Formerly, systemic chemotherapy was believed to play a limited role in the treatment of brain metastases because of the widely held view of the brain as a pharmacologic sanctuary. In the 1980s, several groups observed in prospective trials that systemic chemotherapy alone, without brain irradiation, could induce objective regression of brain lesions. These results indicate that once contrast-enhancing metastases are evident with MRI or CT, the blood-brain barrier is not intact and response rates to chemotherapy are similar in the brain and in extra-CNS sites.^{274, 275} First-line therapy with cranial irradiation may not be necessary, even though this has not been addressed in an RCT setting. Ultimate irradiation of the brain is indicated, however, given an increase in complete response rates with its addition. A meta-analysis of three trials involving 192 patients noted no significant differences in OS for patients receiving whole-brain radiotherapy (WBRT) and topotecan versus no topotecan, teniposide with or without WBRT, and

sequential versus concurrent chemoradiotherapy with teniposide and cisplatin.²⁷⁶ For patients with intracranial relapse, the available data indicate that the efficacy of second-line chemotherapy is generally much less than in previously untreated patients, and initial WBRT is standard. Conversely, patients with recurrent brain metastases after previous cranial irradiation should not be denied a trial of systemic chemotherapy. Small studies investigating gamma knife radiosurgery in both the upfront and recurrent setting are ongoing.

Second-line therapy for SCLC

The prognosis is poor for patients who receive second-line therapy after relapse, with median survival generally in the range of 4–6 months. Response to additional therapy and survival from the time of relapse is influenced by response to initial chemotherapy and the progression-free interval following its completion. Giaccone et al.²⁷⁷ were the first to observe this in a trial with teniposide reported in 1988. In this study, none of seven patients who had not responded to initial treatment responded to teniposide. Of 16 whose progression-free interval was ≤ 2.6 months, only two (12%) responded to teniposide. This contrasted with the 42% response rate (10/24) in those with response to initial chemotherapy and 53% response rate (9/17) with more prolonged progression-free interval. Although the numbers are small in each subgroup, these observations were confirmed in multiple trials that followed in the 1990s. Disease that relapses < 2 –3 months after first-line therapy is commonly termed refractory, and rates of response in this setting are lower than disease that relapses later, which is usually termed sensitive.

Although there is no generally accepted standard regimen for relapse, topotecan is the most extensively studied agent, and it is the only drug with an FDA (Food and Drug Administration) indication for treatment of sensitive relapse SCLC. This indication is derived from a trial that compared topotecan to CAV in patients who had responded to initial chemotherapy and relapsed ≥ 60 days after its completion.¹⁶¹ The response rates were 24.3% in 107 topotecan-treated patients and 18.3% in 104 patients treated with CAV ($p = .285$). There was no difference in median time to progression or median survival duration between the two groups. Symptoms improved to a greater degree in the topotecan group than in the CAV group for four of eight categories evaluated, including dyspnea, anorexia, hoarseness, fatigue, and interference with daily activity ($p = .043$). Grade 4 neutropenia occurred in 38% of topotecan courses and 51% of CAV courses ($p < .001$). Grade 4 thrombocytopenia and grade 3 or 4 anemia occurred more frequently with topotecan, occurring in 10% and 18% of topotecan courses and 1% and 7% of CAV courses, respectively ($p < .001$ for both). Subsequent phase II and III RCTs compared oral versus intravenous topotecan and identified similar efficacy outcomes with the more convenient oral form. Toxicity is altered somewhat with the oral form producing less neutropenia but more diarrhea than the intravenous drug.^{159, 160, 162} The use of weekly topotecan is controversial and is still under investigation.

Oral topotecan has been compared to BSC in a recent trial that documented the survival impact of second-line chemotherapy on SCLC. Patients with both refractory and sensitive relapse who were not candidates for standard intravenous therapy were randomized to BSC versus oral topotecan ($N = 141$).¹⁶³ Although response rates to topotecan were low at 7%, 44% of treated patients attained SD and had improved symptom control and maintenance of quality of life. The impact of topotecan on progression and survival was seen equally in patients with refractory or sensitive relapse. Median survival was 26 weeks versus 14 weeks for topotecan and control patients, respectively ($p = .0104$). Survival at 6 months was also favorably impacted by treatment, 49% versus 26%. The evidence for impact of chemotherapy in this setting was persuasive and should influence our use of chemotherapy in this setting both within and outside of clinical investigation.

Other choices for management of recurrent SCLC include use of the initial induction regimen, especially

if PFS after discontinuation of induction is prolonged, typically 6 months or longer. Irinotecan, while not studied as extensively as topotecan in recurrent patients, appears to have similar benefits, alone or in combination with carboplatin.^{278, 279} Limited evaluation of taxanes and anthracyclines also suggests low-level activity in recurrent disease.²⁸⁰ Amrubicin, an anthracycline, showed promising activity in the second-line setting, but preliminary results of a phase III RCT comparing amrubicin to topotecan did not meet its primary endpoint of OS or PFS, although response rate was improved (31% vs 17%, $P = 0.002$).^{281–284} Palliative radiation to chest, brain, and bone is also effective and used commonly in drug-resistant and recurrent SCLC.

Targeted therapy

Efforts in genomic characterization of SCLC have employed multiple approaches, including whole-exome sequencing, transcriptome profiling, copy number and rearrangement analyses of tissue from both human and murine tumors, and circulating tumor cells (CTCs).^{285–288} SCLC has a very high density of mutations per tumor, although many of these may be passenger, not driver, mutations. The most frequent mutations include those that inactivate the tumor suppressor genes TP53 and RB-1; other interesting observations include PTEN loss, MYC amplification, and alterations in genes involved in PI3K/AKT and stem cell signaling. Despite these research efforts, patients with SCLC have yet to benefit from enhanced knowledge of the abnormal biology that is associated with its development and progression.

Conclusions and future prospects

Elimination of tobacco consumption is the most effective way to reduce lung cancer incidence. However, this goal remains elusive because of continuing social and economic pressures. Lung cancer also occurs in people who have never smoked. Lung cancer will continue to be a significant public health burden well into the twenty-first century. Thus, early detection and new therapeutic options are needed to improve the dismal rate of survival for lung cancer patients. The recent demonstration that low-dose chest CT scans can improve lung cancer mortality in high-risk populations is encouraging. Progress in defining the molecular events involved in lung cancer carcinogenesis and therapeutic resistance has been rapid over the last 15 years, and the potential benefits from this progress for patients may be substantial.

The mainstay of cancer therapy remains surgery, radiotherapy, and chemotherapy, and recent years have shown improvement in patient outcome by their combination and optimization ([Figure 6](#)). A large effort has been dedicated to further impact lung cancer outcome by adding biological therapy. Such an approach utilizes alteration of oncogene expression with recombinant gene constructs to allow reversal of the transformed phenotype. In addition, a wealth of biologically active agents that interfere with signal transduction events in the development and progression of lung cancer is now being explored. Rather than targeting the actual genetic errors, these treatments correct or interfere with the sequelae of those genetic changes. For example, genetic mutations that lead to increased expression or activity of a growth factor receptor could be targeted, either by blocking the receptor itself or by interfering with its downstream signal transduction pathways. The first drugs of this kind are the EGFR TKIs approved for the management of lung cancer. In parallel, monoclonal antibodies to VEGF are combined with conventional chemotherapy to improve survival of patients with lung cancer, colorectal cancer, breast cancer, and renal cell carcinoma, among others. Immunotherapy has recently emerged as a promising therapeutic strategy, exemplified by the approval of nivolumab as a standard of care for the treatment of squamous-cell NSCLC, and the horizon looks bright with many clinical trials investigating new combination approaches.

Figure 6 Most patients with nonsmall-cell lung cancer die from metastatic disease. Treatment in the locally advanced setting will likely require chemotherapy or radiation therapy in combination with biologic therapy to enhance its effectiveness and prevent metastatic spread of tumor.

In summary, lung cancer therapy efforts in recent years have focused on cancer prevention, early detection, and multimodality therapy. Improvements in systemic therapy (chemotherapy, molecular targeted therapy, and immunotherapy) will impact all stages of disease. As lung cancer is a heterogeneous disease, it will also be essential to identify and better understand specific molecular targets and select patients for therapy according to their tumor's biological profile. It is hoped that advances in translational proteomic and genomic research will be the key to identifying reliable, validated predictive biomarkers for these new targeted agents. Progress in these areas will hopefully lead to better control of this disease while minimizing treatment-related side effects.

Chapter 85

Malignant pleural mesothelioma

Daniel R. Gomez, MD ■ Anne S. Tsao, MD ■ Haining Yang, PhD ■ Harvey I. Pass, MD

Overview

Malignant pleural mesothelioma is an aggressive malignancy with an incidence that may be peaking worldwide in the next 5–10 years. While the majority of patients do ultimately die of this disease, there have been substantial treatment and diagnostic shifts over the past decade that may improve long-term outcomes. These changes include worldwide interest in defining early detection biomarkers for the disease, a debate as to the optimal surgical approach (extrapleural pneumonectomy vs lung-sparing methods such as pleurectomy/decortication), further refinement of radiation techniques that allow for conformal treatment fields and the delivery of radiation with the involved lung intact, and the emergence of systemic therapies that are targeted in nature and allow for the increased individualization of care. Indeed, prospective clinical trials assessing the safety and efficacy of novel treatment approaches will be essential to the standardization of paradigms that improve the outcomes. It is hoped that the maturation of these efforts will lead to an optimal approach in which earlier-stage patients will benefit from multiple modalities that will provide synergistic control while limiting toxicity, thereby increasing the number of long-term survivors over the next one to two decades.

Incidence and epidemiology

The incidence of mesothelioma has been underestimated in mortality statistics.¹ Presently, pleural mesotheliomas are responsible for approximately 15,000–20,000 deaths annually worldwide. Cases are clustered in areas of asbestos product plants and shipbuilding facilities, not only in the United States, but also in other industrialized countries, such as England.^{2, 3} Approximately, 3000 cases per year are diagnosed in the United States, and based on a latency period of approximately 20–40 years and estimated asbestos exposure rates, it has been projected that the incidence will peak in 2010–2015.⁴ This timeframe is similar to what has been predicted in other countries, such as the United Kingdom, Australia, and the Netherlands.^{5, 6} The male to female ratio is approximately 4 : 1, and 80% arise from the pleura.⁷ In autopsy studies, the frequency of malignant mesothelioma varies from 0.02% to 0.7%, with a rate of 0.2% in the largest series.⁸ In most hospital series, the pleura is more often involved than the peritoneum, with a predominance of the right side over the left (60 : 40).⁸ In some epidemiologic studies monitoring cohorts of asbestos workers, however, the peritoneal form is more common than the pleural. The mean age of patients is approximately 60 years, but the disease can occur at any age, including in childhood.^{9, 10}

Etiology

It has been well established that one of the primary causes of mesothelioma is *asbestos exposure*. It has been estimated that beginning at 15 years after onset of exposure, approximately 6–10% of asbestos workers older than age 35 years will die of mesothelioma.¹¹ Furthermore, from 1940 to 1979,

approximately 27.5 million workers were occupationally exposed to asbestos in the United States, with a calculated annual death rate from mesothelioma of approximately 2000 in 1980 up to 3000 in the late 1990s.¹² Insulation, construction, shipyard industries, and automobile brakes are among the many sources of occupational exposure.¹³ Although asbestos exposure and cigarette smoking act synergistically to produce lung cancer, smoking is not an established risk factor for mesothelioma, although an association between cigarettes using “micronite” filters has been postulated.¹⁴ Exposure can also occur by household contamination of women and children, usually through the work clothes of an asbestos' worker. Other less-common causative agents include radiation therapy (RT), as has been observed in young adults who have received RT for Wilms tumor (WT) or for mediastinal lymphoma.¹⁵

The role of pleural plaques and their association with mesothelioma has been debated for several years. One recent study addressed this issue through a screening program in France for patients that had previous asbestos exposure. Specifically, 5287 males were followed for 7 years with CT (computed tomography) scans, and both the incidence of mesothelioma and subsequent survival were assessed. Overall, 17 patients were diagnosed with malignant pleural mesothelioma (MPM), and there was a significant association between pleural plaques, with a hazard ratio of 8.9. The authors concluded that the presence of pleural plaques appeared to be an “independent risk factor for mesothelioma.”¹⁶

Molecular biology of mesothelioma

Multiple cytogenetic and molecular abnormalities contribute to the development of MPM. Asbestos inhalation leads to deposition of fibers in the lung parenchyma with eventual migration and implantation of fibers in the pleural lining. Repeated episodes of inflammation and healing, oxygen free radical production from inflammatory cells and the iron moiety within asbestos, and direct damage to DNA by the fibers are generally accepted pathogenic features of asbestos exposure.¹⁷ Karyotype and comparative genomic hybridization (CGH) analyses of primary MPM tumors and cell lines detected frequent deletions, duplications, and translocations with genomic losses more common than gains.¹⁸ Deletions within chromosomes 1p, 3p, 4p, 4q, 6q, 9p, 13q, 14q, and 22q are common and notable for the loss of the tumor-suppressor genes *p16/CDKN2A*, *p53*, and *NF2* located within these loci.¹⁹

HMGB1, tumor necrosis factor alpha (*TNF-α*) and *NF-κ* signaling play an important role in the survival of genetically damaged mesothelial cells.²⁰ *HMGB1* is a typical DAMP (damage-associated molecular pattern)^{21, 22} and a key mediator of inflammation.²³ Moreover, it is a critical regulator in the initiation of asbestos-mediated inflammation leading to the release of *TNF-α* and subsequent *NF-κB* signaling.²⁴ Phagocytic macrophages at sites of inflammation internalize asbestos and release mutagenic reactive oxygen species and numerous cytokines including *TNF-α* and interleukin-1 (*IL*)-1, which have been linked to asbestos-related carcinogenesis.^{20, 25} *HMGB1* is also released by reactive macrophages, other inflammatory cells, and human mesothelial cells (HMC) upon exposure to asbestos.²⁴ During programmed necrosis, *HMGB1* binds several proinflammatory molecules and triggers the inflammatory responses that distinguish this type of cell death from apoptosis. Secreted *HMGB1* stimulates *RAGE*, *TLR2*, and *TLR4* (the three main *HMGB1* receptors) expressed on neighboring inflammatory cells such as macrophages and induces the release of *TNF-α* and *IL-1β*. Asbestos-mediated *TNF-α* signaling then induces the activation of *NF-κB*-dependent mechanisms, promoting the survival of HMCs after asbestos exposure,²⁴ and thus allowing HMCs with accumulated asbestos-induced genetic damage to survive, divide, and propagate genetic aberrations in premalignant cells that can give rise to a malignant clone. In addition, *HMGB1* enhances the activity of *NF-κB*, which promotes tumor formation, progression, and metastasis.²⁶ *HMGB1* has been found to be elevated in the serum of asbestos-exposed individuals and MM (multiple

myeloma) patients, and investigations are underway to confirm the molecule as a biomarker for asbestos exposure ([Figure 1](#)).

Figure 1 Mineral fiber carcinogenesis. Asbestos and erionite cause necrotic cell death in HM, which leads to the release of HMGB1 into the extracellular space. HMGB1 release causes macrophage accumulation, inflammatory response, and TNF- α secretion. TNF- α activates the NF- κ B pathway, which increases HM survival after asbestos/erionite exposure. This allows HM with mineral fiber-induced DNA damage to survive and, if key genetic alterations accumulate, to eventually develop into MM.

Genetic predisposition to mesothelioma: the role of BAP1

Families have recently been identified in the United States, which appear to have unusual susceptibility to asbestos carcinogenesis, and these families have mutations of the BAP1 gene in their germline.²⁷ The familial susceptibility is associated with the presence of uveal melanomas and other rare malignancies. BAP1 (BRCA-associated protein 1) has been identified as a novel MPM tumor-suppressor gene. BAP1 is located at the 3p21, a region frequently deleted in MM, and encodes for a deubiquitinase enzyme known to target histones and other proteins. Bott et al.²⁸ originally described the association of somatic mutations of BAP1 in 23% of mesothelioma samples. In a larger series of patients, the same group confirmed that somatic BAP1 mutations occur in about 20% of pleural MM and reported that the only clinical variable significantly different among those with and without BAP1 mutations was smoking (former or current),

with BAP1 mutations more prevalent among smokers (75% vs 42%).²⁹ More recent studies have reported BAP1 gene alterations (either deletions or sequence-level mutations) in upward of 61% of MM samples,³⁰ and Arzt et al.,³¹ with a separate cohort of 52 pleural MM, reported absence of BAP1 IHC staining in 60% of pleural MM, confirming previous results. In that study, there was no correlation between BAP1 expression and asbestos exposure, and these investigators suggested that expression of BAP1 in tumor samples is inversely correlated to survival.

BAP1 appears to exert its antitumor activities mainly in a BRCA-independent manner²⁷ with regulation of the cell epigenome, via modulation of histone H2A ubiquitination and chromatin accessibility³²; however, the relevance of BAP1 to the biology of normal and cancer cells remains largely unexplained. In fact, manipulation of BAP1 in cancer cells has often yielded unexpected or even contradictory results. For example, silencing of BAP1 in MM and uveal melanoma cell lines resulted in reduced cell growth.^{28, 33}

Germline BAP1 mutations were first reported by Testa et al.³⁴ in two US families having a high frequency of MPMs. In the same study, 22% sporadic MM tumors harbored somatic BAP1 mutations. These findings have promoted speculation that BAP1 germline mutations can cause a novel cancer syndrome characterized by a significant excess of both pleural and peritoneal MM, uveal and cutaneous melanoma, and possibly other tumors.

Diagnosing and staging the patient with possible mesothelioma

Symptoms and signs

The onset of mesothelioma is associated with chest pain, dyspnea, or cough ([Figure 2](#)). Progressive invasion of the chest wall often leads to intractable pain. Pleural effusion is present initially in up to 95% of cases. Often the fluid is viscous owing to high content of hyaluronic acid. Later, tumor growth usually results in complete obliteration of the pleural space and encasement of the lung. Late symptoms of bulky mesotheliomas include mediastinal invasion with dysphagia, phrenic nerve paralysis, pericardial effusion, and superior vena cava syndrome.³⁵ Peritoneal involvement by mesothelioma is characterized by ascites and intestinal compromise leading to cachexia.

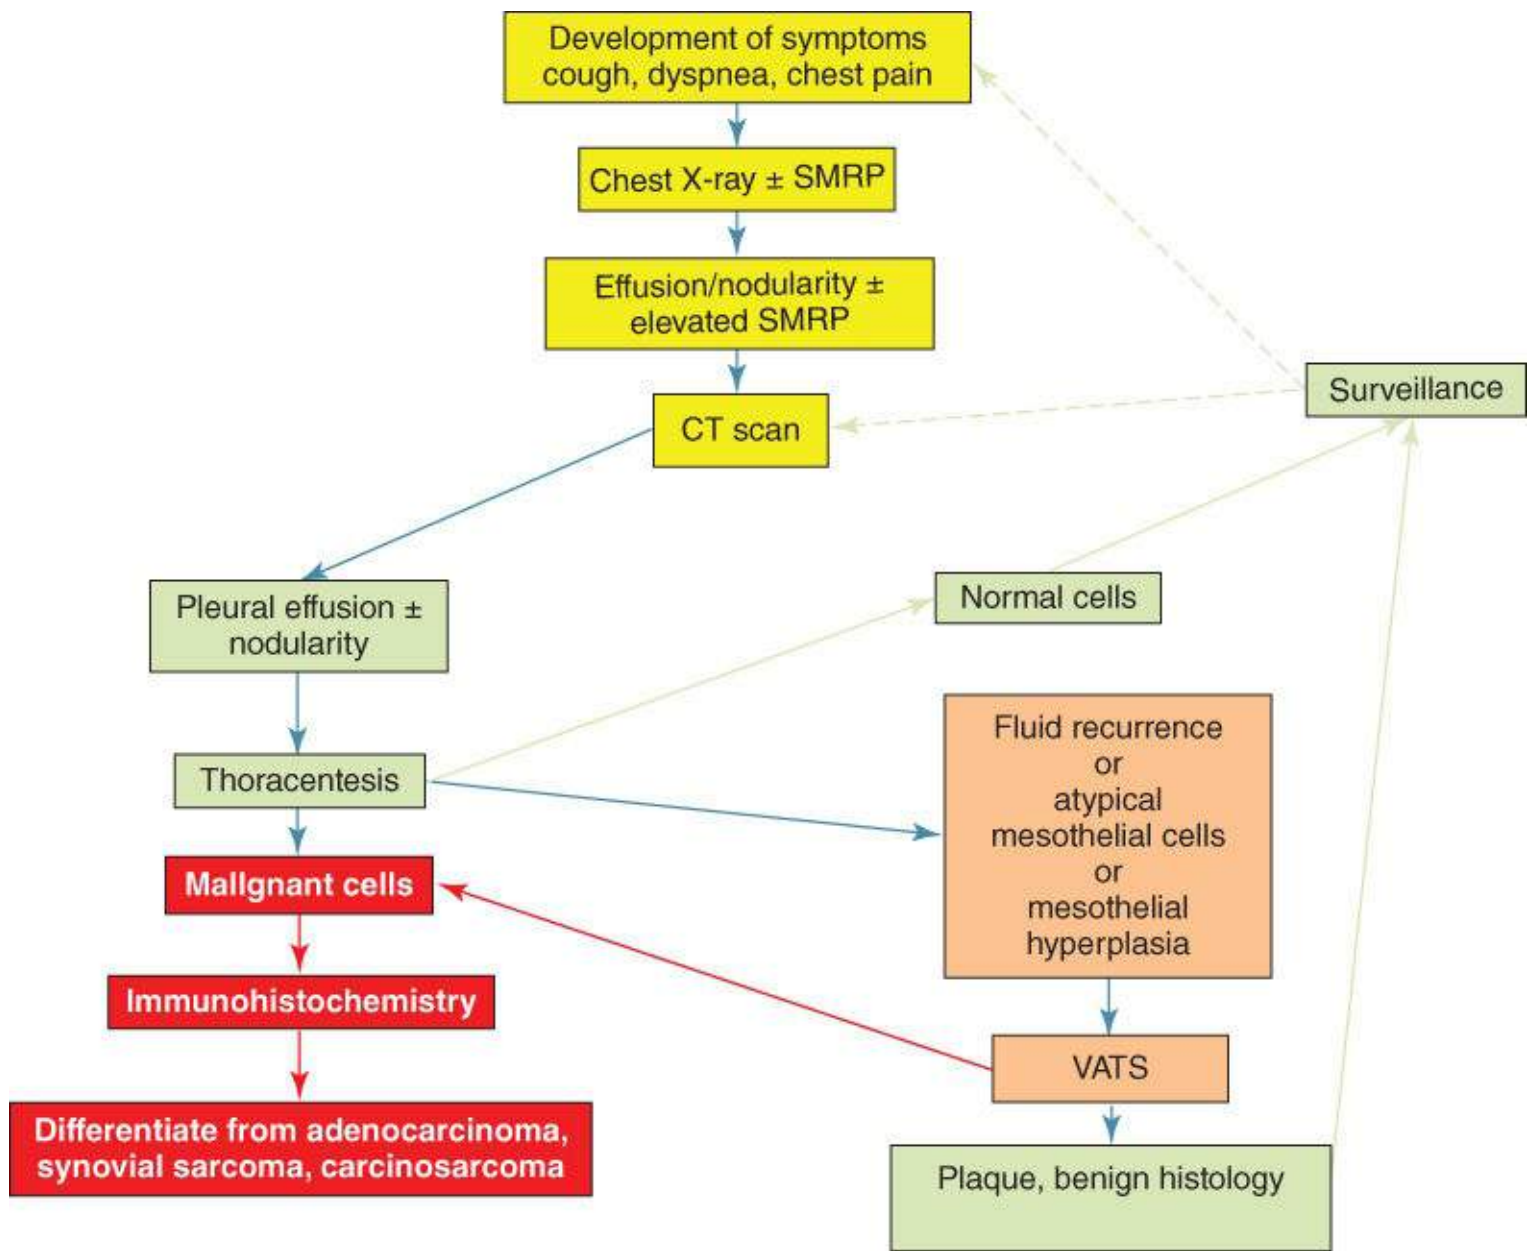

Figure 2 Algorithm for the work up of the asbestos-exposed individual who presents with new symptoms. Any new pleural effusion must have thoracentesis and immunohistochemical analyses. If atypical mesothelial cells are seen, thoracoscopy should be performed for histologic confirmation of malignancy or inflammatory disease.

Laboratory evaluation

There are several laboratory abnormalities associated with mesothelioma. Of these, the presence of thrombocytosis with platelet counts $>400,000$ is probably the most common. Others include hypergammaglobulinemia, eosinophilia, anemia of chronic disease, elevated homocysteine levels, folic acid deficiency, and Vitamin B12 and Vitamin B6 deficiency.³⁵

Histologic subtypes

There are three primary types of mesothelioma. The *epithelial type*, the *fibrous morphology type*, also called the *sarcomatoid type*, and a combination called *biphasic or mixed type*. The majority of mesotheliomas (50–70%) are of the epithelial type, 10% are sarcomatoid, and the remaining mesotheliomas are mixed. Immunohistochemical (IHC) markers are necessary to help distinguish between metastatic carcinomas and mesothelioma. These markers include positive pankeratin, keratin 5/6,

calretinin, and WT-1. Negative markers include CEA, CD15, Ber-EP4, Moc-31, TTF-1, and B72.3. Such markers are important as mesothelioma may be difficult to distinguish from other malignancies, that is, biphasic mesotheliomas from carcinosarcomas or fibrous mesothelioma from metastatic pleural sarcomas.³⁶

Several studies have examined the role of histologic subtype on prognosis. It has consistently been shown that epithelioid type has a better prognosis than the biphasic or sarcomatoid subtypes.³⁷ In addition to these histologies, several other, lower grade mesothelial tumors exist, such as *papillary mesothelioma*, which often occurs in the abdominal cavity, multicystic mesothelioma, which often presents in “clusters” and which can also present in the peritoneum, and adenomatoid mesothelioma, which is a benign mesothelial lesion in the genitourinary system. These subtypes typically have a more indolent course than the epithelioid, biphasic, or sarcomatoid histologies, though the clinical course can vary.³⁸

Tumor markers

Two highly studied tumor markers for mesothelioma are osteopontin (OPN) and mesothelin (SMRP). OPN is a glycoprotein biomarker that is expressed by certain cancers, including lung, breast, colorectal, gastric, ovarian, and melanoma. OPN is also involved in cell-signaling pathways that are associated with asbestos-induced carcinogenesis. A recent study compared OPN levels in patients with mesothelioma with OPN levels in patients with asbestos-related diseases that were not malignant. This study revealed that OPN can be used to separate those patients that had asbestos exposure with mesothelioma from those who had asbestos exposure without malignancy.³⁹ A recent meta-analysis examined the utility of osteopontin in the diagnosis of mesothelioma over seven studies, and found a pooled sensitivity of 0.57 (95% CI 0.52–0.61), specificity of 0.81 (95% CI 0.79–0.84), positive likelihood ratio (PLR) of 3.78 (95% CI 2.23–6.41), and a negative likelihood ratio (NLR) of 0.51 (0.38–0.67). These results support the above correlation between OPN and mesothelioma.⁴⁰ OPN is limited by its lack of specificity and its performance is superior in plasma compared to serum.

SMRP originally described by Pastan,^{41, 42} is also a glycoprotein and is found in mesothelioma, ovarian cancer, and pancreatic cancer. Robinson et al.⁴³ demonstrated in 48 patients that SMRP is a serum biomarker with 83% sensitivity and 95% specificity and was confirmed to be a promising marker for MPM in blood and pleural fluid.⁴⁴ Serum SMRP levels were higher in MPM patients when compared to lung cancer patients, as were the SMRP levels in pleural fluid when compared to benign pleural fluid or other non-MPM pleural effusions.⁴⁴ Indeed, prior studies have suggested that the accuracy of detection is superior in pleural fluid than in serum,⁴⁵ though serum analysis is a more convenient measure of this factor. One recent study examined several combinations of serum markers as diagnostic tools for mesothelioma, and in particular to determine if other markers could enhance the diagnostic yield of using SMRP alone. The study found that combining SMRP and carcinoembryonic antigen (CEA) could improve the differentiation between mesothelioma and lung cancer, as well as the difference between mesothelioma and patients with asbestos exposure that do not have this disease.⁴⁶ A large meta-analysis has confirmed the report that the sensitivity and specificity of SMRP are similar in many studies.⁴⁷

In addition to being used as a diagnostic tool, several studies have focused on these markers in tracking the course of disease. In one prospective study, 41 patients had 165 samples collected and disease status temporally assessed using response evaluation criteria in solid tumors (RECIST) criteria. The authors found that while SMRP was significantly correlated with a response, as measured by absolute change, RECIST criteria, or modified RECIST criteria, no such associations were found with OPN.⁴⁶ Another prospective study of 97 patients found that changes in soluble SMRP were associated with radiologic

response, metabolically active tumor volume, and median survival.⁴⁸ Further validation of SMRP as a prognostic marker and a measure of tumor response is ongoing.

Several other potential tumor markers have been explored as having utility in this clinical scenario. One high-profile tumor marker that has been explored recently is fibulin-3, an extracellular protein located in the basement membrane of the vasculature. When assessing plasma fibulin-3 levels, the investigators found that this marker could distinguish between healthy patients with exposure to asbestos from those patients with malignancy in a cohort of over 200 patients, and this was confirmed by blinded validation studies.⁴⁹ Furthermore, when plasma fibulin-3 is analyzed in conjunction with that measured in the pleural effusion, it was found that the marker is effective in differentiating benign from both benign and other types of malignant effusions. The diagnostic ability of fibulin-3 has been confirmed in other studies.⁵⁰ In one study that compared soluble SMRP and fibulin-3 as tumor markers, the investigators found that while SMRP was superior in diagnosis, fibulin-3 was better in assessing prognosis, thus implying utility of both markers in a complementary manner.⁵¹

Imaging modalities

CT scan is very useful for diagnosis and disease assessment ([Figure 3](#)).⁵² Findings on CT scan include a pleural effusion, pleural nodularity, and concentric pleural thickening. However, investigators from Oxford recently estimated the positive and negative predictive values of approximately 400 patients undergoing a CT scan before thoracoscopy for diagnosis. They found that the positive predictive value of a CT scan that demonstrated “malignant” findings was 80%, while the negative predictive value was 65%. Thus, CT scan alone appears to be insufficient in determining which patients undergo invasive pleural biopsies.⁵³

Figure 3 PET-CT and pleural mesothelioma. (a,b) Posterior and anterior views of the left chest reveals a bulky hypermetabolic tumor (c) maximum intensity projection (MIP) view confirming no disease outside the chest. (d) Sagittal view of CT image reveals bulky disease in the fissures. (e) Coronal view reveals abutment of the subclavian artery and possible diaphragmatic involvement.

Additional imaging modalities that can be used to stage mesothelioma include magnetic resonance

imaging (MRI) and positron emission tomography (PET) scanning. MRI is not frequently used, but may be of additional benefit to detect diaphragm invasion, involvement of the endothoracic fascia, or an isolated area of chest wall involvement in patients that may be candidates for surgical resection. In addition, the role of PET/CT scanning has not been conclusively elucidated, and PET imaging is not recommended for diagnosis or staging in the 2014 National Comprehensive Cancer Network guidelines. However, many prior and ongoing studies are assessing this technique because of its utility in other thoracic malignancies such as lung cancer. In one study, PET was found to have a sensitivity of only 11% in detecting metastatic lymph-node disease⁵⁴; however, the same study found that a high standardized uptake values (SUV) correlated with N2 disease at the time of resection. More recently, research from the same institution showed that an SUV value 10 greater correlated with a significantly shorter survival time and a 3.3 times greater risk of dying compared to SUV levels below 10.⁵⁵ This suggests that PET results may help to stratify patients for different treatments according to their metabolic activity. Integrated CT-PET is more informative than PET alone. In a study of 29 MPM patients, integrated CT-PET correctly assigned the overall stage in 72% of cases, showed increased sensitivity for T4 disease, 67% versus 19% for PET alone, identified 7 patients with extrathoracic disease missed by conventional radiographic studies, and identified 12 patients that would have been precluded from surgical resection based on conventional studies.⁵⁶ In addition, investigators from Memorial Sloan-Kettering Cancer Center examined the accuracy of PET scan in detecting histologic subtype. In 100 patients with MPM who underwent preoperative PET scans, they found that the mixed subtype of epithelioid mesothelioma had higher SUVs than patients with the nonpleomorphic subtype, thus supporting the conclusion that higher SUVs are correlated with aggressive disease.⁵⁷ Another recent study examined the prognostic significance of PET scan after neoadjuvant chemotherapy for resectable MPM in 50 patients, all of whom underwent EPP (extrapleural pneumonectomy) and postoperative hemithoracic radiotherapy. Metabolic response after neoadjuvant chemotherapy was significantly correlated with the overall survival, and the authors concluded that response to therapy may be integrated into the decision-making process for surgical resection after neoadjuvant chemotherapy.⁵⁸

Surgical diagnosis and staging in mesothelioma

The interventions that can be used for diagnostic purposes in mesothelioma include thoracentesis with closed pleural biopsy, VATS (video-assisted thoracoscopy surgery) with pleural biopsy, and open pleural biopsy. It is important to have adequate tissue to classify not only whether the biopsy reveals mesothelioma, but also possibly the subtype of mesothelioma. Although cytologic diagnosis can be difficult, electron microscopy and IHC staining on a cell block of the pleural fluid can be performed to increase diagnostic yield up to 84% in suspected cases. Video-assisted thoracoscopy with direct biopsy and assessment of the involvement of the lung and pleura remains the gold standard for diagnosis. Studies have confirmed the utility of this technique among patients undergoing surgery for mesothelioma, but have also pointed out the difficulty in obtaining correct histologic diagnosis.⁵⁹ Information about parietal, visceral, and diaphragmatic pleural involvement can be obtained, and this might have prognostic value for survival.⁶⁰ Open pleural biopsy is rarely performed, but may be required when there is no free pleural space.

Staging and prognostic indicators

The American Joint Committee on Cancer (AJCC) staging system for mesothelioma has been validated in a number of surgically based trials⁶¹ and has been used since the 1990s. In order to improve the current

staging system, an international database of over 2000 staged patients with MPM was analyzed by the International Association for the Study of Lung Cancer, and covariates predictive of survival included best staging information, age, sex, histology (epithelioid or not), and type of surgical procedure (palliative vs EPP or pleurectomy decortication).⁶² Supplementary prognostic indicators complementing the international database include platelet count, white blood cell count, and the addition of adjuvant therapy.⁶³ Gill,⁶⁴ in a study of 88 epithelial MPMs having EPP, has expanded on the influence of tumor volume and survival in MPM stage-independent model of risk for death in patients having surgical cytoreduction as originally described by Pass et al.⁶⁵ In Gill's report, tumor volume, hemoglobin concentration, platelet count, pathologic TNM (tumour, node, and metastasis) category, and administration of adjuvant chemotherapy or RT were associated with survival.⁶⁴ Richards, using the same MPM cohorts as Gill from the Brigham and Women's Hospital series, has recently described a validated model for survival and time to recurrence in cytoreduced MPM using hemoglobin, CT volume, thickness of the fissures, and histological subtype ([Table 1](#)).⁶⁶

Table 1 The International Mesothelioma Interest Group (IMIG) staging system for pleural mesothelioma

T1	
T1a	Tumor limited to the ipsilateral parietal ± mediastinal ± diaphragmatic pleura, no involvement of the visceral pleura
T1b	Tumor involving the ipsilateral parietal ± mediastinal ± diaphragmatic pleura, tumor also involving the visceral pleura
T2	Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: <ul style="list-style-type: none"> • Involvement of diaphragmatic muscle • Extension of tumor from visceral pleura into the underlying pulmonary parenchyma
T3	Describes locally advanced but potentially resectable tumor Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: <ul style="list-style-type: none"> • Involvement of the endothoracic fascia • Extension into the mediastinal fat • Solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall • Nontransmural involvement of the pericardium
T4	Describes locally advanced technically unresectable tumor Tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: <ul style="list-style-type: none"> • Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction • Direct transdiaphragmatic extension of tumor to the peritoneum • Direct extension of tumor to the contralateral pleura

	<ul style="list-style-type: none"> • Direct extension of tumor to mediastinal organs • Direct extension of tumor into the spine • Tumor extending through to the internal surface of the pericardium with or without a pericardial effusion; or tumor involving the myocardium
N-Lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastases in the ipsilateral bronchopulmonar or hilar lymph nodes
N2	Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes including the ipsilateral internal mammary nodes
N3	Metastases in the contralateral mediastinal, contralateral internal mammary, ipsilateral, or contralateral supraclavicular lymph nodes
M-Metastases	
MX	Presence of distant metastases cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present
Stage I	
Ia	T1a N0 M0
Ib	T1b N0 M0
Stage II	T2 N0 M0
Stage III	Any T3 M0
	Any N1 M0
	Any N2 M0
Stage IV	Any T4
	Any N3
	Any M1

Abbreviations: T, primary tumor; T1, limited to ipsilateral pleura only (parietal pleura, visceral pleura); T2, superficial local invasion (diaphragm, endothoracic fascia, ipsilateral lung, and fissures); T3, deep local invasion (chest wall beyond endothoracic fascia); T4, extensive direct invasion (opposite pleura, peritoneum, and retroperitoneum); N, lymph nodes; N0, no positive lymph node; N1, positive ipsilateral hilar nodes; N2, positive mediastinal nodes; N3, positive contralateral hilar nodes; M, metastases; M0, no metastases; M1, metastases; blood-borne or lymphatic.

Treatment

The treatment options for mesothelioma depend on several parameters, including performance status, medical comorbidities, pulmonary function, stage, and age of the patient as well other factors. Surgical

options are considered as long as the bulk of the disease can be removed without leaving gross disease behind. If this cannot be accomplished, then supportive measures for palliation can be used ([Table 2](#)).

Table 2 Treatment options for mesothelioma

Supportive care	
Effusion control	Talc pleurodesis
	Vats assisted
	Slurry
	Pleurex catheter
	Repeated thoracenteses
Pain control	Narcotics
	Permanent epidural catheter
	Localized radiation
Surgery	Pleurectomy with decortication
	Extrapleural pneumonectomy
Chemotherapy ^a	Pemetrexed (Alimta) and cisplatin ^a
	Gemcitabine and cisplatin ^a
	Vinorelbine (Navelbine)
	Phase I/II trials with targeted agents
Multimodality therapy	Induction chemotherapy, surgery, and postoperative radiotherapy ^b
	Surgery and postoperative radiotherapy
	Surgery and postoperative chemotherapy
	Surgery and novel cytotoxic/targeted agents ^b
	Induction Radiation followed by surgery ^b
Novel intrapleural therapies	Hyperthermic chemoperfusion, ^b chemotherapy, povidone-iodine ^b
	Photodynamic therapy ^b
	Gene therapy ^b
Novel radiation techniques at selected centers	Intensity-modulated radiation therapy

^a Most commonly used in recent phase II/III trials.

^b Under investigation.

Supportive care

The median survival of MPM patients who select supportive care ranges only from 4⁶⁷ to 13 months,⁶⁸ and is influenced by multiple factors including the biology of the tumor as well as whether survival time

is recorded from the time of symptom initiation or from the time of definitive diagnosis. There are a number of options for the control of pleural effusion, including repeated thoracenteses, talc pleurodesis, or placement of a Pleur X (Denver Biomedical, Denver, CO) catheter.⁶⁹ Failure of these techniques is usually associated with lung trapped by the tumor, a large solid tumor mass, a long history of effusion with multiple thoracenteses leading to loculations, age older than 70 years, or poor performance status. In such cases, the PleurX catheter with its one-way valve can be implanted under local anesthesia into pleural effusion, and patients can drain themselves at home using the available disposable drainage kits.⁷⁰ Recently, a randomized trial examined the influence of pleural fluid palliation in mesothelioma. The MesoVats trial was a randomization between 2003 and 2012 of 87 VAT pleurectomy or 88 talc pleurodesis for patients who were not considered for maximal cytoreductive techniques. There was no survival difference, but pleural effusion was better controlled with pleurectomy patients, and a significant benefit in quality of life was recorded in favor of the pleurectomy group.⁷¹

Patients with chest-wall pain due to mesothelioma should be seen in consultation by a dedicated pain management team to consider narcotic control as well as novel pain-control techniques including outpatient epidural catheter use. Palliative radiotherapy is associated with a median survival of 4–5 months.^{72, 73}

Surgery for pleural mesothelioma

Maximal cytoreductive procedures

The goal of cytoreductive surgery in MPM should be the removal of all visible or palpable tumor (R0 or R1) or a “macroscopic complete resection” (MCR), regardless of whether that involves EPP or a lung-preserving operation. The Mesothelioma Domain of the International Association for the Study of Lung Cancer has defined uniform nomenclature for pleural mesothelioma resections⁷⁴ and includes EPP, extended pleurectomy and decortication (ePD) (resection of the diaphragm and/or pericardium), and pleurectomy decortication as potential MCRs. Suspicion and documentation of disease outside the involved hemithorax eliminates the use of an MCR. Patients who present with ECOG performance status 2 or greater, or who have limiting cardiac reserve either with nonreversible myocardial ischemia or compromised ventricular function (ejection fraction <50%) are usually not candidates for cytoreductive procedures. Moreover, patients with compromised pulmonary-function testing who are not felt to be candidates for pneumonectomy must be carefully evaluated for either extended P/D in that the cytoreduction should not compromise the existing lung function but may recruit trapped lung and possibly improve dyspnea.

Extrapleural pneumonectomy (EPP)

As detailed in a recent systematic review of the use of EPP for MPM,⁷⁵ the median overall survival varies from 9.4 to 27.5 months, and 1-, 2-, and 5-year survival rates ranges from 36% to 83%, 5% to 59%, and 0% to 24%, respectively ([Figure 4](#)). Overall perioperative mortality rates ranged from 0% to 11.8%, and centers routinely performing the operation have mortality rates close to 3% through improvements in preoperative staging, anesthesia, resection, reconstruction, and perioperative management of procedure-related complications.⁷⁶ The chief perioperative morbidities include atrial fibrillation, myocardial infarction, and pulmonary complications.⁷⁷ EPP *alone* does not appear to prolong survival. In most EPP series, median survival is <2 years, but 10–20% of patients are 5-year survivors. Patients with sarcomatoid histology and/or lymph-node involvement have an even poorer prognosis and should not be considered as candidates for EPP.⁷⁸

Figure 4 Extrapleural pneumonectomy for mesothelioma: (a) Computer tomography reveals thickened pleura, pericardium, and disease in the fissures. (b) Intraoperative view after the resection with hand on the liver. Stapled bronchial stump, right atrium, and extent of pericardiotomy are seen. (c) Operative specimen reveals diaphragmatic resection to the right and thickened pleura encasing the lung. (d) Reconstruction of the diaphragm and pericardium with Gore-Tex patches.

Trimodality therapy and the move to lung-sparing techniques

Trimodality therapy consists of induction chemotherapy, followed by EPP, and RT either as hemithorax radiation to the pneumonectomy cavity or as intensity-modulated RT.⁷⁹ Overall, the studies of MPM trimodality therapy demonstrate a 3.1% mortality for EPP, along with a 27.7 month median survival in the 60% of presenting patients who complete the full package. The Mesothelioma and Radical Surgery (MARS) was an attempt to validate the use of EPP as part of this radical treatment package. MARS was originally designed as a randomized trial with 670 patients needed comparing induction chemotherapy, EPP, and postoperative RT to induction therapy but no EPP.⁸⁰ When difficulty arose in recruiting patients, an initial feasibility study was performed in 50 patients for EPP or no EPP. The study revealed nonsignificant differences in the 6, 12, 18, and median survivals comparing the surgery arm to the nonsurgical arm, with a median survival of 14.4 versus 19.5 months, respectively. The 18% operative mortality from EPP in MARS must be contrasted to the 3.1% operative mortality from other phase II trimodality trials (3.1%). Moreover, the lack of power of the study, the nonstandardization of the preoperative chemotherapy, and the fact that only a third of the individuals received the full trimodality

have diminished the impact of MARS.⁸¹

Nevertheless, the movement away from the idea that the only surgical MCR for MPM was EPP was already gaining momentum ([Figure 5](#)). A retrospective review of 663 consecutive patients (538 men and 125 women with MPM who underwent EPP or P/D at three US mesothelioma centers reported an operative mortality of 7% for EPP ($n = 27/385$) and 4% for P/D ($n = 13/278$).⁸² Multivariate analysis demonstrated a 1.4-fold greater chance for death with EPP ($P < 0.001$) controlling for stage, histology, gender, and multimodality therapy. This study was the first to postulate that patients who underwent P/D could have comparable survival to those who underwent EPP; however, the reasons for such a conclusion were multifactorial and subject to selection bias. Other studies revealed a doubling of overall survival if the P/D is performed to remove all macroscopic disease in a compulsive manner.^{83–90} In studies where a direct comparison of EPP and P/D performed by the same surgeon have been reported, P/D has less mortality, less morbidity, and a comparable overall survival to EPP. These findings are particularly striking for early-stage mesothelioma. As ePD is a less-extensive operation with lower morbidity and mortality than EPP, a newly designed MARS-2 trial will attempt to demonstrate whether this type of operation can offer survival and/or quality-of-life benefits to patients with MPM.⁹¹ Patients with MPM registered on MARS-2 will receive two cycles of pemetrexed-platinum chemotherapy. Patients who do not progress on CT scan will then be randomized to up to four further cycles of pemetrexed-platinum chemotherapy or ePD followed by up to four further cycles of postoperative pemetrexed-platinum chemotherapy. An EORTC (European Organization for Research and Treatment of Cancer) trial will investigate the timing of the chemotherapy in combination with ePD.⁹² Patients with MPM will be randomly allocated to ePD preceded or followed by four cycles of cisplatin/pemetrexed at standard doses. It is hoped that this randomized trial will address the feasibility of the operation in combination with standard (neo)-adjuvant chemotherapy and set the experimental arm of an ensuing phase III trial exploring the role of surgery in MPM or could be a standard arm for future trials of surgery in MPM.

Figure 5 Pleurectomy for mesothelioma: (a) typical computer tomogram reveals thickened pleura; (b) operative view reveals disease primarily on the parietal pleura; (c) operative specimen; (d) completion of satisfactory cytoreduction with sparing and decortication of the lung.

Novel surgical strategies

An innovative phase I/II approach (surgery for mesothelioma after radiation therapy, SMART) using a short-accelerated course of high-dose hemithoracic intensity-modulated radiation therapy (IMRT) followed by EPP has been investigated by Cho et al.⁹³ Patients received 25 Gy in five daily fractions during 1 week to the entire ipsilateral hemithorax with concomitant 5 Gy boost to areas at risk followed by EPP within 1 week of completing neoadjuvant IMRT. Of the 25 patients accrued, IMRT was well tolerated with no grade 3+ toxicities, and EPP was performed 6 ± 2 days after completing IMRT without any perioperative mortality. After a median follow-up of 23 months, the cumulative 3-year survival reached 84% in epithelial subtypes compared with 13% in biphasic subtypes ($p = 0.0002$). A multicenter approach is planned for validation of these results.

At the University of Pennsylvania, a phase III trial of MCR with and without photodynamic therapy (PDT) is planned. Results with PDT have been associated with increased survival times with the conversion of MCR to lung sparing techniques such as standard or ePD.^{94, 95} Intrapleural hyperthermic perfusions are now more popular especially in Europe but differ from the studies in the United States in that these have not used cisplatin/gemcitabine during the perfusion, electing to study warm povidone-iodine instead.

Moreover, the perfusions are being performed chiefly in patients having pleurectomy-decortications.⁹⁶

Radiation therapy for mesothelioma

RT is typically delivered in the adjuvant setting for MPM. The RT approach and risks are primarily determinant on the type of surgical resection involved, and can be divided into two categories: RT after EPP and RT after P/D or no surgery.

Adjuvant radiation therapy after extrapleural pneumonectomy

As mesothelioma is a malignancy that involves the pleura, it is generally accepted that even when specific regions are found to be involved with malignancy, the entire pleural cavity is at risk for disease. Therefore, attempts to control microscopic disease with RT have typically included treating the entire hemithorax, specifically the entire pleura +/- the ipsilateral lung and pericardium. Historically, hemithoracic radiation has been given using two-dimensional, or “conventional” techniques. These approaches utilize a limited number of fields and nonconformal methods. As a result, a great deal of dose heterogeneity typically occurs, with the target volume being underdosed and surrounding normal tissue, such as the esophagus, lung, heart, and spinal cord, receiving increased dose, or “hot spots.” Rusch et al. performed a prospective phase II trial of surgical resection followed by hemithoracic radiation using conventional methods. From 1995 to 1998, approximately 90 patients at MSKCC (Memorial Sloan Kettering Cancer Center) underwent surgical resection (70% with EPP) and 57 then underwent hemithoracic RT to doses of 41.4–54 Gy. The median survival was 17 months, with approximately 20% of these patients experiencing recurrence at the radiation treatment margins. Most patients that recurred experienced distant metastases.^{97, 98}

In the past decade, the conformal technique of IMRT has been advanced and applied to this clinical context. As a result, conformality has increased with this approach ([Figure 6](#)). Several institutions have reported their outcomes with this approach. In an early study from MD Anderson Cancer Center, 28 patients were treated with hemithoracic IMRT after EPP to doses of 45–50 Gy. One year OS and DFS were 65% and 88%, respectively, and 65% of patients had grade 2 or 3 nausea/vomiting.⁹⁹ These results have since been updated twice, in 2007^{100, 101} and 2013,¹⁰² with the most recent study demonstrating 90% OS at 1 year and 71% at 2 years in this selected group of patients. Grade 3 toxicity was generally <20%, with 15–20% rates of grade 3 dermatitis and gastrointestinal side effects. It should be emphasized, however, that adhering to dose constraints is essential to minimize the risk of high-grade and potentially fatal toxicity. One early report by investigators at the Dana-Farber Cancer Institute demonstrated that 6 of 13 patients treated with IMRT after EPP experienced fatal radiation pneumonitis. While 11 of these patients also received heated intraoperative cisplatin, which may have contributed to this observation, the low-dose region to the remaining lung (particularly the percentage of lung receiving 20 Gy, or V20) was higher than our current acceptable levels.¹⁰³ Thus, conformality with IMRT comes with the tradeoff of a “low-dose radiation bath” to the remaining lung that needs to be closely monitored when performing RT planning.

Figure 6 (a–c) Two axial slices and a coronal view of IMRT after extrapleural pneumonectomy. IMRT offers improved conformality and better dose homogeneity to both the target volume and critical normal structures.

