and TNF- α release.^{261, 266, 267} The agent also induces expression of the gene for TNF- α , but these activities are not related to paclitaxel's disruptive effects on microtubule assembly, which suggests that cytokine activation, in part, confers the anticancer activities of the taxanes.²⁶⁶ In addition, paclitaxel inhibits chorioretinal fibroblast proliferation and contractility in models of proliferative retinopathy, as well as neointimal smooth muscle cell proliferation after cardiac and peripheral vascular angioplasty.^{278, 279} Cardiac and femoropopliteal arterial stents coated with paclitaxel to prevent restenosis from proliferation of neointimal tissue received regulatory approval in the United States and elsewhere.^{280, 281} Finally, paclitaxel inhibits secretory functions in many specialized cells, such as insulin secretion in isolated rat islets of Langerhans, protein secretion in rat hepatocytes, and the nicotinic receptor-stimulated release of catecholamines from chromaffin cells of the adrenal medulla.³⁸

Although PBPI likely affects the microtubules' malignant and nonmalignant tissues similar to conventional formulations of paclitaxel, the binding of paclitaxel to albumin in PBPI increases accumulation of paclitaxel molecules in tumor tissue. Albumin has several characteristics that make it an attractive drug vehicle for cancer drugs. It is a natural carrier of endogenous hydrophobic molecules that are bound in a reversible noncovalent manner and facilitates endothelial transcytosis of protein-bound and unbound plasma constituents principally by binding to a 60-kDa glycoprotein (gp60) cell surface receptor. Following binding of albumin to gp60, the complex then interacts with caveolin-1, an intracellular protein, with subsequent formation of transcytotic vesicles (caveolae) that transport the complex to the intracellular compartment. Osteonectin, which is also known as secreted protein acidic and rich in cysteine (SPARC), also binds albumin because of a sequence homology with gp60.^{201, 282–284} Similar to caveolin-1, SPARC is expressed in several malignancies, including breast, lung, and prostate

cancer, as well as by the stroma of these and others, which may account for the intratumoral accumulation of albumin, as well as the accumulation of albumin-bound drugs like PBPI.^{201, 282–284} However, SPARC expression in tumor and/or stroma has yet to be definitely shown to predict for the anticancer activities of PBPI.^{201, 282–286}

PBPI, which was developed as an alternate paclitaxel formulation to polyoxyethylated castor oil, is an albumin-bound, 130-nm particle formulation of paclitaxel, free from any solvent. It is used as a colloidal suspension derived from the lyophilized formulation of paclitaxel and human serum albumin. Human serum albumin stabilizes the drug particle at an average size of 130 nm to prevent capillary obstruction, and the lack of a solvent requires no particular premedication nor infusion system.^{201, 282–284} Further, preclinical studies conducted in athymic mice with human tumor xenografts have shown that PBPI delivers higher paclitaxel concentrations to tumor cells, resulting in greater anticancer activity than equivalent doses of paclitaxel in polyoxyethylated castor oil. SPARC–albumin interactions may also be responsible for more rapid systemic distribution and clearance of paclitaxel than polyoxyethylated castor oil formulations.

Mechanisms of resistance

Two general types of mechanisms of acquired taxane resistance have been described in cells made resistant by prolonged drug treatment at low concentrations. The best characterized mechanism is the MDR phenotype, which can be mediated by several ABC multidrug transporter family members. The most important ABC transporter with respect to conferring taxane resistance is the 170-kDa Pgp efflux pump or the MDR1-encoded gene product MDR1 (ABC subfamily B1; ABCB1) and MDR2 (ABC subfamily ABCB4) (see sections titled “Vinca Alkaloids, Introduction and Indications” and “Vinca Alkaloids, Mechanisms of Resistance”).^{83, 86, 87, 233, 287, 288} In addition, low-level taxane resistance appears to be conferred by the bile salt export pump (BSEP) (also known as ABCC11).^{293, 294} Unlike the vinca alkaloids, ABCC1 (MRP1) and ABCC2 (MRP2) do not appear to be involved in transporting the taxanes.^{289–292} In murine systems, the particular species of Pgp found in paclitaxel-resistant cells is similar, but not identical, to that found in VBL and colchicine-resistant cells derived from the same parental line.^{92, 287, 288} These cells are cross-resistant with many other natural products, and resistance to both paclitaxel and docetaxel conferred by MDR can be reversed by many classes of membrane-active drugs, including the calcium channel blockers, tamoxifen, cyclosporine A, and antiarrhythmic agents.^{287, 291–294} Even the principal component of the formulations of paclitaxel and docetaxel—polyoxyethylated castor oil and polysorbate-80, respectively—can reverse taxane resistance; however, whereas the plasma concentrations of polyoxyethylated castor oil achieved with paclitaxel are sufficient to reverse MDR, sufficient modulatory concentrations of polysorbate-80 are not achieved with docetaxel in the clinic.^{291, 292} In general, strategies aimed at reversing resistance to taxanes and other MDR substrates in the clinic have not been successful, but most have involved MDR modulators that reduce taxane clearance and increase toxicity (e.g., verapamil, cyclosporine A), thereby confounding the interpretation of the inherent effects of these agents on MDR modulation. However, MDR and/or MRP modulators that do not affect taxane clearance and toxicity do not appear to enhance anticancer activity.^{293, 294}

Although the potency of cabazitaxel is similar to that of docetaxel in cancer cell lines and human tumor xenografts sensitive to docetaxel, cabazitaxel retains relevant activity in docetaxel-resistant cancer cell lines and human tumor xenografts that possess the MDR phenotype, which is due to the lower substrate affinity for Pgp. Resistance ratios range from 1.8 to 10 for cabazitaxel compared with 4.8–59 for docetaxel.^{203, 204} The extent to which the differences in Pgp substrate affinity account for cabazitaxel

activity following failure of docetaxel in castrate-resistant prostate cancer is not known.

Similar to the vinca alkaloids, several human cell lines rendered taxane resistant by treatment with high drug concentrations for protracted periods have structurally altered α - and β -tubulins and an impaired ability to polymerize tubulin dimers into microtubules (see sections titled “Vinca Alkaloids, Introduction and Indications” and “Vinca Alkaloids, Mechanisms of Resistance”).^{106, 107, 295–307} These cells lack normal microtubules in their interpolar mitotic spindles and have an inherently slow rate of microtubule assembly when grown in the absence of drug. The continuous presence of the taxanes is required for microtubule assembly to proceed. Furthermore, these mutants are also collaterally sensitive to the vinca alkaloids. In some experimental systems, paclitaxel-resistant cells had mutated β -tubulin alleles, predominately involving β 1-tubulin, with mutations involving the putative taxane binding sites; specifically, leucines at positions 215, 217, and 228 were mutated to histidine, arginine, or phenylalanine.^{297, 299, 300, 306} Low-level expression resulted in drug resistance, whereas high-level expression of these mutations caused impairment of microtubule assembly, cell-cycle arrest, and failure to proliferate, all of which were reversed by incubation with paclitaxel. Even though mutations of tubulin isotype genes, gene amplifications, and isotype switching have been reported in taxane-resistant cell lines, there is little indication that mechanisms are clinically relevant and, if they do occur, they are likely to be rare events.³⁰⁶ In a study that examined paclitaxel-naïve and paclitaxel-resistant samples from nonsmall cell lung cancer and ovarian cancer, ovarian cancer xenografts, and ovarian cancer cell lines, no β I-tubulin mutations were identified.³⁰⁶ However, silent polymorphisms in exon 1 of β I-tubulin were detected at a very low frequency, suggesting that the polymorphisms are not relevant.³⁰⁶

Alterations in tubulin content, tubulin isotype profiles, and tubulin polymerization dynamics confer resistance to the taxanes in preclinical studies, and available evidence indicates that these mechanisms may explain variability responsiveness to the taxanes in the clinic.³⁰⁶ As previously discussed, there are multiple α - and β -tubulin isotypes that are encoded by different genes that are located on different chromosomes and that have tissue- and cell-specific expression patterns. These tubulin isotypes can undergo posttranslational modifications, which can alter the interaction of microtubules with MAPs and change their function. Predictive molecular modeling, which has been used to examine how the affinity of tubulin-binding agents for different β -tubulin isotypes varies, may explain differential sensitivity. For example, paclitaxel is thought to diffuse through nanopores in the microtubule to reach its binding site on the interior-facing lumen of the microtubule. It has been predicted that this movement is mediated by the formation of a hydrogen bond that involves serine 275 in all β -tubulin isotypes, except β II- and β VI-tubulin.³⁰⁶ Paclitaxel-resistant tumors have been shown to have high levels of class I, III, and IVa isotypes of β -tubulin.^{20, 100–107, 295–306, 308, 309} High intratumoral levels of the β III-tubulin isotype, which is a minor component of cellular β -tubulin, increases dynamic instability, and impedes microtubule assembly, have been identified in cell lines with acquired taxane resistance, as well as in taxane-resistant tumors sampled from patients.^{100–106, 298–307, 310–322} The absence of β III-tubulin is associated with more rapid rates of microtubule assembly *in vitro*, whereas overexpression is associated with a decreased rate of microtubule assembly.³¹⁶

The differential functional aspects of the various tubulin isotypes have not been fully elucidated, and the many posttranslational modifications that tubulins undergo add another layer of complexity. Pro- and antiapoptotic proteins, including the TP53 and Bcl2, are tethered or transported by microtubules. The induction of apoptosis by antimicrotubule agents is mediated through the intrinsic apoptotic pathway, principally by Bcl2 family members.^{23, 306, 317, 318} The proapoptotic protein Bim is tethered to microtubules, and, after treatment with paclitaxel, Bim translocates from microtubules to mitochondria.^{306,}

³¹⁹ Cancer cell lines with high Bim expression are more susceptible to the cytotoxic effects of the taxanes than cells with low expression. How differential expression of β -tubulin isotypes or posttranslational modifications affect the ability of antimicrotubule agents to bind, transport, and release of factors that induce apoptosis is not entirely clear; however, the expression of specific β -tubulin isotypes and MAPs has been related to drug resistance in a range of cancers, including lung, ovarian, breast, and prostate cancers.^{20, 100–107, 295–306, 308, 309}

Aberrant proliferative signaling may contribute to taxane resistance by raising the cell's threshold for taxane-induced apoptosis. Insulin-like growth factor-1, for example, appears to protect responsive breast cancer cell lines from the cytotoxic effects of the anthracyclines and taxanes, possibly by activating the phosphatidylinositol 3-kinase pathway and inducing inactivation of antiapoptotic factors.³²⁰ Other mediators that may influence the cell's threshold for drug-induced apoptosis include TP53, HER-2, aurora 2-kinase, survivin, and BRAC1. The centromere-associated serine/threonine kinase, aurora 2-kinase, which is involved in centrosome, biopolar spindle formation, and chromosomal kinetochore attachment to the mitotic spindle separation (see section titled “Targeting Mitotic Motor Proteins and Kinases”), appears to override the mitotic assembly checkpoint and induce taxane resistance.^{21, 22, 306} Also, overexpression of survivin, a member of the inhibitor of apoptosis family of proteins, inhibits caspase activity and apoptosis induced by antimicrotubule agents. The disruption of the tumor suppressor gene, BRAC1, which maintains genomic stability through DNA repair and appears to be involved in hereditary breast and ovarian cancers, appears to play a role in conferring resistance to paclitaxel, and the inducible expression of BRAC1 may enhance apoptosis induced by paclitaxel.^{306, 321} The mutational loss of the TP53 tumor suppressor does not appear to confer resistance to microtubule-polymerizing agents in contrast to DNA-disruptive agents.³⁰⁶

MAPs play a role in resistance by impeding apoptosis following treatment with the taxanes and other antimicrotubule agents. For example, tau and MAP2, which are principally expressed in neuronal tissues, as well as the principal nonneuronal MAP, MAP4, bind to and stabilizes microtubules against depolymerization.²⁸ Tau expression relates to paclitaxel resistance in breast cancer, which seems to be through steric hindrance as tau masks the outer microtubule wall and limits access of paclitaxel to the inner luminal surface of the microtubule.^{316, 322} MAP4 confers microtubule stability, and induction of TP53 leads to decreased MAP4, resulting in reduced sensitivity to paclitaxel, albeit increased sensitivity to VBL.^{323, 324}

The microtubule-sequestering protein stathmin, which is overexpressed in several hematologic and solid malignancies, is a major cytosolic phosphoprotein that regulates the mitotic spindle by binding to tubulin heterodimers and inducing microtubule destabilization. Overexpression of stathmin decreases breast cancer cell sensitivity to paclitaxel and VBL.³⁰⁶ High stathmin expression has also been associated with an unfavorable prognosis in patients with epithelial ovarian cancer treated with paclitaxel and cisplatin.^{295, 306} Finally, alterations in other cytoskeletal components, particularly reduced γ -actin and regulators of γ -actin, have been related to resistance to antimicrotubule agents.³⁰⁶

Transfection of cells with HER-2, a member of the epidermal growth factor receptor family that is amplified in approximately 30% of breast cancers, increases taxane resistance, and high expression of HER-2 relates to taxane resistance *in vitro*.^{325, 326} Overexpression of HER-2 can also inhibit CDK1 by either inducing p21, which participates in the G2/M checkpoint and contributes to resistance to apoptosis induced by antimicrotubule agents, or directly phosphorylating (inactivating) CDK1, which may block taxane-mediated entry into mitosis and apoptosis. Consistent with this relationship, downregulation of HER-2 by the anti-HER-2 antibody trastuzumab sensitizes breast cancer cells to the taxanes, and the

combination of trastuzumab and either paclitaxel or docetaxel is associated with increased survival compared with the taxanes alone.^{325, 326} Nevertheless, the presence of amplified HER-2 does not adversely influence response to first-line paclitaxel-containing chemotherapy.²¹² In one study, the expression and/or amplification of HER-2 related to benefit is derived from the addition of paclitaxel after adjuvant treatment with doxorubicin plus cyclophosphamide in lymph node-positive breast cancer regardless of estrogen-receptor status, whereas women with HER-2-negative disease derived little, if any, benefit.²¹²

Clinical pharmacology

General

The taxanes are most commonly administered intravenously at every 3-week intervals at dosages ranging from 175 to 225 mg/m² over 3 h (paclitaxel), 75 to 100 mg/m² over 1 h (docetaxel), 260 mg/m² over 30–40 min (PBPI), or 25 mg/m² (cabazitaxel), but other schedules, particularly weekly schedules, are commonly used (see section titled “Administration, Dose, and Schedule”). PBPI is registered at a dose of either 100 or 125 mg/m² on days 1, 8, and 15 of an every 21- or 28-day schedule, respectively, for treating patients with nonsmall cell lung cancer (with carboplatin) or pancreatic cancer (with gemcitabine) in the first-line metastatic setting. For the most part, the oral bioavailability of the taxanes is poor and erratic, which is due, in part, to the constitutive overexpression of Pgp and P-450 metabolizing capability of enterocytes and/or first-pass metabolism. As shown in [Table 2](#), the taxanes share the following pharmacologic characteristics: large Vd, rapid and avid binding to all tissues except for the unperturbed central nervous system, long terminal half-lives and substantial hepatic metabolism, biliary excretion, and fecal elimination. Cabazitaxel differs in some respects, particularly its ability to penetrate the blood–brain barrier, which may be explained by its reduced substrate affinity for Pgp.

Table 2 Taxanes: comparative pharmacokinetic and toxicologic characteristics

Parameter	Paclitaxel	PBPPI	Docetaxel	Cabazitaxel
Standard adult dose				
Range (mg/m ² /3 week)	175–225 (3-h infusion)	260 (30-min infusion)	75–100 (1-h infusion)	25 (1-h infusion)
(mg/m ² /week)	80	100–125 (× 3 weeks every 4 weeks) ^b	30–36	
Pharmacokinetic behavior (clinically relevant doses)	Triphasic	Biphasic	Triphasic	Triphasic
Dose-proportional pharmacokinetics	Saturable taxane elimination and distribution; pseudononlinearity due to vehicle	Dose proportional to 360 mg/m ²	Dose proportional to 115 mg/m ²	Dose proportional to 30 mg/m ²
Plasma half-life (terminal phase)	10–20 h	27 h	10–20 h	95 h
Clearance	20–25 L/h ^a	15 L/h/m ²	36 L/h	48.5 L/h
Primary route	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination
Principal toxicity	Neutropenia	Neutropenia	Neutropenia	Neutropenia
Other toxicities	Alopecia, neurotoxicity, myalgia, arthralgia, hypersensitivity reactions, asthenia	Alopecia, neurotoxicity, arthralgia, hypersensitivity reactions, nausea, vomiting, diarrhea, skin	Alopecia, skin and nail toxicity, asthenia, myalgia, arthralgia, fluid retention, neurotoxicity, hypersensitivity reactions	Diarrhea, fatigue, asthenia, nausea, vomiting, neurotoxicity, constipation, alopecia, skin and nail toxicity, hypersensitivity reactions, arthralgia

^a 175 mg/m² over 3 h (dose schedule).

^b 100 or 125 mg/m²/weekly × 3 weeks every 4 weeks combined with gemcitabine (pancreatic cancer) or carboplatin (nonsmall cell lung cancer), respectively.

Paclitaxel

Paclitaxel's pharmacokinetic behavior is nonlinear or pseudononlinear.^{292, 327–329} Nonlinear behavior is more apparent with shorter infusions that result in higher plasma paclitaxel concentrations and more

effective saturation of both drug elimination and tissue distribution processes. Both saturable distribution and elimination processes are, in part, responsible for paclitaxel's nonlinear behavior, with tissue distribution becoming effectively saturated at lower drug concentrations (achieved with paclitaxel dosages of $<175 \text{ mg/m}^2$ over 3 h) as compared with elimination processes that are saturated at higher concentrations (achieved with paclitaxel dosages $>175 \text{ mg/m}^2$ over 3 h). A potential ramification of true nonlinearity is that dose escalation may result in a disproportionate increase in drug exposure and toxicity, whereas dose reduction may result in a disproportionate reduction in drug exposure. However, the range of effective doses is relatively broad. Further, the use of shorter infusion schedules also results in higher plasma concentrations of paclitaxel's polyoxyethylated castor oil vehicle, which may simulate nonlinearity (pseudononlinearity) by binding paclitaxel and inhibiting drug distribution and clearance.^{330, 331}

The pharmacologic behavior of paclitaxel in plasma has been modeled as either triphasic or biphasic. The initial rapid decline represents distribution to the peripheral compartment and elimination of the drug. The later phase is due, in part, to a relatively slow efflux of paclitaxel from the peripheral compartment. Its V_d is much larger than the volume of total body water, indicating extensive drug binding to plasma proteins or other tissue elements, most likely tubulin, which is ubiquitous. Plasma protein binding is reversible and ranges from 89% to 98%.²⁹² Albumin and α_1 -acid glycoprotein contribute nearly equally to drug binding with a minor contribution from lipoproteins.^{332–334} None of the drugs that are commonly administered with paclitaxel, including ranitidine, dexamethasone, diphenhydramine, doxorubicin, 5-fluorouracil, and cisplatin, significantly alter protein binding.³³⁴ Drug binding to tubulin-rich platelets is extensive and saturable, and animal distribution studies with radiolabeled paclitaxel indicate extensive uptake and retention by virtually all tissues except for normal sanctuary sites such as the brain and testes, possibly due to xenobiotic efflux pumps in these tissues.^{335, 336}

Clearance is closely related to body surface area, providing a rationale for dosing based on this parameter. In humans, peak plasma concentrations achieved with 3- to 96-h schedules (more than $0.05\text{--}10 \text{ }\mu\text{mol/L}$) and drug concentrations in third-space fluid collections such as ascites ($>0.1 \text{ }\mu\text{mol/L}$), are capable of inducing relevant biologic effects *in vitro*, but drug penetration into the unperturbed central nervous system is negligible.^{292, 337, 338} The principal mode of paclitaxel disposition is hepatic metabolism and biliary excretion. The liver metabolizes and excretes both paclitaxel and paclitaxel metabolites into the bile, which is eliminated in the feces.^{292, 336, 339–344} In rats treated with radiolabeled paclitaxel, 98% of radioactivity is recovered from feces collected for 6 days, and approximately 71% of an administered dose of paclitaxel is excreted in the feces over 5 days as either parent compound or metabolites in humans, with 6α -hydroxypaclitaxel being the largest component, accounting for 26% of the dose; unmetabolized paclitaxel accounts for only 5% of the dose. Renal clearance of paclitaxel and metabolites may account for up to 14% of the administered dose.²⁹² In humans, cytochrome P450 mixed-function oxidases are responsible for the bulk of drug disposition, specifically the isoenzymes CYP2C8 and CYP3A4, which metabolize paclitaxel to 6α -hydroxypaclitaxel and another hydroxylated metabolite, both of which are much less active than paclitaxel *in vivo*, possibly due to their greater polarity which precludes intracellular uptake.^{292, 336, 339–342} There is considerable interindividual variability in paclitaxel metabolism that can be attributed to pharmacogenetic differences in P450 metabolism and concurrent medications that alter metabolism.^{292, 341–344}

Pharmacodynamic analyses demonstrate that drug exposure relates to the principal toxicities of paclitaxel, the most important and consistent of which is the relationship between neutropenia and the duration of drug exposure above biologically relevant plasma concentrations ranging from 0.05 to $0.1 \text{ }\mu\text{mol/L}$.^{292, 345} A prospective analysis of pharmacokinetic determinants of outcome in several hundred patients with

advanced nonsmall cell lung cancer treated with the combination of cisplatin and paclitaxel at either 135 or 250 mg/m² over 24 h demonstrated that the magnitude of the steady-state plasma paclitaxel concentration relates to neither objective response, disease-free survival, nor overall survival.³⁴⁵

Docetaxel

The pharmacokinetics of docetaxel (1-h schedule) in plasma are similar to that of paclitaxel. Docetaxel is cleared from plasma in a triphasic manner and linear at doses of 115 mg/m² or less.^{200, 346–351} The distribution phases are rapid (α - and β -phase $t_{1/2}$ values of 4 and 36 min, respectively), and the terminal half-life is long ($t_{1/2\gamma}$ range, 11.1 to 18.5 h in one study) for the same reasons as discussed earlier for paclitaxel. In one population study, plasma concentration data revealed triphasic pharmacokinetics and the following pharmacokinetic parameters: $t_{1/2\gamma}$ of 12.4 h, clearance of 21 L/h/m², and steady-state Vd of 74 L/m².^{200, 346–351} The most important determinants of docetaxel clearance were body surface area, hepatic function, and plasma α 1-acid glycoprotein concentration, whereas age and plasma albumin level had significant, albeit minor, influences on clearance. Like paclitaxel, plasma protein binding is high (>80–97%), and binding is primarily to α 1-acid glycoprotein, albumin, and lipoproteins.^{352, 353} Like paclitaxel, docetaxel is widely distributed to peripheral tissues and released slowly, but the agent does not enter “sanctuary sites” laden with Pgp efflux pump barriers such as the unperturbed central nervous system. In both dogs and mice treated with radiolabeled drug, fecal excretion accounts for 70–80% of total radioactivity, whereas urinary excretion accounts for 10% or less. In limited human studies in which cancer patients were administered radiolabeled docetaxel, about 6% and 75% of the administered radioactivity was excreted in the urine and feces, respectively, over 7 days. Approximately 80% of radioactivity excreted in the feces occurs during the first 48 h as one major and three minor metabolites, with very small amounts (<8%) consisting of unchanged docetaxel. The hepatic cytochrome P450 mixed-function oxidases, particularly CYP3A, the activity of which, in adults, is represented by the combined activities of CYP3A4, CYP3A5, CYP3A7, and CYP3A43, is responsible for most of docetaxel's metabolism.^{354–356} In contrast to paclitaxel, the C-13 side chain, instead of the taxane ring, is metabolized.^{354–357} These metabolites are much less active than docetaxel.

The principal pharmacokinetic determinants of toxicity, particularly neutropenia, are drug exposure and the time that plasma concentrations exceed biologically relevant concentrations.³⁵¹ A population pharmacodynamic analysis of determinants of outcome in phase II trials of docetaxel revealed that the most important determinants of the time to progression in patients with metastatic breast cancer are the pretreatment plasma concentration of α 1-acid glycoprotein, number of prior chemotherapy regimens, and number of disease sites, whereas both drug exposure and the pretreatment plasma concentration of α 1-acid glycoprotein were positive determinants of time to progression in patients with advanced lung cancer.^{347, 349} Conversely, the pretreatment plasma level of α 1-acid glycoprotein was negatively, albeit significantly, related to the probability of experiencing severe neutropenia and febrile neutropenia. Docetaxel clearance has also been related to CYP3A4 activity, as assessed by the [¹⁴C-*N*-methyl]erythromycin breath test.³⁵⁵

PBPPI

In clinical studies that evaluated the administration of PBPPI at doses ranging from 80 to 360 mg/m², paclitaxel pharmacokinetics were dose proportional and independent of infusion duration in the range of 30–180 min.^{285, 286, 358, 359} Clearance was 43% faster and the Vd was 53% higher for PBPPI than for paclitaxel formulated in polyoxyethylated castor oil, and there were no appreciable differences in

terminal $t_{1/2}$. At the recommended dose of 260 mg/m² for patients with advanced breast cancer, total clearance averaged 15 L/h/m², and the Vd averaged 632 L/m², which suggests extensive extravascular distribution and/or tissue binding of paclitaxel following administration of PBBPI. About 89–98% of paclitaxel is protein bound *in vitro*. In a within-patient comparison study, the fraction of unbound paclitaxel in plasma was significantly higher with PBBPI (6.2%) than with solvent-based paclitaxel (2.3%), possibly contributing to higher exposure to unbound paclitaxel with PBBPI compared with solvent-based paclitaxel, when the total exposure is comparable.^{358, 359} As expected, PBBPI and solvent-based paclitaxel have similar metabolic profiles. Fecal and urinary excretion accounts for approximately 20% and 4% of the total dose of PBBPI administered. In a study that examined plasma pharmacokinetics and partitioning of radiolabeled paclitaxel from PBBPI and a polyoxyethylated paclitaxel formulation into red blood cells and tumor tissue for 24 h following tail vein injection of 20 mg/kg paclitaxel in an MX-1 human breast cancer xenograft, the distribution of PBBPI was rapid and extensive, as manifested by a fivefold larger Vd and much lower C_{\max} and area under the concentration–time curve (AUC) values compared with a polyoxyethylated castor oil formulation.^{285, 358, 359} Furthermore, PBBPI demonstrated a significantly lower plasma/blood ratio of paclitaxel across all time points and distributed more effectively into MX-1 tumors. Tumor AUC values of paclitaxel were 1.6-fold higher, on average, with PBBPI, and terminal half-life values for PBBPI were significantly longer than from the polyoxyethylated castor oil formulation (17.1 vs. 4.0 h). The prolonged half-life of PBBPI could be attributed to red blood cell penetration and temporary storage of paclitaxel for PBBPI releasing paclitaxel as plasma levels decrease.

Cabazitaxel

In clinical studies in which cabazitaxel has been administered at doses of 10–30 mg/m², plasma disposition is triphasic and dose proportional.^{203, 360, 361} Similar to paclitaxel and docetaxel, the distribution of the agent from the central compartment is rapid, while elimination from the peripheral compartment is slow, most likely due to extensive tissue distribution and avid binding to tubulin; α -, β -, and γ -phase $t_{1/2}$ values averaged 4.4 min, 1.6 h, and 95 h, respectively, in a population pharmacokinetic study; cabazitaxel had a plasma clearance of 48.5 L/h.^{203, 360, 361} Cabazitaxel is equally distributed between blood and plasma, and its Vd is large, averaging 2.64 L/m² at steady state. The binding of cabazitaxel to human serum proteins, mainly albumin and lipoproteins, ranges from 89% to 92% *in vitro*.

Cabazitaxel is extensively metabolized in the liver (>95%), mainly by the CYP3A4 and CYP3A5 isoenzyme (80–90%) and to a lesser extent by CYP2C8.³⁶¹ Cabazitaxel is the principal circulating moiety in human plasma, but seven metabolites have also been detected, three of which are active and formed by O-demethylation, with the main one accounting for 5% of cabazitaxel exposure. Approximately 20 metabolites of cabazitaxel are excreted into human urine and feces. Following administration of radiolabeled cabazitaxel, approximately 80% of the administered dose was eliminated within 2 weeks, with 76% and 3.7% excreted as cabazitaxel and metabolites in the feces and urine, respectively.

Drug interactions

Both sequence-dependent pharmacokinetic and toxicologic interactions between taxanes and several other chemotherapy agents have been noted.³⁶² The most prominent sequence-dependent effects relate to the platinum compound and the taxanes, particularly with protracted taxane administration schedules. Sequence dependence has been principally noted with paclitaxel, which most likely relates to the fact that

docetaxel has been evaluated on a shorter (e.g., 1-h) schedule. The sequence of cisplatin followed by paclitaxel (24-h schedule) induces more profound neutropenia than the reverse sequence, which is explained by a 33% reduction in the clearance of paclitaxel following cisplatin.^{363, 364} The less toxic sequence, paclitaxel before cisplatin, was demonstrated to induce more cytotoxicity *in vitro*, and therefore it was selected for clinical development.³⁶⁴ Treatment with paclitaxel on either a 3-h or 24-h schedule followed by carboplatin results in equivalent neutropenia and less thrombocytopenia as compared with carboplatin as a single agent, which is not explained by pharmacokinetic interactions.^{365, 366} Both mucositis and neutropenia are more severe when paclitaxel on a 24-h schedule is administered before doxorubicin, as compared with the reverse sequence, which is most likely caused by an approximately 32% reduction in the clearance of doxorubicin and doxorubicinol when the agent is administered after paclitaxel.^{367–369} Neither sequence-dependent pharmacologic nor toxicologic interactions between doxorubicin and paclitaxel on a shorter (3-h) schedule have been noted; however, the doxorubicin clearance is reduced with both sequences, and the combination of paclitaxel (3-h schedule) and doxorubicin (bolus infusion) produces a much higher rate of congestive cardiotoxicity than would have been expected from an equivalent cumulative doxorubicin dose given without paclitaxel (see section titled “Toxicity”).^{367, 368} Although similar decrements in the clearance of epirubicin and its metabolites have been noted in studies of paclitaxel combined with epirubicin, an increased incidence of cardiotoxicity has not been observed.³⁷⁰ The precise etiology for these interactions is unclear. The pharmacokinetic interactions may not be of any sufficient magnitude to account for the enhanced cardiotoxicity of the combination, and there are experimental data indicating that paclitaxel enhances the metabolism of doxorubicin to cardiotoxic metabolites, such as doxorubicinol, in cardiomyocytes. Docetaxel does not appear to influence doxorubicin pharmacokinetics, but, like paclitaxel, docetaxel can enhance the metabolism of doxorubicin to toxic species in the human heart.³⁷¹ Competition for hepatic or biliary Pgp transport of the anthracyclines with paclitaxel or its polyoxyethylated castor oil vehicle, or both, is an alternate explanation.^{291, 362, 367} Similar effects have not been noted with docetaxel, which is not formulated in polyoxyethylated castor oil. Hematologic toxicity has been more profound with the sequence of cyclophosphamide before paclitaxel (24-h schedule) than with the reverse sequence.³⁷² Sequence-dependent cytotoxic effects have been reported when the taxanes are combined with 5-fluorouracil, etoposide, cytosine arabinoside, fludarabine, and flavopiridol, among other agents *in vitro*.³⁶² In human tumor xenografts, both paclitaxel and docetaxel induce thymidine phosphorylase activity, which may increase the metabolic activation of the oral fluoropyrimidine prodrug capecitabine.^{373, 374}

Interactions between the taxanes and other classes of drugs, particularly those dependent on cytochrome P450-dependent metabolism, have been noted as well.³⁷⁴ Strong inducers of cytochrome P450 mixed-function oxidases, such as the anticonvulsants phenytoin and phenobarbital, accelerate the metabolism of the taxanes in microsomal systems, as well as in both children and adults who are concurrently receiving treatment with these anticonvulsants, as manifested by rapid drug clearance and tolerance of higher taxane doses.^{292, 336, 340, 342, 362, 367, 368, 375–378} There is preclinical evidence to suggest that docetaxel has a reduced propensity to cause drug interactions that may entail hepatic CYP3A4 induction.³⁴⁴ Conversely, many types of agents that inhibit cytochrome P450 mixed-function oxidases, especially CYP3A4, such as orphenadrine, erythromycin, cimetidine, testosterone, ketoconazole, fluconazole, midazolam, polyoxyethylated castor oil, and corticosteroids, interfere with the metabolism of paclitaxel (in both albumin and solvent formulations), docetaxel, and cabazitaxel in human microsomes *in vitro*. Besides the potent inhibitors of CYP3A4 listed earlier, other well-established inhibitors and inducers of CYP3A, including grapefruit juice and herbal products (e.g., St. John's wort and *Echinacea*), may potentially

induce pharmacokinetic interactions with the taxanes. Although there has been concern that the use of different H₂-receptor antagonists with variable cytochrome P450 inhibitory activities as components of premedication regimens may differentially affect drug clearance and hence toxicity, neither toxicologic nor pharmacologic differences between the agents were noted in a randomized clinical trial.³⁷⁹ A review of early clinical trial results with docetaxel has not demonstrated significant alterations in docetaxel clearance by corticosteroids. In addition, interactions between warfarin and the taxanes, possibly due to protein-binding displacement effects, have been reported.³⁸⁰ The incidence of congestive heart failure has also been higher in breast cancer patients treated with the combination of trastuzumab and paclitaxel than with paclitaxel alone, but the explanation for this observation has not been determined.^{381–383}

Preclinical studies indicate that PBPI and paclitaxel formulated in polyoxyethylated castor oil are likely to have similar drug interactions.^{286, 359} The protein binding of paclitaxel in PBPI is not affected by cimetidine, ranitidine, nor dexamethasone *in vitro*. Although paclitaxel metabolism is inhibited by many agents, including ketoconazole, verapamil, diazepam, quinidine, dexamethasone, cyclosporine, teniposide, etoposide, and VCR, the concentrations used in these studies exceed those achieved in the clinic. Testosterone, 17 α -ethinyl estradiol, retinoic acid, and quercetin, a specific inhibitor of CYP2C8, also inhibited the formation of the principal metabolite, 6 α -hydroxypaclitaxel, *in vitro*. Similar to paclitaxel in polyoxyethylated castor oil, paclitaxel pharmacokinetics following PBPI administration may be altered as a result of interactions with compounds that are substrates, inducers, or inhibitors of CYP2C8 and/or CYP3A4.

Toxicity

General

Myelosuppression is the principal toxicity of the taxanes. However, despite similar structures, these agents possess modest differences in their toxicity spectra.

Paclitaxel

Neutropenia is the principal toxicity of paclitaxel.³⁸⁴ The onset is usually on days 8–10, and recovery typically occurs by days 15–21. The main clinical determinant for the severity of neutropenia is the extent of prior myelosuppressive therapy; however, neutropenia is typically noncumulative, and the duration of severe neutropenia even in heavily pretreated patients is generally brief. Pharmacokinetic parameters of paclitaxel in plasma that reflect drug exposure, particularly the duration that plasma concentrations are maintained above biologically relevant levels (0.05–0.10 μ mol/L; see section titled “Clinical Pharmacology”), relate to the severity of neutropenia, which may explain why neutropenia is more severe with longer infusion schedules.^{385, 386} Paclitaxel distributes widely and avidly even following treatment on short schedules, and therefore protracted schedules do not seem to confer superior anticancer activity. At paclitaxel dosages exceeding 175 mg/m² on a 24-h schedule and 225 mg/m² on a 3-h schedule, neutrophil counts typically decrease to below 500/ μ L for fewer than 5 days in most courses, even in untreated patients. Even patients who have received extensive prior therapy can usually tolerate paclitaxel dosages in the range of 175–200 mg/m² administered over 3 or 24 h. More frequent schedules, particularly weekly treatment with 80–100 mg/m², have resulted in less severe neutropenia than single-dosing schedules (see section titled “Administration, Dose, and Schedule”). Severe thrombocytopenia and anemia are unusual, except in heavily pretreated patients with diminished hematopoietic stem cell capacity. The incidence of major hypersensitivity reactions (HSRs) in early phase I trials approached

30%, but the incidence is approximately 1–3% following the advent and broad adoption of effective prophylaxis.^{377–393}

Most major reactions are characterized by dyspnea with bronchospasm, urticaria, and hypotension, which typically occur within the first 10 min after the first, and less frequently after the second, treatment. Major HSRs generally resolve completely after stopping treatment and occasionally after treatment with antihistamines, fluids, and vasopressors. Patients who have major reactions have been rechallenged successfully after receiving high doses of corticosteroids, but this approach is not always successful.^{384, 387–390} Patients who have experienced paclitaxel-related HSRs have also received other taxanes, such as docetaxel uneventfully.³⁹⁴ Less severe manifestations of hypersensitivity phenomena, such as flushing and rashes, have been noted in as many as 40% of patients, and it is particularly important to note that minor HSRs do not portend the development of major reactions. The HSRs are most likely caused by a nonimmunologically mediated release of histamine or histamine-like substances in the polyoxyethylated castor oil vehicle, but the taxane moiety may also be contributory.^{384, 393} In some cases, complement activation has been demonstrated.³⁹⁴ Although the incidence of major HSRs is reduced with lower administration rates and longer infusion durations, the rates of major reactions are low on both 3- and 24-h schedules when patients are premedicated with corticosteroids and both H1- and H2-histamine antagonists (see section titled “Administration, Dose, and Schedule”). In an assessment of the relative safety of two different paclitaxel schedules (24 h vs. 3 h), the rates of major reactions were low and similar (2.1% vs. 1.0%) in patients receiving paclitaxel for 3 or 24 h, respectively, with premedication.^{384, 395}

A peripheral neuropathy dominated by sensory manifestations, such as numbness and paresthesia, in a glove-and-stocking distribution is the principal neurotoxic effect of paclitaxel.^{384, 396, 397} There is often symmetric distal loss of sensation carried by both large (proprioception, vibration) and small (temperature, pinprick) fibers. Symptoms may begin as soon as 24–72 h after treatment with higher doses (≥ 250 mg/m²), but usually occur only after multiple courses at 135–250 mg/m² every 3 weeks or 80–100 mg/m² weekly, and are cumulative thereafter. Severe neurotoxicity precludes chronic treatment with paclitaxel at dosages above 250 mg/m² over 3 h or 24 h, but severe neurotoxicity is uncommon at conventional doses (< 200 mg/m²) of paclitaxel alone even in patients who previously received other neurotoxic agents such as cisplatin. Patients treated with paclitaxel over shorter (e.g., 3-h) schedules may be more prone to the neurotoxicity compared with those treated with longer (e.g., 24- or 96-h) schedules, which argues that peak concentration may be a principal pharmacologic determinant of neurotoxicity. Neurotoxicity is particularly common and severe in patients receiving paclitaxel as a 3-h infusion combined with cisplatin. The distal, symmetric, length-dependent neurologic deficits suggest that paclitaxel causes a sensory and motor axonal loss similar to the dying back neuropathies that may have their origin in the cell body or in axonal transport, but a few patients have the simultaneous onset of symptoms in the arms and legs, involvement of the face (perioral numbness), the predominance of large fiber loss, and diffuse areflexia, suggestive of a neuronopathy. Both types of neuropathy depend on the dose of paclitaxel or its combination with cisplatin.^{364, 398} Motor and autonomic dysfunction may also occur, especially at high doses and in patients with preexisting neuropathies caused by diabetes mellitus and alcoholism. Although the administration of amifostine, glutamate, pyridoxine, sulfhydryl group scavenger drugs, and anticonvulsants reduces the neurotoxic effects of paclitaxel in some experimental models, anecdotal reports, or insufficiently powered randomized trials, there is no convincing evidence that any specific measure effectively ameliorates existing manifestations or prevents development or worsening of neurotoxicity.^{398–400}

Optic nerve disturbances, characterized by scintillating scotomata, may also occur.⁴⁰¹ Acute encephalopathy, which can progress to coma and death, has been reported following treatment with high doses ($>600 \text{ mg/m}^2$).⁴⁰² A transient acute encephalopathy following paclitaxel treatment in patients who receive prior cranial irradiation is rare.⁴⁰³

Paclitaxel may produce transient myalgia without physical or biochemical evidence of myositis. Myalgia is typically experienced 2–5 days after treatment with doses above 170 mg/m^2 .^{384, 404} A constellation of muscular and neuropathic effects often precludes continuous treatment with paclitaxel administered on a weekly schedule, requiring the institution of rest periods. In general, nonsteroidal anti-inflammatory agents are effective at palliating or preventing symptoms, and the use of narcotics prophylactically on days 2–5 posttreatment may be useful in previously affected patients. Antihistamines have been anecdotally reported to prevent acute myalgia. Treatment with corticosteroids, specifically prednisone 10 mg twice daily for 5 days beginning 24 h after treatment, has been reported to be effective at reducing myalgia and arthralgia, and gabapentin, glutamate, and antihistamines may be useful for management or prevention.

In the early studies, where routine cardiac monitoring was performed because of the high rate of major HSRs, paclitaxel was noted to cause cardiac rhythm disturbances, an overwhelming majority of which was not associated with symptoms or sequelae; therefore, the clinical relevance of these effects is not known.^{384, 405} The most common rhythm disturbance is transient bradycardia. The cumulative experience to date suggests that isolated asymptomatic bradycardia without hemodynamic effects is not an indication for discontinuing paclitaxel. More important bradyarrhythmias, including Mobitz type 1 (Wenckebach syndrome), Mobitz type 2, and third-degree heart block, have been noted, but the incidence in a large National Cancer Institute database was only 0.1%.⁴⁰⁶ Most documented episodes have been asymptomatic. Because such events were noted in patients enrolled in early trials that required continuous cardiac monitoring, second- and third-degree heart blocks are likely underreported because cardiac monitoring is not usually performed. Interestingly, reports of similar disturbances in both animals and humans who ingested various species of yew plants and related taxanes affecting cardiac automaticity and conduction suggest that the bradyarrhythmias are caused by paclitaxel. Myocardial infarction, cardiac ischemia, atrial arrhythmias, and ventricular tachycardia have been noted, but whether there is a causal relationship between paclitaxel and these events is uncertain. There is no evidence that chronic, long-term treatment with paclitaxel causes progressive cardiac dysfunction. Routine cardiac monitoring during therapy is not necessary, but is recommended for those patients who may not be able to tolerate bradyarrhythmias, such as those with atrioventricular conduction disturbances or ventricular dysfunction. Although patients with a wide range of cardiac abnormalities and cardiac histories were broadly and empirically restricted from participating in early clinical trials, paclitaxel treatment has been reported to be well tolerated in a small series of gynecologic cancer patients with major cardiac risk factors.³⁵⁷ On the other hand, repetitive treatment of patients with the combined regimen of paclitaxel on a 3-h schedule and doxorubicin as a brief infusion is associated with a higher frequency of congestive cardiotoxicity than would be expected to occur with the same cumulative doxorubicin dose given without paclitaxel (see section titled “Drug Interactions”). In one study in previously untreated women with advanced breast cancer treated with escalating doses of paclitaxel as a 3-h infusion and doxorubicin 60 mg/m^2 to a cumulative dose of 480 mg/m^2 , which would be predicted to result in a less than 5% incidence of cardiotoxicity in patients treated with doxorubicin alone, the incidence of congestive cardiotoxicity was approximately 25%.³⁶⁷ However, the incidence of cardiotoxicity was $<5\%$ when similar patients received identical schedules of paclitaxel and doxorubicin, but the cumulative doxorubicin dose did not exceed 360 mg/m^2 .^{407, 408} Both experimental and early clinical results suggest that deferoxamine may

reduce the cardiotoxicity of the doxorubicin–paclitaxel combination.^{407, 408} The incidence of congestive heart failure was also significantly higher in breast cancer patients treated with the combination of trastuzumab and paclitaxel than in those treated with paclitaxel alone in a randomized phase III trial; consequently, careful monitoring of patients receiving this combination is warranted.^{212–214}

Gastrointestinal toxicities, including nausea, vomiting, and diarrhea, are uncommon. Higher paclitaxel doses may cause mucositis, especially in patients with leukemia who may be more prone to mucosal barrier breakdown or in patients receiving protracted infusions. Rare cases of neutropenic enterocolitis and gastrointestinal necrosis have been noted, particularly in patients given high doses of paclitaxel in combination with doxorubicin or cyclophosphamide.^{409, 410} Severe hepatotoxicity and pancreatitis have also been noted, but these events are rare. Acute bilateral pneumonitis occurs in <1% of patients treated on a 3-h schedule in one series, and both interstitial and parenchymal pulmonary toxicities have been reported, but clinically significant pulmonary effects are uncommon.^{391, 411}

Paclitaxel also induces reversible alopecia of the scalp, but all body hair is usually lost with cumulative therapy. Alopecia appears to be dose related and occurs only following repetitive treatment with weekly administration. Although the agent is often not considered a vesicant, extravasation of large volumes can cause moderate soft tissue injury. Inflammation at the injection site and along the course of an injected vein can occur.⁴¹² Nail disorders have been noted, particularly in patients treated on weekly schedules. Radiation recall reactions have been reported. Taxane-induced taste alterations are common.

Docetaxel

Similar to paclitaxel, neutropenia is the principal toxicity of docetaxel.^{200, 413, 414} At dosages ranging from 75 to 100 mg/m² administered as a 1-h infusion, neutrophil counts usually decrease to below 500/μL. The onset of neutropenia is usually noted on day 8 and complete resolution typically occurs by days 15–21. Neutropenia is significantly less when low doses are administered frequently, such as on a weekly schedule (see section titled “Administration, Dose, and Schedule”). The most important determinant of neutropenia is the extent of prior therapy, but α1-acid glycoprotein and the duration of drug exposure above biologically relevant concentrations appear to be important determinants (see section titled “Clinical Pharmacology”). Significant effects on platelets and red blood cells are uncommon.

Even though docetaxel is not formulated in polyoxyethylated castor oil, HSRs have been reported in approximately 31% of patients receiving docetaxel without premedications, but most are not severe.^{200, 413, 414} Nevertheless, major reactions, characterized by dyspnea, bronchospasm, and hypotension, particularly during the first two courses and within minutes after the start of treatment, have been reported. Manifestations generally resolve within 15 min after cessation of treatment, and docetaxel is usually able to be reinstituted without consequences, occasionally after treatment with an H1-histamine antagonist. Both the incidence and severity of HSRs appear to be reduced significantly by premedication with corticosteroids and both H1- and H2-histamine antagonists (see section titled “Administration, Dose, and Schedule”). Like paclitaxel, patients who experience major HSRs have been re-treated successfully after resolution of symptoms and following treatment with corticosteroids and H1-histamine antagonists. Although patients who have experienced HSRs following paclitaxel treatment have been re-treated successfully with docetaxel, this strategy has not been studied in a rigorous fashion.

In early studies, a unique fluid retention syndrome, characterized by edema, weight gain, and third-space fluid collection (e.g., pericardial, pleural, ascites), has been noted in patients treated with multiple courses of docetaxel.^{200, 413–416} Fluid retention did not appear to be related to hypoalbuminemia or cardiac, renal, or hepatic dysfunction, but to increased capillary permeability. Capillary filtration studies

revealed a two-stage process with progressive congestion of the interstitial space by proteins and water, starting between the second and fourth course that progressed to insufficient lymphatic drainage. In early studies in which prophylactic medication was not used, fluid retention was not usually significant at cumulative docetaxel doses below 400 mg/m²; however, the incidence and severity of fluid retention increased sharply at cumulative doses exceeding 400 mg/m² and often resulted in the delay or termination of treatment. Prophylactic treatment with corticosteroids with or without H1- and H2-histamine antagonists reduces the incidence of fluid retention and increases the number of courses and cumulative docetaxel dose before the onset of this toxicity (see section titled “Administration, Dose, and Schedule”).⁴¹⁵ In fact, drug-induced fluid retention has been uncommon following the broad adoption of corticosteroid premedication. Fluid retention resolves slowly after docetaxel is stopped, with complete resolution occurring several months after treatment in patients with severe toxicity. Aggressive and early treatment with progressively more potent diuretics, starting with potassium-sparing diuretics, has been successfully used to manage fluid retention. The incidence of fluid retention appears to be lower in studies that used lower doses (60–75 mg/m²) during each course, but this may be a result of the administration of lower overall cumulative doses, and the effects of lower doses on anticancer activity are unknown.

Although both neurosensory and neuromuscular effects due to docetaxel are similar to paclitaxel, they are less common and appear to be less severe compared with paclitaxel.^{200, 397, 413, 414, 417} In a phase III trial, patients with advanced ovarian carcinoma receiving first-line treatment with docetaxel and carboplatin experienced less severe neurotoxicity than did those receiving treatment with paclitaxel and carboplatin.^{417, 418} Mild to moderate peripheral neurotoxicity is observed in approximately 40% of previously untreated patients. Previous treatment with platinating agents appears to increase the likelihood of developing neurotoxicity. The neurotoxicity is qualitatively similar to that of paclitaxel, with sensory effects predominating.^{364, 396–400} Patients typically complain of paresthesia and numbness, but peripheral motor disturbances may also occur. Severe toxicity is unusual following repetitive treatment with docetaxel doses <100 mg/m², except in patients with antecedent disorders such as alcohol abuse.

Although cardiovascular effects, including angina, arrhythmia, conduction disturbances, congestive heart failure, hypertension, and hypotension, have been noted rarely in the pretreatment period, there is no convincing evidence that directly links docetaxel to these events. Stomatitis appears to occur more frequently with docetaxel than paclitaxel, particularly with prolonged infusions that are used rarely. Nausea, vomiting, and diarrhea have also been observed infrequently, and severe manifestations are rare.

Phlebitis along the course of the infused veins and local inflammation at the injection site are occasionally noted; however, severe tissue damage following drug extravasation is not generally observed. Transient arthralgia and myalgia without inflammatory manifestations are occasionally noted within days following treatment. Malaise, often referred to as asthenia, has been a prominent complaint in patients who have been treated with large cumulative doses, particularly when docetaxel is administered on a continuous weekly schedule.⁴¹⁹

Skin toxicity may occur in as many as 50–75% of patients;^{364, 420} however, premedication may reduce the overall incidence of this toxicity. An erythematous pruritic maculopapular rash that affects the forearms, hands, and/or feet is typical. Desquamation of the hands and feet, which is a component of a more general palmar–plantar erythrodysesthesia syndrome that may respond to pyridoxine or cooling, and onychodystrophy characterized by brown discoloration, ridging, onycholysis, soreness, and brittleness and loss of the nail plate have been reported.^{318, 420} Skin and nail changes appear to be most prominent in patients treated frequently with low doses (i.e., weekly schedules). Excessive lacrimation, occasionally

due to canalicular stenosis, may also occur.⁴²¹ Other rare events that may or may not be related to docetaxel itself include confusion, erythema multiforme, neutropenic enterocolitis, hepatitis, ileus, interstitial pneumonia, seizures, pulmonary fibrosis, hepatitis, radiation recall, and visual disturbances.

PBPPI

The toxicity profile of PBPPI is similar to that of paclitaxel, with neutropenia as the principal dose-limiting toxicity.^{201, 283–286, 358, 359} Most other paclitaxel-related toxicities have also been observed with PBPPI. The rate of HSRs, particularly major reactions, is less with PBPPI than that of paclitaxel formulated in polyoxyethylated castor oil. A premedication regimen to prevent HSRs is not recommended since the rate of HSRs, particularly major reactions, is less with PBPPI than that of paclitaxel formulated in polyoxyethylated castor oil. In randomized studies in patients with either advanced breast or nonsmall cell lung cancer treated with either PBPPI- or paclitaxel-based regimens, toxicity profiles are similar. Neutropenia and neurotoxicity are the principal toxicities of PBPPI. Other relatively common adverse effects include arthralgia, myalgia, asthenia, fatigue, mucositis, and diarrhea. Additional toxicities, most of which are noted with other taxane formulations, include increased lacrimation, conjunctivitis, radiation recall, Stevens–Johnson syndrome, toxic epidermal necrolysis, photosensitivity reactions, and palmar–plantar erythrodysesthesia in patients previously treated with capecitabine.

Cabazitaxel

The adverse effects seen with cabazitaxel are very similar, both qualitatively and quantitatively, to those noted with docetaxel.^{203, 225, 359, 360} The most common toxicity is neutropenia, which, like the other taxanes previously discussed, is noncumulative and brief. In the phase III randomized pivotal trial of cabazitaxel plus prednisone versus mitoxantrone plus prednisone in men with castrate-resistant prostate cancer who had received prior treatment with docetaxel, 82% of the patients experienced grade 3–4 neutropenia, 8% experienced neutropenic fever, and several patients experienced fatal adverse infectious events. Severe anemia (11%) and thrombocytopenia (4%) were far less common.²²⁵ Common nonhematologic toxicities were mainly gastrointestinal in nature: diarrhea (47%, all grades), nausea (34%), vomiting (22%), and constipation (20%). Importantly, in this population of patients who previously received docetaxel, severe (grade 3–4) peripheral neuropathy was noted in <1% of patients. Other common adverse effects, without attribution to disease or drug, included fatigue (37%), asthenia (20%), and hematuria (17%), with the most commonly reported nonhematologic grade 3–4 adverse events being diarrhea (6%), fatigue (5%), and asthenia (5%). Anaphylaxis and severe HSRs (dyspnea requiring bronchodilators, hypotension requiring treatment, syncope, or bradycardia) occurred in <4% of patients. Routine premedication, including histamine H1 and H2 receptor antagonists and corticosteroid (see section titled “Administration, Dose and Schedule”), is recommended 30 min prior to reduce this even further. Myalgia, arthralgia, stomatitis, mucositis, and peripheral edema were seen rarely and were mild in severity (grade 1–2). Alopecia occurred in 33% of patients. Nausea, vomiting, and severe diarrhea, at times, may occur. Death related to diarrhea and electrolyte imbalance occurred in the randomized clinical trial.²²⁵ Other gastrointestinal toxicities, including hemorrhage, perforation, ileus, enterocolitis, gastritis, intestinal obstruction, and persistent constipation, have been reported in patients treated with cabazitaxel. Abdominal pain and tenderness, fever, persistent constipation, diarrhea, and with or without neutropenia may be early manifestations of serious gastrointestinal toxicity and should be evaluated and treated promptly. Cabazitaxel treatment delay or discontinuation may be necessary. Transaminitis has been noted rarely.

Administration, dose, and schedule

Paclitaxel

Discerning the optimal dose and schedule for the taxanes, principally paclitaxel, has been a major focus of many evaluations over the last decade. The collective results of these efforts indicate that paclitaxel has prominent anticancer activity on multiple schedules and, although no particular schedule is superior from an efficacy standpoint across all tumor types, a weekly schedule was demonstrated to be superior to an every-3-week schedule in the adjuvant treatment of breast cancer.^{422, 423} As a rule, however, toxicity profiles are schedule dependent. The earliest clinical studies of paclitaxel were limited to the 24-h schedule, largely as a consequence of an apparent increased rate of severe HSRs on shorter schedules, but the development of effective premedication regimens led to evaluation of a broad range of dosing schedules. Although paclitaxel 135 mg/m² on a 24-h schedule was initially approved for patients with refractory and recurrent ovarian cancer, regulatory approval was later obtained for paclitaxel 175 mg/m² on a 3-h schedule in these and other indications. In patients with advanced breast and ovarian cancer, the collective results of randomized studies indicate that response rates have occasionally been higher with more protracted (24–96-h) infusion schedules, but other indices of efficacy do not appear to relate to infusion duration. The extensive distribution of the taxanes to peripheral tissues, as well as the avid and protracted tissue binding of these agents, may explain the lack of substantial differences in anticancer activity between short and more protracted administration schedules despite substantial differences *in vitro*.^{385, 424, 425} There has also been considerable interest in intermittent schedules, particularly those in which paclitaxel is administered as a 1-h infusion weekly, which results in substantially less myelosuppression than every-3-week schedules.^{422–424, 426, 427} Furthermore, there have been reports of impressive and superior activity of weekly compared with every-3-week schedules in several disease settings, particularly in treatment of both early-stage (adjuvant) and advanced breast cancer patients.^{210, 422, 423} However, there is no convincing evidence that weekly treatment results in relevant activity in tumors unresponsive to the taxanes on less intermittent schedules. The weekly schedule may also be advantageous for patients who are at high risk of developing severe myelosuppression, but it seems to confer a higher incidence of neuromuscular effects.

Paclitaxel is indicated and generally administered at a dosage of 175 mg/m² over 3 h or, less frequently, 135–175 mg/m² over 24 h every 3 weeks. Several randomized trials in patients with advanced lung, head and neck, and ovarian cancers have consistently failed to show that paclitaxel dosages above 135–175 mg/m² on a 24-h schedule are superior to conventional doses.^{385, 424, 428} Nearly identical results have been obtained in a phase III study in patients with metastatic breast cancer, in which greater efficacy was not observed in patients treated with paclitaxel dosages above 175 mg/m² on a 3-h schedule.⁴²⁹ The following dosages have been recommended on less conventional schedules: 200 mg/m² over 1 h as either a single dose or 3 divided doses every 3 weeks, 140 mg/m² over 96 h every 3 weeks, and 80–100 mg/m² weekly or weekly for 3 weeks every 4 weeks. The most common schedules evaluated in patients with Kaposi's sarcoma associated with the acquired immunodeficiency syndrome are paclitaxel 135 mg/m² over 3 h or 24 h every 3 weeks and 100 mg/m² every 2 weeks.²¹⁵ Paclitaxel has also been administered into the pleural and peritoneal cavities. Biologically relevant plasma concentrations have been achieved with intraperitoneal administration, and concentrations in the peritoneal cavity are several orders of magnitude higher than plasma concentrations. The following premedication regimen is recommended to prevent major HSRs: dexamethasone 20 mg orally or intravenously, 12 and 6 h before treatment; an H1-histamine antagonist (such as diphenhydramine, 50 mg intravenously) 30 min before treatment; and an H2-

histamine antagonist (such as cimetidine, 300 mg; famotidine, 20 mg; or ranitidine, 150 mg intravenously) 30 min before treatment. A single dose of a corticosteroid (dexamethasone 20 mg intravenously) administered 30 min before treatment also appears to confer effective prophylaxis of major HSRs.

Hepatic metabolism and biliary excretion are the principal modes of drug disposition of paclitaxel, and dose modifications are required for patients with hepatic dysfunction. Prospective study results suggest that patients with moderate to severe elevations in serum concentrations of hepatocellular enzymes and/or bilirubin are more predisposed to severe toxicity than patients without hepatic dysfunction. It is therefore recommended that paclitaxel doses be reduced by at least 50% in patients with moderate hepatic dysfunction.⁴³⁰ It is recommended that doses of paclitaxel on a 3-h schedule be reduced from 175 to 135 mg/m² for elevations of hepatic transaminases up to 10 times the upper limit of normal (ULN) and bilirubin to 1.26–2.0 times the ULN. For further elevations of bilirubin up to 5.0 times along with transaminase elevations up to 10 times the ULN, paclitaxel 90 mg/m² is recommended. Dose recommendations have not been formulated for more transaminitis and/or hepatic excretory dysfunction. Since renal disposition contributes minimally to overall clearance (5–10%), patients with severe renal dysfunction do not appear to require dose modification.^{292, 431} Based on the pharmacologic behavior, particularly the wide distributive properties of the taxanes, dose modifications are not required solely for peripheral edema and third-space fluid collections.

Contact of the paclitaxel-polyoxyethylated castor oil formulation with plasticized polyvinyl chloride (PVC) equipment or devices must be avoided because of the risk of patient exposures to plasticizers, especially the extractable plasticizer di-(2-ethylhexyl)phthalate (DEHP), that may be leached from PVC infusion bags or sets. Paclitaxel solutions should be diluted and stored in glass or polypropylene bottles or suitable plastic bags (polypropylene or polyolefin) and administered through non-PVC administration sets such as those that are polyethylene lined. Paclitaxel should be administered through an in-line filter with a microporous membrane not >0.22 µm.