Radiation therapy after pleurectomy/decortication (P/D) or unresectable disease

The role of RT after P/D is not yet established. Indeed, there are several reasons why hemithoracic radiation is more challenging when patients do not undergo an EPP. First, functional lung remains that exposes the patient to the risk of high-grade acute lung toxicity bilaterally. Second, presuming that the ipsilateral lung is contributing to the total lung function, because much of that lung will receive radiation dose, patients are at a higher risk for a substantial reduction in lung function after RT (compared to immediately postoperatively). Finally, by treating much of the ipsilateral lung and therefore deeming it to be nonfunctional, a “shunting” effect can be produced whereby perfusion continues in the ipsilateral lung, yet very little air exchange occurs. As a result, initial studies examining this approach demonstrated suboptimal outcomes. In one analysis from Memorial Sloan Kettering, 123 patients were treated with lung-sparing surgery and underwent hemithoracic radiation using conventional techniques to a median total dose of 42.5 Gy, with approximately half of the patients also receiving brachytherapy. Local control was approximately 40%, with 38 cases of grade 3 toxicity and 7 cases of grade 4–5 toxicity. Thus, this technique was associated with low levels of local control and relatively high rates of toxicity.¹⁰⁴

More recent studies have incorporated modern techniques into this paradigm, and several institutions have reported outcomes. [Figure 7](#) demonstrates a patient that has received this treatment, with attempted sparing of the ipsilateral lung through the creation of a “rind” in treatment volume delineation. A study from Memorial Sloan Kettering reported results with 67 patients treated with either lung-sparing surgery or biopsy alone, and found a 1- and 2-year actuarial failure rate of 56% and 74%, respectively. Local recurrence was the dominant failure pattern, and patients undergoing a P/D increased the time to local recurrence (vs biopsy alone).¹⁰⁵ MD Anderson Cancer Center also recently analyzed their data of 24 patients treated with IMRT after P/D, and found OS and PFS rates of 76% and 67% at 1 year, respectively, and 56% and 34% at 2 years, respectively. Measurable changes in pulmonary function were observed after surgery [21% forced vital capacity (FVC), 16% forced expiratory volume in one second (FEV1)], and again after hemithoracic IMRT (31% FVC and 25% FEV1). When comparing this group of patients to historical controls treated with EPP and adjuvant IMRT, no differences were found in high-grade toxicity, and both median OS (28.4 months vs 14.2 months, $p = 0.04$) and PFS (16.4 months vs 8.2 months) favored P/D.¹⁰⁶ Overall, prospective trials are needed to evaluate this approach and incorporate RT after P/D or in the setting of unresectable disease, and one such phase II trial is currently ongoing at

Memorial Sloan Kettering and MD Anderson Cancer Center. In addition, the further advancement of radiation techniques such as proton-beam therapy may improve the extent of sparing that can be achieved when the lung is intact.

Figure 7 (a, b) An axial and a coronal view of a patient treated with IMRT after pleurectomy/decortication. A “rind” is created to attempt to spare the inner portion of the lung, though full sparing of the ipsilateral lung is typically not feasible.

Systemic chemotherapy for mesothelioma

The standard practice in the United States for the treatment of resectable MPM is to consider trimodality therapy that includes four cycles of either neoadjuvant or adjuvant cisplatin-pemetrexed. However, several issues regarding the optimal sequence of trimodality therapy and the choice of systemic regimen remain unclear.

Neoadjuvant or adjuvant systemic therapy choices

The decision to administer neoadjuvant or adjuvant systemic therapy is made in a multidisciplinary setting. Neoadjuvant chemotherapy has the potential to adversely delay surgical resection or induce complications before resection. In addition, significant response rates with tumor shrinkage range between 29% and 44% with cisplatin-pemetrexed.^{107, 108} It is estimated from clinical trials that between 42% and 84% of the time, an EPP after neoadjuvant chemotherapy will be able to be completed.^{107–113} Adjuvant chemotherapy does not compromise surgical resection, but does carry the risk of being unable to be administered after surgery and radiation because of diminished patient performance status. To date, there are no randomized trials comparing neoadjuvant or adjuvant therapy and both approaches are acceptable standard practice. A review of several prospective neoadjuvant clinical trials reveals a median overall survival range of 16.6–25.5 months.^{29–35} One adjuvant trial ($n = 20$) using platinum-gemcitabine or platinum-pemetrexed after EPP reported a comparable median overall survival of 17 months.^{36, 114}

The optimal systemic platinum-doublet is unknown for resectable MPM. Cisplatin-pemetrexed is commonly accepted as the standard of care in the United States; however, other countries prefer alternate

regimens. De Perrot et al.¹¹⁵ conducted a retrospective analysis ($n = 60$) on their centers' use of neoadjuvant chemotherapy and reported that there was no significant difference in survival outcomes. The neoadjuvant regimens assessed included cisplatin-vinorelbine, platinum-pemetrexed, cisplatin-raltitrexed, and cisplatin-gemcitabine.

With the risks in mind, neoadjuvant chemotherapy has the capability to yield prognostic information for surgical resection. In the largest neoadjuvant EPP trial ($n = 75$) completed to date, Krug et al.¹⁰⁷ reported that responding patients (defined as complete or partial response to neoadjuvant chemotherapy) had an improvement in the median overall survival (29.1 months compared to 13.9 months, $P = 0.076$) compared to patients who did not have a response.¹⁰⁷ In this trial, for the intent to treat population, the median time to progression was 13.1 months and the overall survival was 16.6 months. Taken together, the neoadjuvant platinum-doublet systemic therapy trials indicate that a need exists for better systemic agents with higher response rates, low toxicity, and capability to be given as maintenance therapy.

Several investigational approaches to neoadjuvant therapy with novel agents are being attempted in the resectable MPM population. An exploratory window of opportunity trial with neoadjuvant dasatinib was performed at the University of Texas M.D. Anderson Cancer Center. MPM cell lines and tumor cells have overexpression of activated Src kinase, and preclinical studies demonstrated antitumor efficacy of dasatinib.¹¹⁶ This study has completed accrual and demonstrated that the biomarker Src kinase^{Tyr419} was a pharmacodynamics marker and higher baseline levels were predictive of a metabolic response by PETCT to neoadjuvant dasatinib therapy. In addition, distinct patterns of PDGFR α and β expression by immunohistochemistry were predictive of sensitivity or resistance to dasatinib treatment. In addition, the Southwest Oncology Group (SWOG) is developing a neoadjuvant immunotherapy study in resectable MPM using an anti-PDL1 inhibitor. This study will utilize the immunotherapy agent as maintenance therapy after completion of trimodality treatment.

Memorial Sloan Kettering has been pioneering the use of an adjuvant WT-1 (Wilm's Tumor-1) vaccine in a Department of Defense-sponsored clinical trial.¹¹⁷ The peptide vaccine delivered in the trial stimulates host T cells to identify and eliminate WT-1-expressing cells. Eligible patients must express WT-1 by immunohistochemistry on their mesothelioma tumor cells. In normal cells, WT-1 is a transcription factor that is present in young children but is lost once adulthood is reached.

Intrapleural and immunotherapy strategies

There has been significant research on intrapleural administration of chemotherapies for MPM. However, it is not standard of care and is recommended to only perform intrapleural therapy on a well-designed clinical trial. The premise behind the use of intrapleural treatment is to bring the agent into direct tumor cell contact and deliver high concentrations of the drug. In the past, intracavitary platinum-based regimens have been used with median PFS ranging between 7.5 and 13.6 months and median OS between 11.5 and 18.3 months.^{118–123} The most significant adverse event identified in these studies was renal failure from systemic absorption of cisplatin. Hyperthermic intrapleural therapy administered after P/D yields median overall survival ranges between 9 and 13 months.^{122, 124–126}

Intrapleural gene therapy using adenovirus vectors containing the herpesvirus thymidine kinase (Ad-HSVtk) suicide gene^{127–129} and an adenoviral vector containing an immune stimulant, interferon- β (Ad.hu.IFN- β)¹³⁰ has also been explored with some preliminary positive results for successful gene transfer into patient tumor cells. However, this strategy appears to primarily benefit patients with less bulky disease. Intrapleural cytokine administration has been reported in small studies to have a potential antitumor effect.^{131–134} Gamma-interferon and interleukin-2 (IL-2) are the most common agents evaluated,

with fever, flu-like symptoms, and catheter infections comprising the main toxic effects. Astoul et al.¹³² reported that responders to IL-2 had significant overall survival benefit (28 months vs 8 months, $P = 0.01$). Lucchi et al.¹³¹ reported the median overall survival of 26 months with a trial administering neoadjuvant intrapleural IL-2, P/D, adjuvant radiation, systemic IL-2 and cisplatin-gemcitabine chemotherapy, and then maintenance subcutaneous IL-2. Although the majority of the patients developed local recurrence, the use of immune modulatory agents is a worthwhile strategy in resectable MPM.

The role of immunotherapy in resectable mesothelioma is also being explored. Mesothelioma is considered an immunogenic disease and it is surmised that the addition of an anti-PDL1 inhibitor to cisplatin-pemetrexed in the neoadjuvant setting would be clinically beneficial. After surgical resection and adjuvant radiation treatment, maintenance immunotherapy to enhance t-cell activation against microscopic disease would potentially increase the overall survival outcomes. At ESMO 2014, Mansfield et al.¹³⁵ reported a 40% PD-L1 IHC expression in pleural mesotheliomas ($n = 224$) using a mouse monoclonal antihuman B7-H1 (clone 5H1-A3). A score of <5% IHC expression was considered negative. PD-L1 IHC expression was associated with more disease burden and less offers of surgery to the patient. In addition, PD-L1 IHC expression was associated with a worse survival (6 months vs 14 months, $p < 0.0001$).¹³⁵ SWOG is therefore initiating a neoadjuvant trial with cisplatin-pemetrexed with and without MPDL3280A, a PD-L1 inhibitor, in resectable MPM patients.

Systemic therapies for unresectable mesothelioma

In the front-line metastatic setting, cisplatin-pemetrexed is the Food and Drug Administration (FDA) approved regimen in the United States.¹³⁶ Vogelzang et al. conducted a randomized study of 456 patients and randomized them to cisplatin (75 mg/m² intravenous every 3 weeks) monotherapy or cisplatin (75 mg/m²) and pemetrexed (500 mg/m²) given intravenously every 3 weeks for a maximum of six cycles. The cisplatin-pemetrexed regimen improved the response rate (41.3% vs 16.7%, $p < 0.001$), time to progression (5.7 months vs 3.9 months, $p < 0.001$), and median overall survival (12.1 months vs 9.3 months, $p = 0.02$). The main grade 3/4 side effects experienced with the combination regimen in over 10% of patients were neutropenia, nausea/vomiting, and fatigue. Pemetrexed usage must be accompanied by vitamin B12 and folic acid supplementation. In addition, use of corticosteroids during pemetrexed administration is necessary.

Although there is no randomized clinical trial data on maintenance therapy, patients can be given platinum-pemetrexed for 4–6 cycles of therapy followed by pemetrexed maintenance therapy. In the treatment of nonsquamous nonsmall cell lung cancer, continuation maintenance therapy is a standard practice¹³⁷ and appears to work well for unresectable mesothelioma as well. A randomized trial was underway to evaluate this issue in mesothelioma, but accrual was problematic owing to the frequent use of maintenance pemetrexed. In patients who cannot tolerate platinum, single-agent pemetrexed can be given.¹³⁸

In the unresectable setting, carboplatin is a very reasonable alternative to cisplatin and has demonstrated equivalent survival.^{139, 140} Other platinum-antifolate regimens (raltitrexed)¹⁴¹ or platinum-gemcitabine^{142, 143} have been investigated and would be reasonable alternatives if a patient is unable to receive pemetrexed.

There are currently no FDA approved agents in the salvage setting for mesothelioma. Patients are encouraged to enroll in clinical trials with novel agents and immunotherapy. However, off-protocol, the agents that are most commonly prescribed include gemcitabine, vinorelbine, or the combination of gemcitabine–vinorelbine. Gemcitabine (1250 mg/m² intravenous on days 1, 8, and 15 of a 28-day cycle)

has been reported to have response rate 7% and median OS of 8 months in the chemo-naïve setting.¹⁴⁴ Gemcitabine–vinorelbine (1000 mg/m² gemcitabine and 25 mg/m² vinorelbine on days 1 and 8 every 3 weeks for up to six cycles) has reported to have minor efficacy with a response rate of 7.4% and median time to progression of 2.8 months.¹⁴⁵ A phase II trial of single-agent vinorelbine ($n = 63$) reported a response rate of 16% and overall survival of 9.6 months.¹⁴⁶ A retrospective analysis¹⁴⁷ of 60 salvage mesothelioma patients conducted at Memorial Sloan Kettering treated in the second and third-line setting reported minimal response rates to either gemcitabine or vinorelbine but significant stabilization of disease. There was no significant gain in the overall survival benefit. Gemcitabine ($n = 27$) had a median PFS of 1.6 months and median OS of 4.9 months, while vinorelbine ($n = 45$) had a median PFS of 1.7 months and median OS of 5.4 months.

Biologic and novel-targeted agents

The use of novel biologic therapies has been an area of active research in MPM. The earliest biologic monotherapy studies, which were based on preclinical data demonstrating overexpression of the epidermal growth factor receptor (EGFR) and platelet-derived growth factor receptor (PDGFR) on MPM tumor cells, did not demonstrate significant response rates from either EGFR tyrosine kinase inhibitors (gefitinib or erlotinib)^{69, 70, 148, 149} or imatinib mesylate, a PDGFR inhibitor.¹⁵⁰ However, disease stabilization was noted in the imatinib mesylate monotherapy trials. The field has broadened significantly with several new targets and biologic agents.

Agents targeting angiogenesis

Mesothelioma tumor cells typically have high levels of vascular endothelial growth factor (VEGF) secretion, and high serum VEGF levels in patients are correlated to worse outcomes.¹⁵¹ Bevacizumab, a monoclonal antibody to the ligand VEGF, has been the most studied agent so far in mesothelioma. A randomized frontline phase II trial compared cisplatin-gemcitabine with and without bevacizumab in 115 patients and showed that bevacizumab did not benefit survival nor response rates.¹⁵² However, the subgroup analysis of patients with below the median VEGF levels who were treated with bevacizumab had improved progression-free ($p = 0.043$) and overall survival ($p = 0.028$). Two additional single-arm phase II trials utilizing platinum-pemetrexed with bevacizumab followed by maintenance bevacizumab have been conducted but have not demonstrated significant benefit in the unselected population and were not informative for biomarkers.^{153, 154} Dowell et al.¹⁵⁴ treated 53 mesothelioma patients with cisplatin-pemetrexed–bevacizumab and demonstrated a response rate of 34%, 6-month median progression-free survival of 6.9 months, and median overall survival of 14.8 months. Ceresoli et al.¹⁵³ evaluated 76 Italian patients with carboplatin-pemetrexed–bevacizumab and reported a 34% response rate, median progression-free survival of 6.9 months, and median overall survival 15.3 months. Of note, both trials had grade 3–4 small bowel perforation events (one case in the Dowell et al. trial and three cases in Ceresoli et al.). A phase III trial (IFCT-GFPC-0701 MAPS) comparing cisplatin-pemetrexed with and without bevacizumab is ongoing in France.¹⁵⁵ Taken together, these data indicate that antiangiogenic therapy may be beneficial for some MPM patients and that targeting the ligand VEGF may not be sufficient.

The SWOG is in the midst of conducting a phase I/II trial of cisplatin-pemetrexed with and without cediranib in chemo-naïve MPM patients (SWOG 0905). Cediranib is a VEGFR and PDGFR tyrosine kinase inhibitor. The results from the phase I portion of the trial were presented at ASCO 2013 and demonstrated a median PFS of 13–14 months and median OS of 14–16 months.¹⁵⁶ A small phase I trial of cisplatin-pemetrexed–imatinib mesylate ($n = 17$) with no maintenance therapy reported median PFS of 7.9 months and median OS of 8.8 months.¹⁵⁷ However, in the six patients who completed six cycles of the

triplet regimen, median PFS was 9.6 months and median OS 22.4 months. Patients in the trial with higher-than-the-median p-PDGFR α IHC expression in baseline tumor biopsies had the best survival results.

In the salvage setting, several oral multikinase inhibitors that include VEGF/VEGFR pathway inhibition have been evaluated. Most of these trials to date have been in heavily pretreated patients and have utilized the novel agents as monotherapy drugs. It is surmised that antiangiogenic agents may need to be combined concurrently with other therapies (novel agents or chemotherapy) to have the greatest benefit. As an example, thalidomide as a single agent was reported to achieve disease stability,¹⁵⁸ but when investigated in an international trial with MPM patients receiving four cycles of platinum-pemetrexed followed by thalidomide or best supportive care, the trial was negative.¹⁵⁹

In other salvage trials, monotherapy vatalanib (VEGFR-1, -2, and -3; PDGFR; and c-Kit) had an 11% response rate, a 66% stable-disease rate, median progression-free survival of 4.1 months, and median overall survival of 10 months.¹⁶⁰ CALGB 30307 administered sorafenib (VEGFR-2, PDGFR, and Raf) at 400 mg twice daily for MPM that was chemo-naïve or previously treated with pemetrexed reported response rates of 4.4% and 38.8% disease stabilization, median failure-free survival of 4.1 months, and median overall survival of 10.4 months.^{161–163} Interestingly, the chemo-naïve patients had poorer survival outcomes than previously treated patients. Ceritinib monotherapy in SWOG 0509, a phase II trial of 54 previously treated MPM patients, had a 9% response rate with 34% stabilization of disease.¹⁶⁴ The median progression-free survival was 2.6 months, and the overall survival was 9.5 months. Sunitinib (VEGFR-2, PDGFR- β , c-Kit, and Flt-3) in both frontline and salvage therapy settings (National Cancer Institute of Canada, NCIC) has had limited activity.¹⁶⁵ Pazopanib (VEGFR-1, -2, and -3, and PDGFR) is under evaluation by the North Central Cancer Treatment Group.¹⁶⁶

Ribonuclease inhibitors

Ranpirnase (Onconase, Alfacell Corporation) has target specificity to tumor cell tRNA and inhibits protein synthesis. This enables cell cycle arrest at the G₁ phase. A phase II MPM trial with ranpirnase resulted in a 5% response rate, a 43% stable disease rate, and a median overall survival of 6 months.¹⁶⁷ A phase III trial ($n = 105$) compared ranpirnase (480 $\mu\text{g}/\text{m}^2$ weekly) to doxorubicin (60 mg/m^2 every 3 weeks) and showed no difference in the overall survival in the intent-to-treat analysis. However, patients with CALGB prognostic groups 1–4 and EORTC risk criteria had a 2-month survival benefit when treated with ranpirnase over doxorubicin.¹⁶⁸ A large international phase III trial (P30-302) comparing doxorubicin to the combination of doxorubicin and ranpirnase did not reveal a survival effect for the ranpirnase arm.

Histone deacetylase inhibitors

Histone deacetylase inhibitors (HDACIs) are agents that prevent deacetylation and reinstate control over the cell cycle. Although preclinical studies have shown that HDACIs inhibit cell cycle progression and/or induce tumor apoptosis, the exact antitumor mechanism is unknown.¹⁶⁹ Suberoylanilide hydroxamic acid (SAHA), or vorinostat, an oral HDACI, was evaluated in an early phase I trial that included 13 mesothelioma patients (12 previously treated) and demonstrated two clinical partial responses.¹⁷⁰ An international randomized placebo-controlled phase III trial (VANTAGE 14) accrued 660 previously treated MPM patients and compared vorinostat to placebo. Unfortunately, the trial was negative for any overall survival benefit and the drug will not be developed further in mesothelioma (unpublished data).

Proteasome inhibitors

Proteasome complexes process ubiquitinated proteins and regulate protein degradation. Blockade of proteasome activity leads to inhibition of nuclear factor- κ B production and enables tumor cells apoptosis. Preclinical studies in cell lines and murine xenograft models treated with proteasome inhibition have shown antitumor activity.^{171–173} Bortezomib is under evaluation in two European trials using single-agent bortezomib (ICORG/GIME) and the combination of cisplatin and bortezomib (EORTC).

Antimesothelin agents

SMRP is a cell-surface glycoprotein expressed on mesothelioma tumor cells. Anti-SMRP agents have been labeled with toxic molecules and have shown some significant antitumor activity against MPM.^{174, 175} SS1P, a recombinant anti-SMRP immunotoxin, was evaluated in a phase 1 trial in combination with cyclophosphamide and pentostatin, and reported 3 out of 10 patients having a major antitumor response.¹⁷⁶ In addition to SS1P, there are additional anti-SMRP therapies, Morab009 and an anti-SMRP vaccine.^{175, 177, 178} In addition, CRS-207, a *Listeria monocytogene*-SMRP vaccine, is under evaluation in a phase I trial.¹⁷⁹

Conclusion

Mesothelioma remains a very difficult malignancy to treat with poor survival overall. Several new approaches with regard to better staging may help select out the patients who are more appropriately treated with surgery. Multimodality therapy appears to be the most acceptable current approach for treatment. Several new drugs and immune therapies might alter the course of this disease, but overall it remains a challenge to all of those who continue to treat this entity.

Chapter 86

Thymomas and thymic tumors

Ronan J. Kelly, MD ■ Alberto M. Marchevsky, MD

Overview

Thymomas, carcinomas, and other thymic neoplasms are rare and comprise fewer than 1.5% of all solid tumors. They are currently classified according to the recently updated (2015) histologic classification of the World Health Organization (WHO). The histologic features and classification criteria for thymomas and thymic carcinomas are reviewed in this chapter, with an emphasis on various diagnostic problems. Thymomas are staged according to the Masaoka–Koga system, although the American Joint Commission on Cancer (AJCC) is currently developing staging guidelines. There is some current uncertainty regarding how to stage thymic carcinomas. Thymoma patients with stages I and II are treated with radical thymectomy, whereas radiation therapy and chemotherapy are used in patients with more advanced stages. This chapter discusses in detail the current state of the art for the treatment of thymomas and other thymic neoplasms. The results of various therapeutic options are difficult to evaluate with certainty in the absence of a significant number of randomized clinical trials. Indeed, level I and II evidence is difficult to gather for patients with neoplasms that are rare, have a long natural history, and require follow-up for many years. The efforts of the International Thymic Malignancies Interest Group (ITMIG) to develop evidence-based guidelines for the diagnosis, staging, and treatment of thymic neoplasms are described.

Introduction

Thymic tumors are rare and comprise only 0.2–1.5% of all solid tumors or 0.13 per 100,000 person years in the United States.¹ As a result, traditional clinical research has been challenging in these tumors. A number of obstacles have also hindered our progress over the past few decades. One of the most compelling has been the lack of an International consensus surrounding appropriate histopathological and staging criteria. At least 15 different stage classifications have been proposed and used.² This has undoubtedly led to confusion among investigators and made it difficult to compare one clinical trial to another. To date, the most widely used staging classification systems have been the Masaoka and the subsequent Koga modification.^{3,4} The vague wording and difficulty of interpretation in using these systems have hampered clinical research and made it difficult to collaborate on an International level. An ongoing effort by the International Thymic Malignancies Interest Group (ITMIG) and the International Association for the Study of Lung Cancer (IASLC) to develop a tumor, node, metastasis (TNM)-based staging system for thymic malignancies should lead to an official, stage classification system as proposed by the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC).

The World Health Organization (WHO) histological classification distinguishes thymomas (types A, AB, B1, B2, and B3) from thymic carcinomas (previously designated by WHO as type C) based on the morphology of epithelial tumor cells (with increasing degree of atypia along the spectrum from type A

thymomas to thymic carcinomas), the proportion of lymphocytic involvement and resemblance to normal thymic tissue. Incremental improvements in our understanding of the molecular biology of both thymomas and thymic carcinomas have occurred in recent years, thanks to advanced technologies such as comparative genomic hybridization (CGH), expression array analysis, and next generation sequencing. It is becoming more apparent that the subclassifications of types A, AB, B1, B2, B3, and thymic carcinoma have different molecular features that may be clinically relevant. Genomic profiling distinguishes type B3 thymoma and thymic carcinoma as distinct entities from type A and type B2 thymoma. Furthermore, type B2 thymomas can be separated from other subgroups in that it has a more distinctly lymphocytic component than the other groups where epithelial cells predominate.⁵ Next generation RNA sequencing has recently identified a large microRNA cluster on chromosome 19q13.42 in type A and type AB thymomas, while it is absent in type B thymomas and thymic carcinomas. This cluster has been shown to result in activation of the PI3K/AKT pathway, which suggests a possible role for PI3K inhibitors in these subtypes.⁶ The presence of KIT mutations in thymic carcinomas is also well described, and although relatively rare, they can be successfully targeted with small molecules.

Surgical resection continues to be the cornerstone of therapy for early-stage disease while a multidisciplinary approach incorporating surgery, radiation, and chemotherapy is recommended in advanced or recurrent disease. In addition, intense interest is now focused on targeting the immune system in these most intriguing of tumors. Thymomas have been known to be associated with a variety of autoimmune disorders such as myasthenia gravis (MG), which have been linked to T-cell-mediated autoimmunity. Processes such as failure of positive and negative selection of T lymphocytes and defects in the autoimmune regulator gene (AIRE) have been proposed as theories underlying autoimmunity but additional research is required. Studies utilizing checkpoint inhibitors, for example, PD-1 inhibitors, are planned in the near future and immunotherapeutic strategies may hold promise for those patients with chemoresistant disease.

This chapter discusses the new histological and staging systems that are being developed and highlights some of the molecular biology breakthroughs that are improving our understanding of these rare tumors. In addition, we discuss the treatment of thymic malignancies focusing on surgery, radiotherapy (RT), and systemic therapy. Recent clinical trials involving chemotherapy and targeted therapeutics are emphasized and future targets are explored.

Incidence and epidemiology

Although thymic malignancies are relatively rare, they are among the most common mediastinal primary tumors with up to 50% of anterior mediastinal masses proving to be of thymic descent.⁷ Males have a slightly higher risk of developing thymomas than females, and the risk rises with age, reaching a peak in the seventh decade of life, which is in direct contrast to the progressive involution of the thymus with age.⁸ Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program collected for Hispanic and Asian/Pacific Islander subgroups has been available only since 1992 and 1998, respectively. Thymoma incidence in the United States is higher in African-Americans and especially Asian/Pacific Islanders than among whites or Hispanics. Furthermore, thymoma arises at a younger age among African-Americans than among whites (median age at diagnosis, 48 years vs 58 years; SEER data). Similarly, MG may be more common in African Americans than in whites.⁹ Compared with controls, patients with thymoma are more likely to have an autoimmune disease at some point during their lives (32.7% vs 2.4%; $P < 0.001$), most frequently MG (24.5%), systemic lupus erythematosus (2.4%), or red cell aplasia (1.2%).¹⁰ Ethnic variations in terms of higher incidence rates and younger age at

diagnosis suggest a role for genetic factors. The distribution of alleles at the HLA locus on chromosome 6 varies markedly across racial groups.⁸ Both class I and class II HLA proteins are highly expressed on thymic epithelial cells.¹¹ Further research is needed to understand whether particular genetic variants (at HLA or other loci) predispose to thymoma. There are no known etiologic factors for thymic malignancies, although a few cases have developed following radiation therapy to the chest. Epstein–Barr virus (EBV) has been associated with thymic lymphoepithelioma, a rare variant of thymic carcinoma that is usually more frequent in young patients.¹² A few patients with the multiple endocrine neoplasm type I syndrome (MEN I) have had associated thymomas or neuroendocrine carcinomas of thymic origin.

Anatomic pathogenesis

Embryology and anatomy

The thymus is embryologically derived from the endodermal epithelium of the third pharyngeal pouches (which also give rise to the lower pair of parathyroid glands) and, less constantly, the fourth ones as well.^{13, 14} The right and left thymic anlagen migrate downward into the anterosuperior mediastinum, joining together without complete fusion to form a bilobate organ. Although most thymic tumors are located in the anterosuperior mediastinum, variations in migration account for the findings of gross or microscopic thymic tissue anywhere between the hyoid bone superiorly and the diaphragm inferiorly. Wide exposure of the mediastinum and even the neck is therefore necessary if surgical removal of the entire thymus is indicated, as in patients with thymoma or those with MG (with or without associated thymoma). The absolute weight of the thymus reaches its peak in the pubertal years (mean 34 ± 15 g between age 10 and 15 years) and then gradually decreases, although this age-related involution normally is never complete. Histologically, the normal thymus shows distinctive lobules with a sharp demarcation between the cortex, rich in lymphocytes, and the medulla, rich in epithelial cells and characteristic Hassall's corpuscles, formed by concentric layers of mature epithelial cells. The thymus plays a critical role in the maturation of bone marrow-derived lymphocytes into T cells and, as such, in cell-mediated immunity. It has a rich blood supply but no afferent lymphatics. Efferent lymphatics apparently originate from perivascular spaces and drain into the mediastinal and lower cervical nodes.

Thymic neoplasms

The thymus can develop a variety of epithelial, germ cell, lymphoid, mesenchymal, and other neoplasms listed in [Table 1](#).¹³

Pathology of thymic epithelial neoplasms

Thymic epithelial neoplasms include low-grade malignant lesions, designated as thymomas and malignant lesions of moderate to high-grade malignant potential classified as thymic carcinomas.^{13, 15, 16}

Pathology of thymomas

Thymomas appear grossly as single or multiple, usually encapsulated neoplasms that range in size from microscopic lesions to large tumors replacing the entire anterior mediastinum and compressing the

adjacent intrathoracic structures.^{13, 17–21} Grossly, most thymomas are well encapsulated and limited to the thymic gland ([Figure 1](#)) but some lesions are locally invasive extending into mediastinal soft tissues, superior vena cava and other vascular structures, lymph nodes, pleura, pericardium, trachea, and/or other intrathoracic structures adjacent to the thymus ([Figure 2](#)). On section, thymomas exhibit a distinctive fibrous capsule and multiple fibrous septa that divide the lesion into a characteristic lobulated appearance ([Figure 3](#)). They are usually solid tumors but can undergo cystic degeneration. Predominantly, cystic thymomas are distinguished from benign thymic cysts by the presence of focal solid areas.

Figure 1 Gross photograph of thymoma showing an encapsulated tumor with a gray, soft surface exhibiting characteristic fibrous septa.

Figure 2 Gross photograph of invasive thymoma showing invasion of mediastinal soft tissues and bronchial wall.

Figure 3 Photomicrograph of thymoma showing the characteristic lobulations of the lesion. The epithelial and lymphoid cells are separated by thin fibrous septa (H&E; $\times 40$).

Microscopically, thymomas are composed of epithelial cells with spindle-, oval-, or polygonal-shaped nuclei admixed with a variable number of mature lymphocytes. The epithelial and lymphoid cells of thymomas are arranged in solid sheets usually divided by fibrous septa in a somewhat lobulated appearance that can be observed at low-power microscopy in most thymomas ([Figure 3](#)). Other histologic

features of thymomas include perivascular spaces ([Figure 4](#)), medullary areas, pseudorosettes, gland-like structures, Hassall's corpuscles, areas of cystic degeneration, and less frequently hemorrhagic and/or calcified areas. Thymomas are often encapsulated, but can invade the capsule into adjacent tissues ([Figure 5](#)). Mitoses, cellular atypia, and necrosis are unusual in thymomas and should raise the suspicion of a thymic carcinoma.

Figure 4 Photomicrograph of thymoma at higher power showing the tumor cells arranged around blood vessels, in a characteristic perivascular growth pattern. The tumor cells are polygonal, with minimal cytologic atypia. They are admixed with small mature lymphocytes (H&E; $\times 100$).

Figure 5 Photomicrograph of a thymoma showing invasion of the capsule (H&E; $\times 40$).

World Health Organization classification of thymomas

Different classification schema have been proposed for the categorization of thymic epithelial neoplasms, but the most widely used classification scheme of these tumors has been proposed by the WHO in 1999

and has been modified in 2004 and 2015 ([Table 2](#)).

Table 2 World Health Organization classification of thymomas and selected morphological features of the neoplasms

Type A (spindle cell) Atypical type A (spindle cells with focal atypia)
Type AB (mixed spindle and polygonal cells)
Type B1 (lymphocyte-rich, scattered polygonal cells)
Type B2 (lymphocyte-rich with higher density of polygonal epithelial cells and focal, minimal atypia)
Type B3 (lymphocyte poor, polygonal cells with mild atypia)
Rare thymomas <ul style="list-style-type: none">• Micronodular thymoma• Metaplastic thymoma• Microscopic thymoma• Sclerosing thymoma• Lipofibroadenoma

Thymomas A are composed predominantly of spindle epithelial cells with minimal numbers of lymphocytes ([Figures 6](#) and [7](#)).^{19, 20, 22, 23} Patients with thymoma A have a lower incidence of MG than those with other thymoma histologic types and a greater incidence of aplastic anemia. Thymomas B1–B3 are composed of polygonal epithelial cells that are designated as thymoma B and further subclassified into B1, B2, and B3 lesions. B1 thymomas are composed of inconspicuous polygonal epithelial cells admixed with a large number of mature lymphocytes. These lesions characteristically have scattered round, hypochromatic areas designated as medullary areas and have been described in the past as lymphocyte-predominant thymomas because of the sparsity of visible epithelial cells in histologic sections stained with hematoxylin and eosin (H&E). B2 thymomas are composed of polygonal cells that are more conspicuous than those seen in B1 lesions and frequently exhibit slight nuclear variability and focally prominent nucleoli ([Figure 8](#)). B3 thymomas, classified in other schema as “atypical thymoma,” are composed of polygonal or spindled epithelial cells that exhibit moderate variability in cell size and shape (anisocytosis), focal nuclear hyperchromasia, and cytologic atypia. B3 thymomas characteristically have fewer lymphocytes than seen in B1 and B2 lesions and can be difficult to distinguish from low-grade thymic carcinomas. Thymomas AB have >5% lymphocytes and are composed of both spindle epithelial cells and polygonal cells. Thymomas are frequently heterogeneous neoplasms and can exhibit different WHO “types” on different sections taken from the same lesion.²⁴

Figure 6 Photomicrograph of spindle cell thymoma (thymoma A). The tumor cells have elongated nuclei. Note the paucity of mature lymphocytes (H&E; $\times 100$).

Figure 7 Photomicrograph of thymoma A showing small polygonal epithelial cells with round nuclei, lack of visible nucleoli and scanty cytoplasm. They are admixed with numerous lymphocytes (H&E; $\times 200$).

Figure 8 Photomicrograph of thymoma B3 (the so-called atypical thymoma). The tumor cells exhibit considerable variation in size and shape, hyperchromasia and somewhat irregular nuclear membranes. There are relatively few lymphocytes in the background (H&E; ×200).

Immunohistochemistry and other ancillary techniques

The epithelial cells of thymomas exhibit cytoplasmic immunoreactivity to keratin AE1/AE3, a feature that is generally very helpful to confirm the diagnosis of thymoma on needle biopsies and other pathologic materials ([Figure 9](#)). A variety of other epitopes have been shown in the different WHO histologic types of thymomas, such as CD5, laminin, collagen IV, metallothionein, PE-53, cytokeratins such as CAM 5.2, CK7, CK14 and CK18, CD57, and others. However, they have limited diagnostic or prognostic value. CD5 is usually negative in thymomas other than thymoma C. Foxnl, CD205, and desmoglein-3 are novel markers of thymic epithelial cells that may be useful to distinguish different thymomas and thymic carcinoma.

Figure 9 The epithelial cells of thymomas exhibit cytoplasmic immunoreactivity when stained for keratin AE1/AE2 (Immunostain; $\times 200$).

Electron microscopy is seldom used for the routine diagnosis of thymomas.¹³ The tumor cells reveal ultrastructural features that are characteristic for epithelial differentiation such as desmosomes, tonofilaments, elongated cell processes, and a lack of dense core granules. The malignant epithelial cells form an irregular mesh with multiple communicating spaces and channels containing mature lymphomas and resembling the normal ultrastructural features and microenvironment of the thymus gland.

Histologic prognostic features in thymomas

All thymomas are low-grade malignant neoplasms.^{24–27} Thymomas A (spindle cell thymomas) have been considered as benign lesions in the past, but these lesions can recur or metastasize in a small number of patients. Patients with thymomas A, AB, and B1 appear to have the best prognosis, while those with thymomas B3 generally have more frequent recurrences and metastases and shorter survival.

Staging systems for thymomas

As it has been controversial whether thymomas are benign or malignant neoplasms, there is no current American Joint Commission on Cancer TNM system for thymomas. The most widely used system for staging these tumors is the Masaoka–Koga staging system given in [Table 3](#).^{28–32}

Table 3 Masaoka–Koga staging of thymomas

Stage	Extent of disease
I	Totally encapsulated
II	Microscopic (IIa) or macroscopic (IIb) transcapsular invasion into surrounding fat or mediastinal pleura
III	Invasion of surrounding organs (pericardium, lung, and great vessels)
IV	(A) Pleural or pericardial implants (B) Embolic metastasis

Thymic carcinomas

Thymic carcinomas are unusual epithelial tumors comprising approximately 0.06% of thymic neoplasms and composed of epithelial cells that exhibit cytological features characteristic of malignancy, such as considerable pleomorphism, hyperchromasia, prominent nucleoli, increased mitotic activity, and/or necrosis.^{22, 28, 31, 33–38} A variety of histologic variants, described in [Table 4](#), have been described. Squamous cell carcinomas are probably the most frequent variant of these neoplasms. Lymphoepithelioma of the thymus is a particularly interesting variant of thymic carcinoma frequently associated with the EBV expression and exhibits similar histopathologic features to those seen in the head and neck area.¹⁶ Carcinoma with NUT, t(15;19) translocation is a recently described aggressive variant of thymic carcinomas that affects children and young adults.³⁴

Table 4 World Health Organization classification of thymic carcinomas

Squamous cell carcinoma
Basaloid carcinoma
Mucoepidermoid carcinoma
Lymphoepithelioma-like carcinoma
Clear cell carcinoma
Sarcomatoid carcinoma
Adenocarcinoma
NUT carcinoma
Undifferentiated carcinoma
Other rare thymic carcinomas

Thymic carcinoid and neuroendocrine tumors

Carcinoid tumors and other neuroendocrine neoplasms given in [Table 5](#) can arise in the thymus.^{23, 39–43} They are more aggressive than their counterparts in the lung and other organs and with metastases at diagnosis in 30–40% of cases.¹⁵ The association with Cushing syndrome with ectopic ACTH production in a patient with a thymic tumor should raise this possibility because it occurs in 30% of patients with thymic carcinoid tumor but not in patients with thymoma. Other paraneoplastic syndromes, such as osteoarthropathy and Eaton–Lambert syndrome, and an association with multiple endocrine neoplasia (type I or II) have been described.^{39, 43} Carcinoid syndrome has not been reported. Neuroendocrine

tumors exhibit histopathologic features at low-power microscopy characteristic of neuroendocrine differentiation, including the formation of cellular nests, trabeculae, and pseudorosettes.¹³ The tumor cells vary according to the cell type. Carcinoid tumors are composed of round to elongated nuclei with “salt-and-pepper” nuclear chromatin, variable hyperchromasia, and minimal pleomorphism. Typical carcinoid tumors usually lack mitosis and necrosis, while atypical carcinoid tumors exhibit low mitotic activity and focal areas of necrosis. Large cell neuroendocrine carcinoma of the thymus are composed of large, pleomorphic, hyperchromatic cells that can exhibit focally prominent nucleoli. Small cell carcinomas of the thymus are composed of small hyperchromatic cells with nuclear molding and inconspicuous nucleoli. Both variants of high-grade thymic neuroendocrine carcinomas exhibit frequent mitosis, usually higher than 10 mitosis in 10 high-power fields and extensive areas of necrosis. The tumor cells of all variants of thymic neuroendocrine carcinoma exhibit cytoplasmic immunoreactivity to chromogranin and synaptophysin and dense core neuroendocrine granules under electron microscopy. Immunostains for Ki-67 can be used to estimate the proliferative fraction of these lesions.

Table 5 Thymic neuroendocrine tumors

Typical carcinoid
Atypical carcinoid
Large cell neuroendocrine carcinoma
Small cell carcinoma

Thymic lymphomas

Lymphomas are, with thymomas, the most common tumors of the thymus.^{13, 33, 44–46} Although the thymus is a T-cell organ, the most frequent lymphomas of the thymus in adult patients are Hodgkin lymphoma and B-cell lymphomas ([Table 3](#)). Primary Hodgkin lymphoma of the thymus tends to be limited to the gland and is, as a rule, of the nodular sclerosis type. It is frequently associated with cystic change in the adjacent thymic tissue. B-cell lymphomas of the mediastinum frequently involve the thymus and lymph nodes and frequently exhibit histologic features that are unusual for B-cell lesions in other locations, such as sclerosis with compartmentalization of the tumor cells, clear cell features, and focal formation of cellular nests simulating an epithelial malignancy. They tend to follow an aggressive clinical course. Lymphomas involving the thymus and mediastinal lymph nodes in children include Burkitt's lymphoma, lymphoblastic lymphoma, and a lesion of T-cell origin. It is of prime importance to differentiate a lymphoma from a thymoma in view of the different therapeutic approaches. Special stains and electron microscopy may be necessary in difficult cases.

Germ cell tumors of the thymus

The thymus is a classic site of extragonadal primary germ cell tumors ([Table 1](#)). The most common ones are seminomas (sometimes difficult to differentiate from thymoma) and teratomas (mature or immature). Embryonal carcinomas, yolk sac tumors, teratocarcinomas, and choriocarcinomas have also been described.

Other thymic tumors

Other thymic tumors include thymolipomas, which may become quite large, thymic cysts, metastases to the thymus, and other neoplasms listed in [Table 1](#).

TNM staging project—ITMIG/IASLC

As previously outlined, in the past 4 decades, at least 15 different stage classifications have been proposed for thymic malignancies.⁴⁷ The Masaoka staging system was originally proposed in 1981 and focuses on the integrity of the thymic capsule, the presence of micro or macroscopic invasion into adjacent structures, and metastatic spread.³ An updated version from 1994 that is commonly used is the Masaoka–Koga system.⁴ It has long been recognized however that there is a significant need for an American Joint Committee on Cancer/Union for International Cancer Control (AJCC/UICC) validated stage classification system for thymic tumors. This will allow for consistent universal nomenclature facilitating multinational collaborative clinical research. A combined effort by ITMIG and the IASLC is now underway, and a database of more than 10,000 retrospective and prospective cases worldwide has been assembled.⁴⁷ The requirements for this staging system are that it has to contain nomenclature that describes the anatomic extent of the disease only, which is applicable to all types of thymic tumors and that it conforms to the TNM (tumor, node, metastases) structure. The T component of the proposed stage classification is divided into four categories or levels of involvement. A tumor is classified in a particular level if one or more structures in that level is involved regardless of whether other structures of a lower level are involved or not. Encapsulation of a tumor is not included as this does not have a clinically significant impact on outcomes as demonstrated in a retrospective database. T1a involves a tumor that is encapsulated or not with or without extension into mediastinal fat. Pathologically proven involvement of the pericardium is designated as T2 and several different structures are included in the T3 category including lung, brachiocephalic vein, SVC, chest wall, phrenic nerve, hilar, and pulmonary vessels. T4 lesions include several structures that indicate more extensive local involvement, for example, aorta, pulmonary artery, myocardium, trachea, and esophagus. Lymph node status “N” will be assigned into two groups according to their proximity to the thymus with N1 indicating anterior (perithymic) involvement and N2 disease indicating deep cervical or thoracic nodes. Finally, metastatic disease will be categorized as M1a indicating separate pleural or pericardial nodule(s) and M1b indicating a pulmonary intraparenchymal nodule or distant organ metastasis.⁴⁸ This proposed classification system will be applicable to both thymoma and thymic carcinoma, and it is hoped that it will allow for International stage classification consistency.

Molecular differences between thymoma and thymic carcinoma

Until recently, we have had limited information of the genomic changes that occur in thymic epithelial tumors. A significant challenge has been that types AB, B1, and B2 contain a significant number of non-neoplastic thymocytes that outnumber the malignant epithelial cells making CGH and fluorescence *in situ* hybridization (FISH) analyses challenging. Thanks to newer techniques such as next generation sequencing and expression array analysis, our knowledge of the tumor biology underlying the different phenotypes between thymomas and thymic carcinomas has improved in recent years. These studies have shown that thymic tumors as classified by the 2004 WHO system do have different molecular features. Genomic profiling distinguishes type B3 and thymic carcinoma from type A and type B2 thymomas. In addition, type B3 tends to have a more distinct lymphocytic component and thymic carcinomas are C-Kit positive.

The most frequent genetic alterations occur on chromosome 6p21.3 (MHC locus) and 6q25.2–25.3^{5, 49, 50} Cytogenetic studies have demonstrated chromosomal abnormalities in all histological subtypes including the t(15;19)(q13;p13.1) translocation that generates the BRD4-NUT fusion gene that can occur in thymic carcinoma.⁵¹ Molecular similarities do occur most notably between thymic carcinomas and type B3

thymomas where gain of 1q and loss of chromosome 6 is identified in both.⁵ This may have implications for clinical trial design in future years with type B3 and thymic carcinoma being treated together. Additional data from CGH analysis performed on thymic carcinomas has demonstrated frequent copy number gains of 17q and 18 and loss of 3p, 16q, and 17p.^{5, 52} Further aberrations that have been described include multiple losses of genetic material and microsatellite instability (MSI) in different chromosomes (3p22–24.3, 3p14.2 (FHIT gene locus), 5q21 (APC gene), 6p21, 6p21–22.1, 7p21–22, 8q11.21–23, 13q14 (RB gene), and 17p13.1 (p53 gene)).^{52, 53} In addition to the losses in the long arm of chromosome 6 the loss of heterozygosity (LOH) on chromosome 5 (5q21) (APC gene) may be the most significant. It has been demonstrated that alterations in chromosome 6 varies according to the WHO subtype (type A 10%, type AB 12%, type B 20–26%, and in thymic carcinoma 35%) and with clinical stage at diagnosis (stage I 7%, stage II 27%, stage III 21%, and stage IV 24%).⁵⁰ The most frequent LOHs (48.6%) occurred in region 6q25.2. Another hot spot showing LOH in 32.4% of tumors was located on 6q25.2–25.3. The third hot spot (30%) showing LOH appeared in region 6p21.31 including the MHC locus and the fourth (26.3%) was detected on 6q14.1–14.3. MSI has also been described on chromosome 6 in 10% of thymomas, more commonly in type B thymoma. Although the biological significance of many of these changes has yet to be determined, incremental benefits are being realized. The 6p23 region encompasses the *FOXC1* tumor suppressor gene, and chromosomal loss is correlated with lower protein expression. Patients with *FOXC1* negative tumors have a shorter time to tumor progression and shorter disease-related survival.⁵⁴ Next generation RNA sequencing has shown that type A and type AB thymomas are significantly different from other subgroups. A large microRNA cluster on chromosome 19q13.42 has been shown to be significantly over-expressed in these groups, while it is absent in type B thymomas and thymic carcinoma.⁶ This cluster has been shown to result in activation of the PI3K/AKT pathway by downregulating PTEN, which suggests a possible role for PI3K inhibitors in these subtypes.

Utilizing gene signatures to determine prognosis in thymic tumors

The main prognostic indicators in thymic malignancies are tumor stage, histologic subtype, and the extent of surgical resection. As our understanding of the underlying molecular biology improves gene signatures is seen as a next step in helping the oncologist move beyond clinical and morphological features to determine prognosis, aggressiveness of treatment, and extent of surveillance imaging. In an elegant study, whole genome expression was performed and the authors correlated their findings with outcomes in 34 patients with thymoma.⁵⁵ Unsupervised clustering of gene expression data identified four clusters of thymic tumors, which showed significant correlation with histological classification ($P = 0.002$). In addition, the authors identified a number of genes associated with clinical behavior of thymic tumors including stage, relapse, and metastasis and some were confirmed using qRT-PCR. Among the top genes chosen, Aldo-keto reductase family 1 B10 (*AKR1B10*) and junctophilin-1 (*JPH1*) were upregulated in both stage III and stage IV diseases. A hedgehog target gene, *COL11A1*, was downregulated in advanced stage disease. *AKR1B10* and *JPH1* showed a 5.96-fold ($P = 0.05$) and 3.01 ($P = 0.18$)-fold increase in metastasis positive tumors compared to nonmetastatic disease and *COL11A1* was decreased 12.5-fold ($P = 0.11$) in stage IV tumors. As a result of the differential expression levels of these genes, they were selected for validation by qRT-PCR, which confirmed the differential expression in the different phenotypes. The authors have developed a 9-gene signature that can be used to identify patients at high or low risk for developing metastases from thymomas. Additional validation studies are planned as is prospective evaluation in a clinical trial setting. In an effort to distinguish thymic carcinoma from thymoma, the same group has developed a 12-gene signature that may assist pathologists in difficult cases. Although gene signatures are not used clinically at present a validated signature would be of tremendous benefit in patients with Thymomas. These tumors can differ considerably with many being considered

indolent requiring less surveillance than perhaps the more aggressive type B3 thymoma. In rare tumors with limited scope for randomized studies an improved understanding of poor prognostic indicators would be of tremendous benefit in the clinic.

Clinical features of thymomas

Most tumor-related symptoms are vague (cough, dyspnea, and chest pain) or secondary to local and regional mediastinal spread (pleural effusion, superior vena cava syndrome, or pericardial effusion) and, therefore, often indicate invasiveness. Occasionally, thymomas may present as diffuse pleural tumors and simulate malignant mesothelioma.⁵⁶ About half of thymomas occur in asymptomatic persons and are discovered fortuitously on a chest radiograph, which shows a retrosternal mass in the anterosuperior mediastinum forming a bulge in the cardiovascular silhouette. The tumor may be best seen on oblique and lateral views. Computed tomography (CT) is invaluable for detecting small thymomas and assessing possible invasion of surrounding structures, such as the mediastinum, pleura, and pericardium. It can show calcifications in or at the periphery of the tumor in approximately 20% of cases,⁵⁷ although they bear no relation to invasiveness. The presence of a fat plane all around the tumor is a good sign of noninvasiveness, but, conversely, fibrous adherence to surrounding structures may simulate invasion.⁵⁸ CT can also help differentiate thymomas from vascular structures and tumors, such as aneurysms, particularly when intravenous contrast is used.⁵⁸ Thymomas show increased T_1 - and T_2 -weighted image signal intensity by magnetic resonance imaging, but the role of that technique in detecting possible capsular and vascular invasion, compared with CT, needs to be further defined.⁵⁸ The use of positron emission tomography with 18-fluorodeoxyglucose to distinguish malignant from benign mediastinal tumors has been evaluated.⁵⁹ Thymic carcinomas and invasive thymomas show high uptake, whereas noninvasive thymomas show low uptake. It should be emphasized, however, that surgical exploration and pathologic evaluation remain the most reliable means to assess the invasiveness of thymomas.

Associated paraneoplastic syndromes

A remarkable number of paraneoplastic syndromes are associated with thymomas. They are mostly related to autoimmune mechanisms and are dominated by three characteristic entities ([Table 3](#)).

Myasthenia gravis

MG occurs in approximately 33–50% of patients with thymoma, and approximately 10% of patients who have MG have a thymoma.⁶⁰ Such patients are usually older than those with MG without thymoma, although the clinical signs of MG are similar in both groups. Few features distinguish the histologic appearance of thymomas in patients with MG; predominantly, spindle cell thymomas are rare in this group, and the surrounding thymic tissue reveals the presence of lymphoid follicles with germinal centers in approximately 50% of the cases (vs only 5–8% of cases involving thymomas without MG).⁶¹ MG is an autoimmune disorder that is characterized by the presence of antibodies to the acetylcholine receptors of the neuromuscular junction. Such serum antibodies are found in 90% of patients with generalized MG.⁵⁸ The triggering mechanisms are unknown. Myoid cells in the normal thymus raise the possibility of *in situ* sensitization.⁶² Serum striational antibodies directed against elements of the sarcomere, such as titin, are found in 80% of patients with MG and thymoma and in 25% of patients with thymoma but without MG.⁵⁸ Total thymectomy rather than thymomectomy is indicated in patients with MG, even in the absence of a thymoma (see the section titled “Surgery”).