Docetaxel

Docetaxel is indicated at a dosage range of 60–100 mg/m² (1-h intravenous infusion) in advanced breast cancer and 75 mg/m² as either a single agent or combined with other agents in all other indications. It should be noted that most clinical evaluations focused on docetaxel doses at the higher end of this range (75–100 mg/m²) and relatively scant data are available for patients treated with docetaxel (60 mg/m²).²⁰⁰ Although some untreated or minimally pretreated patients generally tolerate docetaxel at a dose of 100 mg/m², which is the only approved dose in select indications in many regions, 75 mg/m² appears to be more reasonable from a toxicologic perspective in more heavily re-treated patients.⁴³² Like paclitaxel, docetaxel has also been administered as a 1-h infusion weekly, but a clear efficacy benefit of a weekly schedule over the conventional every-3-week frequency has not been established.^{210, 418} Additionally, hematologic toxicity is less with the more frequent weekly schedule. Both cumulative asthenia and neurotoxicity are the principal toxicities of docetaxel administered weekly, precluding treatment with dosages exceeding 36 mg/m²/week. Despite the use of a polysorbate-80 formulation instead of polyoxyethylated castor oil, which is used to formulate paclitaxel, a relatively high rate of HSRs and profound fluid retention in patients who did not receive premedication has led to the use of several effective premedication regimens, the most popular of which is dexamethasone 8 mg orally twice daily for 3 days starting 1 day before docetaxel, with or without both H1- and H2-histamine antagonists given 30 min before docetaxel.^{413, 414} For patients with metastatic prostate cancer, given the concurrent use of prednisone, the recommended dose of dexamethasone is 8 mg orally at 8, 3, and 1 h prior to docetaxel.

Administration of docetaxel without corticosteroids is not recommended, even in patients who do not develop HSRs, because drug-related fluid retention, which is a chronic toxicity, requires drug discontinuation.^{414, 415}

A retrospective review of docetaxel pharmacokinetics in patients without hyperbilirubinemia demonstrated that docetaxel clearance is reduced by approximately 25% in patients with elevations in serum concentrations of both hepatic transaminases (1.5-fold or greater) and alkaline phosphatase (2.5-fold or greater), regardless of whether the elevations are a result of hepatic metastases.^{346–349, 433} Therefore, dose reductions by at least 25% have been recommended for such individuals. Although more substantial reductions may be required in patients who have moderate or severe hepatic excretory dysfunction (hyperbilirubinemia), the near exclusive role of the liver in drug disposal has resulted in the manufacturer's recommendation that docetaxel not be administered to subjects with transaminase elevations exceeding 1.5 times the ULN concomitant with an alkaline phosphatase elevation exceeding 2.5-fold, or an elevated bilirubin value. Similar to paclitaxel (see sections titled “Paclitaxel, Administration, Dose, and Schedule”), there is no rationale for dose modification solely for renal deficiency and/or third-space fluid accumulation. Also similar to the case with paclitaxel (see sections titled “Paclitaxel, Administration, Dose, and Schedule”), contact with plasticized PVC equipment or devices is not recommended. In order to minimize patient exposure to the plasticizer DEHP, which may be leached, bottles (glass or polypropylene) or plastic bags (polypropylene or polyolefin) should be used for preparation and storage, and docetaxel should be administered through polyethylene-lined administration sets.

PBPPI

PBPPI received initially regulatory approval in the United States for the treatment of patients with metastatic breast cancer after failure of combination chemotherapy for metastatic disease or relapse within 6 months of adjuvant chemotherapy.²²⁶ The recommended dosage schedule for this indication is 260 mg/m² as a 30-min intravenous infusion; however, notable anticancer activity has been observed on various other schedules, particularly doses in the range of 100–150 mg/m² administered as a 30-min intravenous infusion weekly for 3 out of every 4 weeks, similar to the paclitaxel and docetaxel. PBPPI was soon after registered in the United States and elsewhere as first-line treatment of patients with locally advanced or metastatic pancreatic cancer or nonsmall cell lung cancer as a 30–40-min intravenous infusion weekly for 3 weeks every 28 days at doses of either 125 or 100 mg/m², respectively, with carboplatin or gemcitabine.^{200, 227} No premedication to prevent HSRs or edema is recommended prior to administration. The use of specialized DEHP-free (i.e., PVC-free) solution containers and administration are not necessary, and the use of an in-line filter is not recommended. The most appropriate doses for patients with hepatic insufficiency (bilirubin, 1.5 > mg/dL) and renal insufficiency are not known; however, similar to the case with other taxanes, renal disposition is likely negligible. The manufacturer recommends dose reduction from 260 to 200 mg/m² or 100 to 80 mg/m² for patients with advanced or metastatic breast cancer or nonsmall cell lung cancer, respectively, with moderate or severe hepatic dysfunction as defined by bilirubin elevations that do not exceed five times the ULN with or without transaminase elevations that do not exceed 10 times the ULN. PBPPI is not recommended for pancreatic cancer patients with bilirubin exceeding 1.5 times the ULN. Dose reduction is not necessary for patients with transaminase elevations below 10 times the ULN as long as bilirubin values do not exceed 1.5-fold. The manufacturer does not recommend PBPPI in patients whose bilirubin exceeds 5 times the ULN. It is recommended that patients who experience severe neutropenia and/or thrombocytopenia during PBPPI treatment should have their treatment discontinued until sufficient recovery, followed by dose reduction in

subsequent treatments. In cases of severe sensory neuropathy, it is recommended that treatment be discontinued until resolution to mild or moderate manifestations followed by a dose reduction for all subsequent courses. For patients with pancreatic cancer receiving treatment with PBPPI plus gemcitabine, PBPPI treatment is withheld in the event of grade 3 mucositis or diarrhea and resumed at a lower dose following toxicity resolution to grade 1 or less. Lastly, dose reduction of PBPPI is recommended in the event of grade 2 or 3 cutaneous toxicity in patients treated with PBPPI plus gemcitabine, with discontinuation of treatment if the toxicity persists.

Cabazitaxel

Cabazitaxel is indicated for treatment of patients with metastatic castrate-resistant prostate cancer previously treated with a docetaxel-containing treatment regimen.^{203, 225, 360, 361} It is specifically indicated at a dose of 25 mg/m² as a 60-min infusion administered every 3 weeks in combination with oral prednisone 10 mg daily throughout treatment. Alternate schedules have not been fully evaluated. The following intravenous premedication regimen is recommended at least 30 min prior to each dose of cabazitaxel to reduce the risk and/or severity of HSRs: diphenhydramine 25 mg or an equivalent H1-histamine antagonist, dexamethasone 8 mg or an equivalent steroid, and an H2-histamine antagonist such as ranitidine 50 mg or equivalent. Antiemetic prophylaxis is recommended and can be given orally or intravenously as needed. Like docetaxel, cabazitaxel is formulated in polysorbate-80 and is diluted with ethanol followed by dilution in either 0.9% sodium chloride solution or 5% dextrose solution. Due to the potential for polysorbate-80 to leach plasticizers, neither PVC infusion containers nor polyurethane infusion sets should be used to prepare or administer cabazitaxel. An in-line filter of 0.22 µm nominal pore size (also referred to as 0.2 µm) should be used during administration.

No dedicated hepatic impairment trial for cabazitaxel has been conducted, and therefore no dosing recommendations have been formulated for patients with either hepatic dysfunction or renal impairment. Although docetaxel and cabazitaxel have similar modes of clearance and it may seem reasonable to modify doses similar to docetaxel, the manufacturer does not officially recommend that cabazitaxel be given to patients with hepatic impairment. Based on population pharmacokinetic data, there were no significant differences in clearance in patients with mild to moderate (30 mL/min ≤ creatinine clearance), and dose reduction for such subjects is not warranted. However, caution should be used in patients with severe renal impairment (creatinine clearance < 30 mL/min) and patients with end-stage renal diseases. Similar to paclitaxel, docetaxel, and PBPPI, cabazitaxel doses should be modified and/or treatment held for relevant degrees of neutropenia, diarrhea, and/or peripheral neuropathy. For example, a dose reduction to 20 mg/m² is warranted if the patient experienced grade ≥3 neutropenia lasting at least 7 days despite appropriate medication including growth factors following treatment at the 30 mg/m² dose level. For patients developing grade ≥3 diarrhea or persistent diarrhea despite appropriate medication, fluid, and electrolyte replacement or grade 2 peripheral neuropathy, cabazitaxel treatment should be held until improvement or resolution followed by dose reduction to 20 mg/m². Cabazitaxel should not be administered to patients who have developed peripheral neuropathy of grade 3 severity.

Other natural products that enhance tubulin polymerization

The success of the taxanes has led to efforts to identify other agents that confer cytotoxicity by enhancing tubulin polymerization, yielding several leads over the last two decades, the most relevant of which have been the epothilones. The epothilones are polyketide macrolactones which were initially isolated from the soil-dwelling myxobacterium *Sorangium cellulosum*. Other natural products that enhance tubulin

polymerization include discodermolide (isolated from the Caribbean marine sponge *Discodermia dissoluta*), eleutherobin (isolated from the soft coral *Eleutherobia* sp.) and laulimalide (isolated from the marine sponge *Cacospongia mycofijiensis*), peloruside A (isolated from a New Zealand marine sponge *Mycale hentscheli*), the taccalonolides (plant-derived natural steroids), and sarcodictyins (isolated from the Mediterranean stoloniferan coral *Sarcodictyon roseum*). Some of these compounds compete with paclitaxel for binding to microtubules and appear to bind at or near the taxane site (epothilones, discodermolide, eleutherobins, and sarcodictyins), but others, such as laulimalide and peloruside A, seem to bind to unique sites on microtubules.^{2–7, 237, 316} Eleutherobin, epothilones A and B, and discodermolide competitively inhibit paclitaxel binding to microtubules, and a common pharmacophore that may enable the development of hybrid constructs with more desirable biological characteristics was identified.^{237, 240, 316} Interestingly, discodermolide and paclitaxel demonstrate synergistic cytotoxicity *in vitro*, suggesting that their tubulin binding sites and microtubule effects are not identical.⁴³³ However, unforeseen pulmonary toxicity has been seen in early clinical studies of XAA296, a completely synthetic discodermolide.⁴³⁴ Most of the aforementioned agents, particularly epothilone B, discodermolide, and the taccalonolides, possess either low-level or no substrate affinity for ABC transporters, and others retain various degrees of activity against taxane-resistant cells *in vitro* including β III-tubulin-expressing malignancies (epothilone B, taccalonolides). Although clinical implications of these characteristics are not entirely clear, the epothilones have demonstrated clinically relevant activity in patients who have been previously treated with taxanes, some of whom are clearly taxane resistant. Of the nontaxane tubulin-polymerizing agents, the epothilones are the furthest along in development, and one epothilone B analog, ixabepilone, has been registered for treating patients with advanced breast cancer who no longer benefit from paclitaxel.

Ixabepilone and the epothilones

The epothilones A and B (patupilone) are 16-member polyketide macrolides with nearly identical structures, except that epothilone B has an additional methyl group at the C-12 position. *In vitro* studies in tumor cell lines have shown that epothilone B is more active than epothilone A. Both epothilones A and B have greater potency than paclitaxel or docetaxel *in vitro*, with mean inhibitory concentration (IC₅₀) values in the low nanomolar range.^{435, 436} A semisynthetic derivative of epothilone B, ixabepilone (azaepothilone B), was synthesized by converting the lactone of epothilone B to a lactam ([Figure 4](#)). This structural modification resulted in improved solubility, low plasma protein binding, and higher metabolic stability than its precursor. The distinct mechanism of binding of the epothilones, particularly epothilone B analogs, to β -tubulin may contribute, at least in part, to their increased potency and broader spectrum of activity than the taxanes, as well as their ability to stabilize yeast microtubules.⁴³⁷ The promising activities of epothilones A and B led to further modifications of the macrolactone ring, generating deoxyepothilone B (epothilone D), which possess a similar range of anticancer activity as epothilones A and B.

Figure 4 Chemical structures of ixabepilone and eribulin.

Clinical indications

Ixabepilone is registered as a single agent for treating patients with metastatic or locally advanced breast cancer after failure of a taxane, anthracycline, and capecitabine, whereas the combination of ixabepilone and capecitabine is indicated after failure of an anthracycline and a taxane.⁴³⁸ Both ixabepilone and other epothilones, especially epothilone B, have demonstrated anticancer activity in various other malignancies, mainly those that are sensitive to taxanes such as nonsmall cell lung, prostate, and ovarian cancers.^{439, 440}

Mechanism of action

Like the natural epothilones A and B, ixabepilone stabilizes microtubules and induces apoptosis.^{433, 436, 440, 441} Ixabepilone exhibits prominent activity against human and murine tumor xenografts and is active against paclitaxel-resistant cell lines and tumors, including those with elevated expression of Pgp and/or β III- or β IV-tubulin isotypes.^{433, 435, 436, 440, 441} Both epothilones A and B and their relevant analogs competitively inhibit binding of paclitaxel to tubulin polymers *in vitro*, inferring that the binding sites of the epothilones and taxanes may overlap.^{435–437} They also have similar binding affinities. In fact, the epothilones and taxanes possess a common pharmacophore for microtubule binding.^{237, 240} Epothilones A and B promote tubulin polymerization *in vitro* with kinetics similar to paclitaxel, but epothilone B

appears to be a more potent inducer than both epothilone A and paclitaxel. Similar to the taxanes, the epothilones also induce tubulin polymerization in the absence of GTP and/or MAPs, resulting in microtubules that are long, rigid, and resistant to destabilization by cold temperature, and calcium, resulting in enhanced microtubule stability and microtubule bundling.^{237, 435–437, 439–446} Furthermore, the epothilones induce formation of abnormal mitotic spindles, resulting in cell-cycle arrest in G₂/M. At low concentrations, however, epothilone B does not induce mitotic arrest, but transforms proliferating cells into large aneuploid cells, which undergo apoptotic cell death in G₁. Thus, protracted mitotic arrest may not be essential for apoptotic cell death.⁴⁴⁶

Despite the mechanistic similarities of the epothilones and taxanes, studies using electron crystallography have shown that epothilones interact with β -tubulin through unique and independent molecular interactions, possibly resulting in the ability of these agents to disrupt various β III- and β IV-tubulins and other tubulin isotypes that are less susceptible to the taxanes.⁴⁴⁶ Additionally, various mutations in β -tubulin that confer resistance to taxanes do not significantly alter the cytotoxicity of epothilones A and B, but the clinical relevance of tubulin mutations is not entirely clear.²⁹⁶

An important feature of the epothilones, of which ixabepilone has been studied most, appears to be the mechanism in which cell death is induced following the induction of microtubule perturbations. Whereas taxane-induced apoptosis is conveyed by a mitochondrial-mediated pathway involving cytochrome C release and activation of Apaf-1 and caspase-9, ixabepilone-induced apoptosis involves activation of caspase-3 and caspase-8.^{447–450} In paclitaxel-refractory ovarian cancer cells, ixabepilone was shown to induce p53-dependent induction of the p53 upregulated modulator of apoptosis (PUMA), leading to activation of caspase-2, the death effector Bax, and apoptosis.^{451, 452}

Mechanisms of resistance

In contrast to the taxanes and vinca alkaloids, overexpression of the transporters Pgp and MRP1 minimally affects the cytotoxicity of the epothilones as they are weak substrates for these transporters.^{2, 3, 240, 433, 437, 440, 441, 446} Epothilones A and B possess strong antiproliferative activity in human cancer cells with high expression of Pgp (ABCB1), which are resistant to paclitaxel, and tumor samples obtained from patients with tumors responsive to ixabepilone showed significant expression of both MDR1 and MRP1, also suggesting that these proteins may not confer resistance, at least at a relevant level, to the epothilones in the clinic.^{453, 454} The epothilone B analog ixabepilone is not a substrate for the breast cancer resistance protein (BCRP) *in vitro*.

In preclinical systems, cancer cells with several distinct types of β -tubulin mutations, such as several β I-tubulin mutations that are critical for microtubule stabilization, appear to be resistant to the epothilones, but the clinical implications of these observations are unknown.²⁹⁶ Preclinical reports have also suggested additional mechanisms of resistance such as α -tubulin mutations, altered expression of tubulin isotypes, and altered MAP structure and function.^{433, 435, 440, 443, 454}

Clinical pharmacology

Ixabepilone exhibits dose-proportional pharmacokinetics in the range of 15–57 mg/m² ([Table 3](#)).^{435, 440, 454} Following administration of a single 40 mg/m² dose, the mean C_{\max} was 252 ng/mL (coefficient of variation, 56%), and the terminal phase $t_{1/2}$ averaged 52 h. Therefore, no drug accumulation is expected if

the agent is administered every 3 weeks. Similar to the taxanes and vinca alkaloids, ixabepilone's Vd at steady state is large, with mean values exceeding 1000 L. Binding to human serum proteins ranges from 67% to 77% *in vitro*, and the blood-to-plasma concentration ratios in human blood range from 0.65 to 0.85. The principal mode of systemic elimination of ixabepilone is hepatic metabolism. Following intravenous administration of radiolabeled ixabepilone, approximately 86% of the dose is eliminated within 7 days; fecal and urinary elimination, principally of inactive metabolites, accounts for 65% and 21% of the dose, respectively. The parent compound accounts for approximately 1.6% and 5.6% of the dose in feces and urine, respectively. The principal metabolic pathway *in vitro* is oxidative metabolism via CYP3A4. More than 30 inactive metabolites have been identified in human urine and feces, but no single metabolite accounts for more than 6% of the administered dose.

Table 3 Ixapebilone and eribulin: comparative pharmacokinetic and toxicologic characteristics

Parameter	Ixabepilone	Eribulin
Standard adult dose (mg/m ² /3 week)	40 (3-h infusion); Should be capped at 2.2 mg/m ² for body surface area exceeding this value	—
Standard adult dose (mg/m ² /week)	16 (× 3 every 4 weeks)	1.4 (× 2 every 3 weeks) or 1.4 (× 3 every 4 weeks) as a 2–5-min infusion
Pharmacokinetic behavior (clinically relevant doses)	Multiexponential	Biexponential
Dose proportional in range (mg/m ²)	15–57	0.25–4.0
Plasma half-life (terminal phase)	52 h	40 h
Clearance	36–40 L/h	1.15–2.42 L/h
Primary route	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination
Principal toxicity	Neurotoxicity, neutropenia	Neutropenia
Other toxicities	Hypersensitivity reactions, anemia, thrombocytopenia	Neurotoxicity, fatigue, thrombocytopenia, anemia, fatigue

Drug interactions

In vitro studies using human liver microsomes have indicated that clinically relevant concentrations of ixabepilone do not affect the activities of CYP3A4, CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, or CYP2D6 and therefore would likely not affect the pharmacokinetics and metabolism of drugs that are substrates of these enzymes.^{435, 440, 454} However, coadministration of ixabepilone with ketoconazole, a potent CYP3A4 inhibitor, increased ixabepilone AUC values by 79%, on average, compared to ixabepilone alone. With regard to ketoconazole and similar potent inhibitors of CYP3A4, if alternative treatment cannot be administered, a dose adjustment should be considered, and patients should be monitored for toxicity. Since the effect of mild or moderate CYP3A4 inhibitors (e.g., erythromycin,

fluconazole, or verapamil) on exposure to ixabepilone has not been studied in the clinic, caution should be exercised if such agents must be administered during ixabepilone treatment. Coadministration of rifampin, a potent inducer of CYP3A4 metabolism, reduced ixabepilone AUC by 43% compared to ixabepilone alone, and it would be expected that other potent CYP3A4 inducers, such as dexamethasone, phenytoin, carbamazepine, rifampin, rifabutin, and phenobarbital, may do the same, thereby possibly leading to subtherapeutic ixabepilone concentrations; therefore, agents with no or low CYP3A4 induction potential should be considered for coadministration with ixabepilone. St. John's wort may decrease ixabepilone plasma concentrations unpredictably and should be avoided. If patients must be coadministered with a strong CYP3A4 inducer, a gradual dose adjustment may be considered. In studies involving cancer patients who received ixabepilone (40 mg/m²) in combination with capecitabine (1000 mg/m²), the effects of ixabepilone on the C_{max} and AUC values of capecitabine and 5-fluorouracil, and vice versa, were modest and not apparently relevant.

Ixabepilone does not inhibit CYP enzymes at relevant clinical concentrations and is not expected to appreciably alter the plasma concentrations of other drugs. To this point, ixabepilone C_{max} values decreased by 19%, capecitabine C_{max} values decreased by 27%, and 5-fluorouracil AUC increased by 14%, compared to ixabepilone or capecitabine administered individually in patients who were treated with ixabepilone (40 mg/m²) in combination with capecitabine (1000 mg/m²). Based on clinical efficacy data that supports a unique role for the combination, the interaction is not clinically relevant.

Toxicity

Peripheral neurotoxicity is the most common serious toxicity observed with ixabepilone as both monotherapy and combined with capecitabine, as summarized in [Table 3](#).^{435, 439, 440, 454, 455} A burning sensation, hyperesthesia, hypoesthesia, paresthesia, and other manifestations of neuropathic pain are common symptoms. Approximately 63% and 67% of breast cancer patients who had prior taxane-based treatment develop peripheral neurotoxicity after treatment with ixabepilone alone and combined with capecitabine, respectively; however, more severe (grades 3 and 4) toxicity was noted in 14% and 23%, respectively. In heavily pretreated patients, neuropathy occurs early, with about 75% of new-onset or worsening neuropathy occurring during the first three cycles and the most serious manifestations experienced after four cycles. Although prior exposure to neurotoxic drugs does not seem to predispose to neuropathy based on a large retrospective analysis of clinical trial data, it should be noted that patients with neuropathy of at least moderate severity were excluded from entry of early studies. Patients who have hepatic insufficiency and diabetes mellitus are at increased risk of developing severe neuropathy (see section titled “Administration, Dose, and Schedule”). In clinical trials, peripheral neuropathy was managed using dose reduction, dose delay, and treatment discontinuation (see section titled “Administration, Dose, and Schedule”). After treatment discontinuation and/or dose reduction, manifestations resolve rapidly relative to the taxanes, vinca alkaloids, and eribulin, with median times of 4–6 weeks for resolution of severe manifestation to grade 1 severity, with almost all grade 3–4 events resolving to this level within 12 weeks after onset.

Dose-dependent myelosuppression, principally neutropenia, is common with ixabepilone treatment. Effects on platelets and red blood cells are less common. Grade 4 neutropenia (<500 cells/μL) occurred in 36% of patients treated with ixabepilone in combination with capecitabine and in 23% of patients treated with monotherapy; however, febrile neutropenia and infection with neutropenia have been reported in 5% and 6% of patients treated with ixabepilone in combination with capecitabine, respectively, and 3% and 5% of patients treated with ixabepilone alone. Myelosuppression does not

generally worsen with successive treatment, suggesting that hematopoietic progenitor cells are not significantly affected. Dose reduction is recommended for patients experiencing severe neutropenia, and dose modification is recommended for patients with moderate hepatic dysfunction (see section titled “Administration, Dose, and Schedule”). Since ixabepilone is formulated in polyoxyethylated castor oil, severe HSRs, largely secondary to this diluent, are noted. Manifestations of hypersensitivity include flushing, rash, dyspnea, and bronchospasm. For this reason, it is recommended that patients receive premedication with H1- and H2-histamine antagonists approximately 1 h before treatment (see section titled “Administration, Dose, and Schedule”). In the case of severe HSRs, treatment should be stopped, and aggressive supportive treatment (e.g., epinephrine, corticosteroids) started. In clinical studies, approximately 1% of patients have experienced severe reactions despite various premedication regimens. There have been reports of successful re-treatment of patients who had experienced prior reactions following the addition of a corticosteroid (e.g., dexamethasone 20 mg intravenously 30 min before or orally 60 min before) and H1- and H2-histamine antagonists and extension of the infusion time.

Patients treated with ixabepilone have experienced cognitive dysfunction, lethargy, and discoordinated movements in the peritreatment period, possibly due to the ethanol in the diluent. Myalgia and arthralgia have been noted in the peritreatment period. Various cardiac disturbances, including myocardial infarction, supraventricular arrhythmia, left ventricular dysfunction, angina pectoris, atrial flutter, cardiomyopathy, and myocardial ischemia, have been observed, but these occurrences have not been directly attributed to ixabepilone. Ileus, colitis, impaired gastric emptying, esophagitis, dysphagia, gastritis, gastrointestinal hemorrhage, hepatic insufficiency, erythema multiforme, muscle spasms, trismus, and renal failure have also been reported on rare occasion.

Administration, dose, and schedule

The recommended dosage of ixabepilone is 40 mg/m² intravenously over 3 h every 3 weeks.^{436, 440, 454, 455} Because of the lack of dosing data for patients whose body surface area exceeds 2.2 m², the doses for such individuals should be calculated based on a cap of 2.2 m². Although a range of intermittent dosing schedules have been evaluated, particularly 16 mg/m² weekly for 3 weeks every 4 weeks, most efficacy data relate to the 3-h-every-3-week dosing schedule, and superior efficacy has not been demonstrated on more intermittent schedules to date. Ixabepilone is intended for intravenous use only after constitution with the supplied diluent, which is a nonpyrogenic solution of 52.8% (w/v) purified polyoxyethylated castor oil and 39.8% (w/v) dehydrated alcohol, USP, and after further dilution with Lactated Ringer's Injection, USP, or 0.9% sodium chloride injection, USP (pH adjusted between 6.0 and 9.0 with Sodium Bicarbonate, USP, prior to addition of the constituted ixabepilone solution). To minimize the chance of occurrence of major HSRs, all patients should be premedicated approximately 1 h before treatment with both an H1-histamine antagonist (e.g., diphenhydramine 50 mg orally or equivalent) and an H2-histamine antagonist (e.g., ranitidine 150–300 mg orally or equivalent). For patients who experience an HSR, premedication with corticosteroids (e.g., dexamethasone 20 mg intravenously, 30 min before infusion or orally, 60 min before treatment), in addition to pretreatment with H1- and H2-histamine antagonists, is recommended.

Dose modification and/or treatment delay is recommended for patients who develop clinically relevant grades of neuropathy and/or myelosuppression. Dose reduction by 20% is recommended for patients who develop neuropathic manifestations of grade 2 severity lasting at least 7 days or of grade 3 severity lasting less than 7 days. Discontinuation of treatment is recommended for more protracted grade 3 neuropathy or any grade 4 toxicity. Dose reduction by 20% is also recommended for patients who

experience a neutrophil count $<500/\mu\text{L}$ lasting at least 7 days and/or associated with fever, a platelet count $<25,000/\mu\text{L}$, or a platelet count $<50,000/\mu\text{L}$ with bleeding. A similar dose reduction (20%) is recommended for patients who experience other types of grade 3 (severe) toxicities, except fatigue, palmar–plantar erythrodysesthesia, and/or arthralgia/myalgia. Drug discontinuation is recommended for any grade 4 (i.e., disabling) nonhematologic toxicity. In a study of ixabepilone in patients with mild to severe hepatic impairment, ixabepilone AUC values increased by 22% in patients with bilirubin values ranging from >1 to 1.5 times the ULN or AST values exceeding the ULN with bilirubin <1.5 times the ULN, whereas AUC values increased by 30% in patients with bilirubin elevations ranging from 1.5 to 3 times the ULN and any AST level and increased by 81% in patients with bilirubin values exceeding 3 times the ULN with any AST level. Doses of 10 and 20 mg/m^2 as monotherapy were tolerated in a small number of patients with severe hepatic impairment (bilirubin >3 times the ULN). It is recommended that the dose of ixabepilone as monotherapy be reduced to 32 mg/m^2 in patients with AST or ALT elevations up to 10 times the ULN and bilirubin up to 1.5 times the ULN. For patients with AST or ALT elevations up to 10 times the ULN and bilirubin ranging from 1.5 to 3.0 times the ULN, ixabepilone monotherapy doses should be reduced to 20 mg/m^2 . If tolerated, the dose can be increased up to but not exceeding 30 mg/m^2 in subsequent cycles. Use of ixabepilone is not recommended in patients with severe hepatic dysfunction defined as ALT or AST values exceeding 10 times the ULN or bilirubin exceeding 3 times the ULN. Treatment with ixabepilone combined with capecitabine is not recommended for patients who have AST, ALT, and/or bilirubin levels exceeding the ULN. A standard dose of ixabepilone (40 mg/m^2) is recommended for patients who have AST and ALT <2.5 times the ULN and normal bilirubin values.

Ixabepilone is minimally excreted by the kidney; however, the agent has not been evaluated in patients with creatinine >1.5 times ULN. In a population pharmacokinetic analysis of ixabepilone as monotherapy, the pharmacokinetics of ixabepilone were not affected by mild or moderate renal insufficiency (creatinine clearance >30 mL/min). The regimen of ixabepilone combined with capecitabine has not been evaluated in patients with creatinine clearance values below 50 mL/min . The use of concomitant strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, clarithromycin, atazanavir, nefazodone, saquinavir, telithromycin, ritonavir, amprenavir, indinavir, nelfinavir, delavirdine, or voriconazole) should be avoided (see section titled “Drug Interactions”). Grapefruit juice may also impede metabolic clearance and should be avoided. Based on pharmacokinetic studies, if a strong CYP3A4 inhibitor must be coadministered, dose reduction to 20 mg/m^2 , which should adjust the ixabepilone AUC to that observed without inhibitors, should be considered. If the strong inhibitor is discontinued, a 1-week washout period is recommended before the ixabepilone dose is increased to the indicated dose.

Eribulin mesylate and natural products that enhance tubulin depolymerization

Several other natural and semisynthetic agents that bind to either the vinca or colchicine binding domains of tubulin are approved or under evaluation. Eribulin mesylate, a macrocyclic ketone analog of the marine natural product halichondrin B ([Figure 4](#)) originally isolated from the marine sponge *Halichondria okadai*, is perhaps the most relevant since the agent has been registered worldwide to treat women with advanced breast cancer after failure of anthracyclines and taxanes. Eribulin mesylate and other halichondrin B analogs bind to tubulin and inhibit tubulin polymerization, disrupt mitotic spindle formation and centromere dynamics, induce mitotic arrest followed by apoptosis, and possess growth inhibitory properties in the subnanomolar range and marked anticancer activity in preclinical studies.^{456–458} Synthetic forms of hemiasterlin (HTI-286 and E7974), which is a natural product derived from marine

sponges, are also in clinical development.⁴⁵⁹ Hemiasterlin and its analogs bind to the vinca domain on tubulin, disrupt normal microtubule dynamics, and depolymerize microtubules at stoichiometric concentrations. They are much weaker substrate for Pgp than the vinca alkaloids and taxanes and have prominent anticancer activity in human tumor xenografts, including those that express Pgp.^{460, 461} The hemiasterlins are also cross-resistant with the vinca alkaloids and other agents that bind to the vinca binding site of tubulin but minimally cross-resistant with the taxanes, epothilones, and colchicine. In preclinical studies, resistance appears to be at least partially mediated by α -tubulin mutations and/or an ABC drug pump distinct from Pgp, ABCG2, MRP1, or MRP3.^{460, 461}

Among other potent natural products that enhance tubulin polymerization are the dolastatins, which constitute a series of oligopeptides isolated from the sea hare, *Dolabella auricularia*. The dolastatins inhibit binding (noncompetitively) of vinca alkaloids to tubulin, tubulin polymerization, and tubulin-dependent GTP hydrolysis.⁴⁶² They also stabilize the colchicine binding activity of tubulin and possess cytotoxic activity in the picomolar to low nanomolar range.⁴⁶² Auristatin, a potent dolastatin-10 analog, has been incorporated into several ADCs, including brentuximab vedotin that targets CD-30 (see section titled “Antibody-Drug Conjugates Carrying Antimicrotubule Drug Payloads”)

Most efforts targeting the tumor vasculature involve inhibition of the development of malignant angiogenesis, but several antimicrotubule agents rapidly shut down existing tumor vasculature by inhibiting tubulin function in vascular endothelial cells.^{463, 464} Since the late 1990s, the combretastatins and *N*-acetylcolchicinol-*O*-phosphate which resemble colchicine and bind to the colchicine domain on tubulin have undergone extensive clinical development as antivascular agents in a wide range of cancers; however, they have yet to demonstrate favorable therapeutic indices.

Eribulin mesylate

In 1986, Hirata and Uemura extracted halichondrin B, a large polyether macrolide, from a rare marine Japanese sponge, *H. okadai*. Based on its potent anticancer activity in preclinical models, it was further evaluated against other known antimicrotubule and cytotoxic drugs.⁴⁵⁸ Although the antiproliferative effects of halichondrin B were similar to other antimicrotubule agents, its mechanism of action was distinct.⁴⁵⁸ However, despite its impressive anticancer activity in preclinical studies, sufficient quantities of its natural source were not available. More than one decade later, however, structural activity studies indicated that the antimicrotubule activity of halichondrin B was conferred by its macrocyclic lactone C1–C38 moiety and a completely synthetic and structurally simplified derivative with retained high potency of its parent compound, eribulin mesylate, was developed.

Clinical indications

Eribulin mesylate has demonstrated clinical activity in various solid malignancies, but it is registered worldwide for treating patients with metastatic breast cancer who have previously received at least two chemotherapeutic regimens for the treatment of metastatic disease. The agent demonstrated improved overall survival over a group of other relevant anticancer agents, including taxanes, capecitabine, gemcitabine, and VRL, but the study was not sufficiently powered to gauge the superiority of eribulin mesylate compared to any specific single agent in the group.⁴⁶⁵ In addition, eribulin mesylate has recently demonstrated superior overall survival over dacarbazine in patients with soft tissue sarcoma who had received at least two prior chemotherapy regimens, and has been approved for the treatment of patients with unresectable liposarcoma who have received a prior anthracycline containing regimen. Notable

activity has been noted in patients with advanced cancers of the head and neck, bladder, prostate, ovary, pancreas, and lung.⁴⁵⁸

Mechanism of action

The mechanisms by which eribulin exerts its effects differ from those of other microtubule-depolymerizing agents. Eribulin mesylate binds with high affinity to the plus ends of microtubules to a maximum of 15 sites per microtubule and suppresses dynamic instability. The binding site of eribulin differs from that of taxanes and vinca alkaloids, which is thought to be responsible for eribulin's activity against some cancer cells with MDR or β -tubulin mutations.^{456–458} It is a noncompetitive inhibitor of VBL binding and binds to β -tubulin at a slightly different site than the vinca alkaloids. Like the vinca alkaloids, eribulin inhibits tubulin polymerization and suppresses the microtubule growth phase. In contrast to the vinca alkaloids, however, eribulin does not affect shortening.^{456–458, 466, 467} Referred to as having an “end-poisoning” mechanism, eribulin mesylate either binds directly to microtubule ends or induces tubulin aggregates, which compete with soluble tubulin for addition to the growing ends of microtubules. By doing so, eribulin disrupts mitotic spindle assembly, blocking cell-cycle traverse in G_2/M . Prolonged G_2/M blockade and incomplete repair of relevant perturbations at the mitotic checkpoint are followed by apoptosis, as evidenced by phosphorylation of Bcl-2, cytochrome C release from mitochondria activation of caspase-3 and caspase-9, and cleavage of PARP.⁴⁶⁶ Eribulin mesylate is relatively stable on or near tubulin surfaces, which enables it to be retained in tumor cells for longer periods than other halichondrin B analogs.

While both eribulin and the vinca alkaloids inhibit nucleotide exchange on β -tubulin, as well as cross-linking between β -tubulin residues, the polymer structures formed by these agents differ. Vinca alkaloids create a large, stable structure that inhibits microtubules, whereas both halichondrin B and eribulin form smaller, unstable tubulin polymers. In addition to inhibiting microtubule growth, eribulin sequesters tubules into globular aggregates, which differ from the ring or spiral aggregates seen with vinca alkaloids. Further, in contrast to the vinca alkaloids, eribulin does not cause splaying of microtubule ends or heterodimer linking of α - and β -tubulin. Eribulin's unique mechanism is thought to be important for its clinical activity in patients who have been previously treated with other types of antimicrotubule drugs.

Mechanism of resistance

The mechanisms of cellular resistance to eribulin are not entirely known; however, since eribulin disrupts microtubule dynamics and blocks cell-cycle traverse in G_2/M , cycling cells are most susceptible to its actions.^{458–462, 466, 467} Nevertheless, the relative drug susceptibility of microtubules involved in mitotic spindle dynamics and interphase functions is not known. Like the vinca alkaloids and taxanes, resistance to eribulin appears to be conferred by MDR1; however, the clinical relevance of this phenomenon is not known. In general, eribulin demonstrates greater efficacy than the taxanes and vinca alkaloids against a wide range of human tumors in preclinical studies. It has also induced relevant degrees of inhibition in taxane-resistant human ovarian cancer cells harboring β -tubulin mutations and tumors that express relatively high concentrations of the β III-tubulin isotype.^{458–462, 467}

Clinical pharmacology

Eribulin mesylate exhibits dose-proportional pharmacokinetics in the dose range of 0.25–4.0 mg/m²

(Table 3). When administered intravenously, plasma disposition is biexponential with a rapid and initial distribution phase followed by a slow elimination phase. Eribulin's elimination $t_{1/2}$ averages 40 h; estimates of its V_d range from 43 to 114 L/m², and systemic clearance ranges from 1.15 to 2.42 L/h/m² over the aforementioned dose range. The plasma protein binding of eribulin mesylate ranges from 49% to 65% at concentrations of 100–1000 ng/mL.^{458, 467} Drug exposure achieved with multiple dosing is comparable to that following a single dose. No drug accumulation is observed with weekly administration.

Unmetabolized eribulin is the major circulating species following administration of radiolabeled eribulin mesylate to cancer patients. Eribulin is excreted unchanged in the feces, and metabolite concentrations represent <0.6% of parent compound, confirming that metabolism is negligible. The liver disposes of parent compound and four minor CYP3A4-generated monooxygenated metabolites. A small amount of eribulin (≈9%) is renally excreted as parent compound.

Drug interactions

Eribulin mesylate shows no induction potential for CYP1A, CYP2C9, CYP2C19, or CYP3A in primary human hepatocytes.^{458, 467} It inhibits CYP3A4 activity in liver microsomes, but not enough to substantially increase the plasma concentrations of CYP3A4 substrates. No significant inhibition of CYP1A2, CYP2C9, CYP2C19, CYP2D6, or CYP2E1 has been detected with eribulin concentrations as high as 5 μmol/L in human microsomes. Drug interaction studies *in vitro* indicate that eribulin does not significantly affect the metabolism or plasma concentrations of drugs that are substrates of these CYP enzymes. Eribulin is a low-affinity substrate and a weak inhibitor of the drug efflux transporter Pgp.

As predicted by *in vitro* studies, the results of clinical studies to date indicate that eribulin presents a negligible potential, if any, for drug–drug interactions with both CYP3A4 inhibitors and inducers.⁴⁶⁷ Relevant pharmacokinetic interactions were not observed when eribulin was administered with a ketoconazole, a strong CYP3A4 and a Pgp inhibitor, or rifampin, a strong CYP3A4 inducer.

Toxicity

The most common adverse reactions reported in patients receiving eribulin was neutropenia, with 57% of 503 heavily treated breast cancer patients treated with eribulin 1.4 mg/m² on days 1 and 8 of a 21-day cycle experiencing neutrophil count nadirs of 1000/uL or less in a pivotal trial.^{458, 465, 467} Febrile neutropenia occurred in 5% of patients. Dose reduction or drug discontinuation due to neutropenia was required in 12% and <1% of patients, respectively; granulocyte-colony stimulating factor was used in 19% of patients. The mean time to neutrophil nadir was 13 days, and the mean time to recovery from severe neutropenia (<500/μL) was 8 days. Grade 3 or greater thrombocytopenia and anemia occurred in <1% and 2% of patients, respectively. Other common adverse events in the eribulin group included fatigue (54%), alopecia (45%), and peripheral neuropathy (35%; 8% grade 3 or 4). The neuropathy is predominately sensory but motor effects do occur. Approximately 5% of patients discontinued eribulin primarily due to peripheral neuropathy, the incidence of which was similar to that in the taxane subgroup. The incidence of severe (grade 3 or 4) neuropathy was similar in patients with and without a preexisting mild to moderate neuropathy. A recent randomized phase II study showed no significant difference in the incidence and severity of neuropathy between eribulin and ixabepilone; however, the neuropathy induced by ixabepilone reversed more rapidly.⁴⁶⁷ Higher incidences of severe toxicities were observed in Japanese patients treated with eribulin 1.4 mg/m² administered as a brief intravenous infusion on days 1

and 8 of a 21-day cycle.⁴⁶⁷ In an uncontrolled open-label electrocardiographic study involving 26 patients, QT prolongation was observed on day 8 irrespective of eribulin concentrations, with no QT prolongation observed on day 1. Therefore, electrocardiographic monitoring and restrictions are recommended in patients possibly susceptible to the effects of electrocardiographic disturbances (see sections “Eribulin Mesylate and Natural Products that Enhance Tubulin Depolymerization” and “Administration, Dose, and Schedule”).

Among patients with grade 0 or 1 hepatic transaminase elevation pretreatment, approximately 18% of eribulin-treated patients experience at least grade 2 transaminase elevations. Other adverse events, albeit rarely severe, reported in patients treated with eribulin, albeit rarely severe, include stomatitis, diarrhea, constipation, nausea, vomiting, anorexia, myalgia, arthralgia, increased lacrimation, weight loss, fever, anemia, and headache.

Administration, dose, and schedule

Eribulin mesylate is indicated at a dose of 1.4 mg/m² intravenously over 2–5 min on days 1 and 8 of a 21-day cycle for patients with metastatic breast cancer. It has also been administered at a dose of 1.4 mg/m² on days 1, 8, and 15 of a 28-day cycle. A head-to-head comparison of the two dosing schedules in patients with metastatic breast cancer showed that the 21-day regimen is associated with a slightly, albeit not significantly, higher response rate.^{458, 467} Each vial contains 1 mg of eribulin mesylate as a 0.50 mg/mL colorless, sterile solution for injection in a 5 : 95 ratio of ethanol to water. The required amount of eribulin should be withdrawn from the vial and mixed with 100 mL of 0.9% Sodium Chloride Injection, USP. Dextrose should not be used for dilution or administration. Pretreatment with corticosteroids or antihistamines is not required since its water solubility negates the requirement for a lipophilic vehicle such as polysorbate-80 or polyoxyethylated castor oil, which may result in HSRs.

Lower starting doses of eribulin mesylate, 1.1 and 0.7 mg/m², are recommended for patients with mild (Child–Pugh A) and moderate (Child–Pugh B) hepatic impairment, respectively.^{458, 467} The agent has not been evaluated in patients with severe hepatic insufficiency. For patients with moderate or severe renal impairment (creatinine clearance, 15–49 mL/min), the recommended starting dose is 1.1 mg/m². Eribulin should not be administered on day 8 of a day 1–8 every-21-day schedule, if neutrophil and/or platelet counts are <1000 and <75,000/μL, respectively, and/or in the event of grade 3–4 nonhematologic toxicity. The day 8 dose can be delayed for a maximum of 1 week. The dose should be omitted if the toxicities do not resolve or improve to at least grade 2 severity by day 15. If toxicities resolve or improve to at least grade 2 severity by day 15, eribulin may be administered at a dose of 1.1 mg/m², and the next cycle should be initiated no sooner than 2 weeks later. A second dose reduction to 0.7 mg/m² is recommended in the event of similar toxicity. The dose of eribulin should not be re-escalated after it has been reduced.

Electrocardiographic monitoring is recommended in patient with congestive heart failure, bradyarrhythmias, and electrolyte abnormalities and in those receiving drugs known to prolong the QT interval. Hypokalemia or hypomagnesemia should be corrected prior to treatment, and electrolytes should be monitored periodically during treatment. Eribulin should not be administered in patients with congenitally long QT syndrome.

Targeting mitotic motor proteins and kinases

Although tubulin is the most abundant protein component of the mitotic spindle apparatus, several other

proteins, such as mitotic kinesins, centrosomal proteins, and mitotic kinases, play key roles in the mechanics of mitosis and cell-cycle progression through the premitotic checkpoint. Over the last decade, many of these subcellular constituents have been evaluated as targets for therapeutics against cancer.

Mitotic kinesins

Kinesins are motor proteins that convert energy released by the hydrolysis of ATP into mechanical force for movement of cargo (e.g., organelles, constituents) along microtubules and the intracellular organization of the mitotic spindle, and other microtubule-containing structures.^{28, 29, 468, 469}

The mitotic kinesins function exclusively in mitosis in proliferating cells.^{28, 29, 468–470} During mitosis, different, highly specialized mitotic kinesins play critical roles in various aspects of mitotic spindle formation, including establishment of spindle bipolarity, spindle pole organization, chromosome alignment and segregation, and regulation of microtubule dynamics. The establishment of mitotic spindle bipolarity is among the earliest events in spindle assembly, and it requires the function of a specific kinesin motor protein KSP, also known as Eg5, which has no known role other than in mitosis. The expression profiles of KSP mRNA in normal tissues are consistent with preferential expression of KSP in proliferating cells relative to normal adjacent tissue and postmitotic neurons. As essential elements in mitotic spindle assembly and function, KSP and mitotic kinesins provide attractive targets for intervention into the cell cycle.

Several KSP inhibitors have been evaluated as anticancer therapeutics over the past decade. One of the first, ispinesib, a polycyclic, nitrogen-containing heterocycle and allosteric inhibitor of KSP motor domain ATPase with a K_i of 12 nM and a potent KSP inhibitor, potently induces mitotic arrest in both solid and hematologic malignancies in preclinical models.^{28, 29, 468–470} Similar to various other KSP inhibitors that have entered clinical evaluations, ispinesib is 10,000-fold more selective for KSP relative to other members of the kinesin superfamily and blocks assembly of a functional mitotic spindle, thereby causing cell-cycle arrest in mitosis and subsequent cell death.⁴⁷⁰ In tumor-bearing mice, ispinesib and several other KSP inhibitors have exhibited anticancer activity comparable to or exceeding that of the taxanes and induced formation of monopolar mitotic figures identical to those produced in cultured cells. KSP inhibitors have been shown to be effective on both taxane-sensitive and taxane-resistant cells, which either have multidrug resistance product Pgp overexpression or acquired β -tubulin mutations. Interestingly, the combination of KSP inhibitors with taxanes produce an antagonistic effect on mitotic arrest and cell death, indicating that the combination of an KSP inhibitor with a taxane may not be useful. Although highly specific KSP inhibitors have demonstrated anticancer activity in both solid and hematologic malignancies, including breast cancer, lymphoma, and multiple myeloma, toxicity in tissues with high proliferative rates, namely, neutropenia, has been significant at clinically relevant doses, thereby requiring the use of granulocyte colony-stimulating factors. A unique clinical role for KSP inhibitors has not yet been clearly elucidated.

The mitotic centromere-associated kinesin (MCAK), a member of the kinesin-13 family that regulates microtubule dynamics by removing tubulin subunits from the polymer end, is another potential target for therapeutic development.⁴⁷¹ The depolymerizing activity of MCAK plays pivotal roles in spindle formation, correcting erroneous attachments of microtubule–kinetochore and chromosome movement. Thus, the accurate regulation of MCAK by mitotic kinases, Aurora-A and Aurora-B, polo-like kinase-1, and CDK1 is important for ensuring the faithful segregation of chromosomes in mitosis and for safeguarding chromosome stability. There are increasing data indicating that MCAK is aberrantly regulated in cancer cells, thereby contributing to tumorigenesis, invasiveness, metastasis, and drug resistance, most probably due to increased chromosomal instability and remodeling of the microtubule

cytoskeleton in cancer cells. Most interestingly, recent observations suggest that MCAK could be a novel molecular target for cancer therapy, as a new cancer antigen or as a mitotic regulator.

The centromere-associated protein E (CENP-E) is another type of mitotic kinesin. CENP-E associates with the kinetochores and plays an essential role in chromosome movement in early mitosis and integrates mitotic spindle mechanics with regulators of the mitotic checkpoint, thereby facilitating cell-cycle transition from metaphase to anaphase.⁴⁷² Inhibition of CENP-E induces cell-cycle arrest during cell duplication, leading to subsequent apoptosis or cell death. In preclinical studies, GSK-923295 demonstrated a broad spectrum of activity against a range of human tumor xenografts grown in nude mice, including models of colon, breast, ovarian, lung, and other tumors.⁴⁶⁹

Mitotic kinases

Mitotic kinases, particularly the aurora and polo-like kinases, are being evaluated for anticancer therapeutic development.⁴⁷³ The aurora kinases, which encompass three principal family members known as Aurora-A, Aurora-B, and Aurora-C, regulate chromosome segregation and cytokinesis during mitosis. Aberrant expression and activity of these kinases that may lead to aneuploidy and tumorigenesis occur in many types of human cancer. Aurora-A and Aurora-B kinases have distinct roles in mitosis. Aurora-A kinase, which is typically found in the pericentrosomal region, recruits important components to the mitotic spindle, such as γ -tubulin, while the mitotic spindle is formed from the daughter centrosomes. Aurora-B kinase is localized to the interphase chromosomes proximal to the centromere, and as chromosome condensation occurs at the start of mitosis, both Aurora-A and Aurora-B kinases share responsibility for phosphorylating histone H3. Both kinases also have distinct roles in the function of the contractile ring that participates in the formation of two daughter cells. Aurora-C kinase has a highly specialized, albeit as of yet undetermined, role in mitosis, but it appears to complement Aurora-B kinase, and the expression of all three aurora kinases are increased in several types of cancers. Highly potent and both selective and nonselective small-molecule inhibitors of Aurora-A and Aurora-B kinases, which block cell-cycle progression and induce apoptosis in experimental models of human cancer, are undergoing clinical development. Neutropenia is their principal toxicity, and although anticancer activity has been observed, largely in hematologic malignancies, a unique clinical role for these agents has not yet been demonstrated, most likely due to the narrow therapeutic index of potential susceptible malignancies and hematopoietic cells.⁴⁷³

Like the aurora family of kinases, the polo-like kinases, NIMA-related kinases, and other families of mitotic kinase participate in the centrosome cycle and modulate spindle function, while Bub1, BubR1, and Mps1 kinases regulate the spindle assembly checkpoint.^{474, 475} Family members, like polo-like kinase-1, are also involved in the regulation of key steps during cell division, DNA damage repair pathways, apoptosis, and the progression of the cell cycle. At least one family member, polo-like kinase-3, is a multifunctional stress response protein that responds to signals induced by DNA damage and/or mitotic spindle disruption. After demonstrating broad-spectrum anticancer activity in preclinical studies against both solid and hematologic malignancies, small-molecule inhibitors of polo-like kinase are in clinical development.^{474, 475} Similar to the mitotic kinesins and aurora kinases in clinical development, unique roles in cancer therapeutics have not been discerned, possibly due to the emergence of hematologic toxicity, principally neutropenia, at relevant dose levels.

Antibody-drug conjugates carrying antimicrotubule drug payloads

Antibody therapies offer many advantages over cytotoxic agents, the main one being the specificity of each mAb for its target antigen.^{476, 477} Since their discovery in the early 1970s, mAbs have been evaluated as therapeutic agents and have enjoyed considerable success in recent years. However, mAbs also have their disadvantages, including poor inherent cytotoxicity and suboptimal penetration into malignancies. Combining mAbs with potent cytotoxic agents, however, may provide the best of both worlds—the specificity of a mAb for tumors and the potency of the agent for cytotoxicity. ADCs utilize the exquisite specificity of a mAb for its antigen to selectively deliver a highly toxic drug to the cancer cell, thereby increasing the selectivity and therapeutic window of any potent cytotoxic that is utilized as the ADC's payload. The design of an ADC relies on the proper selection of a tumor-specific antigen that is accessible for antibody binding and delivery to its target. The rationale for ADCs lies in the specificity of antigen expression by cancer cells, which permits drug delivery to target tissues with relative sparing of healthy tissues that express little to no antigen. Likewise, the level of expression of the target antigen on tumor cells determines drug delivery as well as effect on normal tissues. If a target antigen is not expressed at high levels on tumor cells, ADC uptake will be low, which will limit cytotoxicity and lead to accumulation of drug extracellularly and nonspecific toxicity to normal cells. Since antimicrotubule agents act intracellularly, it is crucial that the target antigen transports the ADC intracellularly. If the antigen does not internalize, the drug will not achieve sufficiently adequate concentration to cause cytotoxicity, and the ADC may ultimately expose normal cells to toxic effects. It is also crucial that the antigen be expressed homogeneously among cancer cells that constitute the tumor. Additionally, the target antigen must be easily accessible from the blood. Lastly, the payload must be highly potent because only minute quantities are administered. The maytansinoids and dolastatins, which are highly potent inhibitors of microtubule assembly, have been the principal payloads incorporated into ADCs that are registered in the United States and elsewhere.^{476–479}

The discovery of maytansine, a benzoansamarcrolide that was first isolated from the bark of the Ethiopian shrub *Maytenus ovatus* in the early 1970s, as well as maytansine analogs, generated much interest as they were demonstrated to be 100- to 1000-fold more potent than the vinca alkaloids and other antimicrotubule agents. However, systemic administration resulted in an unacceptably high incidence of adverse gastrointestinal effects, peripheral neuropathy, and hematologic toxicity.^{480, 481} Maytansine binds to tubulin at a site overlapping the vinca alkaloid binding site but differs from the colchicine binding site. Both the vinca alkaloids and maytansinoids bind to the β -tubulin subunit. The structure–activity relationship of maytansinoids for tubulin binding correlates well with their activity *in vitro*; this and the absence of other primary effects suggest that mitotic inhibition represents the main mechanism of anticancer action of the maytansinoids. It has been suggested that maytansine acts by binding to key sulfhydryl groups of tubulin.⁴⁸⁰ Maytansinoids have a high affinity for tubulin located at the ends of microtubules yet lower affinity to sites distributed throughout the microtubules. The suppression of microtubule dynamics results in cell-cycle arrest in G₂/M, ultimately resulting in cell death by apoptosis. The high potency of the maytansinoids makes them ideal candidates for conjugation to antibodies. Two maytansine derivatives—emtansine (also referred to as DM1 ([Figure 5a](#)) and ravtansine (also referred to as DM4 [[Figure 5b](#)])—have been widely used in combination with irreversible and reversible linkers. Trastuzumab-emtansine was the first ADC registered; it is indicated for woman with metastatic breast cancer progressing on trastuzumab (*see* 109). The cytotoxic effects of trastuzumab-emtansine likely vary depending on the intracellular concentration of DM1 accumulated in cancer cells, high intracellular levels resulting in rapid apoptosis, and somewhat lower levels in impaired cellular trafficking and mitotic catastrophe, while the lowest levels lead to poor response to T-DM1.⁴⁸¹ Primary resistance of HER-2-amplified advanced breast cancer to trastuzumab-emtansine appears to be relatively infrequent, but most patients treated with trastuzumab-emtansine develop acquired drug resistance. The mechanisms of resistance are incompletely

understood, but mechanisms limiting the binding of trastuzumab to cancer cells may be involved. The cytotoxic effect of trastuzumab-emtansine may be impaired by inefficient internalization or enhanced recycling of the HER-2-ADC complex in cancer cells or impaired lysosomal degradation of trastuzumab or intracellular trafficking of HER2. The effect of trastuzumab-emtansine may also be compromised by MDR proteins that pump DM1 out of cancer cells.

Figure 5 Representations of the ADCs trastuzumab emtansine (a) and brentuximab vedotin (b) with chemical structures of their cytotoxic payloads emtansine (DM1) and monomethyl auristatin E, respectively.

Dolastatin and many of its synthetic derivatives have been evaluated in a wide range of clinical trials, but these agents have not shown appreciable anticancer activity and/or favorable therapeutic indices (see section titled “Eribulin Mesylate and Natural Products That Enhance Tubulin Depolymerization”). However, the ADC brentuximab vedotin, which is composed of the dolastatin analog monomethyl auristatin E (MMAE) covalently linked to CD30, a type II transmembrane protein belonging to the TNF family, has received regulatory approval for patients with relapsed refractory Hodgkin's lymphoma and anaplastic large cell lymphoma (see 65). Brentuximab vedotin's toxic payload MMAE is stably attached to the antibody with only 2% release following a 10-day incubation in human plasma, but selectively cleaved by lysosomal enzymes, presumably cathepsin B, after CD30 receptor-mediated internalization.⁴⁸⁰ In addition to the requirement for CD30 expression, multiple factors such as internalization, intracellular trafficking, or enzymatic cleavage and undoubtedly factors related to the MMAE determine tumor cell sensitivity *in vitro*.

Chapter 61

Endocrine therapy for hormone receptor-positive breast cancer

Aman U. Buzdar, MD, FACP ■ Shaheenah Dawood, MD, MBBch, FACP, FRCP, MPH, CPH ■ Harold A. Harvey, MD ■ Virgil Craig Jordan, OBE, PhD, DSc, FMedSci

Overview

The importance of the reproductive endocrine system in breast cancer treatment began to be appreciated at the turn of nineteenth century. It was around this time that it was realized that approximately one-third of premenopausal women with advanced breast cancer would respond to oophorectomy. However, it was only when the estrogen receptor (ER) was discovered that it was possible to fully appreciate the mechanisms underlying the activity of ovarian ablation and other associated treatments for breast cancer such as ovarian irradiation, adrenalectomy, and hypophysectomy. Research into both the estrogen and progesterone pathways not only provided a deeper understanding of the underlying mechanism of the carcinogenic pathway involved in the development of breast cancer but also allowed identification of potential targets for therapeutic intervention.

This chapter discusses recent advances in the molecular biology and physiology underlying the estrogen and progesterone receptor (PR) pathways and potential targets for intervention. In addition it examines and compares the pharmacology and efficacy of the different endocrine agents used in the management of both early and advanced stage breast cancer.

Biology of progestin production and action

Progestins are involved in the regulation of development and differentiation, proliferation, apoptosis, and metabolism in many target tissues with broad implications in neoplasia. In addition progestins serve as precursors to the estrogens, androgens, and adrenocortical steroids. Some of the progestin effects on target tissues are mediated by transcription, whereas other effects are more rapid and do not involve direct transcriptional effects. Progestins ([Figure 1](#)) include the naturally occurring hormone progesterone, 17 α -acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives (estrans), and norgestrel and related compounds in the gonane series. In humans progesterone is the most important progestin.

Figure 1 Structure of progesterone, 17 α -hydroxyprogesterone, and synthetic progestins.

Synthesis and sites of production

Progesterone is produced early in the scheme of the synthetic pathway involving the conversion of cholesterol to androgens, progestins, and estrogens. After menopause, in the absence of hormone replacement, the adrenal gland becomes the principal source of progestins (through the conversion of pregnenolone) as well as other sex steroids. In the premenopausal woman, progesterone is principally derived from the corpus luteum of the ovary, but in pregnancy after the eighth week of gestation, placental progesterone production greatly exceeds ovarian-derived progesterone. The placental trophoblast is the dominant cell responsible for progesterone production by the placenta. The development of a secretory endometrium in which the blastocyst can implant requires progesterone. Progesterone levels of 25 ng/mL are usual in the luteal phase of the menstrual cycle, whereas levels up to 150 ng/mL are seen in late pregnancy.

Mechanism of action

Progesterone functions in RNA transcription regulation through a complex series of interactions that is initiated by binding of the hormone to its cognate receptor. There are two isoforms of the progesterone receptor (PR) known as PR-A and PR-B that have distinct biological activities. PR-B has been shown to mediate the stimulatory activities of progesterone, while PR-A functions to inhibit the action of PR-B as well as other steroid receptors.¹⁻³ Both isoforms are encoded by a single gene, and their ratios vary in reproductive tissues as a consequence of developmental status, hormonal levels, and tissue type. Both

isoforms of PR contain AF-1 and AF-2 transactivation domains with PR-B also containing an additional AF-3 domain which functions to contribute to its cell- and promoter-specific activity. The ligand for both isoforms of PR is identical.

In the absence of the hormone, PR is found in the nucleus in an inactive monomeric state associated with a complex of heat shock proteins (HSP -90, 70, 60, and 40) and is transcriptionally inactive.^{4, 5} Binding of progesterone to PR results in the dissociation of the heat shock proteins leading to the formation of receptor-ligand homodimers that remain localized in the nucleus and bind to highly selective progesterone response elements (PREs) located on target genes.⁶ It is important to note that target cells must distinguish not only progesterone from other steroids, present in small amounts, but also progesterone from other hydrophobic molecules that are frequently found in 100-fold or greater excess. Such a high degree of discrimination is limited to differentiated cells that possess PR proteins and activatable PREs in their genome.^{6, 7} The next step in the process is the transcriptional activation by PR, which results from the interaction with a number of coactivators including steroid receptor coactivator 1 (SRC-1), transcription intermediary factor 2, and retinoic acid coactivator 3, among others.⁶⁻⁹ The SRC-1 interacts with the N-terminal AF-1 and the C-terminal AF-2 of the PR. This serves to emphasize that SRC-1 function to synergize the ligand-independent amino terminal AF-1 with the ligand-responsive carboxyl terminal AF-2 of the PR. The PR-coactivator complex then interacts further with additional proteins that have histone acetylase activity that causes chromatin remodeling serving to increase accessibility of transcriptional proteins to the promoter target.⁸

Physiologic actions

Progestins are involved in a number of benign physiologic changes ranging from differentiated secretory activity to edematous changes in stromal tissues of the breast. They also have implications on neoplastic processes being associated with both a decreased risk of endometrial neoplasms and a slightly increased risk of breast neoplasms when used in conjunction with estrogen replacement for menopause. Progestins have a critical role in the support of the products of conception: the differentiation of the endometrium and the promotion of the secretory phase of the endometrium; the maturation and cornification of the vaginal mucosal epithelium; the suppression of ovulation; the inhibition of gonadotropin release; the proliferation of breast epithelium and the induction of secretory activity in breast epithelium; and a natriuretic effect on the kidneys. A number of these biologic effects of progesterone are seen only in concert with priming of the target tissues with estrogen, whereas other effects appear to be interrelated with the actions of other steroid hormones, peptide hormones, and/or growth factors. Possible interactions between progesterone, estrogen, and growth factors must be taken into account when constructing treatment strategies.

Synthetic progestins

Synthetic progestins are derivatives of the steroid structure of either progesterone or testosterone. The synthetic progestins most often encountered include 17-hydroxyprogesterone, medroxyprogesterone (Provera), medroxyprogesterone acetate (MPA), megestrol acetate (MA) (Megace), norethindrone, norethindrone enanthate, norethindrone acetate, norethynodrel, norgestrel, desogestrel, and gestodene. The two most widely used synthetic progestins are MPA and MA, which differ only by a single bond at C6–C7. MPA can be administered as either an oral or intramuscular (IM) preparation, while MA is administered as an oral preparation.

Synthetic progestins are used most frequently in contraception, in conjunction with estrogen in postmenopausal hormone replacement therapy (HRT) and in endocrine treatment of uterine and breast cancer. In postmenopausal HRT, progestins are added to estrogen replacement principally to minimize the

risk of uterine cancer associated with estrogen-only therapy, although the effects of adding progestins to estrogen on the risk of breast cancer have become of increasing concern.¹⁰ In premenopausal women, progestins and antiprogestins are used predominantly in contraceptive preparations.¹¹ Progestins are often used alone in selected women with climacteric symptoms who are advised not to take estrogens.

Metastatic breast cancers

Progestins and PR have been studied extensively in cancerous human breast tissue. Patients whose tumors are PR positive have a higher probability of responding to endocrine therapy (not necessarily progestins) and in most series show a somewhat better prognosis with respect to both survival and disease-free interval.¹² Both MPA and MA have been shown to produce similar reductions in serum estrogen levels and produce responses of approximately 30% in patients with metastatic breast cancer.¹³ The principal progestin used for metastatic breast cancer has been MA. The response of metastatic breast cancer to MA is predicted not only by the presence of ER (estrogen receptor) and/or PR but also by the observation of an objective response to previous hormonal therapy. Randomized studies have shown comparable efficacy of progestins to tamoxifen, aminoglutethemide, and aromatase inhibitors in the second and subsequent lines of treatment of metastatic breast cancer.^{13, 14} Currently progestin therapy for hormone receptor-positive metastatic breast cancer is used principally after disease progression has been observed following use of selective ER modulators (e.g., tamoxifen) and aromatase inhibitors. As such a trial of progestins is commonly used as the third or subsequent line of therapy in patients with hormone receptor-positive metastatic breast cancer ([Figure 2](#)).

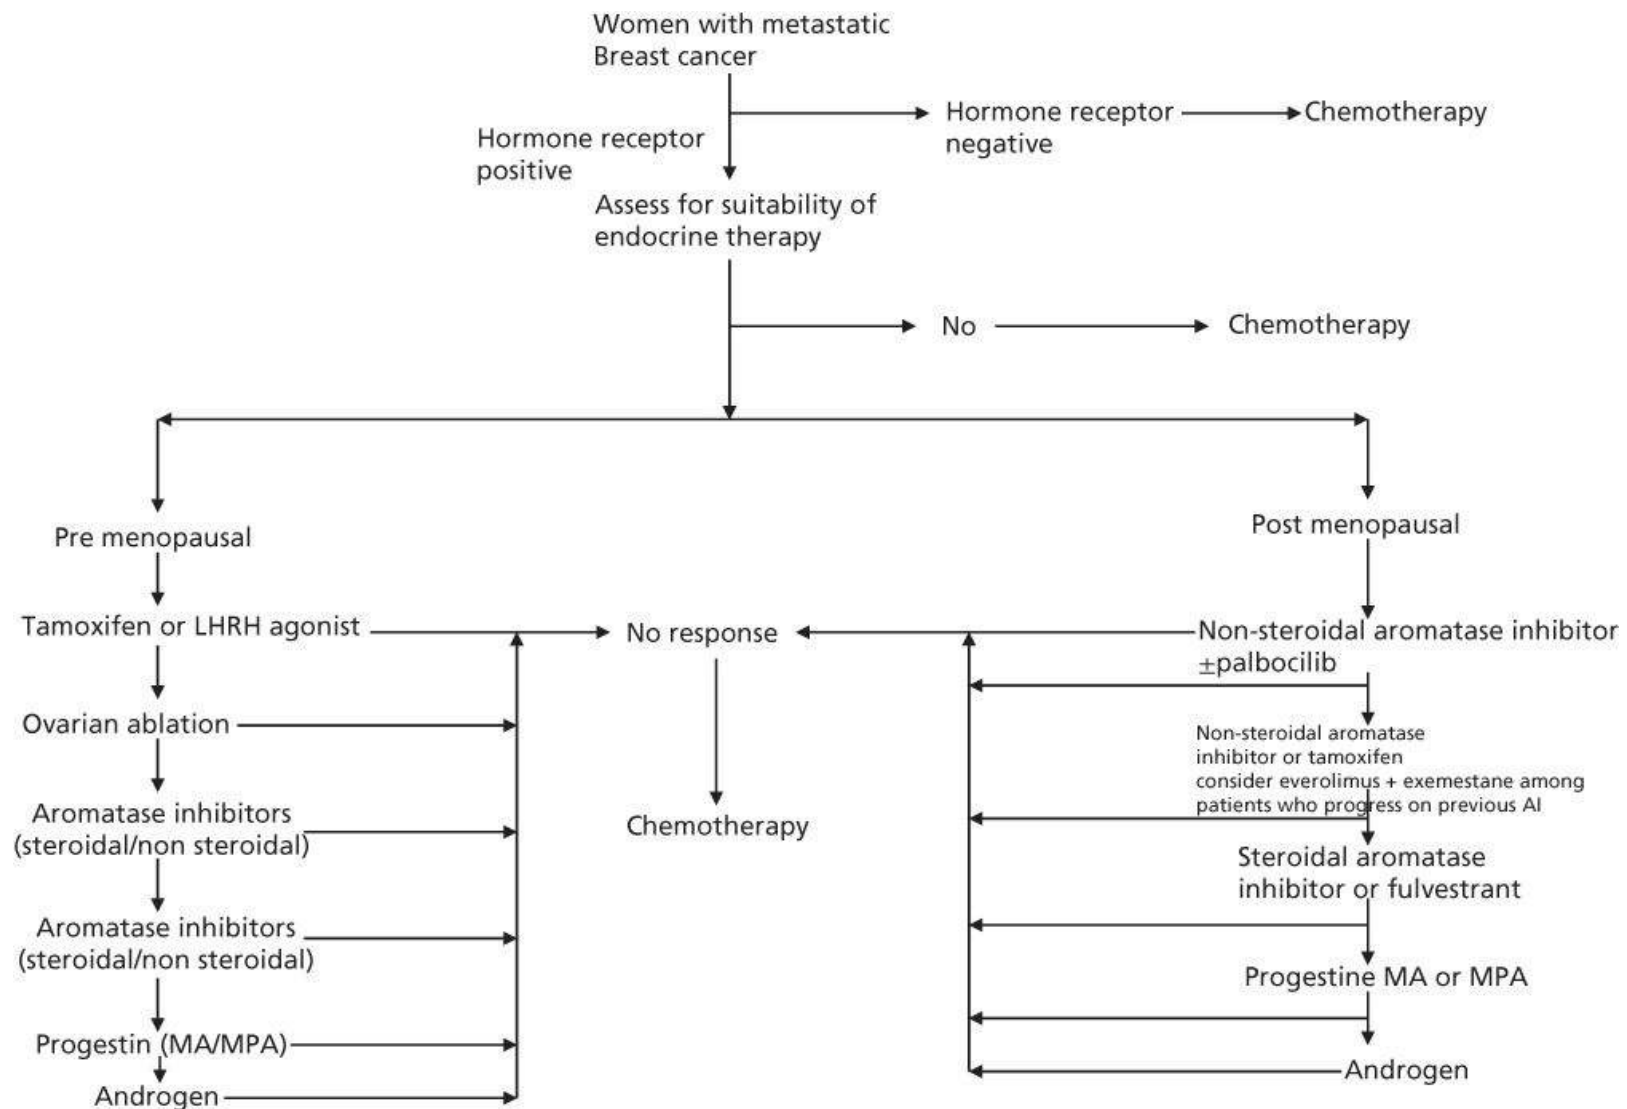

Figure 2 Algorithm for endocrine therapy among women with metastatic breast cancer.

Treatment of uterine cancer

Progestins are also used in the treatment of endometrial carcinoma.¹⁵ When diagnosed, adenocarcinoma of the uterus is cured by local therapy in 80% of cases. In the event of recurrence, exogenous progestin is an effective treatment in a significant fraction of cases: more than 30% of patients with recurrent disease demonstrate an objective response to exogenous progestins. ER and PR can be measured in these tumors, and the presence of these receptors correlates with differentiation of the tumor, prognosis for the patient, and response to progestins. The duration of response is not predicted by the presence of a receptor and varies from months to years. Tumors that lack ER and PR respond objectively to progestins in fewer than 10% of cases.¹⁵

Side effects and dosing of progestin

The most common adverse effect of progestin is weight gain, which occurs as a result of increased appetite and fluid retention. Its appetite-stimulating effect has frequently been used to treat cancer-induced cachexia. Other reported side effects include hot flashes, sweating, vaginal bleeding, nausea, dyspnea, thromboembolism, and rare cardiovascular events such as heart failure. Various dosing regimens of MA and MPA have been studied with a possible dose–response effect observed. The recommended dose of MA is 160 mg/day and that of MPA is at least 400–500 mg/day.¹⁶

Antiprogestins

Antiprogestins have wide and varied therapeutic applications including uses as contraceptives, to induce labor or to treat breast cancer, endometriosis, uterine leiomyomas, and meningiomas.¹⁷ The oldest and most widely used antiprogestin is RU 38486 or mifepristone that is a derivative of the 19-norprogesterone norethindrone containing a dimethyl-aminophenol substituent at the 11 β -position.^{11, 18} This compound is effectively absorbed orally and appears to bind with PR with high affinity and to effect altered coregulatory protein interaction after binding. It has been shown to have both antagonist and some agonist activity and is thus considered to be a PR modulator. Together with prostaglandins it is used for the termination of early pregnancy.¹⁸

Biology of estrogen production and action

A number of naturally occurring endogenous estrogens are produced in women with the most potent for both ER α - and β -mediated actions being estradiol followed by estrone and estriol. All three contain a phenolic A ring with a hydroxyl group at carbon 3 and a β -OH or ketone in position 17 of ring D with the phenolic A ring being the principle structural feature responsible for their selective high-affinity binding to both ERs.

The principle role of naturally occurring estrogens is to modulate cell growth by causing an increase in stimulatory growth factors [e.g., transforming growth factor- α (TGF- α)] and a decrease in inhibitory growth factors (e.g., TGF- β).¹⁹ These growth factors are thought to initiate or prevent progress through the cell cycle by interaction with their respective membrane receptors, with the regulatory mechanism functioning as an autocrine loop. There are also paracrine (cell-cell) influences of growth factors [e.g., insulin-like growth factor 1 (IGF-1)] that can play a role in modulating the replication of epithelial cells.

Biosynthetic pathway

The aromatase enzyme complex is located in the endoplasmic reticulum and consists of a cytochrome P450 hemoprotein (P450 AROM, aromatase) and the flavoprotein nicotinamide adenine dinucleotide phosphate (NADPH) that is common to most cell types and whose principle function is to donate electrons to cytochrome P450.²⁰ The principle enzyme involved in the conversion of androstenedione to estrone in the estrogen biosynthetic pathway is aromatase, a product of the CYP 19 gene that encodes a polypeptide of 503 amino acids with a molecular weight of 55 kilodaltons (KDa). Aromatase catalyzes three separate steroid hydroxylations involved in the conversion of androstenedione to estrone. The first two reactions give rise to 19-hydroxy and 19-aldehyde structures, and the third, although still controversial, probably involves the C-19 methyl group with release of formic acid.²¹

Sites of production

A number of tissues have the capacity to express aromatase and hence synthesize estrogens, and these include the ovary, placenta, hypothalamus, liver, muscle, adipose tissue, and malignant breast tumor tissue²² ([Figure 3](#)).

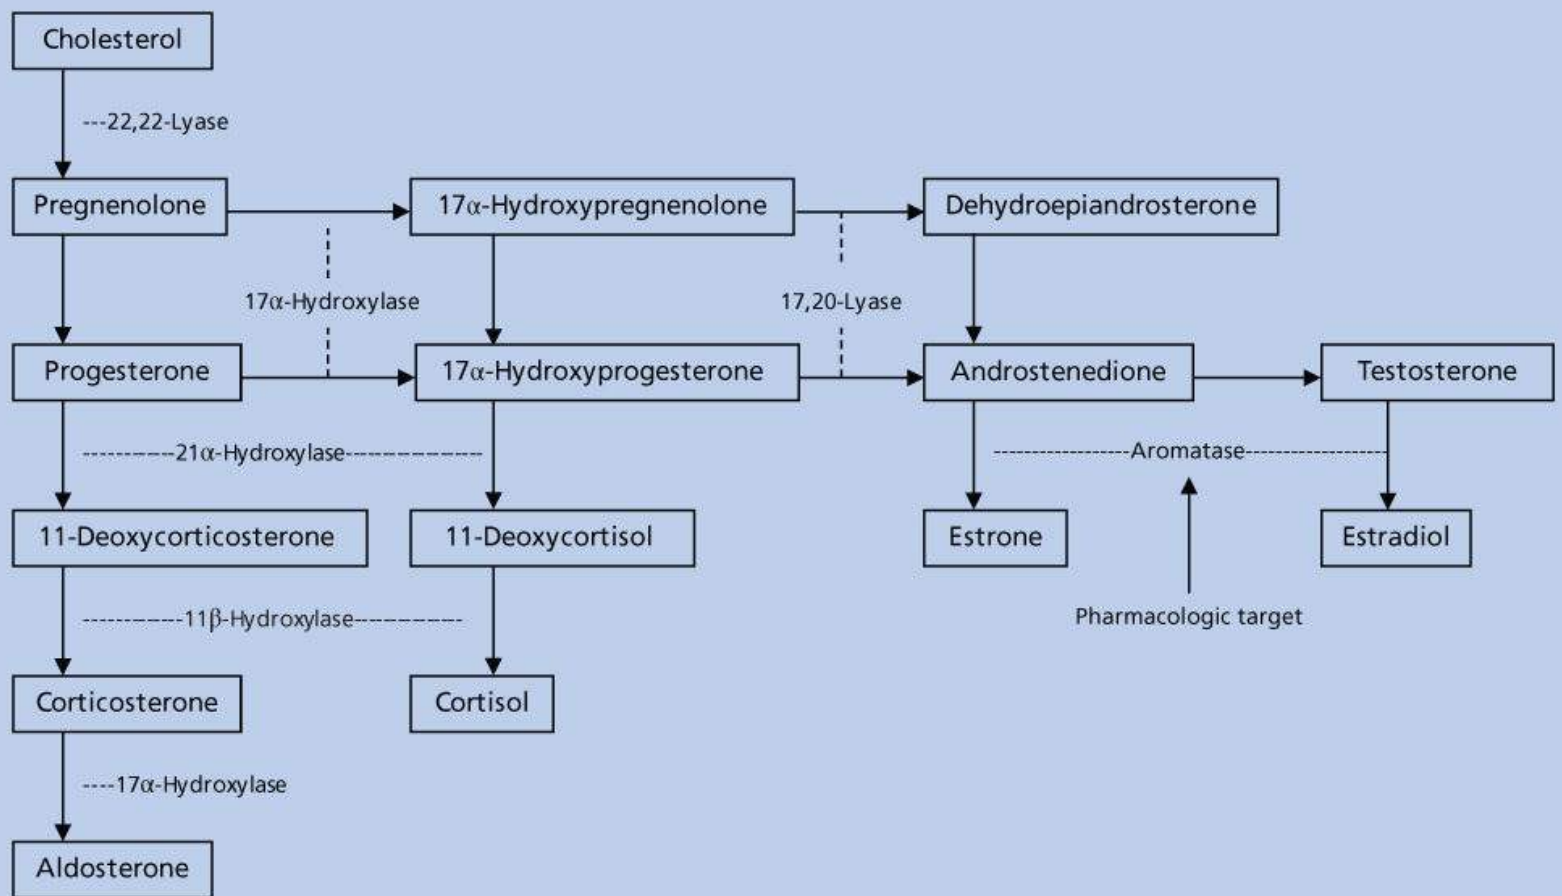

Figure 3 Sources of estrogen in postmenopausal women. The adrenal gland secretes androstenedione (A), which enters plasma and then tissue. Extraglandular and breast tumor tissues contain the enzymes necessary to convert A to estrone (E1) and to estradiol (E2) or to estrone sulfate (E1S). These steroids circulate in the plasma at levels indicated within the brackets and are expressed as picogram per milliliter.

In premenopausal women, the ovary is the most important site of aromatase and estrogen production. Luteinizing hormone (LH) controls production of androstenedione by the theca cell compartment, while follicle stimulating hormone (FSH) upregulates aromatase expression in granulosa cells. Acting in concert, LH stimulates production of the substrate for aromatase, whereas FSH increases the amount of aromatase so that estradiol production can increase by 8- to 10-fold at the time of ovulation.

In postmenopausal women estrogen production takes place almost exclusively in extraglandular tissue. Androstenedione, produced primarily by the adrenal and, to a negligible extent, by the ovary, is converted to estrone by aromatase expressed in peripheral tissue such as adipose tissue²³ and then subsequently converted to estradiol by 17-hydroxysteroid dehydrogenase. Through this pathway postmenopausal women produce approximately 100 mg of estrone per day, with higher levels observed in obese women.²⁴ A fraction of estrone is also converted to estradiol to produce circulating plasma concentrations of approximately 10–20 pg/mL.

Estradiol levels in human breast tumor tissue are estimated to be 4–6 times those observed in plasma.²⁵ Mechanisms by which such high levels are maintained have not been completely defined; however local production via the aromatase pathway is most likely involved with additional pathways involving steroid sulfatase, an enzyme known to hydrolyze estrone sulfate to estrone, having also been implicated.²⁶

Mechanism of action

Circulating estrogens are bound to sex hormone binding globulins (SHBG) from which they dissociate and subsequently enter cells to exert their effects by binding to ERs located predominantly in the nucleus and bound to heat shock proteins (predominantly Hsp90) that stabilize them. The two ERs α - and β - are estrogen-dependent nuclear transcription factors, with different tissue distributions and transcriptional regulatory effects that are encoded by ESR1 and ESR2, respectively, that are located on separate chromosomes.²⁷ ER α is expressed predominantly in the female reproductive tract including the uterus, vagina, and ovaries as well as the mammary gland, hypothalamus, endothelial cells, and vascular smooth muscles. ER β expression is found mainly in the prostate and ovaries with lower expression exhibited in the lung, brain, bone, and blood vessels. Coexpression of both ER α and β receptors are found in several tissues, the most notable being the mammary tissue where they form either homo- or heterodimers.

Binding of estrogen to the ERs results in a conformational change in the receptor leading to the release of ER from the stabilizing proteins. The estrogen–ER homodimeric complex then binds to a specific sequence of nucleotides called estrogen response elements (EREs) that are located in the promoter region of various genes. This binding interaction also involves a number of nuclear proteins, coregulators, as well as other components of the transcription machinery. Thus the genomic effects of estrogen are mainly the result of proteins synthesized from the regulation of transcription of a responsive gene. Two main modalities of treatment have been developed to treat estrogen-responsive breast cancers that either target preventing its production or inhibiting its interaction with ERs.

Carcinogenic effects

The major concern with the use of synthetic estrogens either alone or as a part of the preparation of oral contraceptives has been the development of cancer. Studies that reported the link between the intake of diethylstilbestrol (a synthetic estrogen) during the first trimester of pregnancy and the incidence of clear cell vaginal and cervical adenocarcinoma in later life of the offspring exposed in utero established for the first time that developmental exposure to estrogens was associated with an increase in human cancer.^{28, 29} Studies have also shown that unopposed estrogen as part of the HRT in postmenopausal women increased the risk of endometrial cancer by 5- to 15-fold³⁰ with the increased risk prevented by the addition of a progestin.³¹

The relation of breast cancer risk and HRT in postmenopausal women has also been reported by two large trials. The Women's Health Initiative (WHI) was a large prospective trial that randomized women to either placebo or HRT. The investigators reported an increase in total risk of breast cancer of 24% among women who took an estrogen–progestin combination and a decrease of 23% among women without a uterus who took estrogen only compared to women who took placebo.^{10, 32} In the extended poststopping phases of the WHI trials, the investigators further reported that some elevation in the risk of breast cancer risk still persisted in the cumulative follow-up period [HR 1.28, 95% CI (confidence interval) 1.11–1.48].³³ The Million Women Study (MWS) was a large cohort study that reported an increased relative risk (RR) of invasive breast cancer among women who did and did not take HRT.³⁴ Among women who took an estrogen–progestin combination, the increased RR of invasive breast cancer was 2 and that for women who took estrogen alone was reported as 1.3.

Epidemiological studies have also linked high levels of natural estrogens to the development of cancer. High levels of natural estrogens are observed in women who are overweight. Among postmenopausal women who had never received HRT in the WHI, those who were heavier (body mass index >31.1) had an elevated risk of breast cancer compared to slimmer women (body mass index <22.6) (RR = 2.52; 95% CI = 1.62–3.93).³² High levels of natural estrogens were also found to be associated with breast cancer

risk in a case-cohort study involving women who had never received exogenous estrogens.³⁵ The investigators reported that compared to women with the lowest levels of circulating estradiol, those with the highest levels (≥ 6.83 pmol/L or 1.9 pg/mL) had a RR of 3.6 (95% CI, 1.3–10.0).

Bone mineral density has also been shown to be a surrogate marker of estrogen exposure. A high endogenous estrogen concentration has been reported to be associated with greater bone mineral density in elderly women.³⁶ Postmenopausal women with higher bone mineral densities have also been shown to have a higher incidence of breast cancer.³⁷ Such studies serve to indicate the potential benefit of circulating estrogens as a surrogate marker of breast cancer risk. However its reliability as a surrogate marker is controversial due to the low baseline levels observed among postmenopausal women and the timing of circulating estrogen level measurement with relation to the menstrual cycle being important in premenopausal women. Regardless, enough evidence exists connecting estrogens to the development of hormone-responsive breast cancer that has spawned a number of prevention trials that have used agents targeted either at blocking the production of estrogens or its interaction with its receptor.

Selective estrogen receptor modulators and antiestrogens

The first indication of the role of hormones in the development of breast cancer occurred more than a century ago when in 1896, Beatson observed that remission could be induced by removal of the ovaries in a subset of breast cancer patients.³⁸ Although not originally understood the observed effects occurred as a result of eliminating the primary source of estrogen in premenopausal women. This was confirmed in preclinical studies that demonstrated estradiol to promote proliferation of ER-positive breast cancer cells in culture³⁹ and numerous epidemiological studies that have linked estrogens to breast cancer risk.^{32–37} With the realization of the important role estrogen played in the development and progression of breast cancer, two groups of drugs were developed to counteract the action of estrogens. The first group essentially prevented the interaction of estrogen to its receptor and included the selective estrogen receptor modulators (SERMs) and antiestrogens. SERMs including tamoxifen, raloxifene, and toremifene display unusual tissue-selective pharmacology having estrogen agonist properties in some tissues (bone, liver, and cardiovascular system), estrogen antagonist properties in other tissues (brain and breast), and mixed agonist/antagonist estrogen properties in the uterus. The antiestrogens which include fulvestrant are distinguished from SERMs in that they are uniformly estrogen antagonists. The second group of drugs blocks the production of estrogen by blocking the action of the aromatase enzyme and is known as aromatase inhibitors. In this section we will review the various SERMs and antiestrogens used in clinical practice for the treatment and prevention of hormone receptor-positive breast cancers ([Figure 4](#)).

Tamoxifen

Raloxifene

Fulvestrant

Figure 4 Structure of selective estrogen receptor modulators (SERMs) and antiestrogens.

Tamoxifen

Mode of action

Tamoxifen is a nonsteroidal triphenylethylene compound that exerts its effects by competitively inhibiting the binding of estradiol to ER thereby negating the stimulatory effects of estrogen causing the cell to be held at the G1 phase of the replication cycle.⁴⁰ Tamoxifen is an estrogen antagonist in the breast and an

estrogen agonist in the endometrium and bone, and it is this balance in biological properties that is key to the current strategies for the use of tamoxifen.

Clinical pharmacology

The high therapeutic index of tamoxifen has permitted wide variations in dosage with schedules and dosage of treatment varying depending on the country and its initial clinical trials that evaluated efficacy of this drug. Schedules of 10 mg twice daily or 20 mg once daily are recommended in the United States, although 10 mg three times daily and 20 mg twice daily have been used in other countries.

Tamoxifen is administered orally and is rapidly absorbed, achieving steady state serum levels within 4–6 weeks. It is metabolized in the liver by the cytochrome P450 isoform CYP2D6 and CYP3A4 into *N*-desmethyltamoxifen (major metabolite) and 4-hydroxytamoxifen (minor metabolite); both of which have the potential to be further metabolized to 4-hydroxy-*N*-desmethyltamoxifen (minor metabolite endoxifen) which have 30–100 times more affinity to the ER compared to tamoxifen itself.⁴¹ Tamoxifen has a long serum half-life of 7 days, and the metabolite *N*-desmethyltamoxifen has an even longer half-life of 14 days.⁴² These long serum half-lives are probably why a withdrawal response has not been routinely documented when tamoxifen therapy is discontinued. Currently no clinical cases of teratogenesis have been documented with tamoxifen. As the potential for teratogenicity is unclear, it is as such not recommended in pregnant women. Furthermore tamoxifen is known to cause ovarian stimulation in premenopausal women with ovulatory cycles, and thus women taking tamoxifen who are at risk of getting pregnant should be counseled about various contraceptive options.⁴³

Tamoxifen in advanced breast cancer

Tamoxifen is an endocrine option for metastatic disease in postmenopausal women and those with ER-positive disease are more likely to benefit from this therapy.⁴⁴ More recent data suggests that aromatase inhibitors are a better option as first-line treatment for this cohort of patients so long as resistance to the drug has not developed. This will be discussed in further detail in the section of “Aromatase inhibitors.”

Tamoxifen is an option for first-line endocrine therapy in premenopausal women with advanced breast cancer. A meta-analysis of individual patient data from four studies has demonstrated that tamoxifen produces a response rate and overall survival (OS) similar to what is seen after oophorectomy.⁴⁵ However, with the development of effective luteinizing hormone-releasing hormone (LHRH) agonists such as goserelin (Zoladex), which acts to reduce ovarian steroidogenesis by preventing LH release from the pituitary gland, the combination of LHRH agonist and tamoxifen has become established as an effective therapeutic option, and the combination of which in meta-analysis has been shown to significantly improve progression free and OS compared to LHRH agonist alone.⁴⁶ Hence recent guidelines have suggested that the use of LHRH agonists and tamoxifen alone or in combination are appropriate therapeutic options for premenopausal women with advanced metastatic hormone receptor-positive disease⁴⁷ ([Figure 3](#)).

Tamoxifen in the adjuvant setting

Many randomized trials have addressed the question of tamoxifen efficacy in the adjuvant setting among women with early-stage breast cancer. An overview and meta-analysis of the results from 145,000 women with early-stage breast cancer who were randomized to 194 trials of adjuvant systemic therapy (chemotherapy and/or hormonal therapy) were recently updated by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG).⁴⁸ The EBCTCG reported that 5 years of adjuvant tamoxifen among

women with ER-positive disease resulted in reduction in the annual breast cancer death rate by 31% regardless of age, PR status, menopausal status, or use of chemotherapy with benefit persisting up to 15 years of follow-up. In this report 1 year of tamoxifen conferred little benefit, 5 years of tamoxifen was significantly more effective than 2 years, with long-term follow-up still required for assessing the benefit of more than 5 years of adjuvant tamoxifen treatment. A number of prospective trials have looked at the efficacy of tamoxifen beyond 5 years in the adjuvant setting ([Table 1](#)).^{49–53} The B-14 trial, a National Surgical Adjuvant Breast and Bowel Project (NSABP) trial, in which women with lymph node-negative ER-positive disease still in remission after receiving 5 years of tamoxifen were randomized to receive either placebo or more prolonged therapy with tamoxifen, did not show any advantage from prolonged tamoxifen treatment after 7 years of follow-up.⁴⁹ Indeed longer duration of tamoxifen use was associated with shorter disease-free survival (DFS) compared to the group who had stopped taking tamoxifen after 5 years (78% vs 82%, $p = 0.03$). Recently long-term follow-up data of two large phase III trials that randomized women with early-stage breast cancer who had completed 5 years of tamoxifen to either another 5 years tamoxifen or stopping endocrine therapy have been reported.^{50, 51} In the Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial, 12894 women with early breast cancer were enrolled.⁵⁰ Among the 6846 women who had ER-positive disease, the investigators reported a significant reduction in the risk of breast cancer recurrence ($p = 0.002$), breast cancer mortality ($p = 0.01$), and overall mortality ($p = 0.01$) favoring patients who were randomized to receive 10 years of tamoxifen. The investigators further reported that between years 5 and 14 of follow-up, 10 years of tamoxifen resulted in an absolute reduction in risk of breast cancer recurrence and mortality of 3.7% and 2.8%, respectively. However, between years 5 and 14 of follow-up, there was also an increased cumulative risk of endometrial cancer among patients allocated to 10 years of tamoxifen (3.1% vs 1.6%) which was associated with an absolute mortality increase of 0.2%. In the Adjuvant Tamoxifen Treatment Offer More (aTTom) trial, 6953 women with early breast cancer were enrolled.⁵¹ Similar to the ATLAS trial, the investigators reported reductions in breast cancer recurrence, breast cancer specific mortality, and overall mortality favoring patients who received 10 years of tamoxifen. The investigators observed that continuing tamoxifen beyond 5 years reduced breast cancer recurrence beginning year 7 and breast cancer mortality after year 10. In view of the evidence from these two clinical trials, current guidelines recommend consideration of 10 years of adjuvant tamoxifen.⁴⁷ This should be considered after full discussion about potential associated increase in associated side effects.

Table 1 Efficacy data from trials comparing continuing tamoxifen beyond five years and stopping it

Trial	Intervention	Risk of recurrence	Breast cancer specific mortality	Disease-free survival	Overall survival
ECOG ⁵³ (1996)	Continue vs stop	15% vs 25% ($p = 0.014$ among ER + patients)	8% vs 8.6%	85% vs 73% ($p = 0.10$)	86% vs 89% ($p = 0.81$ among ER+ patients)
NSABP-14 ⁴⁹ (2001)	Continue vs stop	NR	NR	78% vs 82% ($p = 0.03$)	91% vs 94% ($p = 0.07$)
Scottish cancer trials breast group ⁵² (2001)	Continue vs stop	5.2% vs 7.1%	23% vs 15%	54% vs 61% ($p = 0.15$)	59.5% vs 68% ($p = 0.12$)
ATLAS ⁵⁰ (2012)	Continue vs stop	RR = 0.81 (premenopausal) RR = 0.85 (postmenopausal)	12.2% vs 15% ($p = 0.01$) during years 5–14 RR = 0.75 ($p = 0.002$) after year 10	NR	NR

Tamoxifen and chemotherapy

The latest update of the EBCTCG revealed that addition of anthracycline-based polychemotherapy regimens was reported to be associated with annual reduction of mortality of 38% and 20% among women aged <50 years and 50–69 years, respectively.⁴⁸ The question however is whether the addition of an endocrine agent such as tamoxifen could further add to this benefit among women with ER-positive breast tumors. In the EBCTCG among 3330 women with ER-positive or ER-unknown tumors, 28.1% of women who received only chemotherapy experienced a recurrence compared to 17.5% who received chemotherapy and 5 years of tamoxifen, with the difference being statistically significant.⁴⁸ Similarly, among women with ER-positive or ER-unknown breast tumors, for those who were less than 50 years of age and received chemotherapy and tamoxifen, the EBCTCG reported a recurrence rate ratio of 0.64 (SE = 0.08) and annual breast cancer mortality ratio of 0.65 (SE = 0.10) compared to those who received tamoxifen alone. In addition similar trends were observed among women in the 50–69 years age group. Therefore chemotherapy alone is not enough among women with ER-positive tumors with the data clear that the addition of tamoxifen is important. The EBCTCG also explored the question about the sequence of chemotherapy and tamoxifen. Among women 50–69 years of age, a recurrence rate ratio and annual breast cancer mortality rate ratio of 0.80 (SE = 0.03) and 0.90 (SE = 0.03) was reported, respectively, among women treated with chemotherapy and tamoxifen compared to those who received tamoxifen alone. A recurrence rate ratio and annual breast cancer mortality rate ratio of 0.77 (SE = 0.08) and 0.80 (SE = 0.10) was reported, respectively, among women treated with chemotherapy followed by tamoxifen compared to those who received tamoxifen alone.⁴⁸ The question about sequence of therapy was also explored by the Southwest Oncology Study Group (SWOG) 8814 study that reported improved disease-

free and OS outcomes when tamoxifen was given sequentially following CAF (cyclophosphamide, doxorubicin, and 5-fluorouracil) compared with concurrent administration or tamoxifen alone.⁵⁴ Taken together the data are suggestive that the sequential hormonal therapy with chemotherapy may be a better a better option.

Prevention of breast cancer

Observations that long-term tamoxifen therapy reduced the incidence and risk of contralateral breast cancer in women with early-stage breast cancer fueled interest in exploring the effect of tamoxifen in preventing the occurrence of breast cancer. An overview of the main outcomes from the five main breast cancer prevention trials, covering more than 28,000 patients, has shown that tamoxifen produced a 38% reduction in breast cancer incidence ($p < 0.0001$).⁵⁵ There was no effect on ER-negative disease ($p = 0.21$), but ER-positive cancers were reduced by 48% ($p < 0.0001$). However, endometrial cancer rates were increased (consensus RR 2.4; $p = 0.0005$) in patients receiving preventive tamoxifen, as were venous thromboembolic events (relative risk 1.9; $p < 0.0001$). Thus when considering using tamoxifen as a preventive agent, it will be important to balance the risks of developing complications to that of developing breast cancer, and as such the unrestricted use of tamoxifen among young women of reproductive age should be used with caution. An exception to this is when tamoxifen is used for the reduction of breast cancer risk in high-risk women, for which it is the first medicine to be approved by the US Food and Drug Administration. Thus use of tamoxifen in preventive setting should be individualized to a woman's risk of developing breast cancer. As such, women with a prior history of ductal carcinoma *in situ*, lobular carcinoma *in situ*, atypical hyperplasia, or those with a deleterious mutation of BRCA 1 or 2 are considered to be at higher risk of developing breast cancer and represent an ideal cohort to target where benefit outweighs risk of adverse events associated with tamoxifen.^{56–58} The side effects associated with tamoxifen meant that it was important to evaluate the action of other agents such as aromatase inhibitors in the preventive setting. The results of studies evaluating aromatase inhibitors as preventive agents will be discussed under the section titled “Aromatase inhibitors.”

Raloxifene

Raloxifene is a benzothiophene second-generation SERM that is FDA approved for the treatment and prevention of osteoporosis and for the reduction of risk of invasive breast carcinoma in postmenopausal women with either osteoporosis or who are at high risk for invasive breast cancer, respectively.^{59–62} This agent has no significant antitumor activity in the metastatic setting and as such is not approved for the treatment of advanced metastatic breast cancer. Four large prospective trials have reported on the efficacy of raloxifene as a chemopreventive agent for breast cancer. The Multiple Outcomes of Raloxifene Evaluation (MORE) trial that randomized 7705 postmenopausal women with osteoporosis to receive either raloxifene or placebo, whose primary end point was development of a fracture, was the first major trial to suggest raloxifene as a potential agent for chemoprevention of breast cancer.⁵⁹ In this trial, following 4 years of treatment, raloxifene reduced the risk of ER-positive invasive breast cancer by 84% (RR 0.16, 95% CI 0.09, 0.30). The Continuing Outcomes Relevant to Evista (CORE) trial was an extension of the MORE trial to examine the effect of 4 additional years of raloxifene therapy on the incidence of invasive breast cancer in women enrolled in MORE who agreed to continue on the trial.⁶⁰ Combining the 8 years of follow-up of both the MORE and CORE trials, the investigators reported that the incidences of invasive breast cancer overall and ER-positive invasive breast cancer were reduced by 66% (HR = 0.34; 95% CI = 0.22–0.50) and 76% (HR = 0.24; 95% CI = 0.15–0.40), respectively, in the raloxifene group compared with the placebo group. The goal of the Raloxifene Use for the Heart (RUTH)

trial was to investigate the effect of raloxifene on the incidence of coronary events and breast cancer in 10,101 postmenopausal women.⁶¹ The investigators found reductions in breast cancer similar in size to that seen for tamoxifen in other studies. The NSABP P-2 trial is a prospective, double-blinded, randomized clinical trial that compared the efficacy and safety of tamoxifen with raloxifene on the risk of developing invasive breast cancer in a cohort of 19,747 postmenopausal women.⁶² The investigators reported similar efficacy of tamoxifen compared to raloxifene in reducing the risk of invasive breast cancer (RR = 1.02; 95% CI 0.82–1.28). In terms of side effects, compared to tamoxifen, raloxifene had fewer gynecological and thromboembolic events. Interestingly raloxifene reduced the risk of invasive breast cancer but had no effect on the incidence of ductal carcinoma *in situ*.

Lasofoxifene

Lasofoxifene is a third-generation nonsteroidal SERM that has been shown to selectively bind to both ER α - and β with a high affinity and a median inhibitor concentration that is 10-fold higher than reported for raloxifene and tamoxifen. Furthermore it has demonstrated improved oral bioavailability when compared to other SERMs due to its increased resistance to intestinal wall glucuronidation.⁶³ Among postmenopausal women lasofoxifene has been shown to decrease bone loss, bone resorption, and low density lipoprotein (LDL) cholesterol. In a prospective randomized clinical trial, 8556 postmenopausal women who had a bone mineral density T score of -2.5 or less were randomly assigned to receive lasofoxifene or placebo for 5 years.⁶⁴ The investigators reported that compared to placebo, use of lasofoxifene among postmenopausal women with osteoporosis was associated with a reduced risk of ER-positive breast cancer, coronary heart disease, stroke, and nonvertebral and vertebral fractures. However it was also reported to be associated with an increased risk of venous thromboembolic events.

Toremifene

Toremifene (Fareston) is a structural derivative of tamoxifen with similar antiestrogenic and estrogenic properties demonstrated in laboratory animals. In general, toremifene is highly protein bound, which could explain its long serum half-life. Toremifene is less potent than tamoxifen, and, consequently, clinical studies have evaluated doses of toremifene up to 240 mg/day. Toremifene is cross-resistant with tamoxifen, but clinical trials have shown that it exhibits a similar efficacy and side effect profile to tamoxifen and so may be used as an alternative to treat advanced breast cancer.^{65, 66} At this time there is insufficient data to recommend its use in the adjuvant setting.

Trilostane

Trilostane (Modrenal) is an antiadrenal drug that is usually used for short-term adrenal suppression in the treatment of Cushing's syndrome. However, trilostane's ability to modify the binding of estrogen to the ER has prompted interest in its potential to block breast tumor cell proliferation. A meta-analysis of several small studies investigating the use of trilostane in postmenopausal women with advanced breast cancer reported clinical benefit with this agent, and further trials are needed to evaluate its worth as an endocrine therapy for advanced breast cancer.⁶⁷

Fulvestrant

Fulvestrant (Faslodex) is an antiestrogen with no agonist properties and unlike tamoxifen has the following mechanism of action: it binds, blocks, and increases degradation of ER protein, leading to an inhibition of estrogen signaling through the ER together with dramatic loss of cellular ER levels and is

also associated with a significant reduction in PgR expression.^{68, 69} A prospective combined analysis of two phase III trials comparing fulvestrant (250 mg IM injection once monthly) to anastrozole in a cohort of postmenopausal women with advanced breast cancer who had progressed on prior tamoxifen therapy indicated that, after a median follow-up of 15.1 months, fulvestrant was at least as effective as anastrozole [median times to progression (TTP) were 5.5 months vs 4.1 months] with a similar and acceptable adverse event profile.⁷⁰ Subsequently fulvestrant (at a dose of 250 mg IM) as first-line treatment of advanced breast cancer was compared to tamoxifen among postmenopausal women (whose tumors were either hormone receptor positive or hormone receptor unknown) in a randomized clinical trial.⁷¹ At a median follow-up of 14.5 months in the overall population, noninferiority of fulvestrant compared to tamoxifen could not be demonstrated. In a preplanned subgroup analysis focusing on the cohort of patients with hormone receptor-positive disease, fulvestrant was observed to have a similar efficacy to tamoxifen. In the setting of a phase III, randomized clinical trial fulvestrant (at a dose of 250 mg IM) has also been compared to exemestane for the treatment of postmenopausal women with hormone receptor-positive advanced breast cancer who had progressed or recurred on a nonsteroidal aromatase inhibitor.⁷² In this study overall response rate (7.4% vs 6.7%; $p = 0.736$) and time to treatment progression (3.7 months in both groups) were similar between the fulvestrant and exemestane groups suggesting that fulvestrant was no more effective than a steroidal aromatase inhibitor among women who had progressed on a nonsteroidal aromatase inhibitor. Since fulvestrant can take 3–6 months to reach steady state plasma levels at the 250 mg/month dose (previously approved dosing schedule), clinical trials have evaluated the standard dosing regimen to a loading dosing schedule. In a phase III double-blinded multicenter study, postmenopausal women with ER-positive advanced breast cancer who had progressed on prior endocrine therapy were assigned to receive IM monthly fulvestrant at a dose of 500 mg or 250 mg.⁷³ The investigators reported a significantly longer DFS with the 500 mg dosing schedule (HR 0.8, 95% CI 0.68–0.94, $p = 0.006$) with no associated increase in toxicity. Based on these results fulvestrant is approved at a dose of 500 mg a month for the treatment of hormone receptor-positive metastatic breast cancer in postmenopausal who had progressed on prior antiestrogen therapy. As the 500 mg dosing schedule was found to be superior to the 250 mg dosing schedule, trials are underway investigating whether the use of the new approved dose of fulvestrant is superior to aromatase inhibitors in the treatment of advanced hormone receptor-positive breast cancer in the first-line setting. In an open-labeled randomized phase II trial, postmenopausal women with advanced breast cancer were randomized in the first-line setting to either 500 mg of fulvestrant or anastrozole.⁷⁴ The investigators reported a significantly longer time to progression of disease with fulvestrant compared to anastrozole. Updated results of this analysis have recently been presented with the investigators further reporting a significant improvement in OS with 500 mg of fulvestrant compared to anastrozole.⁷⁵ Phase III trials are currently ongoing to confirm these results (FALCON trial).

Side effects of SERMs and antiestrogens

Side effects related to the SERMs and antiestrogens develop mainly as a result of the blockade of the stimulatory function of estrogen on a variety of tissues. The most frequent side effects encountered are hot flashes, night sweats, and vaginal dryness similar to that seen in women undergoing menopause. Other less frequent but important side effects pertain to the bone, blood vessels, and carcinogenic effects.

Osteoporosis

Estrogen is important in maintaining bone health in premenopausal women with HRT and is often recommended to prevent the development of osteoporosis in postmenopausal women. Long-term

administration of an antiestrogen has the potential to cause premature osteoporosis in premenopausal women. However due to the partial estrogen agonist function of SERMs, clinical studies have shown tamoxifen therapy to not be associated with a reduction of bone density,⁷⁶ and raloxifene is an approved treatment for osteoporosis.⁶⁹

Coronary heart disease

Estrogen lowers LDL cholesterol levels and raises high-density lipoprotein (HDL) cholesterol levels, and thus prolonged administration of an antiestrogen could produce a population at risk of premature coronary heart disease. However, the estrogen-like effects of tamoxifen have been shown to lower the circulating levels of cholesterol in female patients^{77, 78} with clinical studies reporting tamoxifen to be associated with either a significant or trend in reduction of risk of coronary heart disease.⁷⁹ Raloxifene has also been shown to reduce serum cholesterol levels⁸⁰; however it has not been shown in a large randomized clinical trial to reduce the risk of coronary heart disease.⁶¹

Thromboembolism

A number of studies have demonstrated an association between the use of tamoxifen and subsequent thromboembolic episodes in both the treatment and preventive setting.^{55, 81} This is comparable with increases noted with HRT or raloxifene⁸¹ Patients with a known history of thromboembolic disorders should be carefully evaluated before a decision is made to use long-term tamoxifen therapy.

Endometrial tumors

Research has demonstrated that increases in endometrial thickness, hyperplasia, and fibroids may follow treatment with tamoxifen.⁸² Endometrial thickening is associated with the stromal component of the uterus rather than the epithelial component.⁸³ Clinical trials evaluating the efficacy of tamoxifen in the treatment and prevention of breast cancer have demonstrated an increased risk of endometrial tumors including carcinomas and to a smaller extent sarcomas.^{84, 85} Endometrial carcinoma that develops on tamoxifen therapy is not of high grade and as such is not associated with poor prognosis, while endometrial sarcomas are generally associated with a poorer prognosis, seemingly because of less favorable histology and higher stage.⁸⁶ Thus when monitoring patients on tamoxifen treatment, all cases of persistent vaginal bleeding should be followed up with a gynecological examination and an endometrial biopsy. It is important to note that this increased risk is restricted to postmenopausal women with premenopausal women not at risk of an increase in endometrial cancer. When raloxifene was directly compared to tamoxifen in the prevention of breast cancer (STAR trial), 36 cases of endometrial cancer were observed in the tamoxifen group compared to 23 cases in the raloxifene group (RR, 0.62; 95% CI, 0.35–1.08).⁶² In the ATLAS and aTTom trials that evaluated the efficacy of 5 years of tamoxifen to 10 years of tamoxifen in the adjuvant setting, the investigators reported that longer duration of tamoxifen was associated with increased incidence of endometrial cancer and associated increase risk of mortality from endometrial cancer.^{50, 51} The risk associated with tamoxifen usage appears confined to the duration of its administration. In the randomized International Breast Cancer Intervention Study (IBIS-I) (a prevention study that randomized patients to tamoxifen vs placebo), the rates of side effects pertaining to tamoxifen including deep vein thrombosis, pulmonary embolism, and endometrial cancer was higher in the tamoxifen arm of the study compared to the placebo arm during the active treatment period of the study but not in the subsequent years posttamoxifen treatment.⁸⁷

Other side effects

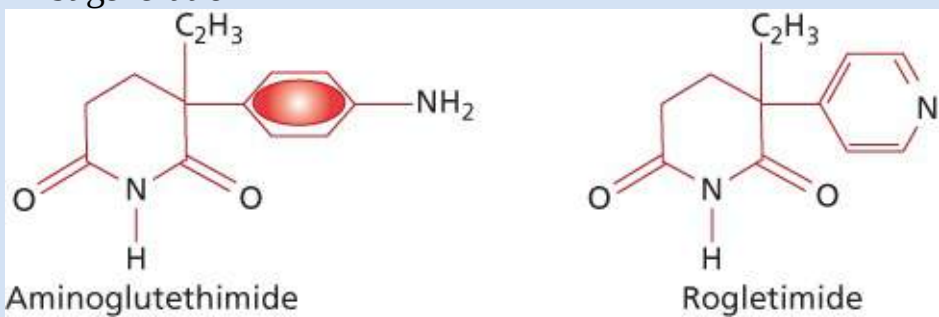

Antiestrogens and SERMs have also been associated with ophthalmic side effects such as cataracts and retinal changes.^{88, 89} Preclinical studies have also demonstrated tamoxifen to cause carcinogenesis in the liver; however an increase in human hepatocellular carcinoma has not been demonstrated.⁹⁰

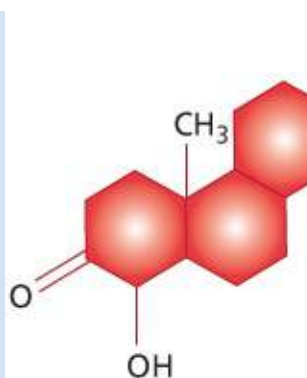

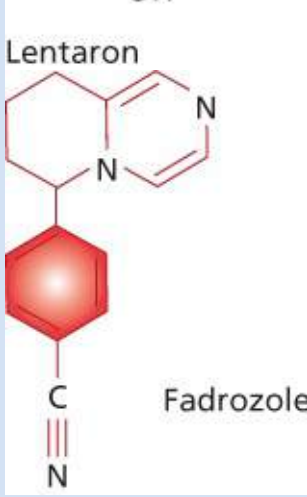

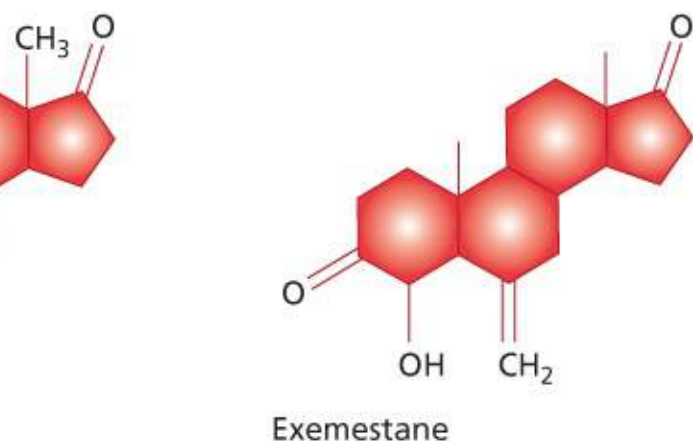

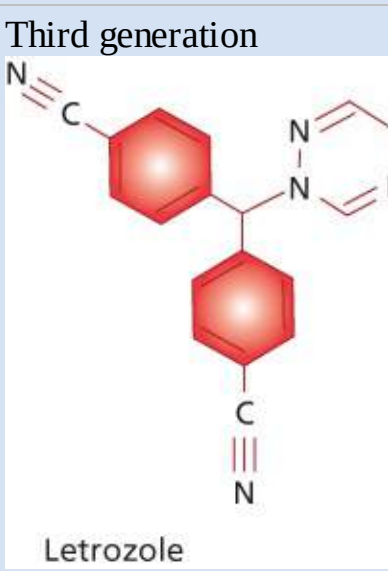

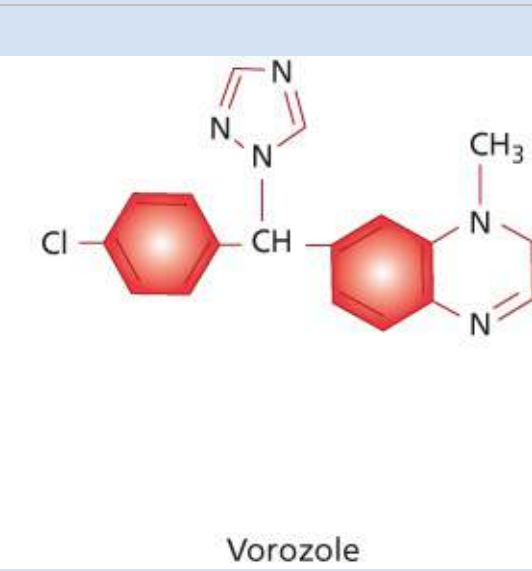

Aromatase inhibitors

In contrast to SERMs and antiestrogens, aromatase inhibitors work by blocking the enzyme complex responsible for the final step in estrogen biosynthetic pathway and is thereby essentially preventing the production of the ER substrate. Moreover, unlike tamoxifen, aromatase inhibitors have no partial estrogen agonist function. Despite the ovaries being a rich source of aromatase, aromatase inhibitors are unable to sufficiently suppress ovarian estrogen production to postmenopausal levels which may be due to compensatory rise in gonadotrophins which maintains adequate estrogen production, despite the presence of the inhibitor. In contrast aromatase inhibitors have been shown to adequately suppress estrogen production in postmenopausal women.

Aromatase inhibitors are classified into first, second, and third-generation aromatase inhibitors according to the specificity and potency with which they inhibit the aromatase enzyme (Table 2). They are further subclassified according to their mechanism of action into steroidal (irreversible, type I) and nonsteroidal (reversible, type II) inhibitors. Type 1 inhibitors, including formestane and exemestane, function by irreversibly inhibiting the aromatase enzyme by covalently binding to it, resulting in permanent inactivation that persists even after discontinuation of the drug until the peripheral tissues synthesize new enzymes. Type II inhibitors, including anastrozole, letrozole, and fadrozole, in contrast bind reversibly to the active site of the aromatase enzyme and prevent product formation only as long as the inhibitor occupies the catalytic site. In this section we will focus on the newer third-generation aromatase inhibitors letrozole, anastrozole, and exemestane that are routinely used in clinical practice today. These aromatase inhibitors have challenged tamoxifen as the gold standard and are now the preferred first-line treatment of postmenopausal women with hormone-responsive breast cancer in either the early or advanced setting, whenever there is a moderate or high risk of relapse.

Table 2 Structure and classification of representative aromatase inhibitors

Generation	Steroidal irreversible type I inhibitors	Nonsteroidal reversible inhibitors
First generation		Aminoglutethimide
		
Second generation	Formestane	Fadrozole

 <p>Lentaron</p>  <p>Fadrozole</p>	 <p>Exemestane</p>		
<p>Third generation</p>  <p>Letrozole</p>  <p>Arimidex</p>  <p>Vorozole</p>		Exemestane	Anastrozole Letrozole Vorozole

Compounds are shown in approximate order of increasing specificity and potency of aromatase inhibition.

First generation

Aminoglutethimide, a derivative of the sedative agent glutethimide, was initially introduced as an inhibitor of cytochrome P450 N-mediated steroid hydroxylations.⁹¹ The effects of this compound, however, are rather nonspecific, because the drug affects a number of hydroxylation steps in the metabolic conversion of cholesterol to active steroid products, and, overall, the use of aminoglutethimide plus glucocorticoid in women with breast cancer produces results similar to those expected from other forms of endocrine therapy. Side effects observed with standard doses of aminoglutethimide (1000 mg/day) include drug rash, fever, and lethargy.⁹¹ With the development of more selective second and third-generation aromatase inhibitors, aminoglutethimide is now rarely used for the treatment of breast cancer

Second generation

The two second-generation aromatase inhibitors on the market are fadrozole and formestane. Fadrozole (4-[5,6,7,8-tetrahydroimidazo-(1,5-a)-pyridin-5yl] benzonitrile), a type II inhibitor, is a highly potent inhibitor of aromatase. Two large multicenter phase III trials have compared fadrozole with MA in patients who had received only tamoxifen as prior hormone therapy. No significant differences were observed between the two treatment arms of the trials with respect to time to treatment progression, overall response rate, response duration, or OS.⁹² When compared to tamoxifen as a first-line treatment among postmenopausal women with advanced breast cancer, similar efficacy was observed between the two agents with fadrozole having a better tolerability profile.⁹³ Fadrozole has also been compared to letrozole in a double-blind randomized trial in the advanced breast cancer setting with letrozole having superior efficacy to fadrozole in this setting.⁹⁴ Toxicity attributed to fadrozole is mild and consists mainly of nausea, anorexia, fatigue, and hot flashes. Fadrozole represents a major improvement over aminoglutethimide, and the drug is approved in Japan for the treatment of patients with breast cancer.

Formestane (4-hydroxyandrostenedione, Lentaron), a type I inhibitor, is given by IM injection and is thus associated with in-site reactions. It has been tested in clinical trials as second-line treatment for postmenopausal women with metastatic disease and demonstrated similar efficacy to MA among those who had progressed on tamoxifen⁹⁵ with clinical benefit also demonstrated in patients who have progressed on nonsteroidal aromatase inhibitors.⁹⁶

Third generation

Third-generation aromatase inhibitors have now become the standard treatment for postmenopausal women with either advanced or early-stage hormone-responsive breast cancer having demonstrated superior efficacy and tolerability compared to tamoxifen. Third-generation aromatase inhibitors include exemestane, letrozole, and anastrozole.

Exemestane (6-methylene-androsta-1,4-diene-3,17-dione, Aromasin), a type I aromatase inhibitor, is an oral analogue of the natural substrate androstenedione. It is rapidly absorbed from the gastrointestinal tract, reaching maximum plasma levels after 2 h and has been shown to lower estrogen levels more effectively than formestane. Single-dose administration of 25 mg/day exemestane inhibits aromatase activity by 97.9% and lowers plasma estrone and estradiol levels by about 90%.⁹⁷ The FDA-approved dosing regimen for exemestane is 25 mg once daily as an oral preparation.

Anastrozole (Arimidex), a type II inhibitor, is a potent and selective benzotriazole derivative absorbed rapidly after oral administration with peak concentration achieved after 2 h and steady state after 7 days and has an elimination half-life in humans of approximately 32.2 h.⁹⁸ Anastrozole at doses of 1 or 10 mg administered once daily for 28 days has been shown to reduce total body aromatization by 96.7% and 98.1%, respectively.⁹⁸ The FDA-approved dosing regimen of anastrozole is 1 mg orally once a day.

Letrozole (4,4'-[(1H-1,2,4-triazol-1-yl) methylene] bis-benzonitrile, Femara), a type II inhibitor, is a highly potent inhibitor of aromatase *in vitro* and *in vivo* and is associated with greater suppression of estrogen plasma levels than is achieved with other aromatase inhibitors.⁹⁹ When administered orally to adult female rats at a dose of 1 mg/L/day for 14 days, letrozole decreased uterine weight to that observed after a surgical ovariectomy.⁹⁹ Clinical studies in normal healthy volunteers, as well as phase I trials in postmenopausal women with advanced breast cancer, showed that letrozole in a dose as little as 0.25 mg/day PO caused maximal suppression of plasma and urinary estrogens.¹⁰⁰ The FDA-approved and recommended dosing regimen for letrozole is 2.5 mg orally once a day.

Vorozole (R83842; R76713; 6-[(S)4-Chlorophenyl)-1H-1,2,4-triazol-1-ylmethyl]-1-methyl-1H-

benzotriazole), another specific type II aromatase inhibitor, has shown little toxicity in animal studies. However, despite results from a phase III study that have demonstrated the clinical efficacy of vorozole in postmenopausal women with metastatic disease,¹⁰¹ this drug has been withdrawn from further clinical development.