Red cell hypoplasia

Also called pure red cell aplasia (PRCA), red cell hypoplasia is an autoimmune disorder that is characterized by an acquired anemia with markedly decreased blood reticulocytes and a virtual absence of erythroblasts in the bone marrow.^{61, 63} There are often changes (an increase or a decrease) in white blood cell and/or platelet counts. PRCA is seen in approximately 5% of patients with thymoma, but 50% of patients with PRCA have a thymoma, which is of the spindle cell type in two-thirds of these patients.⁶¹ PRCA generally occurs in patients older than 40 years of age who have thymoma, and the incidence of local invasion is not different from other thymomas. The bone marrow is usually quite cellular, and erythropoietin levels are typically high.⁶³ An immunoglobulin (Ig)G inhibitor of erythroblastic growth has been described in the serum of some patients.⁶³ Thymectomy produces remission of the anemia in approximately 30% of cases.⁶³ Corticosteroids and immunosuppressive agents are also effective. A prolonged complete remission (with tumor regression) was described in one case with the combination of octreotide and prednisone.⁶⁴

Hypogammaglobulinemia

First reported by Good in 1954,⁶⁵ this acquired syndrome results in extreme susceptibility to recurrent, and often serious, infections. It occurs in approximately 5–10% of patients with thymoma, and a thymoma is found in 10% of patients with acquired hypogammaglobulinemia.^{57, 61} There is a decrease in all major Igs, particularly IgG and IgA, and decreased eosinophils in the blood and bone marrow. A combined deficit in cell-mediated immunity can also be seen. Almost a third of patients also have PRCA. Similar to those with PRCA, the age group is somewhat older (>40 years), and the thymoma is of the spindle cell type in 75% of cases.⁶¹ The pathogenesis is obscure. There is a lack of pre-B cells, B cells, and plasma cells in the bone marrow, with decreased peripheral B cells.⁶⁶ Thymectomy does not result in any improvement; palliative treatment with Igs is indicated.⁶⁶

A large number of other paraneoplastic syndromes or associated disorders have been described in patients with thymoma ([Table 3](#)). It is noteworthy that Cushing syndrome with ectopic adrenocorticotropin (ACTH) production is a typical feature of thymic carcinoids, not thymomas.⁶¹

Diagnosing an anterior mediastinal mass

The diagnosis of an anterior mediastinal mass is guided by the clinical suspicion of its etiology. A structured, clinically orientated approach increases efficacy and eliminates unnecessary investigations. Age and gender are the two most important features to consider from the outset as specific lesions tend to occur more commonly in certain demographic groups. Laboratory investigations include α -fetoprotein, β -human chorionic gonadotrophin, and lactate dehydrogenase. The causes include a wide variety of entities the most common of which include the following: thymic malignancy in approximately 35%, lymphoma in approximately 25% (Hodgkins lymphoma 13% and non-Hodgkins 12%), thyroid and other endocrine tumors in approximately 15%, benign teratoma in approximately 10%, malignant germ cell tumors in approximately 10% (seminoma 4%, nonseminoma 6%), and benign thymic lesions in approximately 5%. Invasive incisional biopsy techniques, with mediastinoscopy or mediastinotomy for thymoma, carry the risk of violating the tumor capsule and disseminating tumor cells.⁶⁷ Otherwise, percutaneous fine-needle aspiration or core biopsy under fluoroscopic or CT guidance is generally considered safe and effective. Combined with special stains and electron microscopy, if necessary, it has a sensitivity of 80% and specificity >90%.⁵⁷ It is of prime importance, however, to establish a firm pathologic diagnosis in view of the many other tumor types that may require specific therapies. The treatment of thymic malignancies is

discussed in the following sections.

Therapy

Surgery

Because there are no reliable histologic criteria for the malignant nature of thymomas, all such tumors should be considered potentially malignant. Total thymectomy (rather than thymomectomy) is the procedure of choice, even for stage I-encapsulated tumors.⁵⁷ It is also the procedure indicated for patients with MG, with or without thymoma. The usual approach is by median sternotomy, although additional thoracic or cervical incisions may be necessary, and some surgeons advocate maximal thymectomy with exploration of all of the possible areas in which ectopic thymic tissue might be found.⁶⁸ There is a need for the surgeon to carefully explore the mediastinum for evidence of local invasion, which is the most reliable indication of malignancy and the most important prognostic factor. The tumor capsule should not be breached. Systematic microscopic examination is necessary to search for capsular invasion and to distinguish it from simple adhesions. Following total thymectomy, the recurrence rate is usually low (about 2%) for stage I-encapsulated thymomas.⁶¹ Recently, video thoracoscopic approaches were performed for well-encapsulated small thymomas but the long-term results are unknown.⁶⁷

In patients with thymoma and MG, remission of MG occurs in approximately 10–30% following thymectomy, often after a delay of up to 2 years or more, compared with a remission rate of approximately 40–80% after thymectomy for MG without a thymoma.^{57, 61, 68, 69} An additional fraction of patients shows improvement of MG. Early thymectomy (within 1 year) after onset of MG is associated with a higher percentage of less invasive thymomas.⁷⁰ Recurrence, and even first occurrence, of MG after apparent total thymectomy has been observed and could be related to tumor regrowth or persistent ectopic thymic tissue.⁵⁷ In the past, MG was a poor prognostic sign in patients with thymoma. Most recent surgical series, however, do not show a significant difference in survival for patients with thymoma, with or without MG.^{3, 71, 72} Such a change is attributed to better surgical and anesthesia techniques, which have largely prevented postoperative deaths from MG.

Local invasion is seen in approximately 30–40% of thymomas at surgery,^{3, 71, 72} but the slow-growing nature of the tumor and the rarity of distant metastases justify attempts at radical surgery. Identification of the phrenic, recurrent laryngeal, and vagus nerves is of major importance.⁶⁸ Extended resections—including one lung, one phrenic nerve, pericardium, or even resection and repair of great vessels, such as the innominate vein or superior vena cava—have been performed. They should be undertaken only if they lead to complete tumor resection. With modern techniques of peri- and postsurgical care, surgical mortality is low (0–5%), even in patients with MG.^{3, 68, 72}

In four large series with a total of 744 patients, the 5- and 10-year survival rates were 75–85% and 63–80%, respectively, for patients with noninvasive encapsulated thymomas.^{3, 71, 72} Survival figures for patients with invasive thymomas were 50–67% at 5 years and 30–53% at 10 years. While invasiveness is the major prognostic factor in patients with thymoma, most series also report a better prognosis for spindle cell thymomas and those with a higher ratio of lymphocytes to epithelial cells.^{3, 71, 72} Local recurrences and/or metastases (often intrathoracic) may also be amenable to surgical resection.

Radiotherapy

Thymomas are radiosensitive, and the efficacy of RT has been emphasized in many reports. Following

surgical biopsy, or partial excision, survival of more than 10 years after RT has been seen.⁷³ Most authors do not believe that it is only the lymphocytic component rather than the epithelial one that is sensitive to RT.⁷³

The role of RT is best discussed according to stage. For stage I disease following total surgical resection, postoperative RT is not indicated in view of the very low relapse rates. For stage II and stage III diseases, the use of postoperative RT is recommended even after total surgical resection.^{3, 57, 71, 74} In a review of the literature, as well as their own experience, Curran and colleagues reported a 28% intrathoracic relapse rate after complete surgical resection without RT, as opposed to 5% when postoperative RT was given.⁷⁵ The latter figure may be unusual, however, because others have reported no such differences in favor of RT after complete surgical resection.⁷⁶ The systematic use of RT after complete resection has been recently questioned particularly for stage II patients, but the small number of cases and the retrospective nature of the collected data as well selection of patients do not allow a definitive conclusion in the absence of prospective randomized trials. The irradiated volume should include the mediastinum with adjacent areas and probably the supraclavicular areas, which are possible sites of relapse.⁷³ The total dose is usually about 45 Gy, with appropriate protection of the spinal cord, although doses of 50 Gy and higher have been given.^{73, 75} Radiation pneumonitis, mediastinitis, pericarditis, coronary artery fibrosis, hypothyroidism, and secondary cancers are potential complications.

RT is also given to patients with residual disease, following biopsy only or incomplete surgical resection for stage III disease. In 20 such cases, Curran and colleagues observed 4 mediastinal recurrences and 5 others outside the mediastinum, whereas no local relapse was seen when RT was given after total surgical resection for stage II or stage III disease.⁷⁵ Partial tumor debulking by surgery before RT in patients with stage III or stage IV disease does not appear to be beneficial.⁷⁷ The 5-year survival rate for such patients was 45% overall, including 61% for stage III and 23% for stage IV disease after RT. Collaboration between the surgeon and the radiotherapist is essential to delineate areas of tumor involvement by radiopaque clips and to plan the treatment.

Chemotherapy

Chemotherapy has activity in both the operable and the metastatic setting ([Table 6](#)). Cisplatin-based chemotherapy remains the standard of care in advanced stage disease. Combination chemotherapy regimens have shown higher response rates than single agent treatments. A four drug regimen of doxorubicin, cisplatin, vincristine, and cyclophosphamide (ADOC) was considered the standard of care for many years with reported overall response rate of 92% and a median survival of 15 months.⁷⁹ An intergroup trial however demonstrated the benefits of the 3 drug combination, cisplatin, doxorubicin, and cyclophosphamide (PAC) with an ORR of 50% and an MS of 38 months.⁷⁸ Various regimens include corticosteroids that have been shown to decrease tumor bulk in all histologic subtypes. The actual impact lies probably with a steroid-induced response in the lymphocytic component of the tumor rather than any anti-neoplastic effect on the malignant epithelial cells. A second three drug regimen that is commonly used is consists of cisplatin, doxorubicin, and methylprednisone (CAMP). This regimen was administered in the neoadjuvant setting and demonstrated an ORR of 93% with a 5-year OS of 81% in a small phase II trial consisting of 17 patients.⁸⁴ The EORTC investigated the doublet of cisplatin and etoposide in 16 patients and demonstrated a response rate of 56% and a median survival of 4.3 years.⁸⁰ The addition of ifosfamide to this doublet (VIP) demonstrated a partial response rate of 32% and an OS of 32 months albeit with higher toxicities.⁸¹ A recently published phase II trial investigated carboplatin AUC5 and paclitaxel 225 mg/m² every 3 weeks up to a maximum of 6 cycles. An overall response rate of 33% and a

progression free survival (PFS) of 19.8 months for thymomas and 6.2 months for thymic carcinomas in 34 treatment naïve patients was reported and this was very well tolerated.⁸² A second multicenter trial investigated the efficacy of carboplatin/paclitaxel in 40 Japanese patients with newly diagnosed thymic carcinoma. An overall RR of 36% (95% CI, 21–53%; *P* = 0.031) and a median PFS of 8.1 months was seen with 1- and 2-year survival rates of 85% and 71%, respectively. The combination of carboplatin/paclitaxel is an effective regimen and if an anthracycline cannot be used then this doublet is a good choice in the first-line setting for thymic carcinoma.⁸⁵

Table 6 Selected studies of chemotherapy regimens used in thymic malignancies

Regimen	Stage	CR + PR (%)
PAC ⁷⁸	IV	50
ADOC ⁷⁹	III/IV	90
PE ⁸⁰	IV	56
VIP ⁸¹	III/IV	32
Carbo-Px ⁸²	IV	35
Pemetrexed ⁸³	IV	17

PAC, cisplatin, doxorubicin, cyclophosphamide; ADOC, doxorubicin, cisplatin, vincristine, cyclophosphamide; PE, cisplatin, etoposide; VIP, etoposide, ifosfamide, cisplatin; Carbo-Px, carboplatin, paclitaxel.

Second-line chemotherapy does have activity in thymic malignancies. A phase II study evaluated single agent pemetrexed at a dosage of 500 mg/m² every 3 weeks in 27 patients with previously treated unresectable stage IVA (*n* = 16) or stage IVB (*n* = 11) recurrent thymic malignancies.⁸³ The median number of cycles administered was 5 (range 1–6). In 23 fully evaluable patients, two complete and two partial responses (RECIST) were noted. All four responding patients had stage IVA thymoma.⁸³ Oral etoposide similarly may have some activity in pretreated patients with a response rate of 15% being reported.⁸⁶ Amrubicin in previously treated patients at a dosage of 35 mg/m² days 1–3 q3 weeks is currently being evaluated.⁸⁷

In recent years that have been a number of small studies and case reports that have evaluated targeted therapies in thymic malignancies after progression on first-line therapy. Unfortunately, the results have been somewhat disappointing but given the rarity of these tumors and the fact that it is extremely challenging to preselect patients based on a certain molecular phenotype they are perhaps not unexpected. It is hoped that future molecular profiling “basket studies” enrolling multiple tumor types with selected oncogenic driver mutations will identify patients with thymic malignancies that have significant sensitivities to targeted therapy.

Targeted therapy—KIT, EGFR/HER2, VEGF

Although large randomized phase III trials are not possible in thymic malignancies, a number of small phase II studies and case reports (Table 7) have highlighted that a subset of patients do derive benefit from personalized medicine. KIT is frequently overexpressed in thymic carcinomas with IHC positivity occurring in up to 73–86% of tumors, but there is limited overexpression in thymomas with only 2% demonstrating positivity.^{95, 96} Unfortunately, despite the high frequency of KIT expression in thymic carcinomas, the rate of KIT mutations remains low at <10%. Case reports have identified that the type of KIT mutation determines the sensitivity to tyrosine kinase inhibitors. A number of mutations have been

described, for example, V560 deletion⁹⁷ and L576P substitution⁹⁸ both found in exon 11, D820E mutation in exon 17,⁹⁹ and the H697Y mutation found in exon 14.⁵² V560 is highly sensitive to both sunitinib and imatinib, L576P has moderate sensitivity to sunitinib and low sensitivity to imatinib, whereas D820E is resistant to both TKIs indicating that “one size does not fit all” when it comes to mutation testing in thymic tumors. The rarity and the sensitivity of mutations explains the disappointing results of a small phase II trial that evaluated imatinib in patients with either type B3 thymoma or thymic carcinoma where no responses were seen.¹⁰⁰

Table 7 Targeted therapies in thymic malignancies

Drug	Number of patients	Thymoma	Thymic Ca	RR (%)
Gefitinib ⁸⁸	26	19	7	4
Erlotinib + Bev ⁸⁹	18	11	7	0
Imatinib ⁹⁰	15	12	3	0
Belinostat ⁹¹	40	24	16	5
Cixutumumab ⁹²	49	37	12	10
Everolimus ⁹³	35	23	12	11
Sunitinib ⁹⁴	39	16	23	18

Epidermal growth factor receptor (EGFR) is similarly overexpressed (70% of thymomas and 50% of thymic carcinomas^{96, 101}) in thymic malignancies, but unfortunately somatic activating EGFR mutations are extremely rare.^{98, 102} There is no correlation between EGFR staining and histological subtype. EGFR gene amplification by FISH occurs in approximately 20% of thymic malignancies, most notably in type B3 thymomas and thymic carcinomas and is associated with more advanced stage and capsule invasion.¹⁰³ Not unexpectedly, there was no activity seen in a study that evaluated the efficacy of gefitinib 250 mg⁸⁸ or the combination of erlotinib and bevacizumab patients with progressive malignant thymic tumors.⁸⁹ Similarly, the EGFR monoclonal antibody cetuximab has limited efficacy although studies are ongoing.^{90, 104} At the present time, the evidence from the literature suggests that both EGFR tyrosine kinase inhibitors and monoclonal antibodies cannot be recommended to treat patients with thymic malignancies. Similarly, no cases of HER2 gene amplification by FISH have been detected¹⁰⁵ and there is no data to recommend HER2-targeted therapies in this disease setting.

Targeting angiogenesis, which is thought to play an important role in thymomagenesis, may be a more successful strategy. Vascular endothelial growth factor (VEGF)-A and VEGFR-1 and -2 are over-expressed in both thymomas and thymic carcinomas.^{106, 107} Although low response rates have been seen with bevacizumab, case reports involving sorafenib and sunitinib have highlighted the activity of these multikinase inhibitors predominantly in thymic carcinomas. Activity has been reported in a patient receiving sorafenib who had a missense mutation in exon 17 (D820E) of the c-KIT gene⁹⁹ and a second patient had prolonged stable disease (>9 months) in a nonmutated but high IHC expressing tumor for KIT, p53, and VEGF.¹⁰⁸ The multikinase inhibitor sunitinib has been evaluated in a phase II clinical trial involving 23 patients with thymic carcinoma. An impressive response rate compared to historical data of 26% and a disease control rate of 91% was reported.¹⁰⁹

Other targets that have been evaluated include the insulin-like growth factor-1 (IGF-1)/IGF-1 receptor (IGF-1R), which has been identified as a poor prognostic indicator in thymic malignancies.^{94, 110}

Expression of IGF-1R does differ between thymomas (4%) and thymic carcinomas (37%) indicating a possible difference in tumor biology that may be targetable.⁹⁴ A phase II study of cixutumumab, an IGF-1R monoclonal antibody in 49 patients with previously treated advanced thymic tumors, demonstrated a modest 14% response rate in thymomas but no activity in thymic carcinoma.⁹² Similarly histone deacetylase (HDAC) inhibitors have been evaluated in thymic tumors most notably the pan-HDAC inhibitor belinostat that demonstrated modest antitumor activity. In a phase I study of belinostat, a patient with thymoma had a minor response that lasted for 17 months on treatment;¹¹¹ therefore, a phase II trial in 41 patients (25 thymoma and 16 thymic carcinoma) in previously treated thymic malignancies was performed.⁹¹ There were two partial responses in thymomas (response rate 8%) and no responses in thymic carcinomas. Ongoing studies targeting the mTOR pathway inhibitors are ongoing.⁹³ Future strategies targeting the PD-1/PD-L1 axis are planned. High PD-L1 expression ranging from 60% to 90% across the spectrum of thymic malignancies indicates that the use of checkpoint inhibitors may prove more successful than targeting individual genetic alterations although the concern about exacerbating autoimmune phenomenon mandates investigation in type B3/thymic carcinomas in the first instance.

Conclusion

Incremental improvements in our understanding of molecular biology allied with improvements in stage classification systems will it is hoped provide a uniform nomenclature and pathway toward larger collaborative efforts by providing consistency of communication across International boundaries. The ongoing TNM stage groupings that are being developed will provide a basis for the 8th edition of the AJCC/UICC stage classification due to be published in 2016. Surgical resection continues to be the cornerstone of therapy for early-stage disease while a multidisciplinary approach incorporating surgery, radiation, and chemotherapy is recommended in advanced or recurrent disease. Gene expression profiling and genomic clustering data indicating that the subclassifications of types A, AB, B1, B2, B3, and thymic carcinoma have different molecular features may allow for subset specific therapeutics. Clear differences have emerged between thymic carcinomas and type B3 thymomas when compared to type A and type B2 thymomas. It is hoped that molecular classification may be more useful to clinicians in the future than the current classification systems. Future strategies using prognostic and predictive biomarker or gene signatures may allow us to preselect patients for the most appropriate treatment. In addition, intense interest is now focused on targeting the immune system in these most intriguing of tumors. The association of thymic tumors with a wide variety of disorders secondary to T-cell-mediated autoimmunity allied to high PD-L1 expression indicates that checkpoint inhibitors such as PD-1 inhibitors may hold promise for patients with chemoresistant disease.

Chapter 87

Tumors of the heart and great vessels

Anthony F. Yu, MD ■ Sai-Ching Jim Yeung, MD, PhD, FACP ■ Carmen P. Escalante, MD ■ Sarina van der Zee, MD ■ A. P. Chahinian, MD ■ Valentin Fuster, MD, PhD

Overview

Primary tumors of the heart and great vessels are rare, but secondary tumors are significantly more common. Clinical manifestations of cardiac tumors depend on the location and size of the mass, not on the histopathology of the tumor. Several noninvasive imaging modalities including echocardiography, cardiac MRI, cardiac CT, and PET are currently available to provide complementary information on the location, extent, and tissue characteristics of a cardiac tumor. The clinical management of patients with cardiac tumors varies based on the type of tumor, clinical symptoms, and overall prognosis.

Introduction

Primary cardiac tumors are extremely rare, with a prevalence of <0.1% to 0.3% based on autopsy series.^{1–4} More than 75% of primary cardiac tumors are benign ([Table 1](#)).^{5, 6} The majority of malignant primary cardiac tumors are sarcomas and lymphomas, which carry a poor prognosis despite treatment.^{7, 8} In contrast to primary cardiac tumors, metastases to the heart are relatively common.^{2, 9–11} While most primary tumors arise from the endocardium, followed by the myocardium and then the pericardium,² the latter is the most common site for metastases.¹²

Table 1 Type and frequency of primary tumors of the heart and pericardium in two series from the armed forces institute of pathology

Clinical features

The clinical manifestations of cardiac tumors frequently reflect the cardiac structure involved, tumor size, and the friability of the tumor rather than its histology.¹² The underlying mechanism responsible for

clinical symptoms is varied and may include embolization, intracardiac or valvular obstruction, or direct invasion of myocardium or adjacent organs. The predominant site of common cardiac tumors is shown in [Figure 1](#).

Figure 1 Predominant sites of common cardiac tumors.

Tumors of the endocardial surface may present with valvular dysfunction or intracavitary obstruction. Right atrial tumors can lead to tricuspid valve obstruction and symptoms of right heart failure (i.e., fatigue, peripheral edema, ascites, hepatomegaly, jugular vein distention). Left atrial tumors tend to cause symptoms by obstructing blood flow and typically present with left heart failure symptoms (i.e., dyspnea, orthopnea, pulmonary edema, or hemoptysis). Myocardial invasion may present as arrhythmia, conduction abnormalities, systolic dysfunction, or diastolic dysfunction. Rarely, complete cavitory obstruction may lead to sudden death. Pericardial involvement can present as pleuritic chest pain or cardiac tamponade. Friable tumors, such as some myxomas and papillary fibroelastomas, may present with evidence of cerebral, pulmonary, visceral, or peripheral emboli. Systemic manifestations, frequently seen in myxomas as well as malignant cardiac tumors, include fever, weight loss, myalgias, arthralgias, fatigue, and weakness.

Patients with cardiac tumors may present with the symptoms described above, or masses may be discovered incidentally on imaging studies, particularly when small in size. Physical examination may disclose a murmur, either systolic or diastolic, that varies with body position if the tumor is mobile. The characteristic “tumor plop” of a mobile tumor such as a myxoma is heard in diastole following the second heart sound and is thought to be due to the tension on the tumor stalk as the mass prolapses from atrium to ventricle or to the tumor striking the myocardium.¹⁰ The tumor plop may be mistaken for a third heart sound or mitral opening snap. The electrocardiogram may show nonspecific ST-T abnormalities, atrial or ventricular arrhythmias, bundle branch block, or low voltage QRS complexes in the case of pericardial effusion. Chest X-ray findings include cardiomegaly and tumor calcification. Laboratory abnormalities include anemia (possibly hemolytic) or erythrocytosis, leukocytosis, thrombocytopenia, increased serum immunoglobulin levels, and elevated acute-phase reactants such as erythrocyte sedimentation rate and C-

reactive protein.¹⁰

Diagnostic evaluation

Several cardiac imaging techniques are available for evaluation of patients with suspected cardiac masses. Two-dimensional transthoracic echocardiography (TTE) provides excellent spatial and temporal resolution of cardiac masses and is often the initial imaging modality of choice.¹³ However, TTE can be limited by poor acoustic windows and lack of tissue characterization. Transesophageal echocardiography (TEE) allows for better tumor localization and characterization as well as assessment of intra- and extracardiac invasion. The use of contrast echocardiography may help to improve echocardiographic resolution and provide information on tumor vascularity.¹⁴ Real-time three-dimensional echocardiography can offer incremental value over two-dimensional echocardiography by providing an accurate assessment of size and shape of the mass and enabling better localization of attachment point.¹⁵

Cardiac computed tomography (CT) and magnetic resonance imaging (MRI) provide cross-sectional images of the heart with high temporal and spatial resolution. Both modalities are able to depict intra- and extracardiac masses, as well as degree of myocardial or pericardial involvement, without limitations owing to body habitus or poor acoustic windows. Cardiac CT provides limited information regarding tissue characterization, but disadvantages of cardiac CT include radiation exposure and potential nephrotoxicity of contrast agents.¹⁶ Cardiac MRI provides the highest degree of soft tissue contrast of any imaging modality and combines outstanding tumor localization, visualization of adjacent structures, and myocardial motion and perfusion assessment ([Figure 2](#)).^{17–19} In addition, tailored imaging sequences allow more specific characterization of particular tumors.¹⁸ Tissue characteristics of the cardiac mass can be evaluated using T1- and T2-weighted images, as well as enhancement with gadolinium contrast.²⁰ Although the spatial resolution of CT is greater than MRI, the soft tissue characterization of CT is inferior to MRI and thus, CT can be considered an intermediate modality appropriate in select patients.¹⁶ Positron emission tomography (PET) can also help to identify cardiac involvement in patients with malignant tumors.²¹ Cardiac angiography, once a mainstay in the diagnosis of cardiac tumors, has fallen out of use given the risk of embolization during the procedure.

Figure 2 Cardiac MRI of a 69-year-old man with lymphoma demonstrating a large homogeneous mass (arrows) occupying most of the right atrium and extending into the right ventricle and posterior mediastinum. (a) Dark-blood image in the four-chamber view obtained using T2-weighted half-Fourier acquisition single-shot turbo spin echo. (b) Bright-blood image in the four-chamber view obtained using steady-state free precession; note the large bilateral pleural effusions.

When a cardiac mass is discovered on an imaging study, the differential diagnosis includes thrombus and vegetation, in addition to primary or secondary tumors.^{22, 23} Thrombi are usually seen in the context of underlying heart disease including arrhythmia (e.g., atrial fibrillation or atrial flutter), cardiomyopathy, or myocardial infarction. Normal anatomic variants, such as a prominent Eustachian valve or Chiari network, may also mimic cardiac tumors.²⁴

Cardiac tumors

Benign primary cardiac tumors

Myxomas

Myxomas represent the most common primary cardiac tumor in the adult population. Histologically, these soft gelatinous tumors are thought to arise from the subendocardial mesenchyme and contain polygonal to stellate myxoma cells (“lepidic cells”), often around vascular channels in an eosinophilic matrix, with various areas of hemorrhage.⁵ The cells are positive for factor VIII and can also express neuron-specific enolase and S-100 protein.²⁵ Most myxomas arise in the left atrium and are usually attached to the fossa ovalis. In a meta-analysis of 32 reports encompassing 1029 patients, 83% of myxomas were found to occur in the left atrium.²⁶ The remainder are found in the right atrium, or uncommonly, in the right or left ventricles. They often present as mobile masses attached by a stalk to the endocardial surface.²⁷ The mean age is 50 years at presentation, and more women are affected than men.²⁶ The classic clinical presentation includes a triad of constitutional symptoms, valvular obstruction, and embolization. Embolic phenomena, seen in 30–40% of patients, are more likely when the tumor surface is irregular (polypoid or myxoid) rather than smooth.¹² Surgery is generally recommended at the time of diagnosis owing to the risk of embolization or other cardiac complications, and involves en bloc resection along with margins of normal

tissue and the fossa ovalis. Recurrence is rare but can occur in 2–5% of patients but long-term follow-up is necessary.^{28–30}

Although most myxomas are sporadic, familial syndromes have been described. The Carney complex is an autosomal dominant multiple endocrine neoplasia syndrome that includes atrial myxomas and endocrine, neural and cutaneous tumors in addition to skin and mucosal pigmentation.^{31–33} Mutations in *PRKAR1A*, a gene located on chromosome 17q22-24, which encodes a regulatory subunit of cyclic-AMP-dependent protein kinase A, have been identified in approximately one-half of affected patients.^{34–37} A variant associated with distal arthrogryposis has been linked to a missense mutation in the myosin heavy-chain gene on 17p12-p13.1.³⁸ Familial myxomas present at a younger age, are more likely to be multiple, and are more likely to recur after resection than sporadic myxomas.³⁹ Identification of first-degree relatives facilitates the identification of myxomas at risk for embolization.

Papillary fibroelastomas

Papillary fibroelastomas are the most common primary tumor of the cardiac valves and are composed of papillary fronds similar to normal chordae tendineae. They usually arise from the valvular endocardium, most commonly the aortic valve, and occur over a wide range of ages.^{40, 41} Fibroelastomas may be asymptomatic (in ~30% of patients) or may present with transient ischemic attack, stroke, heart failure, angina, myocardial infarction, or sudden death. Surgical resection is recommended for patients with prior embolic events, as well as patients with large (≥ 1 cm) and mobile masses at high risk for embolization.^{40, 42, 43}

Other benign tumors

Rhabdomyomas occur almost exclusively in children and are described below. Lipomatous septal hypertrophy is an exaggeration of the normal accumulation of fat within the atrial septum.⁴⁴ There is usually no role for surgical resection of lipomatous septal hypertrophy in the absence of symptoms such as vena cava obstruction, atrial arrhythmia, or congestive heart failure.^{45, 46} Lipomas and hemangiomas may be found anywhere in the heart. Fibromas primarily arise in the interventricular septum and more commonly affect the left ventricle.⁴⁷ Pericardial cysts are most common in the right costophrenic angle, and bronchogenic cysts can be found in the myocardium.⁵ Paragangliomas and mesotheliomas may be benign or malignant. Mesotheliomas may be primary or metastatic to the pericardium or may occur in the AV node, presenting with AV block, arrhythmia, or sudden death.⁴⁸

Malignant primary cardiac tumors

Sarcomas

Soft tissue sarcomas are the most common primary malignant neoplasm of the heart.⁴⁹ Angiosarcomas usually arise in the right atrium near the atrioventricular groove, although other chambers may be involved, and are associated with areas of hemorrhage, pericardial invasion, and effusion.⁵⁰ Angiosarcomas most commonly present between 20 and 50 years of age, with a two- to threefold male predominance.⁵ The clinical presentation may include palpitations, dyspnea, and chest pain (pleuritic and/or pericardial), or signs and symptoms related to congestive heart failure or thromboembolism. The relationship between cardiac angiosarcoma and Kaposi's sarcoma, in which cardiac involvement has been described, requires further investigation.^{51, 52} Rhabdomyosarcomas are the second most common malignant neoplasm of the heart and equally affect the right and left sided heart chambers.⁵³

Endomyocardial-based sarcomas, often with smooth muscle or myofibroblastic differentiation, are rare tumors usually located in the left atrium and consist of multiple subtypes, including undifferentiated pleomorphic sarcoma, osteosarcoma, leiomyosarcoma, fibrosarcoma, and myxofibrosarcoma.

The overall prognosis of cardiac sarcomas is poor, and aggressive local growth and metastatic spread are common. The median survival ranges from 6 to 12 months.^{54, 55} Complete surgical resection of cardiac sarcomas is the treatment of choice, although many patients develop recurrent disease. Orthotopic heart transplantation, at times combined with bilateral lung transplantation, has been described in a few small series and case reports. In most cases, heart transplantation followed by chemotherapy does not affect long-term outcome;⁵⁶ however, selected patients may have good outcomes with transplantation.^{57, 58}

Lymphomas

Primary cardiac lymphomas are rare and should be distinguished from systemic lymphoma with secondary cardiac involvement.⁸ The typical sites are the atria, where infiltration of the wall is frequent, as well as the pericardium. Cardiac lymphoma may be seen in immunocompetent patients but is also associated with acquired immune deficiency syndrome and organ transplant-related immunosuppression. Unlike other cardiac tumors, the mainstay of treatment is chemotherapy, alone or in combination with radiation therapy, and occasionally autologous stem cell transplantation.^{59, 60}

Metastatic cardiac tumors

Secondary tumors of the heart are significantly more common than primary cardiac tumors.⁶¹ Mechanisms of metastasis include direct extension, hematogenous spread, lymphatic spread, and cavoatrial or pulmonary vein extension. The pericardium is the most common location for cardiac metastasis, followed by the epicardium and myocardium. Malignancies likely to metastasize to the heart are shown in [Table 2](#).²⁷ In a recent postmortem review of 7289 cases with malignant neoplasms, the incidence of cardiac metastasis was 9.1%.¹¹ The frequency of heart metastases was, in decreasing order, mesothelioma (48.4%), melanoma (27.8%), lung adenocarcinoma (21%), poorly differentiated lung carcinoma (19.5%), squamous cell lung carcinoma (18.2%), and breast carcinoma (15.5%). Almost any cancer, however, can metastasize to the heart. A high frequency of cardiac metastasis and/or invasion can be seen in patients with malignant pleural mesothelioma.⁶² In 19 autopsies, cardiac invasion was found in 14 (74%), with more than half involving the pericardium and more than one-quarter the myocardium.⁶³ Treatment is generally palliative.

Table 2 Tumors likely to metastasize to the heart

Melanoma
Malignant germ cell tumor
Leukemia and lymphoma
Breast carcinoma
Lung carcinoma
Hepatocellular carcinoma
Renal cell carcinoma
Sarcoma
Esophageal and gastric carcinoma
Mesothelioma (may be primary to pericardium or metastatic)

Pediatric tumors

In contrast to adults, metastases to the heart are rarely observed in the pediatric population. Many cardiac neoplasms in children occur in the context of familial syndromes (see section on the Carney Complex, above). The majority are hamartomas. Rhabdomyomas account for the majority of pediatric cardiac tumors⁶⁴ and are associated with tuberous sclerosis, an autosomal dominant disorder characterized by benign neoplasms of the heart, kidneys, brain, lungs, and skin.⁶⁵ They occur most commonly in the ventricles and, in the context of familial syndromes, often regress spontaneously; surgical resection is usually necessary only if outflow tract obstruction is present.^{66–68} Cardiac fibromas are mainly found in the ventricular septum and can grow to be quite large, often with areas of central calcification. Fibromas occur in a minority of patients with Gorlin syndrome, which is an autosomal dominant disorder presenting with multiple neoplasms, including basal cell carcinomas and medulloblastomas as well as odontogenic keratocysts and skeletal abnormalities.^{69, 70} Neurofibromas are found in patients with von Recklinghausen's disease.²⁷

Tumors of the great vessels

Primary tumors involving the aorta, pulmonary artery, and vena cavae are rare, appearing in the literature mainly as case reports or in small retrospective case series.^{71–73} Risk factors for the development of tumors of the great vessels remain poorly defined. Prior radiation exposure has been postulated as a possible causative factor.⁷⁴ Plastic polymers, such as Dacron, have been linked to aortic tumors in animal studies; nonetheless, aortic tumors arising around a Dacron graft in humans, although reported, are extremely rare.⁷⁵ Tumors of the great vessels typically present with thromboembolic events or an obstructive syndrome.⁷¹ TEE and MRI are useful in differentiating tumors of the great vessels from intraluminal thrombus, mediastinal lymphadenopathy, or adjacent lung tumors.

Benign tumors of the aorta include endothelial papillary fibroelastomas arising in the aortic sinuses, which may present with intermittent prolapse into a coronary artery or with emboli to the heart or brain.⁷⁶ Intra-aortic myxomas have also been described, presenting with recurrent arterial emboli.⁷²

Malignant tumors of the aorta and pulmonary artery are often aggressive, poorly differentiated sarcomas arising from intimal cells and showing myofibroblastic differentiation (“intimal type”). Rarely, malignant

tumors of the great vessels are identified as angiosarcomas, leiomyosarcomas, hemangioendotheliomas, schwannomas, and fibrous histiocytomas.^{71, 77–79} Sarcomas of the inferior vena cava tend to be well-differentiated leiomyosarcomas.⁸⁰ Whereas sarcomas of the aorta present at a mean age of 62 years, sarcomas of the pulmonary artery present at a younger age. In a review of 60 cases of sarcoma involving the pulmonary trunk, the median age was 52 years, with a male-to-female ratio of 1:2 and a median duration of symptoms of 10 months.⁸¹ The clinical picture was suggestive of pulmonary embolism, with dyspnea (70%), chest pain (48%), cough (34%), hemoptysis (30%), and syncope (25%). Metastases to lung (67%) and lymph node (20%) were common.

Although patients with tumors of the great vessels tend to present with advanced disease and prognosis is poor, a minority respond to resection and chemotherapy.⁸² The cornerstone of therapy is complete surgical excision.⁸³ The use of various grafts has been advocated,⁸⁴ along with postoperative radiation and chemotherapy, often with an anthracycline-based regimen.^{71, 77} Although mean survival for patients with tumors of the great vessels is only 10 months, patients with sarcoma of the pulmonary artery may have a better prognosis compared with sarcoma of the aorta (23 vs 5 months).^{71, 84, 85} Prolonged survival is extremely rare but has been reported.⁸⁶ For patients with unresectable disease, endovascular stent grafting may improve quality of life.⁸⁷

Chapter 88

Primary germ cell tumors of the thorax

John D. Hainsworth MD ■ F. Anthony Greco, MD

Overview

Primary germ cell tumors (GCT) of the thorax are rare but potentially curable. Benign teratomas account for approximately 60–70% and usually appear in young adults. The large majority of these tumors are curable with surgical excision. Malignant mediastinal GCT usually occur in young men and can be divided histologically into pure seminoma (~52% of cases) and various nonseminoma histologies. Pure seminomas are highly sensitive to chemotherapy; treatment with three cycles of bleomycin, etoposide, and cisplatin (BEP) as used in testicular cancer is curative in more than 80%. Selected patients with small (<6 cm) localized seminomas have high cure rates with radiation therapy alone. Nonseminomatous mediastinal GCT are associated with Klinefelter's syndrome (5–10% of cases) and are also associated with various acute leukemias. Optimal treatment includes four cycles of BEP chemotherapy (or an equivalent regimen), followed by resection of residual mediastinal masses. The cure rate for these relatively poor prognosis GCT is approximately 45%.

Mediastinal germ cell tumors (GCT), although rare, are of particular interest because they usually affect young males and because curative therapy is now available for many patients.

Benign teratomas of the mediastinum

Although benign teratomas of the mediastinum (mature cystic teratomas or dermoid tumors) account for only 3–12% of mediastinal tumors, they comprise 60–70% of all mediastinal GCT.^{1, 2} These tumors have been described in patients with ages ranging from 7 months to 65 years; however, most occur in young adults, with an approximately equal incidence in males and females.^{2, 3}

Benign mediastinal teratomas have a histologic appearance identical to that of benign teratomas arising in the more common ovarian location. On histologic examination, mature tissue from ectodermal, mesodermal, and endodermal germ cell layers is typically present. Mature tissue that recapitulates the histology of any human organ can be found in these tumors. However, the ectodermal component (i.e., skin, sebaceous tissue, neural tissue) usually predominates.³

Approximately 95% of benign teratomas arise in the anterior mediastinum; the remainder arise in the posterior mediastinum.^{2, 3} These tumors are slow growing, and 50–60% of patients are asymptomatic at the time of diagnosis by routine chest radiography.³ When symptoms are present, dyspnea and substernal chest pain are the most common. Spontaneous rupture of the teratoma into the lung, tracheobronchial tree, pleura, or pericardium can cause an acute onset of symptoms, but these events occur late in the disease course. Cough productive of hair or sebum, caused by rupture into the tracheobronchial tree, is pathognomonic of a benign mediastinal teratoma but occurs rarely. Superior vena cava syndrome is also rare and is a late manifestation. Serum levels of human chorionic gonadotropin (HCG) and alpha-fetoprotein are always normal in patients with benign teratoma.

Surgical excision is the treatment of choice for benign teratoma of the mediastinum. Surgical removal is sometimes difficult because of the large size and involvement of adjacent structures. Approximately 10–15% of patients require additional procedures (e.g., lobectomy, pericardiectomy) for complete tumor resection. Benign teratomas are resistant to radiation and cytotoxic drugs, and these modalities have no role in their treatment.

Tumor recurrence is rare following complete surgical resection.^{2–4} Prolonged survival has been reported following subtotal resection of tumors involving vital mediastinal structures.

Malignant GCT

Etiology

Mediastinal GCT were initially thought to represent isolated metastases from an inapparent gonadal primary site. However, there is now abundant clinical evidence to substantiate the extragonadal origin of these tumors.^{1, 5}

Epidemiology

Malignant mediastinal GCT represent only 3–10% of tumors originating in the mediastinum, and only 1–5% of all germ cell neoplasms.⁶ The great majority of mediastinal malignant GCT occur in males between 20 and 35 years of age. In the rare occurrences reported in females, mediastinal malignant GCT appear histologically and biologically identical to those occurring in males.

Patients with nonseminomatous extragonadal GCT have a subsequent increased risk of developing testicular cancer (approximately 10% at 10 years), strengthening the concept of a precursor abnormality in the germ cells of these patients.⁷

Histopathology

Mediastinal GCT appear to be histologically identical to GCT arising in the testis and contain the same range of histologic subtypes. However, the frequency of yolk sac tumor and teratocarcinoma is higher in mediastinal GCT, while embryonal carcinoma is less common. In a review of 229 malignant mediastinal GCT, pure seminoma was the most common histology, accounting for 52% of cases.⁸ Nonseminomatous histologies included teratocarcinoma (20%), yolk sac tumor (17%), choriocarcinoma (3.4%), embryonal carcinoma (2.6%), and mixed nonseminomatous tumors (5.2%).

Clinical characteristics

Malignant mediastinal GCT are usually symptomatic at the time of diagnosis. Most mediastinal GCT are large and cause symptoms by compressing or invading adjacent structures, including the lungs, pleura, pericardium, and chest wall. Pure seminomas are somewhat slower growing and have less potential for early metastasis than do tumors with nonseminomatous elements. Pure seminomas and tumors with nonseminomatous elements are therefore discussed separately, although substantial overlap exists in their clinical characteristics.

Seminoma

Seminomas grow relatively slowly and often become very large before causing symptoms. Tumors 20–30 cm in diameter can exist with minimal symptomatology. Approximately 20–30% of seminomas are

detected by routine chest radiography while still asymptomatic.⁹ The most common initial symptom is a sensation of pressure or dull retrosternal chest pain. Additional symptoms include exertional dyspnea, cough, dysphagia, and hoarseness. Superior vena cava syndrome develops in approximately 10% of patients. Systemic symptoms related to metastatic lesions are uncommon.

In order to be classified as a seminoma (or dysgerminoma in women), a mediastinal GCT must have no other histologic elements present. Tumors consisting of a mixture of seminoma and nonseminoma elements should be approached as nonseminomatous GCT.

At the time of diagnosis, only 30–40% of patients with mediastinal seminoma have localized disease; remaining patients have one or more sites of distant metastases.¹⁰ The regional lymph nodes (cervical, upper abdominal) are the most common metastatic sites; lung and bone are the most common visceral sites.¹¹

Elevated serum levels of HCG are detected in up to 40% of mediastinal seminomas.¹¹ However, most of these are low-level elevations (2–10 ng/mL); levels of HCG exceeding 100 ng/mL are unusual and suggest the presence of nonseminomatous elements. The serum alpha-fetoprotein level is always normal in pure mediastinal seminoma, and any elevation of this tumor marker indicates the presence of nonseminomatous elements.

Nonseminomatous GCT

These rapidly growing neoplasms cause symptoms by compressing or invading local mediastinal structures, as seen in patients with mediastinal seminoma. Symptoms caused by metastases are much more common, as 85–95% of these patients have at least one metastatic site at the time of diagnosis.^{12–14} Common metastatic sites include the lungs, pleura, lymph nodes (particularly supraclavicular and retroperitoneal), and liver. High levels of HCG are sometimes associated with gynecomastia. Constitutional symptoms are more common in these patients than in those with pure seminoma.

The serum tumor markers HCG and alpha-fetoprotein are usually abnormal in patients with mediastinal nonseminomatous GCT. Alpha-fetoprotein is elevated in 74–90% of patients, and elevation of HCG occurs in 30–38%.^{15–17}

Approximately 5–10% of patients with mediastinal nonseminomatous GCT have Klinefelter syndrome.^{18–20} The explanation for this association is unknown, but underlying germ cell defects related to the XXY chromosomal abnormality are likely to play a role.²¹ The association of Klinefelter syndrome and mediastinal nonseminomatous GCT is specific; gonadal GCT show no association.^{18, 19}

Mediastinal nonseminomatous GCT are also associated with a variety of hematologic neoplasms including acute myeloid leukemia, acute nonlymphocytic leukemia, acute lymphocytic leukemia, erythroleukemia, acute megakaryocytic leukemia, myelodysplastic syndrome, and malignant histiocytosis.^{22–28} Hematologic neoplasms in this setting are not treatment-related but rather arise from clones of malignant lymphoblasts, myeloblasts, or progenitor cells contained within the GCT.^{25–27}

Pretreatment evaluation and staging

The diagnosis of a mediastinal GCT should be considered in all young males with a mediastinal mass. In addition to physical examination and routine laboratory studies, initial evaluation should include CT of the chest and abdomen and determination of serum levels of HCG and alpha-fetoprotein. Any symptoms suggestive of distant metastases should be appropriately evaluated with radiologic studies.

In patients with suspected mediastinal GCT, a histologic diagnosis should be made using the least invasive approach because rapid initiation of definitive systemic therapy is important. Because these neoplasms are poorly differentiated, specimens obtained by fine-needle aspiration biopsy are sometimes insufficient for a definitive diagnosis. In such patients, surgical biopsy via median sternotomy or limited thoracotomy is indicated. Attempts at complete surgical resection of these mediastinal neoplasms are not indicated because curative results with other treatment modalities are superior.

Treatment of seminoma

Pure mediastinal seminomas are curable in the large majority of patients, even when metastatic at the time of diagnosis. These tumors are highly sensitive to radiation therapy and to combination chemotherapy, and the selection of treatment therefore depends on tumor stage and size, as well as the anticipated short- and long-term toxicity of treatment.

Chemotherapy

Cisplatin-based combination chemotherapy, as used in patients with advanced testicular cancer, is highly effective treatment for mediastinal seminoma. Patients who have no extrapulmonary or visceral metastases are classified as good risk GCT by the International Germ Cell Consensus Classification²⁹ and require first-line treatment with three cycles of combination chemotherapy. The most widely used combination regimen is bleomycin, etoposide, and cisplatin (BEP).³⁰ For patients with underlying pulmonary disease, or those who have had previous radiation therapy, bleomycin should be avoided; four cycles of etoposide/cisplatin are preferred. Patients with mediastinal seminoma and metastases to extrapulmonary sites have intermediate risk and therefore require four cycles of BEP. In this category, patients at risk for bleomycin toxicity should receive four courses of the VIP regimen (etoposide, ifosfamide, cisplatin).³¹

Cure rates higher than 80% have been reported in all series of patients treated with modern cisplatin-based regimens.^{10–12, 14, 30, 32–36} In the largest retrospective analysis, 47 of 51 patients achieved complete remission, with subsequent relapses in only 14%.¹¹

Radiation therapy

Radiation therapy is also potentially curative for patients with mediastinal seminoma.^{4, 10, 37, 38} When localized tumors are <6 cm in diameter, the cure rate is high with radiation therapy or chemotherapy, and the choice of treatment should be individualized. For young patients without contraindications, curative treatment with chemotherapy avoids potential long-term consequences of mediastinal irradiation (e.g., coronary artery disease, valvular disease, constrictive pericarditis, second cancers), and is therefore the treatment of choice.^{39, 40} Patients with tumors <6 cm in diameter who are poor candidates for chemotherapy should have radiation therapy (35–50 Gy) using a field that includes the mediastinum and bilateral supraclavicular fossae. Patients who relapse after radiation therapy have a high salvage rate with chemotherapy.^{12, 30}

Residual mass

Following completion of chemotherapy, CT scans frequently show a residual mediastinal mass. In most published experience, residual masses <3 cm contain only fibrosis and necrotic tumor, whereas residual masses >3 cm have up to a 30% chance of containing residual viable cancer.^{41, 42} Therefore, careful follow-up without resection is recommended for patients with residual masses < 3 cm. Larger residual

masses that are negative on PET scan can also be followed.^{43, 44} Follow-up includes CT scans every 3 months during the first year and every 6 months during the second year or until normal. This approach avoids a potentially difficult surgical procedure in most patients; intervention is necessary only if enlargement of masses is evident on serial scans.⁴¹ Resection is recommended for residual masses > 3 cm. Patients with residual seminoma in the resected mass should have additional salvage chemotherapy or, in selected instances, radiation therapy to the mediastinum.

Treatment of nonseminomatous GCT

Most patients with mediastinal nonseminomatous GCT currently receive multimodality therapy, utilizing combination chemotherapy followed by surgical resection of residual mediastinal masses.

Chemotherapy

The use of cisplatin-based chemotherapy developed for the treatment of advanced nonseminomatous testicular neoplasms has improved the previously dismal outlook in patients with mediastinal nonseminomatous GCT. However, cure rates remain lower than those achieved in the treatment of testicular cancer.^{12–17, 32, 33, 36, 45–48} Comparable long-term survival rates of 40–50% have been reported when testicular GCT with far advanced, bulky metastases are treated with similar cisplatin-based regimens.²⁹ Inherent biologic differences between mediastinal and testicular GCT also play a role in determining the relatively low cure rate.⁴⁹

All patients with mediastinal nonseminomatous GCT have poor risk tumors; therefore, first-line treatment should include four courses of BEP or an equivalent regimen.⁵⁰ Following the completion of therapy, patients should be restaged with serum tumor markers and CT scans of the chest and abdomen.

Residual mass

Subsequent management is determined by the response to initial chemotherapy ([Figure 1](#)). Patients with normal CT scans and tumor marker levels require no further therapy. Approximately 20% of these patients subsequently relapse, with almost all relapses occurring during the first 2 years after completion of therapy. Standard follow-up of these patients includes monthly physical examination, chest radiography, and serum tumor marker determinations during the first year and similar evaluations every 2 months during the second year following therapy.

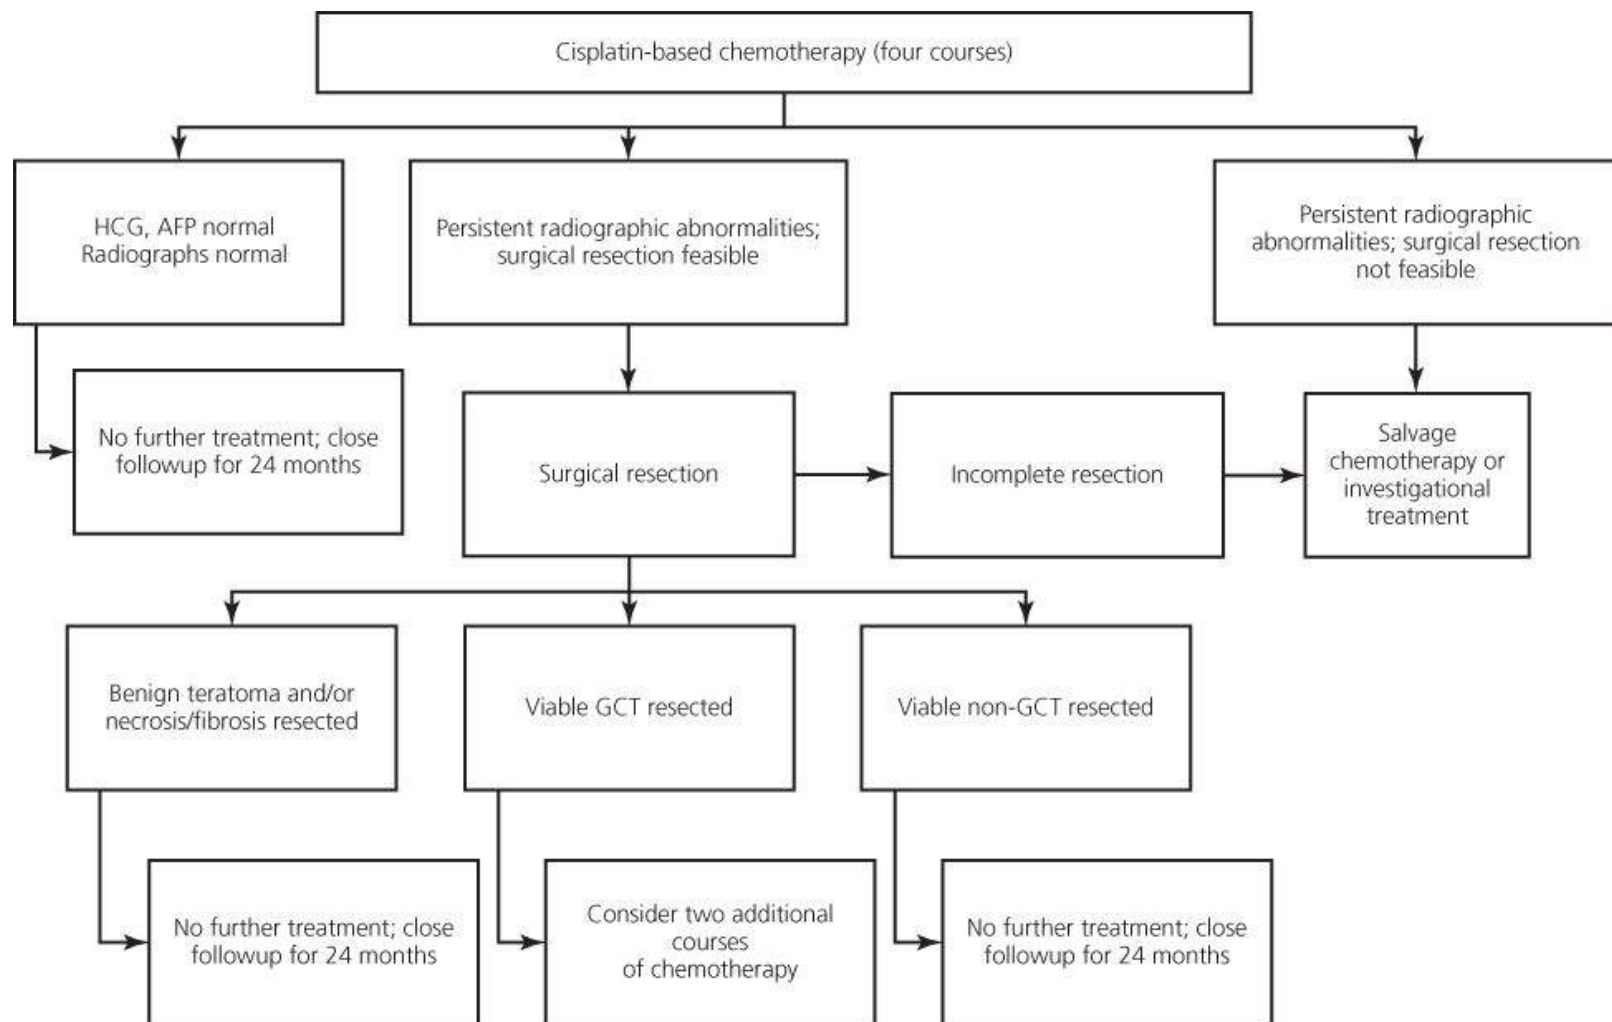

Figure 1 Management of mediastinal nonseminomatous germ cell tumors after completion of first-line chemotherapy.

Most patients have residual radiographic abnormalities in the mediastinum after completion of chemotherapy.¹⁶ In these patients, surgical resection of residual masses should be performed if technically feasible. Persistent elevation of serum tumor markers is not a contraindication to surgical resection in this setting.^{51, 52} Residual GCT is found in the resected specimen in a substantial proportion of patients (25–66%).^{53–56} A few patients have residual cancer of various nongerm cell histologies (e.g., sarcoma, adenocarcinoma, neuroendocrine carcinoma).⁵⁵ The remainder of patients have benign teratoma, necrosis, or fibrosis without active carcinoma.

Complete surgical resection is curative for a substantial proportion of patients. Patients with no tumor remaining (i.e., necrotic tumor, fibrosis, and/or benign teratoma only) have a low risk of subsequent relapse (~20%).^{53, 55} Patients with resection of residual GCT have a high risk of future relapse; however, surgical resection is curative in 20–30%.^{54, 55} In these patients, two additional courses of chemotherapy postoperatively may reduce the recurrence rate. Most patients with residual nongerm cell histologies do poorly even with complete resection, although occasional long-term survivors have been reported.⁵⁵ Further systemic treatment after resection in these patients has been ineffective.

Recurrent/progressive disease

The prognosis is poor for patients in whom complete surgical resection is not feasible and in those who relapse after surgical resection. Standard second-line cisplatin-based regimens and high-dose chemotherapy regimens are curative in 20–50% of patients with recurrent testicular cancer but are

effective in only 11% of patients with mediastinal nonseminomatous GCT.^{51, 52, 57}

Prognosis

In a large retrospective multicenter study, 287 patients treated with current multimodality therapy were reviewed.¹⁷ The complete response rate to chemotherapy was 19%; an additional 45% had normalization of tumor markers with a persistent mediastinal mass. Surgical resection of a residual mediastinal mass was required in 143 patients (50%). The 5-year progression-free and overall survival rates were 44% and 45%, respectively.

Chapter 89

Neoplasms of the esophagus

Max W. Sung, MD ■ Virginia R. Litle, MD ■ Steven J. Chmura, MD, PhD ■ Stephen G. Swisher, MD, FACS ■ David C. Rice, MB, BCh, BAO, FRCSI ■ Jaffer A. Ajani, MD ■ Ritsuko K. Komaki, MD ■ Mark K. Ferguson, MD

Overview

Esophageal cancer remains a leading cause of cancer deaths worldwide, sixth in men and ninth in women. In the past quarter century, esophageal cancer has changed from predominantly squamous-cell carcinoma to adenocarcinoma, but only in North America and Europe. The concurrent increase in cancers of the gastroesophageal junction has led to its currently inclusion in the AJCC TNM (tumor, node, metastasis) staging of esophageal cancer. Treatment options have expanded to include endoscopic mucosal resection for early-stage disease and neoadjuvant chemoradiation followed by surgery for intermediate stage disease. Surgical techniques have also evolved to include less invasive approaches using thoracoscopy and laparoscopy. Advances in systemic chemotherapy have also been reported, with the inclusion of hormonal and targeted therapies, for esophageal adenocarcinomas. A lethal disease when diagnosed in advanced stage, continued progress in therapeutic interventions can be anticipated with early-stage detection in high-risk patients, and the incorporation of molecular strategies in the treatment of advanced stage disease.

Historical perspectives

Esophageal cancer was recognized as early as the twelfth century, and pathologic descriptions were produced in the sixteenth and seventeenth centuries.¹ Initial attempts to treat the tumor included resection of a cervical esophageal cancer in 1877 and an intrathoracic cancer in 1913.^{2, 3} Surgical resection became the mainstay of therapy beginning in the 1940s. Radiotherapy was initially used in the 1920s, but it was not until the development of megavoltage techniques in the 1950s that this modality was used with any frequency. Active chemotherapeutic agents were first identified in the 1960s and have been increasingly incorporated into the treatment of advanced tumors.

Anatomy and histology

The esophagus is a muscular organ that extends from the cricopharyngeus muscle at its cephalad margin to the esophagogastric junction (EGJ). It is divided into regions on the basis of both anatomy and the proclivity for certain neoplasms to develop in specific regions ([Figure 1](#)). The cervical esophagus extends from the cricopharyngeus muscle to the thoracic inlet (15–18 cm from incisors). The upper third of the thoracic esophagus extends from the thoracic inlet to the tracheal bifurcation, just below the level of the aortic arch (18–24 cm). The middle thoracic esophagus extends from the tracheal bifurcation to a point midway between the carina and the EGJ (24–32 cm). The lower thoracic esophagus extends from this midway point to the EGJ (32–40 cm). Tumors of the EGJ and gastric cardia are often included in discussions of esophageal cancer because of their pathophysiologic similarities to adenocarcinomas of

the distal esophagus.⁴ Classifications of EGJ tumors have developed that define the different types of tumors according to the epicenter of the mass (i.e., type I, >1 cm above EGJ; type II, 1 cm above to 2 cm below EGJ; type III, >2–5 cm below EGJ).⁵

Figure 1 The distribution of malignant neoplasms of the esophagus according to cell type and site of occurrence.

The muscle tissues of the esophagus are arranged in an outer longitudinal layer and an inner circular layer. The proximal one-third to one-half of the muscularis propria is derived from the bronchial arches, making it principally skeletal (striated) muscle and giving it the potential to develop rhabdomyosarcomas ([Table 1](#)). The remainder of the esophageal musculature comprises smooth muscle, as does the rest of the foregut, in which leiomyomas or leiomyosarcomas may occur. Fibrous, fatty, and connective tissues interspersed in the wall of the esophagus may also give rise to sarcomas.

The esophagus is lined over most of its length with squamous epithelium, which can give rise to squamous-cell carcinoma (SCC) and is the most common neoplasm of the esophagus in most of the world. These cancers occur most often in the cervical esophagus and in the upper and middle thoracic esophagus. Carcinosarcomas and spindle cell carcinomas, which are subtypes of squamous-cell cancer, infrequently occur in these regions. The distal 2–3 cm of the esophagus and the cardia is lined by columnar epithelium, in which adenocarcinomas may occur.⁵ The development of intestinal metaplasia, known as Barrett esophagus, more proximally because of gastroesophageal reflux and other factors allows the development of adenocarcinomas in the middle and upper thoracic esophagus in isolated instances. Other cellular elements in the mucosa, submucosal glands, and muscularis propria may give rise to unusual neoplasms, such as small cell cancer, malignant melanoma, granular cell tumors, mucoepidermoid carcinoma, and adenoid cystic carcinoma.^{6, 7} The histologic types of benign and malignant tumors of the esophagus are given in [Table 1](#).

Etiology

In most of the world, dietary and nutritional factors are the most common etiologic agents and are associated with the development of predominantly SCCs. Among the most frequently cited carcinogens are nitrosamines, which have been found to be in high concentrations in foods in endemic areas of esophageal cancer in northern China.⁸ Contamination of food by fungi that reduce nitrate to nitrite may

further aggravate this situation. Mechanical factors that have been cited include drinking beverages at excessively high temperatures and consumption of foods containing silica or other substances, such as crushed seeds, that directly irritate the esophagus.^{8,9} Deficiencies of folic acid, vitamins A and C, and riboflavin, molybdenum, and selenium also have been implicated in the development of esophageal neoplasms.^{10,11,12a} Higher intake of fruits and vegetables, on the other hand, has been reported in a meta-analysis of observational studies to be associated with a reduced risk of esophageal SCC.^{12b}

In the western hemisphere, social factors figure more prominently in the development of esophageal cancer. Heavy alcohol consumption increases the risk of cancer 10–25 times, depending on the concentration of alcohol in the beverage.¹³ Cigarette smoking has been linked to the development of both squamous-cell cancers and adenocarcinomas.¹⁴ The combined exposure to low levels of tobacco and alcohol increases the risk of esophageal cancer by a factor of 10–20, whereas the synergistic effect of exposure to high levels of both alcohol and tobacco increases the risk by a factor of over 100.¹⁵ Chronic esophageal injury due to gastroesophageal reflux has also been shown to be a risk factor for the development of adenocarcinoma, with severe, longstanding reflux symptoms increasing the risk of cancer by a factor of 40.¹⁶ Chronic gastroesophageal reflux is believed to be etiologically related to the development of Barrett esophagus, which occurs primarily in white males and is associated with a 40-fold increase in the risk of adenocarcinoma of the esophagus.¹⁷ A relationship between reflux and the development of squamous-cell cancers has also been suggested in patients who consume a diet high in linoleic acid.¹⁸ The lifetime risk of squamous-cell cancer of the esophagus is 5–10% in patients with esophageal achalasia, a 15-fold increase in incidence that is likely due to chronic irritation from retained food.^{19–21}

Race and gender are associated with varying incidences of cancer of the esophagus in the western hemisphere. Men are more commonly affected than are women, blacks develop squamous-cell cancers more often than do whites, and white males develop adenocarcinomas more often than do females or individuals of other race groups.²² However, none of these increased frequencies have yet been linked to genetic factors, and most have been explained by variations in socioeconomic status and the attendant social habits described earlier. The single proven genetic abnormality that is associated with a 25% lifetime incidence of squamous-cell cancer of the esophagus is tylosis A, the late-onset, familial form of palmar, and plantar hyperkeratosis.²³ A number of genetic alterations are associated with neoplasms of the esophagus, including allelic losses at chromosomes 3p, 5q, 9p, 9q, 13q, 17p, 17q, and 18q. Abnormalities of TP53, Rb, cyclin D1, and c-myc have also been associated with esophageal cancer development.²⁴

Infectious agents, including human papillomavirus (HPV), have been implicated in the development of neoplasms of the esophagus. Transforming proteins from high-risk HPV subtypes 16, 18 cause loss of function of the tumor suppressor genes TP53 and Rb, resulting in abnormal proliferative states.²⁵ HPV has been documented in up to 50% of patients with squamous-cell cancers of the esophagus and appears to be more common in areas in which esophageal cancer is endemic.²⁶ These findings have not been universally reproducible, however.^{27a} A systematic review and meta-analysis of 66 case–control studies suggests an association between HPV infection and esophageal SCC.^{27b} There are significant variation and lack of consistency between studies; the International Agency for Research on Cancer (IARC) has concluded that the epidemiologic evidence of the association is inadequate.^{27c}

Epidemiology

The most common esophageal neoplasm worldwide is SCC (90%); in the United States and Europe, the incidence of adenocarcinoma has been rising and has surpassed SCC ([Figure 2](#)). The incidence of esophageal cancer varies more worldwide than any other cancer. In the United States, the incidence of esophageal cancer is approximately seven cases per 100,000 people, whereas in high-risk areas in China, Iran, and Russia, it can be more than 100 per 100,000 people.^{27d} In rural Linxian, China, esophageal cancer is the leading cause of death.^{29, 30a} These geographical variations imply a strong role for local environmental carcinogens in esophageal carcinogenesis. The long-term survival rate for patients with esophageal cancer, regardless of histology, is less than 10%, which is due, in large part, to the advanced stage at which these cancers are detected. Worldwide, the incidence and mortality for esophageal cancer are estimated to be 455,800 and 400,200, respectively, for 2012.^{30b} For the United States, incidence and mortality for 2015 (excluding EGJ tumors) were estimated at 16,890 and 15,590, respectively.³¹ The age-adjusted mortality rate from esophageal cancer in the United States has increased by 11% between 1975 and 2012.³²

Figure 2 The proportion of adenocarcinoma and distal esophageal tumors has increased over time. *Abbreviations:* Adeno, adenocarcinoma and squam, squamous-cell carcinoma.

Source: Hofsetter 2002.^{28a} Reproduced with permission of Wolters Kluwer.

Besides geographical differences, there are other important differences that have been described in the Western hemisphere. Esophageal carcinoma is more common in men than in women regardless of the histologic subtype, and squamous-cell cancers tend to occur more frequently in blacks than in whites. In addition, there has been a striking increase in the incidence of adenocarcinoma in the United States and Europe, whereas SCC has remained stable.³³ Adenocarcinoma of the distal esophagus and cardia has risen by more than 350% among white males since the mid-1970s, increasing at a more rapid rate than any other solid tumor ([Figure 2](#)).^{22, 34-38} The reasons for these dramatic changes in the Western hemisphere are not clear but may include increased Barrett esophagus, gastroesophageal reflux, obesity, and over-the-counter medications as well as changing smoking and alcohol use.¹⁶ In other areas of the world (outside Europe and North America), SCC of the esophagus predominates and adenocarcinoma has not increased.

Patients usually present because of complaints of dysphagia, which requires either the involvement of the

entire circumference of the esophagus by the neoplasm or the growth of a large, polypoid obstructing mass. Dysphagia first develops in response to dense solid foods and progresses to result in difficulties with soft foods and then liquids. Accompanying vomiting and regurgitation are common. Symptoms of heartburn or gastroesophageal reflux (40%) are often associated and occur more frequently in patients with adenocarcinoma.³⁹ The most common symptom in the absence of dysphagia is pain (25% of cases).³⁹ It may be related to swallowing (odynophagia) or local extension of the tumor into adjacent structures such as the vertebral bodies, pleura, or mediastinum. In some instances, it may be due to bony metastases from systemic spread. Weight loss is noted in more than 70% of patients and is due to the inability to swallow or systemic manifestations of the disease.³⁹ Patients with weight loss have a significantly worse prognosis in many series.^{40, 41}

The histology of the tumor depends in large part on its location. Adenocarcinoma is located predominantly in the lower esophagus, whereas SCC predominates in the cervical, upper, and middle esophagus ([Figures 1](#) and [2](#)). Unfortunately, because of the distensible nature of the esophagus, these symptoms often do not occur until the tumors are quite large and no longer localized to the esophagus.

In contrast to patients who present because of symptoms of dysphagia, a smaller subset of earlier stage adenocarcinoma patients are increasingly being identified in North America and Europe with endoscopic abnormalities noted during endoscopic surveillance for gastroesophageal reflux symptoms or Barrett's esophagus. These patients tend to present with smaller, earlier stage tumors that are more likely to be localized and amenable to treatment. In addition, in some areas of China where squamous-cell cancer is endemic, routine cytologic screening is performed, and if results are diagnostic or suspicious, follow-up endoscopy is performed. These mass screening efforts have led to early diagnosis in many areas of China, with 5-year survivals of more than 90%.^{30a} The low incidence of esophageal cancer in most areas of the world, however, makes this type of mass screening impractical and cost ineffective from a public health standpoint.

Treatment overview

Patients who present with suspected esophageal cancer, because of either the above-mentioned symptoms or mass screening efforts, initially require pathologic confirmation of malignancy (see section titled “Diagnosis”). Once the pathologic diagnosis has been obtained, patients are assessed for therapy by determining the clinical stage (see the section titled “Staging Evaluation”) of the tumor and the physiologic status of the patient (see section titled “Pretreatment Assessment”). With this information, an informed decision about treatment can be made that optimizes the chance to cure or palliate the disease while minimizing the treatment-related morbidity (see section titled “Therapy”) ([Figure 3](#)).

Treatment algorithm for esophageal cancer

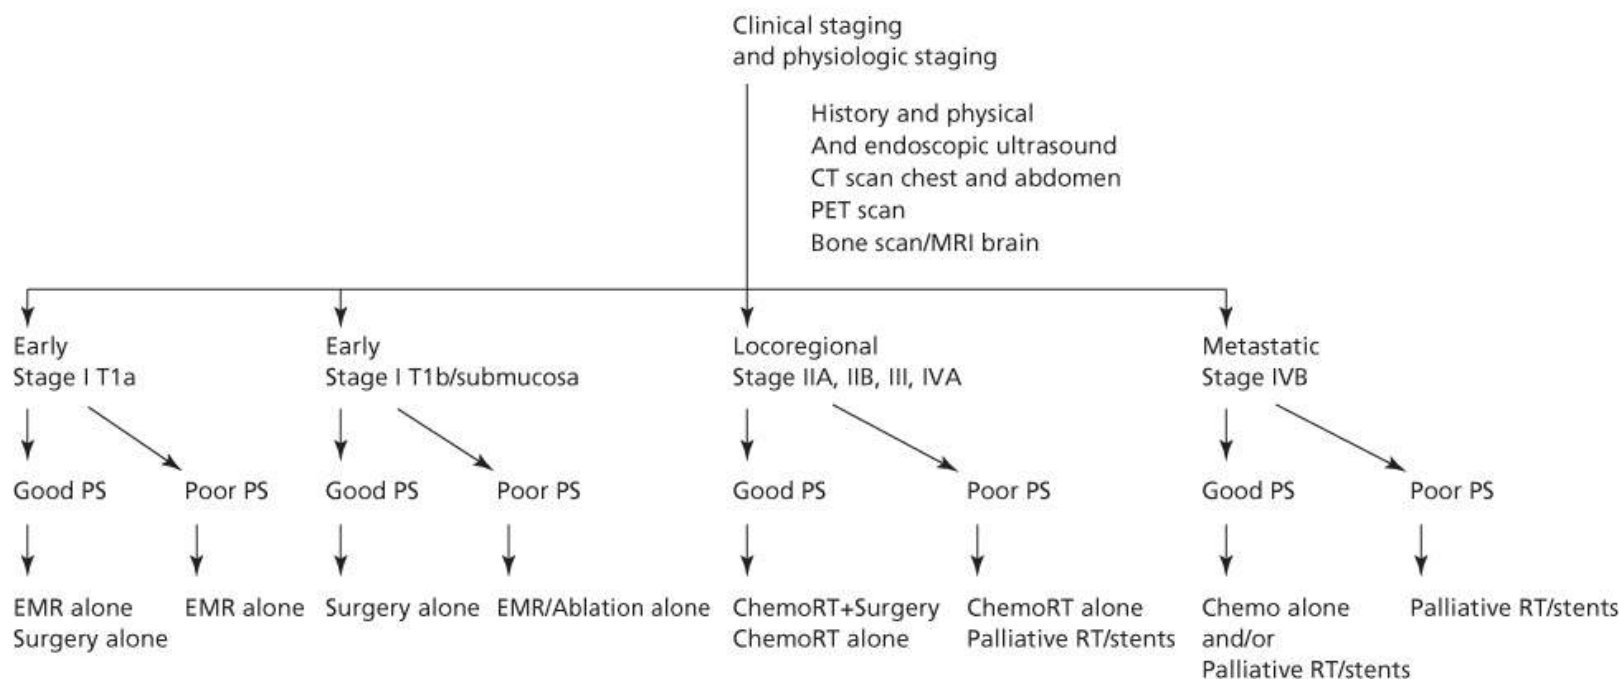

Figure 3 Current treatment recommendations for esophageal cancer based on performance status and clinical stage. *Abbreviations:* Chemo, chemotherapy; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography; PS, performance status; and RT, radiotherapy.

Diagnosis

Symptomatic patients or patients in whom an esophageal mass is diagnosed by screening require endoscopy to enable biopsy for histologic examination and/or brushing for cytologic examination. The overall accuracy of histologic diagnosis of esophageal cancer using flexible endoscopy with biopsy is about 80%.^{42, 43} Endoscopically directed cytologic brushings have a diagnostic accuracy in excess of 90%. Combining these techniques yields an overall diagnostic accuracy of 98%.⁴² If flexible endoscopic diagnostic techniques fail, rigid endoscopy with biopsy, which has a diagnostic accuracy close to 100%, should be considered.⁴³ In selected patients who have symptoms or findings on physical examination suggestive of metastatic disease, biopsy of the suspected metastatic site provides both a tissue diagnosis and a confirmation of stage.

Pretreatment assessment

In addition to a careful history and physical examination, the overall assessment of a patient with esophageal cancer focuses on specific concerns. Factors that are associated with treatment-related morbidity and mortality include patient age, a recent history of alcohol or tobacco abuse, body weight, recent weight loss, nutritional status, performance status, hepatic dysfunction, and renal dysfunction. Specific preoperative risk factors have been identified for esophageal resection and are therefore included in the physiologic assessment. Pulmonary complications are predicted by age, preoperative arterial oxygen tension, abnormal chest radiograph, and forced expiratory volume in one second (FEV₁).⁴⁴ Operative mortality is predicted by age, mid-arm circumference, history of smoking, incentive spirometry, performance status, and the frequency with which the operation is performed in an institution.^{44, 45} Any symptoms of cardiac disease necessitate careful evaluation with electrocardiography (ECG), echocardiography, stress tests, and coronary arteriography as indicated. Patients with significant coronary

artery disease are at increased risk of morbidity and mortality. Cardiac intervention may be warranted before surgical treatment. These physiologic assessments allow patients to be classified as good or poor performance status, which then allows the aggressiveness of treatment to be tailored to their specific risks ([Figure 3](#)).

Staging evaluation

Assessment of stage permits medical practitioners to discuss the status of individual patients with accuracy, allows informed recommendations about therapy, and gives patients and their families necessary information about prognosis. The typical assessment for most patients often includes upper gastrointestinal endoscopy, contrast radiography of the esophagus, computed tomography (CT) of the chest and abdomen, endoscopic ultrasonography (EUS), and positron emission tomography (PET). Other examinations are selected on the basis of specific findings in individual patients, such as neurologic symptoms (magnetic resonance imaging [MRI] of brain), musculoskeletal symptoms (bone scan), or supraclavicular nodes (neck ultrasonography and biopsy). Staging techniques allow patients to be accurately placed into groups in which risk can be assessed as well as the optimum type of therapy selected.

Presentation

Contrast radiography of the esophagus

A contrast study of the esophagus is often the initial diagnostic examination obtained in patients with dysphagia. It allows confirmation of mucosal irregularity and serves as guide for subsequent endoscopy. It also allows evaluation of the esophagus and stomach distal to an area of stenosis, which cannot also be assessed by endoscopy if tight strictures exist.

Endoscopy

Upper gastrointestinal endoscopy allows a pathologic diagnosis to be obtained in the majority of patients. The gross appearance of the tumor can be categorized as advanced or superficial, and the extent of the tumor can be accurately determined. Additional unsuspected malignancies that may be present in up to 20% of patients with squamous-cell cancer may also be identified. Endoscopy also permits assessment of the mobility of a tumor, indicating whether it is fixed within the mediastinum.

Endoscopic ultrasonography

EUS improves the staging accuracy of primary tumors and regional and some nonregional lymph nodes. It has become an essential tool to help identify patients with early-stage carcinoma who may not need multimodality treatment ([Figure 3](#)). EUS depicts the normal esophagus as five alternating hyperechoic and hypoechoic layers representing the mucosa and lamina propria, muscularis mucosa, submucosa, muscularis propria, and adventitia. Depth of tumor invasion is determined by assessing the level to which the tumor extends. EUS is also useful for assessing whether there is involvement of the aorta, but airway invasion is not accurately determined because of interference of the ultrasound signal with the intratracheal air column. The accuracy of EUS determination of primary tumor stage is related to the pathologic tumor stage, being more accurate for more advanced stages of disease, with an overall accuracy of about 80%.^{46–48} EUS is substantially less accurate in staging primary tumors after chemoradiotherapy is administered, primarily because of overstaging. The technique is not able to

distinguish between treatment-induced fibrosis and residual tumor, leading to a mean overall accuracy in this setting of 45%.^{49a,b}

In assessing lymph nodes with EUS, three criteria are used: size, border characteristics, and internal architecture. Lymph nodes that are enlarged, have a well-defined external border, and are characterized by relatively uniform, hypoechoic internal architecture are more likely to be malignant. Using these criteria, the overall accuracy of lymph node staging by EUS is about 75%.^{47, 50} After chemoradiotherapy, the accuracy of EUS for staging lymph nodes decreases to just over 50%.^{49a} Development of fine needle aspiration techniques has allowed pathologic confirmation of enlarged lymph nodes in both regional and nonregional sites.^{48–51}

CT of the chest and abdomen

CT has become a standard technique for esophageal cancer staging since its inception in the late 1970s because it has allowed better identification of patients with metastatic (M1b) and locally invasive tumors (T4). CT is not very accurate for determining the depth of the primary tumor (T) status, but it is helpful in identifying patients who might have direct invasion of local structures, such as the aorta or major airways, either of which precludes surgical intervention.⁴⁶ Aortic invasion is suspected when more than 25% of the aortic circumference is effaced by an esophageal cancer.

CT does not accurately determine lymph node (N) status as normal lymph nodes often vary in size according to their location in the mediastinum and abdomen, and a single size limit for nodes is not possible to establish. In addition, lymph nodes involved by metastatic spread are often not enlarged.^{52–55} The sensitivity for CT detection of involved lymph nodes is therefore poor (30–60%), and the overall accuracy of nodal detection by CT is <60%.^{56–58}

CT is most useful for detecting distant often unsuspected metastatic (M) disease. The most common sites for metastatic spread, aside from nonregional lymph nodes, are (in decreasing order of frequency) the liver, lung, peritoneum, adrenal gland, bone, and kidney. CT of the thorax and abdomen evaluates almost all these regions. Accuracy of the CT detection of liver metastases is in excess of 90%.^{52, 57, 59, 60}

Bronchoscopy

Bronchoscopy should be performed for all patients who are candidates for surgical therapy and whose tumors are adjacent to the trachea or mainstem bronchi, which typically are the mid-esophageal SCCs. This permits direct assessment of tumor invasion into the airway lumen or submucosa, which would be a contra-indication to surgical resection.

Magnetic resonance imaging

As a method for routine staging of esophageal neoplasms, MRI offers no advantages compared with CT and is therefore seldom used as it is a more difficult and expensive test to obtain. Both techniques have similar specificities, sensitivities, and overall accuracy for determining resectability with regard to direct invasion of the aorta and airway.^{53, 54, 57} Neither test provides much useful information about regional or metastatic lymph nodes, and MRI offers no improvements over CT in evaluating the liver for metastatic disease. Whether advances in MRI technology will offer improved staging capabilities remains to be seen.

Positron emission tomography

PET scanning to detect involved lymph nodes and sites of metastatic disease through increased

metabolism with 18F-fluorodeoxyglucose was introduced as an investigational staging technique for esophageal cancer in the mid-1990s. PET is most useful in helping identify patients with unsuspected metastatic disease. Given the possibility of false positive results from inflammation, biopsies are still required to definitively confirm metastatic disease in PET positive patients. The PET scan often serves as a guide to help identify suspected areas of metastatic disease for confirmatory biopsy. Another potential role for PET may be in determining response to chemotherapy and radiation therapy although false positives induced by chemotherapy and radiation-induced inflammation remain a problem.^{61–63} PET may also have a role in identifying recurrent esophageal cancer by allowing targeting of unsuspected areas of increased metabolic activity.⁶⁴

Bone scintigraphy

Bone scans have been used for decades for staging patients with esophageal neoplasms; however, PET-CT scan has essentially replaced bone scans in the work-up of esophageal cancer. In patients without bone pain or other evidence for metastatic disease, the overall likelihood of identifying skeletal metastases is <5%.⁶⁵

Neck ultrasonography

Cervical and supraclavicular lymph nodes are affected by metastatic spread in up to 30% of patients with neoplasms of the thoracic esophagus, and most are not detectable on physical examination. The use of routine ultrasound examination of the neck in patients without palpable lymph nodes yields unsuspected nodal metastases in over 10% of patients.⁶⁶ The overall accuracy of cervical and supraclavicular nodal assessment with ultrasonography is about 90%.⁶⁷, 68a The addition of routine needle aspiration under ultrasound guidance for cytology may improve the yield of this potentially valuable technique.^{68a} At the present time, however, this is not a commonly used screening technique and is reserved for cases where nodes are palpable to confirm metastatic disease

Minimally invasive surgical staging

Laparoscopy has been used since the early 1980s, and thoracoscopy has been used since the early 1990s in an effort to improve staging of esophageal neoplasms. Video-assisted thoracoscopic surgery (VATS) staging was studied in a CALGB study in 1995 and was found to be feasible and 88% accurate.^{68b,c} With the current standard and accurate staging modalities of PET-CT and EUS, surgical staging is not routinely done except in conjunction with placement of a laparoscopic jejunostomy tube for nutritional support before chemoradiation therapy.

Biologic staging

A variety of biologic markers have been investigated for their utility in estimating prognosis in patients with esophageal neoplasms. These include growth factors (epidermal growth factor [EGF], transforming growth factor [TGF]- β , platelet-derived growth factor [PDGF]), oncogenes (*c-myc*, *int-2*, *hst-1*, *cyclin D*, *EGFR*, *HER-2/neu*, *h-ras*), tumor suppressor genes (*Rb*, *TP53*, *p73*, *APC*, *MCC*, *p27*), the cell adhesion molecule E-cadherin, the oncodevelopmental marker CEA, and deoxyribonucleic acid (DNA) content and ploidy.^{69–71} To date, none of these techniques have become generally accepted staging techniques except in isolated referral centers.

TNM (tumor, node, metastasis) staging system

These pretreatment staging evaluations allow patients to be clinically staged by a cTNM (tumor, node,

metastasis) staging system that can help determine the optimum therapy ([Figure 3](#)). The current staging system for esophageal cancer includes epithelial tumors of the cervical, thoracic, and intra-abdominal esophagus, as well as the EGJ ([Table 2](#)).^{72a,b} Tumors are staged according to clinical findings from noninvasive tests and pathologic findings resulting from any invasive staging procedures. It is useful to specify lymph node locations during biopsy and resection because their location determines whether they are considered regional nodes or nonregional metastatic nodal disease ([Figure 4](#)). The prognosis of patients with esophageal cancer is determined by the depth of penetration of the primary tumor (transmural vs nontransmural), whether there is lymph node involvement, the relative number of lymph nodes involved, and whether distant metastases are present.^{28, 72, 74–87} Nonanatomic classifications have been added, including histopathologic cell type (adenocarcinoma, SCC), histology grade (G1-4), and cancer location. The long-term survival in patients with esophageal neoplasms correlates well with the pathologic stage and histopathologic cell type ([Figure 5](#)).^{74, 80} The ability of the clinical cTNM staging system to accurately predict the pTNM status has improved with time as the use of endoscopic ultrasound, CT of the chest and abdomen, and PET scan has increased.^{28a}

[Table 2](#) TNM staging system for esophageal neoplasms

Primary tumor (T)	
TX	Primary tumor cannot be assessed
TO	No evidence of primary tumor
Tis	High-grade dysplasia

Therapy

Standard curative treatment options for esophageal cancer include surgical resection, external beam radiotherapy, chemotherapy, or combinations of two or three of these options. The selection of appropriate therapy is often challenging because few comparisons of these options have been performed in prospective, randomized manner. In addition, these trials have often been performed over a long time period with an inadequate number of patients during which significant changes in histology and types of treatment have occurred (i.e., different radiation equipment, dosages and fields, and different surgical techniques and chemotherapy agents). Clinical staging techniques have also evolved over time, leading to stage migration and poor correlation with pathologic stage, especially from studies before CT scan, endoscopic ultrasound, and PET.^{28a} These problems make comparisons between different trials or treatment arms difficult. Treatment strategies have therefore evolved over time based on regional experiences and biases. In an effort, to guide current treatment strategies, we have included an esophageal treatment algorithm that incorporates different treatment strategies based on the physiologic status and clinical stage of the patient (Figure 3). This algorithm reflects the treatment biases of the authors and is meant only to give some guidance in an otherwise confusing therapeutic arena.

In esophageal cancer, local control of the disease, as well as cure, are the primary objectives of therapy because of the debilitating effects of dysphagia caused by progressive tumor growth and esophageal obstruction. Early-stage cancers (stage 0, I) traditionally have been treated by resection in good performance patients and by radiotherapy with or without radiation-sensitizing chemotherapy in patients who cannot tolerate surgery. Recently, newer less invasive modes of treatment include endoscopic mucosal resection (EMR) and other ablative therapies. Most patients, however, present with locoregionally advanced esophageal cancer because of the long period of asymptomatic tumor growth.

These patients (stages II, III, and IVa) tend to have poor outcomes when treated with a single modality such as surgery or radiation therapy because of the development of metastatic and locoregional recurrences. Attempts have therefore focused on treating these patients with multimodality approaches combining locoregional (surgery/radiation) therapies with systemic (chemotherapy) treatments. Although controversial, many oncologists in North America currently recommend treating these patients with definitive chemoradiation alone or preoperative chemoradiation and surgery. The data to unequivocally support these approaches are lacking as demonstrated in the often conflicting randomized trial results ([Table 3](#)). Some centers have argued that more aggressive en bloc resection and three-field lymphadenectomies are also important. Surgery and chemotherapy are often avoided in poor performance status locoregionally advanced patients because of treatment-related morbidity. In these patients, locoregional palliation can often be achieved with palliative stents and/or radiation. For patients who are initially recognized to be in advanced (metastatic) stages of disease, chemotherapy with or without palliative radiotherapy has been the mainstay of treatment. The development of endoesophageal stents has provided additional locoregional palliation and has limited the need for palliative surgical bypass even in patients with tracheoesophageal fistulas ([Figure 3](#)).

Surgery

Esophagectomy remains the mainstay of treatment for locally or regionally advanced neoplasms of the esophagus. The major paradigm shift in the past 10–15 years has been management of superficial (clinical T1aN0) esophageal carcinomas in which EMR is used to stage and treat these intramucosal lesions. Even in more contemporary series mortality rates after esophagectomy can reach as high as 7% for early cancers , thus, a movement toward a less invasive approach for treatment of high-grade dysplasia and early esophageal cancer began almost 20 years ago.^{28b} In the largest early series, Christian Ell and colleagues published their results of 61 patients with early carcinoma treated with EMR and after a mean 12-month follow-up. Eighty-six percentage of patients were still free of disease.^{28c} Since then, numerous groups have concluded that EMR and ablation of the preneoplastic field of Barrett's esophagus are the standard of care for treatment of early cancers with eradication and 5-year survival rates reaching 80–90%.^{28d,e}

Surgery however remains an integral element in multimodality therapy for regionally advanced cancers because patients who undergo preoperative (neoadjuvant) therapy have a 75% incidence of residual local disease amenable to resection, although this remains controversial as some oncologists argue that surgery should be reserved only for patients who relapse with locoregional disease. This idea of a salvage esophagectomy reserving resection only for those with recurrent disease after definitive chemoradiation therapy has been gaining traction but is associated with higher leak rates, conduit failures, lengths of stay, and 30-day mortality as compared with resection after neoadjuvant therapy. Indications for salvage esophagectomy continue to evolve as nonoperative therapies are refined.^{28f}

Approaches to resection

Surgical approaches to resection include a transthoracic operation, mobilization of the esophagus via a transhiatal route, and thoracoscopic/laparoscopic resection ([Table 4](#); [Figure 6](#)).

Table 4 Operative approaches to resection for esophageal cancer

Transthoracic
<ul style="list-style-type: none">• Ivor Lewis (laparotomy, right thoracotomy, high intrathoracic anastomosis)• McKeown modification of Ivor Lewis (cervical anastomosis)• Left thoracotomy with intrathoracic anastomosis• Left thoracotomy with cervical anastomosis• Thoracoabdominal incision
Transhiatal
Minimally invasive
<ul style="list-style-type: none">• Thoroscopically assisted• Laparoscopically assisted• Thoroscopic/laparoscopic

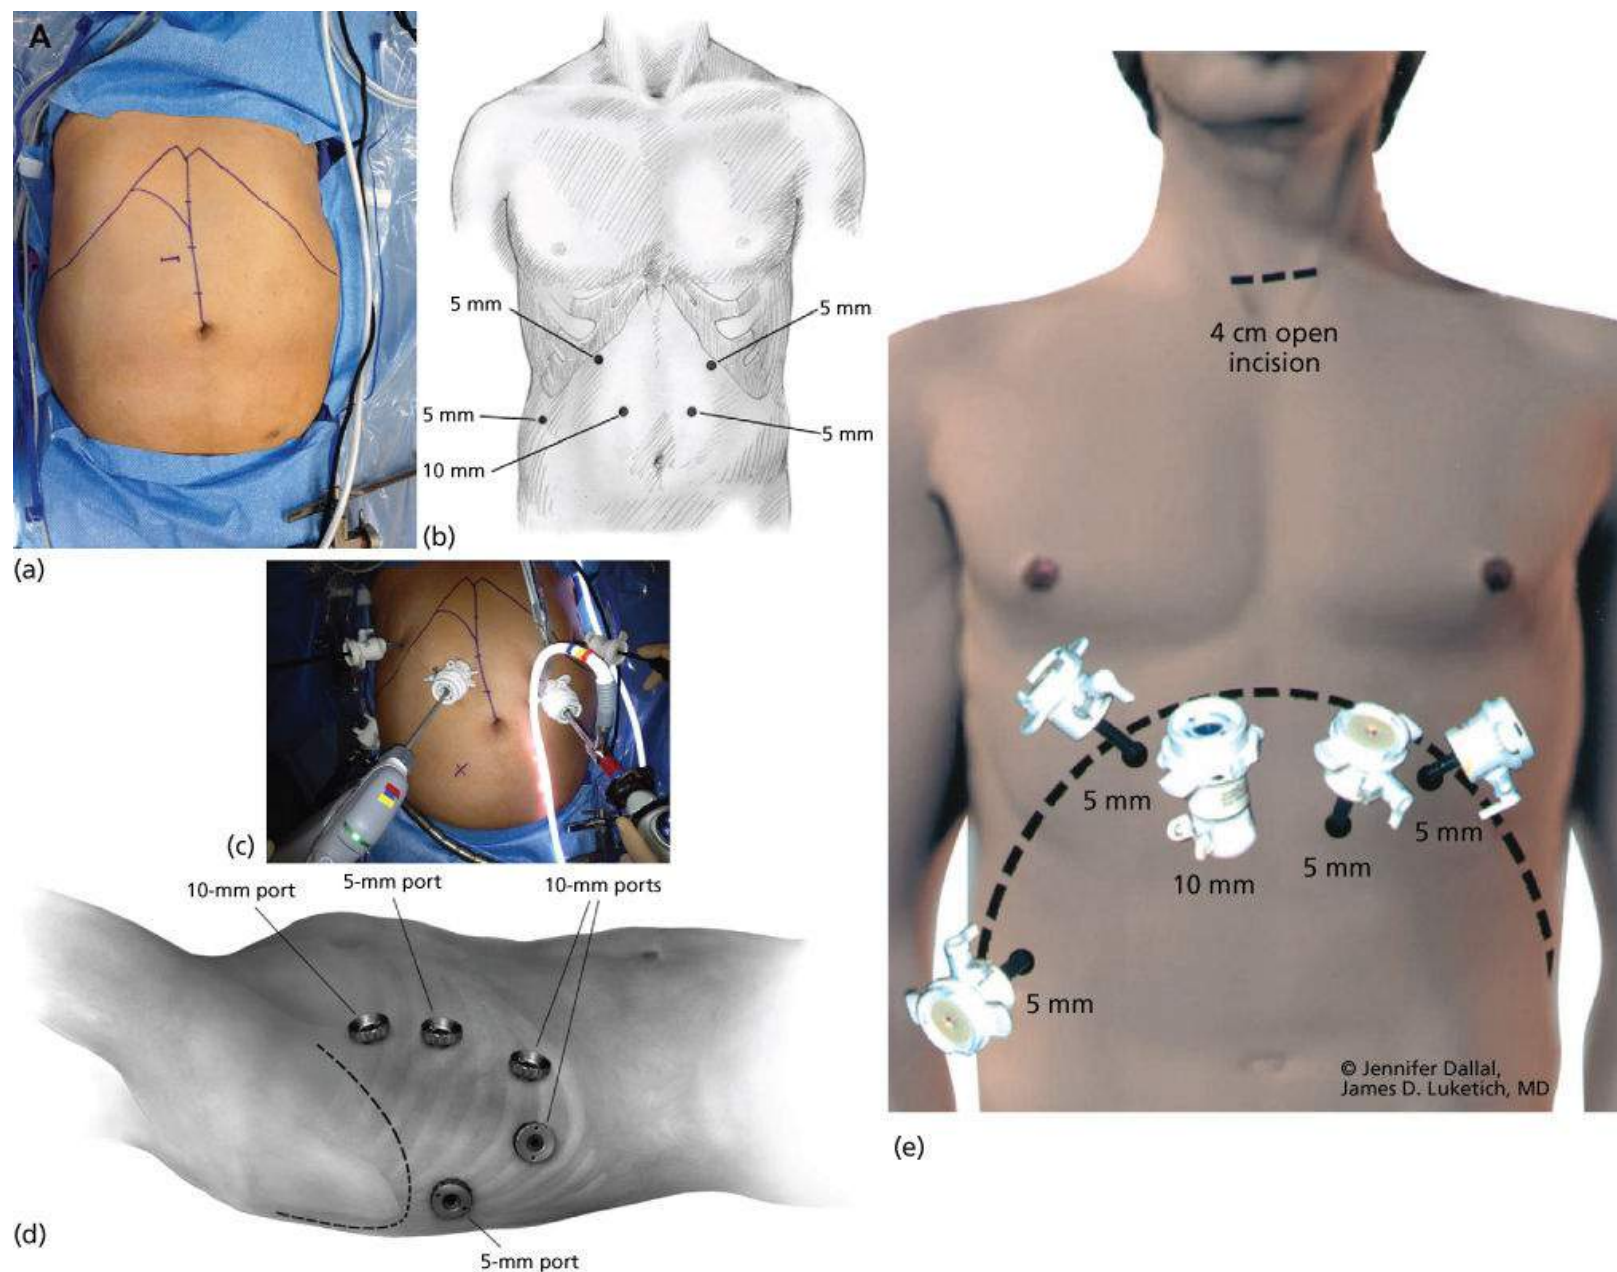

Figure 6 Approaches for esophagectomy. (a) Right thoracotomy and laparotomy with intrathoracic (Ivor Lewis operation) or cervical anastomosis (McKeown modification of Ivor Lewis esophagectomy). (b) Left thoracotomy, accessing the abdomen through a peripheral incision in the diaphragm, with intrathoracic or cervical anastomosis. (c) Transhiatal esophagectomy with cervical anastomosis. (d) Thoracoscopic esophagectomy: Port placement (MIE Ivor Lewis). (e) Laparoscopic esophagectomy: Port placement.

Transthoracic approaches provide the ability to perform a more complete dissection of the primary tumor and lymph nodes than is possible using a transhiatal approach. The transhiatal approach allows the operation to be done more quickly with fewer incisions and avoidance of a thoracic component thus minimizing postoperative pulmonary complications. In the mid-1990s, as laparoscopic approaches were advancing for benign disease, a minimally invasive approach was introduced for oncologic procedures as well. The laparoscopic transhiatal approach was reported as a technically feasible procedure for nine patients in the late 1990s.^{28g} This was followed by advances in total thoracoscopic and laparoscopic approaches first as being feasible, then as associated with shorter length of stay and mortality rates less than 2%.^{28h} Additional studies demonstrated morbidity rates dropping from 60% to 44% with a significant reduction in pulmonary complications as compared with the open approaches.²⁸ⁱ The minimally invasive esophagectomy (MIE) has evolved from a three-hole-modified McKeown to the Ivor

Lewis approach with an intrathoracic component. The benefit of this evolution was avoidance of recurrent laryngeal nerve injury and reduction in anastomotic leak rates.

The question of oncologic soundness with an MIE has been substantiated with longer follow-up. With the goal of retrieving more than 20 lymph nodes to adequately stage a patient with the current AJCC staging system, the median number of nodes is not diminished by a minimally invasive approach.^{28i,j} Three-year survival rates after MIE now approach 60% in experienced hands as reported in the intergroup study of 95 patients with locoregional recurrence rates as low as 7%.^{28k}

The selection of an operative approach is dependent, in part, on tumor location and surgeon preference. Squamous-cell cancers are most often located in the middle and upper thoracic esophagus and are approached with open or minimally invasive transthoracic approaches with cervical anastomosis. In contrast, adenocarcinomas, which most often arise in the distal esophagus or cardia, are easily amenable to transthoracic and transhiatal approaches. Squamous-cell cancers are multifocal in nearly 20% of patients, and near-total esophagectomy is recommended to minimize the risk of performing an incomplete resection.⁸¹ This usually necessitates a cervical anastomosis for reconstruction. In contrast, adenocarcinomas usually are not multifocal but tend to spread submucosally. When negative proximal and distal margins are obtained on frozen section at the time of operation, the extent of the esophageal resection is theoretically satisfactory.

Results from 44 published reports of transthoracic or transhiatal esophagectomy for cancer demonstrate a higher incidence of anastomotic complications in the latter group, but otherwise no important differences in operative morbidity or mortality and similar 5-year survival rates.^{83–87,98a} Currently, the choice of the open versus minimally invasive approach to esophageal resection depends largely on the training, experience, and personal preference of the surgeon. The robot-assisted thoracoscopic esophagectomy (RATE or RAMIE) is also performed by a few surgical groups with varying reports of improved length of stay, overall morbidity, and number of nodes harvested compared with other approaches.^{98b,c} The future of this approach may well remain within the realm of a small number of centers with dedicated robotic teams.

Effects of preoperative therapy

The use of preoperative therapy before surgery has the potential of increasing perioperative morbidity and mortality. One prospective randomized study reported that septic complications, respiratory complications, and operative mortality were higher in patients who underwent preoperative chemotherapy compared with surgery alone.⁹⁹ However, several other studies assessing neoadjuvant chemotherapy or chemoradiotherapy have shown no important differences in postoperative complications or operative mortality.^{40, 100–104} The complexity of esophageal surgery mandates that the procedure be performed at a high-volume referral center to minimize operative morbidity and mortality.⁴⁵ Medicare data suggest that high-volume centers can perform esophageal resections with a mortality of 3%, whereas less experienced centers have a mortality of 19%.⁴⁵ This morbidity and mortality may be even further increased when preoperative therapy is used. At less experienced centers, the morbidity and mortality of the procedure may be greater than the potential benefit, especially when considering the low likelihood of cure in locoregionally advanced patients.

Surgery for cervical esophageal cancer

Neoplasms of the cervical esophagus pose special problems with regard to surgical therapy. To obtain adequate surgical margins in tumors that extend to the cricopharyngeus muscle or invade the proximal

trachea, it is necessary to include a laryngectomy as part of the resection, which adds substantial long-term morbidity to what is often a palliative not curative procedure. As a result, a higher percentage of patients with cervical esophageal cancer are treated nonsurgically than is the case for patients with cancers in other locations. Resection could provide good palliation for dysphagia but does not substantially influence long-term survival, and the morbidity has led most people to recommend chemoradiation in this subset of patients.^{105–108}

Reconstruction after esophagectomy

Reestablishing alimentary tract continuity after esophageal resection in a manner that permits ingestion of a normal diet is an important component of surgery for esophageal cancer. Options for reconstruction include using the stomach as a substitute or interposing a segment of colon or jejunum between the proximal esophageal remnant and the stomach (or duodenum after total gastrectomy). The use of the stomach for reconstruction is by far the most common technique because the stomach has the most reliable blood supply among any of the reconstructive options and because only a single anastomosis is required, compared with the three anastomoses necessary for bowel interposition. Cervical anastomoses are favored by some surgeons because they decrease the incidence of acid reflux into the esophageal remnant and because anastomotic leaks are usually easily managed by simple cervical drainage. The disadvantages of cervical anastomoses are a higher incidence of recurrent laryngeal nerve injury and more frequent anastomotic leaks. Whether the additional tumor-free proximal margin provided by a cervical anastomosis offers a survival advantage has not been proven.¹⁰⁹ Use of the posterior mediastinum (esophageal bed) for reconstruction optimizes emptying of the reconstructive organ but may predispose to tumor infiltration if a complete resection is not performed.¹¹⁰

Radiation therapy

Radiotherapy has been used for decades in the management of neoplasms of the esophagus and as with surgery targets the locoregional tumor rather than the systemic disease. The primary roles of radiotherapy, as with surgery, are as a potentially curative single modality for localized disease and as a palliative therapy for advanced tumors. Results of both uses have been disappointing because of a lack of complete response of the primary tumor and the development of radiation-induced strictures that limit its palliative benefits. More recently, the use of radiation has expanded to include an important adjuvant role in multimodality therapy to further improve the locoregional control obtained with surgery alone.

Treatment is planned to uniformly irradiate gross tumor and margins suspected of harboring microscopic disease, while minimizing injury to adjacent normal tissues, such as the lung, heart, and spinal cord. Regional nodal basins are usually included, typically cervical and supraclavicular nodes for cervical cancers, supraclavicular, and subcarinal lymph nodes for upper thoracic cancers, and celiac axis nodes for lower thoracic and cardiac cancers. Initial treatment is to opposed, anterior–posterior and posterior–anterior fields using high-energy (6–24 MV) photons. In patients receiving potentially curative high-dose therapy, the final treatments are delivered at an oblique angle to minimize the total dose to the spinal cord. Daily treatments of 1.8–2 Gy to a total of 60–70 Gy were formerly used for curative intent, although this has been modified as recent trials have demonstrated equal efficacy and less toxicity with the lower dose (50.4 Gy).⁹⁴ Palliative doses tend to be even lower to further reduce this morbidity (30–40 Gy).