Treatment of metastatic breast cancer

Preclinical studies have shown aromatase inhibitors to be effective after initial treatment with tamoxifen.¹⁰² Following demonstrated efficacy in phase II trials, a number of phase III trials have evaluated the efficacy of third-generation aromatase (letrozole, anastrozole, and exemestane) inhibitors as a second-line agent compared to MA in the treatment of postmenopausal women with metastatic breast cancer who had previously been treated with tamoxifen ([Table 3](#)). In a cohort of 769 postmenopausal women with metastatic breast cancer, exemestane produced a statistically significant increase in median duration of overall clinical benefit (60.1 vs 49 weeks, $p = 0.025$), median time to tumor progression and median survival compared to MA.¹⁰³ In a similar cohort of 764 women from two pivotal phase III trials, patients randomized to either anastrozole (1 mg/day PO) or anastrozole (10 mg/day PO) had estimated hazards of progression of 0.97 (97.5% CI 0.75–1.24) and 0.92 (97.5% CI, 0.71–1.19), respectively, compared to patients receiving MA.¹⁰⁴ No statistically significant dose–response differences were observed between the 1 mg/day and 10 mg/day dosage. With subsequent follow-up 2-year survival was 56.1% for the group of patients receiving anastrozole (1 mg/day), compared with 46.3% for patients treated with MA.¹⁰⁵ Similarly the efficacy of letrozole was evaluated in a pivotal trial of 555 postmenopausal women with metastatic breast cancer that had progressed on tamoxifen.¹⁰⁶ Letrozole (2.5 mg/day) yielded overall response rates of 36% and 35%, respectively, compared with 27% and 33% for letrozole (0.5 mg/day) and 32% for MA, respectively. The median duration of response for letrozole (2.5 mg/day) was 33 months, compared with 18 months for both MA and letrozole 0.5 mg/day. A trend in time to tumor progression and survival that favored letrozole 2.5 mg/day was also observed.¹⁰⁶

Table 3 Combined data from phase III trials comparing anastrozole, letrozole, and exemestane with megestrol acetate in postmenopausal women previously treated with tamoxifen

	Combined data		Initial trial		Second trial		Initial trial	
	Anastrozole	Megestrol acetate	Letrozole	Megestrol acetate	Letrozole	Megestrol acetate	Exemestane	Megestrol acetate

^a Objective response = complete response + partial response.

^b Clinical benefit = complete response + partial response + stable disease for ≥ 6 months.

Abbreviations: NA, not available; TTP, time to progression.

Following the success of third-generation aromatase inhibitors in the second-line treatment of postmenopausal women with metastatic breast cancer, focus shifted to first-line treatment directly comparing these agents with tamoxifen ([Table 4](#)). In a phase II study comparing exemestane (25 mg/day) with tamoxifen (20 mg/day) as first-line treatment for metastatic disease, patients receiving exemestane had better objective response rates (complete response plus partial response) and median duration of response compared to tamoxifen.¹⁰⁷ The study was subsequently extended into a phase III trial where exemestane was reported to be well tolerated and was associated with a significantly longer progression-free survival compared with tamoxifen (10.9 months vs 6.7 months, respectively).¹⁰⁸ In a combined analysis of two pivotal phase III trials that involved 1021 postmenopausal women with metastatic breast cancer, first-line treatment of anastrozole at a dose of 1 mg/day was compared to tamoxifen.¹⁰⁹ At a median follow-up of 18.5 months for patients with hormone receptor-positive tumors (59.8% of patients), median time to progression was significantly superior in the group receiving anastrozole compared to those receiving tamoxifen (10.7 months vs 6.4 months, $p = 0.022$). Similarly a large, multicenter, double-blind, first-line phase III clinical trial in 907 postmenopausal women with locally advanced or metastatic

breast cancer compared letrozole (2.5 mg/day) with tamoxifen (20 mg/day).¹¹⁰ At a median follow-up of 32 months, time to progression (median, 9.4 months vs 6.0 months, respectively; $p < 0.0001$), time to treatment failure (median, 9 months vs 5.7 months, respectively; $p < 0.0001$), and overall objective response rate (32% vs 21%, respectively; $p = 0.0002$) were all reported to be significantly superior in the group receiving letrozole compared to tamoxifen. Median OS was 34 months for letrozole and 30 months for tamoxifen. It is clear from the data presented that aromatase inhibitors, in particular third-generation inhibitors, have demonstrated superior efficacy to tamoxifen among women with advanced breast cancer. However currently there is no evidence to prove superiority of one aromatase inhibitor over another in this setting.

Table 4 Efficacy data from trials comparing anastrozole, letrozole, and exemestane with tamoxifen in the first-line treatment of postmenopausal women with metastatic breast cancer

With the demonstrated efficacy of third-generation aromatase inhibitors among patients with metastatic breast cancer in the first-line setting, research focus shifted to investigating methods to improve on the efficacy. One method was to combine aromatase inhibitors with the antiestrogen fulvestrant. The mechanism of action of aromatase inhibitors is to ultimately result in a low-estrogen environment, and fulvestrant has been shown in preclinical models to work well in such an environment.¹¹¹ Furthermore the combination of fulvestrant and an aromatase inhibitor has been shown in preclinical models to delay the development of resistance by downregulating several signaling molecules that are known to be associated with the development of resistance.¹¹² Three randomized clinical trials have compared the combination of fulvestrant and an aromatase inhibitor to single-agent aromatase inhibitor among postmenopausal women with metastatic hormone receptor-positive disease.^{113–115} The monthly dosing schedule of 250 mg was used for fulvestrant in these trials. In a phase III open-labeled randomized trial [Fulvestrant and

Anastrozole Combination Therapy (FACT)], patients at first relapse after their primary disease were randomized to either fulvestrant and anastrozole or single-agent anastrozole.¹¹³ The investigators observed no clinical benefit with the addition of fulvestrant for both time to progression (10.8 months vs 10.2 months, $p = 0.91$) and median OS (37.8 months vs 38.2 months, $p = 1.00$). In a cohort of patients who had progressed on a nonsteroidal aromatase inhibitor, the authors observed that the efficacy of fulvestrant and anastrozole was similar to either single-agent fulvestrant or exemestane. In a phase III trial conducted by SWOG, women with previously untreated breast cancer were randomized to receive either a combination of fulvestrant and anastrozole or single-agent anastrozole.¹¹⁴ The authors reported a significantly improved progression-free survival (15 months vs 13.5 months, $p = 0.007$) favoring the combination arm. In a multicenter, randomized placebo-controlled phase III trial [Study of Faslodex with or without concomitant Arimidex vs exemestane following progression on nonsteroidal Aromatase inhibitors (SoFEA)], women who had relapsed or progressed with metastatic disease on a nonsteroidal aromatase inhibitor were randomized to receive either a combination of fulvestrant and anastrozole or fulvestrant and placebo or single-agent exemestane.¹¹⁵ There is no doubt that the three trials were different in terms of the types of patients enrolled which could explain the differing results observed. For example, in the FACT trial three quarters of the cohort had received prior treatment with aromatase inhibitor, and in the SoFEA trial, patients had to have progressed on a nonsteroidal aromatase inhibitor to be eligible for the entry into the study. This is in contrast to the cohort enrolled in the SWOG trial where the majority of patients did not receive a prior aromatase inhibitor. However with the variable results observed and the fact that fulvestrant was used at a dose that is now considered to be suboptimal, no definitive conclusions regarding combination therapy between fulvestrant and aromatase inhibitors can be made at this time. As of now current guidelines indicate that among postmenopausal women with hormone receptor-positive metastatic breast cancer, aromatase inhibitors remain the preferred first-line treatment with a sequencing strategy of various available endocrine agents preferred⁴⁷ ([Figure 2](#)).

Adjuvant studies

With the efficacy of third-generation aromatase inhibitors proved in the treatment of postmenopausal women with hormone-responsive metastatic breast cancer, focus then shifted to proving their efficacy in the adjuvant treatment of early-stage breast cancer. With the recognized increased risk of endometrial carcinoma and thromboembolic events associated with the use of tamoxifen, an alternative was the use of aromatase inhibitors.. Adjuvant studies evaluating third-generation aromatase inhibitors have explored their efficacy both as upfront adjuvant treatment and following a course of adjuvant tamoxifen ([Table 5](#); [Figure 5](#)). The following section will review results of the major adjuvant trials.

Table 5 Efficacy data from studies of aromatase inhibitors in the adjuvant treatment of postmenopausal women with early breast cancer

Trial	Drugs	Median follow-up (months)	Disease-free survival (95% CI or <i>p</i> value)
<i>Initial treatment</i>			
ATAC	5 Years of anastrozole vs 5 years of tamoxifen	120	0.86 (0.78–0.95)
BIG 1-98	5 Years of letrozole vs 5 years of tamoxifen	8.7 years	0.86 (0.78–0.96)
<i>Posttamoxifen</i>			
MA 17	5 Years of tamoxifen followed by either 5 years of letrozole or placebo	30	0.58 (0.45–0.76)
IES	2–3 Years of tamoxifen followed by either exemestane or tamoxifen for a total of 5 years	55.7	0.76 (0.66–0.88)
NSABP B-33	5 Years of tamoxifen followed by either 5 years of exemestane or placebo	30	0.68 (<i>p</i> = 0.07)
ITA	2–3 Years of tamoxifen followed by either anastrozole or tamoxifen for a total of 5 years	64	0.56 (0.35–0.89)
ABCSG trial 6a	5 Years of tamoxifen followed by either 3 years of anastrozole or placebo	62.3	0.62 ^a (0.40–0.96)

^a Risk of recurrence.

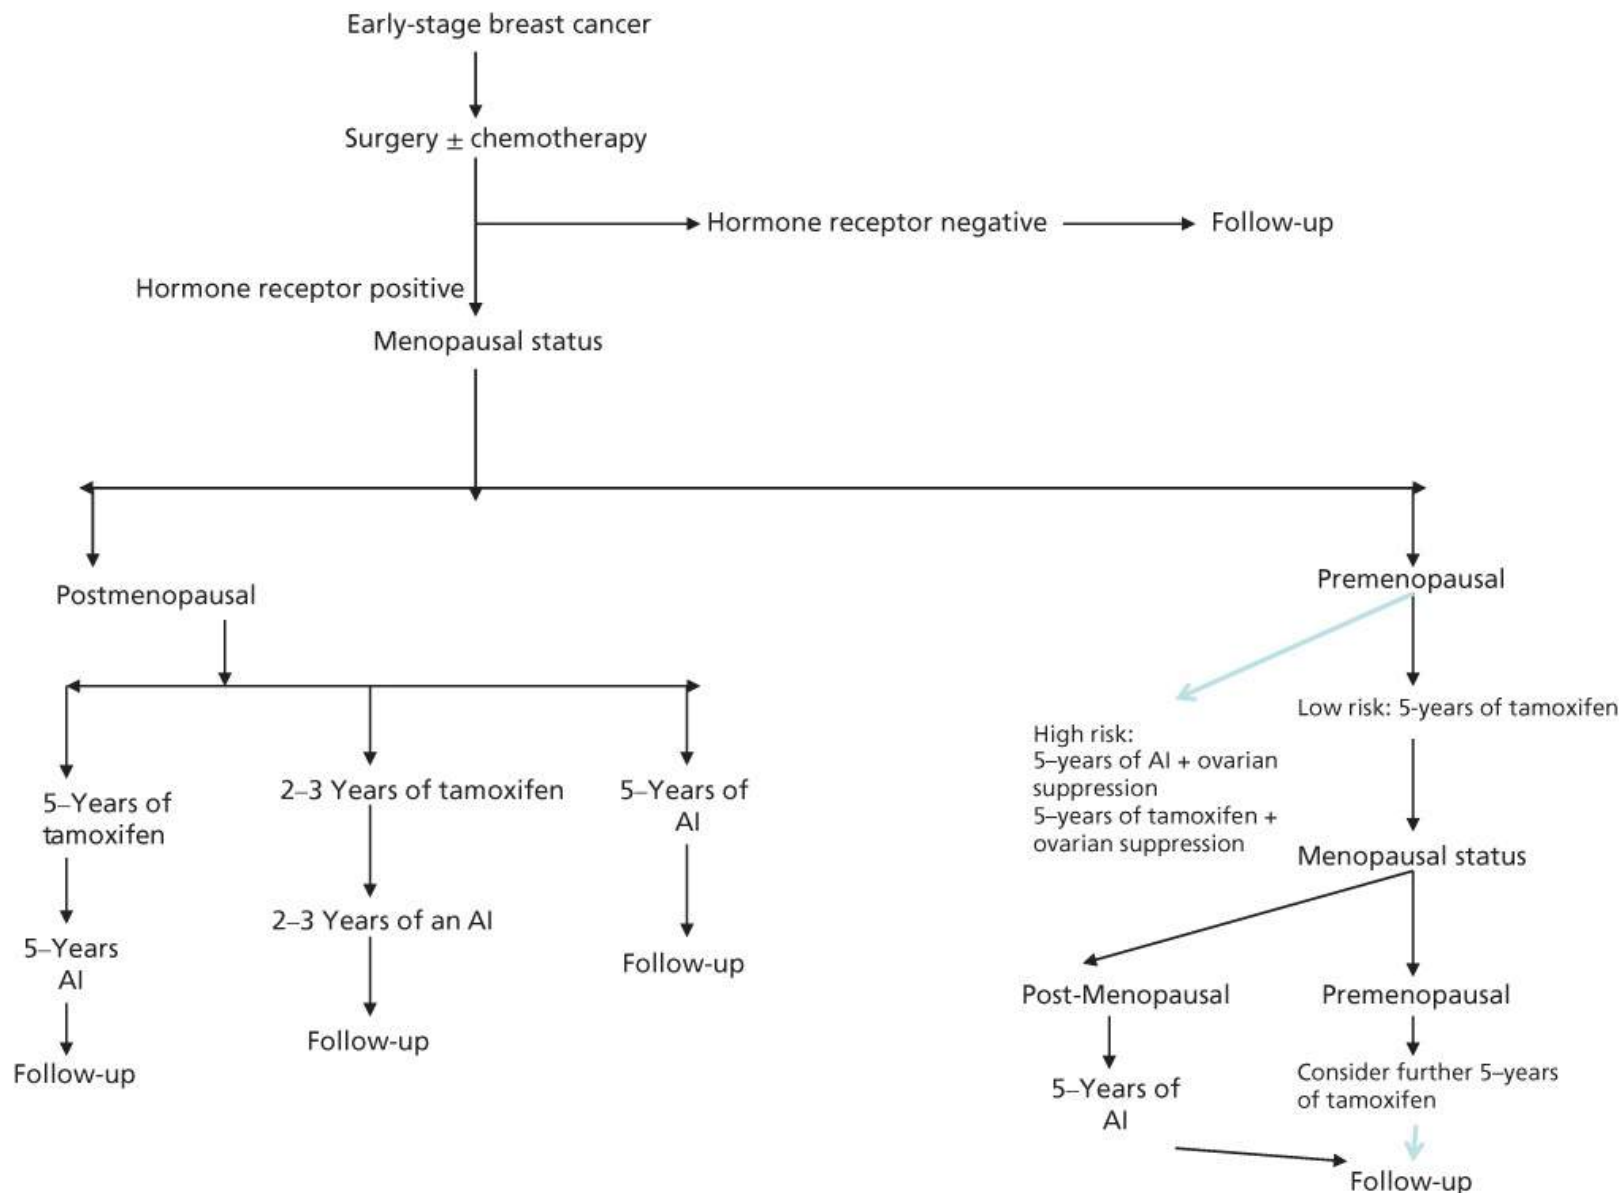

Figure 5 Algorithm for endocrine therapy among women with nonmetastatic breast cancer.

Upfront treatment of early disease in postmenopausal women

The Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial is a randomized, double-blind study of 9366 postmenopausal women with early-stage breast cancer that was designed to compare the efficacy and tolerability of 5 years of treatment with tamoxifen with that of anastrozole versus the combination of anastrozole and tamoxifen.¹¹⁶ A planned analysis at a median follow-up of 33 months resulted in the combination arm being discontinued due to lack of superior efficacy or tolerability to tamoxifen alone. The primary end point for this study was DFS and secondary end points were time to recurrence (TTR), incidence of new contralateral breast cancer, time to distant recurrence (TTDR), and OS. At a median follow-up of 120 months among women with hormone receptor-positive, DFS was significantly superior in the anastrozole group compared to tamoxifen (HR = 0.86, 95% CI 0.78–0.95, $p = 0.003$) as were TTR, TTDR, and incidence of contralateral breast cancer. There was no significant difference in the overall mortality between the two groups (HR = 0.95, 95% CI 0.84–1.06, $p = 0.7$).¹¹⁷

The Breast International Group (BIG) 1-98 trial randomized 8028 postmenopausal women with hormone receptor-positive breast cancer. BIG 1-98 included two primary adjuvant arms comparing 5 years of letrozole with 5 years of tamoxifen and two sequential treatment arms comparing 2 years of letrozole followed by 3 years of tamoxifen and 2 years of tamoxifen followed by 3 years of letrozole.¹¹⁸ The

primary end point was DFI. At a median follow-up of 8.7 years from randomization, women who received letrozole monotherapy had a significantly improved DFI (HR 0.86, 95% CI 0.78–0.96) and OS (HR 0.87, 95% CI 0.77–0.999) compared to the cohort who received tamoxifen monotherapy.¹¹⁹

Posttamoxifen treatment in postmenopausal women (switching strategy)

The second issue to be explored was the sequential use of a third-generation aromatase inhibitor following a period of adjuvant treatment of tamoxifen among postmenopausal women with early-stage breast cancer, a method commonly referred to as a switching strategy. The MA 17 trial was a randomized, double-blind, extended adjuvant, placebo-controlled trial in 5187 postmenopausal women who had received 5 years of adjuvant treatment with tamoxifen with.¹²⁰ Due to superior efficacy observed in the letrozole group compared to the placebo group at the first interim analysis, the study was prematurely terminated. In an updated analysis, at a median follow-up of 30 months, the letrozole group had a significantly longer DFS compared to the placebo group (HR = 0.58, 95% CI 0.45–0.76; $p < 0.001$).¹²¹ Letrozole was found to be well tolerated and was associated with a lower incidence of vaginal bleeding and an increase in low-grade hot flashes, arthritis, arthralgia, and myalgia, compared with placebo. After premature termination of the study, the group who were in the placebo of arm of the trial was offered letrozole. Women who elected to take letrozole did so at a median of 2.8 years from completion of tamoxifen treatment with a recent update reporting improved DFS among those who elected to take letrozole compared to those who did not.¹²² In an exploratory analysis after statistical adjustment for crossover effect, the investigators reported that at a median follow-up of 64 months, extended adjuvant letrozole continued to superior to placebo for both DFS and OS.¹²³ The investigators further noted that although extended adjuvant letrozole after 5 years of tamoxifen was beneficial to women who were either pre- or postmenopausal at initial diagnosis, prognostic impact appeared to be greater among women who were initially premenopausal.¹²⁴

The Intergroup Exemestane Study (IES) examined the efficacy and safety of exemestane therapy after 2–3 years of adjuvant tamoxifen therapy. The trial enrolled 4742 patients who were randomly assigned to continue with tamoxifen or to switch to exemestane for the remainder of the 5-year treatment period. At a median follow-up of 30.6 months, the data indicate that switching to exemestane was associated with a significant improvement in DFS compared with continuing with tamoxifen (HR = 0.68, 95% CI 0.56–0.82; $p < 0.001$).¹²⁵ At a median follow-up of 55.7 months, switching to exemestane resulted in a 24% improvement in DFS (HR = 0.76, 95% CI 0.66–0.88, $p = 0.0001$) and a 15% improvement in OS (HR = 0.85, 95% CI 0.71–1.02, $p = 0.08$) as compared to the tamoxifen group.¹²⁶ The NSABP B-33 trial, similar to the IES trial, is a randomized trial that evaluated 5 years of exemestane to 5 years of placebo following the completion of 5-years of tamoxifen.¹²⁷ Due to the results of the MA 17 study, the NASBP B-33 study was terminated early and was unblinded. Despite a premature closure and crossover of patients, a statistically significant 4-year DFS was observed among the original cohort who received exemestane compared to the placebo group (91% vs 89%; HR = 0.68; $p = 0.07$).¹²⁷

The adjuvant tamoxifen and exemestane in early breast cancer (TEAM) trial was a phase III study; the aim of which was to compare exemestane monotherapy upfront to sequential treatment of exemestane following completion of 5 years of tamoxifen.¹²⁸ Over 9000 patients were recruited on this trial. The investigators noted no significant difference in the 5 year DFS between the two treatment strategies (hazard ratio 0.97, 95% CI 0.88–1.08; $p = 0.60$) and concluded that exemestane either upfront or after a course of tamoxifen were both appropriate options for postmenopausal women with early-stage breast cancer.

Several smaller trials have also looked at the issue of sequential aromatase inhibitors. The Italian Tamoxifen Anastrozole (ITA) and Arimidex Nolvadex 95/Austrian Breast Cancer Study Group 8 (ARNO 95/ABCSG 8) have shown that switching to anastrozole after 2–3 years of tamoxifen significantly reduced the risk of recurrence.^{129, 130} In the ABCSG trial 6a postmenopausal women were randomized to either anastrozole or placebo following 5 years of adjuvant tamoxifen therapy.¹³¹ At a median follow-up of 62.3 months, women in the anastrozole group had a 38% risk reduction in recurrence compared to placebo (HR = 0.62; 95% CI = 0.40–0.96, $p = 0.031$).

When putting all the aforementioned trials together, it is clear that among postmenopausal women with hormone receptor-positive breast cancer, the adjuvant use of an aromatase inhibitor either upfront or as sequential treatment following tamoxifen is superior compared to using tamoxifen alone. Both strategies are recommended and incorporated in a number of international guidelines.

Aromatase inhibitors in premenopausal women

From the data summarized earlier, it is clear that aromatase inhibitors are superior to tamoxifen in the adjuvant setting. Due to their mechanism of action, aromatase inhibitors can only be used among women who are postmenopausal. Tamoxifen has to date been the only agent recommended for use in the adjuvant setting among premenopausal women with hormone receptor-positive breast cancer. The therapeutic value of suppression of ovarian estrogen production among premenopausal women who receive tamoxifen has been uncertain.¹³² Provocative data has also been published, suggesting that ovarian suppression occurring secondary to chemotherapy (i.e., developing an amenorrhea state) is associated with a reduced risk of relapse which led to guidelines for management of breast cancer among young women recommending that the addition of GnRH analogues with tamoxifen be discussed on an individualized basis.^{133, 134} We know that the actual use of ovarian ablation has not resulted in improved outcome despite an observed trend for benefit in terms of recurrence and DFS in premenopausal women <40. However keeping in mind that the majority of these studies have not compared ovarian ablation with tamoxifen included in both arms, it was unclear whether the benefit from ovarian ablation is superior to tamoxifen alone.

As such in 2003 the International Breast Cancer Study Group (IBCSG) launched two phase III randomized clinical trials that focused on premenopausal women with early-stage hormone receptor-positive breast cancer [Suppression of Ovarian Function Trial (SOFT), Tamoxifen and Exemestane Trial (TEXT)] that were designed to determine whether adjuvant aromatase inhibitors improved DFS compared to tamoxifen and to determine the value of ovarian suppression.^{135, 136} The TEXT randomized premenopausal women with early-stage breast cancer to either 5 years of exemestane and ovarian suppression or 5 years of tamoxifen and ovarian suppression. The SOFT randomized premenopausal women with early-stage breast cancer to either 5 years of tamoxifen alone, tamoxifen and ovarian suppression, or exemestane and ovarian suppression. In a preplanned combined analysis of data derived from TEXT and SOFT, the investigators observed that at a median follow-up of 68 months, 5-year DFS was significantly improved among premenopausal women treated with exemestane and ovarian suppression compared to those treated with tamoxifen and ovarian suppression (91.1% vs 87.3%, HR 0.72, 95% CI 0.60–0.85, $p < 0.001$).¹³³ This was however associated with a higher incidence of grade 3 or 4 adverse events among women receiving exemestane (30.6% vs 29.4%).¹³⁵ The SOFT randomized over 3000 premenopausal women with hormone receptor-positive early-stage breast cancer to either tamoxifen alone, tamoxifen and ovarian suppression, or exemestane and ovarian suppression with the underlying goal of trying to determine the value of ovarian suppression in this cohort of patients.¹³⁶ The investigators reported that at a median follow-up of 67 months in the overall study population, the addition of ovarian suppression to

tamoxifen did not significantly improve 5-year DFS compared to tamoxifen alone (86.6% vs 84.7%, $p = 0.10$) on univariate analysis. In the multivariable model after adjusting for covariates, the combination of ovarian suppression and tamoxifen resulted in a 22% reduction in the RR of breast cancer recurrence, a second invasive cancer or death ($p = 0.03$) compared to tamoxifen alone. The authors further observed that among premenopausal women who are at sufficiently high risk of recurrence to receive chemotherapy, the 5-year rate of freedom from breast cancer was 78% among women receiving tamoxifen alone, 82.5% among those receiving tamoxifen and ovarian suppression (when comparing to tamoxifen alone HR 0.78; 95% CI 0.60–1.02), and 85.7% among those receiving exemestane and ovarian suppression (when comparing to tamoxifen alone HR 0.65; 95% CI 0.49–0.87). The investigators reported an increasing rate of nonadherence to ovarian suppression with increasing year from initiation of treatment. Side effects reported to be associated more frequently with ovarian suppression included hot flashes, insomnia, depression, vaginal dryness, musculoskeletal symptoms, hypertension, and glucose intolerance. Rate of osteoporosis was also higher among women receiving ovarian suppression. In a third randomized phase III trial (Austrian Breast and Colorectal Cancer Study Group (ABCSCG)-12), 1803 premenopausal women who undergone surgery for stage I or II hormone receptor-positive breast cancer were randomized to either anastrozole and ovarian suppression or tamoxifen with ovarian suppression with or with zoledronic acid.¹³⁷ The primary end point of this study was DFS with RFS and OS being secondary end points. At a median follow-up of 94.4 months, the investigators reported no significant difference in DFS between the tamoxifen and anastrozole groups although a higher risk of death was observed among group of patients receiving anastrozole and ovarian suppression compared to the group receiving tamoxifen and ovarian suppression (HR = 1.63; 95% CI, 1.05–1.45; $p = 0.030$). Interestingly the addition of zoledronic acid was observed to be associated with improved DFS. Multiple reasons have been hypothesized to account for the discordant results between the ABCSCG-12 and that observed with the TEXT and SOFT; the most important of which is statistical power with the TEXT/SOFT having higher statistical power to answer the question regarding the role of ovarian suppression and aromatase inhibitors in the premenopausal setting. Longer-term follow-up of the TEXT and SOFT will be vital in determining long-term efficacy as well as defining associated toxicity in this young population of patients.

Based on the evidence presented earlier, the author recommends that aromatase inhibitors be offered upfront as adjuvant therapy among postmenopausal women with hormone receptor-positive early-stage breast cancer. Current guidelines of adjuvant endocrine therapy for postmenopausal women recommend an aromatase inhibitor as either initial therapy or after an initial period of treatment with tamoxifen¹³⁸ with the decision based on the risks and benefits of each agent for an individual patient. Using an aromatase inhibitor beyond 5 years is currently not recommended, and ongoing clinical trials will answer the question of the clinical utility of this method. Among premenopausal women the story is a little more complex. The use of 10 years of tamoxifen or the use of ovarian suppression and aromatase inhibitors have both been included in the updated guidelines, and use of either should be based on individual risk assessment and a thorough discussion regarding associated side effects.⁴⁷ Longer-term follow-up of the adjuvant trials described earlier are awaited to better define long-term efficacy results, side effect profile, and delineate duration of required treatment for an aromatase inhibitor used in the adjuvant setting.

Neoadjuvant studies

Neoadjuvant treatment is intended to downstage a tumor before primary locoregional therapy with surgery, thus allowing breast-conserving surgery in a greater number of patients or making surgery possible in cases that were considered inoperable. As the third-generation aromatase inhibitors have demonstrated efficacy in the treatment of advanced and early disease, it is important to examine the

benefits these agents may bring to the preoperative setting.

Compared to neoadjuvant chemotherapy trials, the neoadjuvant studies exploring the effect of endocrine therapy in the treatment of breast cancer are much smaller. Several trials have compared neoadjuvant tamoxifen to a third-generation aromatase inhibitor among postmenopausal women with hormone receptor-positive breast cancer.^{139–143} The Immediate Preoperative Arimidex, Tamoxifen, or Combined with Tamoxifen (IMPACT) trial compared 3 months of preoperative anastrozole with tamoxifen or a combination of both in 330 postmenopausal women with hormone receptor-positive breast cancer.¹³⁹ No difference in overall response was noted in three groups (37% vs 36% vs 39%). However among the 124 women considered to require a mastectomy at baseline, 46% treated with anastrozole were considered to be candidates for breast-conserving surgery by their surgeon, compared with 22% receiving tamoxifen ($p = 0.03$).¹³⁹ Similarly the PReOperative Arimidex Compared with Tamoxifen (PROACT) trial that randomized 451 postmenopausal women to either 3 months of neoadjuvant anastrozole or tamoxifen with or without chemotherapy reported that among the hormone therapy-only group of patients, feasible surgery at baseline improved in 43.0% of patients receiving anastrozole compared to 30.8% receiving tamoxifen ($p = 0.04$).¹⁴⁰

In the P024 study where 337 postmenopausal women were randomly assigned to either 4 months of neoadjuvant letrozole or tamoxifen, overall response rate (55% vs 36%, $p < 0.001$) and rate of breast-conserving surgery (45% vs 35%, $p = 0.022$) were significantly superior in the letrozole arm of the study.¹³⁸ In addition in the P024 study differences in response rates between letrozole and tamoxifen were most marked in the subgroup that was positive for ErbB-1 and/or ErbB-2 (88% vs 21%, $p = 0.0004$); however this part of the study was largely underpowered.¹⁴² In a small randomized study of 151 patients, exemestane was also reported to be more effective than tamoxifen in neoadjuvant setting for both clinical overall response (76.3% vs 40%; $p = 0.05$) and breast-conserving surgery (exemestane 36.8% vs tamoxifen 20%; $p = 0.05$).¹⁴⁰

In the ACOSOG Z1031 phase II trial, the three aromatase inhibitors were compared in the preoperative setting. Over three hundred postmenopausal women with clinical stage II to III breast cancer were enrolled with the primary end point being clinical response.¹⁴⁴ The clinical response among patients receiving exemestane, letrozole, and anastrozole was 62.9%, 74.8%, and 69.1%, respectively. No differences in surgical outcome, Preoperative Endocrine Prognostic Index (PEPI) score, or Ki67 suppression were detected (secondary end points of the study).

At present time, outside the context of a clinical trial, neoadjuvant endocrine therapy with aromatase inhibitors are recommended for postmenopausal patients who are not believed to be candidates for preoperative chemotherapy because of associated existing comorbidity.¹⁴⁵ Several questions still remain to be addressed by future clinical trials including the appropriate duration of neoadjuvant endocrine therapy.

Chemoprevention of breast cancer

As discussed earlier the side effect profile of tamoxifen restricts its use in the prevention of breast cancer. Furthermore trials looking at tamoxifen and raloxifene in the prevention setting reduced the incidence of ER-positive breast cancers by about 50%, and thus looking for an agent that would reduce the incidence further is important. Aromatase inhibitors, with their proven efficacy in the treatment of hormone receptor-positive breast cancers, are a viable option. In the ATAC trial¹¹⁷ at a median follow-up of 100 months, it was observed that the incidence of hormone receptor-positive contralateral breast cancers was significantly lower in the anastrozole group compared to the tamoxifen group (HR 0.60, 95% CI 0.42–

0.85, $p = 0.004$). Similarly in the BIG 1-98 trial,^{118, 119} fewer cases of contralateral breast cancer were identified in the letrozole group than in the tamoxifen group (16 cases vs 27 cases). In the IES study¹²⁶ at a median follow-up of 55.7 months, 17 cases of contralateral breast cancer were observed in the exemestane group compared to 35 cases in the tamoxifen group with the time to development of ER-positive contralateral breast cancer significantly reduced in the exemestane group compared to the tamoxifen group (HR = 0.56, 95% CI 0.33–0.98, $p = 0.04$).

These trials indicated that third-generation aromatase inhibitors reduce the incidence of contralateral breast cancer by approximately 40%–50% above and beyond that observed by tamoxifen. By extrapolation this would imply that on their own these aromatase inhibitors would reduce the incidence of ER-positive contralateral breast cancer by approximately 70%–80%.¹⁴² With such impressive results large randomized clinical trials were designed to look at the use of aromatase inhibitors in the setting of primary prevention.^{147, 148} In a phase III trial, 4560 postmenopausal women who were at moderately increased risk of developing breast cancer were randomized to receive exemestane or placebo.¹⁴⁷ The authors reported that at a median follow-up of 35 months, invasive breast cancer was detected in 11 women in the exemestane cohort compared to 32 cases of invasive breast cancer in the placebo cohort. The use of exemestane in this cohort of women translated into a 65% relative reduction in the annual incidence of invasive breast cancer compared to placebo (HR 0.35, 95%CI 0.18–0.70, $p = 0.002$). Minimal quality of life differences were observed between the two groups with no significant difference observed between the two groups in terms of skeletal fractures, other cancers, treatment-related deaths, and cardiovascular events. In a second phase III trial (IBIS-II), 1920 postmenopausal women at high risk of developing breast cancer were randomized to either anastrozole or placebo for 5 years.¹⁴⁸ At a median follow-up of 5 years, breast cancer was detected among 40 women in the anastrozole cohort and 85 women in the placebo cohort (HR 0.47, 95% CI 0.32–0.68, $p < 0.0001$). The cumulative incidence of all breast cancers after 7 years of follow-up was 2.8% in the anastrozole group and 5.6% in the placebo group. Considering the data described and the better side effect profile compared to tamoxifen current guidelines recommend considering the use of aromatase inhibitors among postmenopausal women who are at moderate to high risk of developing breast cancer.⁴⁷

Side effects

Bone disease

As discussed earlier estrogen deprivation is associated with an increased risk of developing osteoporosis and is more so in women with breast cancer.¹⁴⁹ While tamoxifen, through its estrogen agonist function on the bone, has been shown to have a beneficial effect on bone health,⁷⁶ all three third-generation aromatase inhibitors appear to increase bone loss. In the 120-month analysis of the ATAC trial, fracture rates were significantly higher in the anastrozole group compared to the group receiving tamoxifen (451 fractures vs 351 fractures, HR 1.33, 95% CI 1.15–1.55; $p < 0.0001$); however the fracture rate was not significantly different between the anastrozole and tamoxifen groups after completion of 5-year treatment (110 vs 112, OR 0.98, 95% CI 0.74–1.30, $p = 0.9$).¹¹⁷

In the BIG 1-98 trial at a median follow-up of 60.3 months, 9.3% of patients in the letrozole group experienced a fracture compared to 6.5% of patients in the tamoxifen group with the wrist being the most common site of fracture.¹⁵⁰ Similar observations were also made in the IES trial where at a median follow-up of 55.7 months, a significantly increased fracture rate of 7% was observed in the exemestane group compared to 5% in the tamoxifen group (odds ratio = 1.45, 95% CI 1.13–1.87; $p = 0.003$).¹⁵¹ One method of preventing or reversing bone loss associated with aromatase inhibitors would be to use

bisphosphonates. In the integrated analysis of two randomized Zometa-Femara Adjuvant Synergy Trials (Z-FAST and ZO-FAST), 1667 patients that were receiving adjuvant letrozole received either upfront zoledronic acid or received it only when bone mineral density decreased to below -2 .¹⁵² At 12-month follow-up, the upfront group had lumbar spine bone mineral density that was 5.2% higher than the group of patients who received delayed zoledronic acid. Longer follow-up will be needed to confirm these results.

Cardiovascular disease

Postmenopausal women with breast cancer may be at a higher risk of cardiovascular events due to their age, menopausal status, associated comorbid conditions, and exposure to chemotherapeutic agents used in the treatment of breast cancer. As described earlier, tamoxifen, through its estrogen agonist function, has been shown to have a lipid-lowering effect that has translated into modest reductions in cardiovascular events.⁷⁹ Anastrozole has not been shown to appreciably alter lipid profiles,^{153, 154} and in the adjuvant setting myocardial infarctions experienced by women taking anastrozole was similar compared to the group taking tamoxifen.¹¹⁷ In the BIG 1-98 trial at a median follow-up of 51 months, women in the letrozole group experienced significantly higher low-grade cholesterol elevation and cardiovascular events (other than ischemic heart disease and cardiac failure) compared to women in the tamoxifen group.¹¹⁹ The higher low-grade cholesterol elevation in the letrozole group relative to that of patients in the tamoxifen group may be a reflection of the lipid-lowering effect of tamoxifen as mentioned earlier. Studies with exemestane have shown that apart from a modest drop in HDL cholesterol,¹⁵⁵ exemestane has no appreciable effect on lipid levels. In the IES study, at a median follow-up of 55.7 months, among all patients the incidence of cardiovascular events (excluding thromboembolic events) did not seem to differ between the exemestane and tamoxifen groups with approximately 1.3% of exemestane-treated patients experiencing a myocardial infarction compared to 0.8% of tamoxifen-treated patients ($p = 0.08$). Although longer follow-up will be required to assess the cardiovascular effects of the clinically used third-generation aromatase inhibitors, women with breast cancer are in general at higher risk of developing a cardiovascular event due to a multitude of factors and as such should be monitored and managed appropriately.

Other adverse events

Another important side effect of aromatase inhibitors is the development of arthralgia which can significantly impact quality of life. For example, the incidence of arthralgia associated with the use of letrozole in the BIG 1-198 trial was 20.3% compared to the 12.3% observed among women taking tamoxifen ($p < 0.001$).¹¹⁹ The COMpliance and Arthralgia in Clinical Therapy (COMPACT) trial was an open-label trial; the primary end point of which was to look at arthralgia compliance.¹⁵⁶ Nearly two thousand postmenopausal women received upfront anastrozole. The investigators noted that compliance with anastrozole gradually decreased over time with a significant association observed between arthralgia mean scores and noncompliance. Other side effects commonly associated with aromatase inhibitors include vaginal dryness and dyspareunia. Although treatment with aromatase inhibitors increases the risk of vasomotor symptoms and vaginal bleeding/discharge, large trials have shown that the incidence of these events are lower compared to that experienced on tamoxifen treatment.^{116–130} Furthermore these trials also reported that the incidence of thromboembolic events and endometrial carcinoma were also lower in women taking an aromatase inhibitor compared to those taking tamoxifen.

Resistance to endocrine therapy

We have certainly come a long way in the management of women with hormone receptor-positive breast cancer in both the adjuvant and metastatic setting. However although endocrine therapy is effective in the metastatic setting, only 30% of patients with hormone receptor-positive breast cancer have an objective response with approximately only 50% gaining clinical benefit from endocrine therapy.¹⁵⁷ In clinical practice, the sequential use of hormonal agents can produce long-term palliation of hormone-dependent metastatic breast cancer. Eventually, however, the problem of hormone resistance is encountered. In the adjuvant setting clinical trials have demonstrated that approximately fifty percent of patients with hormone receptor-positive breast cancer benefit from endocrine therapy, while the rest develop either a primary or acquired resistance. Several patterns of resistance are commonly encountered in clinical practice. A primary resistance describes a scenario whereby a tumor is inherently resistant to ER targeting despite ER expression. An acquired resistance describes a situation where an ER-positive tumor initially responds and then progresses on endocrine therapy. Agent-selective resistance describes a scenario where the ER-positive tumor is resistant to a specific endocrine agent.

The mechanisms by which tumors become resistant to hormones, in general, are only partially understood.¹⁵⁸ Refractoriness to therapy with aromatase inhibitors is related not to the failure of these agents to suppress estradiol levels but rather because of alterations in other cellular components, such as the growth factor receptor pathways.¹⁵⁹ Some of the mechanisms of endocrine resistance include activation of the cell surface growth factor receptors [including epidermal growth factor receptor, human epidermal growth factor receptor 2 (HER2), and IGF-1 receptor] and downstream elements of the receptor tyrosine kinases (including phosphatidylinositol 3-kinase (PI3K), AKT, and mammalian target of rapamycin (mTOR)). Activation or dysregulation of any of these pathways ultimately results in ligand-independent activation of the ER-signaling pathways that results in these pathways becoming resistant to endocrine agents used in the clinic. With an increased understanding of the mechanisms of resistance, selective targeted inhibitors have been introduced which when used in combination with endocrine therapy can overcome resistance.

Targeting the HER2 pathway

The HER2 is known to be over expressed or amplified in approximately one-fifth of patients with newly diagnosed breast cancer and is typically associated with a poor prognostic outcome. The introduction of a number of anti-HER2 agents (e.g., trastuzumab, lapatinib, pertuzumab, and TDM-1) has effectively altered the natural history of this breast tumor subtype. Preclinical evidence indicates that crosstalk between the HER2 and ER pathways results in resistance to established endocrine therapies.^{160–162} Based on this evidence a number of clinical trials investigated the combination of an anti-HER2 agent and endocrine therapy with the underlying hypothesis that the combination would be superior to endocrine therapy alone. The TANDEM trial was a phase III study that randomized postmenopausal women with hormone receptor-positive/HER2-positive metastatic breast cancer to either a combination of trastuzumab and anastrozole or anastrozole alone.¹⁶³ The investigators noted that the combination was associated with a statistically significant although clinically modest improvement in progression-free survival (HR 0.63; 95% CI, 0.47–0.84; median PFS, 4.8 months vs 2.4 months; $p = 0.0016$) although there was no difference in OS between the two groups. In a second trial where postmenopausal women with hormone receptor-positive/HER2-positive breast cancer were randomized to receive lapatinib and letrozole or letrozole alone, the investigators observed that the addition of lapatinib to letrozole significantly reduced the risk of disease progression compared to letrozole alone (HR 0.71; 95% CI 0.53–0.96; $p = 0.019$, median PFS 8.2 months vs 3.0 months).¹⁶⁴

Targeting the PI3Kinase pathway

The PI3K pathway is known to modulate cell growth, proliferation, and survival with mTOR being a signal transduction kinase in this pathway. mTOR exists in two multiprotein complexes. mTORC1 consists of mTOR that is associated with a regulatory protein of mTOR (raptor) and is located downstream of AKT, while mTORC2 is associated with rapamycin-insensitive companion of mTOR (rictor) and it phosphorylates AKT. Pathway PI3K activation results in phosphorylation of AKT which in turn leads to phosphorylation of mTORC1 and its effectors [4E binding protein 1 (4E-BP-1) that enhances cell proliferation, survival, and angiogenesis and S6 kinase 1 (S6K1) that regulate cell growth]. Preclinical evidence has shown that activation of the PI3K pathway is associated with endocrine therapy resistance with S6K1 being responsible for phosphorylating the activating domain of ERs.^{165, 166} A number of studies also indicated that inhibition of mTOR reversed endocrine resistance especially when mTOR inhibitors were combined with endocrine therapy.^{167, 168} Such evidence led to the development of a number of mTOR inhibitors that were investigated in combination with endocrine therapy in clinical trials. In a phase III (HORIZON) trial, that tested the clinical efficacy of the mTOR inhibitor temsirolimus, 1112 patients with hormone receptor-positive metastatic breast cancer who had not received a prior aromatase inhibitors were randomized to receive either letrozole or letrozole combined with temsirolimus. This study was closed for futility when it was observed that the combination of letrozole and temsirolimus was highly unlikely to demonstrate an improvement in PFS over letrozole alone.¹⁶⁹ Everolimus (rapamycin analogue that inhibits mTORC1 kinase) was tested in the phase III Breast Cancer Trial of Oral Everolimus 2 (BOLERO-2) trial where patients with hormone receptor-positive metastatic breast cancer who had progressed on a prior nonsteroidal aromatase inhibitor were randomized to receive either everolimus and exemestane or exemestane alone.¹⁷⁰ To enroll in the study patients had to have disease that was previously refractory to either letrozole or anastrozole, and this was defined as recurrence during or within 12 months of completion of adjuvant treatment or in the case of metastatic disease, patients had to have experienced progression of disease either during treatment or within 1 month of ending treatment. In this population of patients who were resistant to nonsteroidal aromatase inhibitors, the investigators demonstrated a statistically significant improvement in median PFS of 4.6 months ($p < 0.0001$) in the combination arm. However this improvement did not translate into a significant improvement in the secondary end point of OS (31 months vs 26.6 months, $p = 0.14$). The addition of everolimus to exemestane increased toxicities including stomatitis (grade 3 8% vs 1%), pneumonitis (grade 3, 3% vs 0%), liver dysfunction, and hyperglycemia. A third trial [tamoxifen plus everolimus (TAMRAD)] was a randomized phase II trial that evaluated the combination of everolimus and tamoxifen compared to tamoxifen alone among 111 women who had been previously treated with an aromatase inhibitor.¹⁷¹ The primary end point of the TAMRAD study was clinical benefit rate at 6 months which was found to be significantly improved among patients receiving tamoxifen and everolimus compared to tamoxifen alone (61% vs 42%). By restricting enrollment to patients who had progressed on a prior aromatase inhibitor, the BOLERO-2 and TAMRAD trials are likely selected for patients whose tumors were being driven by the PI3K/AKT/mTOR pathways which would explain the discordant results observed compared to the HORIZON study. At present the combination of everolimus and exemestane has been recommended for use among patients whose disease has progressed on a prior aromatase inhibitor.⁴⁷ Since the addition of everolimus is associated with unique and significant toxicities, a thorough discussion with the patient is important prior to commencing treatment.

Targeting the CDK 4/6 pathway

The cyclin-dependent kinases (CDKs) together with regulatory proteins cyclins have a critical role in the

controlled progression through the cell cycle. Alterations in the genes controlling the cell cycle are potential targets for treatment with CDK-targeted agents being the most attractive.¹⁷² CDK4/6 and cyclin D regulate the phosphorylation of pRb (retinoblastoma) which when hyperphosphorylated results in the release of transcription factors that allow cells to transition from the G1 to the S phase of the cycle.¹⁷³ Palbociclib (PD-0332991) is a selective, reversible small molecule inhibitor of CDK 4/6 which in preclinical studies of human breast cancer cell lines has been shown to have potent activity in the ER-positive and HER2-amplified subtypes.¹⁷⁴ In these subtypes it was found to result in blockade of pRb hyperphosphorylation that ultimately resulted in cycle arrest in G1 phase. Synergistic growth inhibitor effect was seen with the combination of tamoxifen and palbociclib in a model with acquired tamoxifen resistance. In a single arm phase II trial of 36 patients with heavily pretreated metastatic breast cancer that was positive for Rb protein expression, single-agent palbociclib showed activity in some patients with hormone receptor-positive breast cancer.¹⁷⁵ Associated grade 3/4 toxicities included transient neutropenia and thrombocytopenia. In a randomized open-label phase II PALOMA trial, 165 postmenopausal women with hormone receptor-positive and HER2-negative metastatic breast cancer who had not received treatment for their advanced disease were randomized to receive letrozole or letrozole and palbociclib.¹⁷⁶ The addition of palbociclib to letrozole was noted to improve progression-free survival from 10.2 to 20.2 months (HR 0.488, 95% CI 0.319–0.718, $p = 0.0004$). Grade 3/4 neutropenia (54% vs 1%) and fatigue (4% vs 1%) were reported with higher frequency in the palbociclib/letrozole group compared to the single-agent letrozole group. Based on these results the FDA granted accelerated approval for palbociclib in combination with letrozole as a first-line treatment among patients with hormone receptor-positive metastatic breast cancer. Recently the results of the PALOMA-3 trial, that randomized over 500 patients with hormone receptor-positive and HER2-negative metastatic breast cancer who had either relapsed or progressed during endocrine therapy to either fulvestrant alone or in combination with palbociclib, were published.¹⁷⁷ This phase III trial included premenopausal and perimenopausal patients who receive goserelin. The investigators reported a significant improvement in the progression-free survival (9.2 months vs 3.8 months, $p < 0.001$) with the addition of palbociclib to fulvestrant.

GnRH analogues and ovarian function preservation

With the improvement in prognostic outcome associated with adjuvant chemotherapy among younger premenopausal women with early-stage breast cancer, the issue of premature menopause and infertility associated with chemotherapy has become an important one. Among women who receive chemotherapy those younger than age 35 years, the long-term incidence of amenorrhea is at approximately 10%, while it is approximately 50% among women between the ages of 35 and 40 years and can be up to 85% among those above age 40 years.¹⁷⁸ Infertility associated with premature ovarian failure can impact treatment decisions in almost 30% of younger women with breast cancer.¹⁷⁹ Currently there are no standards for fertility preservation among premenopausal women who receive chemotherapy. The 2013 guidelines from the American Society of Clinical Oncology (ASCO) on fertility preservation recommend that a thorough discussion on the risks of infertility with chemotherapy and/or radiation therapy be discussed upfront before commencing treatment with the issue of trying to preserve fertility be addressed as early possible.¹⁸⁰ Recommended options for fertility preservation among women of reproductive age include embryo and oocyte cryopreservation and ovarian transposition in the case of pelvic radiation therapy. The use of GnRH analogues concurrently with chemotherapy has also been explored as a method of ovarian function preservation. Ovarian function preservation with GnRH analogues has been postulated to occur via several mechanisms including interruption of FSH secretion, decrease in utero-ovarian perfusion, and

protection of undifferentiated germline stem cells.¹⁸¹ Data from a number of animal and human models have suggested that temporary ovarian suppression associated with use of GnRH analogues may preserve ovarian function.^{181–185} However clinical data regarding the use of GnRH analogues for ovarian function preservation has been conflicting. In the ZOladox Rescue of Ovarian Function (ZORO) trial that randomized 60 women with ER-negative breast cancer who were scheduled to receive chemotherapy with an anthracycline and taxane to either chemotherapy alone or chemotherapy in combination with goserelin, the investigators found no statistical difference in resumption of ovarian function between the two arms of the study.¹⁸⁵ Similarly in the Ovarian Protection Trial in Premenopausal Breast Cancer Patients (OPTION) trial that randomized 227 patients to chemotherapy alone or in combination with goserelin, no difference in ovarian protection between the two groups was noted.¹⁸⁶ In contrast a number of studies have noted a benefit with the use of GnRH analogues. In the phase III PROMISE-GIM6 trial that randomized 281 premenopausal women with early-stage breast cancer to either chemotherapy alone or chemotherapy and the GnRH analogue triptorelin, the investigators observed a 17% absolute reduction in the occurrence of early menopause.¹⁸⁷ Recently the long-term results of this trial were reported.¹⁸⁸ The investigators noted that at a median follow-up of 7.3 years, there was no difference in 5-year DFS (83.7% with chemotherapy alone vs 80.5% with chemotherapy in combination with triptorelin, $p = 0.519$). Four pregnancies were noted in the chemotherapy alone groups, and 8 pregnancies occurred in the group who received chemotherapy and triptorelin (OR 1.84; 95% CI 0.54–6.27, $p = 0.39$). In the IBCSG-/SWOG-coordinated phase III trial (POEMS), premenopausal women with hormone receptor-negative breast cancer were randomized to either receive chemotherapy alone or in combination with goserelin.¹⁸⁹ The primary end point was 2-year primary ovarian failure. Two year ovarian failure rate was 22% in the chemotherapy alone arm and 8 % in the chemotherapy and goserelin arm of the trial (OR = 0.30, 95% CI 0.10–0.87, $p = 0.03$). Thirteen pregnancies were noted in the chemotherapy alone arm, and 22 pregnancies were noted in the chemotherapy in combination with goserelin arm (OR = 2.22, 95% CI 1.00–4.92, $p = 0.05$). Limitations of this study included the fact that it did not reach its target accrual (416 target accrual, 214 randomized and reported), missing end point data for 38% of patients, and the data was not stratified for disease risk factors (HER2, nodal status, and stage of disease). The 2013 ASCO guidelines currently do not recommend the use of GnRH analogues as a method of fertility preservation noting that there is insufficient evidence regarding its effectiveness in ovarian function preservation.¹⁸⁰ The authors of this chapter recommend that the issue of fertility preservation be discussed as early as possible and that all methods be discussed including the pros and cons of each.

Conclusion

In summary a number of endocrine agents are now available for the management of both early and advanced stage hormone response breast cancer, each unique in its mechanism of action targeting different points in the ER and PR pathways. Tamoxifen has been ubiquitous as the frontline therapy for the treatment of all stages of breast cancer and remains the central choice for the treatment of premenopausal women. Emerging data suggests that the use of aromatase inhibitors with ovarian function suppression among premenopausal women with early-stage breast cancer who are at high risk of recurrence may be associated with improved prognostic outcome. Among postmenopausal women the introduction of the noncross-resistant aromatase inhibitors has changed recommendations being now at the forefront of treatment of both early and advanced staged breast cancers. However several questions regarding the use of aromatase inhibitors still remain including duration of use in the adjuvant setting and sequence of use with tamoxifen. Moreover among the three third-generation aromatase inhibitors, there are no head to head comparisons to support the superiority of one aromatase inhibitor over another. Furthermore the use

of aromatase inhibitors are not without side effects with various methods available (e.g., use of zoledronic acid, denosumab) for preventing bone loss which can have a significant impact on quality of life. We have also come a long way in understanding mechanisms underlying the development of endocrine resistance with agents such as everolimus now approved for use in combination aromatase inhibitors. Progestins including MA and MPA are useful agents to try when resistance to tamoxifen and aromatase inhibitors has developed.

Lastly, as more antihormonal therapies become available and our understanding of the molecular pathways underpinning resistance increases, it is essential that the optimal sequence of endocrine agents be established in the treatment of breast cancer. This may prolong the time during which endocrine therapies can be used, so postponing the time when cytotoxic chemotherapy becomes a necessary option.

Chapter 62

Drug resistance and its clinical circumvention

Jeffrey A. Moscow, MD ■ Kenneth H. Cowan, MD, PhD ■ Branimir I. Sikic, MD

Overview

Tumors initially sensitive to chemotherapeutic agents frequently develop resistance to them, resulting in the familiar clinical pattern of initial response, followed by a recurrence that no longer responds to therapy. Laboratory and clinical investigations have identified a plethora of drug-resistance mechanisms, some that are particular to an individual agent and others that are generalizable across classes of agents. These mechanisms include altered cellular accumulation and detoxification of drugs, mutation of the drug target, change in expression of the drug target, and activation of alternative signaling pathways. The identification of drug-resistance mechanisms has led to strategies to overcome resistance and improved clinical outcomes.

Systemic therapy with cytotoxic drugs or targeted agents is the basis for most of the effective treatments of disseminated cancers. Additionally, adjuvant chemotherapy can offer a significant survival advantage to selected patients, following the treatment of localized disease with surgery or radiotherapy, presumably by eliminating undetected, minimal, or microscopic residual tumor. However, the responses of tumors to chemotherapeutic regimens vary, and failures are frequent owing to the emergence of drug resistance.

The phenomenon of clinical drug resistance has prompted studies to clarify mechanisms of drug action and to identify mechanisms of antineoplastic resistance. It is expected that through such information, drug resistance may be circumvented by rational design of new noncross-resistant agents, by novel delivery or combinations of known drugs, and by the development of other treatments that might augment the activity of or reverse resistance to known antineoplastics. While earlier mechanisms of drug resistance were identified experimentally by generation of resistant cell lines, recent advances in genomic technology have allowed the direct determination of resistance mechanisms present in clinically resistant tumors.

General mechanisms of resistance to single agents

Experimental selection of drug resistance by repeated exposure to single antineoplastic agents will generally result in cross-resistance to some related agents of the same drug class. This phenomenon is explained based on shared drug transport carriers, drug metabolizing pathways, and intracellular cytotoxic targets of these structurally and biochemically similar compounds.

Generally, the resistant cells retain sensitivity to drugs of different classes with alternative mechanisms of cytotoxic action. Thus, cells selected for resistance to alkylating agents or antifolates will usually remain sensitive to unrelated drugs, such as anthracyclines. Exceptions include emergence of cross-resistance to multiple, apparently structurally and functionally unrelated drugs, to which the patient or cancer cells were never exposed during the initial drug treatment. Despite apparent differences in their presumed sites of action within cells, the drugs associated with multidrug-resistance (MDR) phenotypes frequently share common metabolic pathways or efflux transport systems.

In this section, the processes related to drug resistance will be described. A more comprehensive discussion of selected mechanisms of resistance to specific classes of drugs will be discussed in subsequent sections.

Decreased drug accumulation

Decreased intracellular levels of cytotoxic agents is one of the most common mechanisms of drug resistance. As polar, water-soluble drugs cannot penetrate the lipid bilayer of the cell membrane and require specific mechanisms of cell entry, resistance to these drugs is readily mediated by downregulation of drug uptake mechanisms in tumor cells. For example, antifolates such as methotrexate require specific transporters to gain intracellular access, including high-affinity folate receptors, the reduced folate carrier (SLC19A1), and the proton-coupled folate transporter (SLC46A1) and downregulation of these mechanisms of uptake has been described as causes of methotrexate resistance.¹ For hydrophobic, nonpolar drugs that can easily diffuse across the cell membrane, decreased intracellular drug concentrations can be achieved by increasing the activities of drug efflux pumps. For example, overexpression of the P-glycoprotein (*MDR1/ABCB1*) drug efflux pump is an important example of this mechanism of resistance.²

Altered drug metabolism

Decreased drug activation, increased drug inactivation, or alterations in necessary cofactors can also confer resistance to selected antineoplastic agents. For example, decreased conversion of nucleobase analogs to their cytotoxic nucleoside and nucleotide derivatives by alterations in specific kinases and phosphoribosyl transferase salvage enzymes can lead to resistance to these anticancer drugs.³ Another example associated with resistance is decreased levels of carboxylesterase—an activity necessary to convert a topoisomerase I inhibitor, CPT-11, to its active metabolite, SN-38.⁴

On the other hand, enhanced inactivation of pyrimidine and purine analogs by increased expression of deaminases is linked to resistance toward these agents.⁵ Finally, alterations in cofactor levels can also modify drug toxicity. For example, optimal formation of inhibitory complexes between 5-fluorodeoxyuridine monophosphate (FdUMP) and its target enzyme, thymidylate synthase, require the cofactor 5,10-methylene tetrahydrofolate.⁶ Alterations in the intracellular levels of this cofactor can lead to resistance to fluoropyrimidines.

Increased repair or cellular tolerance to drug-induced damage

Cells contain multiple complex systems involved in the repair of damage to membranes and deoxyribonucleic acid (DNA), and changes in these repair processes can influence drug sensitivity. For example, resistance to cisplatin, a drug whose cytotoxic action involves intrastrand DNA crosslinkages, is associated with increased DNA repair. Conversely, defects in mismatch repair (MMR) are associated with tolerance to cisplatin-induced DNA damage. In this form of platinum resistance, the repair system is apparently unable to recognize platinum-DNA adducts and fails to activate the normal, appropriate programmed cell death response.

Increased rate of detoxification

The manner in which cells metabolize cancer drugs and other xenobiotics is often described as involving three phases of detoxification. Although none of these phases are obligatory steps in the metabolism of every drug, the concept represents a useful framework with which to view cellular detoxification

mechanisms. Alterations in any of these three phases can influence the sensitivity or resistance to a particular drug or xenobiotic toxin. Phase 1 drug metabolism is mediated by cytochrome P-450 mixed-function oxidases. Generally, the drug or xenobiotic is rendered into a more electrophilic, reactive intermediate—a process that may enhance toxicity. These metabolites may then be converted to a less-reactive, presumably less-toxic form in phase 2 reactions, which include the formation of drug/xenobiotic conjugations with glutathione (GSH), glucuronic acid, or sulfate—reactions that are catalyzed by multiple isozymes, each of glutathione S-transferases (GSTs), uridine diphosphate (UDP)-glucuronosyl transferases, and sulfatases, respectively. Phase 3 detoxification consists of export of the parent drug/xenobiotic or its metabolites by energy-dependent transmembrane efflux pumps, including MRP (ABCC) family members as described above.

Altered drug targets

Qualitative changes in the enzyme targets of antineoplastic drugs can compromise drug efficacy and have been associated with resistance to targeted agents, especially tyrosine kinase inhibitors (TKIs). These mutations that are acquired through selective pressure often occur in locations that alter the binding site of the TKI. Similarly, other direct targets of enzyme inhibitors develop mutations that overcome resistance to cytotoxic chemotherapy agents, including dihydrofolate reductase (DHFR) resistance to methotrexate, thymidylate synthase resistance to fluoropyrimidines, and topoisomerases I and II resistance to camptothecins.

Altered gene expression

Increased or decreased expression of target enzymes can also lead to drug resistance. These alterations may result from changes that occur at any point along the pathways of gene expression and regulation, including DNA deletion or amplification, altered transcriptional or post-transcriptional control of ribonucleic acid (RNA) levels, and altered post-translational modifications of proteins. In addition, the same molecular mechanisms that lead to oncogenesis can also lead to drug resistance through altered expression of drug targets. Increased expression of DHFR is a mechanism of resistance to methotrexate, while decreased expression of topoisomerase I is a mechanism of resistance to camptothecins.

Activation of alternative signaling pathways

Resistance to targeted agents such as TKIs can be mediated by activation of alternative signaling pathways that provide continued growth stimulation signaling despite successful inhibition of a primary oncogenic event. Activations of several bypass track-signaling pathways have been found in lung cancer patients treated with inhibitors of mutant EGFR and ALK.⁷ These alternative pathways include amplification of *MET*, increased HGF expression, *PIK3CA* mutation, *BRAF* mutation, and *HER2* amplification. The alternative resistance pathways can be identified, and patients treated with relevant inhibitors. In melanomas treated with inhibitors of mutant BRAFV600, mechanisms of resistance include *BRAF* amplification, increased activity of A-RAF and C-RAF, mutations of *NRAS* and *MEK1*, and loss of *NF1*.⁸ One strategy for overcoming drug resistance to BRAF inhibitors is concurrent inhibition of more than one kinase in the RAF–MEK–ERK pathway. This strategy was successfully tested in a randomized clinical trial in BRAF-mutated metastatic melanomas of the BRAF inhibitor vemurafenib alone versus vemurafenib plus the MEK inhibitor cobimetinib.⁹ The combination resulted in a median progression free survival of 9.9 months and remission rate of 68%, compared to 6.2 months and 45% for vemurafenib alone.

Key Points

Mechanisms of resistance to single agents

- Decreased drug accumulation
- Altered drug metabolism
- Increased DNA repair
- Increased detoxification
- Mutation of drug target
- Altered drug target expression

General mechanisms of resistance to multiple agents

Transport-mediated multiple drug resistance (MDR)

De novo and acquired cross-resistance to multiple antineoplastic agents can result from increased expression of a host of promiscuous drug efflux pumps known as ATP-binding cassette (ABC) proteins ([Table 1](#)). ABC proteins constitute a large family of 48 transport proteins organized into seven subfamilies, ABCA–ABCG. Of these, at least three have been directly shown to cause MDR, namely MDR1/P-glycoprotein (ABCB1), multidrug resistance-associated protein 1 (MRP1), (ABCC1), and BCRP/MXR/ABC-P (ABCG2). Classic MDR associated with resistance to drugs listed in [Table 2](#) is mediated by P-glycoprotein (MDR1 or ABCB1). A similar but distinct MDR phenotype was attributed to the energy-dependent drug efflux activities of multidrug-resistance protein (MRP) family members, including MRP1 or ABCC1.¹⁰

Table 1 ABC transporters associated with multidrug resistance (MDR)

• P-Glycoprotein/MDR 1/ABCB1-mediated classic MDR
• MRP family member-mediated MDR (currently at least three members, MRP1, 2, and 3 in ABCC1, ABCC2, and ABCC3 implicated in MDR drug efflux and detoxification)
• BCRP (ABCG2)-mediated MDR (putative ABC half-transporter implicated in mitoxantrone and anthracycline resistance)

Table 2 Cross-resistance pattern of classic (P-glycoprotein-mediated) MDR

Class	Drug
Anthracyclines	Doxorubicin
	Daunorubicin
	Mitoxantrone
Antibiotics	Actinomycin D
	Plicamycin
Antimicrotubule drugs	Vincristine
	Vinblastine
	Colchicine
Epipodophyllotoxins	Etoposide
	Tenoposide

The genetic basis of acquired MDR has been studied by whole genome sequencing of tumor samples from high grade, serous ovarian cancers. The sequencing disclosed acquired mutations associated with increased expression of the *ABCB1* multidrug transporter gene in approximately 8% of patients with recurrent disease after chemotherapy.¹¹ These patients had all been treated with taxanes and/or doxorubicin, which are substrates for the P-glycoprotein transporter. The mutations included fusions at the *ABCB1* promoter and translocations in the 5' region of the gene.

Inhibition of P-glycoprotein during exposure of cancer cells to taxanes such as cabazitaxel has revealed other, alternative mechanisms of resistance to taxanes.¹² These alternate mechanisms of resistance include induction of an epithelial to mesenchymal transition (EMT) and increased dynamic instability of microtubules by overexpression of the TUBB3 isoform of beta tubulin.

Another overlapping but discrete MDR phenotype is associated with increased expression of the recently isolated putative efflux transporter, breast cancer resistance protein (BCRP or ABCG2).¹³ MDR has also been described in association with overexpression of the lung resistance protein (LRP). The mechanism of LRP-associated resistance is unclear, and whether LRP alone is sufficient to confer resistance is unknown. It is speculated that as a major vault protein, LRP is involved in nucleocytoplasmic transport and may be able to prevent entry of drugs into the nucleus.¹⁴

Multidrug resistance related to suppression of cell death pathways

Although chemotherapeutic drugs initiate cytotoxicity through their interactions with a variety of molecular targets, cancer drugs affect cell death, at least partially, via downstream events that converge upon pathways mediating type 1 (apoptotic) or type 2 (autophagic) programmed cell death or apoptosis. Apoptosis refers to an orderly cellular death program with predictable molecular and morphologic changes, including nuclear pyknosis and fragmentation, internucleosomal endonucleolytic DNA fragmentation, formation of cytoplasmic apoptotic bodies, and plasma membrane changes, such as transposition of phosphatidylserine to the extracellular surface.^{15, 16} Autophagy is a pathway for bulk degradation of subcellular constituents that occurs in response to stresses such as nutrient deprivation.¹⁷ It involves the creation of autophagosomes/autolysozymes, and can be inhibited by PI3 kinase inhibitors such as 3-methyladenosine and wortmannin.

Although apoptosis may be either TP53-dependent or -independent, frequently the cellular response to DNA damage is regulated by TP53.¹⁸ As shown in a simplified diagram ([Figure 1](#)), cancer therapy-induced DNA damage is sensed by TP53 by incompletely understood mechanisms. Depending on the particular cell type and damage, TP53 expression may then initiate one of two possible pathways: apoptosis or a process of cell-cycle arrest and repair. In cells where the apoptotic pathway dominates, changes that cause dysfunction or deletion of TP53 are likely to result in reduced apoptosis in response to DNA damage, leading to relative resistance and cell survival with damage.

Figure 1 Alternative cellular responses to cancer therapeutic stress.

Other components of cell death-signaling pathways include: the mitogen-activated protein kinase (MAPK)-signaling cascades, which are involved in the regulation of cellular response to exogenous factors, including geno- and cytotoxic cancer treatments; the extracellular stimulus-regulated kinase (ERK1/2) pathway, which is implicated in the proliferative response to growth factors; and the p38 and stress-activated/c-Jun *N*-terminal protein kinase (SAPK/JNK) pathway. Modulation of these interacting pathways can have a profound effect on whether a cancer cell responds to cytotoxic challenge by activation of apoptosis or by cell-cycle arrest and repair, leading to resistance to treatment.¹⁹

Although their mechanism(s) of action is incompletely known, the balance of expressed antiapoptotic family members (Bcl-2 and Bcl-XL) and proapoptotic family members (Bax, Bak, Bad, and Bid) can influence the relative sensitivity of cells to toxic stressors.²⁰ Indeed, increased Bcl-2 and its antiapoptotic homologs are associated with increased resistance of lymphoid cells to the cytotoxic effects of corticosteroids, radiation, and DNA damage from chemotherapeutic drugs.^{21, 22} It has been proposed that increased levels of antiapoptotic proteins Bcl-2 or Bcl-XL may result in reduced sensitivity to DNA-damaging cancer drugs—a resistance phenotype characterized by cell survival and increased tolerance to DNA damage and genomic instability. This genomic instability may lead to further mutations activating additional resistance mechanisms and conferring more aggressive tumor behavior.²⁰ Although the role of Bcl-2 family proteins and the multidomain proapoptotic members of this family in the development of type 1 (apoptotic) programmed cell death has been extensively characterized, recent studies indicate that

these proteins also control type 2 (autophagy) and nonapoptotic programmed cell death.²³

The members of the BCL2 family also play important roles in resistance to targeted therapies.²⁴ BIM and PUMA are both proapoptotic BCL2 family members whose expression is induced by targeted kinase inhibitors of oncogenes such as mutated EGFR and BRAF, the BCR-ABL fusion protein, and amplified HER2. Loss of BIM expression has been shown to inhibit apoptosis and results in resistance to inhibitors of these oncogenes. Thus, the expression of mutant and wild-type TP53, Bcl-2 family members, MAPK family members, and other proteins associated with the control of apoptosis and/or autophagy may contribute significantly to the clinical sensitivity of tumor cells. Each of these proteins are the targets of investigational agents.^{20, 25}

Resistance factors due to host-tumor interactions

The failure of chemotherapy to eradicate a tumor in vivo despite exquisite sensitivity to drug in vitro might be a result of anatomic or pharmacologic sanctuaries. For example, the failure to deliver adequate amounts of many drugs across blood–brain and blood–testicular barriers probably accounts for the relatively high frequency of acute lymphoblastic leukemia relapse at these sites prior to addition of CNS-directed therapy to the treatment plans.²⁶ In large solid tumors, chemotherapeutic failures are frequently attributed to decreased drug delivery to a tumor that has overgrown its vascular supply. Additionally, development of acidosis and hypoxia in poorly perfused areas of large tumors may interfere with the cytotoxicity of some drugs. Altered prodrug activation by liver or other normal tissues may profoundly influence the efficacy of drugs such as cyclophosphamide.

Studies by Teicher and Herman²⁷ suggest that tumor–host interactions may influence drug pharmacokinetics and tumor resistance in unexpected ways. In this study, tumor cells selected for cyclophosphamide and cisplatin resistance in vivo were normally sensitive to drugs in vitro. When the tumor cells were reimplanted into nude mice, in vivo drug resistance was restored. These results suggest that resistant tumors may harbor cellular resistance factors that are operative only in conjunction with host factors and, therefore, mediate resistance by altered drug pharmacokinetics in vivo only. If this novel host-dependent mechanism of tumor resistance proves common, these results would provide one explanation for the failure of conventional in vitro testing to predict clinical responsiveness in all cases.

Cancer stem cells and drug resistance

The concept of cancer stem cells (CSCs) developed from observations that individual malignant cells within a cancer differ in their capacity to form tumors. These CSCs, or “tumor initiating cells” form a few to less than 1% of the population, have the property of plasticity or ability to change between tumorigenic and nontumorigenic states, and are a significant factor in the drug resistance of cancers.²⁸ Relapsed cancers are enriched in CSCs, and this subpopulation is known to express high levels of multidrug transporters as well as other drug-resistance genes. At the same time, CSCs offer new targets for cancer therapy, including inhibition of the Notch, Wnt, and Hedgehog pathways.

Genetic basis of acquired drug resistance and tumor heterogeneity

High resolution, deep sequencing of individual cancer genomes has revealed intratumoral heterogeneity of many cancers.²⁹ These data support a branched evolutionary model of tumor growth, with many competing clones differing in growth rates, metastatic potential, and sensitivity to various drugs. There are many implications for anticancer drug resistance that arise from this model. The dominant clone of a cancer derived from a drug-resistant normal tissue, such as colon or kidney, usually reflects the intrinsic

resistance of the normal cells from which the cancer is derived. For cancers where the dominant clone is sensitive to a particular drug, the chances are high that drug-resistant minor clones are present at the time of cancer diagnosis. The oncogenic mutations that cause a cancer can contribute to drug sensitivity, by driving cell replication and increasing cancers' vulnerability to chemotherapy drugs that kill proliferating cells. However, acquired resistance to an anticancer therapy after remission results from resistant clones, some of which may have been present before treatment and some that may have developed during therapy. The emergence of drug resistance is reflected in the disappearance of drug-sensitive clones and overgrowth of resistant clones, an example of Darwinian “survival of the fittest” within cancer populations.³⁰ Heterogeneity in drug-resistance mechanisms and the nature of these mechanisms is also increasingly evident from comparisons of DNA sequences of sequential specimens from individual patients, as well as the evolution of resistance among different patients.³¹

Deep sequencing is also disclosing differences in genomic instability and apparent rates of mutation among cancers. The factors underlying these differences in genomic instability are not well understood, except for the subset of cancers that have MMR deficiencies. MMR deficiency is associated with a high rate of point mutations, and this may actually lead to more favorable outcomes for immunotherapies that enhance antitumor immunity via immune checkpoint controls (e.g., CTLA4, PD-1, and PDL-1).³⁰ In addition to mutational load, sequencing of melanoma specimens has identified a neo-antigen landscape that was strongly associated with a good response to CTLA-4 blockade by ipilimumab or tremelimumab.³²

Both whole genome and targeted genomic sequencing can disclose “actionable mutations” such as BRAFV600E or HER2 amplification that can guide selection of specific targeted drugs, a concept that is being tested in several clinical trials, such as NCI-MATCH (NCT02465060), TRACERx (NCT01888601), DARWIN (NCT02183883), and BATTLE-2 (NCT01248247). Moreover, subclones may be detected that predict eventual failure of a particular therapy, and inform the selection of a noncross-resistant drug active against those subclones.³⁰ The so-called “liquid biopsies” analyzing the circulating free tumor DNA in blood can also detect targetable mutations and the presence of drug-resistant mutations in cancer patients.

In summary, the concept that tumor masses and their metastases were composed of genetically identical clones has given way to a model that pictures each tumor as a tree-like structure with tumor stem cells at the center and multiple evolving clones branching out from the trunk. Therefore, a tumor becomes a heterogeneous collection of related but not identical cells, both in the primary mass and in distant metastases. Selection pressures such as prior therapy can shape the characteristics of the overall tumor cell population in a patient, and spatially separated clones can develop different mechanisms of resistance. This picture of a tumor with its own organism-like qualities has emerged from studies that have performed deep sequencing on multiple biopsies from primary tumor masses and their metastases. The heterogeneity of a tumor extends to both genetic and epigenetic diversity. Thus, strategies to overcome drug resistance must take into account the diversity of mechanisms of resistance to any agent because distinct populations of cells within a patient may harbor different resistance mechanisms.

Key Points

Mechanisms of acquired resistance to multiple agents

- Increased activity of drug efflux pumps

- Suppression of cell death pathways
- Host–tumor interactions
- Quiescent cancer stem cells
- Tumor heterogeneity

Potential clinical application of strategies to avert or overcome drug resistance

Approaches to overcome chemotherapeutic failures include efforts to prevent the emergence of drug resistance ([Table 3](#)). An appreciation of factors that induce resistance mechanisms may lead to the choice of more efficacious treatment regimens. Classically, aggressive combination chemotherapy with noncross-reacting drugs have been developed to eliminate tumor cells rapidly enough to prevent the selection of tumor cell clones with multiple resistance. Another approach is to develop therapies aimed at reversing or circumventing clinical drug resistance.

Table 3 Approaches to overcome or circumvent drug resistance

Prevention	Aggressive multiple-agent therapy
	Appreciation of factors that induce resistance mechanism
	Concurrent blockade of a resistance pathway
Circumvention	Drug-screening programs and rational drug design
	Circumvention of drug uptake defects
	Dose escalation
	Drugs that use alternative transport mechanisms
	Agents that reverse increased efflux
	Cofactors that augment drug activation or efficacy
	Inhibition of drug inactivation
	Novel treatment modalities
	Immunotherapy
	Inhibit alternative signaling pathways
	Enhance apoptotic pathways
	Noncross-resistant analogs against the same target

Reversal of ABC transporter-mediated resistance

Although preclinical studies in murine models showed efficacy of P-glycoprotein inhibitors, most clinical studies involving the use of MDR-reversing agents in the treatment of solid human tumors have been disappointing, and despite the plethora of MDR-reversing agents identified in hundreds of preclinical studies, none have evolved into clinically useful agents. Clinical trials of MDR-reversing agents encountered significant obstacles, including (1) increased toxicity of the chemotherapy agents caused

profound effects on the pharmacokinetics and pharmacodynamics of MDR1-reversing agents on the cytotoxic drugs associated with MDR, (2) the toxicity of some of the early MDR1-reversing agents themselves, such as verapamil, prevented adequate exposure to them; (3) lack of screening of patients for *MDR1/ABCB1* expression in tumors; (4) involvement of other transporters and other mechanisms of resistance at the time of recurrence; and (5) lack of understanding of how MDR1 polymorphisms affect susceptibility to MDR1 inhibition.² While P-glycoprotein and other ABC transporters may play important roles in tumor biology and drug resistance, no pharmacologic strategy has emerged that can improve clinical outcomes by inhibiting the activity of these transporters once clinical drug resistance has been established.

Reversal of resistance to nucleoside analogs

While cellular accumulation of lipophilic cytotoxic agents that are substrates for ABC transporters can be limited by upregulation of these transporters, the problem is reversed for hydrophilic nucleoside analogs that depend on specific transporters for cellular uptake. So, in contrast to MDR, where the problem is reversing the activity of an efflux pump, overcoming resistance to nucleoside analogs can involve strategies to increase cellular uptake. This can include making nucleoside analog prodrugs that are more lipophilic, so they can more easily diffuse across the cell membrane; using nanoparticle delivery systems to bypass nucleoside transporters; and even gene therapy to increase expression of nucleoside transporters in tumors.^{33, 34}

Resistance to targeted agents

BCR/ABL

The first approved kinase inhibitor was imatinib, with remarkable activity against chronic myeloid leukemia (CML), a disease driven by the BCR/ABL fusion mutation. Imatinib and BCR/ABL have become a paradigm of an important class of resistance mechanisms to kinase inhibitors, point mutations directly affecting drug binding or changing the conformation of the BCR/ABL protein to reduce drug binding.^{35, 36} More than 100 such point mutations have been found in resistant CML specimens. Deep sequencing of the *BCR/ABL* fusion gene in CML specimens has enabled the identification of emerging resistant clones, and even the detection of such clones early in the course of imatinib treatment. Genomic instability, increased by the perturbation of several DNA repair pathways by BCR/ABL, contributes to the high frequency of imatinib-resistant point mutations.³⁶ Remarkably, the FDA has approved several new kinase inhibitors that are active against imatinib-resistant BCR/ABL, including dasatinib, nilotinib, bosutinib and ponatinib.

EGFR

Agents directed at the Epidermal Growth Factor Receptor, EGFR, fall into two categories. Antibodies directed at EGFR are approved for use in colon cancer and in head and neck cancers, malignancies where tumor cells are dependent on signaling of WT EGFR, while small molecule TKIs of EGFR are indicated in the treatment of nonsmall-cell lung cancer (NSCLC) with activating mutations of EGFR. Resistance develops to both anti-EGFR antibodies and TKIs, and the mechanisms have predictable similarities and differences. Resistance can develop through mutation of EGFR, but the resistance mutations occur at different sites depending on the agent: for first-generation EGFR TKIs such as erlotinib and gefitinib, the major resistance mutation is T790M, which affects the ATP-binding domain targeted by these agents; while resistance to the anti-EGFR antibody cetuximab occurs at several sites that alter the binding epitope

of the antibody, including S492R, S464L, G465R, and I491M.¹¹

Resistance to both types of EGFR-inhibitory agents can occur through activation of bypass-signaling pathways, which continue to activate the same downstream effectors, such as activation of HER2, a tyrosine kinase receptor belonging to the same family as EGFR, as well as MET. Moreover, resistance to both anti-EGFR TKIs and antibodies has been ascribed to histologic transformation of the tumor, often described as an EMT, which is marked by the loss of the pan-epithelial marker E-cadherin, increased expression of the mesenchymal-associated antigens vimentin and fibronectin, and loss of sensitivity toward EGFR-directed agents. An unexpected mechanism of resistance to mutant EGFR inhibitors in lung cancers was the transformation from nonsmall cell to small cell lung cancers in 14% of cases.³⁷

It is not known why individual tumors develop different mechanisms of resistance or why one bypass pathway is activated in one tumor and not in another. However, one difference between NSCLC and colon cancer is that the activating EGFR mutation in NSCLC appears to be a driver mutation in that disease, so resistance mutations of EGFR play a more prominent role, whereas EGFR signaling is one of many signaling pathways upregulated in colon cancers, so activation of bypass signaling occurs more frequently in that context.

Strategies to overcome resistance to EGFR-targeted agents fall into four categories. First, for NSCLC, new agents are under development that are more active against mutated EGFR, including both activating mutations and the T790M resistance mutations, that promise to increase the therapeutic index of these agents as well as diminish the possibility of the development of resistance mutations. Two third-generation EGFR inhibitors have been shown to be effective in the common, drug-resistant T790M mutation. These are rociletinib (CO-1686)³⁸ and AZD9291.³⁹

Second, dual inhibition of EGFR by combining an anti-EGFR TKI with an anti-EGFR antibody, testing the hypothesis that this approach more completely suppresses EGFR signaling, is in clinical testing. Third, several inhibitors of bypass signaling, such as inhibitors of MET and MEK, have been combined with anti-EGFR therapies. Finally, agents that might inhibit EMT, such as histone deacetylase inhibitors, have also been combined with EGFR inhibitors to both prevent and reverse resistance.

ALK

A genomic rearrangement of the anaplastic lymphoma kinase (*ALK*) gene is the second most common oncogenic mutation in lung adenocarcinomas (after *EGFR*). Crizotinib was the first FDA-approved ALK kinase inhibitor, but resistance to crizotinib invariably develops and includes point mutations of ALK as well as activation of bypass-signaling pathways.⁴⁰ The FDA has approved ceritinib as a second-generation ALK inhibitor that overcomes some of the resistance mechanisms to crizotinib.^{41, 42} In crizotinib-resistant patients, ceritinib produced a remission rate of 56%, with a median progression-free survival of 7 months.⁴²

BRAF

Approximately 50% of malignant melanomas are caused by an activating mutation of the *BRAF* gene, most commonly the V600E mutation. The FDA has approved two kinase inhibitors, vemurafenib and dabrafenib, that inhibit this V600E mutant BRAF. However, resistance to these kinase inhibitors occurs in almost all cases, including *NRAS* and *MEK1* mutations, *BRAF* amplification, loss of NF1, and other MAPK pathway alterations.⁸ As previously noted, concurrent inhibition of both mutated BRAF and MEK has been a successful strategy to delay resistance to BRAF inhibitors in melanomas.⁹

Activating BRAF mutations occur in a small percentage of other cancer types, including 10% of colorectal cancers. Resistance mechanisms to BRAF inhibitors in colorectal cancers are predominantly alterations in MAPK pathway genes that produce sustained MAPK pathway activity, including amplifications of KRAS and BRAF, and MEK1 mutation.⁴³

Bruton's tyrosine kinase (BTK)

Ibrutinib is an irreversible binder of Bruton's tyrosine kinase (BTK), which is an enzyme crucial for B-cell development and survival. Inhibition of BTK by ibrutinib is clinically effective in many B-cell malignancies, including mantle cell lymphoma and chronic lymphocytic leukemia. Mechanisms of resistance to ibrutinib include mutation C481S in the *BTK* gene at the drug-binding cysteine residue and mutations of *PLCY2* that result in autonomous B-cell receptor activity.⁴⁴

Conclusion and future directions

The diversity of mechanisms of antineoplastic drug resistance, combined with the biologic heterogeneity of tumors, presents a formidable therapeutic challenge. Nevertheless, the identification of the drug-resistance mechanisms has led to useful approaches to overcoming clinical drug resistance and improving therapeutic outcomes. These approaches include the design of novel drugs that are less likely to share resistance mechanisms and the development of combination therapies that target resistance pathways. Despite these efforts, many tumors will remain refractory to conventional and targeted chemotherapeutic agents.

Biological and Gene Therapy

Chapter 63

Cytokines, interferons, and hematopoietic growth factors

Suhendan Ekmekcioglu, PhD ■ Elizabeth A. Grimm, PhD

Overview

Cytokines are important mediators of immune responses and produced by almost every cell in the body. Growth stimulatory or inhibitory cytokines could be subclassified as interleukins (ILs), lymphokines, monokines, chemokines, and hematopoietic growth factors. In cancer, certain cytokines act directly on the growth, differentiation, or survival of endothelial cells, whereas others act by attracting inflammatory cell types affecting angiogenesis or by inducing secondary cytokines or other mediators regulating angiogenesis. Proinflammatory and chemotactic cytokines influence the tumor environment and control the quantity and nature of infiltrating hematopoietic effector cells, with inhibiting or enhancing effects on tumor growth. The important role of cytokines in regulating immune responses may permit an effective immune response against the tumors or suppress the function of antigen-presenting cells (APC).

The understanding of cytokines has now emerged as complex picture of interacting stimulatory and inhibitory factors. Many of the molecules that govern this process have been cloned and have entered clinical trials. It is now clear that regulatory cytokines are characteristically pleiotropic and, at the same time, exhibit significant functional redundancy.

The biologic characterization of the known clinically relevant ILs, interferons and selected growth factors, the rationale for their use in therapy for patients with cancer, and the accumulated clinical experience represent the subjects of this chapter.

Cytokines, a diverse family of signaling molecules, are important mediators of immune responses and produced by almost every cell in the body, including various cancer cells. In general, some cytokines are growth stimulatory and others are inhibitory. Cytokines with clinical relevance to cancer include those subclassified further as interleukins (ILs), monokines, chemokines, and hematopoietic growth factors. IL designates any soluble protein or glycoprotein product of leukocytes that regulates the responses of other leukocytes. ILs produce their effects primarily through paracrine interactions. In cancer, certain cytokines act directly on the growth, differentiation, or survival of endothelial cells, whereas others act by attracting inflammatory cell types affecting angiogenesis or by inducing secondary cytokines or other mediators regulating angiogenesis. Proinflammatory and chemotactic cytokines influence the tumor environment and control the quantity and nature of infiltrating hematopoietic effector cells, with inhibiting or enhancing effects on tumor growth. The important role of cytokines in regulating immune responses may permit an effective immune response against the tumors or suppress the function of APC. Presuming antigens exist on tumor cells, various immunostimulatory cytokines, and particularly ILs, are now administered to patients in an attempt to initiate, augment, or otherwise stimulate a weak or previously nonexistent antitumor immune response. In addition to immune response stimulation, some ILs have been used to stimulate the growth and differentiation of various subpopulations of blood cells after chemotherapy or bone marrow transplantation (BMT) in a restorative role.

It is now clear that the pleiotropic nature of many cytokines allows them to influence virtually all organ

systems ([Figure 1](#)). Cytokines may have their own private receptor but may also share a “public” receptor with other cytokines ([Tables 1](#) and [2](#)).

Figure 1 In addition to their effects on hematopoiesis and immunocompetence, “hematopoietic” growth factors influence multiple organ systems, including (but not limited to) bone remodeling, cardiorespiratory function, hepatic function, and the gastrointestinal tract.

Table 1 Types of hematopoietic growth factor receptors

Type	Characteristics	Receptor examples
Type I cytokine receptor	Does not possess intrinsic kinase activity. Receptor acts as docking site for adaptor molecules, which leads to phosphorylation of cellular substrates	IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-13, IL-18, IL-21, GM-CSF, G-CSF, EPO, TPO, and leukemia inhibitory factor
Type II cytokine receptor	Contains extracellular fibronectin III type domain	Interferon and IL-10
Receptors with tyrosine kinase domains (type III)	Large extracellular immunoglobulin-like domain, single transmembrane spanning region, and a cytoplasmic tyrosine kinase domain(s)	fms (M-CSF receptor), FLT-3, c-kit (SCF receptor), and PDGFR
Chemokine receptor	Seven transmembrane spanning G protein-linked regions	IL-8
Tumor necrosis factor family	Cysteine-rich repeats in the extracellular domain, and cytoplasmic 80 amino acid “death domain”	Tumor necrosis factor and Fas

Abbreviations: EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte macrophage colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

Table 2 Interleukins

	Chromosomal location	Receptors	Selected biologic activities
IL-1	2q13	IL-1RI and IL-1RII	Promotes acute-phase response. IL-1 acts on nearly every organ system. Induces production of multiple cytokines
			Upregulates cell-surface cytokine expression
			Synergizes with other cytokines to stimulate hematopoietic progenitor proliferation
			Influences immune regulation
			Modulates endocrine function
			Affects bone formation
			IL-1R acts as a cofactor in neural transmission
IL-2	4q26-q27	$\alpha\beta\gamma$ heterotrimeric complex	Induces proliferation and activation of T cells, B cells, and NK cells
IL-3	5q31	IL-3 receptor (heterodimer of IL-3-specific α subunit and β subunit)	Stimulation of multilineage hematopoietic progenitors, especially when used in combination with other cytokines (SCF, IL-1, IL-6, G-CSF, GM-CSF, EPO, and TPO)
IL-4	5q31	Type I IL-4 receptor (IL-4R α and	IL-4 and IL-13 are involved in allergic

and IL-13		IL-2 receptor γ c chain subunits) transduces IL-4	reaction (induce switch to IgE)
		Type II IL-4 receptor (IL-4R α and the IL-13 R α 1 subunits) transduces IL-4 and IL-13	
		IL-4R α and IL-13 R α 2 complex or two IL-13 R α transduce IL-13	
IL-5	5q31	Consists of IL-5R α (IL-5-specific) and a β subunit	Regulates production, function, survival, and migration of eosinophils
		β subunit is common to IL-3 and GM-CSF complexes	Enhances basophil number and function
IL-6	7p21	IL-6R α together with gp130	B- and T-cell development and function
			Thrombopoiesis
			Acute-phase protein synthesis
			Inhibition of hepatic albumin excretion
			Osteoclastic bone resorption
			Neural differentiation
IL-7	8q12-q13	Composed of IL-7R α (CD127) and the common γ c chain subunits	Critical for T- and B-cell development
IL-8	4q12-q13	IL-8R α and IL-8R β exist	Potent chemoattractant agent for a variety of leukocytes, especially neutrophils
			Suppresses colony formation of immature myeloid progenitors
			Increases keratinocyte and endothelial cell proliferation
IL-9	5q31.1	IL-9 receptor	Supports clonogenic maturation of erythroid progenitors
			Acts as a mast cell differentiation factor
			Protects lymphomas from apoptosis
			Cooperates with IL-4 in B-cell responses
			Enhances neuronal differentiation
IL-10	1q31-q32	IL-10 receptor interferon receptors	Inhibits cytokine synthesis by Th1 cells and monocytes/macrophages
			Stimulates B-cell proliferation
			Involved in transformation of B cells by Epstein–Barr virus and tumor necrosis factor (TNF) receptors
IL-11	19q13.3-q13.4	IL-11R α and gp 130 subunits gp 130 = CD130 on 5q11 IL-6, oncostatin M, and leukemia	Best known as a thrombopoietic factor Stimulates multilineage progenitors, erythropoiesis, myelopoiesis, and

		inhibitory factor also use gp130 subunit	lymphopoiesis Decreases mucositis in animal models Stimulates osteoclast development Inhibits adipogenesis Stimulates proliferation of neuronal cells
IL-12	IL-12A:3p12-q13.2	IL-12R β 1 and IL-12R β 2 chains are related to gp 130	Proinflammatory cytokine important in resistance to infections
	IL-12B:5q31.1-q33.1		Th1 development
			Stimulatory and inhibitory effects on hematopoiesis
IL-15	4q31	High-affinity receptor requires IL-2R β and γ chains and IL-15 R α chain	Triggers proliferation and immunoglobulin production in preactivated B cells Number of CD8 ⁺ memory T cells may be controlled by balance of IL-15 (stimulatory) and IL-12 (inhibitory)
			Stimulates proliferation of NK cells and activated CD4 ⁺ or CD8 ⁺ T cells
			Facilitates the induction of LAK cells and CTLs
			Stimulates mast cell proliferation
			Promotes proliferation of hairy-cell leukemia and chronic lymphocytic leukemia cells
IL-16	15q26.1	Requires CD4 for biologic activities Tetraspanin CD9	Chemoattractant for CD4 ⁺ cells (T cells, monocytes, and eosinophils) May be involved in asthma and in granulomatous inflammation Has antiviral effects on HIV-1
IL-17	2q31	IL-17 receptor	May mediate, in part, T-cell contribution to inflammation
			Stimulates epithelial, endothelial, fibroblastic, and macrophage cells to express a variety of inflammatory cytokines
			Promotes the capacity of fibroblasts to sustain hematopoietic progenitor growth
			Promotes differentiation of dendritic cell progenitors
			May be involved in the pathogenesis of rheumatoid arthritis and graft rejection
IL-18	11q22.2-q22.3	IL-18 receptor	Promotes production of IFN- γ and TNF

			Targets are T cells, NK cells, and macrophages
			Promotes Th1 responses to virus
IL-19	1q32	IL-20R1 and IL-20R2	Induces IL-6 and TNF- α
IL-20	1q32	IL-20R1 and IL-20R2	Induction of genes involved in inflammation such as TNF- α , MRP14, and MCP-1
IL-21	4q26–27	IL-21 receptor	Mainly regulates T-cell proliferation and differentiation
			Regulates cell-mediated immunity and the clearance of tumors
IL-22	12q14	IL-22R1 and IL-10R2	Upregulates the production of acute-phase reactants
			Induces the production of ROS in resting B cells
IL-23	12q13	IL-12Rb1 and IL-23R	A unique function of IL-23 is the preferential induction of proliferation of the memory subset of T cells
IL-24	1q32	IL-20R1 and IL-20R2	Induces IL-6, TNF-a, IL-1b, IL-12, and GM-CSF
		IL-22R1 and IL-20R2	Functionally it has opposite effects with IL-10
			Infection with Ad-IL24 results in downregulation of Bcl-2 and Bcl-XL (antiapoptotic proteins) and upregulation of Bax and Bak (proapoptotic proteins) in cancer cells
IL-25	14q11	IL-17BR	IL-25 induces IL-4, IL-5, and IL-13 gene expression and protein production
IL-26	12q14	IL-20R1 and IL-10R2	Immune-protective role against viral infection
IL-27	12q13	TCCR/WSX-1 and GP130	Early Th1 initiation
			Synergizes with IL-12 in inducing IFN- γ production by T cells and NK cells
IL-28A, 28B, and 29	19q13	IL-28R1 and IL-10R2	Antiviral activities
IL-31	12q24	IL-31 receptor A and oncostatin M receptor	Responsible for promoting the dermatitis and epithelial responses that characterize allergic and nonallergic diseases
IL-32	16p13.3	Proteinase 3	Induces other proinflammatory cytokines and chemokines such as TNF- α , IL-1 β , IL-6, and

			IL-8
			Induces IκB degradation
			Phosphorylates p38 MAPK signaling pathway
IL-33	9p24.1	ST2	Activates NF-κB and MAP kinases
			Drives production of Th2-associated cytokines from in vitro polarized Th2 cells
			Induces the expression of IL-4, IL-5, and IL-13
			Leads to severe pathologic changes in mucosal organs
IL-35	19p13.3	IL-12Rβ2 and gp130	Contributes Treg suppressor activity
			Induces IL-10 and IFN-γ serum levels
			Reduces induction of IL-17
IL-36	IL36A;2q12-q14.1	IL-1Rrp2 and IL-1RAcP	Activates NF-κB and MAP kinases
	IL36B;2q14		Plays important role in skin biology
	IL36G;2q12-q21		Involved in the initiation and regulation of immune responses
	IL36RN;2q14		
IL-37	2q12-q14.1	IL-18R	Regulates inflammatory responses
IL-38	2q13	IL36R	Reduces IL-36g-induced IL-8 production

The biologic characterization of selected ILs (those for which we discuss a role in cancer), interferons (IFNs) and selected growth factors, the rationale for their use in therapy for patients with cancer, and the accumulated clinical experience represent the subjects of this chapter.

Interleukins

Interleukin-1

IL-1 (IL-1α and IL-1β) is the prototypic pleiotropic cytokine and influences nearly every cell type.^{1, 2} Because IL-1 is a highly inflammatory cytokine, the margin between salutary effects and serious toxicity in humans is exceedingly narrow. Compounds that attenuate the production and/or activity of IL-1 are therefore being explored in clinical trials.

Biologic effects of IL-1

IL-1 can increase the expression of itself as well as many other cytokines (including IL-1RA), cytokine receptors (including IL-2, IL-3, IL-5, granulocyte macrophage-colony-stimulating factor [GM-CSF], and c-kit), inflammatory mediators (such as cyclooxygenase and inducible nitric oxide synthase), hepatic acute-phase reactants, growth factors, clotting factors, neuropeptides, lipid-related genes, extracellular matrix molecules, and oncogenes (e.g., *c-jun*, *cabl*, *c-fms*, *c-myc*, and *c-fos*).¹ Data suggest that an inflammatory component is present in the microenvironment of most neoplastic tissues, including those not

causally related to an obvious inflammatory process. Thus, as a proinflammatory cytokine, IL-1 may also be a major proangiogenic stimulus of both physiological and pathological angiogenesis.

The IL-1 family has been implicated in the function and the dysfunction of virtually every human organ system. Indeed, increased IL-1 production has been reported in patients with infections (viral, bacterial, fungal, and parasitic), intravascular coagulation, cancer (both solid tumors and hematologic malignancies), Alzheimer's disease, autoimmune disorders, trauma, ischemic diseases, pancreatitis, graft-versus-host disease, transplant rejection, and in healthy subjects after exercise.¹

It has been suggested that the balance between IL-1 and its naturally occurring antagonists is most relevant to illness.³ This balance may be altered in different ways, depending on the disease. In AML, IL-10 is spontaneously expressed, but IL-1RA gene expression is suppressed even when stimulated with GM-CSF.^{4, 5} CML patients with advanced disease and poor survival have suppressed IL-1RA accompanied by high IL-1 β .⁶ In AML and CML patients, IL-1 β acts as an autocrine growth factor; exposure to molecules that decrease the activity of IL-1 suppresses leukemic proliferation.^{7, 8} Constitutive production of IL-1 α , IL-1 β , and/or IL-1RA in solid tumors (melanomas, hepatoblastoma, sarcomas, squamous cell carcinomas, transitional cell cancers, and ovarian carcinomas) has been described and may, in some cases, contribute to metastatic potential. However, the relationship between IL-1 and tumor growth is complex.

IL-1 in the clinic

IL-1 α and IL-1 β have both been administered in clinical cancer trials.¹ In general, the acute toxicities of both isoforms were greater after intravenous than subcutaneous injection. Subcutaneous injection was associated with significant local pain, erythema, and swelling. Dose-related chills and fever were observed in nearly all patients, and even a 1 ng/kg dose was pyrogenic. Nearly all patients receiving intravenous IL-1 at doses of 100 ng/kg or greater were experienced significant hypotension, probably because of induction of nitric oxide.

IL-1 infusion into humans significantly increased circulating IL-6 levels and resulted in a rise in leukocyte counts, even at doses as low as 1 or 2 ng/kg. Increases in platelets, peripheral monocyte count, and phorbol-induced superoxide production were also observed in patients with normal marrow reserves. In contrast to the results in patients with good marrow function, patients with aplastic anemia treated with five daily doses of IL-1 α (30–100 ng/kg) had no increases in peripheral blood counts or bone marrow cellularity.⁹ However, after chemotherapy, two doses of IL-10 significantly shortened the duration of neutropenia,¹⁰ and IL-1 α (5 days) significantly reduced thrombocytopenia.¹¹ Overall, the benefits of IL-1 therapy were compromised by its toxicity.

Interleukin-2

Originally described as a T-cell growth factor, the function of IL-2 extends beyond lymphocyte activation and population expansion, although T cells still appear to be its major target.¹²

Biologic activities of IL-2

IL-2 primarily acts as a T-cell growth factor, but B cells, natural killer (NK) cells, and lymphokine-activated killer (LAK) cells are also responsive to this cytokine. Following binding of IL-2 with the trimeric receptor complex, internalization occurs and cell-cycle progression is induced in association with the expression of a defined series of genes.¹³ A second functional response occurs through the IL-2 β , dimeric receptor, also known as the intermediate affinity dimeric complex (kDa, 10⁻⁹), and involves the

differentiation of several subclasses of lymphocytes into LAK cells.¹⁴ This response occurs in patients with cancer who receive IL-2^{15, 16} and was originally considered to be a critical part of the anticancer effect of IL-2.

IL-2 in the clinic

IL-2 has had a profound impact on the development of cancer immunotherapy. The administration of IL-2 and the adoptive transfer of antitumor T cells grown in IL-2 represented the first effective immunotherapies for cancer in humans.¹⁷ Since 1992, numerous clinical trials using high-dose IL-2 (HD IL-2) have delivered a remarkably consistent 7% complete response rate in two advanced cancer types, renal cell carcinoma (RCC) and malignant melanoma.^{18–22} Many of these complete responses have been durable beyond 10 years. HD IL-2 likely enhances the immune response against cancer cells. Its anticancer activity is strongly related to its ability to act as a growth factor for T lymphocytes, its capacity to stimulate antigen-independent NK cells and LAK cells, and its ability to increase lymphocytes at the site of malignancy. The significant adverse effects of HD IL-2 are largely a result of severe vasodilation and capillary leak syndrome, and include hypotension, arrhythmias, and liver and renal toxicities. Its administration requires an inpatient intensive care-like setting, thus it is recommended in patients with few comorbidities and an excellent performance status. There is a 1–2% risk of mortality with IL-2, which highlights the importance of choosing a well-suited patient for this treatment modality.²³

Historically, HD IL-2 was first used in a combinational biochemotherapy (BCT) setting, usually involving cisplatin, vinblastine, and dacarbazine (CVD) or cisplatin, vinblastine, and temozolomide (CVT), plus the biologic agents IFN α and IL-2. However, a modest increase in survival came with a substantial increase in toxicity.²⁴ More recently, as drugs such as ipilimumab demonstrate durable responses, the role of HD IL-2 as a single agent is becoming more controversial. One rational approach is to combine the two approved immunotherapies for stage IV melanoma, ipilimumab and IL-2. No data are currently available regarding the correct sequencing of immunotherapies. Some melanoma experts believe that IL-2 is best used very early on in therapy when subjects have more limited disease (M1a disease) and good performance status. A small study has indicated that there may be a higher response rate (47%) in patients with NRAS-mutant melanoma, but further validation of this finding is needed.²⁵ A 2005 study in 36 patients with advanced melanoma who received a combination of ipilimumab (0.1–3 mg/kg every 3 weeks) and IL-2 demonstrated an overall response rate of 22%.²⁶ Studies evaluating the role of ipilimumab with adoptive cell therapy are ongoing. Another approach to extend or enhance the efficacy of HD IL-2 or ipilimumab therapy is to combine immunotherapy with BRAF inhibitors for treatment of patients with BRAFV600-mutant advanced melanoma.²⁷ Preclinical studies showed an increase in melanoma antigen expression and the number of tumor-infiltrating lymphocytes in tumor biopsies after BRAF inhibitor therapy, which correlated with a reduction in tumor size and an increase in necrosis.^{28, 29} Current efforts are examining tumor biopsies from patients receiving vemurafenib to assess the mechanisms and kinetics of T-cell accumulation within tumors and characterize the specificity and function of immune infiltrating cells to design more successful combination treatments of BRAF inhibitor and immunotherapy regimens.

Interleukin-3

IL-3 was first described as a T-cell product involved in the pathogenesis of Moloney leukemia virus-induced T-cell lymphomas.³⁰ This molecule is of interest because of its ability to stimulate multilineage hematopoietic progenitors both *in vitro* and *in vivo*.^{30–37}

Biologic properties of IL-3

In vitro, IL-3, in combination with other cytokines, such as stem cell factor (SCF), IL-6, IL-1, GM-CSF, GM-CSF, erythropoietin (EPO), or thrombopoietin (TPO), induces the proliferation of colony-forming unit (CFU)-GM, CFU-Eo, CFU-Baso, BFU-E, and CFU-GEMM in semisolid medium and stimulates the proliferation of purified CD34+ cells in suspension culture.³¹ Indeed, IL-3 is combined with other cytokines, in particular SCF, IL-6, IL-1, FL, G-CSF (granulocyte colony-stimulating factor), and/or EPO, in almost all protocols to expand hematopoietic stem and progenitor cells *in vitro*.

IL-3 in the clinic

IL-3 has been used in a variety of clinical trials; peripheral blood stem cell mobilization, postchemotherapy and transplantation, and bone marrow failure states. The majority of studies show only modest effects of IL-3 by itself but significant salutary effects in conjunction with other growth factors. For instance, in mobilization studies, treatment with IL-3 did not mobilize by itself but significantly potentiated G-CSF-induced yield of all progenitor cell types used to restore hematopoiesis after high-dose chemotherapy. After transplantation, the combination of IL-3 and GM-CSF proved more efficient to support bone marrow engraftment than IL-3 or GM-CSF alone. The combination of IL-3 and GM-CSF was more efficient than G-CSF for supporting platelet recovery but was of similar benefit for the reconstitution of myelopoiesis. Following chemotherapy, IL-3 was found to attenuate neutropenia and/or thrombocytopenia in some but not all clinical studies.

Interleukin-4 and interleukin-13

IL-4 and IL-13 are closely related.^{38–40} They share biologic and immunoregulatory functions on B cells, monocytes, dendritic cells, and fibroblasts. Both IL-4 and IL-13 genes are located in the same vicinity on chromosome 5. The major regulatory sequences in the IL-4 and IL-13 promoters are identical, thus explaining their restricted expression pattern in activated T cells and mast cells. Furthermore, the IL-4 and IL-13 receptors are multimeric and share at least one common chain—IL-4RA. This, together with similarities in IL-4 and IL-13 signal transduction, explains the striking overlap of biologic properties between these two cytokines. The inability of IL-13 to regulate T-cell differentiation due to a lack of IL-13 receptors on T lymphocytes, however, represents a major difference between these cytokines. Therefore, despite the impact redundancy of these two molecules, regulatory mechanisms are in place to guarantee their distinct functions.

Biologic activities of IL-4 and IL-13

IL-13 elicits many, but not all, of the biologic actions of IL-4. IL-4 is, however, distinguished from IL-13 by its T-cell growth factor activity and its ability to drive differentiation of Th0 precursors toward the Th2 lineage. Th2 cells secrete IL-4 and IL-5 and lead to a preferential stimulation of humoral immunity. In contrast, Th1 cells, which produce IL-2 and IFN- γ , lead to a preferential stimulation of cellular immunity.

IL-4 and IL-13 possess potent antitumor activity *in vivo* in mice.⁴¹ They can inhibit the proliferation of some human cancer cell lines *in vitro* and *in vivo* in nude mice. A similar antiproliferative effect of IL-13 on human breast cancer cells has been described. Moreover, a chimeric protein composed of IL-13 and a truncated form of *Pseudomonas* exotoxin A exhibits specific cytotoxic activity toward human RCC but not against normal hemopoietic cells.⁴²

Clinical trials of IL-4

Despite the preclinical promise of IL-4, to date, clinical trials in humans demonstrated that although the molecule is safe and nontoxic, only sporadic antitumor activity is observed in a variety of cancers, including melanoma, lung cancer, and AIDS-related Kaposi's sarcoma.^{43–45}

Interleukin-6

IL-6 was first cloned in 1986.⁴⁶ It is a typical cytokine, exhibiting functional pleiotropy and redundancy. IL-6 is involved in the immune response, inflammation, and hematopoiesis. IL-6 is a 21- to 30-kDa glycoprotein of 212 amino acids that binds to a specific receptor that requires the same 130-kDa membrane glycoprotein for mediation of signal transduction, as has been described for several cytokines, including IL-2.^{47, 48}

Biologic activities of IL-6

IL-6 affects the hypothalamic-pituitary axis, bone resorption, and both the humoral and cellular arms of the immune system^{49–53} and is a potent and essential factor for the normal development and function of both B and T lymphocytes.⁵⁴ IL-6 is also involved in the differentiation of myeloid leukemic cell lines into macrophages, megakaryocyte maturation, neural differentiation, and osteoclast development. As a major inducer of acute-phase protein synthesis in hepatocytes,⁵⁵ this cytokine may play a role in the pathogenesis of sepsis.

IL-6 acts as a growth factor for myeloma/plasmacytoma, keratinocytes, mesangial cells, RCC, and Kaposi sarcoma and promotes the growth of hematopoietic stem cells. On the other hand, IL-6 inhibits the growth of myeloid leukemic cell lines and certain carcinoma cell lines. Significant correlations between serum IL-6 activity and serum levels of acute-phase proteins have been demonstrated in a variety of inflammatory conditions. IL-6 has been implicated as a mediator of B symptoms in lymphoma.⁵⁶ Elevated serum IL-6 levels have also been associated with an adverse prognosis in both Hodgkin lymphoma and non-Hodgkin lymphoma (NHL).^{57–60} In diffuse large-cell lymphoma, IL-6 levels were found to be the single most important independent prognostic factor selected in multivariate analysis for predicting complete remission rate and relapse-free survival.⁵⁸ IL-6 levels may also be exploitable as a prognostic factor in RCC and multiple myeloma (MM), and high levels are observed in prostate and ovarian cancers. IL-6 probably also plays an etiologic role in the systemic manifestations of the lymphoproliferative disorder Castleman's disease.⁶¹ High IL-6 levels are also an adverse prognostic factor in pancreatic cancer.⁶²

IL-6 in the clinic

In patients undergoing chemotherapy or autologous transplantation, IL-6 has minimal to no platelet-enhancing activity at tolerable doses. Toxicity includes fever and anemia.^{63–65} IL-6 has also been tested as an antitumor agent in melanoma and RCC. Response rates have been low (<15%).⁵⁵ Because high levels of IL-6 correlate with an adverse outcome in many cancers and function as an autocrine/paracrine growth factor in some tumors, clinical studies of an IL-6 inhibitor may be worthwhile.

IL-6 is one of the most ubiquitously deregulated cytokines in cancer, and increased levels of IL-6 have been observed in virtually every tumor studied. Preclinical and translational findings support a role for IL-6 in diverse malignancies, including breast, lung, colorectal, ovarian, prostate, pancreatic cancers, MM, glioma, melanoma, RCC, leukemia, lymphoma, and Castleman's disease, and provide a biologic rationale for targeted therapeutic investigations. Various compounds antagonize IL-6 production, including corticosteroids, nonsteroidal anti-inflammatory agents, estrogens, and cytokines. Targeted biologic

therapies include IL-6 conjugated toxins and monoclonal antibodies directed against IL-6 and its receptor. As an example, a chimeric murine antihuman IL-6 antibody, CNTO 328, has been used in a phase 1 trial in subjects with B-cell NHL, MM, and Castleman's disease.⁶⁶ The treatment resulted in tumor response and disease control, especially in Castleman's disease, where striking responses have been seen.⁶⁷

Interleukin-7

IL-7 was identified and cloned on the basis of its ability to induce proliferation of B-cell progenitors in the absence of stromal cells.^{68–76} It is now known that this cytokine is secreted by stromal cells in the bone marrow and thymus and is irreplaceable in the development of both B and T cells.^{69–71} Indeed, the nonredundant nature of IL-7 is underscored by the observation that ablation of IL-7 or parts of the IL-7 receptor in gene knockout mice ineluctably leads to a major defect in lymphocyte development.

Biologic activities of IL-7/IL-7 receptor

While most single cytokine knockout mice show relatively normal B- and T-cell compartments, indicating that many cytokine functions are redundant, IL-7-deficient mice present with striking lymphocyte depletion in both the thymus and bone marrow. Collectively, these genetic experiments identify clearly distinct *in vivo* roles for various lymphoid factors. IL-2 and IL-4 function by influencing mature lymphocyte populations during immune responses, whereas IL-7 plays a singularly dominant role for the production and expansion of lymphocytes. The upregulation of IL-7R occurs at the stage of the clonogenic common lymphoid progenitor that can give rise to all lymphoid lineages at a single-cell level.⁷⁴ There are at least three principal means by which IL-7R-mediated signals act in lymphocyte development: enhancement of proliferation, triggering of lineage-specific developmental programs, and maintenance of viability of appropriately selected cells.

High IL-7 levels are found in states of T-cell depletion and may, therefore, play a role in promoting T-cell expansion.⁷⁵ High levels of IL-7 are also found in CLL and Burkitt lymphoma, and transgenic mice overexpressing the IL-7 gene show dramatic changes in lymphocyte development, which, in some instances, can result in the formation of lymphoid tumors.⁷⁶

Interleukin-8

IL-8 was first identified in 1987 as a potent, proinflammatory chemokine that induces trafficking of neutrophils across the vascular wall (chemotaxis).⁷⁷ This molecule belongs to a chemokine superfamily whose members include neutrophil-activating peptide-2, platelet factor-4, growth-related cytokine (GRO), and IFN-inducible protein-10, all of which are responsible for the directional migration of various cells.⁷⁸ IL-8 receptor demonstrates strong homology to a gene encoded by human herpesvirus-8 (HHV-8).^{79, 80}

Biologic activity of IL-8

The chemotactic agents generated by inflammatory stimuli recruit circulating leukocytes, in particular neutrophils, for defensive purposes and direct them to injury sites. Among the neutrophil-affecting chemokines, IL-8 is one of the most potent.⁸¹ On exposure to a chemokine, neutrophils are activated, and within seconds, their shapes change. The process of shape change is crucial. It is modulated by perturbations of cellular integrins and the actin cytoskeleton. The activation and upregulation of integrins also permits the adherence of neutrophils to the endothelial cells of the vessel wall, to allow for subsequent migration into the tissues. Leukocytes follow the IL-8 concentration gradient and accumulate at

the location of elevated concentration. These processes play a fundamental role in the host defense as activated leukocytes act to kill and engulf invading bacteria at the site of injury.

IL-8 can induce tumor growth, an effect attributed to its angiogenic activity. On the one hand, the administration of anti-IL-8 to SCID mice bearing xenografts of IL-8-expressing human lung cancer has been shown to have beneficial effects.⁸² On the other hand, antitumor effects of IL-8 have also been reported. Of interest in this regard is the fact that increased levels of IL-8 have been discerned in lung carcinomas and in melanomas. IL-8 may be a growth factor for pancreatic cancer and for melanoma.⁷⁸ In melanomas, IL-8 levels correlate with the growth and metastatic potential of the tumor cells, and exposure of the cells to IFN (an agent with known antitumor activity in melanoma) decreases IL-8 levels and cancer cell proliferation.⁸³ Blocking IL-8 or IL-8R has been suggested as a therapeutic strategy.⁷⁸

Interleukin-9

Human IL-9 was initially identified and cloned as a mitogenic factor for a human megakaryoblastic leukemia. Subsequently, IL-9 targets were found to encompass a wide range of cells.^{84, 85}

Biologic activities of IL-9

Cellular elements responsive to IL-9 include erythroid progenitors, human T cells, B cells, fetal thymocytes, thymic lymphomas, and immature neuronal cell lines.⁸⁴

IL-9 can support the clonogenic maturation of erythroid progenitors in the presence of EPO. In contrast, granulocyte or macrophage colony formation (CFU-GM, CFU-G, or CFU-M) is usually not influenced by IL-9. IL-9 is more effective on fetal than adult progenitors and in cells that are activated. In addition to its proliferative activity, IL-9 also seems to be a potent regulator of mast cell effector molecules.

There is an interesting paradox between the unresponsiveness of normal T cells to IL-9 and the potent activity of this molecule on lymphoma cells. This contrast is illustrated by the observation that murine T cells acquire the ability to respond to IL-9 after a long period of *in vitro* culture, while they simultaneously acquire characteristics of tumor cell lines. Observations made with transgenic mice also demonstrate the oncogenic potential of dysregulated IL-9 production as 5–10% of mice that overexpress this cytokine develop lymphoblastic lymphomas.⁸⁵ In line with these data, constitutive IL-9 production by human Hodgkin lymphomas and large-cell anaplastic lymphomas has now been clearly documented.⁸⁴ Even so, the pathophysiologic role of IL-9 remains elusive.

Interleukin-10

IL-10 is a pleiotropic cytokine discovered in 1989 as an activity produced by murine type 2 helper T cells (Th2).^{86, 87} It was initially designated as cytokine synthesis inhibitory factor because of its ability to inhibit the production of certain cytokines.⁸⁸ Of interest, IL-10 exhibits strong DNA and amino acid sequence homology to an open reading frame—BCRF1—in the Epstein–Barr virus (EBV) genome.⁸⁸ Indeed, the BCRF1 protein product displays many of the biologic properties of cellular IL-10 and has, therefore, been termed viral IL-10.

Biologic activities of IL-10

IL-10 inhibits the synthesis of Th1-derived cytokines, including IL-2, IFN- γ , GM-CSF, and lymphotoxin and of monocyte-derived IL-1 α and β , IL-6, IL-8, TNF- α , GM-CSF, and G-CSF. Exogenous IL-10 can also suppress expression of IL-10.⁸⁷ At the same time, IL-10 induces the synthesis of the IL-1 receptor

antagonist by macrophages. IL-10 also suppresses the CD28 costimulatory pathway and hence acts as a decisive mechanism in determining if a T cell will contribute to an immune response or become anergic.

From the molecular standpoint, IL-10 suppresses cytokine expression at a transcriptional and posttranscriptional level.⁸⁹ Both these mechanisms appear to require new protein synthesis. At a cellular level, Th1 cytokines synthesis inhibition is mediated indirectly through the effect of IL-10 on APC, as suppression occurs when macrophages, but not B cells, are used as APC.⁹⁰

In the presence of monocytes/macrophages, IL-10 inhibits proliferation of resting T cells, including Th0, Th1, and Th2 CD4+ T-cell clones. This inhibition can only be partially reversed by high concentrations of IL-2, suggesting that the reduced proliferation is only partially a reflection of reduced IL-2 production. IL-10 can also enhance the cytotoxic activity of CD8+ T cells. All these effects support an important role of IL-10 in regulating inflammatory responses. In contrast to the inhibitory effects on other lineages, IL-10 has a stimulatory effect on B cells and mast cells.⁹¹ For instance, IL-10 strongly stimulates proliferation and differentiation of activated B cells.

The role of IL-10 in cancer should be considered within the frame of a highly complex biological puzzle. It is known that IL-10 can have pleiotropic effects on adaptive and innate immunity cell mediators. Although several studies show that IL-10 can actively mediate immune suppression, some experimental models describe relatively opposite conclusions. Recent data on the relationship between IL-10 and anticancer immunity support an effective immune attack against malignant cells, which challenges the common belief that IL-10 acts as an immunosuppressive factor promoting tumor immune escape.

Interleukin-11

Originally characterized as a thrombopoietic factor, IL-11 is now known to be expressed and have activity in a multitude of other systems, including the gut, testes, and the central nervous system.^{92, 93} Clinically, this cytokine has been approved by the FDA for amelioration of chemotherapy-induced thrombocytopenia.

Biologic activities of IL-11

IL-11 was originally isolated from cells derived from the hematopoietic microenvironment and may act as a paracrine or autocrine growth factor in this environment. IL-11 acts synergistically with other early- and late-acting growth factors, including IL-3, IL-4, IL-7, IL-12, IL-13, SCF, FLT-3 ligand, and GM-CSF, to stimulate various stages and lineages of hematopoiesis.⁹² The synergistic effects of IL-11 and TPO on multilineage cells may be mediated in part by SCF/c-kit interactions.