Radiation as single modality therapy

The use of radiation therapy as a single modality for esophageal cancer is sometimes indicated as a potentially curative therapy in patients who are unable to tolerate (or who refuse) resection or combined

definitive chemoradiotherapy. Radiation therapy alone achieves 5-year survival rates of 0–20% in patients without distant metastatic disease, with the majority of survival rates being less than 10%. Although low, these survival rates may be biased by patient selection as good performance status patients are usually treated with surgery while radiation is often reserved for the poor performance status group. Treatment of unresectable but localized esophageal cancer with radiotherapy yields results similar to those reported for potentially resectable cancers, with survival rates at 5 years of less than 10%.^{88–93, 111, 112} One small randomized study has demonstrated increased survival with surgery alone versus radiation therapy alone, although the authors focused more on endpoints of quality of life.¹¹³

Radiotherapy as an adjuvant to resection

In an effort to obtain better local control of disease, radiotherapy has been used both preoperatively and postoperatively as an adjunct to resection ([Table 5](#)).^{114–116, 118, 122} The interval between completion of radiotherapy and resection is typically 3–5 weeks (1 week/10 Gy), which is felt to minimize perioperative complications from bleeding and radiation-induced fibrosis. In the proper setting, postoperative complication and mortality rates are not increased by the administration of preoperative radiotherapy, although this may be contingent on performing the surgical procedure in a high-volume center.⁴⁵ Most randomized, controlled studies have not demonstrated a survival advantage compared with surgery alone although these studies were often performed with outdated radiation therapy techniques.^{114–116, 118, 122} Meta-analysis of the combined data from all randomized studies that have been published do not demonstrate improved survival with preoperative radiotherapy.¹²³

The use of radiotherapy postoperatively enables the administration of higher radiation doses than are feasible with preoperative radiotherapy although this treatment has been associated with increases in the incidence of anastomotic strictures and prolonged recovery from surgery, adversely affecting the quality of life.^{117, 120, 121} There is also some evidence that median survival is worse in patients who undergo postoperative radiotherapy, compared with resection only, as a result of an earlier appearance of distant metastatic disease and because of irradiation-induced deaths, although selection bias may also play a role.¹²⁰ Postoperative irradiation appears to decrease the local recurrence rate but overall has no proven influence on long-term survival.

Intraluminal brachytherapy has been added in some centers to curative or palliative external beam radiotherapy in an effort to improve local control of disease. Doses of 10–20 Gy are administered after completion of external beam treatment in one or more fractions using Iridium-192. In patients with potentially curable disease, the addition of intraluminal brachytherapy appears to enhance locoregional control, compared with external beam radiotherapy alone, but is associated with a higher incidence of radiation-induced esophageal strictures.^{119, 124, 125} Reducing the dose per fraction of intraluminal brachytherapy may in the future limit the incidence and severity of these local complications.¹²⁶ The use

of brachytherapy in patients with unresectable or recurrent esophageal cancer is still under investigation but may provide better symptomatic relief than other modalities, such as gastric bypass surgery, chemotherapy, laser therapy, and stenting.^{127–129}

Systemic therapy

A discussion of systemic chemotherapy for esophageal cancer must take into account the changing epidemiology of esophageal cancer in the past 50 years.

In the 1970s, when chemotherapy drugs were beginning to be tested in clinical trials, esophageal cancer was predominantly SCC histology and localized mostly in the upper two-thirds of the esophagus. Chemotherapy agents found to be effective were therefore not surprisingly ones that were also active for head and neck SCC.

In the past two decades, in the United States and other developed countries in the West, esophageal cancer has shifted to primarily adenocarcinoma histology and localized mainly in the distal third of the esophagus, the EGJ extending into the gastric cardia. Chemotherapy regimens tested to be effective are also active against gastric adenocarcinoma, which also led to the development of targeted therapy against the Her-2-neu receptor (trastuzumab) and the vascular endothelial growth receptor (bevacizumab, ramucirumab). SCC still remains the predominant histology for esophageal cancer in non-Western countries, including those in the esophageal cancer belt in central Asia, and in Africa and Southeast Asia.

Single-agent chemotherapy

Previous phase II trials have identified a number of chemotherapy drugs with 15–30% response rates when administered as single agent for esophageal cancer. These drugs included cisplatin, mitomycin, 5-FU, paclitaxel and vindesine.^{130a} The responses were unfortunately short lived and did not lead to any meaningful prolongation of survival.

Multiagent chemotherapy

Combination of agents, which has been shown to have activity against esophageal cancer as single agents, has yielded response rates of up to 50% ([Figure 3](#)). The combination of bleomycin–vindesine–cisplatin has been reported with response rates of 53% and a median duration of response of 7 months.

A more commonly used and better-tolerated combination regimen is 5FU–cisplatin, which in a randomized phase II study versus cisplatin alone was shown to have superior response rates (35% vs 19%) but median survival remained similar (33 weeks vs 28 weeks).

The addition of paclitaxel to the 5FU–cisplatin backbone in a phase II trial has been reported with response rates of 48% with a median duration of response of 5.7 months and median survival of 10.8 months. It was further noted that response rates were comparable for SCC (50%) and adenocarcinoma (46%).^{130b}

The paclitaxel–cisplatin combination without 5FU has also been found to be active for both SCC and adenocarcinoma in a phase II trial with response rates of 40% with clinical benefit (relief of dysphagia, weight gain) achieved in 70% of patients.^{130c} The combination of paclitaxel–carboplatin in a phase II trial showed response rates of 43%, median duration of response 2.8 months, and median survival 9 months. One-year survival was 43%. The combination was well tolerated with no treatment-related deaths.^{130d}

Epirubicin–cisplatin–5FU (ECF) has been previously shown to be an active regimen for gastric

adenocarcinoma. Its activity in esophagogastric cancer (SCC/adenocarcinoma) was demonstrated in a phase III trial versus mitomycin–cisplatin–5FU with reported similar efficacy (response rates of 44.1% vs 42.4%, median survival of 9.4 months vs 8.7 months).^{130e} The substitution of cisplatin and 5FU with oxaliplatin and oral capecitabine (EOX) was evaluated in a phase III trial (REAL-2) in 964 evaluable patients in a two-by-two design showed improved overall survival in the EOX group as compared to the ECF group, while progression-free survival and response rates were similar between the two groups.^{130f}

The combination of irinotecan–cisplatin in a weekly regimen has been reported in a phase II trial to be active in esophageal cancer with response rates of 57%, median duration of response 4.2 months, and median actuarial survival 14.6 months. Similar response rates were observed for adenocarcinoma (52%) and SCC (66%).^{130g}

Targeted Therapy

Trastuzumab, a monoclonal antibody directed against the Her-2-neu receptor, has been tested in the phase III ToGA trial of 5FU/capecitabine–cisplatin with and without trastuzumab.^{130h} Patients with gastric or esophagogastric adenocarcinoma were eligible if their tumors were positive for positive Her-2-neu expression by IHC (1 to 3+) or FISH. Response rates were higher with trastuzumab (47% vs 35%) as was median survival (13.8 months vs 11.1 months). Further studies showed that trastuzumab was most effective for IHC 3+ tumors.

Ramucirumab, a monoclonal antibody that inhibits the VEGF-2 receptor, has been tested in the phase III REGARD trial versus placebo in previously treated gastric or esophagogastric adenocarcinoma.¹³⁰ⁱ The study showed in favor of ramucirumab with median progression-free survival was 2.1 month versus 1.3 month, overall survival 5.2 month versus 3.8 months, response rates 8% versus 3%. Disease control rates (responses plus stable disease) were 49% for ramucirumab versus 23% for the placebo group. A survival benefit was seen for the combination of ramucirumab in combination with paclitaxel in the phase III RAINBOW trial versus paclitaxel plus placebo in previously treated metastatic gastric or esophagogastric adenocarcinoma.^{130j} The ramucirumab–paclitaxel combination was superior in median overall survival (9.6 months vs 7.4 months), progression-free survival (4.4 months vs 2.9 months), and response rates (28% vs 16%).

Bevacizumab, a monoclonal antibody directed against soluble VEGF, has been tested in combination with capecitabine–cisplatin in the phase III AVAGAST trial versus placebo plus capecitabine–cisplatin in patients with previously untreated gastric or esophagogastric adenocarcinoma. Although response rates and median progression-free survival were higher in the bevacizumab group (46% vs 37%, 6.7 months vs 5.3 months), no significant survival benefit was demonstrated (12.1 months vs 10.1 months).^{130k}

Similarly, no survival benefit could be demonstrated in phase III trials of adding an anti-EGFR agent to chemotherapy in patients with gastric or esophagogastric adenocarcinoma. The phase III EXPAND trial of capecitabine–cisplatin with and without cetuximab showed median progression-free survival of 4.4 months versus 5.6 months for the control arm.^{130l} In the phase III REAL3 trial, patients with esophagogastric adenocarcinoma were randomized to epirubicin–oxaliplatin–capecitabine with or without panitumumab.^{130m} Median overall survival in an interim analysis was 8.8 months versus 11.3 months in favor of the control arm, and the study was halted.

Combined modality therapy

In locoregionally advanced esophageal cancer, combination chemotherapy has been investigated in

combination with radiation or surgery to try to reduce the high rate of systemic relapse noted when surgery or radiation therapy alone is used. Attempts to use chemotherapy with surgery have included preoperative and postoperative strategies usually with cisplatin-based multiagent regimens. The randomized trials with preoperative chemotherapy usually consist of two or three chemotherapy cycles followed by resection. Some studies have also added postoperative chemotherapy to the regimen. There is no apparent difference in response to chemotherapy based on histology. There is no clear increase in perioperative complications noted with preoperative chemotherapy when the surgery is performed at an experienced center. As [Table 6](#) demonstrates, recent randomized trials have demonstrated a survival benefit with preoperative chemotherapy especially when larger number of patients are randomized.^{41, 101, 104, 105, 123, 131–133, 135} The reasons for the failure of the majority of trials may be due in part to the small numbers of patient in each study. Meta-analyses have suggested with larger number of patients that there is a significant benefit to preoperative chemotherapy especially in patients with adenocarcinoma.¹³⁶

Postoperative chemotherapy (cisplatin, 5-FU) for patients after esophagectomy has not demonstrated to date a survival advantage compared with surgery alone and has been associated with increased treatment-related complications ([Table 7](#)).¹³⁷ Even in meta-analyses, there has not been a clear benefit demonstrated with postoperative chemotherapy.¹⁴³

Definitive chemoradiotherapy with selective surgery has also been evaluated as a strategy to improve survival in locoregionally advanced esophageal cancer. These studies have used both sequential and concurrent treatment strategies. The concurrent use of chemotherapy and radiotherapy is theoretically appealing because, in addition to the systemic effects of chemotherapy, certain agents behave as radiosensitizers. Randomized studies with a concurrent strategy demonstrate an advantage to combined treatment versus radiation therapy alone (Table 4).^{88, 90–92, 95, 111–113} Definitive chemoradiotherapy strategies with surgery used only as salvage appear most effective in SCC and less effective in adenocarcinoma where long-term survival is lower.¹⁰⁵ Two trials have been performed in Europe randomizing SCC patients to definitive chemoradiation or preoperative chemoradiotherapy and surgery.^{95,96a} These studies demonstrated similar survivals between groups and suggest that definitive

chemoradiation may be an acceptable strategy for SCC of the upper and middle esophagus. The optimum dose for definitive chemoradiotherapy is currently 50.4 Gy as suggested by a randomized trial in which increased doses of radiation were associated with increased treatment-related mortality without a survival advantage.⁹⁴ Interestingly, the higher dose had no impact on local failure or continued persistent disease. Both arms of the trial report roughly 50% local failure after 24 months of cumulative follow-up.

Preoperative chemoradiotherapy has also been investigated in locoregionally advanced esophageal cancer as a strategy in an attempt to reduce both the high locoregional and systemic relapse rate noted with surgery alone or preoperative chemotherapy and surgery. The theoretical advantages to preoperative as opposed to postoperative chemoradiation therapy include (1) the ability to control subclinical systemic metastases before the immune suppression that results from surgery; (2) downstaging locoregional disease to increase the likelihood of a complete resection at surgery; and (3) the ability to administer full doses of chemoradiation that would not be possible to administer postoperatively because of perioperative debility. As [Table 7](#) demonstrates, the results are not consistent, although sequential chemoradiation does not appear to be beneficial.^{95, 137–141} There have been several trials that have been encouraging for concurrent preoperative chemoradiation in locoregionally advanced esophageal cancer especially in adenocarcinoma, but statistical significance has not been achieved in all trials. Meta analyses with larger numbers of patients have suggested that preoperative chemoradiation and preoperative chemotherapy have survival advantages compared with other strategies, although these studies are limited by different preclinical staging techniques and heterogenous patient populations ([Figure 7](#)).¹³⁶ A survival benefit for combined therapy is evident in most studies in patients who are found to have a complete pathologic response in the surgical specimen and have provided strong incentives to continue the investigations of this strategy. In addition, as surgery alone or radiation therapy alone has such poor outcomes, many oncologists currently use definitive chemoradiotherapy alone or preoperative chemoradiation and surgery for nonmetastatic, locoregionally advanced esophageal cancer ([Figure 3](#)). Two randomized trials from Europe have been reported comparing definitive chemoradiation versus preoperative chemoradiation and surgery in SCC.^{95,96a} Preliminary results demonstrated improved locoregional control with surgery but no survival advantages. Although operative mortality was higher than expected, these trials suggest that definitive chemoradiation may be an acceptable strategy in SCC of the upper and middle esophagus especially in institutions where trimodality treatment-related mortality is high.^{95,96a} The impact of neoadjuvant chemoradiotherapy on pathologic complete response and overall survival has been debated owing to lack of a survival benefit in most randomized trials. Most of these trials have been criticized for the poor design and lack of power to detect an overall survival benefit. A recent and updated meta-analysis of 12 surgery ± neoadjuvant chemoradiotherapy encompassing 1854 patients demonstrated that the hazard ratio for all-cause mortality was improved for neoadjuvant chemoradiotherapy (0.78, 95% CI 0.70–0.88; $p < 0.0001$). The benefit was seen for both the squamous (0.80, CI 0.68–0.93; $p = 0.004$) and adenocarcinoma (0.75, CI 0.59–0.95; $p = 0.02$) histologies. While increased postoperative morbidity and mortality were seen in this analysis, the impact on survival remained.

Figure 7 Improved long-term survival noted in patients undergoing preoperative chemoradiation (Preop C/RT) before surgery (surg) at the University of Texas M.D. Anderson Cancer Center ($n = 879$).

In an effort to decrease the operative mortality and maintain high rates of R0 resections, a phase II trial using paclitaxel and carboplatin with radiotherapy demonstrated low morbidity and 100% complete resection rates.^{96b} The definitive phase III trial randomizing this regimen against surgery alone in patients with clinical stage T1N1, M0 or T2-3N0-1, M0 was recently reported.^{96c} Of the 366 patients randomized, 75% were adenocarcinoma. Complete (R0) resection was obtained in 92% of the chemoradiotherapy arm versus 69% in the surgery alone arm ($p < 0.001$). Postoperative complications did not significantly differ between the arms. However, the primary endpoint of overall survival was significantly better in the chemoradiotherapy arm. With a median follow-up of 45 months, median overall survival was 49.4 months in the chemoradiotherapy arm versus 24 months in the surgery alone arm ($p = 0.003$). Overall 5-year survival was 47% versus 34%. Interestingly, the benefit in OS was maintained in both the squamous and the adenocarcinoma histologies.

On the basis of these randomized data and meta analysis, NCCN guidelines 3.2015 now recommended preoperative chemoradiation as a treatment choice for medically fit patients.

For patients with early-stage esophageal carcinoma (stage I or II), a randomized trial from Europe comparing neoadjuvant chemoradiotherapy (4500 cGY plus 5FU-cisplatin) following by surgery versus surgery alone reported interim analysis, which showed that 3-year overall survival was similar between the two groups: 47.5% versus 53.0% (HR 0.99). R0 resection rates were similar 93.8% versus 92.1% ($p = 0.749$), but postoperative mortality was higher in the neoadjuvant chemoradiotherapy group, 11.1% versus 3.4% ($p = 0.049$).^{96d}

Recommendations for therapy

As our treatment algorithm suggests ([Figure 3](#)), good performance patients with localized, early-stage disease should undergo endoscopic resection or esophagectomy depending on tumor depth, whereas poor performance patients or patients refusing surgery can be treated with definitive chemoradiation or radiation alone. Locoregionally advanced esophageal cancer patients with good performance status are seldom cured with surgery or radiation therapy alone and may therefore be candidates for investigational trials, definitive chemoradiation, or preoperative chemoradiation and surgery. Poor performance patients with locoregionally advanced esophageal cancer should be treated with chemoradiation or palliative radiation therapy and/or stents. Metastatic esophageal cancer patients who are good performance status may be offered chemotherapy alone with the addition of palliative radiation and/or stents for locoregional control. Chemotherapy should not be used if the patients have a poor performance status as the focus should be on palliation.

Palliative therapy of esophageal obstruction

In patients with advanced esophageal cancer not amenable to potentially curative therapy, a primary goal of treatment is relief of dysphagia.¹⁴⁴ This can be accomplished with palliative resection, but high operative morbidity and mortality rates as well as the prolonged period of recovery that is necessary preclude meaningful palliation and most oncologists currently recommend nonsurgical means for palliation. External beam radiotherapy, as an isolated modality or in combination with chemotherapy, is noninvasive but requires considerable time to complete and results in strictures in up to 30% of patients. Intraluminal brachytherapy is another option that is considered in some centers.^{145, 146} Photocoagulative laser therapy is another option that is usually performed with an Nd:YAG laser, with an initial improvement in dysphagia in 85% of patients and a mean duration of response of less than 1 month. PDT offers a similar initial efficacy but provides a more enduring response, although skin photosensitivity is an undesirable side effect.¹⁴⁷

The development of endoesophageal stents has offered another therapeutic option in these difficult patients. Endoesophageal stent placement has led to rapid and enduring improvement in swallowing for many patients with advanced disease who are obstructed locoregionally. The introduction of self-expanding wire mesh stents has greatly simplified stent placement and associated complications and has improved palliation of dysphagia, compared with plastic prostheses.^{148, 149} This method of palliation has provided a much less invasive mechanism to palliate these patients and has replaced surgical bypass as the primary modality to relieve dysphagia.

Malignant esophagorespiratory (tracheoesophageal) fistulas pose a special problem in patients with esophageal cancer. These patients were previously treated with surgical bypass although the high morbidity and short life expectancy of these patients were significant problems.¹⁵⁰ The introduction of coated wire mesh stents offers a better option for the treatment of such fistulas because they palliate dysphagia while occluding the fistula without requiring an extensive surgical procedure in an often debilitated and poor performance status patient.^{151, 152}

Chapter 90

Carcinoma of the stomach

Carl Schmidt, MD ■ Mariela Blum Murphy, MD ■ James C. Yao, MD ■ Christopher H. Crane, MD

Overview

Gastric cancer is the second most common cause of cancer-related death worldwide and risk factors include autoimmune gastritis, chronic *Helicobacter pylori* infection, obesity, and other causes. Some countries with higher incidence have established screening programs but methodology and eligibility remain controversial. Despite knowledge of risk factors and screening for high-risk populations, identification of earlier stage potentially curable disease remains a challenge.

Multiple genetic mutations are involved in gastric cancer pathogenesis, and mutations in the cellular adhesion protein CDH1 result in familial diffuse gastric cancer. Certain patterns of metastatic disease have been associated with particular molecular alterations. Increasing understanding of molecular pathways involved in gastric cancer has led to efficacious use of targeted biologic therapies with cytotoxic chemotherapy in the advanced setting, such as use of trastuzumab in patients with gastric cancer and *HER2/neu* overexpression.

Surgical resection is the primary potentially curative therapy in those without metastatic disease. Type of resection and extent of lymphadenectomy are not consistent, and standards for best practice are needed. Chemotherapy and radiation play an important role in the adjuvant setting and, therefore, decisions regarding choice and timing of these therapies require accurate staging by thorough evaluation with endoscopy, cross-sectional imaging and, in some cases, endoscopic ultrasound or positron emission tomography.

Palliative interventions and therapy are often important, both for patients with symptoms in the metastatic setting and after recurrence as cure is not achieved in either situation. Results of recent clinical trials are encouraging, and there have been multiple positive phase III trials in the adjuvant and metastatic setting during the past 10 years. Despite this, most people diagnosed with gastric cancer will die from it eventually, so much more research is needed.

Incidence and epidemiology

Despite a worldwide decline in gastric cancer incidence, gastric cancer remains the second most common cause of cancer-related death. Gastric cancer is particularly common in China (accounting for 42% of cases worldwide), South America, Eastern Europe, Japan, and Korea, where it is the most common malignancy.¹ The age-adjusted death rate has been on the decline in the United States over the past 30 years and was 3.8 per 100,000 in 2005.² However, this is mostly due to declining incidence; survival in patients with diagnosed gastric cancer remains poor with only modest improvements during recent years. According to the Surveillance, Epidemiology, and End Results (SEER) registry, the 5-year survival rate for gastric cancer (all stages) increased from 16.3% between 1975 and 1979 to 23% in 2000.² It should be noted these data predate the publication of major trials of multimodality therapy with positive results and widespread acceptance.

Risk factors

Environmental insults to the gastric mucosa may eventually lead to atrophic gastritis resulting in metaplasia, a precursor condition for some gastric cancers.³ Other factors associated with increased risk include low serum ferritin levels, pernicious anemia, history of distal gastrectomy for peptic ulcer disease, and endemic *H. pylori* infection.^{4–6} While some evidence is suggestive, it remains unknown whether eradicating *H. pylori* infection reduces the incidence of gastric cancer.⁷ Behavioral associations with gastric cancer have long been thought to include dietary exposure to nitrates, nitrites, and bacterial or fungal contamination of food given decreasing incidence with the advent of refrigeration.⁸ Studies have also documented increased incidence of proximal gastric cancers with obesity and a protective effect of physical activity on overall rates of gastric cancer.^{9, 10} Red meat consumption has been examined by multiple observational studies and found to be associated with increased risk of gastric cancer.^{11, 12} Some studies suggest a dose–response relationship between amount of red meat consumption and risk lending further support to this possibility. Consumption of fruit conversely may reduce the risk of gastric cancer.¹³

Familial clustering has been noted to occur in approximately 1% of gastric cancer cases. Germ line mutations account for only a small portion of these cases. Hereditary Diffuse Gastric Cancer (HDGC) syndrome results from germ line mutations of the CDH1 gene; however, CDH1 mutation accounts for only a small percentage of families with a history of diffuse gastric cancer. The CDH1 gene is involved in cellular adhesion, and defects in this gene are also associated with lobular breast cancer.¹⁴ Affected individuals with gastric cancer inherit one copy of the defective CDH1 gene. Somatic mutation, deletion, or promoter methylation inactivates the other copy. Gastric cancers follow an autosomal dominant inheritance pattern with high penetrance.

Prophylactic gastrectomy is a consideration for members of families affected by HDGC syndrome. When prophylactic gastrectomy is performed, multifocal early gastric cancers are nearly always found in the resected specimen.¹⁵ Genetic counseling is recommended in suspected cases, considering the degree of penetrance and age of onset of known cases of gastric cancer in the family and the paucity of long-term outcomes data for prophylactic gastrectomy. Worster et al.¹⁶ studied the impact of prophylactic total gastrectomy on health-related quality of life (HRQOL). In 32 patients who underwent total gastrectomy, HRQOL was compared to 28 patients at risk for HDGC who did not undergo total gastrectomy. While physical and mental function returned to baseline by 12 months after operation, some symptoms persist, specifically, loose stools (70%), fatigue (63%), discomfort when eating (81%), reflux (63%), eating restrictions (45%), and body image (44%).

Gastric polyps occur in 27–70% of individuals with FAP (familial adenomatous polyposis).^{17, 18} While fundic gastric polyps are usually thought to be hamartomas, foveolar dysplasia and invasive adenocarcinoma have been described. Hereditary non-polyposis colorectal cancer (HNPCC) is a genetic disorder characterized by germ line mutations in a group of mismatch repair genes, including *hMSH2*, *hMLH1*, *hMSH6*, *hPMS1*, and *hPMS2*. Defects in these genes result in genomic instability characterized by microsatellite instability (MSI). Although colorectal and endometrial cancers are the most common manifestations of HNPCC, gastric carcinoma has also been observed. An analysis of the Korean Hereditary Tumor Registry showed a 3.2-fold increase in the relative risk of gastric cancer in families carrying the HNPCC mutation.¹⁹ However, germ line mutation of one of the mismatch repair genes accounts for only a small percentage of gastric cancers with MSI.

- Gastric cancer is the second leading cause of cancer-related death worldwide

- Risk factors include autoimmune gastritis, *H. pylori* infection and obesity
- Germ line mutations in the *CDH1* gene are associated with hereditary gastric cancer

Pathology

Adenocarcinoma is the dominant histology in gastric cancer. The Lauren and World Health Organization (WHO) classifications are the two major systems used. The Lauren's system classifies cancer as intestinal, diffuse, or mixed.²⁰ The simplicity of this system has resulted in widespread use. Intestinal-type gastric cancer is also called epidemic-type gastric cancer. It features a retained glandular structure and cellular polarity. Grossly, it usually has a sharp margin. It arises from the gastric mucosa and is associated with chronic gastritis, gastric atrophy, and intestinal metaplasia. The diffuse-type histology is associated with an invasive growth pattern. Scattered clusters of uniform-sized malignant cells frequently infiltrate the submucosa with little glandular formation and mucin production is common ([Figure 1](#)).

Figure 1 Photograph of histologic sections from intestinal (a) and diffuse (b) type gastric cancers.

Studies of gastrectomy specimens obtained from patients without clinical disease have shown early diffuse-type gastric cancer arising below normal-appearing epithelium.¹⁵ Tumor cells in this type appear to arise from the superficial layer of the lamina propria. An infiltrative growth pattern in diffuse-type gastric cancer often results in the absence of a mass. The cancer may be difficult to identify using endoscopy, but thickened gastric folds and a difficult to distend stomach are hallmarks of diffuse gastric cancer. Malignant cells can infiltrate well beyond the apparent tumor margin. In advanced cases, this leads to the condition known as linitis plastica (leather-bottle-like stomach) characterized by involvement of the entire stomach, rapid progression, resistance to therapy, and poor prognosis.

Pathogenesis and natural history

Molecular alterations

Multiple molecular alterations are important in the pathogenesis of gastric cancer ([Table 1](#)). Epigenetic phenomena include hypermethylation of promoter regions for many genes including *CDH1*, *hMLH1*, and *p16*, which may be involved in early carcinogenesis.^{21–27} Further, MSI caused by mutations in DNA repair genes has been reported in up to 39% of gastric cancers.²⁸ Tumor suppressor genes such as *p53*,

APC, MCC, and DCC are also mutated in gastric cancer, and the incidence often varies with histology and stage.^{29–31}

Table 1 Molecular markers with clinicopathological correlations

Marker	Involvement	Dominant histology	Clinical correlation
<i>Epigenetic</i>			
Hypermethylation	Common	Both	—
MSI	31–39%	Intestinal	Conflicting for survival, favorable or no difference
<i>Tumor suppressor</i>			
p53	47–74%	Both (intestinal early event and diffuse late event)	Correlates with stage in diffuse-type cancer
APC	8–34%	Intestinal	—
MCC	24–33%	Diffuse	—
DCC	12–49%	Intestinal	—
FHIT	49–67%	—	Correlates with stage, conflicting for survival
<i>Adhesion</i>			
CDH1	54–83%	Diffuse	—
α-Catenin	83–92%	Diffuse	—
γ-Catenin	91–100%	Diffuse	—
β-Catenin	—	Intestinal (GSK3β region)	Poor survival
CD44	31–72%	CD44v6-intestinal	CD44v6 in intestinal-type cancer correlates with inferior survival
<i>Tyrosine kinases</i>			
EGFR	35–81%	Both	Correlates with stage, conflicting for survival
HER2/neu	10–38%	Intestinal	Poor survival
PDGF α	42–45%	Both	Correlates with stage and poor survival
c-Met	34–71%	Diffuse	Correlates with stage and peritoneal metastasis
<i>Angiogenesis</i>			
VEGF	—	Intestinal	Correlates with hepatic metastasis
bFGF	—	Intestinal	Increased recurrence

Loss of normal cellular adhesion is an important feature of human cancer development and prevalent in genetic alterations of gastric cancer. Diffuse-type gastric cancer is characterized by aberrant cellular adhesion with a pattern of infiltrative growth by a small cluster of or sometimes single tumor cells. The cadherin–catenin complex at the cell surface plays a critical role in cell adhesion and polarity, and up to 90% of gastric cancer cases have an abnormality in at least one component of the complex including

CDH1 and α - and γ -catenin.^{32, 33} The *CD44* transmembrane glycoprotein, expressed in 31–72% of gastric cancers, may modulate invasion and metastasis.³⁴

Similar to other adenocarcinomas, alterations in cellular signaling pathways occur in gastric cancer and provide potential targets for biologic therapies. *HER2/neu*, an oncogene in the *erbB* family of membrane receptor tyrosine kinases, is overexpressed in 10–38% of gastric cancer cases and is associated with intestinal-type distal cancer and worse prognosis.^{30, 35} Expression of other cellular receptors in gastric cancer correlates with oncogenic behavior, such as associations between the transmembrane receptor *EGFR* (epidermal growth factor receptor) with invasion and *c-Met* with peritoneal metastasis.³⁶ Angiogenesis appears essential for growth of gastric cancer and other solid tumors, and increased angiogenesis in gastric tumor specimens portends an unfavorable prognosis.³⁷ Vascular endothelial growth factor (*VEGF*) and basic fibroblast growth factor (*bFGF*) are major regulators of angiogenesis, have prognostic value, and are potential targets for antiangiogenic therapy in patients with gastric cancer.^{38, 39} Expression of multiple transcription factors by gastric cancer cells, such as *Sp1* and *mTOR*, promotes abnormal cell growth, survival, and angiogenesis.^{40, 41}

Progression and patterns of metastasis

Gastric cancers metastasize in several ways. Adjacent organs such as the liver, diaphragm, pancreas, spleen, and colon (or its mesentery) may become involved by direct extension. Gastric cancers have a high tendency to spread through the lymphatic system to regional and distant nodes. Hematogenous metastatic disease is often found in the liver. Peritoneal metastatic disease is also common in the metastatic setting and may result in abdominal pain, bowel obstruction, cachexia, or all three. Japanese investigators have noted that histology and patient age may affect the pattern of spread of gastric cancer. In an autopsy study of 173 cases of gastric cancer, they found diffuse histology to be associated with peritoneal metastasis and intestinal histology to be associated with hepatic metastasis.⁴² They also found peritoneal metastasis to be more common in younger patients. In another study, case records of 216 patients with synchronous peritoneal or hepatic metastasis found at surgical exploration more commonly had poorly differentiated histology associated with peritoneal metastases and well to moderately differentiated histology associated with hepatic metastases.⁴³

On a molecular level, expression of *VEGF* and its receptor *KDR* has been associated with liver metastasis.^{37, 44} Expression of *VEGF-C*, which can cause neogenesis of lymphatic vessels, is associated with lymph node metastasis.^{45, 46} In addition, dysregulation of cellular adhesion is likely central to the development of peritoneal metastasis. *CD44H* has been linked with increased gastric cancer cell adhesion to mesothelial cells and increased peritoneal metastasis in animal models.⁴⁷ *C-met* amplification has also been linked with peritoneal metastasis.^{36, 48} Further translational research of the molecular biology of metastasis may improve our ability to predict sites of failure and refine therapeutic strategies.

- Molecular alterations of many genes and cellular pathways are involved in the pathogenesis of gastric cancer including modifications in methylation of promoters, MSI, cellular adhesion, growth factors, and angiogenesis
- Metastatic involvement of regional lymph nodes is very common
- Peritoneal surfaces and liver are other common sites of metastasis

Screening

Large-scale screening programs have been established in several countries with a high incidence of gastric cancer, including Japan, Korea, Venezuela, and Chile. Available screening tests include, among others, upper gastrointestinal endoscopy and radiologic studies using oral contrast agents such as barium. The method for most efficacious screening remains controversial, and there is no uniformity in terms of recommended age, interval, or type of screening exam. Comparisons between screening methods by large controlled trials are lacking. Screening of asymptomatic people in countries with lower risk of gastric cancer, such as the United States, is not feasible or cost-effective.

Importantly, symptoms of gastric cancer are often nonspecific, leading to diagnosis at an advanced stage. This is caused in large part because both the stomach and abdominal cavity are large and distensible. Early symptoms, such as vague discomfort, episodic nausea/vomiting, or anorexia are common in patients without cancer. Thus, physicians may not attribute such symptoms to gastric cancer for many months. In fact, patients may undergo several months of therapy for presumptive peptic ulcer disease before a diagnosis of gastric cancer. As such, more research is needed to develop better methods of early detection even in countries with lower incidence.

Diagnosis

Common symptoms of gastric cancer at diagnosis include abdominal pain and weight loss. Although anemia is also a frequent finding, overt upper gastrointestinal bleeding is much less common. Dysphagia may occur predominantly in patients with proximal cancer, whereas nausea and vomiting are more common in patients with nonproximal cancer. Early satiety can be especially prominent in patients with linitis plastica. Abnormal physical examination findings often indicate advanced disease, such as a palpable epigastric mass that may indicate a large locally advanced tumor. Jaundice usually indicates hepatic metastasis or metastatic lymphadenopathy in the portal region.

There are several aspects of appropriate clinical staging of gastric cancer that should be performed in a stepwise manner. Potentially helpful laboratory studies include a complete blood count, electrolytes, blood urea nitrogen, creatinine, alkaline phosphatase, transaminases, and bilirubin. Evaluation of tumor markers CEA, CA19-9, and CA125 may be considered. At the time of referral to surgeon or oncologist, upper endoscopy has typically been performed and made the diagnosis. Endoscopic findings should be reviewed by the primary treating surgeon with regard to tumor size and location, especially for gastroesophageal junction (GEJ) tumors as some may be more appropriately treated like distal esophageal cancers. Computed tomography (CT) scan of the chest, abdomen, and pelvis is performed to provide further information about the primary tumor and detect evidence for malignant lymphadenopathy or metastatic disease including carcinomatosis. The finding of even a small amount of ascites may indicate peritoneal disease.

Endoscopic ultrasound (EUS) is accurate for assessing T stage and enables needle biopsy of suspicious perigastric nodes and even some left liver masses. EUS may not always be needed when CT scan findings are suggestive of advanced cancer. EUS should be considered for patients entering neoadjuvant therapy trials and for assessment of small masses amenable to endoscopic mucosal resection (EMR) or early-stage cancers for which operation without neoadjuvant therapy is considered. The role of positron emission tomography (PET) for gastric cancer is evolving; there is some evidence PET can be used to evaluate response to therapy.⁴⁹ Laparoscopy is controversial but considered essential by many for complete staging of gastric cancers. Laparoscopy results in upstaging in one-fifth to one-fourth of patients,

primarily through detection of peritoneal metastases not seen on CT scans.^{50–52}

TNM stage classification

[Table 2](#) displays a portion of the current staging system for gastric cancer from the American Joint Committee on Cancer Staging Manual, seventh edition (Springer, New York 2010). This table applies to patients without metastatic disease (M1). In the current staging system, stages I to III are defined by various combinations of T (tumor) and N (nodal) stage without metastatic disease; prior versions of the system classified some patients with extensive nodal disease as stage IV. In the current system, stage IV disease is defined only by the presence of distant metastatic disease.

[Table 2](#) AJCC stage grouping for gastric cancer without distant metastatic disease

T stage	Nodal stage			
	N0	N1	N2	N3
Tis	0			
T1a/b	IA	IB	IIA	IIB
T2	IB	IIA	IIB	IIIA
T3	IIA	IIB	IIIA	IIIB
T4a	IIB	IIIA	IIIB	IIIC
T4b	IIIB	IIIB	IIIC	IIIC

The following definitions are used to classify T and N stage:

- Tis—[intraepithelial tumor with no invasion into lamina propria](#)
 - T1a—[tumor invades lamina propria or muscularis mucosae](#)
 - T1b—[tumor invades submucosa](#)
 - T2—[tumor invades muscularis propria](#)
 - T3—[tumor penetrates subserosal connective tissue without serosal invasion](#)
 - T4a—[tumor invades serosa](#)
 - T4b—[tumor invades adjacent organ or structure](#)
 - N1—[regional nodal metastases, 1–2 nodes](#)
 - N2—[regional nodal metastases, 3–6 nodes](#)
 - N3a—[regional nodal metastases, 7–15 nodes](#)
 - N3b—[regional nodal metastases, 16 or more nodes](#)
- [Early gastric cancer may be detected by screening in countries with such programs](#)
 - [Possible symptoms of gastric cancer include abdominal pain, bleeding, dysphagia, nausea, anorexia, weight loss, and early satiety](#)
 - [Clinical staging is based on upper endoscopy and cross-sectional imaging of the chest, abdomen, and pelvis \(typically CT scan\)](#)

- Other potentially useful staging studies include laparoscopy, EUS and PET

Multidisciplinary care

For patients with small tumors and low histologic grade, EMR is gaining acceptance as the primary method for local therapy. Such therapy is predicated on these tumors having a very low incidence of node-positive disease.⁵³ The incidence of nodal positivity with T1 tumors is approximately 10%, and other features of the primary tumor delineate patients with even lower risk. Tumors confined to the mucosa have a 1–3% incidence of nodal positivity versus a tumor with submucosal invasion with an incidence of up to 15%.⁵⁴ Other factors that increase the incidence of nodal disease include poor differentiation, signet-ring cells, lymphatic invasion, and tumor size >2 cm.⁵⁵ It is reasonable, therefore, to consider EMR for patients with small, well-differentiated T1 tumors confined to the mucosa. However, specialists at some high-volume centers have proposed expanded criteria for use of newer techniques using endoscopic submucosal dissection.⁵⁶ Removal of larger even ulcerated masses has been done. In our opinion, this more aggressive approach requires careful histological evaluation of the resected specimen and confirmation of T1a (mucosal) disease.

Surgery

The choice of operation for gastric cancer depends on tumor location, histological type, and disease stage. Gastrectomy is the most widely used approach for invasive gastric cancer, and the most common techniques are total gastrectomy, distal subtotal, and proximal subtotal gastrectomy. Segmental resection is less commonly used for invasive gastric cancer but is very common and appropriate for other gastric malignancies such as gastrointestinal stromal tumors. Prospective and randomized studies reveal no survival advantage of total gastrectomy for tumors of the distal stomach compared to distal subtotal gastrectomy when all disease is removed with adequate margins. Both techniques are associated with similar rates of mortality (1–3%), complications, and 5-year survival (around 60%).^{57, 58} In most series, the quality of life after subtotal gastrectomy is superior to that after total gastrectomy.^{59, 60}

Tumors of the proximal stomach and GEJ generally require more complex considerations for resection and reconstruction. Siewert's classification is very useful and commonly used to describe GEJ tumors.^{61, 62}

- Type I: adenocarcinoma of the distal esophagus, which usually arises in Barrett's esophagus and may infiltrate the GE junction from above
- Type II: true carcinoma of the cardia arising immediately at the GEJ within 1 cm above and 2 cm below the junction
- Type III: subcardial gastric carcinoma infiltrating the junction and distal esophagus from below

In patients with an advanced tumor involving the GEJ, the site of origin (esophagus or stomach) may be unclear. Patients with type I tumors are often treated as distal esophagus cancers with consideration of preoperative chemoradiation for more advanced tumors and surgical resection using a gastric conduit with anastomosis in the neck or chest. In some cases, the jejunum or colon is used instead of the stomach for the conduit. Type II and III tumors may be removed with either total gastrectomy or proximal subtotal gastrectomy often through a transabdominal approach depending on the local extent of the tumor.^{63, 64} Total gastrectomy is generally favored in the United States over proximal gastrectomy because reflux

esophagitis is rare after Roux-en-Y esophagojejunostomy reconstruction compared to roughly one-third of patients who will have significant reflux after proximal subtotal resection.^{59, 65, 66} Further, proximal subtotal gastrectomy may fail to remove enough nodal tissue from the lesser curvature, a common site of nodal metastasis. However, some surgeons continue to advocate for proximal subtotal gastrectomy.⁶⁴

The extent of lymph node dissection is one of the most controversial surgical topics in the management of gastric cancer. Radical lymph node dissection involves removal of lymph nodes beyond the usual field of gastrectomy. The Japanese Gastric Cancer Association defines extent of lymph node dissection using the designation “D.”⁶⁷ Generally, D1 dissection includes perigastric lymph nodes. D2 dissection extends the lymphadenectomy to include nodes along the hepatic, left gastric, celiac, and splenic arteries ([Figure 2](#)). D3 dissection includes nodes along the porta hepatis and in the retropancreatic and periaortic regions.

Figure 2 Area of critical modified D2 lymphadenectomy including celiac, hepatic, left gastric, and splenic artery lymph nodes (shaded area).

The largest prospective study examining the potential benefit of extended lymphadenectomy is the Dutch D1D2 lymphadenectomy trial which randomized more than 1000 patients (711 treated with curative intent) to D1 or D2 lymphadenectomy in the setting of gastrectomy for cancer, with surgical quality carefully controlled.^{68, 69} Operative morbidity and mortality rates were significantly greater in the D2 group than in the D1 group (43% and 10%, respectively, vs 25% and 4%, $p < 0.01$). However, the increase in mortality rate was associated with either male patients undergoing D2 dissection or patients undergoing splenectomy and distal pancreatectomy for complete nodal dissection. Patients who underwent D2 dissection with preservation of the spleen/tail of the pancreas had operative mortality similar to that of patients who underwent D1 dissection. After median follow-up of 15.2 years, the D2 lymphadenectomy group had a higher disease-specific survival (DSS) rate compared to the D1 group and lower rates of local (12% vs 22%, $p = 0.02$) and regional (13% vs 19%, $p = 0.02$) recurrence.⁷⁰

A recent trial from the Italian Gastric Cancer Study Group evaluated the role of modified organ-preserving D2 lymphadenectomy.⁷¹ Patients with potentially curable gastric cancer were randomized (intraoperative) to D1 or D2 dissection. Partial pancreatectomy or splenectomy was done only when local invasion was suspected. A total of 267 patients were randomized, and morbidity and mortality were 12% and 3%, respectively, for the D1 group and 18% and 2% for the D2 group. Five-year DSS rates were 71% and 73% for the D1 and D2 groups; subgroup analysis revealed that in patients with node-positive disease the 5-year DSS rate was 61% in the D2 group versus 46% in the D1 group. Further, in patients with T-stage 2–4 and positive lymph nodes, the 5-year DSS was 59% in the D2 arm versus 38% in the D1 arm ([Figure 3](#)). The National Comprehensive Cancer Network (NCCN) gastric cancer panel has recommended consideration of modified D2 lymphadenectomy sparing distal pancreas and spleen in the setting of gastrectomy for cancer if available from an experienced surgeon at a high-volume center.⁷²

Figure 3 Kaplan–Meier curves of overall survival (a) and disease-specific survival (b) for patients with pathologic T2-4 and node-positive disease from the Italian Gastric Cancer Study Group D1D2 lymphadenectomy trial.⁷¹

Linitis plastica is an extremely virulent form of gastric cancer and is considered incurable by many clinicians. Some feel that patients with linitis plastica should never undergo gastrectomy since at best the 5-year survival is <10%.⁷³ One approach to patients with linitis plastica is to evaluate with staging laparoscopy and, in the absence of metastatic disease, treat first with neoadjuvant therapy in the hope of selecting patients who do not develop metastatic disease for eventual gastrectomy. If a patient with linitis plastica has a positive margin of resection after operation, one should be cautious as to whether this

deserves consideration or specific therapy given that isolated local recurrences are uncommon and rarely impact survival compared to the risk of metastatic disease. Recent evidence from the U.S. Gastric Cancer Collaborative suggests the traditional teaching that wide > 5 cm proximal margins are best for resection of distal cancers may not be necessary.⁷⁴ In their retrospective cohort study combining data from seven academic medical centers, the proximal margin distance was not an independent factor associated with overall survival (OS). Rather, T and N-stage were the primary associated factors, and a 3 cm margin was adequate in most patients.

While studies mentioned earlier indicate multivisceral resection should not be done routinely during lymphadenectomy, resection of other organs is sometimes needed when involved by the primary tumor or grossly involved nodes. Investigators from Memorial Sloan-Kettering Cancer Center found that roughly one-third of 800 patients who underwent R0 resection of gastric cancer over 15 years required removal of at least one additional organ.^{75, 76} The operative mortality rate was 4% in these patients, similar to that reported in the Dutch trial for limited dissection and far lower than that for D2 dissection with adjacent organ resection. Interestingly, the likelihood of actual adjacent organ invasion was low (14%) after final pathological examination. The 5-year survival rate in these patients was 32% compared to 50% in patients who did not require multivisceral resection. These data support application of multivisceral resection when required to achieve R0 resection at centers where the operative mortality rate is low.

Minimally invasive approaches to the conduct of subtotal or total gastrectomy have increased in recent years using laparoscopy, computer-aided (robotic) surgery, or hybrid procedures. Prospective high-quality comparisons of these techniques to open surgery have not been done. There are multiple retrospective studies comparing them, which suggest that short- and long-term patient outcomes are improved or not adversely affected by minimally invasive techniques.^{77, 78} While operating time and cost may increase with these approaches, especially early in the surgeon's learning curve, such costs may be balanced by other possible cost savings with shorter length of stay and more rapid overall recovery. However, all studies so far without randomization are subject to patient selection bias and, therefore, require caution when interpreting any possible benefits.

- EMR is considered with small T1a gastric cancers without adverse pathologic features
- Surgical resection is typically partial or total gastrectomy with upper abdominal (D1 or modified D2) lymphadenectomy
- Removal of other organs when needed due to local invasion is appropriate
- Use of laparoscopic and robotic techniques deserves further study

Radiation oncology

Use of postoperative chemoradiation for gastric cancer is supported by the results of the Intergroup trial (INT 0116).⁷⁹ Patients with gastric cancer after potentially curative resection were randomized to undergo postoperative chemoradiation with 45 Gray (Gy) external beam radiation with bolus fluorouracil (5-FU) or observation. The majority of the 556 evaluable patients had positive lymph nodes (85%) or T3/T4 tumors (68%). At 3 years, patients in the adjuvant chemoradiation arm had a 50% survival compared to 41% in the control arm ($p < 0.01$). There were increased gastrointestinal (33% grade 3/4) and hematological (54% grade 3/4) side effects in the therapy group. This trial established postoperative adjuvant chemoradiation as the standard of care for resected gastric cancer in the United States. There is

no uniform agreement about which lymph node groups should be treated in the setting of gastric cancer, but treatment volumes should be tailored to the location of each individual tumor. There are detailed data regarding the risk of nodal involvement from lymphadenectomy series that can guide physicians.⁸⁰ Depending on the location of the primary tumor in the stomach, perigastric, gastroepiploic, celiac, porta hepatis, subpyloric, gastroduodenal, splenic-suprapancreatic, and retropancreaticoduodenal nodes can be at risk for metastatic spread. The gastric remnant, the perigastric nodes, and the branches of the celiac axis should be treated in all cases.

Primary systemic treatment

Preoperative chemotherapy

The Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial changed the landscape of treatment options for patients with locally advanced gastric cancer.⁸¹ This randomized phase III trial compared surgery alone to surgery with three cycles of both preoperative and postoperative epirubicin, cisplatin, and 5-FU (ECF) chemotherapy. Among 503 patients accrued, ECF toxicity was manageable and the rates of postoperative morbidity and mortality were similar in the surgery alone and ECF groups. The resected tumors were smaller (3 cm vs 5 cm) with less advanced T and N stages than the ECF group. With a median follow-up of 4 years, patients in the ECF group had significantly better 5-year OS (36% vs 23%, $p < 0.01$) and disease-free survival (DFS) rates. This trial clearly establishes the perioperative ECF treatment regimen as a viable option for patients. It is important to realize only 42% of patients completed the prescribed protocol.

The French Action Clinique Coordonnées en Cancérologie Digestive (ACCORD-07) study confirmed the use of preoperative chemotherapy to be beneficial in patients with GEJ cancers despite closing prematurely due to low enrollment.⁸² A total of 224 patients with adenocarcinoma of the lower esophagus, GEJ, or stomach (25%) were randomized to receive 2–3 cycles of 5-FU/cisplatin followed by surgery followed by 3–4 cycles of the same chemotherapy versus surgery alone. The median follow-up was 5.7 years. Only 50% of the patients received postoperative chemotherapy. Five-year survival rates were 38% in the chemotherapy/surgery group versus 24% in the surgery alone group. In contrast, a study by the European Organization for Research and Treatment of Cancer (EORTC) randomized patients with locally advanced adenocarcinoma of the stomach or GEJ to preoperative chemotherapy with cisplatin, leucovorin, and 5-FU followed by surgery or surgery alone. This trial did not find a survival difference between these two strategies but was possibly underpowered due to poor accrual.⁸³

Postoperative adjuvant chemotherapy

Numerous trials of systemic chemotherapy for gastric cancer have been performed in the adjuvant setting. Many of the early trials were underpowered, included improper control groups or used suboptimal methodology. These limitations along with heterogeneous inclusion criteria rendered much of their results unreproducible.⁸⁴ Meta-analyses of these trials were fraught with difficulties and could not recommend a particular regimen. Nevertheless, two large analyses were performed with conflicting results.^{85, 86} Each analysis recommended treatment for subgroups such as patients with node-positive disease and Asian patients. Win and coauthors pooled data from several prospective studies to compare chemoradiation after R0 resection for gastric cancer to adjuvant chemotherapy.⁸⁷ The basic finding was that chemoradiation was associated with improved DFS without a difference in OS.

Most of the chemotherapy agents considered to be active against gastric cancer have reported response rates of 15–20% when administered alone which makes it uncertain whether any single-agent adjuvant

therapy will have a strong benefit. Despite this, prolonged continuous administration of an oral 5-FU prodrug (S-1) has been attractive to a number of investigators with some promising results. Investigators in one study randomly assigned 1059 patients with stage II or III gastric cancer after R0 gastrectomy and D2 or higher lymphadenectomy to surgery alone or surgery and postoperative S-1.⁸⁸ Improved DFS and OS were observed in the S-1-treated group. The 3-year OS rates were 80.1% in the S-1-treated group and 70.1% in the surgery-alone group ($p < 0.01$). The update analysis after 5 years demonstrated 5-year OS was 71.7% in the S-1-treated group and 61.1% in the surgery-alone group.

It should be noted that the safety profile of S-1 differs between Western and Asian patients and that S-1 is currently not available in the United States. A Korean study, the capecitabine and oxaliplatin adjuvant study in stomach cancer (CLASSIC), examined the use of adjuvant chemotherapy with capecitabine and oxaliplatin for 6 months after gastrectomy with D2 lymphadenectomy versus surgery alone.⁸⁹ The study demonstrated a benefit in DFS and OS, specifically, 3 year-OS of 83% in the treatment group compared to 78% in the observation group. In a subgroup analysis, the survival benefit was lacking in patients with N0 disease. A published meta-analysis of 17 randomized controlled trials of adjuvant chemotherapy in gastric cancer demonstrated a statistically significantly benefit in OS and DFS for patients treated with fluorouracil-based adjuvant chemotherapy versus surgery alone.⁹⁰

Integration of multimodal care

Surgery is the cornerstone of potentially curative therapy for localized gastric cancer, but the importance of adjuvant therapies cannot be overemphasized. Long-term survival rates with surgery alone remain suboptimal for all but the earliest gastric cancers (T1N0M0). As mentioned earlier, multicenter randomized studies demonstrate significant survival benefits for adjuvant therapy compared to surgery alone with two basic approaches ([Table 3](#)). Regardless of patient population, tumor location or extent of lymph node dissection, surgery alone is no longer adequate for patients with more than early gastric cancer who are fit for adjuvant therapy. A direct comparison across studies is not advisable due to differences in study design, patient population, proportion of patients with node positive disease, and extent of node dissection. It is perhaps interesting that many adjuvant therapy strategies and extended lymph node dissection are generally associated with a survival benefit around 10%.

Table 3 Selected adjuvant therapy options

<i>Postoperative chemotherapy and chemoradiation (INT0116 study—MacDonald regimen)</i>
Chemotherapy (one 28-day cycle) <ul style="list-style-type: none">• 5-FU 425 mg/m²/day IV on days 1–5• Folinic acid 20 mg/m²/day IV on days 1–5
Chemoradiation (5 weeks) <ul style="list-style-type: none">• 5-FU 400 mg/m²/day IV on days 1–4 and on the last 3 days of radiotherapy• Folinic acid 20 mg/m²/day IV on days 1–4 and on the last 3 days of radiotherapy• External-beam radiation, 45 Gy at 1.8 Gy/day 5 days per week
1-month recovery period
Chemotherapy (two 28-day cycles) <ul style="list-style-type: none">• 5-FU 425 mg/m²/day IV on days 1–5• Folinic acid 20 mg/m²/day IV on days 1–5
<i>Perioperative chemotherapy (MAGIC trial regimen)</i>
Chemotherapy ECF (three 21-day cycle) <ul style="list-style-type: none">• Epirubicin 50 mg/m² IV on day 1• Cisplatin 60 mg/m² IV on day 1• 5-FU 200 mg/m²/day CIV infusion on days 1–21
3–6 weeks recovery period
Surgical resection (gastrectomy/lymphadenectomy)
6–12 weeks recovery period
Chemotherapy ECF (three 21-day cycle) <ul style="list-style-type: none">• Epirubicin 50 mg/m² IV on day 1• Cisplatin 60 mg/m² IV on day 1• 5-FU 200 mg/m²/day CIV infusion on days 1–21

IV, intravenous and CIV, continuous intravenous infusion.

We advise the following approach for consideration of adjuvant therapy. Patients with apparent early disease (stage IA) or patients with an indication for surgical resection first (acute bleeding or obstruction) should first undergo gastrectomy including modified D2 lymphadenectomy. Following this, postoperative chemoradiation as in the INT0116 study should be given to those with stage IB to IIIC on final pathology. Patients with more advanced disease should be considered for perioperative chemotherapy as in the MAGIC study. In either group, diagnostic laparoscopy with cytologic washings should be considered before choice of initial therapy. For institutions where this is not routine, laparoscopy or PET should be

considered if any other studies suggest possible metastatic disease. For Asian patients, postoperative chemotherapy with S-1 should be considered if available and when appropriate. Any patient eligible for clinical trials should be encouraged to enroll including nontherapeutic biomarker and other studies.

- It is proven that adjuvant therapy for most patients with gastric cancer is associated with higher cure rate than with surgical resection alone
- Randomized phase III trials support use of either perioperative chemotherapy or adjuvant postoperative chemotherapy combined with chemoradiation

Monitoring for recurrence

Surveillance for all patients after potentially curative therapy for gastric cancer is recommended by the NCCN gastric cancer panel.⁹¹ Suggested follow-up studies include only history and physical examination routinely with laboratory studies, endoscopy, and imaging limited to the evaluation of specific symptoms or concerns. This approach is presumably influenced by the relatively limited benefit of any therapy in the recurrent or metastatic setting. It is important to evaluate patients after gastrectomy for nutritional deficiencies, particularly vitamin B₁₂, iron, and calcium.

Management of metastatic disease

Systemic therapy for advanced disease

For patients with advanced, recurrent or metastatic gastric cancer, therapy is mainly palliative. Despite numerous randomized trials, the survival rates in such patients remain poor. Poor performance status or multiple sites of metastases are associated with significantly worse outcomes. An analysis of the SEER registry showed only modest improvements in OS for patients with metastatic disease over the past three decades.⁹² The median survival duration in unselected patients diagnosed with metastatic gastric cancer in 2004 was <5 months.⁹³ The median survival durations reported in clinical trials have ranged from 7 to 10 months. Considering this dismal prognosis, several investigators have examined systemic chemotherapy to evaluate its role for advanced gastric cancer.

Four small random assignment trials assessed the impact of palliative chemotherapy on survival duration and quality of life.^{94–97} All four trials reported superior survival in patients receiving treatment when compared with those who received best supportive care (BSC). Those who received BSC had median survival ranging from 3 to 5 months, whereas those who received chemotherapy had median survival ranging from 8 to 12 months. Improvements in symptoms and quality of life were also apparent in the chemotherapy group. These findings are consistent with the fact that gastric cancer is a somewhat chemosensitive disease. Side effects of chemotherapy must be balanced against the potential benefits of it and symptoms associated with unchecked cancer growth. Palliative chemotherapy should be considered for most patients with an adequate performance status and nutritional support.

One difficult and controversial area is therapy for nonevaluable disease in asymptomatic patients (such as those with low-volume abdominal carcinomatosis). Although some advocate the immediate use of chemotherapy, others advise observation. The rationale for observation lies in the fact that only 30–40% of patients will have an objective response to any particular chemotherapeutic regimen. Delaying treatment until the appearance of early symptoms or evaluable disease may spare patients from experiencing unnecessary toxic effects and preserve their quality of life. These patients should be closely

observed with a medical history, physical examination, and CT scans if necessary. Treatment may be initiated when evaluable disease is established or symptoms appear, although if obstructive symptoms occur (due to peritoneal disease) systemic therapy may not be feasible.

A number of combination chemotherapy programs have been developed based on agents with known single agent activity in gastric cancer. One of the pivotal trials compared ECF with FAMTX (5-FU, doxorubicin, and methotrexate).⁹⁸ In this phase III trial, 274 patients received treatment. The response rate in the ECF group was 46%, whereas that in the FAMTX group was 21%. Moreover, the median survival duration was longer in the ECF arm (9 months vs 6 months; $p < 0.01$).⁹⁹ ECF has also been compared to the combination of mitomycin, cisplatin, and protracted venous infusion 5-FU (MCF) in previously untreated patients with advanced esophagogastric cancer.¹⁰⁰ In that trial, 580 patients received either ECF or MCF. The overall response rate was 42% with ECF and 44% with MCF ($p = 0.69$). There were only two deaths due to toxicity. Median survival was 9.4 months with ECF and 8.7 months with MCF ($p = 0.32$). This study confirmed the response and survival benefits of ECF.

Built on earlier success with the ECF regimen, the phase III study REAL-2 investigated the role of capecitabine and oxaliplatin in gastric and gastroesophageal cancer using a two-by-two design.¹⁰¹ The study randomly assigned 1002 patients to treatment with either ECF or epirubicin and cisplatin plus capecitabine (ECX) or treatment with either epirubicin and oxaliplatin plus fluorouracil (EOF) or epirubicin and oxaliplatin plus capecitabine (EOX). Approximately 65% of patients had carcinoma of stomach or GEJ, and 88% had adenocarcinoma histology. Response rates and median OS were 41% and 9.9 months for ECF, 46% and 9.9 months for ECX, 42% and 9.3 months for EOF, and 48% and 11.2 months for EOX. Investigators concluded noninferiority of capecitabine compared to 5-FU and oxaliplatin compared to cisplatin. These findings were further confirmed in two phase III studies investigating the role of capecitabine or oxaliplatin in gastric cancer. In one study, 220 patients were randomly assigned to treatment with infusional 5-FU and leucovorin plus cisplatin (FLP) or 5-FU and leucovorin plus oxaliplatin (FLO).¹⁰² While the response rates were higher in the FLO arm (34% vs 25%; $p < 0.01$), differences in time to progression were not statistically significant. A second contemporaneous phase III study compared cisplatin plus capecitabine (XP) and cisplatin plus 5-FU (FP).¹⁰³ Three-hundred-sixteen patients were randomly assigned to XP or FP. The response rate was higher in the XP group (41% vs 29%; $p = 0.03$). There were, however, no significant differences in progression-free survival (PFS) or OS.

Docetaxel-based chemotherapy regimens have also been extensively studied in patients with gastric cancer. A randomized phase III trial compared the combination of docetaxel, cisplatin, and 5-FU (DCF) with 5-FU plus cisplatin in a study that involved 445 patients.¹⁰⁴ Use of DCF resulted in a superior response rate (37% vs 25%; $p = 0.01$), PFS (median 5.6 months vs 3.4 months; $p < 0.01$) and OS (median 9.2 months vs 8.6 months; $p = 0.02$). However, the DCF regimen resulted in substantial treatment-related toxic effects. Specifically, 82% of the patients had grade 3/4 neutropenia, and 69% of the patients had at least one grade 3/4 treatment-related adverse event.

S-1 has been tested for efficacy in the advanced gastric cancer setting in several trials using differing combinations. Japanese investigators tested the combination of S-1 and cisplatin in a phase III trial (SPIRITS).¹⁰⁵ In this study, 305 patients were randomly assigned to treatment with S-1 or S-1 plus cisplatin. Response rate (54% vs 31%), PFS (median, 6 months vs 4 months; $p < 0.01$), and OS (median, 13 months vs 11 months; $p = 0.04$) were superior in the combination arm. Again, the toxicity profile of S-1 differs between Asian and Western patients due to differences in pharmacokinetics. A global phase III study which enrolled over 1000 patients compared S-1 or 5-FU plus cisplatin using a lower dose of S-1

and different schedule. Unfortunately, the study failed to achieve its primary endpoint of superior OS.¹⁰⁶ Irinotecan in combination with 5-FU (IF) was compared to cisplatin and 5-FU (CF) in chemo-naïve patients with adenocarcinoma of the stomach or GEJ.¹⁰⁷ In this study, IF did not prolong OS over CF and the results of noninferiority of IF were borderline. Irinotecan plus S1 also failed to prolong OS compared with S-1 alone in a Japanese study.¹⁰⁸ However, a recent phase III trial of 416 patients reported the median time to treatment failure (TTF) was significantly longer with FOLFIRI than with ECX (5.1 months vs 4.2 months; $p < 0.01$).¹⁰⁹ There were no differences in PFS, median OS (9.5 months vs 9.7 months), or response rates. The irinotecan and 5-FU combination is an acceptable first-line regimen.

In the second-line setting, three agents have been shown to improve survival over BSC. The Arbeitsgemeinschaft Internistische Onkologie (AIO) study compared irinotecan with BSC to BSC alone in patients with advanced gastric or GEJ adenocarcinoma.¹¹⁰ Irinotecan showed an OS advantage over BSC. In the COUGAR-02 study, 186 patients were randomized to docetaxel with BSC versus BSC alone. The chemotherapy group had a median OS of 5.2 months compared to 3.6 months in the BSC group ($p = 0.01$).¹¹¹

Molecularly targeted agents

Despite the incorporation of newer agents, the median survival of patients with advanced gastric cancer remains <1 year using cytotoxic chemotherapy. The addition of targeted agents has resulted in modest improvements in OS, PFS, and response rate. Molecular targeted agents are also being explored in the second-line setting. One of the most extensively studied receptors is the *EGFR* family. Several studies have investigated the addition of *EGFR* inhibitors to cytotoxic chemotherapy. Initial phase II trials had produced promising results. However, phase III trials rendered disappointing results. In the EXPAND trial, the addition of cetuximab (a chimeric monoclonal antibody (mAb) against *EGFR*) to capecitabine and cisplatin (XP) provided no additional benefit over XP alone.¹¹² Furthermore, panitumumab (a fully humanized mAb against *EGFR*) resulted in worse OS of 8.8 months versus 11.3 months when added to epirubicin, oxaliplatin, and capecitabine (EOC) versus EOC alone.¹¹³ The use of these two agents in gastric cancer is not recommended.

More promising results have been reported for other agents. *HER2/neu* (also a member of the *EGFR* family) is overexpressed in 20% of gastric and 30% of GEJ cancers. This receptor has been shown to be a key target for the treatment of these tumors. Trastuzumab (a humanized mAb) has been shown to prolong survival when added to chemotherapy with increase in OS from 11.1 to 13.8 months ($p < 0.01$).¹¹⁴ As in other solid tumors, angiogenesis has been shown to be an important part of gastric cancer progression. Bevacizumab, a *VEGF* inhibitor, was studied in a phase III trial.¹¹⁵ A total of 774 patients with advanced gastric or gastroesophageal cancer were randomized to receive bevacizumab or placebo plus cisplatin and capecitabine. The median OS was 12.1 months in the triple therapy group versus 10.1 months in the placebo group ($p < 0.01$). The PFS (6.7 months vs 5.3 months) and response rate (46% vs 37%) were also improved in the bevacizumab group. However, the study did not reach its primary endpoint. Further subgroup analysis revealed that North and Latin American patients appeared to have a survival benefit with the addition of bevacizumab (median 11.5 months vs 6.8 months compared to placebo), whereas patients enrolled in Asia (90% from Japan and Korea) appeared to have no benefit. European patients had intermediate results.

The REGARD trial, a randomized phase III trial comparing ramucirumab versus placebo for patients with advanced, pretreated gastric cancer, was recently published.¹¹⁶ Ramucirumab, a mAb that binds *VEGF-R2* and prevents its activation, improved OS over placebo (5.2 months vs 3.8 months, $p = 0.05$). The

addition of paclitaxel to ramucirumab versus paclitaxel alone in a subsequent trial, the RAINBOW trial, has also shown a survival advantage of ramucirumab in advanced gastric cancer.¹¹⁷ In that study, 665 patients were assigned to receive paclitaxel plus placebo or paclitaxel plus ramucirumab. The median OS was significantly longer in the ramucirumab plus paclitaxel group (9.6 months vs 7.4 months, $p = 0.02$). This combination has been proposed as the new standard second-line treatment for patients with advanced gastric cancer.

Other studies with targeted agents in pretreated patients with metastatic gastric cancer have been disappointing. The GRANITE-1 study randomized 656 patients to everolimus with BSC versus placebo with BSC.¹¹⁸ Everolimus did not improve OS (median 5.4 months with everolimus and 4.3 months with placebo). Similarly, lapatinib was added to paclitaxel versus paclitaxel alone in 420 patients with *HER2/neu* positive gastric cancer.¹¹⁹ Median OS was 11.0 months in the lapatinib and paclitaxel group versus 8.9 months in the paclitaxel alone group ($p = 0.21$). Despite different treatment strategies and incorporation of new targeted agents with standard chemotherapy, the outcome of patients with advanced gastric cancer remains poor; further research is certainly needed.

Supportive care

Patients with gastric cancer may present with symptoms including bleeding, obstruction, pain, early satiety, and weight loss. The indications for surgical resection of gastric cancer must be carefully considered in terms of intent of operation, whether for potential cure or palliation of symptoms or other cancer-related problems. Severe symptoms in patients without metastatic disease may prompt the decision to proceed with gastrectomy first followed by adjuvant therapy. For 307 patients with gastric cancer who underwent noncurative resection at Memorial Sloan-Kettering Cancer Center, roughly half of the patients had a truly palliative resection, most commonly for bleeding (20%), obstruction (43%), or pain (29%).¹²⁰ In patients with metastatic disease, palliative gastrectomy is associated with high postoperative mortality (14%) and complications (27%).¹²¹ In recent series, mortality has decreased to <5%, but caution remains important. Surgical bypass is also associated with high mortality in the palliative setting and frequently fails to achieve the desired benefit.^{122, 123}

When considering palliative resection, the surgeon should explicitly determine the degree of patient symptoms. For instance, while a patient with complete obstruction may only benefit from intervention such as resection, bypass, or endoscopic stenting, symptoms of incomplete obstruction may improve in up to 80% of patients with the use of chemotherapy.¹²⁴ Therefore, obstruction may be a relative indication for procedure rather than absolute. Pain in patients with gastric cancer may be caused by invasion of the celiac plexus, intestinal obstruction, or bone metastases. Obstruction can further confound the problem of pain management. In the absence of obstruction, short and long-acting oral narcotics are appropriate for pain. However, if obstruction is present, other methods must be employed.

Massive life-threatening bleeding may be treated with arterial embolization or endoscopy; however, resection may be required to control hemorrhage in some cases. Patients with significant bleeding from gastric cancer should be considered for resection, but without complete staging evaluation, one must be prepared that intraoperative findings of metastatic disease may change the intent of operation. In the metastatic setting, physicians must decide whether patients who are bleeding massively are surgical candidates and, if not, focus on BSC. Occasionally, endoscopic and embolization maneuvers can provide the necessary time to have these often difficult discussions. For patients who are experiencing slow oozing and need a transfusion every 1–2 weeks, endoscopy may be successful. Several series have indicated that 50–75% of patients experience improvement of bleeding, gastric outlet obstruction, and

pain with chemoradiation.^{125, 126}

Treatment options for obstruction include laser recanalization, stenting, radiotherapy, bypass, drainage tubes, and resection. The technology of expandable stents has grown dramatically over the past two decades. Dormann reviewed 136 publications reporting the use of self-expanding metal stents for gastroduodenal malignancies in 32 case series and reported stent placement to be technically successful in over 90% of patients with no procedure-related mortality and a relatively low number of complications.¹²⁷ Relief of symptoms may be temporary; in 18% of cases, the stent became occluded secondary to tumor ingrowth. Generally, patients with malignant gastric outlet obstruction due to unresectable primary or metastatic cancers have poor survival (median around 2 months), but interventions such as endoscopic stenting or surgical bypass are associated with acceptable postprocedure quality of life.¹²⁸ In our opinion, surgical bypass should be considered for patients with high performance status and longer life expectancy. Patients with short length, single sites of obstruction located in the pylorus or early duodenum are excellent candidates for endoscopic stenting. Patients with poor performance status, rapidly progressive cancer, carcinomatosis, malignant ascites, multiple sites of obstruction, and very short life expectancy may be best served by percutaneous gastrostomy or no intervention.

Unmet needs and future directions

There are many opportunities for clinicians and researchers to develop improvements for the care of patients with gastric cancer. Many exciting studies have been published in recent years examining novel ways to improve outcomes, such as intravenous lidocaine infusion to improve postoperative pain control,¹²⁹ sentinel node mapping,^{130, 131} early postoperative enteral immunonutrition,¹³² and improved pathologic staging through use of surgical *ex vivo* dissection.¹³³ Further advancements must continue to build upon the foundation of our collective understanding of the molecular pathogenesis of gastric cancers and robust high-quality clinical outcomes and comparative effectiveness research.

In the area of prevention and screening, several questions remain. Should we promote widespread efforts at *H. pylori* eradication? Should screening programs with upper endoscopy be developed for higher risk patients in the West? In terms of proper staging of gastric cancers, we have not yet defined which patients most benefit from pretreatment EUS or PET. With many methods available for surgical removal of gastric cancers including EMR and minimally invasive operations, developing widely accepted standards for the conduct of procedures, large registries, and public reporting of preoperative quality and long-term oncologic outcomes is imperative. While some decisions such as palliative gastrectomy will always require an individualized approach, other considerations such as extent of lymphadenectomy may be best defined by evidence and best practice rather than individual surgeon bias.

Which patients should be chosen for the two basic adjuvant therapy strategies of preoperative chemotherapy or postoperative chemoradiation is not clear. Also, for patients who do not respond or progress after preoperative chemotherapy, what therapy should be given postoperatively, an alternate chemotherapy regimen or chemoradiation? Such questions regarding best therapy are only part of the puzzle. Management of challenging postoperative symptoms such as delayed gastric emptying or poor stomach function is ripe for novel research. There are many unmet needs in gastric cancer but, fortunately, there is high interest in ongoing research.

Conclusions

Fortunately, the incidence of gastric cancer is decreasing around the world. However, outcomes for many remain poor and overall cure rates low. Despite encouraging progress in all areas of gastric cancer treatment (surgery, chemotherapy, and radiation), many patients with gastric cancer still suffer symptoms, decreased HRQOL and will die eventually of disease despite best therapy. For the future, we must hope the ability to define at-risk populations will facilitate development of cost-effective screening programs and preventive measures. As we enter the age of molecular targeted therapy and personalized medicine, improvements in our understanding of molecular biology and molecular classification of gastric cancer may lead to the rational development of novel therapeutic strategies. The authors have a realistic hope that in our lifetime the landscape of gastric cancer will change such that most people are cured after therapy.

Chapter 91

Primary neoplasms of the liver

Junichi Shindoh, MD, PhD ■ Kristoffer W. Brudvik, MD, PhD ■ Jean-Nicolas Vauthey, MD

Overview

Primary liver cancer is the second leading cause of cancer death in men and the sixth leading cause among women. Hepatocellular carcinoma (HCC) constitutes 70–85% of primary hepatic neoplasms, followed by intrahepatic cholangiocarcinoma (ICC) (10–15%) and other less common hepatic malignancies (5%) such as hepatic angiosarcoma, epithelioid hemangioendothelioma, or hepatic lymphoma. Primary hepatic malignancies are generally associated with poor survival, and only a limited evidence of systemic therapy have been available, prevention, surveillance, early diagnosis, and multidisciplinary treatment approach are important factors to maximize treatment outcomes. In addition, most of the primary hepatic neoplasms are associated with chronic liver disease or cirrhosis, and the decreased hepatic functional reserve often precludes aggressive treatment for tumors. Therefore, for treatment selection, one should consider two intrinsic conflicting factors, curability and safety of treatment. Currently, several clinical staging systems and treatment algorithms are available to adequately select therapeutic options for HCC. The choice of therapy is individualized based on the tumor burden, degree of underlying liver disease, patient performance status, and the overall possibility of side effects or complications balanced with acceptable results. Selection of treatment should be determined in a multidisciplinary approach with the local expertise. The most curative treatment options including surgical resection, radiofrequency ablation, and orthotopic liver transplantation (OLT) should be the first priority as long as such treatments are approved. For the other hepatic malignancies, only limited clinical evidence is available and surgical resection or OLT is considered as the first-line treatment.

The liver is a specific site where all the visceral venous flow passes through before it reaches the heart. Therefore, the liver is the most common site of metastases from gastrointestinal malignancies which is termed secondary hepatic neoplasms. However, tumors can also arise from the cells within the liver and are termed primary hepatic neoplasms. Of the primary hepatic neoplasms, hepatocellular carcinoma (HCC) is the most common malignancy constituting 70–85% of the primary liver cancer, followed by intrahepatic cholangiocarcinoma (ICC) (10–15%) and other less common hepatic malignancies (5%) such as hepatic angiosarcoma, epithelioid hemangioendothelioma (EHE) or hemangiopericytoma, or hepatic lymphoma. Because primary hepatic malignancies are generally associated with poor survival and only a limited evidence of systemic therapy have been available, early diagnosis and multidisciplinary treatment approach are of most importance to expect favorable long-term outcomes. This chapter will review and discuss the clinical features and current treatment approaches for HCC, ICC, and the other less common primary liver cancers.

Hepatocellular carcinoma

Incidence and epidemiology

Primary liver cancer is the fifth most common cancer in men and the seventh in women, and the second leading cause of cancer death in men and the sixth leading cause among women, with about 695,500 deaths annually worldwide.¹ Nearly 85% of the cases occur in developing countries especially in sub-Saharan Africa and in East and Southeast Asia, with typical incidence rates of >20 per 100,000 individuals. The incidence rates are generally lowest in developed countries, with the exception of Japan where hepatitis C virus (HCV) infection is the most common cause for HCC.

Globally, the incidence of HCC is increasing in areas with historically low rates, including parts of Oceania, Central Europe, and North America.^{2, 3} A study reported in 2009 indicated that age-adjusted incidence rates of HCC tripled between 1975 and 2005 in the United States from 1.6 to 4.9 per 100,000 people.² In contrast, the incidences of liver cancer are decreasing in historically high-risk areas, such as China and Singapore, most likely due to reduction in hepatitis B virus (HBV) infection through improved public health.

The rates of HCC are more than twice as high in men as in women across geographic regions.⁴ The incidence of HCC increases with age, although the age threshold varies among countries because of differences in predominant etiologies for HCC. The age threshold for HCC is generally younger when the predominant risk factor is vertical transmission of HBV (e.g., Southeast Asia and Africa), and older where acquired HCV infection during adulthood is the most common cause of HCC (e.g., Japan and United States).

Risk factors

Cirrhosis is the main risk factor and present in 80–90% of patients with HCC. It is hypothesized that chronic hepatocellular injury and inflammation from a variety of causes lead to cirrhosis and HCC as a result of hepatocyte regeneration and hyperplasia predisposing to mutations and malignant transformation.

Viral hepatitis (HBV and HCV)

It has been estimated that 75–80% of HCC are associated with chronic infections with HBV (50–55%) or HCV (25–30%).⁵ Transmission of HBV occurs during delivery (vertical transmission), blood transfusions, sexual intercourse, or intravenous drug abuse. Transmission of HCV can also occur via parenteral exposure, however, primarily through blood transfusions and intravenous drug abuse.

HBV is a double-stranded DNA virus and chronic infection to HBV is the most common etiology for HCC, especially in China and Korea. Patients with positive hepatitis B surface antigen (HBsAg) are at high risk of developing cirrhosis and HCC. However, it has been reported that those who are positive for anti-hepatitis B core antibodies (HBcAb) are also at high risk for HCC even when HBs-Ag is serologically negative.⁶ In contrast to HCV-related HCC which usually arises in the liver with severe fibrosis or cirrhosis, approximately 20% of HBV-related HCC occurs in the absence of cirrhotic changes. A direct mutagenic effect that causes carcinogenesis has been postulated for HBV. Integration of HBV DNA in the host genome adjacent to cellular oncogenes or transactivating effect of the HBx protein on cellular gene expression may be attributable to the development of HCC without cirrhosis.^{7–9} In fact, HBV-DNA integration has been detected in hepatocytes before tumor development among patients positive for HBsAg, which may enhance chromosomal instability and facilitate HCC development.^{10, 11}

HCV is a small, single-stranded RNA virus. The prevalence of HCV infection varies widely according to geographical areas. A meta-analysis of 21 case–control studies reported that HCC risk was 17 times higher among HCV-positive individuals as compared to HCV-negative individuals.¹² It has been

suggested that oxidative stress is one of the mechanisms involved in inflammation-related carcinogenesis in patients infected with HCV.¹³ In response to viral antigens, the activated macrophages and other recruited leukocytes release reactive oxygen species, causing areas of focal necrosis and compensatory cell division.¹⁴ When these oxidants overwhelm the antioxidant defenses of neighboring cells, damages to biomolecules, particularly to oncogenes or tumor suppressor genes, may increase the carcinogenic potential of the underlying liver. HCV displays a high genetic variability. On the basis of nucleotide sequence homology, whole-sequenced HCV isolates are classified as genotype 1a, 1b, 2a, and 2b. The geographic distribution of these genotypes demonstrated that genotypes 1a, 1b, and 2a are predominant in Western countries and East Asia, whereas genotype 2b is predominant in the Middle East.¹⁵ The HCV genotype 1b is reportedly more aggressive and more closely associated with advanced chronic liver diseases such as liver cirrhosis and HCC. However, these observations can be partially explained by the refractoriness to antiviral therapy, and recent studies have reported that lower HCV viral load is correlated with improved survival outcomes after surgical resection of HCC irrespective of the genotypes of HCV.^{16, 17}

Alcohol

Excessive alcohol consumption is a major risk factor for chronic liver disease and HCC, causing various degrees of liver damage from simple fat accumulation to cirrhosis. Various studies have concluded that excessive alcohol intake is an important risk factor for HCC development. A US case-control study demonstrated approximately threefold increase in HCC risk among individuals with heavy alcohol consumption defined as more than 60 ml ethanol per day.¹⁸ HCC rarely develops in the absence of cirrhosis; however, the risk is increased with concurrent HBV or HCV infection.^{19, 20} A meta-analysis of 20 studies published between 1995 and 2004 that involved more than 15,000 patients with chronic HCV infection reported that the pooled relative risk of cirrhosis associated with heavy alcohol intake was 2.33, compared with no or low-quantity alcohol intake.¹⁹ Therefore, alcohol consumption should be avoided among patients with viral hepatitis.

Aflatoxins

Aflatoxins (AFs) are potent hepatocarcinogens produced by *Aspergillus flavus* and *Aspergillus parasiticus* that grow readily on foods such as corn and peanuts stored in warm, damp conditions. There are four AF compounds: B₁, B₂, G₁, and G₂, and the most common and most toxic AF compound is AFB₁. When ingested, AFB₁ is metabolized to a highly active 8,9-epoxide metabolite, which can bind to and damage DNA. A consistent genetic mutation in codon 249 in the tumor suppressor p53 gene has been identified and positively correlated with AF exposure.^{21, 22} Although AFB₁ contributes to hepatocarcinogenesis, its role in pathogenesis of HCC is primarily mediated by its synergic effects on chronic hepatitis B because the areas where AFB₁ exposure is an environmental problem also have a high prevalence of chronic HBV infection. A prospective study from China showed that urinary excretion of AF metabolites was associated with increased risk for HCC up to fourfold, and HBV infection independently increased the risk sevenfold. However, the patients who excreted AFB₁ metabolites and had concomitant infection of HBV showed a 60-fold increase in risk of development of HCC.²³ These results suggest that prevention of HBV-related HCC would reduce the effects of AF on HCC risk.

Obesity

It is well established that obesity is significantly associated with a wide spectrum of hepatobiliary

diseases, including fatty liver diseases, steatosis, steatohepatitis, and cryptogenic cirrhosis.^{24, 25} In a large prospective cohort study of more than 900,000 individuals in the United States followed up for a 16-year period, liver cancer mortality rates were five times greater among men with the greatest baseline body mass index (range, 35–40) compared with those with a normal body mass index, whereas the risk of liver cancer was not as increased in women, with a relative risk of 1.68.²⁶ Two other population-based studies from Northern Europe have also shown that obesity is correlated with increased HCC risk.^{27, 28}

Diabetes mellitus

Recently, diabetes has been recognized as a risk factor for chronic liver disease and HCC. Although adjustment of potential biases in cross-sectional and case–control studies is difficult, several studies have clearly demonstrated positive correlation between diabetes and HCC.^{29–33} The postulated mechanisms for liver cell damage induced by type 2 diabetes mellitus involve insulin resistance and hyperinsulinemia.^{34, 35} Hyperinsulinemia reportedly reduces liver synthesis and blood levels of insulin growth factor-binding protein-1 (IGFBP-1), which increases (1) bioavailability of insulin-like growth factor-1 (IGF-1), (2) promotion of cellular proliferation, and (3) inhibition of apoptosis.³⁶ Excessive insulin binds to insulin receptor and activates its intrinsic tyrosine kinase, leading to phosphorylation of insulin receptor substrate-1 (IRS-1),³⁷ and hyperinsulinemia is also associated with production of reactive oxygen species, which may cause damage to DNA. Overexpression of IRS-1 is associated with decreased apoptosis, which is mediated by transforming growth factor β .³⁸ Given these evidences in basic researches and pathologic observation that HCC tumor cells overexpress both IGF-1 and IRS-1,³⁹ diabetes mellitus seems to contribute to liver cell damage and development of HCC.

Hemochromatosis

Hemochromatosis is an autosomal recessive genetic disorder of iron metabolism, with a prevalence rate of 2–5 per 1000 in the Caucasian population. In this inherited disorder, mutations have been documented in the *HFE* gene on chromosome 6 (Cys282Tyr [C282Y] and His63Asp [H63D]), the *HFE-2* gene on chromosome 1, and the *HFE-3* gene on chromosome 7. The C282Y mutation is the most commonly detected mutation and C282Y homozygotes or C282Y/H63D compound heterozygotes^{40–42} is associated with increased absorption of dietary iron and accumulation in tissues such as the skin, heart, and liver, resulting in heart failure or liver cirrhosis.

There is growing evidence that even mild accumulation of iron is harmful to the liver, especially when other hepatotoxic factors such as chronic viral hepatitis or heavy alcohol intake are present. Iron enhances the pathogenicity of microorganisms, adversely affects the function of macrophages and lymphocytes, and enhances fibrogenic pathways.⁴³ A synergistic relationship between HCV infection and iron overload has been suggested,⁴⁴ and iron depletion has been reported to improve liver function tests in patients with chronic hepatitis C.⁴⁵ Although diagnosis of hemochromatosis is relatively difficult, treatment with therapeutic phlebotomy or iron chelation therapy before onset of cirrhosis may be effective in preventing the development of cirrhosis and HCC in these patients.

α_1 -Antitrypsin deficiency

α_1 -Antitrypsin deficiency (AATD) is an autosomal dominant disorder with mutations in the serine protease inhibitor (Pi) gene. Over 75 different Pi alleles have been identified, most of which are not associated with the disease,⁴⁶ and a relationship exists between Pi phenotypes and serum concentrations of α_1 -antitrypsin. Typical clinical presentation of patients with AATD includes emphysema, hepatic

necroinflammation, cirrhosis, and HCC. Because no effective medical treatment is available, liver transplantation is indicated for patients with decompensated cirrhosis in correcting the underlying metabolic disorder.

Other potential risk factors

The higher incidence of HCC reported in men compared to women suggest the influence of hormonal factors on hepatocarcinogenesis. Long-term use of oral contraceptives has been thought to be a potential risk factors for HCC; however, a review of 12 case–control studies have yielded an overall adjusted odds ratio of 1.6 (95% CI, 0.9–2.5),⁴⁷ and the correlation between the oral contraceptives and risk for HCC remains inconclusive.

Hypothyroidism has also been reported to be a potential risk factor for HCC especially in women.^{48, 49} Patients with hypothyroidism may experience weight gain⁵⁰ and insulin resistance,^{51, 52} both of which are significant factors for nonalcoholic steatohepatitis. Although the actual mechanism is unclear and only limited clinical evidence is available, development of chronic liver disease and hepatocarcinogenesis might be influenced by these hormonal factors to some extent.

Prevention

Prevention of HCC is highly dependent on avoiding the risk factors, adequate treatment for the underlying chronic liver disease, and early diagnosis of precursor lesions. Because the most common cause of HCC is cirrhosis associated with viral hepatitis, prevention of infection to HBV/HCV and treatment of chronic hepatitis with antiviral therapy are of most importance in cancer prevention.

For hepatitis B, parenteral exposure is the most common cause of transmission in developing countries and improvements in hygiene conditions and public education are essential to avoid viral transmission. In addition, vaccination and effective antiviral therapy are currently available for HBV. After the initiation of HBV vaccination, significant declines in the incidence of HCC have been documented in high-risk countries such as Taiwan.⁵³ When HBV infection has been established, various effective antiviral agents are currently available and reduction of viral load has reportedly correlated with reduced risk of HCC and improved survival outcomes in patients with chronic hepatitis B.^{54–56}

For hepatitis C, interferon (IFN)-based combination treatment has been the standard of care and reduction of HCC risk has been shown especially in patients who achieved sustained viral response (SVR).^{57–60} However, genetic variability of HCV highly affects the effectiveness of antiviral therapies. Although only a few clinical evidences are available, recently introduced new direct-acting antiviral agents (DAAs) have dramatically improved virologic response rate and will likely contribute to prevent HCC among patients with chronic hepatitis C in the near future.^{61–63}

Pathology

The malignant transformation of hepatocytes to HCC is considered as a multistep process associated with genetic mutations, allelic losses, epigenetic alterations, and perturbation of molecular cellular pathways. However, the molecular process of carcinogenesis in HCC is poorly understood. The phenotypic expression of these potential multistep changes can be manifested by precursor lesions that can be distinguishable from surrounding regenerative nodules associated with cirrhosis with regard to size, color, texture, and degree of bulging of the cut surface. Changes in the tumor blood supply correspond to each step of the multistep process, from precursor lesions to classical HCC, and helps differential diagnosis on dynamic studies in CT or MRI ([Figure 1](#)).

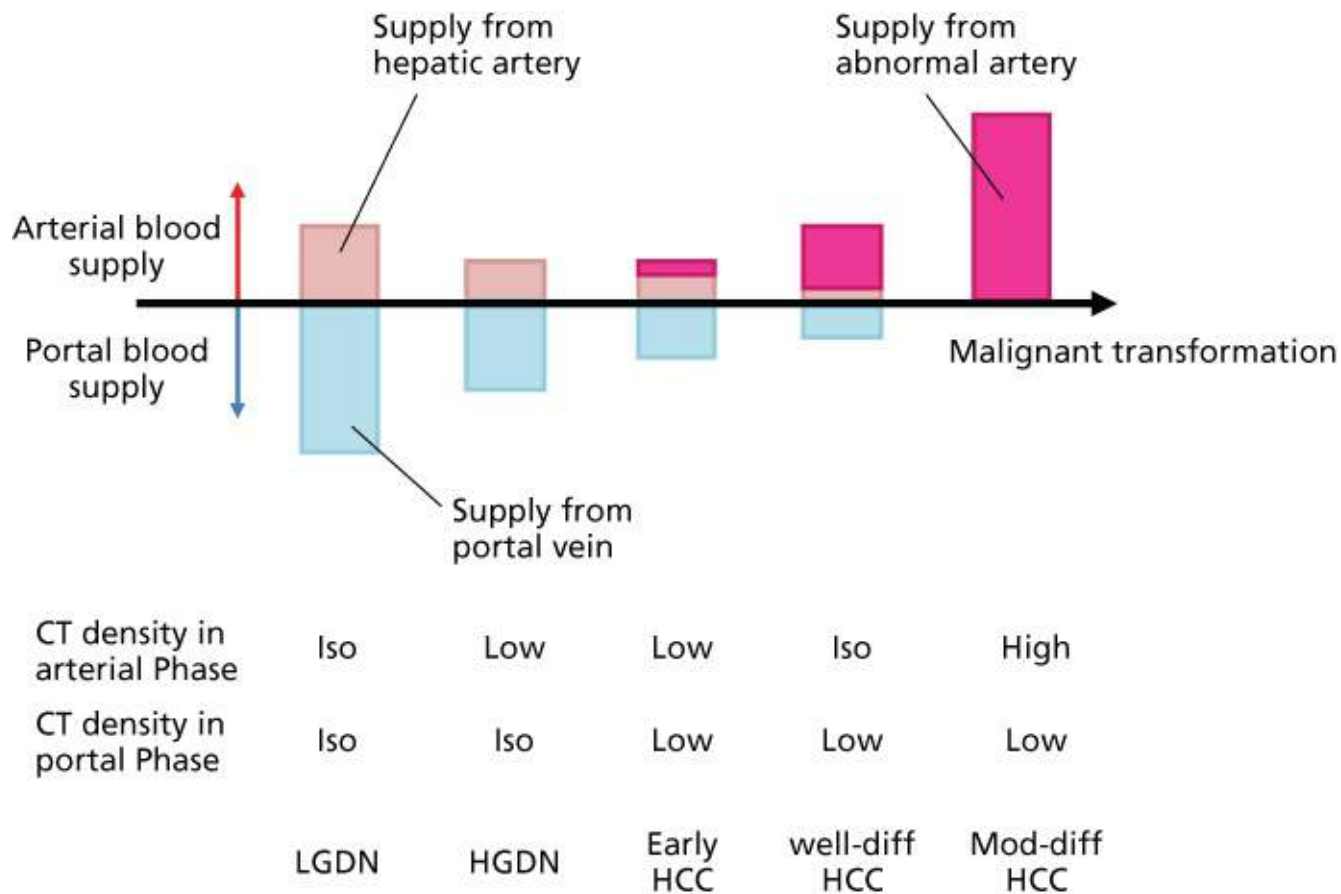

Figure 1 A model of dynamic changes in blood supply from precursor lesions to classical hepatocellular carcinoma. Dynamic changes in arterial and portal supply and exponential increase in abnormal arterial supply correlate with the typical patterns of enhancement in dynamic CT or MRI. *Abbreviations:* LGDN, low-grade dysplastic nodule; HGDN, high-grade dysplastic nodule; HCC, hepatocellular carcinoma; well-diff, well differentiated; mod-diff, moderately differentiated.

Dysplastic nodules

It is commonly accepted that there is a stepwise progression from cirrhotic nodule to HCC. A unified nomenclature of such liver nodules has recently been reviewed by the International Working Party of the World Congress of Gastroenterology.⁶⁴ Dysplastic nodule (DN) is a distinct nodular lesion >5 mm in diameter and subclassified into low-grade dysplastic nodule (LGDN) and high-grade dysplastic nodule (HGDN). LGDNs show only mild dysplasia without architectural atypia, whereas HGDNs are characterized by architectural and/or cytologic atypia, which is insufficient for a diagnosis of HCC. HGDNs often show increased cell density with an irregular trabecular pattern. Small cell change (small cell dysplasia) is the most frequently seen form of cytologic atypia in HGDNs.

Early HCC

Early HCCs are vaguely nodular up to around 2 cm in diameter and are characterized by various combinations of the following major histologic features.⁶⁴

1. Increased cell density more than two times that of the surrounding tissue, with an increased nuclear/cytoplasm ratio and irregular thin-trabecular pattern.
2. Varying numbers of portal tracts within the nodule (intratumoral portal tracts).
3. Pseudoglandular pattern.
4. Diffuse fatty change.

5. Varying numbers of unpaired arteries.

Distinguishing early HCCs from HGDNs is an unresolved challenge. Stromal invasion, defined as the presence of tumor cells invading into the portal tracts or fibrous septa, has been proposed as the most relevant feature discerning early HCC from HGDN. However, such feature may be difficult to identify, especially on biopsy specimens. In that context, a panel of three immunohistochemical markers of malignant transformation, heat shock protein 70, glutamine synthetase, and glypican 3, has been used to distinguish HCCs from HGDNs as well as CK 7 immunostaining for recognition of stromal invasion in early HCC.^{65, 66}

Macroscopic presentation of HCC

HCC forms a soft mass with a heterogeneous macroscopic appearance, polychrome with foci of hemorrhage or necrosis ([Figure 2](#)). Grossly, three main growth patterns that were described by Eggel in 1901 remain widely used.⁶⁷ The *nodular* type consists of well-circumscribed tumor nodules. *Massive* HCCs are circumscribed, huge tumor masses occupying most or all of a hepatic lobe. This type is commonly observed in patients without cirrhosis. The *diffuse* type is rare and characterized by innumerable indistinct small nodules studding the entire liver. The different patterns of growth are associated with various risks of spread, both intrahepatic and extrahepatic.⁶⁸ The Liver Cancer Study Group of Japan (LCSGJ) has proposed a modification, with the nodular category being divided into three subtypes: single nodular subtype, single nodular subtype with perinodular tumor growth, and confluent multinodular subtype.⁶⁹

Figure 2 Gross appearance of hepatocellular carcinoma.

Multicentricity of tumor is noted in 16–74% of HCCs resected in cirrhotic livers.^{68–72} Although it is sometimes difficult to distinguish intrahepatic metastases from HCCs generated by multicentric neocarcinogenesis, tumor nodules are considered as intrahepatic metastases when (1) they show a portal vein tumor thrombus or grow contiguously with a thrombus, (2) multiple small satellite nodules surrounding a larger main tumor, or (3) a single lesion is adjacent to the main tumor but is significantly smaller in size and presents the same histology.⁷³

Vascular invasion and formation of tumor thrombus are frequently observed especially in poorly differentiated HCC or large tumor. The portal vein is the most common site of vascular invasion,

followed by hepatic veins, biliary tract, and hepatic arteries. The degree of tumor extension through the vascular structure is closely associated with prognosis. When a portal vein tumor thrombus extends up to the left or right portal pedicle (Vp3) or main portal trunk (Vp4), most patients develop recurrence and die within 2 years after surgery.⁷⁴

Microscopic presentation of HCC

Grading of HCC has relied on Edmondson and Steiner classification for many years, which divided HCC into four grades from I to IV on the basis of histological differentiation.⁷⁵ Tumors with well-differentiated neoplastic hepatocytes arranged in thin trabeculae correspond to grade I. The larger and more atypical neoplastic cells are sometimes organized in an acinar pattern in grade II. Architectural and cytologic anaplasia are prominent in grade III, but the neoplastic cells are readily identified as hepatocytic in origin. When composed of markedly anaplastic neoplastic cells not readily identified as hepatocytic origin, the tumor is classified as grade IV.

Histologic variants of HCC

Fibrolamellar HCC

Fibrolamellar variant is a rare entity accounting for <1% of all cases of primary liver cancer, which is commonly encountered in young population without chronic liver disease. Fibrolamellar carcinomas are firm, sharply demarcated, and usually single tumors, ranging from 5 cm to over 20 cm. Histologically, it is characterized by the presence of lamellar stromal bands surrounding nests of large polygonal eosinophilic tumor cells with prominent nucleoli. Intensive surgical approaches have been reported to offer a chance of long-term survival despite occurrence of extrahepatic recurrences for patients with fibrolamellar HCC.⁷⁶

Combined HCC and cholangiocarcinoma

Combined HCC and cholangiocarcinoma (HCC-CC) contain unequivocal elements of both HCC and ICC. These tumors show variable combinations of characteristic features of HCC (e.g., bile production, intercellular bile canaliculi, or a trabecular growth) as well as ICC (e.g., glandular structures, intracellular mucin production, or immunoreactivity for MUC-1, CK7, and CK19).^{77–79} Although the surgical outcomes of combined HCC-CC remain indeterminate, intermediate postoperative long-term survival between HCC and ICC has been reported in several studies.^{80, 81}

Pathogenesis and natural history

The pathogenesis of HCC in cirrhosis is a multistep dedifferentiation process that progresses from regenerative nodule to dysplastic borderline nodule to frank HCC. DNs and early HCC are generally asymptomatic and are usually incidental findings on radiographic studies or detected as a result of screening procedures. Early HCC is a usually slow-growing lesion and remains indolent before acquiring oncological features of classical HCC. With stepwise sequence, small HCC acquires progression ability with angiogenesis, increases in tumor size, invades into the vascular structures, and metastasizes within the liver. These microscopic cancer spread process can evolve toward macroscopic formation of vascular tumor thrombi or multiple tumor presentation. HCC is characterized by early development of such intrahepatic metastasis, whereas distant organs are usually involved late in this disease. HCC usually remains asymptomatic until stretching liver capsule, compressing biliary structures, or tumor rupture with increase in size. In some cases, however, hyperbilirubinemia or hypercalcemia is observed

without evidence of biliary obstruction or bone metastases as a paraneoplastic syndrome.

Dissemination or extrahepatic metastases occurs in later stages, primarily via the blood stream to the lungs, bones, and brain. The prognosis for patients with extrahepatic disease is dismal with overall survival up to 1 year depending on the extent of tumor involvement and other prognostic factors.

Screening and diagnosis

The primary objective of screening and surveillance for HCC should be to reduce mortality as much as possible in patients who actually develop the cancer and in an acceptably cost-effective manner. Surveillance is not recommended for the general population, given the low incidence of HCC among individuals with no risk factors. Therefore, the first step in HCC screening should be the identification of patients at risk of HCC development. Traditionally, two methodologies have been employed in HCC surveillance for high-risk patients: tumor marker determination, specifically serum alpha-fetoprotein (AFP) concentration, and diagnostic imaging studies.

The American Association for the Study of Liver Disease (AASLD) has established guidelines regarding the use of these screening techniques based on the best existing evidence.⁸² The AASLD currently recommends serial hepatic ultrasound and serum AFP measurement every 6 to 12 months in at-risk populations (e.g., any patient with cirrhosis). Similarly, the Japanese Society of Hepatology has recommended hepatic ultrasound and serum AFP/plasma des-gamma carboxyprothrombin (DCP) every 3 to 4 months and dynamic CT or MRI every 6–12 months for very high risk population (HBV-related cirrhosis or HCV-related cirrhosis) and hepatic ultrasound and tumor markers every 6 months for high-risk population (HBV-related chronic hepatitis, HCV-related chronic hepatitis, or cirrhosis with other etiologies) with or without dynamic CT or MRI every 6–12 months, as appropriate.⁸³ A randomized-controlled trial from China reported that the use of ultrasound and AFP enable early detection of HCC and lower HCC-related mortality by 37% in hepatitis B patients.⁸⁴ Various nonrandomized studies also confirmed prognostic improvement through regular surveillance programs among patients at high risk of HCC.^{85–87} Regarding the interval of screening, recent meta-analysis revealed that every 6 months of surveillance is significantly better than every 12 months of screening in early detection of HCC. Sant et al.⁸⁸ reported that 70% of newly diagnosed HCC was within Milan criteria (solitary tumor ≤ 5 cm or ≤ 3 tumors with each tumor ≤ 3 cm)⁸⁹ when screened every 6 months or less, whereas the proportion of HCC within Milan criteria was 57% and the overall survival rate was inferior with surveillance every 6–12 months. When a suspected nodule was detected in the regular screening, a contrast-enhanced dynamic CT or MRI is needed. Because HCC is mainly fed by arterial flow, early enhancement and washout of contrast on the delayed phase of the scan are typical findings suggestive of HCC ([Figure 3](#)). These enhancement characteristics increase the specificity of the scan to $>95\%$.⁹⁰

Figure 3 Typical enhancement pattern of hepatocellular carcinoma in dynamic CT scan. Early enhancement in the arterial phase (a) and washout in the late phase (b) are typically observed in moderately differentiated hepatocellular carcinoma.

An update of AASLD recommendations for diagnosis of HCC has been recently published ([Figure 4](#)).⁹¹ These guidelines suggested that, for patients with cirrhosis, a liver mass detected on a radiographic study does not need biopsy confirmation for the diagnosis of HCC as long as the liver lesion exhibits typical vascular enhancement patterns on dynamic imaging studies with CT scan or MRI for lesions >1 cm in diameter. Lesions <1 cm in diameter should be followed with ultrasound every 3 months. If there is tumor growth or changes in character, further investigation is recommended according to size of tumor.

Staging

Because of close association of HCC with underlying chronic liver disease, the prognosis of patients with HCC depends on both the extent of malignant involvement and the severity of chronic liver disease. Thus, currently available staging systems for HCC are broadly divided into clinical and pathological staging systems. The clinical staging systems are particularly useful in guiding treatment selection, including Okuda staging system,⁹² Cancer of the Liver Italian Program (CLIP) score,⁹³ and Barcelona Clinic Liver Cancer (BCLC) staging system.⁹⁴ The pathologic staging systems are established based on the surgical outcomes and include the LCSGJ staging system,⁹⁵ Japanese Integrated Staging (JIS) score,⁹⁶ Chinese University Prognostic Index (CUPI),⁹⁷ and American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) staging system.⁹⁷ Each staging system has strengths and weaknesses. However, combining cancer staging with treatment algorithm is usually difficult, resulting in being too conservative in some cases for one therapy while being too aggressive regarding other therapy in other cases. Therefore, hepatic functional reserve and oncologic status of tumor should be classified separately. Overall status of the hepatic functional reserve and risk of treatment are stratified by Child-Turcotte-Pugh (CTP) score, which is calculated by the presence of encephalopathy, the presence of ascites, serum bilirubin concentration, serum albumin concentration, and prothrombin time (Table 1). CTP score is

nowadays included in various treatment algorithms for hepatic neoplasms,^{82, 98, 99} and liver resection is usually indicated for CTP class A patients or highly selected patients classified as CTP class B. Consensus exists that CTP class C patients should not undergo surgical resection owing to high perioperative mortality rate.⁹⁸

Table 1 Child-Turcotte-Pugh (CTP) classification

	Points		
	1	2	3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	<2.0	2.0–3.0	>3.0
Prothrombin time	—	—	—
Seconds	<4	4–6	>6
International normalized ratio (INR)	<1.7	1.7–2.3	>2.3
Ascites	None	Moderate	Severe
Encephalopathy	None	Grade I–II	Grade III–VI
CTP class A	5–6 Points	—	—
CTP class B	7–9 Points	—	—
CTP class C	10–15 Points	—	—

The AJCC/UICC seventh edition TNM staging system ([Table 2](#)) is a modification of sixth edition, which was based on a study from the International Cooperative Study Group on Hepatocellular Carcinoma that included data from the United States, Japan, and France who all underwent surgical resection.¹⁰⁰ A major strength of the AJCC/UICC staging system was the use of centralized pathological review. Although the AJCC/UICC staging system was developed using a cohort dominated by hepatitis C-related HCC, it has also been independently validated in a Chinese cohort with a high prevalence of hepatitis B.¹⁰¹ Recently, a new international multicenter study reported that microvascular invasion or tumor differentiation does not affect the surgical outcomes in small HCC measuring up to 2 cm, and this specific group of patients can be classified as a new subset of patients associated with good prognosis.¹⁰²

Table 2 American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) seventh edition staging system for hepatocellular carcinoma.⁹⁷

<i>T classification</i>	
T1	Solitary with no vascular invasion
T2	Solitary with vascular invasion or multifocal ≤5 cm
T3a	Multiple tumors >5 cm
T3b	Single tumor or multiple tumor of any size involving a major branch of the portal or hepatic vein
T4	Invasion of adjacent organs or perforation of visceral peritoneum
<i>Stage grouping</i>	
Stage I	T1N0M0
Stage II	T2N0M0
Stage IIIA	T3aN0M0

Treatment

The choice of therapy for HCC is individualized based on the tumor burden, degree of underlying liver disease, patient performance status, and the overall possibility of side effects or complications balanced with acceptable results. BCLC staging system⁹⁴ is widely used to adequately stratify patients for specific therapies ([Figure 5](#)). However, the limitation of BCLC algorithm is that it is fairly conservative with regard to the application of surgical therapy ([Figure 5](#), red color). Patients with larger solitary tumors are not considered as surgical candidates despite a growing experience with resection with acceptable outcomes ([Figure 6](#)) in this group.^{102–104} Investigators have acknowledged that the BCLC algorithm limits resection criteria, and a modified BCLC algorithm has been proposed as a response to extend the indications for resection of HCC ([Figure 7](#)).¹⁰⁵ Resection guidelines currently used at MD Anderson Cancer center are summarized in [Table 3](#). In the guidelines on liver cancer treatment proposed by the Japan Society of Hepatology,⁹⁹ surgical resection is currently indicated for CTP class A or class B patients with HCC ≤ 3 nodules irrespective of the size of each tumor, whereas liver transplantation is limited only for CTP class C patients meeting with the Milan criteria. Selection of treatment should be determined in a multidisciplinary approach considering the local expertise. However, the most effective treatment including surgical resection, radiofrequency ablation (RFA), and orthotopic liver transplantation (OLT) should be the first priority as long as such treatments are permitted.