IL-11 acts synergistically with IL-3, TPO, or SCF to stimulate various stages of megakaryocytopoiesis and thrombopoiesis.^{94, 95} IL-11, alone or in combination with other cytokines (IL-3, SCF, or EPO), can stimulate multiple stages of erythropoiesis. IL-11 also modulates the differentiation and maturation of myeloid progenitor cells. IL-11 in combination with SCF stimulates myeloid colony formation. The combination of IL-11 with IL-13 or IL-14 can reduce the proportion of granulocytes and blasts in myeloid colonies, with a concomitant increase in macrophages. IL-11 in combination with SCF or IL-4 effectively supports the generation of B cells in primary cultures. IL-11 and IL-4 can also reverse the inhibitory effect of IL-3 on early B-lymphocyte development. The promotion of B-cell differentiation may be mediated by T cells.

IL-11 acts as a synergistic factor with IL-3, GM-CSF, and SCF to stimulate proliferation of human primary leukemia cells, myeloid leukemia cell lines, megakaryoblastic cell lines, and erythroleukemic

cell lines and to stimulate leukemic blast colony formation. IL-11 mRNA expression in leukemic cells and inhibition of leukemic cell growth by IL-11 antisense oligonucleotides suggest that IL-11 may function as an autocrine growth factor in leukemic cell lines.⁹⁶ Although IL-11 stimulates the proliferation of murine plasmacytoma cells and murine hybridoma cells, the effect of IL-11 on the growth of human myeloma/plasmacytoma cells is controversial.⁹²

Clinical use of IL-11

IL-11 was the second IL to receive FDA approval. It is indicated for the secondary prevention of chemotherapy-induced thrombocytopenia and for the reduction of the need for platelet transfusion in patients with nonmyeloid malignancies.

Interleukin-12

IL-12 was first identified as an NK-cell stimulatory factor.⁹⁷ Subsequently, it was demonstrated that IL-12 is crucial to the development of Th1 cells.⁹⁸ Indeed, there appears to be a common pathway leading from the innate immune response to adaptive immunity; intracellular pathogens stimulate macrophages to produce IL-12, which then promotes the development of Th1 cells from a naïve cell population. This pathway may be exploitable in the design of novel immunotherapies and vaccines.

Biologic activities of IL-12 and role in human disease

IL-12 is a potent proinflammatory molecule, which is essential for resistance to bacterial, fungal, and parasitic infections. It is produced within a few hours of infection, activates NK cells, and, through its ability to induce IFN- γ production, enhances the phagocytic and bactericidal activities of phagocytic cells and their ability to release proinflammatory cytokines, including IL-12 itself. IL-12 is also a key immunoregulatory molecule, especially of Th1 responses. It is produced during the early phases of infection and inflammation and sets the stage for the ensuing antigen-specific immune response, favoring the differentiation and function of Th1 T cells, while inhibiting the differentiation of Th2 T cells. IL-12 does not induce proliferation of resting peripheral blood T cells or NK cells; it does potentiate the proliferation of T cells induced by various mitogens and has a direct proliferative effect on preactivated T and NK cells.

IL-12 synergizes with other hematopoietic factors to promote survival and proliferation of early multipotent hematopoietic progenitor cells and lineage-committed precursor cells.⁹⁹ Although *in vitro* IL-12 has mostly stimulatory effects on hematopoiesis, *in vivo* IL-12 treatment results in decreased bone marrow hematopoiesis and both transient anemia and neutropenia, an effect mediated by IFN- γ .

IL-12 in the clinic

IL-12 has potential for exploitation in allergy and as an adjuvant for infectious disease therapy.¹⁰⁰ In addition, the ability of IL-12 to revert existing states of tolerance or anergy makes it a candidate for use in the composition of vaccines for infectious agents or tumors. Phase 1 clinical trials have been started in the past few years in oncology, as well as in the setting of HIV infection and chronic hepatitis B and C. To date, administration of IL-12 to patients with chronic hepatitis C does not appear advantageous.¹⁰¹ What is more worrisome is that in cancer patients treated with high doses of IL-12, acute hematopoietic, hepatic, and gastrointestinal toxicities were observed and several deaths were reported. In long-term treatments, toxicity was mostly pulmonary. It has been suggested that some of the severe toxicity of IL-12 can be attenuated if a single injection is administered 1 to 2 weeks before initiating daily dosing.¹⁰²

Interleukin-15

IL-15 shares biologic activities with IL-2.¹⁰³

Biologic activities of IL-15

Similar to IL-2, IL-15 is able to trigger both proliferation of and immunoglobulin production by normal B lymphocytes. These biologic functions may be acquired, however, only when B cells have been preactivated *in vitro* with polyclonal mitogens or when they are cultured in association with other stimuli. IL-15 also stimulates the proliferation of NK cells and activated CD4⁺ and CD8⁺ T cells and facilitates the induction of cytolytic effector cells (such as LAK cells). Finally, the numbers of CD8⁺ memory T cells are maintained in animals by a balance between the stimulatory effect of IL-15 and the suppressive effects of IL-12.¹⁰⁴

IL-15 responsiveness distinguishes malignant B cells from normal B lymphocytes. In contrast to normal B lymphocytes, which require preactivation in order to proliferate in response to IL-15, leukemic cells from patients with chronic B-cell malignancies proliferate in response to IL-15 regardless of *in vitro* preactivation, which is mainly related to the presence of the β and γ chains of the IL-2R system on the malignant B lymphocytes.¹⁰³ Even so, IL-15 cannot be considered an autocrine factor in these leukemias, as it is not produced by the leukemic cells themselves. Rather, the major reservoir of IL-15 in these patients is from cells belonging to the monocyte/macrophage lineage.¹⁰³

Interleukin-17

Human IL-17 has 72% overall sequence identity at the amino acid level with open reading frame 13 of herpesvirus Saimiri (HVS).¹⁰⁵

Biologic activities of IL-17

Although limited in number, studies suggest that IL-17 may be a soluble factor by which T cells induce or contribute to inflammation.¹⁰⁶ IL-17 can also stimulate epithelial, endothelial, and fibroblastic cells, and macrophages to express a variety of cytokines,⁹⁹ which appear to be cell specific. For instance, fibroblast cells produce IL-1, G-CSF, IFN- γ , IL-6, and IL-8 in response to IL-17, whereas macrophages produce TNF- α , IL-1 β , IL-1R α , IL-6, IL-10, and IL-12.¹⁰⁷

IL-17 also exhibits indirect hematopoietic activity by enhancing the capacity of fibroblasts to sustain the proliferation of CD34⁺ hematopoietic progenitors and their differentiation into neutrophils.^{108, 106} IL-17 can also promote the maturation of dendritic cell progenitors.¹⁰⁹ Because IL-17 acts to differentiate early dendritic cells, it has been implicated in host T-cell allostimulation and graft rejection.¹⁰⁹

Interleukin-18

IL-18 (IFN-inducing factor) was first described as a serum activity that induced IFN- γ production in mouse spleen cells.¹¹⁰ IL-18 has a molecular weight of 18–19 kDa and has homology to IL-1.^{111, 112} Like IL-1 β , IL-18 is initially synthesized as an inactive precursor molecule (pro-IL-18) lacking a signal peptide and is cleaved by ICE to yield an active molecule.^{113, 114}

Biologic activities of IL-18

T lymphocytes, NK cells, and macrophages are primary targets for IL-18. For example, IL-18 directly

stimulates production of tumor necrosis factor (TNF) in human blood CD4⁺ T lymphocytes and NK cells and plays an important role in promoting a long-lasting Th1 lymphocyte response to viral antigens. IL-18 does not appear to be an endogenous pyrogen but may nevertheless contribute to inflammation and fever because it is a potent inducer of TNF, chemokines, and IFN.¹¹⁵ In the case of IFN- γ induction, IL-18 acts as a costimulant with mitogens or IL-2. Indeed, mice deficient in ICE, the molecule that cleaves pro-IL-18 to its mature form, fail to produce IFN- γ in response to endotoxin.

Interleukin-21

IL-21, a cytokine most closely related to IL-2 and IL-15, is involved in the proliferation and maturation of NK-cell populations from bone marrow, as well as in the proliferation of mature B-cell and T-cell populations.¹¹⁶ IL-21 has been implicated in the activation of innate immune responses and in the Th1 response. IL-21 also plays a critical role in regulating immunoglobulin production of B cells.¹¹⁷

Interleukin-24

IL-24 was originally named melanoma differentiation-associated gene-7 (*mda-7*) when it was discovered in 1995. It was identified by subtractive hybridization after the treatment of melanoma cells with IFN- β and mezerein, which caused their terminal differentiation and growth arrest.¹¹⁸ In 2001, it was discovered that *mda-7* encodes a secreted protein that exhibits significant homology to IL-10. This molecule was officially designated as IL-24.¹¹⁹ Human IL-24 is secreted by activated peripheral blood mononuclear cells and is the ligand for two heterodimeric receptors, IL-22R1/IL-20R2 and IL-20R1/IL-20R2.¹²⁰ IL-24 also acts as a tumor-suppressor gene and the protein product was found to be constitutively expressed by melanocytes, nevus cells, and some primary melanomas but not metastatic lesions of melanoma.^{121, 122} This is possibly the first example of a tumor-suppressor gene exhibiting immune stimulatory properties.¹²³

Biologic activities of IL-24

IL-24 has a number of interesting and unique properties, including direct cancer-killing activity, potent bystander antitumor activity, immune-modulating activity, and antiangiogenic properties. As an antitumor agent, *mda-7/IL-24* is truly unique, displaying selective antitumor activity in cancer cells and having the capacity to utilize diverse signaling pathways in mediating tumor cell death.

IL-24 in the clinic

On the basis of its remarkable attributes and effective antitumor therapy in animal models, this cytokine has taken the important step of entering the clinic. In a phase 1 clinical trial, intratumoral injection of adenovirus-administered *mda-7/IL-24* (INGN 241) was safe, elicited tumor-regulatory and immune-activating processes and provided clinically significant activity.^{124, 125}

Interleukin-26

Subtraction hybridization coupled with representational differential analysis identified IL-26/AK155 as a gene upregulated in human T cells following infection with vesicular stomatitis virus (VSV), human cytomegalovirus (HCMV), and herpes simplex virus type 1 (HSV-1).¹²⁶ It has the capacity to transform these cells in culture. The IL-26 protein has 24.7% amino acid identity and 47% amino acid similarity with human IL-10. Structural analysis revealed that IL-26 contains six helices with four highly conserved cysteine residues, which are assumed to be relevant for dimer formation as is the case with IL-10. It was determined that IL-26 mRNA is specifically overexpressed by T cells after HVS transformation.

Interleukin-27

In 2002, Pflanz et al.¹²⁷ described a new heterodimeric cytokine, related to IL-12. This cytokine was designated IL-27. It acts together with IL-12 to trigger IFN- γ production by naïve CD4⁺ T cells. They also identified IL-27 as the ligand for TCCR/WSX-1, a novel member of the class I cytokine receptor family shown to be important for Th1 development.¹²⁸ Studies revealed that IL-27 has the ability to induce tumor-specific antitumor activity and protective immunity and that the antitumor activity is mediated mainly through CD8⁺ T cells, and IFN- γ .¹²⁹

Interleukin-28 and interleukin-29

The IL-28 family has been identified from the human genomic sequence, designated IL-28A, IL-28B, and IL-29. These molecules were originally described as distantly related to type I IFNs and the IL-10 family. IL-28 and IL-29 are induced by viral infection and show antiviral activity. Moreover, IL-28 and IL-29 interact with a heterodimeric class II cytokine receptor that consists of IL-10R β and an orphan class II receptor chain, designated IL-28R α . Now, they are subclassified as type III IFNs and seem to be promising candidates for the development of alternatives to type I IFNs, as suggested by their potent antiviral and antitumor properties. Given the fact that IL-28/29 primarily influence epithelial cells, melanocytes and tumor cells derived thereof, as well as hepatocytes, there are several potential therapeutic fields in which these cytokines could be applied, including as antitumor therapy for carcinoma and melanoma.¹³⁰

Interleukin-31

IL-31 has been identified as a four-helix bundle cytokine that is preferentially produced by T helper type 2 cells. IL-31 signals through a receptor composed of IL-31 receptor A and oncostatin M receptor. Expression of IL-31 receptor A and oncostatin M receptor mRNA is induced in activated monocytes, whereas epithelial cells expressed both mRNAs constitutively. More specifically, the data indicate that IL-31 may be involved in promoting the dermatitis and epithelial responses that characterize allergic and nonallergic diseases.¹³¹

Interleukin-35

IL-35 represents a new member of the heterodimeric IL-12 cytokine family. IL-35 is a novel inhibitory cytokine that is produced by Treg cells and contributes to their suppressive activity. Moreover, ectopic expression of IL-35 confers regulatory activity on naïve T cells, whereas recombinant IL-35 suppresses T-cell proliferation. Because IL-35 may be secreted exclusively by Treg cells and other cell populations with regulatory potential, it represents a novel potential target for the therapeutic manipulation of Treg activity to treat cancer and autoimmune diseases.¹³²

Interleukin-37

Since the discovery of IL-1 in 1977, the IL-1 family of cytokines list is continually evolving.¹³³ IL-37 was originally defined as IL-1 family member 7 (IL-1F7) and transcripts are detected in lymph nodes, thymus, bone marrow, lung, testis, uterus, and placenta.¹³⁴ TGF- β and several Toll-like receptor (TLR) ligands induce production of high levels of IL-37 by PBMCs; proinflammatory cytokines such as IL-18, IFN- γ , IL-1 β , and TNF moderately increase IL-37 levels.¹³⁵ In addition, expression of IL-37 in monocytic cells has been shown to reduce several intracellular kinases important for transducing proinflammatory signals,

such as focal adhesion kinase (FAK), STAT1, p38 MAPK, and c-jun. Therefore, IL-37 is considered one of the many key modulators of inflammation.

Interferons

The IFNs are a large family of multifunctional secreted proteins involved in antiviral defense, cell growth regulation, and immune activation. There are three types of IFNs; types I (IFN α , β), II (IFN γ), and III (IFN λ). Each IFN type has sequence similarity, signals via specific cell-surface receptor complexes ([Table 3](#)), and mediates its effect by activating multiple signaling pathways, including the JAK-STAT pathway, among others. JAK-STAT signaling events lead to the activation of transcription factor complexes and homo- or heterodimerized STAT molecules, and their subsequent binding to IFN-stimulated response element (ISRE), γ -activated sequence (GAS), and STAT-binding sites in promoters of IFN-regulated genes (IRG), resulting in the transcriptional activation of those IRGs.¹³⁶

Table 3 Interferons (IFN)

Type		Stimuli	Receptors	Signaling molecules
Type I IFNs	IFN α IFN β	• Viruses• Other microorganisms	IFNAR: IFNAR1–IFNAR2	• JAK1 and TYK2• STAT1–STAT2–IRF9 complexes• STAT1–STAT1 complexes
Type II IFN	IFN γ	• Antigen–MHC complexes• Activating NK-cell ligands• IL-12 plus IL-18• TLRs	IFNGR: IFNGR1–IFNGR2	• JAK1 and JAK2• STAT1–STAT1 complexes
Type III IFN	IFN λ	• Viruses• Other microorganisms	IL10R2 and IFNLR1	• JAK1 and TYK2• STAT1–STAT2–IRF9 complexes• STAT2–STAT2 complexes

The genes that encode type I, II, and III IFNs are clustered on chromosomes 9, 12, and 19, respectively, in humans. Cellular action follows binding to a relatively small number of high-affinity receptors. Regulatory proteins then transcriptionally regulate gene expression resulting in production of proteins that are not expressed constitutively or only at low levels. The products of these IFN-stimulated genes (ISGs) underlie the pleiotropic biologic effects: virus inhibition, immunomodulation, inhibition of cell proliferation, alterations in differentiation, increased apoptosis, and angiogenesis inhibition. However, which of the specific ISG products result in the various biologic and therapeutic effects remains undefined, as do the specific cellular mechanism(s) of antitumor action. Antitumor effects result from either a direct effect on viability and proliferation or antigenic expression of tumor cells, or an effect on modulation of immune effector or endothelial cell populations. IFNs regulate gene expression, modulate expression of proteins on the cell surface, and induce synthesis of new enzymes. Alterations in gene expression result in modulation of receptors for other cytokines, concentration of regulatory proteins on the surface of immune effector cells, and activities of enzymes that control cellular growth and function. On a cellular basis, these effects translate into alterations of the state of differentiation, rate of proliferation and death, and functional activity of many cell types. Induced proteins and their products can be identified on cells and in serum of treated patients. Their measurement or the quantitation of immune effector cell function can be used to define biologically active molecules, doses, schedules, and routes of administration.

Antitumor effects in humans

Both natural and recombinant IFNs have shown definite antitumor activity in patients with various malignancies. Clinically beneficial therapeutic activity of IFN- α 2 as a single agent has been demonstrated in more than a dozen malignancies. The unique molecular and cellular effects of IFNs also complement the mechanisms of actions of other therapies. Most gene and biologic response modulatory effects peak at 24–48 h, which contrasts with maximal serum levels of minutes to hours after intravenous or subcutaneous administration.^{137–139} After intravenous bolus administration, the $t_{1/2\alpha}$ of IFN- α 2 is short (<60 min); mean terminal half-life is 4–5 h with no serum levels measurable at 12 h. After intramuscular or subcutaneous administration, peak levels are 3–8 h.¹³⁷ The pharmacologic hallmark of IFN- β is virtual absence of serum levels with subcutaneous or intramuscular administration; yet, biologic response modulatory and therapeutic effects occur.¹³⁹ Pegylated IFNs have markedly different kinetics than do unmodified IFNs.^{140–142} Once-weekly administration has resulted in measurable serum levels of IFN- α 2 at 7 days—in excess of that required for gene induction and cellular effects *in vitro*. Pegylated IFN- α 2 has resulted in tumor responses in metastatic renal carcinoma, CML, and melanoma.^{142, 143}

Hematologic malignancies

In CML, IFN- α 2 resulted in sustained therapeutic response in a majority (>75%) of newly diagnosed patients in early clinical studies.^{144, 145} Complete cytogenetic remissions were noted in a minority of patients and the rate was higher in younger patients. However, owing to the considerable side effects from IFN, many clinicians chose to stop therapy if cytogenetic improvement was not seen after approximately 1 year of treatment. Before the development of the tyrosine kinase inhibitors (TKIs), IFNs were the treatment of choice for most patients with CML. With the development of imatinib mesylate and the increased toxicity of IFN compared with TKIs, it has been used much less commonly for the treatment of CML. More recently, combinational therapies, such as IFN plus imatinib, have produced long-term remissions in patients with CML in clinical trials and have become the standard therapy for patients with newly diagnosed CML in chronic phase. The French SPIRIT trial demonstrated higher rates of molecular response using the combination of imatinib and peg-IFN compared with IFN alone,¹⁴⁶ but another study failed to demonstrate an improvement in progression-free survival.¹⁴⁷ Therefore, additional clinical data are necessary before this combination can be recommended.

IFN- γ has been used as therapy in CML and demonstrated varying degrees of cytogenetic improvement¹⁴⁸ but failed to show any effect in subsequent studies and hence, it is not recommended for treatment of CML.

Solid tumors

Response rates for metastatic melanoma in patients who received IFN- α 2 as a single agent have approximated 15%, comparable to cytotoxic agents used alone.^{149–152} Suggestions of response durability set IFN apart from DTIC as a therapy for metastatic melanoma. When combined with chemotherapy and IL-2, response rates can exceed 45% but with increased toxicity and with no marked prolongation in progression-free survival or overall survival.^{24, 152–156} Increase in disease-free survival with an impact on overall survival has, however, emerged in some trials from the use of IFN- α 2 as an adjuvant to surgery for melanoma for patients at high risk for disease recurrence (stage IIb or stage III).^{143, 157–160} Analysis of quality-of-life adjusted survival in the adjuvant setting has also identified an advantage for the use of IFN- α 2.¹⁶¹ Thus, IFN- α 2 has become a standard of care for patients with stage IIb or stage III melanoma in the United States, a use supported by meta-analyses.^{161, 162} A large European trial that used pegylated IFN- α 2 for longer duration has confirmed benefit on disease-free survival in high-risk primary patients.¹⁶³

Pegylation has resulted in responses in metastatic melanoma leading to an innovative trial design of long-duration treatment with dose adjusted for fatigue and anorexia with confirmed increase in disease-free survival.^{143, 160, 164}

IFN has been extensively used in the treatment of RCC. Response rates from 4% to 26% have been reported in trials of IFN- α 2 in metastatic RCC, with a mean response of 15% in a cumulative summary of several trials.¹⁶⁵ Subsequent efforts have been made to evaluate IFN together with other biological response modifiers including IL-2 or in combination with chemotherapeutic agents, in particular 5-fluorouracil (5-FU). The combination of IFN- α and IL-2 has been extensively investigated in patients with metastatic RCC. Phase I and II trials have demonstrated response rates of approximately 20%, with 5% CR.¹⁶⁶ In two randomized trials comparing IFN- α alone or in combination with other treatments, a statistically significant increase in survival resulted.^{167, 168} Other randomized trials have suggested survival prolongations that may be greatest for patients who have nephrectomies despite the presence of metastases and who then receive IFN- α .^{169, 170} In summary, as numerous studies have failed to show a survival advantage for patients with metastatic RCC receiving combination cytokine therapy, it cannot be recommended as standard treatment. Other solid tumors, such as ovarian, bladder, and basal cell carcinomas, have responded to IFN- α administered regionally, particularly in patients with lesser tumor bulk.^{171–173}

The shared gene induction profile of type I and type III IFNs has led to investigations of the potential role of type III IFN in cancer therapy. The hope is that type III IFN will be effective against responsive cancer cells while showing fewer side effects than type I IFN owing to the restricted distribution of the receptor.¹⁷⁴ The favorable side effect profile of type III over type I IFN was recently demonstrated in a phase I study of the effect of type III IFN against HCV. While some of the patients treated with type I IFN developed neutropenia or anemia, patients treated with type III IFN remained symptom free.¹⁷⁵ The data suggest that type III IFN can play a positive role in cancer therapy with few or no side effects, yet it is still in its infancy.

Hematopoiesis and the role of growth factors

Through a series of well-orchestrated divisions, hematopoietic stem cells give rise to all blood cells. Functionally, these early progenitors are capable of self-renewal as well as proliferation and differentiation. The development, homeostasis, trafficking, and response capacity of the hematopoietic system are tightly regulated by a complex communications network that is mediated by intercellular signals. These signals are triggered by direct cell-to-cell or cell-to-matrix contact or by the release of soluble cytokine mediators.

The identification and cloning of hematopoietic growth factors have revolutionized hematology practice. Raising white blood cell counts in neutropenic patients was unimaginable until the advent of G-CSF and GM-CSF. Today, growth factors are routinely used to alleviate neutropenia and, to a lesser extent, thrombocytopenia and anemia after chemotherapy. They can also help mobilize stem cells for transplantation, reverse cytopenias in a variety of nonmalignant illnesses, and may have the potential to mobilize the immune system against infection or cancer.

Erythropoietin

EPO is the major hormone regulator of erythropoiesis. It has an established role in the treatment of anemia associated with a variety of illnesses ([Table 4](#)).

Table 4 Hematopoietic growth factors

	Chromosomal location	Receptors	Selected biologic activities
EPO	7q21	EPO receptor	Promotes the proliferation, differentiation, and survival of erythroid precursors
GM-CSF	5q31.1	Type I receptor with α (CD116) and β (CDw131) subunits	Stimulates growth of multilineage progenitors, BFU-E, granulocyte, macrophage, and eosinophil colonies
			Induces migration and proliferation of vascular endothelial cells
			Activates mature phagocytes (neutrophils, macrophages, and eosinophils)
G-CSF	17q11.2-q12	G-CSF receptor (CD114)	Regulates production and function of neutrophils
M-CSF	1p21-p13	Fms (CD115)	Influences most aspects of monocyte/macrophage development and function
			Stimulates hematopoiesis
			Induces osteoclast production
			Helps maintain pregnancies
			Lowers cholesterol levels
			Affects microglial function
SCF	12q22-12q24	c-kit (CD117)	Promotes hematopoiesis at multiple levels
			Influences primordial germ cell and melanocyte migration during embryonic life
			Affects immunoregulatory cells (B and T cells, mast cells, NK cells, and dendritic cells)
			Influences hematopoietic cell adhesive properties
TPO	3q27-q28	Mpl (CD110)	Major regulator of platelet production
			Acts in synergy with EPO to stimulate growth of erythroid progenitors
			Acts in synergy with IL-3 and SCF to stimulate proliferation and prolong survival of hematopoietic stem cells

Biologic activities of EPO

EPO provides a proliferative signal to early erythroid progenitors [burst-forming unit erythroid (BFU-E)] and a differentiation signal to a later erythroid precursor [colony-forming unit erythroid (CFU-E)]. EPO can also promote megakaryocyte differentiation, B-cell proliferation, and endothelial cell chemotaxis.

EPO in malignancy

High levels of endogenous EPO are often found in patients with anemia due to cancer, especially hematologic malignancies. In contrast, in many patients with anemia, even anemia due to cancer, there is a relative deficiency in endogenous EPO. In other words, although the levels of this molecule are elevated, they are not as high as they should be for the degree of anemia. Certain cases of familial erythrocytosis have been attributed to the presence of EPO-hypersensitive cells. This heightened EPO response results from the formation of a truncated EPO receptor, which is missing a negative regulatory domain.¹⁷⁶

EPO in the clinic

EPO is most useful in those anemias where there is an absolute or a relative deficiency in endogenous EPO levels. First used successfully as replacement therapy to correct the anemia associated with chronic renal failure, EPO is also effective in increasing hemoglobin in some patients with both solid tumors and hematologic malignancies as well as in those with a variety of other conditions.¹⁷⁷

EPO has generally been used for patients with significant anemia, i.e., hemoglobin <10 g/dL. The US FDA suggests that EPO should be used conservatively to avoid transfusion but not to normalize hemoglobin levels. In the case of cancer, however, not all patients respond, and those with the highest levels of endogenous EPO are probably less likely to benefit.

Granulocyte macrophage colony-stimulating factor

GM-CSF was the first CSF to enter clinical trials. It has now been approved in many countries for treatment of neutropenia after chemotherapy or transplantation, for treatment of graft failure, and for peripheral blood stem cell mobilization.

Major biologic activities of GM-CSF

GM-CSF stimulates proliferation of multilineage progenitors and the growth of BFU-E, granulocyte, macrophage, and eosinophil colonies. GM-CSF also enhances the functional activity of most phagocytes, including neutrophils, macrophages, and eosinophils.

GM-CSF in malignancy

Autocrine expression of GM-CSF in myeloid leukemia cells and cell lines has been proposed to play a role in neoplasia.¹⁷⁸ Autonomous production of GM-CSF (or G-CSF) by the tumor has also been implicated as one possible pathophysiologic mechanism underlying leukemoid reactions in cancer patients.¹⁷⁹ In addition, the presence of GM-CSF biologic activity in synovial fluid from patients with rheumatoid arthritis suggests that it may enhance the tissue destruction associated with this disorder.

GM-CSF has been shown to be safe and effective in the treatment of patients with acute myelogenous leukemia (AML) who are undergoing induction therapy. This molecule shortens the neutropenic period and decreases the rate of serious infections in older individuals. GM-CSF is also indicated for accelerating myeloid reconstitution after allogeneic BMTs. It also enhances survival in patients who experience engraftment failure or delay after allogeneic or autologous transplantation. Finally, peripheral blood stem cells mobilized in the presence of GM-CSF yield significantly higher colony counts than those mobilized without this molecule and, after transplantation, recipients of GM-CSF-mobilized progenitors have quicker neutrophil, platelet, and red blood cell recovery and shorter hospital stays.

Granulocyte colony-stimulating factor

G-CSF has revolutionized the treatment of neutropenia and its sequelae (infection). It has been used

worldwide and has been found to be remarkably effective and virtually devoid of side effects.^{180, 181}

Biologic activities of G-CSF

G-CSF is a relatively specific stimulator of the growth and differentiation of hematopoietic progenitor cells committed to the neutrophil lineage. It also protects neutrophils from apoptosis and enhances their function. Finally, G-CSF moves mature neutrophils from the marrow into the circulation.

G-CSF in human disease

In healthy persons, mean \pm SD G-CSF levels are 25 ± 19.7 pg/mL. G-CSF levels increase by 30-fold in infection and by 10,000-fold in septic shock.¹⁸² Some patients with solid tumors present with significantly increased leukocyte counts. In several of these individuals, elevated serum levels of G-CSF (or GM-CSF) have been demonstrated and probably account for the rise in white blood cell count.¹⁷⁹ Presumably, G-CSF (or GM-CSF) is produced by the tumor itself.

Point mutations in the gene for the G-CSF receptor have been described in patients with AML, which evolved from severe congenital neutropenia. These mutations truncate the C-terminal cytoplasmic region of the G-CSF receptor and hence are presumed to disrupt the maturation signal of the receptor.¹⁸³

Studies of G-CSF as an adjunct to standard-dose cytotoxic chemotherapy for solid tumors and lymphomas demonstrate that the duration of neutropenia, the number of days of hospitalization, and the number of days of antibiotic treatment are reduced significantly during G-CSF cycles. Placebo-controlled studies in patients with small-cell lung cancer showed a clinically significant protective effect of G-CSF against febrile neutropenia.¹⁸⁴ After high-dose chemotherapy, recovery from neutropenia and its associated complications is more rapid when patients receive G-CSF. These studies suggest that the dose intensity of nonmyeloablative chemotherapy can be increased with G-CSF support. In the transplantation setting, the administration of G-CSF results in reductions in neutropenia and infection.¹⁸⁵ G-CSF also mobilizes autologous peripheral blood progenitor cells; these cells are used to accelerate hematopoietic recovery in patients who have received myeloablative or myelosuppressive chemotherapy.¹⁸⁶

A new form of G-CSF has been developed; a conjugate of G-CSF and monomethoxypolyethylene glycol. Pegylated G-CSF has a prolonged half-life because of its reduced renal clearance. Serum clearance is directly related to neutrophil number. As a result, only a single SC dose of pegylated G-CSF (Neulasta) is required after chemotherapy. On the basis of the results of randomized, blinded trials, this molecule is indicated to decrease the incidence of infection in patients with nonmyeloid malignancies receiving myelosuppressive chemotherapy with a significant incidence of febrile neutropenia.¹⁸⁷

Macrophage colony-stimulating factor

Although macrophage colony-stimulating factor (M-CSF) is known to affect a variety of organ systems, its cardinal effect remains its ability to influence most aspects of monocyte/macrophage development and function.

Biologic activities of M-CSF

M-CSF stimulates differentiation of progenitor cells to mature monocytes and prolongs the survival of monocytes. It enhances cytotoxicity, superoxide production, phagocytosis, chemotaxis, and secondary cytokine production (G-CSF, IL-6, and IL-8) in monocytes and macrophages. In addition to stimulation of hematopoiesis, M-CSF also promotes differentiation and proliferation of osteoclast progenitor cells and

has profound effects on lipid metabolism.

M-CSF in malignancy

M-CSF is intricately involved in atherosclerosis, but information about its role remains contradictory. For instance, M-CSF administration lowers cholesterol levels. Paradoxically, it appears that an absence of M-CSF protects against atherosclerosis even in the presence of hyperlipidemia.¹⁸⁸ M-CSF and Fms are expressed in the brain. This cytokine induces microglial proliferation, activation, and survival.

In malignancy, mutations in Fms (the M-CSF receptor) have been reported at codon 969 in about 10% of cases of human myeloid malignancies (including myelodysplasia and AML).

M-CSF in the clinic

In a large-scale study, it has been shown that the administration of M-CSF to AML patients after consolidation chemotherapies shortens the periods of neutropenia and thrombocytopenia after chemotherapy and reduces the incidence and shortens the duration of febrile neutropenia.¹⁸⁹ Similar benefits have been reported after chemotherapy or BMT. M-CSF can elevate neutrophil counts in children with chronic neutropenia. Finally, preliminary results in uncontrolled trials suggest that this molecule may improve outcome after fungal infections.¹⁹⁰

Stem cell factor

SCF is also known as kit ligand, mast cell growth factor, or steel factor. It functions as a hematopoietic cytokine that triggers its biologic effect by binding to c-kit (the SCF receptor).¹⁹¹

Biologic activities of SCF

SCF is constitutively produced by marrow stromal elements. It is now well established that SCF acts on hematopoietic stem cells and, in some lineages, mature cells.

SCF synergizes with other cytokines (including EPO and IL-3) to support the direct colony growth of BFU-E, CFU-GM, and CFU-granulocyte/erythroid/macrophage/megakaryocyte in semisolid media, and current data suggest that SCF can act on a more primitive cell (pre-CFU-C) capable of generating the direct colony-forming cells. SCF can also promote progenitor cell survival, accelerate stem cell entry into cell cycle, and function as a chemotactic and chemokinetic factor for these cells. Synergistic proliferative effects on megakaryocytic progenitor cells are observed when SCF is combined with TPO or IL-3.¹⁹² SCF is also involved in processes of cell adhesion and trafficking. SCF induces progenitor cell adhesion to fibronectin, a process that may involve alteration of integrin avidity through an inside-out signal initiated in response to c-kit receptor kinase activation after ligand binding. Alternatively, it is possible that the transmembrane form of SCF displayed on fibroblasts binds directly to the c-kit receptor on the surface of hematopoietic cells and, thus, helps to anchor the hematopoietic cells in the microenvironment.¹⁹²

The effects of SCF when combined with G-CSF are even more pronounced.¹⁹³ Phase 1 clinical studies show that treatment with SCF increases the numbers of progenitor cells of many types (including BFU-E, CFU-GM, CFUMeg, and CFU-GEMM) in the marrow.¹⁹⁴

SCF and c-kit in malignancy

The concentration of SCF in normal human serum is, on average, 3.3 ng/mL. Serum SCF levels are not

elevated in patients with aplastic anemia, myelodysplasia, chronic anemia, or after marrow ablative therapy.¹⁹² Thus, the level of SCF in the circulation, unlike the level of EPO, is not inversely related to the hematocrit.

Alterations in the local distribution of SCF within the skin have been implicated in the pathogenesis of cutaneous mastocytosis.¹⁹² Point mutations in the c-kit receptor cytoplasmic domain have been identified in murine and human mast cell lines and in hematopoietic cells from patients with mast cell disorders.¹⁹² Activating mutations in kit characterize a type of leiomyosarcoma known as gastrointestinal stromal tumors.

Neoplastic human hematopoietic cells can also display the c-kit receptor. Receptor density is highest in erythroleukemia cell lines, which may express up to 50,000 to 100,000 c-kit receptors per cell. Solid tumor cell lines and a variety of fresh human tumor tissues also express c-kit receptor protein.¹⁹²

SCF in the clinic

Clinical trials of SCF in a number of situations have been undertaken. SCF factor seems to be reasonably well tolerated, with the predominant side effects being transient local erythema and long-lasting hyperpigmentation at injection sites. The most worrisome toxicity is a mast cell effect resulting in allergic-like reactions characterized by urticaria, with or without respiratory symptoms.¹⁹² The side effects of SCF, including the allergic phenomenon, appear to be dose dependent.

Of special interest is the role of mutations in the SCF receptor (kit) in gastrointestinal stromal tumors. These mutations activate the kinase enzymatic activity of kit. A kinase inhibitor targeted against kit (STI571 or imatinib mesylate) has been found to be dramatically effective in these notoriously chemotherapy-resistant tumors.¹⁹⁵

Thrombopoietin

The humoral basis of megakaryocyte and platelet production has been more enigmatic than that of other lineages. Factors that have now been implicated in at least some aspects of thrombocyte development include IL-3, IL-6, IL-9, IL-11, G-CSF, GM-CSF, SCF, leukemia-inhibiting factor, and TPO. The latter molecule is believed to be of paramount importance in the physiologic regulation of platelet production. Unfortunately, however, compared with the striking effects of the granulopoietic factors in neutropenic patients, the use of the thrombopoietic molecules in the clinic setting has met with less success.

Biologic properties of TPO

TPO participates in hematopoiesis in general, in addition to thrombopoiesis, as supported by experiments demonstrating that genetic elimination of TPO or its receptor causes a 65–95% reduction in the numbers of transplantable stem cells. The survival of TPO in the circulation is longer than that of other hematopoietic growth factors (half-life = 30 h).

TPO in malignancy

High serum levels of TPO have been found in patients with autosomal dominant hereditary thrombocythemia.¹⁹⁶ Overproduction has been attributed to a splice donor mutation in the gene for TPO, which leads to a shortened 5'-untranslated region that is more efficiently translated than its normal counterpart.¹⁹⁶ Because platelets themselves regulate the level of circulating TPO, high levels of TPO are also found in patients with bone marrow failure states. Homozygous elimination of *c-mpl* (TPO receptor)

results in congenital amegakaryocytic thrombocytopenia.

TPO in the clinic

Two forms of TPO have entered clinical trials^{197, 198}: TPO (the full-length polypeptide) and PEG-conjugated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF).

Because its biologic action is prolonged, parenteral administration of TPO for 7–10 days results in increased platelet production 6–16 days later.¹⁹⁹ Results of clinical trials of PEG-rHuMGDF or recombinant human TPO in patients with cancer who were receiving chemotherapy, albeit with regimens that produce only moderate thrombocytopenia, suggest that platelet counts return to baseline significantly faster and the nadir platelet counts are higher.^{200, 201} However, the effectiveness of these molecules in accelerating platelet recovery after myeloablative therapy has not been impressive.²⁰² Furthermore, in patients with delayed platelet recovery after peripheral blood stem cell or BMT, recombinant human TPO did not significantly raise platelet counts in most patients.²⁰³

Future perspectives

The inchoate understanding of cytokines of some decades ago has now emerged as a complex picture of interacting stimulatory and inhibitory factors. Many of the molecules that govern this process have been cloned and have entered clinical trials. It is now clear that regulatory cytokines are characteristically pleiotropic and, at the same time, exhibit significant functional redundancy.

The history of medicine is replete with examples that show how innovative technologies improve clinical outcomes. The genetic engineering techniques that permitted the rapid cloning of newly identified cytokines and their translation into clinical therapies in hematology and oncology are an exciting example of this phenomenon.²⁰⁴ However, it should be remembered that many, if not most, cytokines and their respective natural inhibitors are ubiquitously expressed and have myriad biologic properties that influence virtually every organ system ([Figure 1](#)). It is already apparent that these molecules may also be effective in allergic and inflammatory conditions. Furthermore, the emerging understanding of their role and the availability of recombinant molecules for therapeutics suggests that the clinical role of these agents will continue to grow and may ultimately impact most fields of medicine.

Acknowledgment

This chapter combined and updated from the earlier chapters, called “Interferons” and “Cytokines and Hematopoietic Growth Factors”, in the prior edition of *Cancer Medicine*. In this earlier edition, these chapters were written by the authors, Dr. Ernest C. Borden (Interferons) and in collaboration with Dr. Razelle Kurzrock (Cytokines and Hematopoietic Growth Factors), whose prior contributions provided important basis of this update.

Chapter 64

Monoclonal serotherapy

Robert C. Bast Jr. MD ■ Michael R. Zalutsky, PhD, MA ■ Arthur E. Frankel, MD

Overview

Monoclonal antibodies have impacted significantly the care of patients with cancer. Some 22 monoclonal antibodies, cytotoxic drug conjugates, radionuclide conjugates, and targeted toxins have been approved by the US FDA for the treatment of a dozen different malignancies, although three of these biologicals are no longer marketed. Useful monoclonal antibodies have targeted proteins on the cancer cell surface most frequently (CD20 by rituximab and HER2 by trastuzumab and pertuzumab), inhibiting growth, inducing apoptosis, and enhancing chemotherapy, but some have targeted cytokines (IL-6 by siltuximab), growth factors [vascular endothelial growth factor (VEGF) by bevacizumab], and growth factor receptors (VEGFR2 by ramucirumab) that can affect endothelial cells in tumor vessels, or have altered the immune response by neutralizing checkpoint inhibitors (CTLA4 by ipilimumab and PD1 by nivolumab or pembrolizumab). In the case of trastuzumab and pertuzumab, binding of the two antibodies to different sites on HER2 cell surface receptors has produced greater antitumor activity than either alone. Enhanced cancer cell killing has also been achieved by conjugation of antibodies with cytotoxic drugs (emtansine to anti-HER2 trastuzumab and vedotin to anti-CD30 brentuximab) or radionuclide conjugates (^{90}Y to anti-CD20 ibritumomab tiuxetan) permitting effective treatment for patients who had failed therapy with unconjugated antibodies. There are several barriers to effective therapy with monoclonal antibodies including antigen specificity, antigenic modulation, heterogeneity of antigen expression, effective delivery of antibodies to cancer cells, potency of effector mechanisms, and response to foreign globulin. The latter problem has been circumvented with the use of chimeric constructs, humanization of murine antibodies, and developing genetically engineered mice with the ability to develop fully human antibodies. Use of unconjugated antibodies is likely to improve as our knowledge of tumor biology and immunology grows, identifying targets such as OX-40 ligand. Use of smaller molecularly engineered binding constructs may improve pharmacokinetics and pharmacodynamics of serotherapy. Combinations of antibodies may be required to compensate for antigenic heterogeneity. Development of antibody drug conjugates will require the identification of monoclonal reagents that target tumor initiating stem cells. Pretargeting and the use of α -emitters are promising approaches to improving antibody-radionuclide conjugates. Development of targeted toxins must be further explored.

Introduction

Following the initial report of Kohler and Milstein,¹ monoclonal antibody technology exerted a prompt and substantial impact on laboratory investigation. Over the past four decades, the availability of monoclonal reagents has permitted the development of novel markers for *in vitro* applications, including monitoring response to treatment, detecting malignant cells histochemically, identifying subsets of patients with particularly favorable or unfavorable prognoses, and distinguishing some tumors of unknown origin.

Application of monoclonal antibodies for the *in vivo* treatment of human cancer has been more gradual, but serotherapy with monoclonal antibodies and their conjugates now has an established role in the management of a dozen hematopoietic and solid cancers.²⁻⁵

By 2015, the United States Food and Drug Administration (FDA) has approved 43 unconjugated monoclonal antibodies, drug conjugates, and radionuclide conjugates for therapeutic indications, including transplant rejection, coronary thrombosis, respiratory syncytial virus and anthrax infections, rheumatoid arthritis, systemic lupus erythematosus, paroxysmal nocturnal hemoglobinuria, macular degeneration, inflammatory bowel disease, psoriasis, asthma, and cancer.^{6, 7} Twenty-one of the 43 have been approved for the treatment of different cancers, as has one targeted toxin ([Table 1](#)). Three previously approved antibodies with anticancer activity have been withdrawn from the market. Unmodified monoclonal antibodies contribute to the care of patients with acute lymphoblastic and chronic lymphocytic leukemias (CLLs), Hodgkin and non-Hodgkin lymphomas (NHLs), Castleman disease, neuroblastoma, HER2-amplified breast cancer, non-small-cell lung cancer (NSCLC), head and neck cancer, renal cell cancer (RCC), colorectal cancer, and gastric cancer. With the general availability of these agents, it appears that monoclonal serotherapy has a well-established role in clinical oncology.

Table 1 Monoclonal antibodies, radionuclide conjugates, and targeted toxins approved in the United States for treatment of cancer⁷

Antibody	Product name	FDA approved	Type	Antigenic target	Indication
Rituximab	Rituxan	1997	Chimeric	CD20	Relapsed or refractory follicular and low-grade non-Hodgkin lymphoma
Trastuzumab	Herceptin	1998	Humanized	HER-2	Metastatic breast cancers that overexpress HER-2
Denileukindefitox	Ontak	1999	Humanized	CD25	Cutaneous T-cell leukemia
Gemtuzumab	Mylotarg	2000 ^a	Humanized ADC	CD33	Relapsed acute myelogenous leukemia in elderly patients
Alemtuzumab	Campath	2001 ^a	Humanized	CD52	B-cell chronic lymphocytic leukemia
⁹⁰ Y-ibritumomab tiuxetan	Zevalin	2002	Murine ARC	CD20	Relapsed or refractory follicular and low-grade non-Hodgkin lymphomas in elderly patients and rituximab-resistant disease
¹³¹ I-tostuzumab	Bexxar	2003 ^a	Murine ARC	CD20	Relapsed or refractory follicular and low-grade non-Hodgkin lymphomas in elderly patients and rituximab-resistant disease
Cetuximab	Erbitux	2004	Chimeric	EGFR	Metastatic colorectal cancer with irinotecan
		2006			Head and neck cancers with radiotherapy
Bevacizumab	Avastin	2004	Humanized	VEGF	Metastatic colorectal cancer
		2006			Non-small cell lung cancer
		2008 2009 2009 2014			Advanced breast cancer ^a Renal Cell Glioblastoma Ovarian

In an attempt to exert greater antitumor activity *in vivo*, monoclonal antibodies have been linked to cytotoxic drugs, radionuclides, and immunotoxins. Extensive preclinical and clinical studies have now been performed with each type of immunoconjugate, with several approved by the FDA for the treatment of different cancers.⁸ This chapter considers the current use as well as some of the challenges and additional opportunities for the further clinical application of monoclonal reagents, drug conjugates, radionuclide conjugates, and targeted toxins for the treatment of patients with cancer.

Serotherapy for leukemia and lymphoma with unmodified monoclonal antibodies

With rare exceptions, murine monoclonal antibodies raised against human neoplasms recognize tumor-associated antigens, which are also expressed by normal adult or fetal tissues. Some antigens, however, are expressed by only a small number of normal cells that may not be essential to a patient's well-being. Unconjugated monoclonal antibodies have contributed significantly to the care of patients with lymphoma³ and leukemia.^{9, 10}

Anti-idiotypic antibodies

In the early 1980s, Levy and colleagues prepared tumor-specific murine monoclonal antibodies against the unique idiotypes associated with cell surface membrane immunoglobulin present on human B-cell lymphomas, but expressed by a very small subset of normal B cells.^{11, 12} Treatment of 18 lymphoma patients with anti-idiotypic antibodies alone produced an objective response rate of 67% with little toxicity, and one patient remained in complete remission for 72 months and survived for >17 years.⁶ In subsequent trials, anti-idiotypic antibodies were combined with interferon (IFN)- α , chlorambucil, or interleukin (IL)-2. Most of the antibodies that produced responses *in vivo* were of the murine immunoglobulin G1 (IgG1) isotype, which is generally least efficient in fixing complement or participating in antibody-dependent cell-mediated cytotoxicity (ADCC). Anti-idiotypic antibodies that bind to the B-cell receptor complex appear to induce apoptosis (programmed cell death) by delivering a death signal. In a fraction of patients treated with anti-idiotypic antibodies, recurrence of lymphoma is associated with loss of the relevant antigen from the cancer cells. Genes encoding the cell surface membrane immunoglobulin continue to undergo point mutations, resulting in the loss of idiotypic determinants.¹³ Use of anti-idiotypic antibodies has provided critical proof of concept, but widespread application has been hindered by the logistic challenge of developing reagents for each patient.

Anti-CD20 antibodies

Rituximab (Rituxan®)

Monoclonal antibodies against B cell differentiation antigens expressed by malignant cells from different patients have been used to treat NHL, as well as acute and chronic leukemias. One useful target is CD20, a 35-kDa phosphoprotein calcium channel expressed on the surface of all normal B cells and in 80% of NHLs but not on other normal tissues. Antibodies specific for different epitopes on CD-20 are classified as type I antibodies that translocate CD20 into detergent-insoluble lipid rafts in the cell membrane facilitating complement-dependent cytotoxicity (CDC) and type II antibodies that do not induce lipid rafts and facilitate ADCC by Fc γ receptor-bearing natural killer (NK) cells and macrophages.³ Repeated weekly administration of the type I chimeric mouse/human IgG1 anti-CD20 antibody rituximab produced a 48–50% response rate in patients with relapsed low-grade follicular NHL, with a median time to progression of 10.2–13.2 months.^{14, 15} In 37 newly diagnosed patients, treatment with rituximab produced an overall response rate (ORR) of 72%, with 36% complete responses and median time to disease progression of 2.2 years.¹⁶ Consequently, rituximab was used initially to treat patients with relapsed or refractory indolent follicular NHL. Use was extended to treat newly diagnosed low-grade NHL patients with rituximab alone or in combination with chemotherapy as well as for maintenance therapy.¹⁷ Rituximab has also contributed to the care of patients with diffuse large B cell NHL, CLL and autoimmune diseases.

Follicular and indolent NHL

Since regulatory approval by the US FDA in 1997 for the treatment of patients with recurrent or refractory

follicular or indolent NHL, indications have been extended to provide 8 rather than 4 weekly courses and to retreat patients who had responded previously.¹⁸ After relapse, retreatment with a similar course of rituximab produced an overall response rate of 38% in 60 patients, with 10% complete remissions. Median time to progression exceeded 15 months.¹⁹ Combination of rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy (R-CHOP) in 40 patients with low-grade follicular lymphoma, some of whom had been treated previously, resulted in an overall response of 100%, with 58% complete remissions and 42% partial remissions. Median time to progression exceeded 40.5 months.²⁰ In a meta-analysis of 7 trials with 1943 patients with follicular lymphoma, other indolent lymphomas, and the more aggressive mantle cell lymphoma, the addition of rituximab to chemotherapy improved overall survival (OS), although the statistical significance was higher with indolent lymphomas than with the mantle cell histotype.²¹ The addition of rituximab to cyclophosphamide, vincristine, and prednisone (CVP) chemotherapy prolonged time to progression in patients with newly diagnosed follicular NHL, resulting in FDA approval in 2006 for use of rituximab in first-line therapy.²² Maintenance therapy with rituximab has prolonged progression-free survival (PFS) in four randomized trials, while OS has been extended in some but not all studies.²³ In 2011, the US FDA approved rituximab for maintenance therapy based on a randomized comparison of rituximab (up to 12 8-week cycles) to no maintenance therapy in 1018 patients with high tumor burden follicular NHL who had complete or partial response to rituximab plus one of three chemotherapy regimens. Maintenance rituximab reduced the risk of a PFS event by 46% ($P < 0.0001$). At 3 years, PFS in the rituximab maintenance group was 74.9% versus 57.6% in the observation group ($P < 0.0001$).²⁴

Diffuse large B-cell NHL

More aggressive diffuse large B-cell lymphoma (DLBCL) has been less responsive to rituximab alone. Among 54 patients with disease in relapse, the overall response rate to 8 cycles of rituximab was 31%, including 9% complete remissions with a median time to progression in responders of 8 or more months.²⁵ Subsequently, 399 elderly patients with more aggressive DLBCL were randomized to receive R-CHOP or CHOP alone. A complete response rate of 76% was observed with the combination, compared with 60% with CHOP alone.²⁶ Event-free survival ($P < 0.005$) and OS ($P < 0.01$) were prolonged significantly by the addition of rituximab. Similar results were obtained in two confirmatory trials,^{27, 28} both in young and elderly individuals, resulting in FDA approval in 2006 for use of R-CHOP in DLBCL, and providing the first improvement in the systemic treatment of DLBCL in two decades. In a recent meta-analysis of 7 trials involving 1470 patients with relapsed or refractory DLBCL, maintenance therapy with rituximab provided numerically improved PFS and OS, but the differences were not statistically significant, whereas incorporation of rituximab in salvage therapy led to statistically significantly better OS ($P = 0.02$) and PFS ($P < 0.05$) than rituximab-free regimens.²⁹ However, the rate of infection-related adverse events was higher with rituximab treatment (RR = 1.37; $P = 0.001$).

CLL and Waldenstrom macroglobulinemia

Treatment with rituximab, alone or in combination with fludarabine, has been extended to CLL.³⁰ In early studies, only a very modest response rate (15%) was observed with low standard doses of rituximab, possibly related to the lower concentration of CD20 on the CLL cell surface (8–15,000 vs 90,000 sites/cell) and to the shedding of soluble CD20, creating an “antigenic sink.”^{31, 32} Treatment with higher doses of rituximab or thrice weekly administration achieved an overall response rate of 46%, with an even higher response rate in previously untreated patients.³¹ A Cancer and Leukemia Group B (CALGB) trial of fludarabine and rituximab in 42 patients with CLL yielded a 100% response rate, with 48% of

patients achieving complete remission.³³ On the basis of the two randomized phase III studies where the addition of rituximab to fludarabine and cyclophosphamide extended PFS by 10–19 months in previously treated and untreated patients with CLL,^{34, 35} the US FDA approved rituximab in combination with fludarabine and cyclophosphamide in 2010. Rituximab has also been used with alkylating agents to treat Waldenstrom macroglobulinemia. One study reported a 74% response rate and 67% 2-year PFS with a combination of rituximab, dexamethasone, and cyclophosphamide.³⁶

Autoimmune disease

Depletion of B lymphocytes has contributed to the management of autoimmune diseases. Rituximab has been approved in combination with methotrexate for the treatment of rheumatoid arthritis that has failed anti-tumor necrosis factor (TNF) therapy, as well as for treatment of granulomatosis polyangiitis (Wegener's granulomatosis) and microscopic polyangiitis (MPA) with glucocorticoids.³⁷

Toxicity

Rituximab therapy is generally well tolerated. Most side effects are infusion related and occur within the first few hours of treatment. Adverse events generally last minutes to hours and include chills, fever, nausea, vomiting, fatigue, headache, pruritus, and the sensation of throat swelling.³⁸ Although side effects are experienced by up to 77% of patients, they are severe in only 10%.³⁹ Normal B-lymphocyte counts can decrease to zero after initial infusion; recovery begins by 6 months and is generally complete by 9–12 months. As CD20 is not expressed on mature plasma cells, immunoglobulin levels are maintained, and intercurrent infections requiring hospitalization occurred in only 2% of patients during 1-year follow-up. Following FDA approval in 1997 and before 2002, >125,000 patients were treated with rituximab in the United States. Among these individuals, only eight deaths were associated with treatment related to the development of infusion reactions, paraneoplastic pemphigus, Stevens-Johnson syndrome, and toxic epidermal necrolysis.⁴⁰ More than 120 cases of interstitial lung disease have been reported, generally when rituximab has been given with chemotherapy, but associated with monotherapy in 25%.⁴¹ In recent years, rituximab treatment has been linked to reactivation of hepatitis B virus (HBV) in HBsAg-negative/HBcAb-positive patients. In one meta-analysis of 578 patients across 15 studies, the risk of reactivation was estimated at 6.3%,⁴² suggesting that patients should be tested and antiviral prophylaxis given to patients with evidence of previous HBV infection who are receiving rituximab.

Mechanism of action and resistance

The mechanism(s) by which rituximab kills leukemia and lymphoma cells is not completely understood but probably involves ADCC, CDC, and the direct effect of CD20 ligation.⁴³ In cancer cells, cross-linking CD20 can induce cell cycle arrest, inhibit DNA synthesis, activate caspases, and induce apoptosis.³³ Sensitization to chemotherapy may relate to inhibiting the constitutive activation of AKT, thus downregulating the antiapoptotic protein Bcl-XL.⁴⁴ NK cells, macrophages, and polymorphonuclear leukocytes can be important effectors for ADCC,³³ and a correlation has been observed in some studies, between clinical response to rituximab and the presence of specific allelic polymorphisms in the FcγRIIIa and FcγRIIa receptors for IgG that are required to mediate ADCC.⁴⁵ Individual NK cells are capable of “serial killing” of multiple lymphoma cells, particularly in the presence of rituximab that creates a “cap” at one pole of the cancer cell containing CD20, ICAM-1, and the microtubule-organizing center that enhances sensitivity to NK killing.^{3, 46} The response to rituximab is impaired in mice genetically deficient in C1q that lack the first component of the CDC pathway but that have intact ADCC.⁴⁷ Clinical resistance to rituximab treatment rarely involves loss of CD20 expression but can be associated with upregulation of

complement resistance proteins CD55 and CD59.⁴⁸ Interestingly, different patterns of gene expression have been observed in lymphoma cells obtained before treatment from responders and nonresponders to rituximab.⁴⁹ Gene expression in tumors that failed to respond resembled that in normal lymphoid tissues and exhibited higher expression of genes encoding certain complement components and genes involved in cytokine, T cell, and TNF signaling.

Ofatumumab (Arzerra®)

Ofatumumab (Arzerra®) is a type I human anti-CD20 IgG1 that binds to an epitope distinct from that recognized by rituximab with greater avidity and slower off-rates facilitating both CDC and ADCC. Ofatumumab was approved by the US FDA in 2009 for treatment of CLL based on a multicenter, randomized, open-label trial comparing ofatumumab in combination with chlorambucil to single agent chlorambucil.⁵⁰ The trial enrolled 447 patients for whom fludarabine-based therapy was considered inappropriate by the investigator for reasons that included advanced age (median 69 years) or presence of comorbidities (72% with two or more comorbidities). Median PFS was 22.4 months for patients receiving ofatumumab in combination with chlorambucil compared to 13.1 months for patients receiving single-agent chlorambucil ($P < 0.001$).

Toxicity

The most common (>5%) adverse reactions with ofatumumab in combination with chlorambucil were infusion reactions, neutropenia, asthenia, headache, leukopenia, herpes simplex, lower respiratory tract infection, arthralgia, and upper abdominal pain. Overall, 67% of patients who received ofatumumab experienced one or more episodes of infusion reaction and 10% experienced a grade 3 or greater infusion reaction.

Obinutuzumab (Gazyva®)

Obinutuzumab (Gazyva®) is a type II humanized anti-CD20 IgG1 that acts predominantly through ADCC and has been glycoengineered to enhance binding to FcγR on effector cells.³ Binding of obinutuzumab to CD20 can initiate intracellular signaling, reorganizing actin fibers, increasing lysosomal membrane permeability, and producing nonapoptotic cell death.⁵¹ Obinutuzumab was approved by the US FDA in 2013 for treatment of CLL based on a randomized open-label multicenter trial comparing chlorambucil alone and in combination with obinutuzumab in 781 previously untreated participants who were elderly or had comorbidities.⁵² Patients receiving obinutuzumab in combination with chlorambucil demonstrated a significant improvement in average PFS of 26.7 months compared to 11.1 months with chlorambucil alone.

Toxicity

The most common side effects in participants receiving obinutuzumab in combination with chlorambucil were infusion-related reactions, neutropenia, thrombocytopenia, anemia, musculoskeletal pain, and fever. Obinutuzumab was approved with a boxed warning regarding HBV reactivation observed with other anti-CD20 antibodies and rare cases of progressive multifocal leukoencephalopathy identified in participants on other trials of obinutuzumab.

Chlorambucil in combination with either obinutuzumab or ofatumumab provides an alternative for elderly CLL patients with comorbidities who are unlikely to tolerate fludarabine-based therapy.¹⁰

Antibodies against other lymphocyte-associated cell surface proteins

Over the past three decades, clinical trials have been conducted to evaluate antibodies against CD22, CD23, CD40, CD74, and CD80 in patients with different B cell-derived cancers.²³ In early studies of CD10-positive acute lymphoblastic leukemia (ALL), anti-CD10 antibody-induced prompt modulation of the common ALL antigen, preventing effective therapy.⁵³ Intravenous infusion of anti-CD5 also produced antigenic modulation and only transient, partial regression in a fraction of patients with T-cell leukemia/lymphoma and CLL.⁵⁴ In one of the first studies of serotherapy with monoclonal reagents, a serum-blocking factor was demonstrated that prevented binding of the monoclonal antibody to circulating lymphosarcoma cells, consistent with the presence of shed tumor antigen.⁵⁵

Antibodies against IL-6

Castleman disease is a lymphoproliferative disorder caused by release of IL-6 or other cytokines that can be localized to a single lymph node group or can be multicentric. Cytokine release can be stimulated by HHV-8 infection, but a fraction of Castleman disease cases are HHV-8 negative and the source of IL-6 has not been well defined.