Table 3 MD Anderson Cancer Center liver resection criteria in patients with hepatocellular carcinoma

<i>Minor resection</i>	
Child Pugh	A
Bilirubin	≤1.0 mg
Ascites	Absence
Platelets counts	>100,000/mm
<i>Major resection</i>	
Child Pugh	A
Bilirubin	≤1.0 mg
Ascites	Absence
Platelets counts	>100,000/mm
Portal hypertension	Absence
Future liver remnant	>40% or indication for portal vein embolization
Hypertrophy	>5% after portal vein embolization

Surgical resection

For liver resection, strict assessment of hepatic functional reserve is needed for patients with HCC because HCC usually develops in an injured liver, and accordingly, maximum extent of resection is needed to be estimated carefully. Functional investigations have been proposed to better evaluate the

severity of chronic liver disease. The measurement of indocyanine green retention rate at 15 min (ICG-R15) is the most frequently used test. For patients with obstructive jaundice or congenital intolerance to indocyanine green, ^{99m}Tc -galactosyl human serum albumin (GSA) scintigraphy sensitively estimates the hepatic functional reserve.

Liver resection is indicated only for CTP class A or B patients with controllable ascites and serum total bilirubin level of <2.0 mg/dL, and the maximum extent of resection can be determined based on the measurement of ICG-R15.¹⁰⁶ At the University of Tokyo, the maximum extent of resection is set up to 60% (right hepatectomy or trisectionectomy) for patients with ICG-R15 $< 10\%$, up to 50% (left hepatectomy or sectorectomy) for those with ICG-R15 $< 20\%$, segmentectomy for those with ICG-R15 $< 30\%$, and only limited resection is indicated for patients with ICG-R15 $> 30\%$. Following strictly this algorithm, no mortality due to hepatic insufficiency was reported in 1056 consecutive patients.¹⁰⁷ At MD Anderson Cancer Center, portal vein embolization (PVE) has been used to increase the candidacy of HCC patients for major hepatectomy and improve postoperative outcomes and safety.¹⁰⁸ The procedure has shown to be safe and well tolerated with increased survival rates.¹⁰⁹ In fact, PVE has another major benefit in HCC. Most patients with HCC have underlying cirrhosis and it is clinically challenging to assess liver function and make validated treatment decisions, especially when a major liver resection is required. The degree of hypertrophy after PVE is inversely associated with the regenerative potential of the liver. Subsequently, the degree of hypertrophy provides valuable information of potentially missed liver injury: $<5\%$ hypertrophy after PVE is associated with increased mortality after liver resection.¹¹⁰

Orthotopic liver transplantation (OLT)

Liver transplantation is another surgical approach with theoretically higher chance of eradication of tumor burden especially for patients with severe hepatic dysfunction. Clinical outcomes of liver transplantation for HCC were poor in the early era. However, after the landmark study by Mazzaferro et al.,⁸⁹ it has been widely recognized that preferable survival outcomes can be expected in a selected population with limited size and number of HCC (Milan criteria). The selection criteria for transplantation used by Mazzaferro et al.⁸⁹ was tumor diameter of 5 cm or less in patients with single HCC or 3 cm or less if the patient had two or three lesions. Nowadays, this criterion is extended with or without tumor markers or biopsy findings in several high-volume transplant centers.^{111–122}

Locoregional ablation therapies

Image-guided ablation is accepted as the best therapeutic choice for patients with early-stage HCC when surgical options are precluded. Several methods for local tumor destruction have been developed and clinically used over the two decades. RFA has shown superior ablative effect and greater survival benefit compared to conventional percutaneous technique, ethanol injection, in meta-analyses of randomized controlled trials,^{123–127} and is now established as the standard ablative modality. Currently, thermal or nonthermal ablation methods including microwave ablation and irreversible electroporation are under investigation as potential alternatives to RFA.

Transarterial chemoembolization (TACE)

The normal liver receives dual blood supply from the hepatic artery (25%) and the portal vein (75%). HCC exhibits intense neo-angiogenic activity during its progression and is mostly dependent on the hepatic arterial supply. This provides the rationale of using arterial obstruction with or without regional chemotherapy as an effective therapeutic option for HCC. Transarterial therapies are usually considered palliative and should be offered to patients with intermediate stage disease without extra-hepatic

metastases and sufficient hepatic functional reserve. The most commonly used agents for transarterial chemoembolization (TACE) are doxorubicin and cisplatin, followed by epirubicin, and none was found superior to the others in RCTs.^{128, 129} Regarding the embolizing material, gelatin sponge (gelfoam) has conventionally been used. However, it could provide only short-term arterial occlusion up to 2 weeks. Currently, polyvinyl alcohol (PVA) particles are used in many centers, which offer permanent arterial occlusion and also achieves more distal embolization with its small particle size.¹³⁰ Drug-eluting beads have been recently developed to provide a combined local ischemic and cytotoxic effect. Although its superiority to conventional TACE remains controversial, at least equal efficacy and safety compared to conventional TACE have been shown in several studies.^{131, 132}

Systemic treatment

Systemic chemotherapy is commonly the only option for patients with advanced and/or disseminated disease in patients with HCC. For decades, various systemic therapies have been explored for the treatment of advanced HCC. Nevertheless, no satisfactory results have been obtained in cytotoxic chemotherapy so far. Sorafenib is a polyvalent molecule that has been shown in HCC cell line to inhibit the serine-threonine kinase Raf-1 and several receptor tyrosine kinases such as vascular endothelial growth factor receptor (VEGFR2), platelet-derived growth factor receptor (PDGFR), FLT3, Ret, and c-Kit. Two phase III studies: the SHARP trial¹³³ and the Asia-Pacific trial,¹³⁴ respectively, demonstrated survival benefit of sorafenib in patients with HCC, and this is only the biologic agent approved for clinical use in systemic therapy for HCC at present. However, the overall response rate was only 3% and there is no established treatment with sufficient tumor response rate.

Recently, our group has shown that cisplatin/interferon α -2b/doxorubicin/5-fluorouracil (PIAF) combination therapy improves response, resectability, and patient survival in patients with initially unresectable HCC when limiting the indication only for patients with no hepatitis or cirrhosis.¹³⁵ As such, this traditional chemotherapy regimen might provide an option for unresectable HCC developed in noncirrhotic patients ([Figures 8](#) and [9](#)).

Figure 8 Kaplan–Meier plots of survival with initially unresectable HCC ($n = 117$) stratified on treatment with PIAF (cisplatin/interferon $\alpha 2b$ /doxorubicin/5-flourouracil regimen).

(c) After treatment with Platinum Interferon, Adriamycin, 5-flourouracil, and transarterial chemoembolization. (d) After extended left hepatectomy including resection of the caudate lobe and the inferior vena cava. The patient is alive without evidence of disease 8 years after surgery.

Intrahepatic cholangiocarcinoma

Incidence and epidemiology

ICC is the second most common primary hepatic malignancy after HCC. There is considerable geographic variation in the incidence of ICC, with a greater incidence in East Asia.¹³⁶ In the United States, the age-adjusted incidence of ICC increased from 0.32 in 1975 to 0.85 per 100,000 population in 2000 and has yet to plateau.¹³⁷ The overall survival rate in unresectable tumor is dismal, with 5-year survival rate of 5% to 10%. Because systemic therapy for ICC has not yet been established, surgical resection offers the only chance for cure. However, the overall survival after curative-intent surgery is disappointing, with a 5-year survival rate of 20% to 35%.¹³⁸

Risk factors

ICC is thought to derive from a common hepatic progenitor cell that may also give rise to HCC,¹³⁹ and combined hepatocellular-CC having histopathologic features of HCC and ICC is sometimes observed. Risk factors for ICC have not yet been established, although chronic liver disease and cirrhosis are reportedly correlated with ICC.

Predisposing conditions include infections that affect the biliary tract, such as viral hepatitis, *Opisthorchis viverrini*, or *Clonorchis sinensis*, as well as sclerosing cholangitis, the presence of choledochal cysts, hepatolithiasis, or cirrhosis.¹⁴⁰ Because common predisposing conditions are lacking and rarity of tumor, it is difficult to determine target population for routine surveillance to facilitate making an early diagnosis.

Pathology

There are three morphologic subtypes of ICC that can be characterized on cross-sectional appearance: mass forming, periductal infiltrating, and intraductal growth ([Figure 10](#)). Mass-forming type is the most common subtype of ICC. Unlike with HCC, ICC shows invasive tumor growth without tumor capsule. Therefore, when a tumor is attaching to a major vascular structure, microscopic invasion to the vascular wall should be suspected and en-bloc resection is usually needed.

Figure 10 Gross classification of intrahepatic cholangiocarcinoma.

Source: Adapted from Liver Cancer Study Group of Japan 2008.

Diagnosis

On dynamic imaging studies, ICC is not enhanced owing to its hypovascular nature. However, various degrees of ring enhancement are observed surrounding the lesion, reflecting the fibrous connective tissue frequently observed around the tumor ([Figure 11](#)). In laboratory test, elevation of CEA or CA19-9 in primary solid liver lesion is suggestive of ICC.

Figure 11 (a) Typical ring enhancement in enhanced CT scan and (b) gross appearance of intrahepatic cholangiocarcinoma.

Staging

Until the sixth edition, AJCC classification system for ICC was the same with that for HCC. In the 7th edition, however, an original staging system was adopted ([Table 4](#)) based on the survival outcomes of 598 patients who underwent liver resection of ICC from the SEER database.¹⁴¹ This revised staging system has been validated externally and independently by the French Surgical Association (AFC)-IHCC 2009 study group.¹⁴²

Table 4 American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) seventh edition staging system for intrahepatic cholangiocarcinoma.⁹⁷

<i>T classification</i>	
Tis	Carcinoma <i>in situ</i>
T1	Solitary tumor without vascular invasion
T2a	Solitary with vascular invasion
T2b	Multiple tumors, with or without vascular invasion
T3	Tumor perforating the visceral peritoneum or involving the local extrahepatic structures by direct invasion
T4	Tumor with periductal invasion
<i>Stage grouping</i>	
Stage 0	TisN0M0
Stage I	T1N0M0
Stage II	T2N0M0
Stage III	T3N0M0
Stage IVA	T4N0M0 or Any T N1 M0
Stage IVB	AnyT Any N M1

Treatment

For ICC, only surgical resection offers a chance of cure because there are no established other curative treatment options. Surgical treatment for ICC involves hepatectomy, extrahepatic bile duct resection, and systematic nodal dissection according to the extent of tumor. Significance of systematic nodal dissection remains controversial. However, nodal involvement is a significant prognostic factor for ICC,¹⁴¹ and it has been reported that up to 30% of patient will have lymph node metastases.¹⁴³

OLT for the treatment of CC has been reported with 5-year survival rates of 23%, with a median time to recurrence of 9 months,¹⁴⁴ both of which are significantly poor and insufficient compared to HCC. However, it has been reported that OLT in combination with neoadjuvant chemoradiation has 1-, 3-, 5-year survival rates of 92%, 82%, 82% compared to 82%, 48%, 21% with resection alone,¹⁴⁵ and OLT might be advantageous in selected patients.

For patients with advanced ICC, systemic chemotherapy has made some progress in the past decade. The response rate to single-agent 5-fluorouracil-based or gemcitabine-based systemic therapy is only about 10% to 30%.^{146, 147} The ABC-02 phase 3 randomized controlled trial, which studied 510 patients who had locally advanced or metastatic biliary tract cancer, has shown that the combination of gemcitabine plus cisplatin demonstrated improved progression-free survival and overall survival (11.7 vs 8.1 months) compared with gemcitabine alone,¹⁴⁸ and nowadays, doublet therapy with gemcitabine and cisplatin is considered the standard-of-care, first-line treatment for patients who have advanced cancer of the bile ducts and gallbladder. Recently, there has been growing interest in examining novel, targeted anticancer agents based on an existing understanding of the molecular carcinogenesis of biliary tract cancers.¹⁴⁰

Hepatic angiosarcoma

Hepatic angiosarcoma is a rare tumor derived from the malignant transformation of hepatic endothelial cells, and close association with environmental carcinogens such as thorotrast (contrast agent used in 1940s and 1950s), vinyl chloride, arsenicals, and androgenic-anabolic steroids has been reported. Because no clear etiology or association with chronic liver disease has been identified, hepatic angiosarcoma is usually advanced at the time of diagnosis. Although complete surgical resection or OLT may provide a chance of prolonged survival, prognosis is generally poor even after liver transplantation.¹⁴⁹ The efficacy of chemotherapy has not been well documented for this tumor.

Epithelioid hemangioendothelioma

EHE is a very rare, low-grade malignant neoplasm of endothelial origin with a reported incidence of <0.1 per 100,000 people.¹⁵⁰ EHE presents heterogeneous clinical features, nonspecific radiological characteristics, and a variable natural history.¹⁵¹ The management options for EHE include liver resection, OLT, chemotherapy, and radiotherapy. However, it is difficult to compare the clinical outcomes among these therapeutic options because of the rarity of the disease. Favorable outcomes have been reported after liver resection for EHE, with 1- and 5-year survival rates of 100% and 75%, respectively.¹⁵² However, owing to frequent diffuse presentation of the disease, liver resection is unsuitable in majority of the cases. The result of OLT is also encouraging with 1- and 5-year survival rates of 96% and 54.5%, respectively. A recent study has also shown favorable long-term outcomes after OLT with 5- and 10-year survival rates of 83% and 74%, irrespective of the presence of nodal involvement or extrahepatic disease.¹⁵³ Owing to the indolent nature of the disease, a recent study

concluded that initial observation followed by resection or OLT in the patients who remained candidates for surgery could be beneficial to stratify treatment options.¹⁵⁴ However, because of the rarity of the disease, strong evidence-based management strategies are difficult to establish and large multicenter prospective trials maybe necessary for improved understanding of EHE.

Chapter 92

Gallbladder and bile duct cancer

Ahmed O. Kaseb, MD ■ Marc Uemura, MD ■ Melanie B. Thomas, MD, MS ■ Steven A. Curley, MD, FACS

Overview

Primary gallbladder and bile duct cancers are relatively rare tumors of the gastrointestinal tract. Both are mainly adenocarcinomas that start as abnormal growths within the mucous lining of the gallbladder and bile ducts. Bile duct tumors, or cholangiocarcinomas, are further differentiated by their location within the liver (intrahepatic) or outside the liver (extrahepatic). Both tumor types have distinct pathophysiologies and modes of hepatocarcinogenesis. Gallbladder cancers, for example, are associated with gallstones, chronic cholecystitis, and the porcelain gallbladder. They are commonly found incidentally on cholecystectomy specimens. On the other hand, cholangiocarcinomas have frequent associations with parasitic infections and other diseases causing chronic inflammation in the bile ducts (primary sclerosing cholangitis). While both gallbladder and cholangiocarcinomas can be cured if surgically resected, unresectable or advanced tumors have a poor prognosis and usually require systemic chemotherapy.

Gallbladder cancer

Adenocarcinoma of the gallbladder is the sixth most common digestive system malignancy in the United States. In Western countries such as the United States, where there is a lower incidence of hepatocellular carcinoma (HCC), gallbladder cancer is relatively more common. The American Cancer Society estimates that about 10,910 new cases of gallbladder cancer and bile duct cancer (excluding bile ducts within the liver) would be diagnosed in 2016 in the United States. About 3700 people died of these cancers in 2015. Of these new cases and deaths, about half are due to gallbladder cancer.¹ Between 1980 and 1995, mortality rates from gallbladder cancer decreased in the United States, Canada, Australia, and the United Kingdom, while increasing in Japan, Italy, Spain, and Chile.² Unlike HCC and cholangiocarcinoma, gallbladder carcinoma has a higher incidence in females than in males.² The preponderance of this cancer in females is even greater in patients <40 years old, with a female-to-male ratio of 20 : 1.³

Gallbladder carcinoma is more common in Southwest Native Americans than in the general American population. Incidence rates for U.S. white males, black males, and Native American males in New Mexico are 0.4, 0.6, and 3.8 cases per 100,000 per year, respectively. The corresponding rates for females are 1.0, 0.8, and 10.3.² Gallbladder carcinoma has been found in 6% of Southwest Native Americans undergoing biliary tract surgery.⁴ Gallbladder carcinoma is the second most common gastrointestinal malignancy in this population, and the youngest reported case of gallbladder carcinoma occurred in an 11-year-old Navajo girl.⁵

Other human populations also have an increased incidence of gallbladder cancer. In Chile, the incidence of gallbladder cancer is rising, and gallbladder cancer is the number one cause of cancer mortality in

Chilean women.⁶ The geographic and population-based variations in the incidence of gallbladder cancer suggest that environmental risk factors, including carcinogens, infectious agents like *Salmonella typhi* and *Helicobacter pylori*, and diet have a role in gallbladder tumorigenesis.

Causative factors

There are no apparent associations between gallbladder carcinoma and hepatitis B or C virus infection, cirrhosis, or mycotoxin exposure. Similarly, chemical hepatocarcinogens have not been clearly demonstrated to increase the risk of developing gallbladder carcinoma. However, there are suggestions that workers exposed to carcinogenic substances, such as methylcholanthrene and nitrosamines, have a higher incidence and earlier onset of gallbladder carcinoma when compared with control populations.⁷ There is a significant association between gallstones and gallbladder carcinoma, with gallstones present in 74–92% of patients with gallbladder carcinoma.^{8,9} The risk of developing gallbladder carcinoma increases directly with increasing gallstone size.¹⁰ Patients with gallstones 2.0–2.9 cm in diameter have a 2.4 times higher relative risk of developing gallbladder carcinoma, whereas patients with gallstones greater than 3.0 cm in diameter have a 10.1 times higher risk. Patients with long-standing chronic cholecystitis can develop calcification of the gallbladder wall, also known as porcelain gallbladder. It is possible that chronic inflammation and/or infection of the gallbladder increases the risk of developing gallbladder carcinoma because 22% of patients with calcified gallbladders have gallbladder carcinoma.¹¹ Furthermore, pathogenic bacteria are cultured from the gallbladders of patients with gallbladder cancer at a significantly greater frequency than from patients with simple cholelithiasis.¹² Cholelithiasis and cholecystitis are more common in females, which may in part explain the higher incidence of gallbladder carcinoma in females.¹³

Patients with these premalignant lesions may progress to invasive gallbladder carcinoma. Epithelial dysplasia, atypical hyperplasia, and carcinoma *in situ* have been identified in the gallbladder mucosa of 83%, 13.5%, and 3.5%, respectively, of patients undergoing cholecystectomy for cholelithiasis or cholecystitis.¹⁴ Areas of mucosal dysplasia can be observed in >90% of patients with invasive gallbladder carcinoma.¹⁵ There is also evidence that adenomatous polyps arising from the gallbladder mucosa are premalignant lesions. A review of 1605 cholecystectomies reported 11 benign adenomas, 7 adenomas with areas of malignant transformation, and 79 invasive gallbladder carcinomas.¹⁶ There appears to be an increased expression of epithelial growth factors and proto-oncogene, particularly *ras*, in the progression from chronic cholecystitis to dysplasia and then to invasive carcinoma.¹⁷ In patients with anomalous pancreaticobiliary ductal union, a condition known to be associated with an increased risk of developing gallbladder cancer, chronic inflammation results in hyperplasia of the gallbladder epithelium.¹⁸ *K-ras* mutations were noted in some of these patients with high-grade dysplasia, suggesting that mutations in this proto-oncogene may be an early event in gallbladder mucosal proliferation leading to carcinogenesis. Previous studies performed in patients with invasive gallbladder carcinoma have demonstrated that the majority have abnormal or mutated tumor suppressor (*p53* and *p16*), cell cycle regulation (cyclin E), and apoptosis regulation (Bcl-2) genes, as well as increased expression of angiogenesis factors (VEGF).^{19,20} More recently, comprehensive genomic profiling has shown that invasive gallbladder carcinomas have alternations in other proteins necessary for cell cycle regulation (CDKN2B), chromatin remodeling (ARID1A), and in important growth pathways, specifically epidermal growth factor receptor family (ERBB2) and PIK3CA/MTOR.²¹

Pathology

The gross appearance of gallbladder carcinoma varies, depending on the stage of the disease and extent of spread. Early-stage lesions that have not infiltrated through all layers of the gallbladder wall may be indistinguishable from chronic cholecystitis. Occasionally, a sessile or pedunculated tumor is present and suggests the diagnosis of a gallbladder carcinoma.²² More advanced gallbladder carcinomas are grossly evident by infiltration into the liver or contiguous organs, such as the duodenum or stomach.²³

Microscopically, >90% of gallbladder carcinomas are adenocarcinomas, with the remaining cases being adenosquamous, squamous, anaplastic carcinomas, and, rarely, carcinoid tumors or embryonal rhabdomyosarcoma.^{8, 22} Carcinoma *in situ* is an early lesion, with the malignant cells involving only the mucosal layer of the gallbladder wall. Gallbladder adenocarcinomas generally have a predominant papillary or tubular arrangement of cells.²² Papillary adenocarcinoma is characterized by an extended stroma covered by columnar cells. The tubular formations of tubular adenocarcinoma may be lined by tall columnar cells or by cuboidal epithelium. Mucin production and signet ring cells can be identified frequently in gallbladder adenocarcinomas.²² More poorly differentiated carcinomas have solid sheets or nests of small, scattered cells infiltrating into the stroma and destroying the normal gallbladder wall architecture. Vascular, lymphatic, and perineural invasion by the carcinoma can be demonstrated frequently.

Advanced locoregional disease usually is present at the time of diagnosis of gallbladder carcinoma. Only 10% of patients with this disease have cancer confined to the gallbladder wall.⁸ Direct extension of the carcinoma into the gallbladder fossa of the liver is present in 69–83% of patients.^{23–25} Direct invasion of the liver usually indicates the presence of other regional disease because fewer than 12% of patients with liver involvement have no other sites of regional disease. Direct invasion of the extrahepatic biliary tract occurs in 57% of cases; the duodenum, stomach, or transverse colon is involved in 40%; and the pancreas is involved in 23%. The hepatic artery or portal vein is encased by tumor in 15% of patients. Regional lymph node metastases in the cystic, choledochal, or pancreaticoduodenal lymphatic drainage basins are present in 42–70% of patients.²³ More distant lymph node metastases occur along the aorta or inferior vena cava in approximately 25% of cases. Importantly, lymph node metastases can occur in the absence of liver or other contiguous organ involvement by the gallbladder carcinoma.

The pattern of lymph node metastases from gallbladder carcinoma is predictable on the basis of anatomic studies that have identified three pathways of lymphatic drainage of the gallbladder ([Figure 1](#)).²⁶ The main pathway is the cholecysto-retropancreatic pathway, with lymphatic vessels on the anterior and posterior surfaces of the gallbladder that converge at a large retroportal lymph node. This principal retroportal lymph node communicates with the choledochal and pancreaticoduodenal lymph nodes. The cholecysto-celiac pathway consists of lymphatics from the anterior and posterior walls of the gallbladder that run to the left in front of the portal vein and then communicate with groups of pancreaticoduodenal lymph nodes or aorticocaval lymph nodes lying near the left renal vein. The final pattern of spread of gallbladder carcinoma is related to vascular invasion. Noncontiguous liver, pulmonary, and bone metastases have been found in 66%, 24%, and 12% of gallbladder carcinoma patients, respectively.²³

Figure 1 Patterns of lymphatic drainage from the gallbladder. (A) The main pathway of lymphatic drainage and, thus, lymph node metastasis from gallbladder cancer is to the cholecysto-retropancreatic nodes. This pathway drains from the gallbladder to nodes along the cystic duct and common bile duct and then to nodes posterior to the duodenum and pancreatic head. (B) The cholecysto-celiac pathway courses from the gallbladder through the gastrohepatic ligament to celiac nodes. (C) The third lymphatic drainage route is the cholecysto-mesenteric pathway, coursing from the gallbladder posterior to the pancreas to aortocaval lymph nodes.

The staging systems used for gallbladder carcinoma are based on the pathologic characteristics of local invasion by the tumor and lymph node metastases. Before the American Joint Cancer Committee (AJCC) developed a tumor-node metastasis (TNM) staging schema for gallbladder carcinoma, the Nevin and colleagues staging system was used frequently.²⁷ Studies of gallbladder carcinoma performed in Japan generally apply the staging system of the Japanese Society of Biliary Surgery.²⁸ Most recent studies stage patients according to the TNM criteria. Carcinoma *in situ* corresponds to a T1aN0M0 tumor in the AJCC staging system. The characteristics of these three staging systems are outlined in [Table 1](#).

Table 1 Comparison of the three most commonly used staging systems for gallbladder carcinoma

Stage	Nevin	JSBS	AJCC-TNM
I	Cancer confined to the mucosa	Cancer confined to subserosal layers	T1aN0M0, T1bN0M0
II	Cancer involves the mucosa and muscularis	Direct invasion of the liver and/or bile duct, porta hepatis lymph node metastases	T2N0M0
III	Cancer extends through the serosa (all three layers of the gallbladder wall involved)	More extensive liver invasion by cancer, more extensive regional lymph node metastases (gastrohepatic, retropancreatic)	T1N1M0, T2N1M0, T3AnyNM0
IV	Tumor extends through all three layers of the gallbladder wall with cystic lymph node metastasis	Liver, peritoneal, and/or distant organ metastases	T4AnyNM0, any TAnyNM1
V	Tumor invades the liver by direct extension and/or metastasis to any distant organ	No stage V	No stage V

Abbreviations: AJCC, American Joint Committee on Cancer; JSBS, Japanese Society of Biliary Surgery; T, primary tumor; Tx, primary tumor cannot be assessed; T1, tumor invades mucosa or muscle layer; T1a, tumor invades mucosa; T1b, tumor invades muscle; T2, tumor invades perimuscular connective tissue, no extension beyond serosa or into liver; T3, tumor invades beyond serosa or into one adjacent organ or both (extension <2 cm into liver); T4, tumor extends >2 cm into liver and/or into two or more adjacent organs (stomach, duodenum, colon, pancreas, omentum, extrahepatic bile ducts); N, regional lymph nodes; Nx, regional lymph nodes cannot be assessed; N0, no regional lymph node metastasis; N1, regional lymph node metastasis; N1a, metastasis in cystic duct, pericholedochal, and/or gastrohepatic lymph nodes; N1b, metastasis in peripancreatic, periduodenal, periportal, celiac, and/or superior mesenteric artery lymph nodes; M, distant metastasis; Mx, presence of distant metastasis cannot be assessed; M0, no distant metastasis; M1, distant metastasis.

Clinical presentation

The most common symptoms and signs in patients with gallbladder carcinoma are nonspecific. Right upper quadrant abdominal pain, which may or may not be exacerbated by eating a fatty meal, is the predominant presenting complaint in 75–97% of patients.^{2, 8, 29} Right upper quadrant abdominal tenderness is present in a slightly smaller percentage of patients. These symptoms and signs usually are ascribed to cholelithiasis or cholecystitis. Nausea, vomiting, and anorexia are present in 40–64% of patients; clinically evident jaundice is present in 45%; and weight loss greater than 10% of normal body weight is noted in 37–77%.

Although 45% of patients are jaundiced at presentation, 70% of patients present with a serum bilirubin elevated at least two times greater than normal.²⁹ Serum alkaline phosphatase levels are elevated in two-thirds of patients with gallbladder carcinoma. Alanine aminotransferase and aspartate aminotransferase levels are elevated in one-third of patients and are consistent with advanced hepatic invasion and metastases. In these patients with TNM stage III or IV disease, the serum CEA level is elevated in >80% of patients.²⁹ The incidence of elevated serum CEA levels in early-stage disease is not known.

Diagnostic studies

Before ultrasonography and CT (computerized tomography) became widely available, the preoperative diagnosis rate for gallbladder carcinoma was only 8.6–16.3%.² Ultrasonography is the primary imaging study for symptomatic patients with presumed cholelithiasis or choledocholithiasis. High-resolution

ultrasonography is able to detect early and locally advanced gallbladder carcinoma.³⁰ An early tumor as small as 5 mm can be recognized as a polypoid mass projecting into the gallbladder lumen or as a focal thickening of the gallbladder wall.³¹ In patients with locally advanced gallbladder carcinoma, ultrasonography can demonstrate extrahepatic and intrahepatic bile duct obstruction, porta hepatis lymphadenopathy, direct hepatic extension of tumor, and hepatic metastases. Preoperative ultrasonography may suggest the correct diagnosis in up to 75% of patients with gallbladder carcinoma.^{31, 32} However, ultrasonography does not accurately detect celiac or paraortic lymphadenopathy or peritoneal tumor dissemination.³³ Blood flow studies with color Doppler ultrasonography are also useful because gallbladder cancers have high-velocity arterial flow in 90% of cases, while benign lesions have minimal flow.³⁴ Recent advances in endoscopic ultrasonography, including the use of contrast-enhancing agents, may improve the diagnostic accuracy in assessing the T stage of the gallbladder cancer.³⁵

CT scans are performed less frequently in patients with presumed benign biliary tract disease. However, if gallbladder carcinoma is suspected, CT findings can correctly predict the diagnosis in 88–95% of patients.^{36, 37} The CT characteristics of gallbladder carcinoma include diffuse or focal gallbladder wall thickness of greater than 0.5 mm in 95% of patients, gallbladder wall contrast enhancement in 95%, intraluminal mass in 90%, direct liver invasion by tumor in 85% ([Figure 2](#)), regional lymphadenopathy in 65%, concomitant cholelithiasis in 52%, dilated intrahepatic or extrahepatic bile ducts in 50%, noncontiguous liver metastases in 12%, invasion of contiguous gastrointestinal tract organs in 8%, and intraluminal gallbladder gas in 4%.³⁶ CT can also demonstrate calcification of the gallbladder wall ([Figure 3](#)).

Figure 2 High-resolution, helical CT scan in a patient with gallbladder carcinoma. Direct tumor invasion into the hepatic parenchyma is evident.

Figure 3 A high-resolution, helical CT scan in another patient with gallbladder cancer. A locally invasive tumor is again noted with areas of calcification (arrow) seen in the thickened gallbladder wall.

Treatment

Resection

The curative resection rates for gallbladder carcinoma range from 10% to 30%.³⁸ The majority of patients are not candidates for curative resection because of extensive locoregional disease, noncontiguous liver metastases, and/or distant metastases. Although it is clear that long-term survival can be achieved in some patients with resectable lesions, the extent of resection remains a controversial issue.

Simple cholecystectomy is an adequate therapy for gallbladder carcinoma confined to the mucosa (T1aN0M0). The 5-year survival rate for patients undergoing simple cholecystectomy for disease confined to the mucosa ranges from 57% to 100%.^{39, 40} However, employing simple cholecystectomy as the sole therapy for patients with T1aN0M0 tumors is not universally agreed upon. Some authors recommend that extended cholecystectomy (cholecystectomy, wedge resection of the gallbladder fossa including a 3–5 cm margin of normal liver, and a cystic, pericholedochal, gastrohepatic, pancreaticoduodenal, and paraortic lymphadenectomy) be performed to treat patients with these very early-stage lesions.^{41, 42}

These authors recommend that all gallbladders be opened at the time of cholecystectomy for frozen section evaluation of any suspicious areas in the mucosa. If an unsuspected gallbladder carcinoma is diagnosed by frozen section biopsy or if a T1aN0M0 gallbladder carcinoma is diagnosed on final pathology, these authors advocate that an extended cholecystectomy be performed. The bias for this aggressive surgical treatment of T1aN0M0 gallbladder carcinoma is based on the small number of cases of regional lymph node recurrence in patients treated with simple cholecystectomy alone. No rationale is provided for the liver resection because the small number of patients who did fail after simple cholecystectomy developed metastases in the pericholedochal or cystic lymph nodes and not in the liver. Furthermore, the incidence of subsequent lymph node metastases in T1aN0M0 patients was <10% in the small groups of 32 and 36 patients, respectively.^{41, 42} The incidence of lymph node metastases in 201 patients with gallbladder carcinoma confined to the mucosa was only 2.5% in a study of patients who underwent cholecystectomy and regional lymphadenectomy.³⁹ The mortality rate for extended resection ranges from 2% to 5%, and major postoperative morbidity occurs in 13–40%.^{39, 40, 43} Therefore, the morbidity and mortality associated with extended cholecystectomy is excessive compared with the

potential survival benefit that would occur in <5% of patients with T1aN0M0 lesions.

There is a rationale for performing extended cholecystectomy in patients with T1b tumors or AJCC-TNM stage II and III gallbladder carcinomas ([Figure 4](#)). In 165 patients with T1b gallbladder carcinomas, there was a 15.6% incidence of regional lymph node metastasis.³⁹ Of 867 patients with a T2 primary lesion, 56.1% had regional lymph node metastases.³⁹ The 453 patients with T3 tumors had a 74.4% incidence of regional lymph node metastases. The 5-year survival rate following extended cholecystectomy for AJCC stage II and III gallbladder carcinoma ranges from 7.5% to 71%.^{39, 40, 43, 44} Regional lymph node metastases and/or direct tumor invasion of the hepatic parenchyma are indicators of poor prognosis, with significant reductions in 5-year overall survival rates associated with these pathologic findings.^{45, 46} Microscopically positive liver resection margins also have a negative impact on survival because these patients had a median survival of 8.9 months compared with 67.2 months for patients with tumor-free margins.⁴⁵ Preoperative helical CT scans and intraoperative ultrasonography are used to assess the extent of direct invasion into the hepatic parenchyma, which assists with decision making regarding the extent of liver resection necessary to clear all disease. If adequate tumor-negative resection margins are attained, the radicality of liver resection does not affect survival, as attested by similar long-term survival rates following right lobectomy, extended right lobectomy, right trisegmentectomy, and central bisegmentectomy for gallbladder cancer.^{39, 40, 47–49} T1b patients are classified as stage I in the AJCC system, but, arguably, with a 15.6% incidence of regional lymph node metastases, long-term survival benefit may occur in a significant number of these patients who undergo an extended cholecystectomy ([Figure 4](#)).

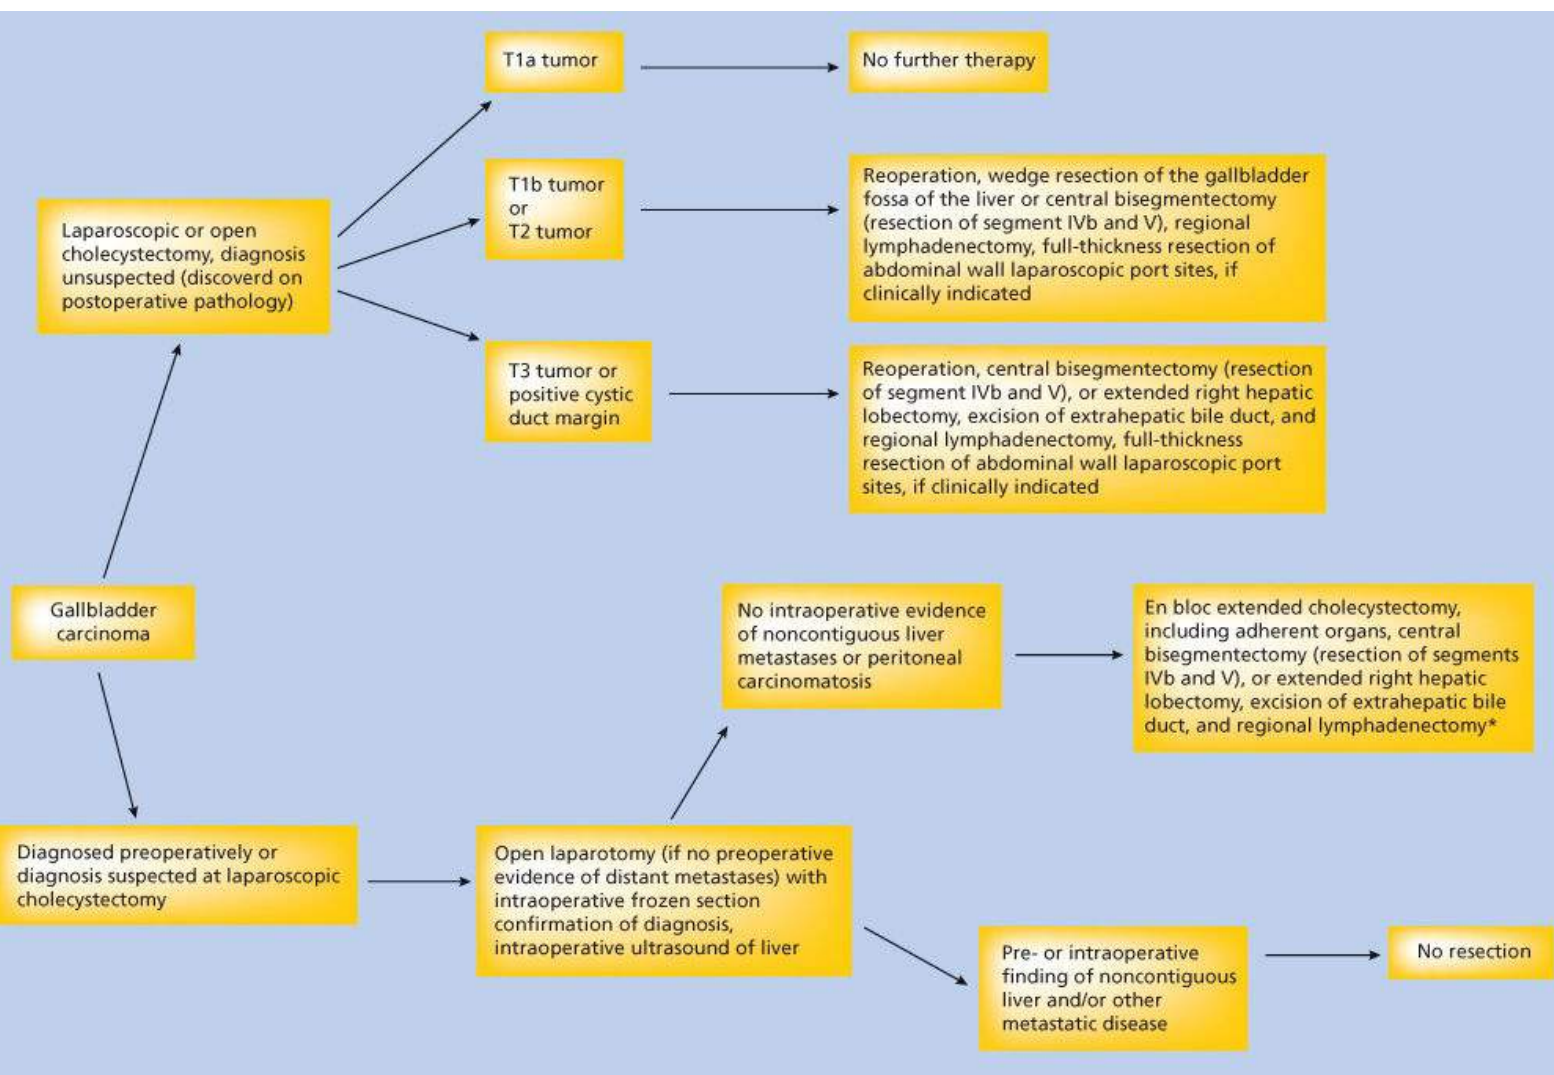

Figure 4 Algorithm to guide surgical decision making for patients with gallbladder cancer. *Regional lymphadenectomy includes complete dissection and removal of the cystic, pericholedochal, pancreaticoduodenal, gastrohepatic, and paraortic lymph nodes.

All authors do not perform an en bloc resection of the extrahepatic bile duct as part of an extended cholecystectomy. Because gallbladder carcinoma is found to invade the extrahepatic bile duct in 57% of cases, with almost all cases occurring in patients with T3 or T4 tumors, an en bloc resection of the proper hepatic and common bile ducts with Roux-en-Y hepaticojejunostomy should be included in an extended cholecystectomy of transmurally invasive tumors. This includes those individuals in whom a clinically unsuspected gallbladder carcinoma is diagnosed pathologically following a simple cholecystectomy with a positive margin at the cystic duct. Gallbladder cancer involving the cystic duct and gallbladder neck frequently grows along the proper hepatic and right bile ducts, necessitating a right or extended right hepatic lobectomy and excision of the extrahepatic ducts to remove all disease.⁵⁰

Extremely radical operations have been proposed for patients with extensive T3N1M0 or T4N01M0 tumors. This includes hepatopancreatic duodenectomy and abdominal organ cluster transplantation for locally advanced gallbladder carcinoma.^{39, 51, 52} The operative mortality rate for these radical procedures is at least 15%, with a greater than 90% incidence of major morbidity. Resection of the portal vein and/or hepatic artery with vascular reconstruction frequently is necessary to resect completely all gross malignant disease. The largest report of patients undergoing hepatopancreatic duodenectomy for gallbladder carcinoma is 150 cases from Japan, with a 5-year survival rate of 14%.³⁹ The patients who did not die from intraoperative or postoperative complications all succumbed to recurrent and/or metastatic carcinoma.

It is estimated that 80,000 laparoscopic cholecystectomies are performed each year in the United States. On average, gallbladder carcinoma is diagnosed in 2% of patients undergoing cholecystectomy for presumed benign biliary tract disease. Thus, approximately 1600 patients who annually undergo laparoscopic cholecystectomy could suffer inadvertent dissemination of gallbladder carcinoma.^{53–56} However, the potential laparoscopic dissemination of tumor cells may not significantly alter the natural history of gallbladder cancer in most patients. A review of our experience at the University of Texas MD Anderson Cancer Center with diagnostic and therapeutic laparoscopy in patients with gastrointestinal malignancies indicated that port site recurrence is a harbinger of widespread metastasis in >95% of patients; thus, it is rarely an isolated site of recurrent malignant disease.⁵⁷ Furthermore, a report drawn from the National Cancer Data Base between 1989 and 1995 revealed no change in incidence or survival from gallbladder cancer during the time laparoscopic cholecystectomy supplanted open cholecystectomy as the procedure of choice for gallbladder disease presumed benign.⁵⁸ Nonetheless, because of the large number of cholecystectomies being performed laparoscopically and the small but measurable risk of dissemination of tumor cells, it has been recommended that (1) unless the surgeon feels capable of performing a definitive extended cholecystectomy for gallbladder carcinoma, patients in whom gallbladder carcinoma is suspected preoperatively by clinical or radiologic criteria should be referred without laparoscopy, laparotomy, or percutaneous biopsy, and (2) if gallbladder carcinoma is suspected on visual inspection during an attempted laparoscopic cholecystectomy, either an open definitive operation should be performed or the operation should be terminated without biopsy and the patient referred for appropriate surgical therapy.⁵³ Patients who underwent laparoscopic cholecystectomy and were then found on pathologic analysis to have gallbladder cancer should still be considered for aggressive surgical treatment because long-term disease-free survival will result in a subset of these patients.⁵⁹

Palliation/chemotherapy

The majority of patients with gallbladder carcinoma are diagnosed at an advanced, unresectable stage of disease. As in patients with hilar bile duct cancer, relief of symptomatic jaundice should be considered. Patients with unresectable gallbladder carcinoma frequently have extensive involvement of the extrahepatic bile duct and may have bulky porta hepatis lymphadenopathy, which makes endoscopic placement of an internal stent difficult. When unresectable gallbladder carcinoma is diagnosed at the time of laparotomy, a surgical biliary bypass, such as an intrahepatic cholangioenteric anastomosis, can be performed and results in significant symptomatic relief in >90% of patients.⁶⁰ When the diagnosis is made on the basis of radiographic and percutaneous biopsy findings, jaundice can be relieved by placement of percutaneous transhepatic biliary catheters.

In contrast to patients with hilar bile duct carcinoma, in whom gastroduodenal obstruction is a relatively rare event, between 30% and 50% of patients with advanced gallbladder carcinoma will develop a clinically significant element of gastroduodenal obstruction.⁶¹ This can be treated surgically with a bypass procedure such as gastrojejunostomy, by endoscopic placement of an expandable metal stent, or by placement of a decompressing gastrostomy tube and feeding jejunostomy tube. A percutaneous endoscopic gastrostomy tube can also be used to decompress the obstructed stomach in patients with advanced disease and limited expected survival time.

Chemotherapy studies that describe the results of chemotherapeutic treatment of unresectable or metastatic gallbladder carcinoma suffer from small numbers of patients and inclusion of patients with hilar bile duct carcinoma. In general, primary treatment options for patients with advanced gallbladder carcinoma include a fluoropyrimidine-based or gemcitabine-based chemotherapy regimen. A study of 53 patients

with gallbladder carcinoma who received systemic chemotherapy with 5-fluorouracil (5-FU) or 5-FU plus other chemotherapeutic agents showed objective antitumor responses in 12% or less of the patients in each treatment arm.⁶² Fluoropyrimidines combined with doxorubicin administered systemically have produced objective response rates of 30–40%.^{63, 64} A meta-analysis of three randomized studies comparing chemotherapy with gemcitabine alone versus gemcitabine plus platinum agents showed improved median overall survival of 3.8 months ($P < 0.001$) and median progression-free survival of 3.3 months ($P < 0.001$) in patients receiving doublet chemotherapy for advanced gallbladder and biliary tract malignancies.⁶⁵ Complete remission is rare and in most studies, median survival is 11 months or less. However, the literature regarding treatment results with specific regimens is limited because most series are small, and many reports consist of a mix of bile duct cancers, gallbladder cancer, and either pancreatic or hepatocellular cancer. More details about systemic treatment options are explained in the cholangiocarcinoma section.

Radiation therapy

Analysis of the patterns of failure after resection of gallbladder carcinoma revealed that local recurrence was the first and, in a significant number of cases, the only site of failure in more than one-half of patients.⁶⁶ External beam radiation therapy (EBRT) to a total dose of 45 Gy can produce radiographic evidence of tumor reduction in 20–70% of these tumors and provide temporary relief of jaundice in up to 80% of patients.^{67–69} In general, EBRT is a palliative treatment. The median survival for locally advanced gallbladder carcinoma patients treated with radiation therapy is approximately 10 months.^{66–69} Occasional long-term survivors are reported following treatment with higher doses of radiation therapy or with administration of radiation-sensitizing chemotherapeutic agents such as 5-FU during EBRT.⁶⁶ However, extrahepatic bile duct stricture has been reported in several of the long-term survivors treated with high doses of radiation therapy.⁷⁰

Multidisciplinary approaches

The majority of patients who undergo an extended cholecystectomy or more radical resection for AJCC stage II, III, or IV gallbladder carcinoma develop tumor recurrence and die as a result of their disease. Nonrandomized studies and case reports have suggested that overall survival can be improved by administering adjuvant radiation therapy and/or chemotherapy after resection of stage II, III, or IV tumors.^{71–73} Unfortunately, the number of patients who have received postsurgical adjuvant treatment is small, and a variety of treatment regimens have been used. In a nonrandomized study, 9 patients with stage IV gallbladder carcinoma were treated with complete surgical resection alone, while 17 patients were treated with complete resection combined with 20–30 Gy of intraoperative radiation therapy.⁷⁴ Ten of these 17 patients also received 36.4 Gy of postoperative EBRT. The surgical procedures performed in both groups of patients included extended cholecystectomy and a variety of more radical procedures, including hepatopancreatic duodenectomy. There were no 3-year survivors among the 9 patients treated with resection alone, but there was a 3-year survivorship of 10.1% in the 17 patients treated with resection and radiation therapy. There is a single report of 18 patients treated with preoperative chemoradiation therapy (4500 cGy, 180 cGy/fraction, 5 days/week, continuous intravenous infusion of 5-FU 350 mg/m²/day on days 1–5 and 21–25) prior to a planned resection of known gallbladder cancer.⁷⁵ Thirteen of the 18 patients underwent resection; one patient refused operation, one patient did not complete preoperative chemoradiation, one patient had disease progression after chemoradiation, and two patients had unresectable disease found at laparotomy. The actuarial 5-year survival rate in the 13 resected patients was 57%.

While most additional literature about postoperative therapy comes from single-institution retrospective reviews, a recently reported nonrandomized phase 2 study evaluated the role of adjuvant chemotherapy and concurrent chemoradiotherapy in 79 patients with a pathologic diagnosis of extrahepatic cholangiocarcinoma or gallbladder carcinoma (but not ampullary cancer) after radical resection, with pathologic stage T2-4 or N1 or positive resection margins.⁷⁶ Patients received four cycles of gemcitabine (1000 mg/m² on days 1 and 8) and capecitabine (1500 mg/m²/day on days 1–14) every 21 days followed by concurrent capecitabine (1330 mg/m²/day) and radiotherapy (RT) (45 Gy to regional lymphatics; 54–59.4 Gy to tumor bed). For all patients, the 2-year survival rate was 65%; it was 67% and 60% in R0 and R1 patients, respectively. Median overall survival was 35 months (R0, 34 months; R1, 35 months).

Furthermore, a recent meta-analysis that included 20 studies involving 6712 patients with resected gallbladder or bile duct cancers did show a nonsignificant survival benefit in patients who received adjuvant chemotherapy or chemoradiotherapy, especially in those with lymph-node-positive disease.⁷¹ However, owing to limited clinical trial data, the optimal adjuvant treatment strategy for patients who have undergone surgical resection for gallbladder carcinoma has not been established.

Bile duct cancer

Cholangiocarcinomas are malignant tumors that arise from the epithelium of the intrahepatic or extrahepatic bile ducts. In the United States, approximately 3000 patients are diagnosed with cholangiocarcinoma of both the intra- or extrahepatic biliary system annually.⁷⁷ There is only a slight male preponderance of cases of cholangiocarcinoma. Cholangiocarcinomas can arise at any site in the intra- or extrahepatic biliary system, but perihilar tumors comprise two-thirds of the cases of cholangiocarcinoma ([Figure 5](#)).⁷⁸

Figure 5 The distribution of 294 cholangiocarcinomas into intrahepatic, perihilar, and distal subgroups.