Siltuximab (Sylvant®)

Siltuximab (Sylvant®) was approved by the US FDA and the EU in 2014 for treatment of HIV-negative, HHV-8-negative multicentric Castleman disease. Approval was based on an international, multicenter, randomized (2 : 1), phase 2 study comparing intravenous infusions of siltuximab and best supportive care (BSC) in 53 patients to placebo and BSC in 26 patients.⁵⁶ Siltuximab produced a greater fraction of durable (18 weeks) tumor and symptomatic responses (34% vs 0%; $P = 0.0012$), tumor responses (38% vs 4%; $P < 0.05$), median time-to-treatment failure (>422 days vs 134 days; $P < 0.05$), and increased hemoglobin (36% vs 0%; $p < 0.05$) relative to the placebo controls. Despite success in the management of Castleman disease, siltuximab has failed to demonstrate clinical activity against other malignancies where IL-6 signaling is thought to be important, including multiple myeloma, RCC, and prostate cancer.⁵⁷

Toxicity

Common adverse reactions (>10% compared to placebo) during treatment with siltuximab include pruritus, increased weight, rash, hyperuricemia, and upper respiratory tract infections. Consequently, siltuximab provides an excellent example of a targeted therapy against a cytokine that drives a rare, but debilitating lymphoproliferative disease.

Serotherapy for solid tumors with unmodified monoclonal antibodies

The HER family of transmembrane tyrosine kinase growth factor receptors has provided targets for serotherapy in solid tumors. As outlined in 108, interaction of peptide growth factor ligands with HER family receptors triggers signaling through the Ras-mitogen-activated protein kinase (MAPK) pathway and the phosphatidylinositol 3-kinase (PI3K) pathways, enhancing cell cycle progression, proliferation, and survival in normal cells and cancer cells. Of the four HER family receptors, most attention has been given to HER-1 (epidermal growth factor receptor or EGFR) and to HER-2.

Anti-EGFR antibodies

Several monoclonal antibodies have been prepared against the extracellular domain of the 170-kDa

EGFR that is overexpressed in a number of carcinomas, including NSCLC, head and neck cancers, pancreatic cancer, and colorectal cancers.

Cetuximab (Erbix®)

Cetuximab (Erbix®) is a chimeric IgG1 monoclonal antibody that blocks the ligand-binding site of EGFR, preventing receptor activation, inducing internalization, and downregulating receptor levels. In experimental systems, treatment of human cancer cells with cetuximab produces cell-cycle arrest in G0–G1, induces p21, directs hypophosphorylation of Rb, inhibits proliferation, and blocks the production of angiogenic factors such as vascular endothelial growth factor (VEGF).⁵⁸ In addition, treatment with cetuximab potentiates the activity of doxorubicin, paclitaxel, topotecan, and irinotecan as well as radiation therapy in nude mouse heterografts of human cancer. Potentiation of cytotoxic chemotherapy and radiation therapy may relate to inhibition of MAPK and PI3K with induction of BAX, activation of caspase 8, and downregulation of BCL-2 and NFκB, rendering cancer cells more sensitive to apoptotic stimuli.⁵⁹ In addition, cetuximab can induce ADCC in the presence of peripheral blood mononuclear cells. Very little EGFR expression is required to mediate cancer cell death from ADCC.⁶⁰ As in the case of rituximab, FcγR polymorphisms correlated with PFS after treatment with cetuximab, consistent with the importance of ADCC as a mechanism of cancer cell killing.⁶¹

Colorectal cancer

Weekly treatment with cetuximab alone produced partial remissions in 9% of 57 patients with chemotherapy-refractory colorectal cancer.⁶² In two larger trials, a combination of irinotecan and cetuximab was used to treat a total of 450 patients with documented metastases from EGFR-positive colorectal cancer who had received irinotecan previously.⁶³ A combination of cetuximab and irinotecan produced a partial response in 17–23% compared with 11% of patients retreated with irinotecan alone. In one study, PFS, but not OS, was prolonged significantly from 1.1 to 4.1 months with the combination. In a subsequent phase III study, 1289 patients with recurrent EGFR expressing colorectal cancer who had been treated previously with first-line fluorouracil- and oxaliplatin-containing regimens were randomized to cetuximab plus irinotecan or irinotecan alone. Cetuximab improved disease-free survival significantly, but not OS, possibly related to cross-over in 47% of patients.⁶⁴ Interestingly, the level of EGFR expression has not correlated with response to cetuximab-based therapy. Consistent with this observation, 4 of 16 previously treated patients (25%) with EGFR immunohistologically negative cancers responded to a combination of cetuximab and irinotecan.⁶⁰ Consequently, patients should not be excluded from treatment based on immunohistochemical evaluation of EGFR. In 2004, the US FDA provided accelerated approval for cetuximab in combination with irinotecan to treat patients with irinotecan-resistant colorectal cancer. In 2007, regular approval was given, based on a trial where 572 patients with advanced EGFR-positive colorectal cancers that had failed oxaliplatin- and irinotecan-based regimens were randomized to BSC with or without cetuximab until progression. Cetuximab improved OS from 4.6 to 6.1 months ($P = 0.0048$).⁶⁵ Approval was given also for use of cetuximab as a single agent to treat colorectal cancer that had failed oxaliplatin- and irinotecan-based regimens.

Similar to clinical results with small molecule inhibitors and other monoclonal antibodies reactive with EGFR, responses to cetuximab are rare in cancers with *KRAS* mutations.⁶⁶ In retrospect, exclusion of patients with *KRAS* mutations affected the outcome substantially of the CRYSTAL trial where 1217 previously untreated patients with metastatic colorectal cancer were randomized to FOLFIRI alone or in combination with cetuximab, irrespective of *KRAS* mutation status.^{67, 68} Addition of cetuximab prolonged median PFS from 8.1 to 8.9 months ($P = 0.036$) and did not affect OS. When cancers were tested for

KRAS mutations, the addition of cetuximab to FOLFIRI increased OS (19.5–23.5 months), PFS (8.1–9.5 months), and ORR (39% vs 57%) in patients with *KRAS* wild-type tumors. In patients with *K-RAS* mutant cancers, no improvement in OS, PFS, or ORR was associated with the addition of cetuximab to FOLFIRI. Supportive data were found in two other randomized trials where only patients with *KRAS* wild-type cancers benefitted,^{69, 70} resulting in approval in 2012 for cetuximab in combination with FOLFIRI for previously untreated patients with colorectal cancer.

Head and neck cancer

Cetuximab has also been approved for use in squamous cell carcinoma of the head and neck (SCCHN). In a pivotal multinational, phase III study, 424 patients with locally advanced head and neck cancers were randomized to high-dose radiotherapy or to a combination of radiotherapy with cetuximab.⁷¹ The addition of cetuximab increased the duration of locoregional control from 15 to 24 months and increased OS from 29 to 49 months. When cetuximab was administered to patients with recurrent SCCHN who had progressed on platinum-based therapy, response rates of 10–13% were observed over three prospective trials ($n = 103$) with disease control rates of 46–56%.⁷² The median time to disease progression ranged between 2.2 and 2.8 months, and the median OS ranged between 5.2 and 6.1 months.

Cetuximab has also improved the efficacy of platinum-based chemotherapy for SCCHN. Approval by the US FDA in 2011 was based on a multicenter trial in 442 patients with locoregionally recurrent or metastatic head and neck cancer who were randomly assigned to receive cisplatin (or carboplatin) with 5-FU with or without cetuximab.⁷³ Significant improvements were seen in OS (10.1 months vs 7.4 months; $P = 0.34$), PFS (5.5 months vs 3.3 months; $P < 0.0001$), and objective response rates (35.6% vs 19.5%; $P = 0.0001$) in patients receiving cetuximab plus chemotherapy.

Toxicity

Side effects in a majority of patients included an acneiform rash, predominantly on the face and upper torso ([Figure 1](#)), and a composite syndrome of asthenia, fatigue, and malaise or lethargy. Treatment with minocycline can reduce the severity of the acneiform rash.⁷⁴ Meta-analysis has found that the intensity of the rash correlates with OS, PFS, and ORR.⁷⁵ Hypomagnesemia results from the direct effect of cetuximab on EGFR in distal renal tubules, producing magnesium wasting.⁷⁶ A small minority of patients have experienced severe anaphylactic reactions, often on the initial infusion of cetuximab, related to a preexisting IgE antibody against galactose- α -1,3-galactose oligosaccharide found on the Fab portion of the cetuximab heavy chain.⁷⁷

Figure 1 Recurrent melanoma, unresponsive to radiotherapy, before immunotherapy with intralesional injections of human monoclonal antibody to GM2 or GD2.

Panitumumab (Vectibix®)

Panitumumab (Vectibix®) is a fully humanized IgG2 anti-EGFR antibody that was given accelerated approval by the US FDA in 2006 based on a trial in 463 patients with EGFR-positive colorectal cancer resistant to standard drugs who were randomized to single-agent antibody therapy or BSC. Treatment with panitumumab produced an objective response of 10% compared to 0% in the BSC control group and extended mean PFS from 60 to 96 days.⁷⁸ As with cetuximab, responses were limited to patients with wild-type nonmutated *KRAS*.⁷⁹ Interestingly, in a recent meta-analysis, neither panitumumab nor cetuximab improved OS, PFS, or ORR in patients with *HRAS* wild type but *BRAF* mutant colorectal cancer, suggesting that sequencing *BRAF* might also identify patients who would not benefit from anti-EGFR treatment.⁸⁰ Approval of the antibody by the EU for use in colorectal cancer occurred in 2007. In previously untreated recurrent colorectal cancer, attempts to add panitumumab to bevacizumab plus FOLFOX-4 or FOLFIRI were discontinued when interim analysis of >1000 patients showed a statistically significant advantage in the control arm without panitumumab.⁸¹

Toxicity

A similar spectrum of side effects has been observed with panitumumab and cetuximab. Acneiform rash and hypomagnesemia have been most notable.⁸¹ To date, fewer allergic reactions have been observed with panitumumab than with cetuximab.

Anti-HER-2 antibodies

Approximately 20–30% of breast cancers overexpress the 185-kDa tyrosine kinase growth factor receptor c-erbB2 (HER-2).⁸² While HER-2 lacks a functioning ligand-binding domain, it is the preferred dimerization partner for the other HER family members including EGFR, HER-3, and HER-4.⁸³ Overexpression of HER-2 by breast cancer cells is associated with poor prognosis, particularly in node-

positive disease, as well as with resistance to paclitaxel, CMF, and tamoxifen; however, it is associated with an improved response to doxorubicin.^{84, 85} Resistance to systemic therapy, increased risk of recurrence, and shortened survival reflect the biological consequences of HER-2 overexpression, including increased proliferation, increased cell survival, increased invasion and metastasis, and increased angiogenesis. Monoclonal antibodies directed against the extracellular domain of this receptor can inhibit growth of cancer cells that overexpress HER-2.^{86, 87} In addition, treatment with anti-HER-2 antibodies can increase the susceptibility of cancer cells to platinum compounds, taxanes, doxorubicin, and 4-hydroperoxy-cyclophosphamide.^{88, 89} Interestingly, binding of anti-HER-2 antibodies to HER-2 receptors in the juxtamembrane region⁹⁰ can activate the tyrosine kinase⁸⁷ but may prevent ligand-driven interaction of HER-2 with HER-3 to activate the PI3 kinase pathway, decreasing the antiapoptotic activity of phospho-AKT.^{87, 91, 92} Antibodies have been developed that bind to different sites on the HER-2 molecule.

Trastuzumab (Herceptin®)

Trastuzumab (Herceptin®) is a humanized IgG1 antibody that binds to subdomain 4 of the extracellular domain of the HER-2 receptor preventing homodimerization to other HER-2 receptors and downregulating HER-2 receptor levels. *In vivo*, inhibition of proangiogenic factors and mediation of ADCC may also play a role. Trastuzumab has received FDA approval for treatment of metastatic breast cancer, early breast cancer, gastric cancer, and gastro-esophageal junction (GEJ) cancer.

Breast cancer

In early clinical studies, trastuzumab produced objective regression of recurrent breast carcinoma in 12–15% of 269 heavily pretreated women.^{93, 94} Although cisplatin has demonstrated marginal activity against breast cancer in previous studies, a combination of cisplatin and trastuzumab produced an objective clinical response in 24% of 37 patients, with median duration of 8.4 months.⁹⁵ A critical international multi-institutional study was performed in 469 women with recurrent breast cancer.⁹⁶ Patients who had not previously received adjuvant therapy with doxorubicin were randomized to doxorubicin (or epirubicin) and cyclophosphamide, with or without trastuzumab. Women who had received adjuvant doxorubicin were randomized to paclitaxel with or without trastuzumab. The addition of trastuzumab to chemotherapy was associated with longer time to disease progression (median 7.4 months vs 4.6 months; $P < 0.001$), higher objective response rate (50% vs 32%; $P < 0.001$), longer duration of response (median 9.1 months vs 6.1 months; $P < 0.001$), and longer survival (median 25.1 months vs 20.3 months; $P = 0.01$). This study resulted in the approval of trastuzumab by the US FDA in 1998 and the EU in 2000 for the treatment of recurrent HER-2-overexpressing breast cancers. Subsequently, six large, multicenter adjuvant trials were undertaken (reviewed in Breast Cancer Neoplasms) to test whether the addition of trastuzumab improved the ability of chemotherapy to prevent recurrence of primary HER-2-positive breast cancer. Interim analysis in five of the six trials demonstrated sufficiently dramatic improvement in disease-free survival to terminate the clinical studies and to recommend use of trastuzumab in this setting.^{97–99} Addition of trastuzumab produced a 46–58% reduction in risk of recurrence, associated with an absolute reduction of 8–12% at 3 years in the 5 positive trials. Similarly, mortality was reduced 33–59%, producing an absolute decrease of 2–6% at 3 years.

On the basis of the results of two of these trials (NSABP B31 and NCCTGN9831) including 3752 women, the FDA granted approval in 2006 for the addition of trastuzumab to cyclophosphamide, doxorubicin, and paclitaxel for adjuvant therapy of women with HER-2-overexpressed cancer.

Trastuzumab enhances the response rate to several other cytotoxic agents used to treat breast cancer,

including vinorelbine, gemcitabine, and platinum compounds.^{100–104} A randomized trial in 81 patients with metastatic HER-2-positive breast cancer who had not received chemotherapy for recurrent disease demonstrated a 51% response rate to vinorelbine and trastuzumab compared to a 40% response rate with paclitaxel and trastuzumab.¹⁰⁵ In most studies, only those breast cancers with strong expression of HER-2, driven by gene amplification, responded to the antibody alone or to a combination of antibody with chemotherapy. Immunohistochemistry can provide an initial screen for HER-2 overexpression, but 2+ to 3+ reactions should be confirmed with the more reliable fluorescence *in situ* hybridization assay.¹⁰⁶ HER-2 gene amplification can be acquired as breast cancers progress, arguing for repeated testing for HER-2 overexpression.¹⁰⁷ Because only a fraction of patients responds, overexpression of HER-2 is necessary, but not sufficient reason to ensure response to trastuzumab. Lack of response to trastuzumab correlated with lack of expression of the PTEN phosphatase, the enzyme that removes phosphate groups from PI3 and interrupts signaling through AKT.¹⁰⁸ Treatment with trastuzumab increased PTEN membrane localization and phosphatase activity by reducing PTEN tyrosine phosphorylation through inhibition of Src that could no longer dock on the HER-2 receptor.

Gastric and GEJ cancers

In 2010, the FDA granted approval for trastuzumab in combination with cisplatin and a fluoropyrimidine (either capecitabine or 5-fluorouracil) for the treatment of patients with HER-2-overexpressing metastatic gastric or GEJ carcinomas who had not received prior treatment for metastatic disease. The approval was based on results of a single international multicenter open-label randomized clinical trial, BO18255 (ToGA trial), which enrolled 594 patients with locally advanced or metastatic HER2-overexpressing adenocarcinoma of the stomach or GEJ.¹⁰⁹ Patients were randomly assigned to receive trastuzumab plus chemotherapy or chemotherapy alone. The trial was closed after the second interim analysis, when the addition of trastuzumab was associated with improved median survival (13.5 months vs 11.0 months; $P = 0.0038$). An updated survival analysis demonstrated a persistent advantage to trastuzumab (13.1 vs 11.7) with the greatest benefit seen in HER-2 overexpressing cancers.

Toxicity

Treatment with trastuzumab is well tolerated and is associated with low-grade fever, chills, and fatigue that, generally, are observed with the first administration. In many studies, trastuzumab has been administered weekly, but it has been administered every 3 weeks at higher dosage with acceptable toxicity and trough levels.¹¹⁰ When trastuzumab has been combined with doxorubicin or paclitaxel, increased cardiotoxicity has been observed. In the pivotal trial that demonstrated the efficacy of trastuzumab in recurrent breast cancer, American Heart Association class III and IV cardiac dysfunction occurred in 27% of the group given trastuzumab with anthracycline and cyclophosphamide compared to 8% of the group given anthracycline and cyclophosphamide alone.¹¹¹ A similar degree of cardiac dysfunction was observed in 13% of patients who received paclitaxel and trastuzumab compared with 1% who received paclitaxel alone. Long-term treatment of 218 breast cancer patients with trastuzumab-based therapy for at least 1 year was associated with an 11% incidence of class III cardiac dysfunction.¹¹² In the six adjuvant trials where trastuzumab was given sequentially or concurrently with paclitaxel or carboplatin, but not doxorubicin, class III/IV cardiac dysfunction was observed in 0.5–4.1%.^{98, 99} Cardiac dysfunction generally responds to discontinuing trastuzumab and providing medical management. Thus, the benefits of trastuzumab for recurrent disease or adjuvant treatment generally outweigh the risks in patients with normal baseline cardiac function. The mechanism for trastuzumab-induced cardiac dysfunction remains obscure. Only low levels of HER-2 are found on cardiac myocytes, but trastuzumab

can localize to the myocardium, and the ligand heregulin that binds to HER-2-HER-3 and HER-2-HER-4 dimers appears critical to the fetal development and survival of cardiac tissue under apoptotic stress.¹¹³ Use of less cardiotoxic anthracyclines in combination with trastuzumab offers one alternative. A neoadjuvant trial has been reported where concurrent epirubicin, paclitaxel, and trastuzumab produced a significantly higher pathological complete response (pCR) rate than did chemotherapy alone (67% vs 25%) without development of clinically evident congestive heart failure.¹¹⁴

Pertuzumab (Perjeta®)

Pertuzumab (Perjeta®) is an IgG1-humanized monoclonal antibody that binds to the dimerization domain of HER-2 at a site distinct from trastuzumab, preventing ligand-driven dimerization of HER-2 with multiple HER family members.^{115, 116} Use of pertuzumab in combination with trastuzumab synergistically inhibited survival of a breast cancer cell line that overexpressed HER-2 associated with increased apoptosis and blockade of signaling through AKT but not through MAPK.¹¹⁷ Pertuzumab was approved by the US FDA in 2012 and by the EU in 2013 for treatment of HER-2 amplified breast cancer based on a single clinical trial, Cleopatra, involving 808 patients with HER2-positive metastatic breast cancer who were randomly assigned to receive pertuzumab, trastuzumab and docetaxel, or trastuzumab and docetaxel with a placebo.¹¹⁸ Patients receiving pertuzumab had a median PFS of 18.7 months versus 12.4 months in the placebo group. With further follow-up, the addition of pertuzumab to trastuzumab and docetaxel increased OS by 15.7 months from 40.8 to 56.5 months ($P < 0.001$) and improved PFS by 6.3 months.¹¹⁹

In 2013, pertuzumab became the first FDA-approved drug for the neoadjuvant treatment of breast cancer in patients with HER-2-positive, locally advanced, inflammatory, or early-stage breast cancer (>2 cm in diameter or with positive lymph nodes) who are at high risk for recurrence and death. Pertuzumab was approved for use in combination with trastuzumab and other chemotherapy before surgery and, depending on the treatment regimen used, can be followed by chemotherapy after surgery. Following surgery, patients should continue to receive trastuzumab to complete 1 year of treatment. Pertuzumab's accelerated approval for neoadjuvant treatment was based on a study designed to measure pCR in accordance with a new FDA advisory that this could be used as a surrogate endpoint. In the NeoSphere study, 417 participants were randomly assigned to receive one of four neoadjuvant treatment regimens: trastuzumab plus docetaxel, pertuzumab plus trastuzumab and docetaxel, pertuzumab plus trastuzumab, or pertuzumab plus docetaxel.¹²⁰ About 39% of participants who received pertuzumab plus trastuzumab and docetaxel achieved pCR, compared to 21% who received trastuzumab plus docetaxel. The confirmatory trial for this accelerated approval is being conducted in participants with HER2-positive breast cancer who have had prior breast cancer surgery and are at high risk of having their cancer return. More than 4800 participants are enrolled in this trial, which will provide further data on efficacy, safety, and long-term outcomes. Results are expected in 2016.

Toxicity

The most common side effects reported in participants receiving pertuzumab plus trastuzumab and paclitaxel or docetaxel were hair loss, diarrhea, nausea, and neutropenia. Other significant side effects included decreased cardiac function, infusion-related reactions, hypersensitivity reactions, and anaphylaxis. There is a black box warning for cardiac failure and fetal damage.

Antiganglioside antibodies

GD2 is a disialoganglioside expressed on neuroblastomas and melanomas as well as on normal neurons, melanocytes, and pain fibers. Expression on cancer cells is relatively uniform and GD2 is not lost from

the cell surface after treatment with monoclonal antibodies.¹²¹

Dinutuximab (Unituxin®)

Dinutuximab (Unituxin®) is a chimeric anti-GD2 IgG1 antibody that was approved by the US FDA in 2015 for treatment of newly diagnosed pediatric patients with high-risk neuroblastoma who have achieved at least a partial response to first-line multiagent, multimodality therapy. Addition of dinutuximab improved outcomes for patients who received maintenance therapy with granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-2, and 13-cis-retinoic acid (RA).¹²² The pivotal COG trial randomized 226 patients to either dinutuximab/RA or RA alone for six cycles of treatment. An improvement in event-free survival (EFS) (HR 0.57; $P = 0.01$, log-rank test) was demonstrated during follow-up and the trial terminated. At that time, the median EFS was not reached [3.4 years, NR, in the dinutuximab/RA arm, and 1.9 years (1.3, NR) in the RA arm]. An analysis of OS conducted 3 years later documented an improvement in OS in the dinutuximab/RA arm compared to the RA arm (HR 0.58), although median OS had not yet been reached in either arm.

Toxicity

The most common (>25%) adverse drug reactions in the dinutuximab/RA group were pain, pyrexia, thrombocytopenia, infusion reactions, hypotension, hyponatremia, increased alanine aminotransferase, anemia, vomiting, diarrhea, hypokalemia, capillary leak syndrome, neutropenia, urticaria, hypoalbuminemia, increased aspartate aminotransferase, and hypocalcemia. The most common (>5%) serious adverse reactions in the dinutuximab/RA group were infections, infusion reactions, hypokalemia, hypotension, pain, fever, and capillary leak syndrome.

Antivascular therapy

Angiogenesis is critical for normal fetal growth and wound healing but is also required for tumor growth and metastasis.¹²³ Novel approaches to inhibiting angiogenesis have exploited the presence of antigens displayed on tumor-associated endothelium or the proangiogenic factors produced by tumor cells.

Bevacizumab (Avastin®)

Bevacizumab (Avastin®) is a humanized IgG1 that binds to the proangiogenic VEGF-A that has also been characterized as vascular permeability factor (VPF). Blockade of VEGF/VPF can inhibit tumor-driven angiogenesis in xenografts.¹²⁴ Expression of VEGF/VPF has correlated with formation of ascites in mice with ovarian cancer xenograft models.¹²⁵ Treatment with bevacizumab can completely inhibit ascites formation.¹²⁶ In addition, cancer cells themselves can express VEGF receptors. Autocrine stimulation with VEGF can enhance proliferation and resistance to chemotherapy. Bevacizumab has received FDA approval for treatment of colorectal cancer (2004, 2006, and 2013), NSCLC (2006), breast cancer (2008; withdrawn 2011), RCC (2009), glioblastoma (2009), cervical cancer (2014), and ovarian cancer (2014), but its place in oncologic practice is still being defined.¹²⁷

Colorectal cancer

In patients with previously untreated metastatic colorectal carcinoma, the addition of bevacizumab to irinotecan, fluorouracil, and leucovorin increased the overall response rate (34.8–44.8%) and significantly prolonged median PFS (7.4–10.4 months) and median OS (15.6–20.3 months).¹²⁸ This trial led to the initial FDA approval in 2004 of bevacizumab for use with chemotherapy for first-line therapy

of colorectal cancer. Two subsequent randomized phase 2 trials have demonstrated improved response rate, PFS, and OS when bevacizumab was added to 5-FU and leucovorin.^{129–131} In phase 3 studies where bevacizumab has been added to more effective first-line regimens, including FOLFOX-4 and XELOX, response rate, and OS were not significantly improved.^{132, 133} A number of combinations of bevacizumab and multiple drug combinations have provided similar results in noninferiority studies.¹³⁴ In second-line therapy, however, addition of a higher dose of bevacizumab to FOLFOX-4 significantly increased response rate (9–23%), PFS (4.7–7.3 months), and OS (10.8–12.9 months) in bevacizumab-naïve patients, leading to the approval of bevacizumab for second-line therapy in 2006.¹³⁵ In patients with metastatic colorectal cancer who had progressed on bevacizumab in combination with irinotecan-based chemotherapy or oxyplatin-based regimens, continued use of bevacizumab in combination with the complementary chemotherapy regimen improved OS (11.2 months vs 9.8 months; $P = 0.0062$) and PFS (5.7 months vs 4.0 months; $P < 0.0001$), leading to approval for continued use of bevacizumab in second-line therapy.¹³⁶

Non-small-cell lung cancer

In previously untreated metastatic NSCLC, three phase III trials have studied the addition of bevacizumab to carboplatin/paclitaxel,^{137, 138} or to gemcitabine/cisplatin.¹³⁹ Significant increases have been observed in response rates (range 14–28.1%) with a more modest increase in PFS (0.6–2.7 months) or OS (0.5–2.0 months).¹³⁴

Breast cancer

Addition of bevacizumab to paclitaxel in first-line treatment of patients with recurrent metastatic breast cancer significantly increased response rate (21–37%) and PFS (5.9–11.8 months).¹⁴⁰ A modest, but significant, increase in PFS (8.0–8.8 months) was observed when bevacizumab was added to docetaxel.¹⁴¹ In second-line therapy, the addition of bevacizumab to capecitabine significantly increased the response rate (9–20%) but not PFS (4.2–4.9 months) or OS (14.5–15.1 months).¹⁴² Given the limited effect of bevacizumab in confirmatory trials, approval of the drug was withdrawn for breast cancer.

Renal cell cancers

A majority of sporadic RCCs exhibit inactivation of the von Hippel Lindau (VHL) gene with consequent overexpression of VEGF.¹⁴³ In a randomized phase 2 trial that compared two doses of bevacizumab (3 or 10 mg/kg every 2 weeks) with placebo in previously treated patients with RCC, a significant prolongation of PFS was observed when high-dose bevacizumab was compared with placebo (2.5–4.8 months, $P < 0.01$).¹⁴⁴ IFN- α is a standard initial therapy for RCC with a modest response rate and a survival advantage demonstrated in randomized trials. Two phase 3 trials have compared treatment with IFN- α and bevacizumab to IFN- α alone in previously untreated patients with RCC.^{145, 146} PFS was increased significantly from 5.2–5.4 to 8.5–10.2 months.

Glioblastoma multiforme (GBM)

Bevacizumab demonstrated activity against GBM (glioblastoma multiforme) in two single-armed trials, AVF3708g and NCI 06-C-0064E, where monotherapy produced a 20–25% response rate lasting a median of 3.9–4.2 months in a total of 141 patients who had relapsed after surgery, radiotherapy, and temozolomide.¹⁴⁷ This prompted accelerated FDA approval for use in this setting. A recent double-blind, randomized trial evaluated whether the addition of bevacizumab to radiotherapy and temozolomide would

improve outcomes in 637 patients with newly diagnosed GBM.¹⁴⁸ Addition of bevacizumab increased PFS from 7.3 to 10.7 months ($P = 0.007$), but did not affect OS.

Ovarian cancer

In heavily pretreated patients with recurrent ovarian cancer, administration of bevacizumab, alone^{149, 150} or in combination with daily oral low-dose cyclophosphamide to provide “metronomic” therapy,¹⁵¹ has produced response rates of 16–24% with PFS of 4.4–7.2 months. Stabilization of disease for 6 months has been observed in approximately 40% of ovarian cancer patients. Four randomized studies have been performed evaluating the addition of bevacizumab to standard chemotherapy for front-line treatment (GOG 218¹⁵² and ICON7¹⁵³) and for recurrent “platinum sensitive” (OCEANS¹⁵⁴) and “platinum resistant” (AURELIA¹⁵⁵) disease.¹⁵⁶ PFS was improved in these studies by 3.8 months ($P < 0.001$), 1.7 months ($P = 0.001$), 3.3 months ($P = 0.001$), and 4.0 months ($P < 0.0001$), respectively. OS was not improved in any of the studies, but subsets of patients in GOG 218 and ICON7 with poor prognosis appeared to benefit. Lack of impact on OS overall and similar enhancement of PFS in first-line and recurrent disease has raised the question of whether treatment with bevacizumab should be delayed until disease recurrence.¹⁵⁶ Approval for use of bevacizumab in combination with chemotherapy for recurrent disease was granted based on the Aurelia trial.

Cervical cancer

Addition of bevacizumab to a combination of carboplatin with paclitaxel or topotecan increased OS by 3.7 months (from 13.3 to 17.0 months, $P = 0.004$) and increased the rate of response from 36% to 88% ($P = 0.008$) in a randomized trial including 452 women with recurrent, persistent, or metastatic cervical cancer.¹⁵⁷

Toxicity

In patients with NSCLC, RCC, colorectal, breast, cervical, and ovarian cancer, bevacizumab administration has been well tolerated by the majority. Grade 3 hypertension has been observed in approximately 20% of patients. While hypertension has been readily managed in most cases, malignant hypertension and fatal hemorrhagic stroke have been observed, arguing for aggressive monitoring and management of blood pressure. Significant proteinuria occurs in <5% of cases. Nasal bleeding has been observed. Greater risk for delayed wound healing and bleeding has been observed when bevacizumab was administered within 60 days of surgery.¹⁵⁸ In patients with NSCLC, major hemoptysis was associated with 4 deaths among 35 patients in one early trial. Life-threatening hemoptysis occurred most frequently in elderly males with squamous cell histology, tumor necrosis, and cavitation, as well as disease close to major vessels. Patients with these characteristics have been excluded from many trials. Thromboembolic events have been observed in 5–7.4% of participants on randomized trials in ovarian cancer.¹⁵⁶ Arterial thromboembolism has been observed in 2% of patients in large phase 3 trials across disease sites. In heavily pretreated patients with ovarian cancer, perforation of the bowel has been observed in 5–7% of cases, generally in the setting of partial small bowel obstruction and treatment response in lesions that involve the bowel wall. Bowel perforation has occurred in 2.6–3% of ovarian cancer patients on front-line adjuvant trials¹⁵⁶ and in only 1% of colorectal cancer patients when bevacizumab was administered with FOLFOX.¹³⁵

Ramucirumab (Cyramza®)

Ramucirumab (Cyramza®) is a human IgG1 monoclonal antibody that binds to the human VEGFR2 and

prevents interaction with VEGF ligands. Ramucirumab has been approved by the US FDA for treatment of gastric and GEJ cancers (2014), lung cancer (2014), and colon cancer (2015).

Gastric and GEJ cancers

Ramucirumab can be used for treatment of fluoropyrimidine-resistant or platinum-resistant gastric or GEJ cancer as a single agent or with paclitaxel. Approval of ramucirumab as a single agent was based on a multinational, randomized double-blind trial in 655 patients with previously treated advanced or metastatic disease who were randomized (2 : 1) to ramucirumab or placebo plus BSC. Addition of ramucirumab to paclitaxel significantly improved OS (9.6 months vs 7.4 months, $P = 0.017$) and PFS (4.4 months vs 2.9 months, $P < 0.001$).¹⁵⁹

Lung cancer

Ramucirumab in combination with docetaxel was approved for treatment of metastatic NSCLC that had progressed on platinum-containing regimens or anti-EGFR or anti-ALK targeted therapy. Approval of ramucirumab in combination with docetaxel was based on a double-blind, placebo-controlled clinical trial that enrolled 1253 patients with previously treated metastatic NSCLC.¹⁶⁰ Addition of ramucirumab to docetaxel significantly increased OS (10.5 months vs 9.1 months; $P = 0.024$) and PFS ($P < 0.001$).

Colorectal cancer

Ramucirumab can be used in combination with FOLFIRI for the treatment of patients with metastatic colorectal cancer whose disease has progressed on a first-line bevacizumab-, oxaliplatin- and, fluoropyrimidine-containing regimen. This approval is based on the results of a randomized, double-blind, multinational trial enrolling 1072 patients who were randomly allocated to receive FOLFIRI plus placebo or FOLFIRI plus ramucirumab.¹⁶¹ Addition of ramucirumab to FOLFIRI improved OS (13.3 months vs 11.7 months; $P = 0.023$) and PFS (5.7 months vs 4.5 months; $P < 0.001$).

Toxicity

Ramucirumab treatment can be associated with fatigue, weakness, hypertension, hyponatremia, diarrhea, and nose bleeds. When combined with paclitaxel or docetaxel, neutropenia, febrile neutropenia, and anemia have been observed. Other rare, but important risks described in product labeling include hemorrhage, arterial thromboembolic events, infusion-related reactions, gastrointestinal obstruction, gastrointestinal perforation, impaired wound healing, clinical deterioration in patients with cirrhosis, and reversible posterior leukoencephalopathy. Hypothyroidism has been observed in patients with colorectal cancer.

Immune checkpoint inhibitors

Anti-CTLA4

Anti-CTLA4 monoclonal antibodies have been used to intervene in immunoregulation. CD4⁺CD25⁺ T regulatory (Treg) cells express cytotoxic T-lymphocyte antigen 4 (CTLA4). The presence of Treg cells in tumor tissue has been associated with a poor prognosis in several human cancers and their elimination can potentiate antitumor responses in preclinical models. In addition, effective activation of tumor immunity can be blocked by the interaction of CD80/86 on antigen-presenting cells with CTLA4 on T lymphocytes. Inhibiting this interaction with anti-CTLA4 antibody could enhance tumor-specific

immunity.¹⁶²

Ipilimumab (Yervoy®)

Ipilimumab (Yervoy®) is a fully human IgG1 monoclonal antibody that reacts with CTLA4 and was approved for use by the US FDA and the EU in 2011 based on a single international study of 676 patients with melanoma who had stopped responding to other FDA approved or commonly used treatments for melanoma and were randomized to ipilimumab, ipilimumab plus a gp100 vaccine, or vaccine alone. Those who received the combination of ipilimumab plus vaccine or ipilimumab alone lived an average of about 10 months, while those who received only the experimental vaccine lived an average of 6.5 months. Administration of ipilimumab as a single agent has produced a 7–15% objective response rate in human melanomas and RCC.^{163, 164} Greater activity might be anticipated using these reagents to augment the effects of specific tumor vaccines. Among 1861 patients, median OS was 11.4 months, which included 254 patients with at least 3 years of survival follow-up. The survival curve began to plateau around year 3. Three-year survival rates were 22%, 26%, and 20% for all patients, treatment-naïve patients, and previously treated patients, respectively.¹⁶⁵ In an adjuvant study, 951 patients with completely resected stage III melanoma were randomized to ipilimumab or placebo. Median recurrence-free survival was prolonged by ipilimumab (26.1 months vs 17.1 months; $P = 0.0013$). Five (1%) patients died of drug-related events in the ipilimumab group.¹⁶⁶ Response to CTLA4 blockade correlates with mutational load, neo-antigens, and expression of cytolytic markers.^{167, 168}

Toxicity

Common side effects that can result from autoimmune reactions associated with ipilimumab use include fatigue, diarrhea, skin rash, uveitis, hypophysitis, endocrine deficiencies, and inflammation of the intestines (colitis) and hepatitis.¹⁶⁴ Severe to fatal autoimmune reactions were seen in 12.9% of patients treated with ipilimumab. When severe side effects occurred, ipilimumab was stopped and corticosteroid treatment was started. Not all patients responded to this treatment. Patients who did respond, in some cases, did not see any improvement for several weeks.

Anti-PD1

Anti-PD1 antibodies target T cell associated PD1, a second regulator of T-cell immunity, preventing interaction with the PD-L1 and PD-L2 ligands on cancer cells and macrophages. Blocking this interaction, releases inhibition of immune responses, including those to cancer cells.¹⁶⁹

Pembrolizumab (Keytruda®)

Pembrolizumab (Keytruda®), a humanized IgG4 that targets PD1 and prevents interaction with PD-L1 and PD-L2, was approved by the US FDA in 2014 for the treatment of melanoma that had progressed on ipilimumab but had not yet been treated with BRAF inhibitors. Approval was based on the results of a multicenter, open-label, randomized, dose-comparative, activity-estimating cohort including 173 patients with unresectable or metastatic melanoma who were randomized to receive 2 mg/kg ($n = 89$) or 10 mg/kg ($n = 84$) of pembrolizumab intravenously once every 3 weeks until disease progression or unacceptable toxicity. The ORR was 24% in the 2 mg/kg arm, consisting of one complete response and 20 partial responses. Among the 21 patients with an objective response, 3 (14%) had disease progression at 2.8, 2.9, and 8.2 months after initial response. The remaining 18 patients (86%) have ongoing responses, ranging from 1.4+ to 8.5+ months; 8 patients had ongoing responses of 6 months or longer. Similar ORR results were observed in the 10 mg/kg arm. In an extended randomized phase II trial, 6-month PFS was

34% in the 2 mg/kg arm, 38% in the 10 mg/kg arm, and 16% in a group receiving chemotherapy of the investigators' choice.¹⁷⁰ Pembrolizumab every 2 or 5 weeks has been compared to ipilimumab in a randomized trial with 834 patients. Six month PFS was 47.3% for pembrolizumab every 2 weeks, 46.4% for pembrolizumab every 3 weeks, and 26.5% for ipilimumab ($P < 0.001$).¹⁷¹

Toxicity

The most common (>20%) adverse reactions among patients receiving pembrolizumab 2 mg/kg every 3 weeks were fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgia, and diarrhea. The most frequent ($\geq 2\%$) serious adverse drug reactions observed with pembrolizumab were renal failure, dyspnea, pneumonia, and cellulitis. Additional clinically significant immune-mediated adverse reactions included pneumonitis, colitis, hypophysitis, hyperthyroidism, hypothyroidism, nephritis, and hepatitis.

Nivolumab (Opdivo®)

Nivolumab (Opdivo®), a human IgG4 anti-PD1 antibody, was approved by the FDA in 2014 for the treatment of previously-treated unresectable or metastatic melanoma that had failed ipilimumab and BRAF inhibitors. Approval was based on a single arm trial including 120 participants with a 32% objective response rate where approximately one-third of responders remained in remission for 6 months or more. When nivolumab was compared to dacarbazine in 418 previously untreated patients with BRAF wild-type melanoma, nivolumab produced >1 year OS (72.9% vs 42%, $P < 0.001$), PFS (5.1 months vs 2.2 months, $P < 0.001$), and objective response rate (40% vs 13.9%, $P < 0.001$).¹⁷² In patients who had progressed on anti-CTLA4, nivolumab improved objective response rate compared to the investigators' choice of chemotherapy (37.7% vs 10.6%).¹⁷³

Non-small-cell lung cancer

FDA approval was obtained in 2013 for nivolumab to treat patients with NSCLC who had failed platinum-based therapy based on a randomized trial where patients with metastatic squamous NSCLC who had experienced disease progression during or after one prior platinum-based chemotherapy regimen were assigned to nivolumab (135) or docetaxel (137).¹⁷⁴ Nivolumab demonstrated a statistically significant improvement in OS as compared with docetaxel (9.2 months vs 6 months; $P = 0.00025$). Approval was supported by a single-arm, multinational, multicenter trial in patients with metastatic squamous NSCLC who had progressed after receiving a platinum-based therapy and at least one additional systemic regimen. Patients ($n = 117$) who received nivolumab exhibited an ORR of 15%. All were partial responses, but 10 of the 17 responding patients (59%) had response durations of 6 months or longer.

Toxicity

The most common (>30%) adverse reactions among the 117 patients receiving nivolumab in the above single-arm trial were fatigue, dyspnea, musculoskeletal pain, decreased appetite, and cough. The most frequent grade 3 and 4 adverse drug reactions observed in at least 5% of patients treated with nivolumab were dyspnea, fatigue, and musculoskeletal pain. Clinically significant immune-mediated adverse reactions included pneumonitis, colitis, hepatitis, nephritis/renal dysfunction, hypothyroidism, and hyperthyroidism.

Combined nivolumab and Ipilimumab

A combination of nivolumab and ipilimumab improved objective response rate when compared to ipilimumab alone (61% vs 11%; $P < 0.001$) in 142 previously untreated melanoma patients with BRAF wild type cancer. Complete responses were observed in 22% of patients receiving the combination and 0% in patients receiving ipilimumab alone. PFS was prolonged in the combination arm ($P < 0.001$). Similar results were observed in patients with BRAF mutant melanomas.¹⁷⁵ A second randomized phase III study compared nivolumab plus ipilimumab to ipilimumab or nivolumab monotherapy in previously untreated stage III or stage IV melanoma. PFS was 11.5, 2.9, and 6.9 months, respectively ($P < 0.001$ for the combination). Grade 3–4 treatment-related adverse events occurred in 55% of patients in the combination arm compared to 27.3% in the ipilimumab arm.¹⁷⁶

Bispecific antibodies

Immunoglobulins can be engineered to contain binding sites with two different specificities. The same can be done with smaller single-chain variable fragments (scFv) that contain the relevant binding sites and have better tissue penetrance. Bispecific constructs with one scFv fragment that recognizes a determinant found only on B cells with a second scFv fragment that binds to a determinant found only on T cells can enhance contact between cytotoxic T cells and malignant B cells, encouraging immunologic cancer cell killing.

Blinatumomab (Blincyto®)

Blinatumomab (Blincyto®) is a bispecific antibody with scFv fragments that bind to the CD3 T-cell determinant and the CD19 B cell determinant that is expressed on ALL cells. Blinatumomab was approved by the US FDA in 2014 for the treatment of ALL refractory to conventional therapy based on a study involving 185 adults with Philadelphia chromosome-negative relapsed or refractory precursor B-cell ALL. All participants were treated with blinatumomab for at least 4 weeks via infusion, producing CR in 32% for 6.7 months.¹⁷⁷

Toxicity

Blinatumomab carries a boxed warning that some clinical trial participants had experienced cytokine-release syndrome at the start of the first treatment and experienced a short period of encephalopathy. The most common side effects seen in blinatumomab-treated participants were fever, headache, peripheral edema, febrile neutropenia, nausea, hypokalaemia, fatigue, constipation, diarrhea, and tremor.

Barriers to treatment with unmodified monoclonal antibodies

Antigen specificity

Few, if any, monoclonal antibodies react only with tumor cells and fail to react with normal tissues. The remarkable efficacy and modest toxicity of anti-idiotypic antibodies reflect, at least in part, their limited reactivity with the vast majority of human B cells. The toxicity of Campath-1, now withdrawn from the market, reflects reactivity with normal lymphocytes and monocytes. To treat cancers in some organs, such as ovary or thyroid, tissue-specific antibodies rather than tumor-specific antibodies may suffice because all normal tissue is removed during primary therapy.

Antigenic modulation

Antigens that modulate and are shed into the circulation, such as CD10 in ALL, have generally proven to

be poor targets for serotherapy. An exception to this generalization has been observed with trastuzumab treatment of breast cancers that overexpress HER-2. The extracellular domain of HER-2 is cleaved and has been used as a marker for receptor overexpression.

Heterogeneity of antigen expression

Heterogeneity has been observed in antigen expression within and between cancers from different individuals. Cells that lack antigen expression cannot be targeted effectively. With unconjugated antibodies that lack “bystander” activity, a combination of several reagents may be required to target all cells. In the case of different breast cancers, a combination of five monoclonal reagents can target >90% of cells in >90% of cancers from different individuals.¹⁷⁸

Effective delivery of antibody to tumor cells

Most attempts to develop effective serotherapy have utilized IgG antibodies with an Mr of 150 kDa. In contrast, most conventional cytotoxic drugs have a mass of <1 kDa. Consequently, monoclonal antibodies have slower kinetics of distribution and less tissue penetration than do conventional drugs.¹⁷⁹ For example, intravenous injection of an IgG2a murine monoclonal antibody against a 250-kDa melanoma-associated chondroitin sulfate proteoglycan core protein resulted in selective localization of antibody in metastatic nodules of malignant melanoma.¹⁸⁰ The greater the amount of antibody administered, the greater was the accumulation of murine immunoglobulin that could be demonstrated immunohistochemically in biopsied material. Even after the infusion of 500 mg of antibody, complete saturation of antigenic sites was not achieved in all patients, consistent with limited access of antibody to tumor cells outside the vascular compartment. Successful tumor localization of an antibody depends on several factors. The ability of monoclonal antibodies to reach tumor cells can be limited by abnormal vascularity, elevated interstitial pressure, and relatively large distances for transport of immunoglobulins through the interstitium.^{181, 182} Disordered tumor vessels permit greater leakage of albumin and other plasma proteins into the interstitial space around cancer cells. Blockage of lymphatic outflow by tumor cells prevents clearance of interstitial protein, increasing oncotic pressure, and fluid accumulation. Increased interstitial pressure impedes effective translocation of antibody. Biodistribution studies indicate that distance from blood vessels is an important factor affecting antigen recognition and binding. The central areas of bulky disease not only have increased fluid pressure but also are poorly perfused, making these regions less accessible to antibodies.¹⁸³ In addition, large tumor masses can act as antigenic sinks, decreasing drug delivery to other tumor sites.¹⁸⁴ Modeling studies led Juweid and colleagues to formulate the hypothesis of the binding-site barrier, which postulated that antibody molecules could be prevented from penetrating tumors by the very fact of their successful binding to peritumoral antigen.¹⁸⁵ Subsequent experimental studies have supported this hypothesis. Intracavitary therapy has been used in an attempt to improve access of antibody to tumor cells, but antibody generally penetrates only a few millimeters beneath the serosal surface.

Immune response to foreign immunoglobulin

Substantial effort has been expended on the development of human monoclonal antibodies that should be less immunogenic, but their titer, specificity, isotype, and affinity continue to limit the clinical utility of these reagents.^{186–188} Because a large number of antibodies used clinically are derived from mice, they can induce the development of human antimouse antibodies (HAMAs). The presence of HAMAs can prevent effective delivery of murine monoclonal antibodies to tumor cells, particularly when multiple doses must be administered to obtain optimal antitumor activity. Genetic manipulation of murine

monoclonal antibodies has been used to generate less immunogenic reagents. Chimeric (60% human) and humanized (95% human) antibodies have been engineered to retain the murine antigen-binding complementarity regions in association with human framework regions.¹⁸⁶ Although the immunogenicity of such antibodies can be reduced substantially and HAMA responses can be limited, their injection can still evoke an anti-idiotypic response. The availability of antibodies derived entirely from humans, isolated from combinatorial libraries using the process of phage display, has revolutionized therapeutic strategies.¹⁸⁸ Transgenic genetically engineered mice have also been created with human immunoglobulin genes that can produce fully human antibodies. Unlike murine antibodies, human or humanized antibodies that contain the human Fc antibody portion trigger ADCC and CDC. An array of novel affinity maturation techniques such as bacterial cell surface scFv display and cell-free ribosome display is emerging to isolate rare high-affinity clones.¹⁸⁹ Genetic engineering has also been used to produce single-chain antigen-binding proteins that may have more favorable pharmacokinetic properties than intact immunoglobulin or Fab fragments.¹⁹⁰

Potency of effector mechanisms

To the extent that unmodified monoclonal antibodies inhibit tumor growth, several mechanisms may be important for antitumor activity, including direct growth inhibition, induction of apoptosis, inhibition of angiogenesis, CDC, and ADCC, in addition to possible intervention in the specific immunoregulatory network of the host. Antibodies that react with EGFR or HER-2 can inhibit the growth of tumor cells *ex vivo* in the absence of complement components or host effector cells.^{87, 191} Antibodies that block EGF binding to the EGFR, such as cetuximab, affect growth more readily than do antibodies that bind to other sites on the receptor. Inhibition of ligand binding appears important for the inhibition of anchorage-dependent, but not anchorage-independent, growth. Antibodies have been described that produce apoptosis in some lymphoid cell lines, activated T cells, and certain carcinoma cell lines.¹⁹² Murine antibodies of the IgM, IgG2a, and IgG3 isotypes can fix human complement but often rather poorly. The rat monoclonal antibody, Campath-1G, is an important exception to this generalization in that the antibody can mediate lysis of human cells that bear the appropriate antigen in the presence of human complement components.¹⁹³ Murine antibodies of IgG3, IgG2a, and IgG2b have been reported to mediate ADCC in which large granular lymphocytes (LGLs), monocytes, macrophages, or polymorphonuclear leukocytes are bound to tumor cells through Fc receptors after antibody has bound to specific antigenic determinants on the tumor cell surface. IgG3 appears to be particularly important for ADCC with LGLs, whereas IgG2a may interact more effectively with human monocytes.¹⁹⁴ In some instances, arming mononuclear leukocytes with antibody before interaction with tumor targets has been possible. *In vivo*, ADCC may be compromised in cancer patients owing to a paucity of appropriate effector cells or to the presence of circulating immune complexes that occupy or downregulate Fc receptors. Antibodies that react against GD3 on melanoma cells can also bind to GD3 on the surface of T cells, enhancing their cytotoxic and proliferative responses.¹⁹⁵ Hybrid antibodies have been generated with one binding site for T-cell-associated antigens and one binding site for tumor-associated antigens.¹⁹⁶ Such hybrid antibodies enhance tumor cell killing by IL-2-activated T cells, possibly by encouraging contact between effector cells and tumor targets.¹⁹⁷

Serotherapy with monoclonal antibody drug conjugates (ADCs)

Murine monoclonal antibodies have been coupled to a variety of conventional cytotoxic agents, including

antifolates, anthracyclines, vinca alkyls, and alkylating agents. Prepolymerization of some drugs, such as doxorubicin, before conjugation can achieve higher ratios of drug to antibody. Drugs can be bound to the amino side chains of lysine residues, provided that the most reactive residues are not found in the antigen-binding site. Linkage of drugs to antibody through the carbohydrate moieties of the murine immunoglobulin has provided site-specific conjugation that generally does not impair antibody binding.^{198, 199}

One concern raised by some investigators is based on the observation that many cell surface antigens have fewer than 10^5 copies per cell. Release of $1-3 \times 10^6$ drug molecules at the cell surface might or might not be sufficient to eliminate tumor. Another concern relates to the ability of large immunoglobulin carrier complexes to translocate across tumor capillaries. In preclinical studies, however, drug-monoclonal antibody conjugates proved substantially more effective than did the free drug. Only some of these conjugates are more potent, but many are less toxic, providing an improved therapeutic index. Therapeutic advantage may relate to different rates or patterns of drug uptake when linked with monoclonal reagents. In some instances, novel linkages have been devised that would release drug at low pH or only in the presence of lysosomal proteases.

Gemtuzumab ozogamicin (Mylotarg®)

Calicheamicin has been conjugated with an anti-CD33 antibody.²⁰⁰ CD33 is a 67-kDa glycoprotein expressed on the surface of >90% of AMLs and on early myeloid progenitor cells but not on normal pluripotent stem cells. Gemtuzumab ozogamicin, a conjugate of humanized anti-CD33 antibody and the cytotoxic antibiotic calicheamicin, is rapidly internalized by myeloblasts and induces apoptosis.²⁰¹ Three multicenter trials evaluated gemtuzumab ozogamicin in 142 patients with CD33 + AML in first relapse, administering two doses of 9 mg/m² on days 1 and 15 by 2-h intravenous infusion.²⁰² Complete remission, with or without full platelet recovery, was observed in 30% of patients.

Toxicity

Because CD33 is expressed on hematopoietic precursors, grade 3 or 4 neutropenia and thrombocytopenia were observed in 99% of 101 patients age 60 years or above. Infections (27%) and mucositis (4%) were observed less frequently.²⁰³ Veno-occlusive disease occurred in 14 of 119 patients (12%) who received gemtuzumab ozogamicin-based regimens, including 5 patients who had not undergone stem cell transplantation previously.²⁰⁴ Despite these toxicities, gemtuzumab ozogamicin was given accelerated approval by the FDA in 2000. The confirmatory trial was stopped in 2004 owing to lack of benefit at interim analysis, and the conjugate was voluntarily withdrawn from the market in 2010. Recent meta-analysis indicated that while gemtuzumab ozogamicin improved PFS, it did not improve OS.²⁰⁵

Brentuximab vedotin (Adcetris®)

Brentuximab vedotin (Adcetris®), a conjugate of an anti-CD30 chimeric IgG1 antibody and 3–5 units of vedotin (monomethyl auristatin E), a small molecule inhibitor of mitosis, was granted accelerated approval by the US FDA in 2011 and the EU in 2012 for treatment of relapsed Hodgkin lymphoma (HL) and anaplastic large cell lymphoma (ALCL). The effectiveness of brentuximab vedotin in patients with HL was evaluated in a single clinical trial involving 102 patients where 73% of patients achieved either a complete or partial response to the treatment for an average of 6.7 months. The effectiveness of brentuximab vedotin in patients with systemic ALCL was evaluated in a single-arm clinical trial in 58 patients where 86% experienced either a complete or partial response on average for 12.6 months.²⁰⁶ Regular approval was based on a randomized, double-blind, placebo-controlled, post-human stem cell

transplant (HSCT), phase III clinical trial in 329 patients with classical HL at high risk of relapse or progression based on pretransplant factors.⁸⁵ Following an auto-HSCT, patients were randomized to brentuximab vedotin or placebo once every 3 weeks for a maximum of 16 cycles. The median PFS in the brentuximab vedotin arm was 42.9 months compared to 24.1 months in the placebo arm ($P = 0.001$).

Toxicity

The most common adverse reactions (>20%) in patients treated with brentuximab vedotin were neutropenia, peripheral sensory and motor neuropathy, thrombocytopenia, anemia, upper respiratory tract infection, fatigue, nausea, and diarrhea. Twenty-five percentage of patients reported serious adverse reactions. The most common serious adverse reactions were pneumonia, pyrexia, vomiting, nausea, hepatotoxicity, and peripheral sensory neuropathy. In the registration trial, adverse reactions led to discontinuation of treatment in 32%.

Ado-trastuzumab-emtansine (TDM-1; Kadcyla®)

Ado-trastuzumab-emtansine (TDM-1; Kadcyla®) is a conjugate of the humanized anti-HER-2 humanized IgG1 antibody trastuzumab and a 148 D cytotoxic drug emtansine (DM1) that binds to tubulin. The conjugate was approved by the US FDA and the EU in 2013 for treatment of recurrent HER-2-amplified breast cancer based on a randomized, multicenter, open-label trial enrolling 991 patients who had failed prior taxane and trastuzumab-based therapy before enrollment. Patients were randomly allocated to receive intravenous ado-trastuzumab emtansine or oral lapatinib and capecitabine. Ado-trastuzumab emtansine produced greater PFS (9.4 months vs 6.4 months, $P < 0.0001$) and OS (30.9 months vs 25.1 months, $P = 0.0006$) compared to lapatinib and capecitabine.²⁰⁷

Toxicity

The most common adverse reactions observed in patients receiving ado-trastuzumab emtansine are fatigue, nausea, musculoskeletal pain, thrombocytopenia, headache, transaminasemia, anemia, and constipation. The most common (>2%) grade 3–4 adverse reactions were thrombocytopenia, transaminasemia, anemia, hypokalemia, peripheral neuropathy, and fatigue. The most common adverse events leading to ado-trastuzumab emtansine withdrawal were thrombocytopenia and transaminasemia. Serious hepatobiliary disorders, including at least two fatal cases of severe drug-induced liver injury and associated hepatic encephalopathy, have been reported in clinical trials with ado-trastuzumab emtansine. Other significant adverse reactions include left ventricular dysfunction, interstitial lung disease, and infusion-associated reactions.

Radioimmunotherapy of cancer

Radioimmunotherapy (RIT) is a method of cancer treatment that involves the selective delivery of a radionuclide emitting cytotoxic radiation to tumor cells via an antibody or antibody fragment. While the concept of antibody-based targeting of radionuclides to cancer cells has long been appreciated, this approach did not become practical until the development of monoclonal reagents, which has permitted more specific targeting and the large-scale production of conjugates for clinical trials. With external beam therapy, only a limited area of the body is irradiated, with the dimensions defined to match the known limits of tumor location. While conventional radiotherapy can be effective for localized disease, diffuse cancers generally are difficult to treat because of normal tissue toxicity concerns and because metastatic disease beyond the margins of the radiation field escape treatment. With RIT, if the targeted antigen or

receptor is also present on metastases, in principle, they can also be treated, even if their presence is unknown at the time of treatment.

Perhaps the largest impediment to the acceptance of RIT is fear of radioactive materials among physicians and patients, which can be ameliorated by better education. On the other hand, RIT offers several important advantages compared with other antibody-based strategies discussed in this chapter. First, the antibody can be labeled with a small dose of either the therapeutic radionuclide or an analogous radionuclide and then the pharmacokinetics of the RIT agent can be determined in individual patients by nuclear medicine imaging. This information can then be used to select patients most likely to benefit from RIT and determine patient-specific radioactivity levels required to deliver the desired radiation dose to tumor.²⁰⁸ Second, unlike ADCs (antibody drug conjugates) and immunotoxins that kill only the targeted cell, the cytotoxic effects of radionuclides, summarized in a review,²⁰⁹ can extend beyond the targeted cell and include self-irradiation, crossfire irradiation, and a bystander effect. Crossfire occurs because the range of most therapeutic radiation is multicellular, while the bystander effect can kill neighboring cells not directly traversed by radiation by a mechanism not fully understood.^{210, 211} Both can result in the destruction of adjacent cells not taking up the labeled antibody, helping to compensate for heterogeneities in antibody delivery, target molecule expression, or both.

Role of the radionuclide

An advantage of RIT is the potential to match the range of action of the radionuclide to the need to balance normal toxicity constraints and the desire to maximize homogeneity of tumor dose deposition for a given clinical application. Other factors that must be considered in the selection of radionuclides for RIT include (1) compatibility of physical half-life with antibody pharmacokinetics, (2) existence of labeling chemistry that provides acceptable stability, and (3) commercial availability of the radionuclide in a form suitable for clinical use. The characteristics of the radionuclides that have been most widely investigated for RIT and other targeted radiotherapy approaches have been discussed in a review.²¹² The vast majority of RIT studies have utilized radionuclides decaying by the emission of β particles or α particles, which have tissue ranges of 1–10 mm and 50–90 μm , respectively. Recently, radionuclides that emit subcellular range (<1 keV) Auger electrons, originally thought to be cytotoxic only when localized in close proximity to the cell nucleus, have been evaluated.²¹³ However, at least one study suggests that Auger electron emitters may also be effective when delivered by noninternalizing antibodies.²¹⁴

β emitters

Most clinical RIT trials and the only two FDA-approved RIT products involve radionuclides that decay by the emission of β particles. The cytotoxic effects of radiation agents depend largely on their linear energy transfer (LET), which is the amount of energy they deposit over a given distance. β Particles have an LET of approximately 0.2 keV/ μm , are considered sparsely ionizing radiation, and produce mostly single-stranded DNA lesions that are readily repairable.²⁰⁷ Given their path length in tissue, β emissions are most appropriate for treating tumors >0.5 cm because under these circumstances, most of their decay energy will be absorbed by the tumor and not neighboring normal tissues. Shorter-range β emitters such as ^{131}I , ^{177}Lu , and ^{67}Cu might be better in minimum residual disease settings because a greater fraction of their decay energy would be deposited within small tumor cell clusters. Conversely, more energetic, longer-range β emitters such as ^{90}Y and ^{186}Re could destroy larger tumor deposits and eliminate tumor cells that escape direct targeting owing to lack of antigen expression or poor vascularity.

α Emitters

α Particles generally have higher energies than β particles and exhibit very short path lengths ($<100\ \mu\text{m}$) in tissue. α Particles have an LET of about $100\ \text{keV}/\mu\text{m}$, are densely ionizing, and produce clusters of DNA damage, including double-strand DNA breaks, which are difficult to repair.²⁰⁷ Moreover, the cytotoxic effectiveness of α particles is largely independent of dose rate and oxygenation, offering the possibility of treating hypoxic tumor regions. Because of their short range, α emitters may be most effective in RIT directed against blood-borne tumor cells, micrometastatic disease, and cancer cells on the surface of cavities, such as ovarian carcinoma and neoplastic meningitis. α -Particle-emitting radionuclides that have been most widely investigated for use in RIT include 61-min ^{212}Bi , 46-min ^{213}Bi , 7.2-h ^{211}At , 10-day ^{225}Ac , and most recently, 18.7-day ^{227}Th .^{215, 216} The half-lives of ^{212}Bi and ^{213}Bi are so short that they complicate the logistics of antibody radiolabeling and patient management. The much longer half-lives of ^{225}Ac and ^{227}Th , while advantageous in terms of convenience and commercialization potential, are challenging from a radiochemistry perspective because strategies must be devised to maintain a stable link between the radionuclide and the antibody over a multi-week time course. This is complicated further by the need to trap multiple α -emitting daughter radionuclides with diverse chemistries in the tumor and avoid dose-limiting toxicities to normal tissues. For these reasons, the most widely used α emitter for labeling antibodies has been ^{211}At .²¹⁷ Clinical RIT trials with α emitters will be described in a later section of this chapter.

Radioimmunotherapy of lymphoma

Hematological malignancies, particularly lymphomas, are attractive targets for RIT because of their inherent radiosensitivity. The only two RIT agents that have FDA approval are indicated for relapsed or refractory low-grade B-cell NHL ([Table 2](#)). These are ^{90}Y -ibritumomab tiuxetan and ^{131}I -tositumomab, which received clearance in 2002 and 2003, respectively. Both target the CD20 cell surface antigen that is expressed not only on about 95% of B-cell lymphoma but also on normal B cells. For this reason, an essential part of the treatment protocol is the administration of a relatively large dose of cold antibody in order to saturate normal B cell-binding sites before administration of the radiolabeled antibody. Standard protocols and other practical aspects for the use of these RIT agents have been described.^{218, 219}

Table 2 Approved radioimmunotherapy treatments for non-Hodgkin lymphoma

Property	⁹⁰ Y-Ibritumomab Tiuxetan	¹³¹ I-Tositumomab
Product name	Zevalin	Bexxar
Antibody for labeling	Ibritumomab	Tositumomab
Form	Murine IgG1	Murine IgG2a
Antibody for blocking	Chimeric rituximab	Murine tositumomab
Dose	250 mg/m ²	450 mg
Therapy radionuclide	Yttrium-90 (⁹⁰ Y)	Iodine-131 (¹³¹ I)
Half-life	2.7 days	8.1 days
Maximum beta energy	2.28 MeV	0.61 MeV
Maximum tissue range	11.3 mm	2.3 mm
γ Ray emission	No	Yes
Labeling method	Bifunctional chelate (tiuxetan)	Electrophilic radiohalogenation
Imaging radionuclide	Indium-111 (¹¹¹ In)	Iodine-131 (¹³¹ I)
Role of imaging	Demonstrate acceptable biodistribution	Determine whole-body clearance kinetics
Patient-specific dosimetry	No	Yes
Administered activity	20–30 mCi	50–200 mCi
Parameter for dosing	mCi per kg body weight	Calculated whole-body dosimetry
Benchmark if platelets >150,000/mm ³	0.4 mCi/kg	75 cGy
Benchmark if platelets 100,000–149,000/mm ³	0.3 mCi/kg	65 cGy

⁹⁰Y-ibritumomab tiuxetan (Zevalin®)

⁹⁰Y-ibritumomab tiuxetan (Zevalin®) consists of the anti-CD20 murine monoclonal antibody parent of the chimeric antibody rituximab covalently linked to ⁹⁰Y via the MX-DTPA (tiuxetan) chelate. Initially, imaging the patient with ibritumomab labeled with another radiometal, ¹¹¹In, was performed to document acceptable antibody biodistribution before treatment with ⁹⁰Y.²²⁰ A number of early studies demonstrated significantly enhanced therapeutic effectiveness for ⁹⁰Y-ibritumomab tiuxetan RIT compared with rituximab immunotherapy in patients with recurrent follicular lymphoma. In a randomized trial comparing ⁹⁰Y-ibritumomab tiuxetan and rituximab treatment in 143 patients with relapsed lymphoma, ⁹⁰Y-ibritumomab tiuxetan produced an 80% response rate compared with 56% with rituximab (*P* = 0.002).²²¹ Treatment of 54 patients with rituximab-refractory follicular NHL with ⁹⁰Y-ibritumomab tiuxetan resulted in an overall response rate of 74%, with 15% achieving complete remission.²²² Extended follow-up of 211 patients documented long-term responses of >12 months in 37% of patients with a median time to progression in the long-term responder group of 29.3 months.²²³ More recent trials have evaluated the therapeutic potential of ⁹⁰Y-ibritumomab tiuxetan in combination with high-dose chemotherapy protocols,²²⁴ as consolidation after induction therapy, including in other forms of B-cell lymphoma,^{225–228}

and as a front-line monotherapy in patients with follicular lymphoma^{229, 230} with significant improvements in PFS and OS observed in most studies.

¹³¹I-tositumomab (Bexxar®)

Clinical procedures with ¹³¹I-tositumomab are similar to those for ⁹⁰Y-ibritumomab tiuxetan except that in order to minimize thyroid radiation dose resultant from dehalogenation of the radioiodinated antibody, a thyroid protective dose of potassium iodide (or Lugol's solution) is administered before treatment.²³¹ In addition, injection of a 5 mCi dosimetry dose of ¹³¹I-tositumomab is performed to determine the whole-body clearance rate in order to calculate total body dose—the antibody is then labeled with the ¹³¹I activity estimated to yield a total body dose of 65 or 75 cGy, depending on whether the platelet count is above or below 150,000/mm³. Objective response rates of 47–68% and complete response rates of 20–38% following ¹³¹I-tositumomab treatment were reported in a long-term analysis of 250 heavily pretreated patients with indolent lymphoma.²³² For complete responders, the median duration of response after the last qualifying chemotherapy was 6.1 months, whereas the median duration of response after RIT was >47 months. These results were similar to those obtained with the chimeric anti-CD20 antibody rituximab when labeled with ¹³¹I.²³³ With regard to long-term follow-up, 6 of 12 patients with relapsed indolent lymphoma treated with ¹³¹I-tositumomab remained disease free for a mean of 9.8 years after RIT.²³⁴ RIT with ¹³¹I-tositumomab at myeloablative doses followed by autologous stem cell infusion in relapsed/refractory NHL patients resulted in an overall response rate of 87% and median PFS of 47.5 months and OS of 101.5 months.²³⁵ Finally, two recent phase III studies have shown similarly encouraging responses for single doses of ¹³¹I-tositumomab and multiple doses of rituximab when combined with BEAM and CHOP chemotherapy for the treatment of relapsed DLBCL²³⁶ and previously untreated follicular NHL,²³⁷ respectively.

Despite the compelling response data obtained with Zevalin and Bexxar, neither RIT agent has become the standard first-line treatment for patients with lymphoma. Because of poor sales, GlaxoSmithKline stopped selling Bexxar in February 2014, and there is speculation that Zevalin (Spectrum Pharmaceuticals) could suffer a similar fate. This situation can be attributed to a number of factors. Current regulations require radioactive drugs to be administered by nuclear medicine or radiation oncology staff, not by the oncologists who are responsible for the care of NHL patients. This results in a financial disincentive for oncologists who are paid to administer chemotherapy and rituximab but not RIT agents. Moreover, RIT is performed in the hospital setting, not in an outpatient facility, and performance of the low-radiation dose imaging study to determine patient-specific dosing complicates scheduling of other procedures. Finally, with these RIT treatments, there is a risk of developing secondary malignancies, leukemia, and myelodysplasia,²³⁸ although in these heavily pretreated populations, other drugs likely contribute to these adverse effects.

Radioimmunotherapy of solid tumors

The successful treatment of solid tumors with RIT has been much more difficult to achieve owing to a number of factors, not the least of which is their lower sensitivity to radiation. With external beam radiation, doses as low as 4 Gy can be effective in lymphoma while with solid tumors including breast, lung, prostate, colorectal, and pancreatic carcinoma as well as glioblastoma, clinical responses generally require doses ranging from 50 to 80 Gy.²³⁹ That apoptosis is the predominant mechanism in cell killing in NHL, but not solid tumors, plays a role in their differential response to radiation.²⁰⁷ Other barriers to effective treatment of solid tumors by RIT include accessibility of large intact antibodies in the face of

tumor interstitial pressure and heterogeneous blood flow, and tumor hypoxia. The results of trials in patients with solid tumors have been summarized in two recent reviews,^{240, 241} and, in general, variable tumor responses were observed that were less impressive than those seen in hematological malignancies. Some of the most encouraging results have been obtained in minimum residual disease settings, which minimize the deleterious effects of heterogeneous dose deposition and are difficult to treat by conventional approaches. Examples of promising work are the treatment of colorectal cancer, prostate cancer, and brain tumors after surgical debulking.

Colorectal cancer

In a phase II study, the therapeutic efficacy of ¹³¹I-*labetuzumab*, a humanized anticarcinoembryonic antigen (CEA) monoclonal antibody, was evaluated as an adjuvant treatment after salvage resection of liver metastases in patients with colorectal cancer.²⁴² Iodine-131 was utilized as the radiolabel because the relatively short range of its β -particles was considered a good match for the dimensions of micrometastatic disease. Twenty-three patients received 40–60 mCi/m² ¹³¹I-*labetuzumab* and 19 were evaluated for response in comparison to a contemporaneous control group that did not receive RIT. At a median follow-up of 91 months, the median survival in patients receiving RIT was 58 months, compared with 31 months for the control group, with a 5-year survival of 42.1%.

Prostate cancer

J591 is a humanized monoclonal antibody specific for the extracellular domain of prostate-specific membrane antigen (PSMA) that has been labeled with ⁹⁰Y²⁴³ and ¹⁷⁷Lu²⁴⁴ and evaluated in phase I studies as a targeted radiotherapeutic in patients with metastatic castrate-resistant prostate cancer. The ¹⁷⁷Lu-labeled version was selected for phase II evaluation based on its lower β particle energy, resulting in less bone marrow toxicity and its emission of a γ ray that permits imaging.²⁴⁵ A total of 47 patients were treated with 65 or 70 mCi/m² ¹⁷⁷Lu-J591; the lower dose resulted in 30% PSA declines in 13.3% of patients and a median survival of 11.9 months, while at the maximum tolerated dose, 30% PSA declines occurred in 46.9% of patients with a median survival of 21.8 months. Gamma camera imaging of ¹⁷⁷Lu activity distribution revealed that metastatic sites were targeted in 93.6% of patients.

Brain tumors

Because brain tumors in adults rarely metastasize outside the cranium, locoregional approaches for RIT can be utilized, where the labeled antibody is injected directly into a surgically created tumor resection cavity. More than 300 brain tumor patients have been treated to date with radiolabeled antibodies that bind to tenascin-C, an extracellular matrix glycoprotein that is overexpressed in >90% of GBM biopsies, with the level of expression increasing with advancing tumor grade.²⁴⁶ Encouraging responses were obtained in a series of phase I and II trials with ¹³¹I-labeled *antitenascin 81C6* antibody in patients with both recurrent and newly diagnosed GBM. These were performed on a fixed radioactivity basis, as mandated by the FDA. In the most recent trial, the efficacy of ¹³¹I-labeled 81C6 administered at the ¹³¹I dose required to deliver an average radiation dose of 44 Gy to the 2-cm surgically created resection cavity was investigated.²⁴⁷ The 44 Gy benchmark was based on analysis of prior fixed activity level protocols that demonstrated that this dose provided maximum tumor control without accompanying radionecrosis. Median OS in these newly diagnosed patients (16 GBM, 5 anaplastic astrocytoma) was 97 and 91 weeks for all patients and GBM patients, respectively.

Strategies for improved radioimmunotherapy

Particularly for the treatment of patients with solid tumors, improving RIT therapeutic outcomes will require the development of more sophisticated strategies both in terms of the antibody-based delivery vehicle and the nature of the radionuclide. A variety of enzymatically and genetically derived antibody fragments of varying size have been evaluated^{248, 249} with the goal of seeking the best balance between better tumor penetration and more rapid normal tissue clearance, achievable with smaller constructs and longer tumor residence time, generally better with intact IgG antibodies. Tumor vasculature plays an important role in that it provides an impediment to homogeneous antibody delivery, which might be overcome through the use of vascular disruptive agents such as combretastatin.²⁵⁰ On the other hand, tumor vasculature provides an intriguing target for RIT, because damaging tumor blood vessels could increase the efficiency and homogeneity of treatment.²⁵¹ Two approaches for improving RIT that have received particular attention are pretargeting and α -particle-emitting radionuclides.

In pretargeting, the antibody is administered first, and after a delay period to achieve sufficient uptake in the tumor and normal tissue clearance, a radiolabeled lower molecular-weight compound is injected. By shifting the label from the antibody to a smaller molecule, enhanced tumor-to-normal tissue ratios and tumor radiation dose can be achieved.²⁵² Initial approaches used antibody-streptavidin conjugates followed by radiolabeled biotin, with or without an intermediate clearing agent²⁵³; however, immunogenicity and interference by endogenous biotin were confounding factors. A second pretargeting tactic that has also entered the stage of clinical investigation involves the use of bispecific antibodies that bind to a tumor-associated molecular target as well as to a small molecule or peptide containing a radiometal-chelate complex.²⁵⁴ The feasibility of this approach has been evaluated in patients with recurrent medullary thyroid carcinoma.²⁵⁵ Patients first received a bispecific anti-CEA antibody and then after 4 days, ¹³¹I-labeled peptide bearing two hapten groups. Median OS was 110 months, significantly longer than that observed in untreated patients (61 months).

The most attractive feature of α -particle-emitting radionuclides for RIT is their markedly increased potency compared with other types of radiation. Studies in cell culture have demonstrated that human tumor cells can be killed after only a few α particles traverse a cell.²⁵⁶ Furthermore, the cytotoxicity of α particles is nearly independent of dose rate, oxygen concentration, and cell-cycle stage.²⁰⁷ While the conceptual advantages of α particles for RIT were known for a long time, practical investigation in patients required developments in radionuclide production, protein-labeling chemistry, and radiation dosimetry.

The first RIT clinical trial with an α -particle-emitting radionuclide involved ²¹³Bi-labeled HuM195, a humanized antibody reactive with the CD33 antigen that is overexpressed on human leukemia cells.²⁵⁷ A phase I trial was conducted in 18 patients with relapsed and refractory AML or chronic myelomonocytic leukemia. Because of the 46-min half-life of ²¹³Bi, the labeled antibody was administered in multiple doses (3–7) in order to achieve the desired administered activity levels (602–3515 MBq). Absorbed dose ratios between potential tumor sites (bone marrow, liver, and spleen) and whole body were about 1000 times higher than seen previously when this antibody was labeled with β emitters. Large leukemia volume reductions were achieved in many patients; however, no complete remissions were observed. A follow-up phase I/II trial evaluating the efficacy of ²¹³Bi-labeled HuM195 after partial cytoreductive chemotherapy with cytarabine reported complete remissions and partial responses in 6 of 25 patients. A phase I trial has recently been initiated of HuM195 labeled with the 10-day half-life α particle emitter ²²⁵Ac.²⁵⁸

A phase 1 trial has been reported in which the pharmacokinetics and response to ²¹¹At-labeled chimeric 81C6 antitenascin monoclonal antibody was evaluated in recurrent glioma patients after administration

into surgically created tumor resection cavities.²⁵⁹ The patient population consisted of 14 patients with GBM, 3 with anaplastic astrocytoma and 1 with anaplastic oligodendroglioma. Serial gamma camera imaging and blood counting demonstrated that the ²¹¹At-labeled immunoconjugate was stable *in vivo* with $96.7 \pm 3.6\%$ of the decays occurring in the resection cavity. The median survival in patients with recurrent GBM was 54 weeks, markedly better than that obtained with conventional treatment (31 weeks). The survival of two of these recurrent GBM patients for 150 and 151 weeks is particularly encouraging and a clinical trial is planned with ²¹¹At-labeled 81C6 antibody in newly diagnosed GBM patients.

Therapy with targeted toxins

Targeted toxins are hybrid protein drugs that contain cell-binding domains and toxin domains. The cell-binding domain delivers the drug to the cell surface. After processing and/or internalization, the toxin domain triggers cell death. The toxins may create pores (proaerolysin) or catalytically inactivate cytosolic protein synthesis (diphtheria toxin, *Pseudomonas* exotoxin, or saporin). In some cases, specificity is provided by protease-specific cleavage sequences added to the toxin. A major challenge in the construction of targeted toxins is to identify target receptors or proteases that permit cell selective killing. Most of the agents consist of a single polypeptide, although several compounds have separate cell binding and effector/toxin peptides. Targeted toxins were designed to be clinically useful in patients with malignancies or other cell disorders that are resistant to standard cytotoxic or pathway inhibitor agents. None of the targeted toxins is absolutely tumor-specific, different side effects are observed dependent upon the binding or activation specificity and the particular toxin. While the synthesis and scaleup of such complex protein compounds are challenging, several agents have shown excellent clinical benefit with mild-moderate side effects in a range of human cancers and other chronic diseases. We will address only agents that are either approved or in middle-late stage clinical testing in humans. Pharmacokinetics, immune response, toxicities, and response are described for each—although many share common pharmacologic and toxicologic properties.

Targeted toxins for leukemia and lymphoma

Denileukin diftitox

Diphtheria toxin is a 58-kDa Mr protein with three domains. An *N*-terminal domain catalyzes ADP-ribosylation of elongation factor-2 (EF-2) that inactivates cellular protein synthesis leading to cell death. The middle domain is a hydrophobic domain, facilitating transfer of the catalytic domain to the cell cytosol. The *C*-terminal domain is a beta sheet-rich region that causes cell binding. Denileukin diftitox replaces the normal cell-binding domain with human IL-2. In the pivotal phase 3 study, patients with IB to IVA cutaneous T-cell lymphoma (CTCL) received 9 or 18 $\mu\text{g/kg/day}$ IVC drug for 5 days every 3 weeks for up to 8 cycles.²⁶⁰ The drug half-life was 30 min, and the side effects included an acute cytokine reaction (fever, chills, nausea, vomiting, myalgias, arthralgias, chest pain, and back pain), transient liver enzyme abnormalities (transaminasemia), and a vascular leak syndrome (hypotension, hypoalbuminemia, dyspnea, and edema). Most patients developed an immune response to the agent, but this did not correlate with toxicities or response. More responses were noted at 18 $\mu\text{g/kg}$ versus 9 $\mu\text{g/kg}$. Clinical responses were seen in 30% of patients including 20% with partial responses and 10% with complete responses lasting a median of 6 months. In later follow-up, there were a number of patients with maintained responses over 2 years.²⁶¹ On the basis of these results, denileukin diftitox was approved for refractory CTCL. Denileukin diftitox also yields responses in T-cell NHL (48% response), CLL (27%), B-cell NHL (25%) and in isolated case reports in systemic mastocytosis, extranodal NK/T-cell lymphoma, peripheral

T-cell lymphoma, subcutaneous panniculitis-like T-cell lymphoma, and adult T-cell leukemia.^{262–269} Further, rare toxicities of thyrotoxicosis and vision loss have been reported.^{270, 271} Combination of denileukin diftitox with other agents such as cytotoxic drugs, rituximab, bexarotene, or electron beam radiation may enhance responses.^{272, 273} Currently, denileukin diftitox is not available for use owing to manufacturing problems.

Moxetumomab pasudotox

Pseudomonas exotoxin is a 68-kDa Mr polypeptide with an *N*-terminal cell-binding domain followed by an amphipathic helix-containing translocation domain and a *C*-terminal ADP-ribosylation domain. *Pseudomonas* exotoxin was altered to eliminate normal tissue binding by deleting amino acid residues 1–252 and 365–380; a disulfide-stabilized anti-CD22 Fv was fused to the 38-kDa Mr modified toxin (PE38). Then hot-spot mutagenesis was used to increase the affinity of the molecule. A threonine-histidine-tryptophan replaced serine-serine-tyrosine in the antigen-binding site of the heavy chain. Administration of moxetumomab pasudotox to 28 patients with hairy cell leukemia at doses of 5–30 µg/kg every other day 3 times for 1–16 cycles yielded no dose-limiting toxicities.²⁷⁴ Side effects included grade 2 hemolytic uremic syndrome, hypoalbuminemia, transaminasemia, edema, headaches, hypotension, nausea, and fatigue. Only 5% of patients developed neutralizing antibodies beyond cycle 1. The overall response rate was 86% with 46% complete remissions. Median disease-free survival time exceeded 2 years. Moxetumomab pasudotox also produced remissions in ALL patients.

SL-401

The catalytic and translocation domains of diphtheria toxin were fused via a Met-His linker to human IL-3. SL-401 was administered IV over 15 min every other day for up to 6 doses to 45 patients with poor-risk, relapsed, or refractory acute myeloid leukemia or myelodysplasia.²⁷⁵ Half-life was 30 min and peak levels were dose dependent. An interpatient dose escalation schema was used with doses from 4 to 12.5 µg/kg/dose. Dose-limiting toxicity was not observed, but side effects included transient transaminasemia, hypoalbuminemia, fever, chills, nausea, and vomiting. Antifusion protein antibodies occurred between day 15 and day 30 in most patients. Responses included one complete remission lasting 8 months and two partial remissions of 3 and 4 months duration. Separately, SL401 was given as 12.5 µg/kg IV over 15 min daily for up to 5 doses to 11 patients with blastic plasmacytoid dendritic cell neoplasm.²⁷⁶ Seven of the nine evaluable patients (78%) had major responses including five complete remissions and two partial remissions. The median duration of response was 5 months but 2 patients remain in remission for >2 years.

DT2219

The catalytic and translocation domain of diphtheria toxin was fused with bispecific scFv of antibodies targeting human CD19 and human CD22 to produce DT2219 that was administered as 2-h IV infusions every other day for 4 total doses from 0.5 to 80 µg/kg/day to 25 patients with mature or precursor B-cell lymphoid malignancies expressing CD19 and/or CD22.²⁷⁷ Drug half-life was 1–2 h. Neutralizing antibodies developed in 30% of patients after 1 week. Dose-limiting toxicity was vascular leak syndrome. Other side effects included transient weight gain, edema, hypoalbuminemia, fever, fatigue, and transaminasemia. Maximal tolerated dose exceeds 80 µg/kg. Two patients achieved partial remissions lasting 2+ and 8+ months.

Resimmune

The catalytic and translocation domains of diphtheria toxin were fused to two single-chain antibody fragments reactive with an acidic loop on the extracellular domain of CD3 ϵ . Resimmune was given as 15-min IV infusions twice daily for up to 4 days at doses of 2.5–11.25 $\mu\text{g/kg}$ in an interpatient dose escalation to patients with CD3-positive lymphomas.²⁷⁸ Dose-limiting toxicities were EBV reactivation and vascular leak syndrome. The maximal tolerated dose was 7.5 $\mu\text{g/kg}$. Other common adverse events were fever, chills, hypophosphatemia, and transaminasemia. Among 25 CTCL patients, there were 9 responses for a response rate of 36%. Median complete remission duration exceeds 5 years.

Targeted toxins for solid malignant and benign tumors

PRX302

The furin cleavage site of proaerolysin was modified to a prostate-specific antigen-selective cleavage site. Proaerolysin is a channel-forming bacterial protoxin that binds to ubiquitous cell surface receptors. The recombinant-modified proaerolysin, PRX302, was administered interstitially to 24 patients with locally recurrent prostate cancer after primary radiotherapy failure and to 92 patients with benign prostatic hyperplasia (BPH).^{279, 280} The drug was well tolerated in each study with only mild, transient local discomfort, and irritative urinary symptoms occurring in the first few days. Doses ranged from 0.03 to 3 $\mu\text{g/g}$ tissue for prostate cancer and 0.6 $\mu\text{g/g}$ tissue for BPH. Delivery was by a single ultrasound-guided transperineal intraprostatic injection. PSA decreased in 63% of prostate cancer patients, and prostatic symptoms improved in BPH patients. Median response duration in the BPH patients exceeded 1 year.

SS1P

The binding site-deleted *Pseudomonas* exotoxin PE38 fragment used to construct moxetumomab pasudotox was fused to an antimesothelin disulfide-stabilized Fv to create the recombinant immunotoxin, SS1P. SS1P was given as a 30-min IV infusion every other day for 3–6 doses to 34 patients with advanced mesothelioma, ovarian cancer, and pancreatic cancer at doses of 18–45 $\mu\text{g/kg/dose}$.²⁸¹ Dose-limiting toxicities were urticaria, vascular leak syndrome, and pleuritis. The maximal tolerated dose was 45 $\mu\text{g/kg}$ on a three-dose schedule. There were 4/33 minor responses, and 19/33 stable disease. In a separate study, 24 patients with mesothelioma, ovarian cancer, or pancreatic carcinoma received 4–25 $\mu\text{g/kg/day}$ SS1P by continuous infusion for 10 days.²⁸² The maximal tolerated dose was 25 $\mu\text{g/kg/day}$, and the dose-limiting toxicity was vascular leak syndrome. Immunogenicity was observed in 75 patients. Constant plasma levels of SS1P were maintained for 10 days with a median peak level of 153 ng/mL. One patient showed a partial response. Dramatic antimesothelioma activity for SS1P has been observed when combined with pentostatin plus cyclophosphamide or premetrexed plus cisplatin.^{283, 284} In the former case, 3/10 patients had major tumor responses. In the latter case, 12/20 patients exhibited partial remissions.

IL13-PE

IL13-PE is a recombinant cytotoxic consisting of human IL-13 fused to a truncated form of *Pseudomonas* exotoxin. Eight patients with metastatic adrenocortical carcinoma received 1 or 2 $\mu\text{g/kg}$ of IL13-PE IV.²⁸⁵ The mean peak serum concentration was 21 ng/mL and the half-life was 30 min. Five out of eight patients developed neutralizing antibodies within 14–28 days. Toxicities were thrombocytopenia and renal insufficiency. One patient showed stable disease.

Targeted toxins for cancer-associated illness

SP-SAP

The neuropeptide substance P was chemically conjugated to recombinant saporin. SP-SAP has been given to cancer patients with refractory pain in the lower half of the body.²⁸⁶ A single intrathecal dose was administered via lumbar puncture over 2 min. To date, patients have received 1–16 µg. Dose escalation is proceeding, but transient pain reductions and reductions in opioid use have been observed.

Targeted toxins: conclusions

Toxicities appear predictable with targeted toxins. In cases where the receptor/antigen recognized by the targeted toxin is present on normal tissues, side effects related to the damaged normal tissue are observed. SS1P binds normal pleural surface mesothelin and yields pleuritis. Other toxicities are independent of ligand binding and are mediated by binding hepatocyte, vascular endothelia, and macrophage protein receptors. The nonspecific uptake of targeted toxins by these normal tissues produces transaminasemia, vascular leak syndrome, and acute infusion reactions. Prophylactic corticosteroids may ameliorate some of these toxicities.

Most of the targeted toxins have circulating half-lives of 30–120 min. Clearance occurs in the kidney and liver. Penetration of these drugs to extravascular sites is limited owing to their large size. Thus, higher response rates are seen in hematologic neoplasms with more accessible malignant cells. Immunogenicity of the targeted toxins has impacted pharmacokinetics and retreatment response rates in some of the studies.

Response rates are excellent for some of these agents—particularly in the setting of cytotoxic drug-resistant disease. The catastrophic death induced by toxins may trigger immune activation and be partly responsible for the long duration of remissions. Combinations of targeted toxins with other therapeutics with non-cross-resistant mechanisms of action and nonoverlapping toxicities offer additional hopes for clinical benefit.^{287, 288} Thus, the field retains an important niche in the anticancer drug armamentarium.

Chapter 65

Vaccines and immunostimulants

Jeffery Schlom, PhD ■ James L. Gulley, MD, PhD, FACP ■ James W. Hodge, PhD, MBA

Overview

The U.S. Food and Drug Administration approvals of the prostate cancer therapeutic vaccine sipuleucel-T, the checkpoint inhibitor anti-CTLA-4 and anti-PD-L1/PD-1 monoclonal antibodies, along with the results of recent clinical studies involving cancer vaccines and other immunotherapeutics, have placed immunotherapy into the mainstream of the management of many cancer types. This chapter reviews the various cancer vaccine platforms now under clinical evaluation, the range of potential tumor-associated antigen vaccine targets, and the use of cancer vaccines in combination with so-called nonimmune standard-of-care therapies as well as other immunotherapeutics. The distinction in the clinical evaluation of cancer vaccines versus more conventional cytotoxic therapies is also discussed.

The U.S. Food and Drug Administration (FDA) approvals of (1) the prostate cancer therapeutic vaccine sipuleucel-T, (2) anti-CTLA-4 monoclonal antibody (MAb) ipilimumab for metastatic melanoma, and (3) the MAbs directed against the programmed death ligand 1 (PD-L1)/PD-1 immunosuppressive axis for the therapy of metastatic melanoma and lung carcinoma, along with the results of recent clinical studies involving immunotherapeutics, have placed immunotherapy into the mainstream of the management of many cancer types.

This chapter reviews the various cancer vaccine platforms now under clinical evaluation, the range of potential tumor-associated antigen (TAA) vaccine targets, and the use of cancer vaccines with so-called nonimmune standard-of-care therapies as well as other immunotherapeutics. The distinction in the clinical evaluation of cancer vaccines versus more conventional cytotoxic therapies is also discussed.

Targets for vaccine therapy

Many potential TAA targets for cancer immunotherapy have been identified. Targets of vaccine therapy need not be cell-surface proteins. When a molecule is a target for vaccine therapy, the activated T cells induced by vaccination recognize complexes of tumor antigen peptide and major histocompatibility complex (MHC) molecules on the cell surface. TAA vaccine targets can be grouped into several major categories ([Table 1](#)).

Tumor-specific antigens

Tumor-specific antigens (TSAs) comprise gene products that are uniquely expressed in tumors, such as point-mutated *ras* oncogenes, p53 mutations, and products of ribonucleic acid (RNA) splice variants and gene translocations. Three mutations at codon 12 represent the vast majority of *ras* mutations, which are found in approximately 20% to 30% of some human tumors.¹ Although the *ras* protein is not found on the cell surface, one can envision vaccine therapy directed against peptide–MHC complexes on the cell surface. Indeed, there have been clinical trials in pancreatic carcinoma that target *ras*.^{2,3} B-cell

lymphomas overexpress a single immunoglobulin (Ig) variant on their cell surface; therefore, each B-cell lymphoma displays a unique target for immunotherapy.^{4–6} The gene products of RNA splice variants and deoxyribonucleic acid (DNA) translocations also represent unique fusion proteins that can be specific targets for immunotherapy, including c-erb-B2 RNA splice variants and the bcr/abl product of DNA translocation of chronic myelogenous leukemia.

Several viruses are associated with the etiology of some cancers. An excellent example of this is the connection between human papillomavirus (HPV) and cervical cancer. This has led to FDA approval of the HPV vaccine for prevention of cervical cancer.⁷

Tumor-associated antigens

TAAAs can be categorized into three major groups: oncofetal antigens, oncogene products, and tissue-lineage antigens ([Table 1](#)). Oncofetal antigens, normally found during fetal development, are greatly downregulated after birth. This class of antigens, which includes prostate-specific membrane antigen (PSMA), carcinoembryonic antigen (CEA), and the cancer mucin MUC-1, are often overexpressed in tumors compared with normal tissues. The MUC-1 TAA is overexpressed in the majority of human carcinomas and several hematologic malignancies. Much attention has been paid to the hypoglycosylated variable number of tandem repeats (VNTR) region of the N-terminus of MUC-1 as a vaccine target. While previous studies have described MUC-1 as a tumor-associated tissue differentiation antigen, studies have now determined that the C-terminus of MUC1 is an oncoprotein, and its expression is an indication of poor prognosis in numerous tumor types.⁸

Table 1 Spectrum of current and potential therapeutic cancer vaccine targets

Target type	Examples
	<i>Tumor-associated antigens</i>
Oncofetal antigen	CEA, MUC-1
Stem cell/EMT	Brachyury, SOX-2, OCT-4, TERT, CD44 ^{high} /CD24 ^{lo} , CD133 ⁺
Oncogene	MUC-1 C terminus, p53, EGFR, HER2/neu, WT1
Cancer—testes	MAGE-A3, BAGE, SEREX-defined, NY-ESO, survivin
Tissue lineage	PAP, PSA, gp100, tyrosinase, glioma antigen
Glycopeptides	STn-KLH
Anti-angiogenic	VEGF-R
	<i>Tumor-specific antigens</i>
Oncogene	point mutated: ras, B-raf, frame shift mutations, undefined unique tumor mutations
Viral	HPV, HCV
B-cell lymphoma	Anti-id

BAGE, B melanoma antigen; CEA, carcinoembryonic antigen; EMT, epithelial–mesenchymal transition; gp100, glycoprotein 100; HCV, hepatitis C virus; HPV, human papillomavirus; MAGE-A3, melanoma-associated antigen-A3; MUC-1, mucin 1; NY-ESO, New York esophageal carcinoma antigen 1; OCT-4, octamer-binding transcription factor 4; PAP, prostatic acid phosphatase; PSA, prostate-specific antigen; SOX-2, (sex-determining region Y)-box-2; STn-KLH, sialyl-Tn-keyhole limpet hemocyanin; TERT, telomerase reverse transcriptase; VEGF-R, vascular endothelial growth factor receptor; WT-1, wild-type 1.

Oncogene and suppressor gene products, such as nonmutated HER2/*neu* and p53, are analogous to oncofetal antigens in that they can be overexpressed in tumors and may be expressed in some fetal and

normal tissues. Similarly, telomerase, an enzyme important in cellular replication and chromosomal stability, is overexpressed in malignant cells as compared with most normal cells. Epitopes derived from human telomerase have been reported and presumably may be overexpressed by neoplastic cells.⁹

Tissue-lineage antigens such as prostate-specific antigen (PSA) and the melanocyte antigens MART-1/Melan A, tyrosinase, gp100, and TRP-1/gp75 are usually expressed in a tumor of a given type and the normal tissue from which it is derived. Tissue-lineage antigens are potentially useful targets for immunotherapy if the normal organ/tissue in which they are expressed is not essential, such as the prostate, breast, or melanocyte.

Antigens associated with driving EMT, the metastatic process and drug resistance

The most provocative potential targets for vaccine therapy are those molecules associated with cancer “stem cells” and/or the epithelial-mesenchymal transition (EMT) process, both of which are associated with drug resistance. Drivers of EMT are also associated with tumor cell extravasation and intravasation to the metastatic site. Recent studies have described the plasticity of the so-called cancer stem cells and the similarities between cells undergoing EMT and the acquisition of “stemness” characteristics.¹⁰ Gene products associated with EMT and cancer “stemness” are SOX-2, OCT-4, and carcinoma cells with the phenotype CD44^{high}/CD24^{lo}, and/or are CD133⁺.^{11–15} Each of these gene products is currently being evaluated for immunogenicity in terms of generating human T-cell responses *in vitro*, but some also have a relatively broad range of expression in some normal adult tissues. The T-box transcription factor brachyury has recently been identified as a major driver of EMT.¹⁶ It has been shown to be selectively expressed on both primary and metastatic lesions of several carcinoma types. Vaccines that have the ability to generate human T cells capable of lysing a range of human carcinoma cells have been developed.¹⁷ Vaccines are currently in clinical trials to target gene products associated with EMT and cancer cells with “stemness” characteristics.^{18–20}

Types of vaccines

Numerous vaccine-delivery platforms have been analyzed in experimental models and many of these are now being evaluated in the clinic ([Table 2](#)). Each of these platforms has advantages and disadvantages. Some of these modalities may eventually prove to be most beneficial when used in combination or in tandem.

Table 2 Spectrum of current vaccine platforms in phase II/III clinical studies

Vaccine platform	Example	Cancer type
		<i>Peptides/proteins</i>
Peptide	gp100, MUC-1, HER2/neu	Melanoma, lung
Protein	MAGE-A3, NY-ESO	Melanoma
Antibody	Anti-idiotypic	Lymphoma
Glycoproteins	sTn-KLH	Melanoma
		<i>Recombinant vectors</i>
Adenoviruses	Adeno-CEA, alpha-CEA	Carcinoma
Poxvirus	Vaccinia virus, MVA, fowlpox, (PROSTVAC)	Prostate
<i>Saccharomyces cerevisiae</i> (yeast)	Yeast-CEA	Pancreatic
<i>Listeria</i>	Listeria-mesothelin	Pancreatic
		<i>Tumor cells</i>
Allogeneic	GVAX (+ GM-CSF)	Pancreatic
Dendritic cell/autologous tumor cell fusions		Myeloma
Autologous	Adeno-CD40L, colon (BCG)	Chronic lymphocytic leukemia, colon, melanoma
		<i>Dendritic cells/APCs</i>
Dendritic cell–peptide	Glioma peptides	Glioma, melanoma
Dendritic cells–vector infected	rV, rF-CEA-MUC1-TRICOM (Panvac-DC)	Colorectal
APC-protein	Sipuleucel-T (PAP-GM-CSF)	Prostate

APC, antigen-presenting cell; BCG, Bacillus Calmette–Guerin adjuvant; CD40L, CD40 ligand; CEA, carcinoembryonic antigen; gp100, glycoprotein 100; GM-CSF, granulocyte macrophage colony-stimulating factor; MAGE-A3, melanoma-associated antigen 3; MUC-1, mucin 1; NY-ESO, New York esophageal carcinoma antigen 1; PAP, prostatic acid phosphatase; PSA, prostate-specific antigen; rF, recombinant fowlpox; rV, recombinant vaccinia; sTn-KLH, sialyl-Tn-keyhole limpet hemocyanin.

Whole-tumor-cell vaccines

The major advantage of using whole-tumor-cell vaccines is that tumor-cell-mutated TSAs and TAAs, some identified and most as yet undefined, may be present in the vaccine preparation. The two types of whole-tumor-cell vaccine platforms being examined clinically are (1) autologous (i.e., manipulating the tumor from a patient into a vaccine for that patient) and (2) allogeneic, in which tumor cells from other patients, usually from established tumor cell lines, are used. Preparing an autologous tumor cell vaccine requires an enormous amount of effort, as fresh tumor needs to be obtained at surgery and prepared in a similar manner for each patient. Due to the considerable variability of tumors among patients, and costs associated with custom vaccine production, most current whole-tumor-cell vaccine approaches have centered on the use of allogeneic cell lines and cell banks.^{21–26} Moreover, the cell lines used in the

preparations can be infected with vectors that express cytokine genes such as granulocyte-macrophage colony-stimulating factor (GM-CSF)²⁷ or other immunostimulatory transgenes²⁸ to enhance the immunogenicity of the tumor cell. Studies employing tumor cell lines transfected to express GM-CSF have met with some success in treating pancreatic cancer and other tumor types.^{24–27, 29, 30}

Direct injection of cytokine genes or costimulatory molecule genes into tumor (in situ autologous whole tumor cell vaccines)

Two signals are required for the efficient activation of T cells. The first signal is mediated through a peptide–MHC complex on the cell surface of the antigen-presenting cell (APC), which binds to the T-cell receptor (TCR) on the surface of the T cell. The second signal involves the interaction of a T-cell costimulatory molecule on the surface of the APC with its ligand on the surface of the T cell. To date, the most studied of the T-cell costimulatory molecules is B7-1, which interacts with two ligands on the T-cell surface: CD28 for upregulation of T-cell function and CTLA-4 for downregulation of T-cell function. Numerous preclinical studies show that the addition of B7-1 to a weakly immunogenic tumor will make it more immunogenic.²⁸ This phenomenon has also occurred when other costimulatory molecules, such as intercellular adhesion molecule (ICAM)-1 and lymphocyte function-associated antigen (LFA)-3, have been added to tumors. Thus, one can envision the direct injection of a vector expressing one or more costimulatory molecules into a tumor mass to induce an antitumor immune response. The advantage of this direct-injection approach is that the “vaccine” is the patient's own tumor, which may express unique mutated TSAs or TAAs. In clinical studies, vaccinia- and avipox-based recombinants expressing the B7-1 costimulatory molecule have been directly injected into melanoma or carcinoma lesions.³¹ A clinical study has been reported with interesting findings in which recombinant vectors containing a triad of costimulatory molecules (B7-1, ICAM-1, and LFA-3; designated TRICOM) were directly injected into melanoma tumor lesions.^{32, 33} Cytokines can also be introduced into the tumor mass using vectors as delivery vehicles, as in the case of a recombinant vaccinia virus expressing GM-CSF directly injected into melanoma lesions.³⁴

Peptides

Most peptides used to induce an immune response are from TSAs or TAAs and are approximately 8 to 11 amino acids in length. These peptides can bind with the appropriate class of the MHC molecule on the APC surface. These MHC-restricted responses are thus effective only if the appropriate MHC allele is present in a patient. The most studied MHC restriction element in the human population is the MHC class I allele, human leukocyte antigen (HLA)–A2, which is found in approximately 50% of the Caucasian population.

Using peptides as immunogens has some advantages: (1) preparation is relatively easy and affordable; (2) because the immunogen is extremely well-defined, the immune response can be analyzed in several ways and quantitated; and (3) peptides can be modified to be more immunogenic in the form of peptide agonists. The same property that makes a peptide vaccine attractive—its specificity—can also be a disadvantage. For example, a CTL (cytotoxic T-lymphocyte) epitope peptide may induce a CTL response that is short lived because of the lack of help provided by helper peptides. Moreover, peptides are useful only in the vaccination of patients who have that specific allele. Some peptide vaccines under study include HPV,³⁵ *ras*,^{36, 37} *HER-2/neu*,³⁸ *MAGE*,³⁹ *MART-1*, tyrosinase,⁴⁰ gp100,^{41, 42} *CEA*,⁴³ *MUC-1*,⁴⁴ and *PSMA*,^{45, 46} among others.⁴⁷

Agonist peptides

Peptide agonists fall into two general categories. In the first category, amino acids of the peptide that bind to the MHC are modified. More vigorous MHC binding (i.e., higher affinity for the MHC molecule) often leads to the generation of a more vigorous T-cell response. Examples of this are the alterations in the brachyury, gp100 melanoma, and MUC-1 peptides.^{8, 41, 48} The second category of agonist has been termed a TCR agonist. In this case, an amino acid of the peptide that interacts with the TCR on the T cell is modified; this can also result in a more vigorous induction of the T-cell response. An example of this is the generation of the TCR agonist for CEA.⁴⁹

Anti-idiotypes

The idiotypic network is involved in the control of immune regulation. B-cell lymphomas present unique Igs on their cell surface, which make exquisite targets for immunotherapy. For this malignancy, anti-idiotypic (Id) MAb vaccines have been quite successful clinically.^{4, 5, 50–55} But the specificity inherent in these vaccine strategies is both an advantage and a disadvantage; different B-cell lymphomas will display unique Ids on their cell surface, making their preparation for each patient labor intensive.⁵⁶

Vectors

Vectors are among the more flexible means of vaccine delivery. Several major platforms of both viral and bacterial vectors are now in use in the clinic ([Table 2](#)). Each vector category and type has its own potential advantages and disadvantages. Review articles have been published on the potential merits of these vectors.^{57–63} In general, the advantage of a vector-based vaccine is that (1) multiple genes (including genes for costimulatory molecules and cytokines) can be inserted into some types of vectors; (2) the relative cost of production is low compared to the preparation and purification of proteins or whole-tumor-cell vaccines; (3) many vectors have the ability to infect professional APCs so that the antigens they express can be processed; and (4) viral and bacterial vectors are composed of prokaryotic proteins that act as natural vaccine adjuvants in stimulating the host immune response. The disadvantage of some, but not all, vectors is the development of host-induced immunity to the vector itself, thus limiting its continued use.

Viral vectors

One of the most studied groups of vaccine vectors is the poxvirus group. Vaccinia virus, which was derived from a benign pox disease in cows, has been administered to more than 1 billion people and is responsible for the worldwide eradication of smallpox.⁶⁴ As a result, smallpox vaccinations in the United States and most Western countries were halted approximately 40 years ago. However, most cancer patients are older than 40 and, therefore, have some level of preexisting immunity to vaccinia virus. For this reason, recombinant vaccinia viruses cannot be given multiple times in vaccine protocols. The poxvirus family contains the replication-incompetent modified vaccinia Ankara (MVA), a derivative of vaccinia virus.⁵⁷ MVA is thought of as a safer alternative to the smallpox vaccine because it can infect mammalian cells but cannot replicate.⁶⁵ Other replication-defective members of the poxvirus family are the avipox vectors (fowlpox and canarypox/ALVAC).⁵⁸ These avipox vectors infect human cells and express their transgenes for 2 to 3 weeks before cell death; they are incapable of reinfecting cells. Clinical studies have shown that avipox-based CEA vectors can be given to patients numerous times with a resulting increase in CEA-specific T-cell responses.^{47, 66} Preclinical and clinical studies^{47, 67–69} show that optimal use of recombinant vaccinia or MVA may be to prime the immune response, followed by boost vaccinations with other vectors such as replication-defective pox vectors, peptides, or DNA. Advantages of using vaccinia virus or the replication-incompetent MVA avipox are (1) large amounts of

foreign DNA can be inserted into the vector and (2) proteins expressed in poxviruses are more immunogenic than the native protein, which is most likely a result of the inflammatory responses triggered against highly immunogenic poxvirus proteins. Several clinical trials with recombinant poxviruses containing TAAs such as CEA, MUC-1, PSA, and HPV have been completed and others are ongoing.

Adenovirus has also been proposed as a vector in recombinant vaccine design because its viral genome can be altered to accept foreign genes that are stably integrated. To produce recombinant adenovectors, endogenous viral DNA sequences are typically deleted from replication-competent regions, which results in an attenuated form of the virus with potentially improved safety. A new viral vector gene delivery platform, adenovirus serotype-5 (Ad5) [E1-, E2b-],^{70–79} has been described. The platform consists of a replication-defective Ad5 in which portions of the early 1 (E1), early 2 (E2b), and early 3 (E3) gene regions have been deleted; the deletions have been reported to result in a dramatic decrease of late gene expression, which results in a marked reduction in host inflammatory responses and anti-Ad host responses. Human cells transfected with these adenovirus constructs were shown to express the encoded transgene(s) for prolonged times *in vivo* compared to other adeno vector platforms. In a Phase I/II clinical trial, cohorts of patients with metastatic colorectal cancer (mCRC) were vaccinated with escalating doses of the Adeno platform carrying a gene for CEA. CEA-directed T-cell responses were induced and patients exhibited evidence of a favorable survival probability.⁸⁰

Yeast and bacterial vectors

One advantage of recombinant *Saccharomyces cerevisiae* as a vaccine vehicle is its lack of toxicity. Besides being inherently nonpathogenic, this particular species of yeast can be heat killed before administration and has been shown to be safe in humans in several clinical trials, with maximum tolerated dose not reached.^{63, 81, 82} *S. cerevisiae* can be easily engineered to express one or more antigens in large quantities, can be propagated and purified rapidly, and is very stable.⁸³ In addition, recombinant yeast has been shown to induce a robust host immune response to non-self-antigens.^{19, 63, 83–86}

Bacterial vectors, such as *Salmonella*^{87, 88} and *Listeria*,⁶² have the advantage of tropism for professional APCs, such as macrophages. While these vectors are potentially virulent in humans, several attenuated strains have been developed for human use. From a clinical perspective, both recombinant *Salmonella* and recombinant *Listeria monocytogenes*-based vectors may be administered orally.

Plasmid DNA

Polynucleotide vaccines are easy to prepare, but the mode of action of these vectors in inducing an immune response is not fully understood because most studies have involved intramuscular inoculations, and it is not known how antigens get to professional APCs. Many preclinical and clinical studies using infectious disease agents and cancer antigens have been carried out with DNA vectors.^{89–92}

Dendritic cell vaccines

The dendritic cell (DC) is considered the most potent APC and, therefore, one of the most attractive means of immunization.^{93, 94} DCs can be employed by (1) loading with a peptide, protein, or anti-Id Ab, (2) infecting with a viral vector, (3) loading with apoptotic bodies from tumor cells, or (4) fusing with a tumor cell.^{95–98} The major disadvantages of this approach are the great cost and effort involved. Large amounts of peripheral blood mononuclear cells (PBMCs) must be obtained from patients via leukapheresis. The PBMCs must then be cultured for several days in the presence of cytokines such as GM-CSF, IL-4, and/or TNF- α , and then reinfused into the patient. This must be done for each patient. A

successful strategy, approved by the FDA, involves immunization with autologous DCs loaded *ex vivo* with a recombinant fusion protein consisting of the tumor antigen prostatic acid phosphatase (PAP) linked to GM-CSF for patients with metastatic prostate cancer, as is discussed below.

Combination of vaccines

Although each of the various methods of immunization described has advantages and disadvantages, the most effective immunization protocol may involve priming with one type of immunogen and boosting with another. This method may be advantageous because (1) two different arms of the immune system may be enhanced by using two different modalities (i.e., CD4⁺ and then CD8⁺ T cells); (2) one methodology may be more effective in priming naive cells while another modality may be more effective in enhancing memory cell function; and (3) some of the most effective methods of immunization, like the use of recombinant vaccinia virus or adenoviruses, can be used only a limited number of times because of host anti-vector responses. These vectors may be most effective when used as priming agents, followed by boosts with other agents. Numerous preclinical and clinical studies demonstrate the advantages of diversified prime-and-boost protocols.^{47, 66, 67, 99–103}

Non-specific immune stimulants

TAAAs and TSAs are, by definition, weak immunogens because tumors develop, persist, and grow in the presence of an intact immune system. Conventional adjuvants such as incomplete Freund's adjuvant (IFA) will allow the immunogen to be maintained at the injection site (the so-called depot effect) so that infiltrating APCs and effector cells can initiate a more vigorous immune response. Immunostimulants also work by crossing membrane barriers. In this case, proteins must be taken up by professional APCs and presented in the context of MHC molecules for effective presentation to the immune system. Adjuvants with lipophilic components and liposomes¹⁰⁴ facilitate this process.

Microbial products such as those present in certain adjuvants (i.e., IFA), bacillus Calmette–Guerin adjuvant (BCG), and even viral vectors also are potent activators of DCs, partly because they contain agonists of toll-like receptors (TLRs). TLRs are expressed by DCs and other innate immune cell types and comprise a family of approximately 10 to 15 receptors.^{105, 106} Activation of DC via their TLRs augments expression of adhesion, chemokine, and chemokine receptor molecules, which, in turn, regulate cellular trafficking to sites of inflammation and pathogenic encounters. Thus, the biological consequences of TLR engagement lead to inflammation, characterized by the recruitment of key immune and nonimmune effector cells to mediate pathogen destruction. In regard to TLR agonists, CpG motifs constitute the most studied of these sequences.^{107–110}

In addition, certain cytokines and chemokines have been shown to enhance the level of APC and/or effector cell function either locally or systemically. For example, GM-CSF has been reported to enhance antigen-specific T-cell responses, delayed-type hypersensitivity reactions, and antitumor responses.^{111–120} Clinical studies using GM-CSF along with protein immunogens have shown an enhancement of the antigen-specific immune response.^{50, 121} Flt-3L administration has been shown to enhance the number of DCs systemically, both in animal models and clinically.^{122, 123} Finally, several cytokines and chemokines have been shown to play a critical role in enhancing T-cell function.^{124–128} The most studied of these is IL-2.^{129, 130} When used as a single agent, IL-2 has been shown to have antitumor effects in melanoma and renal cell carcinoma (RCC) patients^{129, 131} and, as recently reported, to enhance the effectiveness of melanoma-based peptide vaccines.⁴¹ Other cytokines, such as IL-7, IL-12, and IL-15, have been shown to

enhance T-cell responses and antitumor activity in experimental models and may have more potential clinical utility than IL-2.^{125, 132–134}

One strategy for improving the safety of proinflammatory cytokines, such as IL-2 and IL-12, is to direct their delivery to tumors via fusion to a tumor-targeting antibody. Such antibody-cytokine fusion proteins, or “immunocytokines,” have previously demonstrated the ability to enhance antitumor immunity in preclinical models.¹³⁵ To maximize immunocytokine tolerability, the antibody selected as a vehicle must bind specifically to an antigen found in tumors. A tumor-targeted IL-12 immunocytokine, called NHS-IL12, was engineered by genetically fusing two human IL-12 heterodimers to the C-termini of the heavy chains of the NHS76 antibody. NHS-IL12 was superior to recombinant IL-12 when evaluated as an antitumor agent in three murine tumor models. In preclinical studies combining NHS-IL12 treatment with a cancer vaccine, radiation, or chemotherapy resulted in greater antitumor effects than each individual therapy alone.¹³⁶

Vaccine clinical trials

Below is a representative description of prior and ongoing vaccine clinical trials.

Prostate cancer

PAP, which is expressed on over 95% of prostate cancer cells, has been used as a target of the vaccine sipuleucel-T, also called Provenge® (PAP-GM-CSF-pulsed APCs). After early clinical trials of the sipuleucel-T vaccine demonstrated safety, larger trials were conducted in asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer (mCRPC). A Phase III trial¹³⁷ was conducted with overall survival (OS) as the endpoint, enrolling more than 500 patients. No change in time to progression (TTP) was seen, but OS was improved in the vaccine arm (25.8 months vs 21.7 months; $p = 0.032$). In April 2010, the FDA approved sipuleucel-T for the treatment of minimal or nonsymptomatic mCRPC. A second prostate cancer vaccine has also been evaluated in this same prostate cancer population. This “off-the-shelf” platform (PROSTVAC) consists of a recombinant vaccinia prime and multiple fowlpox booster vaccinations. Each vector contains transgenes for PSA and three costimulatory molecules (B7-1, ICAM-1 and LFA-3, designated TRICOM).^{138, 139} A randomized placebo-controlled 43-center Phase II trial enrolled 125 minimally symptomatic mCRPC patients.¹⁴⁰ Similar to the experience with sipuleucel-T, PROSTVAC did not alter TTP, yet improved median OS relative to placebo (control vector), 25.1 versus 16.6 months. Patients receiving PROSTVAC also had a 44% reduction in death rate compared to the control cohort ($p = 0.0061$).¹⁴⁰ The median OS in a second single-arm Phase II study¹⁴¹ was 26.6 months, similar to the larger PROSTVAC randomized trial. A global Phase III placebo-controlled trial of PROSTVAC in patients with minimally symptomatic prostate cancer ($n = 1298$) has now completed accrual. The endpoint is OS.

A recent review¹⁴² analyzed the immune impact induced by PROSTVAC (PSA-TRICOM) in prostate cancer patients. Of 104 patients tested for T-cell responses, 57% demonstrated an increase in PSA-specific T cells 4 weeks after vaccine, and 68% of patients mounted post-vaccine immune responses to TAAs not present in the vaccine (antigen spreading/antigen cascade). Measurements of systemic immune response to PSA may underestimate the true therapeutic immune response (as this does not account for cells that have trafficked to the tumor) and does not include antigen spreading/antigen cascade (as described below). Furthermore, although the entire PSA gene is the vaccine, only one epitope of PSA is evaluated in the T-cell responses. Because this vaccine is directed at generating a cellular/Th1 immune

response, less than 0.6% of patients tested had evidence of PSA antibody induction following vaccine. Active surveillance is becoming an increasingly utilized approach in men diagnosed with “low-risk” prostate cancer. A randomized, multicenter, placebo-controlled study of PROSTVAC vaccination versus active surveillance in patients with newly diagnosed clinically localized prostate cancer is under way. The endpoints of this study will be the changes in immune infiltrate and tumor extent at the 12-month biopsy versus initial biopsy.

GVAX, a GM-CSF-secreting vaccine, is an admixture of two prostate cancer cell lines that have been transduced with a replication-defective retrovirus for GM-CSF expression. In two separate multicenter Phase II trials, patients with asymptomatic CRPC given GVAX had a median survival of 26.2–35.0 months.^{24, 143} By estimating predicted survival based on a commonly used nomogram,¹⁴⁴ patients in both trials exceeded anticipated survival by > 6 months.¹⁴⁵

Nineteen HLA-A2-positive patients with rising PSA without detectable metastatic disease or local recurrence received a vaccine containing 11 HLA-A*0201-restricted and two HLA class II synthetic peptides derived from prostate carcinoma tumor antigens subcutaneous (s.c.) for 18 months or until PSA progression. PSA doubling time of 4/19 patients (21%) increased from 4.9 to 25.8 months during vaccination.¹⁴⁶ A Phase II adenovirus/PSA vaccine trial was conducted in patients with recurrent or hormone refractory prostate cancer. The majority of the patients demonstrated anti-PSA T-cell responses above pre-injection levels. Sixty-four percent of the patients demonstrated an increase in PSA doubling time.¹⁴⁷ Clinical trials have also been carried out using peptide-pulsed DCs loaded with peptides of human PSMA,^{148–150} as well as DCs transfected with PSA tumor RNA.¹⁵¹ In these studies, antigen-specific immune responses have been observed and some decreases in serum PSA have also been noted.

Melanoma

The vast majority of vaccine clinical trials have been conducted in patients with melanoma because (1) interferon (IFN) and IL-2 have both shown clinical responses in melanoma; (2) melanoma lesions often are readily accessible and thus can be studied for immune infiltrate and cells from melanoma lesions can be grown in culture to obtain both tumor cells and tumor-infiltrating lymphocytes (TILs); and (3) numerous melanoma-associated antigens have been identified.

Clinical trials have been conducted using various peptides derived from melanoma-associated antigens, including tyrosinase, MART-1, gp100, Melan-A (a modified gp100 epitope¹⁵²), and members of the MAGE family.^{152–157} Vaccination-induced immune responses as well as clinical benefits were reported. Newer approaches have combined these peptides with GM-CSF emulsified in Montanide ISA-51.¹⁵⁸ Another peptide approach is vaccination with autologous tumor-derived heat shock protein/peptide complexes.¹⁵⁹ Immune responses and clinical responses have also been observed using melanoma peptide vaccination in conjunction with anti-CTLA-4,¹⁶⁰ melanoma peptide-pulsed DCs,^{94, 154} tumor RNA-transfected DCs,¹⁶¹ and intratumoral administration of autologous DCs.¹⁶² A randomized Phase III study showed no benefit using an autologous peptide-pulsed DC vaccine compared to dacarbazine in first-line treatment of patients with metastatic melanoma.¹⁶³

A randomized Phase III trial was conducted involving 185 patients with stage IV or locally advanced stage III cutaneous melanoma, expression of HLA*A0201, and suitability for high-dose IL-2 therapy. Patients were randomly assigned to receive IL-2 alone or gp100 plus IFA, followed by IL-2. The vaccine–IL-2 group, as compared with the IL-2-only group, had a significant improvement in overall clinical response (16% vs 6%, $p = 0.03$). The median OS was also longer in the vaccine–IL-2 group than

in the IL-2-only group (17.8 months vs 11.1 months; $p = 0.06$).¹⁶⁴ In a multicenter randomized trial, 175 patients with stage IV melanoma were enrolled into four treatment groups. Best clinical response was partial response in 7/148 evaluable patients (4.7%) without significant difference among study arms.¹⁶⁵ In another trial, three HLA class I peptides were administered in a factorial 2×2 design: peptide vaccine alone, or combined with GM-CSF, or combined with IFN- α 2b, or combined with both. At a median follow-up of 25.4 months, the median OS of patients with vaccine immune response was significantly longer than that of patients with no immune response (21.3 months vs 13.4 months; $p = 0.046$).¹⁶⁶