Causative factors

There are distinct differences between the factors associated with cholangiocarcinoma and those associated with HCC (Table 2). Only 10–20% of cholangiocarcinomas occur in cirrhotic patients, compared with the 70–90% of HCCs that arise in cirrhotic livers.^{77, 79, 80} A cohort study in Denmark of 11,605 patients with cirrhosis indicated a 60-fold increased risk of developing hepatocellular cancer and a 10-fold increased risk of cholangiocarcinoma.⁸⁰ Frequently, the cirrhosis associated with cholangiocarcinomas is a subacute secondary biliary type that results from the neoplastic obstruction of the bile ducts, indicating that, in some cases, cirrhosis in cholangiocarcinoma patients is the result of the tumor rather than its cause.

Table 2 Factors associated with increased risk to develop cholangiocarcinoma versus hepatocellular carcinoma

Cholangio carcinoma	Hepatocellular carcinoma
Liver fluke infection	Cirrhosis
<i>Opisthorchis sinensis</i>	Chronic hepatitis B virus infection
<i>Opisthorchis viverrini</i>	Chronic hepatitis C virus infection
Congenital/chronic cystic dilation	Aflatoxin B1 ingestion of the bile ducts
Choledochal cyst	Chronic ethanol ingestion
Caroli disease	Primary biliary cirrhosis
Hepatoslithiasis	Hemochromatosis
Primary sclerosing cholangitis	α-1-Antitrypsin deficiency
Ulcerative colitis	Glycogen storage disease
Thorotrast exposure	HypercitruUlinemia
Cholelithiasis	Porphyrias
Asbestos	Hereditary tyrosinemia
Dioxin (Agent Orange)	Wilson disease
Polychlorinated diphenyls	Hepatotoxin exposure
Nitrosamines	Thorotrast
Isoniazid	Polyvinyl chloride
Methyldopa	Carbon tetrachloride

Cholangiocarcinoma is more prevalent in Southeast Asia than in other parts of the world. The higher incidence in this geographic region is related to parasitic infection with the liver flukes *Opisthorchis sinensis* and *Opisthorchis viverrini*.^{81, 82} Liver flukes induce hyperplasia, fibrosis, and adenomatous proliferation of human biliary epithelium and are associated with hepatolithiasis. The fluke infestation suggests a direct etiologic role in the subsequent development of cholangiocarcinoma, but this relationship is not established unequivocally.

Several disorders that can produce chronic inflammation of the bile ducts have been associated with an increased risk of developing cholangiocarcinoma. These include polycystic liver disease, choledochal cysts, congenital dilation of the intrahepatic bile ducts (Caroli syndrome), sclerosing cholangitis

(occasionally in association with inflammatory bowel disease), hepatolithiasis, and cholelithiasis.^{83–88} Hepatolithiasis is not a common disorder, and only 5–7% of patients with documented hepatic stones develop cholangiocarcinoma.^{87, 88} The reported incidence of cholangiocarcinoma developing in areas of congenital cystic dilation of the bile duct, including choledochal cysts and Caroli disease, ranges from 3% to 30%.^{89, 90} Patients with primary sclerosing cholangitis are also at increased risk to develop cholangiocarcinoma, with incidence rates ranging from 9% to 40%.^{91, 92} Patients with ulcerative colitis may also develop sclerosing cholangitis, but cholangiocarcinoma occurs in only 0.4–1.4% of individuals with ulcerative colitis.⁹¹ In patients with sclerosing cholangitis, whether associated with ulcerative colitis or not, radiologic distinction between sclerosing cholangitis and cholangiocarcinoma is often impossible. One study showed that the serum tumor marker CA19-9 had an 89% sensitivity and 86% specificity in diagnosing cholangiocarcinoma in patients with sclerosing cholangitis.⁹³ Combining serum CA19-9 levels with serum CEA levels may further increase the diagnostic accuracy to detect cholangiocarcinoma in patients with sclerosing cholangitis.⁹⁴

Patients who underwent diagnostic radiography with intravenous injection of Thorotrast (thorium dioxide) are at high risk of developing HCC, angiosarcoma, and cholangiocarcinoma.⁹⁵ Cholangiocarcinoma is the most frequent hepatic neoplasm reported in patients who have received Thorotrast. Exposure to several drugs or carcinogens has also been linked to an increased risk to develop cholangiocarcinoma ([Table 2](#)). Because cholangiocarcinoma is a relatively rare neoplasm, it has been difficult to prove its pathogenesis related to any of these factors, but it is clear that chronic inflammation of the biliary tree by any cause is associated with an increased risk of developing cholangiocarcinoma.

Chronic inflammation of the biliary system or exposure to genotoxic agents concentrated in bile may produce damage to the DNA of biliary epithelial cells, leading to the development of cholangiocarcinoma. Mutations in the p53 tumor suppressor gene and in the *K-ras* proto-oncogene have been identified in cholangiocarcinoma patients.^{96, 97} There may be geographic and population-based differences in the mutation rates of these two genes in cholangiocarcinoma, but alterations in p53 and *K-ras* are observed in significant proportions of patients with any of the identified factors ([Table 2](#)) that increase risk to develop cholangiocarcinoma. Overexpression of *c-erbB-2*, a proto-oncogene that encodes a transmembrane protein that is highly homologous to epidermal growth factor receptor (EGFR), has been confirmed in human cholangiocarcinoma cells and in benign proliferative biliary epithelium from patients with hepatolithiasis, primary sclerosing cholangitis, and liver fluke infestation.⁹⁸ Alterations in *c-erbB-2* expression may occur early in the chronic inflammation-induced proliferation of biliary epithelium leading to malignant transformation. Chronic inflammation may also produce the overexpression of the *Bcl-2* proto-oncogene observed in cholangiocarcinomas, which may promote tumorigenesis by inhibiting normal apoptotic processes.⁹⁹

Lastly, recent comprehensive genomic profiling has also shown that intra- and extrahepatic cholangiocarcinomas share frequent genomic alterations in cell cycle regulation (*CDKN2B*) and chromatin remodeling (*ARID1A*).²¹ Intrahepatic cholangiocarcinomas are further characterized by *FGFR* fusions, *IDH1/2* (isocitrate dehydrogenase) substitutions, *BRAF* substitutions, and *MET* amplification while extrahepatic cholangiocarcinomas have frequent *PIK3CA/MTOR* pathway alterations.

Clinical presentation

The clinical features of cholangiocarcinoma are nonspecific and depend on the location of the tumor. The usual clinical presentation of patients with hilar cholangiocarcinoma is painless jaundice. Patients may also report concomitant onset of fatigue, pruritus, fever, vague abdominal pain, and anorexia. The serum

liver function tests in patients with hilar cholangiocarcinoma commonly demonstrate obstructive jaundice, with alkaline phosphatase and total bilirubin levels elevated in greater than 90% of patients.⁷⁷ Cholangiocarcinomas that arise in peripheral bile ducts within the hepatic parenchyma usually reach a large size before becoming clinically evident. Patients with these large peripheral hepatic tumors usually present with hepatomegaly and an upper abdominal mass, abdominal and back pain, and weight loss.⁷⁷ Jaundice and ascites are late and usually preterminal sequelae in patients with large intrahepatic cholangiocarcinomas. Jaundice associated with a large hepatic cholangiocarcinoma is caused by a combination of extension of the tumor to the bifurcation of the left and right hepatic ducts, and by compression of the contralateral bile ducts by the expanding tumor.

Serum alkaline phosphatase levels are elevated in >90% of patients with cholangiocarcinoma.⁷⁸ Serum bilirubin also is elevated in the majority of cholangiocarcinoma patients, particularly in those with a tumor arising in the central portion of the liver or the extrahepatic hilar bile ducts.¹⁰⁰ In contrast to HCC, serum α -fetoprotein levels are abnormal in fewer than 5% of cholangiocarcinoma patients.⁷⁸ There is an increase in serum CEA levels in 40–60% of cholangiocarcinoma patients.^{78, 101} Another tumor marker, CA19-9, is elevated in >80% of patients with cholangiocarcinoma.¹⁰¹

Pathology

Cholangiocarcinomas originating in the periphery of the hepatic parenchyma usually are solitary and large, but satellite nodules occasionally are present.¹⁰² Gross tumor invasion of the large portal or hepatic veins occurs much less frequently than in HCC. The gross and microscopic appearance of intrahepatic cholangiocarcinomas may have prognostic significance because tumors with periductal infiltration have a higher incidence of lymph node and intrahepatic metastasis.¹⁰³ Metastases to the regional lymph nodes, lungs, and peritoneal cavity are more common in cholangiocarcinoma than in HCC. When the tumor causes long-standing biliary obstruction, the liver may show secondary biliary cirrhosis.

Microscopically, low cuboidal cells that resemble the normal biliary epithelium characterize cholangiocarcinomas. Varying degrees of pleomorphism, atypia, mitotic activity, hyperchromatic nuclei, and prominent nucleoli are noted from area to area in the same tumor. Rarely, a clear cell variant of cholangiocarcinoma occurs, which must be distinguished from clear cell renal carcinoma with liver metastasis.¹⁰⁴ Cholangiocarcinomas are mucin-secreting adenocarcinomas, and intracellular and intraluminal mucin often can be demonstrated. The presence of mucin is useful in differentiating cholangiocarcinoma from HCC. The absence of bile production by cholangiocarcinoma can also be useful in distinguishing this tumor from HCC. Immunohistochemical staining that is positive for epithelial membrane antigen and tissue polypeptide antigen may be useful in confirming a diagnosis of cholangiocarcinoma.^{105, 106} Immunohistochemical staining for cytokeratin subtypes can be helpful in differentiating cholangiocarcinoma from metastatic colorectal carcinoma.¹⁰⁷ Cholangiocarcinomas are usually locally invasive, which spread along nerves or in subepithelial layers of the bile ducts.

Diagnostic studies

Peripheral intrahepatic cholangiocarcinoma is often difficult to distinguish pathologically and radiographically from a deposit of metastatic adenocarcinoma within the liver. Although transabdominal ultrasonography can detect an intrahepatic malignant tumor greater than 2 cm in diameter, ultrasound findings do not differ between cholangiocarcinomas, liver metastases from extrahepatic adenocarcinomas, and multinodular HCC.¹⁰⁸ CT demonstrates a rounded, low-attenuation mass with irregular or lobulated margins ([Figure 6](#)). Satellite lesions may be evident, particularly when using helical CT during the

optimal period of hepatic contrast enhancement. Calcification within the tumor is present in 25% of cases, and a central scar is observed in 30%.¹⁰⁹ MRI (magnetic resonance imaging) shows a nonencapsulated mass with irregular margins that is hypointense compared with the normal liver on T1-weighted and hyperintense on T2-weighted images. The peripheral rim of the tumor usually enhances following MRI contrast administration. A hyperintense central scar is best seen on T2-weighted images, but the CT and MRI characteristics of intrahepatic cholangiocarcinomas may be present in other types of hepatic tumors.¹⁰⁹

Figure 6 High-resolution, helical CT scan during the arterial contrast phase in a patient with an intrahepatic cholangiocarcinoma. The periphery of the tumor (arrow) has irregular margins and enhances with contrast. A relatively hypovascular area of scar and tumor necrosis is evident in the center of the tumor.

A diagnosis of hilar cholangiocarcinoma should be suspected in the patient with painless jaundice whose CT scan demonstrates dilated intrahepatic bile ducts with a normal gallbladder and an extrahepatic biliary tree. High-resolution, helical CT scans can provide information on the location of an obstructing biliary tumor and may suggest the extent of involvement of the liver and porta hepatis structures by the tumor ([Figure 7](#)). Multiphasic helical CT can correctly identify the level of biliary obstruction by a hilar cholangiocarcinoma in 63–90% of patients.^{110, 111} Preoperative helical CT is also useful in demonstrating lobar or segmental liver atrophy caused by bile duct obstruction or portal vein occlusion ([Figure 8](#)).¹¹¹ However, helical CT is not accurate in assessing the resectability of hilar cholangiocarcinomas because of limited resolution in evaluating intraductal tumor spread and significant false-positive and false-negative rates in demonstrating portal vein or hepatic artery involvement by tumor.^{110, 111}

Figure 7 High-resolution, helical CT scan in another patient presenting with obstructive jaundice. The tumor mass (a), (large arrow) producing marked intrahepatic biliary duct dilatation is evident. Areas of tumor invasion of the portal vein (b), (small arrows) suggested on the CT scan were confirmed at the time of operation to be tumor invasion of the portal vein.

Figure 8 High-resolution, helical CT scan in a patient presenting with several months of increasing pruritus followed by the development of clinically evident jaundice. The relatively hypodense hilar cholangiocarcinoma (large arrow) is evident. Marked atrophy of the left hepatic lobe is noted with dilated intrahepatic bile ducts (small arrow), but little remaining hepatic parenchyma is evident.

Like the CT scan, ultrasonography can demonstrate a nondilated gallbladder and common bile duct associated with dilated intrahepatic ducts. In addition, as grayscale ultrasonography has improved, the diagnosis of cholangiocarcinoma is supported by finding a hilar bile duct mass in 65–90% of patients.¹¹² Ultrasonography and CT scan may be used to demonstrate the presence of intrahepatic tumor due to direct extension or noncontiguous metastases and enlarged periportal lymph nodes, suggesting nodal metastases.¹¹³ Even intraoperative ultrasonography is suboptimal for detecting intraductal spread by hilar cholangiocarcinoma, correctly demonstrating the extent of tumor spread away from the primary biliary

tumor in only 18% of cases.¹¹⁴ Intraoperative ultrasonography can be used to screen for noncontiguous liver metastases from the primary biliary cancer and can accurately detect direct tumor invasion of the portal vein and hepatic artery in 83.3% and 60% of cases, respectively.¹¹⁴

Similar to the intrahepatic variety, hilar cholangiocarcinoma usually shows hypointensity on T1- and hyperintensity on T2-weighted MRI. Dilated intrahepatic bile ducts are evident in patients with obstructing tumors, and lobar atrophy is seen in cases of portal venous occlusion. Fast low-angle shot (FLASH) MR with contrast-enhanced coronal imaging has been used to demonstrate intraluminal extension of tumor and to distinguish between blood vessels and bile ducts.¹¹⁵ Magnetic resonance cholangiopancreatography (MRCP) and MR virtual endoscopy can demonstrate hilar bile duct obstruction by tumor with dilated intrahepatic ducts.^{115, 116} The advantages of MRCP over direct cholangiography include noninvasiveness and possible visualization of isolated bile ducts.

Cholangiography definitively demonstrates a lesion obstructing the left and right hepatic ducts at the hilar confluence ([Figure 9](#)), and percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) are both useful in assessing patients with extrahepatic biliary obstruction. A prospective, randomized comparison of PTC and ERCP in patients with jaundice concluded that the two techniques had similar diagnostic accuracy.¹¹⁷ PTC was 100% accurate in demonstrating obstruction at the confluence of the left and right hepatic ducts, while ERCP had an accuracy of 92% in demonstrating these lesions. ERCP has the additional benefit of providing a pancreatogram. A normal pancreatogram helps exclude a small carcinoma of the head of the pancreas as a cause of biliary obstruction. Cytologic specimens can be obtained at the time of PTC and ERCP. The presence of malignant cells in bile or bile duct brushings is confirmed in approximately 50% of patients undergoing PTC or ERCP.^{112, 117–119}

Figure 9 Endoscopic retrograde cholangiopancreatography showing a focal stricture of the proper hepatic bile duct (arrow) with marked dilatation of the intrahepatic bile ducts. This hilar cholangiocarcinoma was completely resected with Roux-en-Y hepaticojejunostomy reconstruction of biliary-enteric continuity.

Drainage of the obstructed biliary tree with partial or complete relief of jaundice and associated symptoms can be achieved with PTC. Improvements in catheter technology led to the development of endoprotheses that can be placed across the malignant obstruction into the duodenum to allow internal drainage.¹²⁰ It must be emphasized that providing symptomatic relief for patients by decompressing the biliary tract should not be the primary reason to place these catheters. Prospective, randomized studies

have failed to demonstrate a benefit in terms of a decrease in hospital morbidity or mortality by preoperative decompression of biliary obstruction.¹²¹ However, the catheters are useful in identifying and dissecting the hepatic duct bifurcation at the time of operation and aid in the reconstruction of the biliary tract following extirpation of the tumor.^{122, 123}

Positron emission tomography (PET) is being evaluated as a diagnostic tool in patients with all types of malignant tumors. PET assesses *in vivo* metabolism of positron-emitting radiolabeled tracers like [¹⁸F] fluoro-2-deoxy-D-glucose (18FFDG), a glucose analog that accumulates in various malignant tumors because of their high glucose metabolic rates. FDG-PET does not provide anatomic detail to assess resectability of hilar cholangiocarcinomas or intrahepatic malignancies, but it may prove useful in detecting distant metastatic disease that would preclude a curative resection. In patients with primary sclerosing cholangitis, FDG-PET studies may be able to detect small hilar and intrahepatic cholangiocarcinomas and thus may be useful in therapeutic and transplant decision making in these patients.¹²⁴ PET has recently been used to aid in the diagnosis and staging of patients with bile duct cancer.¹²⁵ PET scan images correctly detected the primary cholangiocarcinoma in 24 of 26 patients (sensitivity 92.3%) and was true negative in 8 patients with benign bile duct disease (adenoma, sclerosing cholangitis, Caroli disease). Distant metastatic disease was diagnosed correctly in 7 of 10 patients with histologically proven metastases, but regional lymph node metastases were identified in only 2 of 15 patients (13.3%).

The role of laparoscopy as part of the diagnostic and staging evaluation of patients with hilar cholangiocarcinoma is being evaluated at our institution. Several patients with seemingly resectable tumors have avoided an exploratory laparotomy when peritoneal tumor implants were found with laparoscopy. In addition, positive cytologic specimens obtained from laparoscopic washings may identify patients at high risk of developing peritoneal carcinomatosis. Finally, laparoscopic ultrasonography can be used to exclude the presence of noncontiguous liver metastases or extensive hilar tumor infiltration in patients with extrahepatic bile duct cancers.¹²⁶

Treatment of intrahepatic cholangiocarcinomas

Resection

Intrahepatic cholangiocarcinomas may be detected in 30–45% of patients before they metastasize or cause jaundice.^{127, 128} These patients should be considered for operation because long-term survival has been reported in a proportion of the patients undergoing curative liver resection for intrahepatic cholangiocarcinoma.^{79, 124, 128, 129} A study of 19 patients who underwent resection of intrahepatic cholangiocarcinoma demonstrated that patients with no porta hepatis lymph node metastases had a 3-year survival rate of 64% compared with 0% for patients with nodal metastases.¹²⁴ A larger cohort of 32 patients who underwent resection of intrahepatic cholangiocarcinomas confirmed the negative prognostic impact of regional lymph node metastases and large size (>5-cm diameter) of the primary tumor.¹²⁹ The 5-year overall survival rates reported for patients who underwent a margin-negative liver resection for intrahepatic cholangiocarcinoma range from 20% to 48%, with regional lymph node metastases, presence of satellite tumor nodules, portal vein invasion by tumor, and large tumors identified as a poor-prognosis indicator.^{124, 128, 129} Large size of the primary tumor is a poor-prognosis indicator because of the increased frequency of vascular and lymphatic invasion by the tumor as well as growth along neighboring bile duct walls.¹³⁰

Multidisciplinary approaches

As with gallbladder carcinoma, the optimal adjuvant treatment strategy after surgical resection for intrahepatic cholangiocarcinoma has not been determined owing to lack of clinical trial data. Regardless, adjuvant chemotherapy or chemoradiotherapy can be considered in this setting, especially for patients with positive lymph nodes or surgical margins.⁷¹ For patients with unresectable disease, locoregional therapies like radiofrequency ablation (RFA), transarterial chemoembolization (TACE), drug-eluting bead TACE, EBRT, and transarterial radioembolization (TARE) have all been shown to be safe and effective in small retrospective studies.¹³¹ Recently, 79 patients with inoperable intrahepatic cholangiocarcinoma were treated at MD Anderson Cancer Center with high-dose (ablative) RT. RT doses were 35 to 100 Gy (median 58.05 Gy) in 3 to 30 fractions for a median biologic equivalent dose (BED) of 80.5 Gy (range, 43.75–180 Gy).¹³² Median overall survival was 30 months. Radiation dose was the single most important prognostic factor and higher doses correlated with an improved local control rate and overall survival. The 3-year overall survival rate for patients receiving BED > 80.5 Gy was 73% versus 38% for those receiving lower doses (P 0.017); 3-year local control rate was significantly higher (78%) after a BED > 80.5 Gy than after lower doses (45%, P 0.04).¹³²

In addition, the more traditional approach to unresectable and metastatic disease involves systemic chemotherapy with a fluoropyrimidine or gemcitabine-based regimen. A more detailed discussion of chemotherapy in this setting follows in the treatment section on “Hilar Bile Duct Cholangiocarcinomas”.

Hilar bile duct cholangiocarcinoma

In 1890, Fardel first described a primary malignancy of the extrahepatic biliary tract. A report in 1957 described three patients with small adenocarcinomas involving the confluence of the left and right hepatic ducts.¹³³ Such primary cholangiocarcinomas arising at the bifurcation of the extrahepatic biliary tree are known commonly as Klatskin tumors, following his report in 1965 of a larger series of patients with these lesions.¹³⁴

Prognostic factors

In contrast to reports, the most important factor affecting prognosis is the resectability of the tumor. Patients who undergo curative resection (margin-negative) have 3-year survival rates from 40% to 87% and 5-year survival rates between 10% and 73%.^{60, 135} The wide range of survival rates is explained by variations in the incidence of factors that portend a poor prognosis in the various series. Significant determinants of improved prognosis in patients undergoing curative resection include well-differentiated tumors, absence of lymph node metastases, absence of direct tumor extension into the liver, papillary histology (vs nodular or sclerotic), serum bilirubin at presentation of <9 mg/dL, and a near-normal or normal performance status. Palliative resection, surgical bypass procedures, and various types of intubation and drainage procedures are associated with 3-year survival rates of 0–4%.¹³⁵ Hilar cholangiocarcinomas have a poorer prognosis than do carcinomas arising in the middle or distal thirds of the extrahepatic bile duct, which is related directly to the presentation of hilar tumors at a more locally advanced stage with bilobar liver involvement by tumor and resultant lower rates of curative resection.¹³⁶ However, like hilar cholangiocarcinoma, the presence of regional lymph node metastases reduces the 5-year overall survival rate following resection of middle or distal third bile duct cancer to 21% compared with the 65% survival rate in patients with node-negative disease.

Pathologic features of the bile duct cancer are predictors of outcome after resection. Prognosis is affected adversely if the tumor infiltrates the serosa of the bile duct, invades directly into the liver, demonstrates

vascular invasion, or has metastasized to regional lymph nodes. Histologic type and grade are also important factors. Patients with the relatively unusual papillary bile duct adenocarcinoma have the most favorable prognosis, with 3-year survival rates up to 75%.^{135, 137} Patients with the more common nodular or sclerotic types of hilar cholangiocarcinoma have 3-year survival rates of <30%. A pathologic study that correlated gross tumor type with patterns of spread provides evidence that may explain the observed differences in survival outcomes. Papillary and superficial nodular tumors spread predominantly by mucosal extension, rarely invading the deeper layers of the bile duct wall or lymphatic channels, whereas nodular infiltrating or diffuse infiltrating tumors spread by direct or lymphatic extension in the submucosa.¹³⁸ The distance of mucosal or submucosal spread away from the gross tumor can be as great as 30 mm, but there were no local or anastomotic recurrences if at least a 5-mm tumor-free margin was attained. Patients with well- or moderately differentiated carcinomas have a 3-year survival rate of up to 51%, whereas no patient with a poorly differentiated carcinoma survived longer than 2 years.¹³⁹

Treatment of hilar bile duct cholangiocarcinomas

Resection

Resection of a hilar cholangiocarcinoma affords the patient the best chance for significant survival; however, 5-year survival rates after resection of hilar cancers are 40% in the most hopeful reports and 10% or less in other accounts. Long-term survival rates after resection of middle or distal common bile duct cholangiocarcinomas, the latter requiring pancreaticoduodenectomy, are generally higher compared with hilar tumors.⁷⁸ This is most likely related to higher rates of margin-negative resection with middle or distal extrahepatic bile duct tumors and the absence of direct tumor extension into the liver.

The patterns of failure after curative extrahepatic bile duct resection for hilar cholangiocarcinoma have been described in a few series of patients ([Table 3](#)).¹³⁹ Locoregional tumor recurrence developed in a high percentage of patients, with failure in the liver (62%), tumor bed (42%), and regional lymph nodes (20%). The caudate lobe is the most frequent site of liver recurrence. Regional lymph nodes include porta hepatis, retroduodenal, and perigastric node groups along the gastrohepatic ligament. Distant metastasis develops in the majority of patients who exhibit a locoregional recurrence; however, it was the site of first failure in only 24%.

Table 3 Sites of tumor recurrence after curative resection of proximal hilar cholangiocarcinomas

Site	Frequency (%)
Liver	62
Tumor bed	42
Regional lymph nodes	20
Peritoneum	16
Lungs	71
Bone	31
Skin	7

Detailed anatomic studies have offered an explanation for the high incidence of liver and local recurrence following resection of a hilar cholangiocarcinoma. In a series of 25 patients undergoing surgery for hilar cholangiocarcinoma, direct invasion of hepatic parenchyma at the hilum was noted in 12 patients (46.2%), with 11 patients (42.3%) also having carcinoma extending into the bile ducts draining the

caudate lobe or directly invading the caudate lobe parenchyma.¹⁴⁰ A study of 106 adult human cadavers showed that 97.2% had bile ducts draining the caudate lobe that entered directly into the main left hepatic duct, right hepatic duct, or both. These caudate lobe bile ducts frequently enter the main left or right hepatic ducts within 1 cm of the proper hepatic duct. Thus, a carcinoma arising at the confluence of the right and left hepatic ducts need not be large to extend into the bile ducts draining the caudate lobe.

Because cholangiocarcinoma is known to spread along the wall of the bile ducts and because the caudate lobe and hepatic hilum are frequent sites of tumor recurrence following extrahepatic duct resection, a number of authors now recommend more aggressive resections to include the caudate lobe and hepatic hilar parenchyma.^{141–145} An understanding of the Bismuth–Corlette classification of hilar cholangiocarcinoma is useful in planning the extent and site of liver resection ([Figure 10](#)).¹⁴⁶ The median survival associated with a more radical surgical approach has varied from 10 to 37 months, with 5-year survival rates of 20–44% and 10-year survival rates as high as 14%.^{141–145} Although aggressive surgical resection of hilar cholangiocarcinomas, including hepatic resection, provides the best chance for long-term survival, these operative procedures are associated with significant risk. The operative mortality rate in modern series ranges from 5% to 12%, with postoperative liver failure following an extensive liver resection being the most common cause of death.^{141–145} Surgical complications are reported in 25% to 45% of the surviving patients. Infectious complications are the most common postoperative problem, and preoperative placement of biliary stents with resultant contamination of the obstructed biliary tree increases the incidence of infection.¹⁴⁷

Figure 10 Bismuth–Corlette classification of hilar cholangiocarcinoma. Types I and II can be resected with excision of the extrahepatic bile duct with or without the hilar plate and caudate lobe. Types IIIA and IIIB can be resected with the addition of an en bloc right or left hepatic lobectomy, respectively. Type IV is, by definition, unresectable.

Source: Bengmark 1988.¹⁴² Wolters Kluwer Health, Inc.

A review of patients with extrahepatic cholangiocarcinoma treated at the University of Texas MD Anderson Cancer Center was reported.¹⁴⁸ Of 91 patients evaluated between 1983 and 1996, 51 (56%) presented with unresectable disease and 40 (44%) underwent resection. The median survival for the resected patients was 22.2 months versus 10.7 months in patients with unresectable disease ($P < 0.0001$). Nine patients, five with hilar and four with distal common duct cholangiocarcinoma, were treated with preoperative chemoradiation therapy (continuous intravenous infusion of 5-FU at 300 mg/m²/day combined with external beam irradiation). Three of these nine patients had a pathologic complete

response to chemoradiation treatment; the remaining six patients had varying degrees of histologic response to treatment. The rate of margin-negative resection was 100% for the preoperative chemoradiation group compared with 54% for the group not receiving preoperative treatment ($P < 0.01$). The patients treated with preoperative chemoradiation had no operative or postoperative complications related to treatment. Thus, it appears that neoadjuvant chemoradiation for extrahepatic bile duct cancer can be performed safely, produces significant antitumor response, and may improve the ability to achieve tumor-free resection margins.

Liver transplantation

Total hepatectomy with immediate orthotopic liver transplantation (OLT) has been described in patients with hilar cholangiocarcinoma.^{149–154} The 90-day mortality from hemorrhage, sepsis, and graft rejection was 23.1%. Of the patients who survived <3 months following transplantation, the median survival was 11 months in the series prior to 1992 but has improved to 23 months in the recent series. In the older series of patients, the 5-year survival rate was 5.0%. In patients who died 3 months after transplantation, death was due to tumor recurrence in 85.4%. The 5-year survival rate following OLT for extrahepatic cholangiocarcinoma in current studies is 25%, and in the highly selected subset of patients with stage I or II disease, 5-year survival is 73%. Nonetheless, because of the poor results in most reports, many transplantation centers no longer perform liver transplantations in patients with hilar cholangiocarcinoma. Liver transplantation for hilar cholangiocarcinoma should probably be considered only as part of a prospective protocol evaluating multimodality treatment.

Palliation

In general, curative surgical resection is possible in <30% of patients with hilar cholangiocarcinoma.^{60, 135, 136} In patients deemed unresectable on the basis of the findings of diagnostic studies, laparotomy can be avoided by placing percutaneous external drains or endoscopically placed endoprosthesis.^{155, 156} Conventional 10- or 12-French polyethylene endoprosthesis have a high rate of occlusion and cholangitis.¹⁵⁶ However, new expandable metal wall stents appear to have improved long-term patency rates and may be used to deliver palliative high-dose rate endoluminal brachytherapy.^{157, 158} When unresectability is determined at the time of laparotomy, a decision must be made on a surgical bypass versus an operative intubation to provide drainage of the obstructed biliary tree. It is clear that techniques for surgical bypass, operative intubation, and percutaneous external drainage are equivalent in partial or complete relief of jaundice in 70–100% of patients.⁶⁰ Seemingly, the only potential advantage to the patient who undergoes surgical bypass instead of operative intubation is the absence of an external drainage catheter in the former group. The advantage of not having an external biliary drainage catheter or an internal endoscope is considering the quality-of-life issues related to chemotherapeutic toxicity; systemic chemotherapy has not demonstrated a distinct advantage in patients with hilar cholangiocarcinoma.

Radiotherapy

RT for bile duct cancer is even more confusing because of the various types, doses, routes of administration, and association with resected and unresected tumors, all in small numbers of patients. Internal radiation with ^{16}Ir wires or seeds may have a palliative role in improving the patency of obstructed bile ducts; however, the number and frequency of episodes of cholangitis were not reduced, so the overall benefit is uncertain.¹⁵⁹ Internal radiation has been associated with prolongation of survival to an average of 16 months, and occasionally patients with unresectable disease survived >5 years.^{160–162}

Although the use of EBRT alone to treat patients with unresectable hilar cholangiocarcinoma has not provided significant differences in overall patient survival, rare long-term survivals have been reported.¹⁶³ Intraoperative RT also has been evaluated in association with resectable and unresectable tumors.^{164, 165} Again, there is a suggestion of a slight prolongation of survival in patients with unresectable tumors, but the most interesting use of intraoperative RT may be as an immediate surgical adjuvant in the resected high-risk tumor bed.

Chemotherapy

Given the high percentage of unresectable hilar and intrahepatic cholangiocarcinomas, various chemotherapeutic regimens and radiotherapeutic regimens have been used in the hope of providing improved palliation and prolongation of survival. One early trial suggested a benefit for chemotherapy over best supportive care alone. The study randomly assigned 90 patients with advanced pancreatic or biliary cancer ($N = 37$) to 5-FU-based systemic chemotherapy versus best supportive care alone and reported a median survival of 6.0 months versus 2.5 months, respectively.¹⁶⁶ Thereafter, single-agent gemcitabine was tested in 23 chemotherapy-naïve patients with locally advanced or metastatic biliary tract adenocarcinomas.¹⁶⁷ After a median follow up of 13.4 months, the median time to progression was 8.1 months and overall survival was 13.1 months. This trial supported gemcitabine having clinical benefit in patients with advanced biliary cancers. In general, the more active chemotherapy agents for cholangiocarcinoma now include 5-FU, gemcitabine, capecitabine, cisplatin, and oxaliplatin.¹⁶⁸

Multiple combination chemotherapy regimens have been tested in the hope of improving response over single agents. 5-FU interferon alpha 2b (IFN-a2b) was tested in 35 patients with biliary tract cancer and reported a 34% partial response (11 of 32 patients), a median time to progression of 9.5 months, and a median survival of 12 months.¹⁶⁹ In a study of 75 patients (45 cholangiocarcinoma, 3 ampulla of Vater, and 27 gallbladder), gemcitabine plus capecitabine combination was well tolerated.¹⁷⁰ The study reported a response rate of 29%, median progression-free and overall survival rates were 6.2 and 12.7 months, respectively. In another study of gemcitabine and oxaliplatin (GEMOX) combination, those who had a good performance status of 0–2, bilirubin $<2.5\times$ normal and received GEMOX as first-line chemotherapy ($N = 33$) had a response rate of 33%, a median progression-free survival of 5.7 months, and a median survival of 15.4 months.¹⁷¹

A pooled analysis of 104 trials that included 2810 patients receiving different chemotherapy regimens in advanced biliary cancer concluded that the gemcitabine/cisplatin combination offered the highest rates of objective response and of tumor control (objective response plus stable disease) compared to either gemcitabine-free or cisplatin-free regimens.¹⁷² Unfortunately, this did not translate into significant benefit in terms of either time to tumor progression or median overall survival. The ABC-02 study, which included 410 patients with unresectable or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer, also tested the efficacy of combination gemcitabine/cisplatin versus gemcitabine alone.¹⁷³ In this trial, the combination therapy improved OS (11.7 months vs 8.1 months; HR, 0.64; 95% CI, 0.52–0.80; $P < 0.001$) and PFS (8.0 months vs 5.0 months; HR, 0.63; 95% CI, 0.51–0.77; $P < 0.001$) over gemcitabine alone. The combination therapy was well tolerated and suggested a significant clinical benefit of combination therapy. Thereafter, another study that included 84 patients with advanced biliary cancer reported similar findings with combination gemcitabine/cisplatin.¹⁷⁴ Because of this, gemcitabine/cisplatin remains the first-line chemotherapy regimen for patients with unresectable or metastatic cholangiocarcinoma or gallbladder cancer. Second-line regimens include 5-FU-based or other gemcitabine-based chemotherapy combinations, which are supported by numerous phase II trials.^{175–179}

More recently, several targeted agents have been studied in biliary tract cancers. One study of 42 patients suggested benefit from anti-EGFR by the oral tyrosine kinase inhibitor erlotinib.¹⁸⁰ There were three partial responses and seven patients remained progression-free at 6 months. The latest targeted therapy trial reported on GEMOX with or without cetuximab in 150 patients with advanced biliary cancer.¹⁸¹ Unfortunately, overall survival and progression-free survival were no different in the treatment arms. Multiple other targeted agents, including sorafenib and panitumumab, have been tested in combination with chemotherapy but have not yielded significantly improved results over chemotherapy alone.^{182–186}

Interventional radiology and internal radiotherapy

A combination of external beam plus endoluminal boost irradiation is an attractive treatment program. The favored treatment sequence is to start with external beam irradiation to obtain tumor regression, which provides a better dose distribution from the endoluminal boost irradiation to treat any residual tumor. The use of endoluminal ¹⁷⁰Ir alone for palliative treatment of patients with unresectable hilar bile duct cancers has been reported.¹⁸⁷ Endoluminal doses ranged from 15 to 35 Gy when combined with external beam irradiation (usually 45–50 Gy), or when endoluminal doses of up to 60 Gy were used alone. The dose reference point may vary from 0.5 to 1.0 cm from the central catheter. The total nominal doses of external beam plus endoluminal boost irradiation are between 60 and 70 Gy to the tumor, and although this range exceeds the liver and small intestine tolerance, the highest doses are confined to a small volume of tissue. The median survival for patients treated by this endoluminal method, with or without external beam irradiation, is 15–18 months. Several patients survived for >4 years after treatment; however, the majority of patients had local failure.

Chapter 93

Neoplasms of the exocrine pancreas

Robert A. Wolff, MD ■ Christopher H. Crane, MD ■ Donghui Li, PhD ■ Douglas B. Evans, MD ■ Anirban Maitra, MD ■ Susan Tsai, MD

Overview

Adenocarcinoma of the pancreas is one of the most morbid and lethal malignancies. Worldwide, it accounts for 330,000 deaths annually. Smoking and obesity are both risk factors for pancreatic cancer and current estimates suggest half of all cases may be preventable. Genetic predisposition to pancreatic cancer is associated with some genetic syndromes to include BRCA1 or BRCA2 germline mutations, Peutz–Jeghers syndrome, and hereditary nonpolyposis colon cancer. Somatic mutations in KRAS, CDKN2A/INK4A, TP53, and SMAD4/DPC4 are common. Pancreatic cancer is often diagnosed when the primary tumor is inoperable or there is metastatic spread rendering the cancer incurable. At present, clinical staging defines the malignancy as resectable (and potentially curable), borderline resectable, locally advanced, or metastatic. Surgery with curative intent is possible for patients with resectable disease and for a subset of patients with borderline resectable disease. While chemotherapy has been proved to prolong survival as a component of adjuvant therapy, and as therapy for locally advanced or metastatic disease, the role of radiation therapy in treatment is less-well defined and not universally accepted. Thus far, molecular targeted therapy has shown no clinically meaningful benefit. Adjuvant and neoadjuvant approaches are employed in patients with resectable and borderline resectable disease. Intense research in the molecular biology of pancreatic cancer continues with increasing interest in the role of the tumor microenvironment in invasion, metastatic potential, and resistance. Novel therapeutic strategies that focus on stromal modification and immunologic manipulation are at the forefront of clinical and translational research efforts.

Introduction

In common parlance, the moniker of “pancreatic cancer” most often refers to the entity known as pancreatic ductal adenocarcinoma (PDAC). This is one of the most lethal and morbid of all solid tumors, notorious for local invasiveness, early spread to regional lymph nodes, and vascular dissemination to distant sites. Cure is possible only in the setting of localized, resectable disease with relapse after surgery occurring in about 80% of patients. PDAC is currently the fourth leading cause of cancer-related death in the United States.¹ In 2015, PDAC will lead to about 40,500 deaths.¹ Worldwide, it is blamed for over 330,000 deaths annually,² and by 2020, PDAC is predicted to become the second leading cause of cancer death by 2020.³

In this chapter, we will summarize the current literature relevant to the epidemiology, pathology, molecular and cellular biology, and diagnosis and treatment of pancreatic cancer. Future directions in prevention, early detection, clinical management and translational research in genomics, epigenetics, tumor metabolism, and the microenvironment will also be discussed.

Epidemiology

Worldwide, pancreatic cancer is the thirteenth most common type of cancer and the eighth leading cause of cancer-related death.² The incidence rates of pancreatic cancer are the highest in industrialized societies and western countries.⁴ The age-adjusted incidence rates range from 10 to 15 per 100,000 people in parts of Northern, Central, and Eastern Europe to <1 per 100,000 in areas of Africa and Asia.⁵ In the United States, the age-adjusted incidence rate for all races was 13.0 per 100,000 men and 10.3 per 100,000 women per year based on SEER's (Surveillance Epidemiology and End Results) 2001–2005 data.⁶ The age-adjusted mortality rate per 100,000 person-years was 15.4 for black men, 12.4 for black women, 12.1 for white men, and 9.0 for white women. The black/white disparity in incidence rate is likely related to environmental influences as the rates are considerably higher in African-Americans than in native Africans.

Most patients are diagnosed between the ages of 60 and 80 years.^{4, 6} Historically, pancreatic cancer had a male: female ratio of 1.2 : 1, now the incidence is about the same for both sexes.⁴

Etiologic factors

As most other types of human cancers, pancreatic cancer etiology involves both genetic and nongenetic factors ([Figure 1](#)).

Figure 1 Schematic presentation of known and suspected risk factors for pancreatic cancer.

Hereditary risk factors

Inherited or familial pancreatic cancers represent approximately 5–10% of all pancreatic cancers.⁷ At-risk patients for familial pancreatic cancer include those with a minimum of two first-degree relatives

with pancreatic cancer.⁸ Although the genetic mutations responsible for the majority of clustering of pancreatic cancer in families have not been identified, several pancreatic cancer genes that are associated with either a known cancer syndrome or chronic inflammatory diseases have been identified ([Table 1](#)).⁷

Table 1 Susceptibility genes for pancreatic cancer

Gene	Syndrome	Chromosome location	Function
<i>PRSS1</i> <i>SPINK1</i>	Hereditary pancreatitis	7q35 5q32	Trypsinogen, serine protease Serine peptide (trypsin) inhibitor
<i>CFTR</i>	Cystic fibrosis	7q31.2	ABC transporter chloride channel
<i>BRCA1</i> <i>BRCA2</i>	Hereditary breast ovarian cancer	17q21 13q12.3	DNA damage repair
<i>CDKN2A/P16</i>	Familial atypical multiple mole melanoma	9p21	Cyclin-dependent kinase inhibitor
<i>STK11/LKB1</i>	Peutz–Jeghers syndrome	19p13.3	Serine/threonine kinase
<i>MSH2, MLH1</i> <i>PMS1/2,</i> <i>MGH6</i>	Hereditary nonpolyposis colorectal cancer	2p21 3p21.3	Mismatch repair
<i>APC</i>	Familial adenomatous polyposis	5q21	Negative regulator of β- catenin
<i>PALB2</i>	Breast and pancreatic cancer	16p12.2	Partner and localizer of BRCA2
<i>ATM</i>	Ataxia-telangiectasia	11q22–q23	DNA damage response

PRSS1 and SPINK1

Germ line mutations in *PRSS1* and *SPINK1* genes are associated with hereditary pancreatitis. *PRSS1* gene encodes the cationic trypsinogen protein and premature activation of the trypsinogen results in acute pancreatitis. *SPINK1* gene encodes a trypsin inhibitor and mutation of this gene has been associated with chronic pancreatitis. Individuals with hereditary pancreatitis have been shown to have a 53-fold increased risk for developing pancreatic cancer and a lifetime risk (age 70) of pancreatic cancer of 30–40%.⁷

BRCA1 and BRCA2

Hereditary breast–ovarian cancer syndrome is associated with mutations in *BRCA1* or *BRCA2*. The risk of pancreatic cancer among *BRCA1* mutation carriers varied between studies.⁷ Germ line mutations in the *BRCA2* gene have been found in 10% of patients with familial pancreatic cancer and in 7% of patients with sporadic pancreatic cancer.^{9–11} Germ line *BRCA2* mutations represent the most common inherited predisposition to pancreatic cancer and are associated with an up to a 10-fold greater risk of pancreatic cancer than in the general population.¹²

LKB1/STK11

Peutz–Jeghers syndrome, an autosomal dominant trait, is caused by mutations in the *LKB1/STK11* tumor suppressor gene. Individuals with Peutz–Jeghers syndrome have a highly increased risk of pancreatic cancer ranging from 96- to 132-fold higher risk than average risk individuals; the lifetime risk is 5–36%.^{13, 14} Biallelic inactivation of the *LKB1/STK11* gene has also been found in 4% of patients with resected sporadic PDAC.¹⁵

CDKN2A (p16)

Germ line mutations of the *CDKN2A (p16)* tumor suppressor gene are mostly related to familial atypical multiple-mole melanoma (FAMMM) syndrome. It has been reported that individuals from FAMMM kindreds have a 13- to 22-fold increased risk of developing PDAC¹⁶ and individuals who carry *p16/CDKN2A* mutations have a 38-fold increased risk compared with the general population.¹⁷ *CDKN2A* gene is also frequently inactivated in sporadic pancreatic cancer.

HNPCC and FAP

The hereditary nonpolyposis colon cancer (HNPCC, also known as Lynch syndrome), is caused by germ line mutations in several DNA mismatch repair genes.¹⁸ Families with Lynch syndrome have an 8.6-fold increased risk of developing pancreatic cancer.¹⁹ Families with familial adenomatous polyposis (FAP), which is caused by genetic defect in *APC* tumor suppressor gene, have also been reported to have increased risk of PDAC.²⁰

PALB2 and ATM

Mutations of the *PALB2* and *ATM* genes have been discovered in familial pancreatic cancer cases.^{21–23} *PALB2* protein binds with *BRCA2* protein stabilizing it in the nucleus, and this complex acts in double stranded DNA repair. *ATM* is an important regulator of cellular response to DNA damage. It is estimated that *PALB2* mutations may account for 1–3% of the familial clustering of pancreatic cancer.^{21, 22}

A recent study conducted in 727 unrelated familial pancreatic cancer probands has found that the prevalence of deleterious mutations was *BRCA1*, 1.2%; *BRCA2*, 3.7%; *PALB2*, 0.6%; and *CDKN2A*, 2.5%. *BRCA2* and *CDKN2A* account for the majority of mutations in familial pancreatic cancer.²⁴

Susceptibility variants

Three genome-wide association studies (GWAS) have been conducted in the United States with a majority of the study population of European ancestry.^{25–27} Polymorphic variants of the *ABO*, *NR5A2*, *LINC-PINT*, *PDX1*, *BCAR1/CTRB1/CTRB2*, *ZNRF3*, and *TERT* genes and a nongene chromosome region 13q22.1 have been identified as susceptibility factors for pancreatic cancer with genome-wide significance ($p < 5 \times 10^{-8}$). Two additional GWAS have also been conducted in Chinese²⁸ and Japanese populations.²⁹ Post GWAS analyses suggest that genes involved in the pancreas development pathway may play an important role in modifying the risk of pancreatic cancer.^{30–32} Initial examination on the interactions of genes with known etiological factors, such as smoking,³³ obesity, and diabetes,^{34, 35} has generated interesting clues to the genetic factors that predispose individuals with such exposure to pancreatic cancer. Identification of the causal alleles and functional characterization of the genes or variants may involve many genes with modest effect on the phenotype.^{36, 37}

Tobacco and alcohol

The risk factor most firmly associated with pancreatic cancer is cigarette smoking. It is estimated that approximately 25% of cases of pancreatic cancer are due to cigarette smoking with a 1.5- to 2.0-fold increased risk.^{38–41} The risk increases as the amount and duration of smoking increase. Long-term smoking cessation (>10 years) reduces the risk by approximately 30% relative to current smokers.^{38, 42} Whether smokeless tobacco products, pipe or cigar smoking increases risk remains controversial.^{43, 44}

The mechanisms of smoking-induced pancreatic cancer involve tobacco carcinogen-induced DNA damage and pancreatic tissue injury.⁴⁵ Tobacco carcinogens can be metabolically activated to cause DNA damage and gene mutations.^{46, 47} Nicotine also plays an important role in tumor promotion and progression via nicotinic acetylcholine receptor and adrenergic receptor-mediated signaling in multifactorial events that lead to pancreatic injury.^{45, 46, 48}

The association between alcohol consumption and PDAC has also been investigated. In general, heavy alcohol consumption (30–40 g alcohol or ≥ 3 drinks/day) but not light or moderate consumption has been associated with increased risk.^{49–52} It appears that alcohol may account for 2–5% of all pancreatic cancer.

Obesity

Similar to tobacco, it has been estimated that obesity accounts for another 25% of the pancreatic cancer cases in the US population.⁵³ Positive associations between obesity and pancreatic cancer risk have been reported in several large prospective studies and meta-analyses.^{54–62} In addition to BMI (body mass index), abdominal fat, as measured by waist to hip ratio, has been related to increased risk of pancreatic cancer, especially in women.^{60, 61} Obesity at younger age has been associated with a higher risk of pancreatic cancer than weight gain at older age. Furthermore, obesity has been associated with a younger age of disease onset and reduced overall survival (OS).⁶³

Biological mechanisms linking obesity to pancreatic cancer are insulin resistance and inflammation.⁶⁴ Studies using prediagnostic blood samples have shown positive associations of PDAC risk and markers for hyperglycemia and insulin resistance.^{65–68} Insulin and insulin-like growth factors are key regulators for cellular metabolism and growth and their signaling transduction networks play an important role in tumor development and progression.^{69–71} The mechanisms driving pancreatic carcinogenesis may have similarities to other inflammatory conditions associated with an increased risk of cancer. Fatty infiltration of the pancreas may lead to steatopancreatitis, suggesting a potential link among obesity, nonalcoholic fatty pancreatic disease, nonalcoholic steatopancreatitis, and PDAC.^{72, 73}

Diabetes mellitus and antidiabetic medication

Diabetes mellitus has been implicated as both an early manifestation of pancreatic cancer and a predisposing factor.⁷⁴ A consistent association of long-term diabetes and risk of pancreatic cancer has been reported from three large-scale meta-analyses^{75–77} and three pooled data analyses^{68, 78, 79} with each involved more than 1500 PDAC cases. Of note, PDAC can induce peripheral insulin resistance⁸⁰ and type 3c (pancreatogenic) diabetes.⁸¹ It was observed that hyperglycemia could occur 2 years before clinical diagnosis of pancreatic cancer, and one in 125 new-onset diabetics would develop PDAC in 3 years.^{82, 83} Biomarkers that could help to distinguish type II diabetes mellitus from type 3c diabetes are being pursued.^{84, 85}

Since the discovery that biguanides, the most commonly used antidiabetic medications, inhibited

pancreatic tumor development in experimental animals,⁸⁶ the role of antidiabetic therapy in PDAC risk reduction has been intensely studied. Other experimental evidence supports the antitumor effect of metformin.^{87, 88} Metformin has diverse regulatory effects and the major molecular targets of metformin are the liver kinase B1 (LKB1)-AMP-activated protein kinase (AMPK) signaling and mammalian target of rapamycin (mTOR) pathways, which are central in the regulation of cellular energy homeostasis, cell division, and cell proliferation.⁸⁹ Metformin also inhibits the inflammatory response associated with cellular transformation and selectively targets the cancer stem cell.^{90, 91} In humans, eight cohort studies^{92–98} and three case–control studies^{99–101} have examined the impact of metformin use on risk of PDAC. Meta-analysis of these studies estimates RR of 0.63.¹⁰² Two additional studies have reported that metformin use in patients with pancreatic cancer and concurrent diabetes is associated with longer survival and reduced risk of death.^{103, 104}

Pancreatitis and other medical conditions

Chronic pancreatitis is a risk factor for pancreatic cancer, and new onset pancreatitis could be a sign of occult pancreatic cancer.¹⁰⁵ Data pooled from 10 case–control studies with adjustment for obesity and alcohol consumption, demonstrated that the risk of pancreatic cancer was nearly threefold for patients with an interval of >2 years between the pancreatitis and pancreatic cancer diagnoses.¹⁰⁶

Infectious diseases

Helicobacter pylori may cause subclinical pancreatitis or increased gastrin levels, with resultant trophic effects on the pancreas. Several studies have examined the association between *H. pylori* and pancreatic cancer; with large meta-analyses being showing a weak yet statistically significant association between prior *H. pylori* infection and pancreatic cancer.¹⁰⁷ It has been hypothesized that ABO genotype/phenotype status influences the behavior of *H. pylori* that in turn affects gastric and pancreatic secretory function, and these ultimately influence the pancreatic carcinogenicity of dietary- and smoking-related *N*-nitrosamine exposures, and thus risk of PDAC.¹⁰⁸

Hepatitis B may also be a risk factor for pancreatic cancer.¹⁰⁹ Subsequent studies were conducted mostly in Asian and a meta-analysis of nine such studies reported that the pooled RR was 1.39 (95% CI: 1.22–1.59) in chronic HBV (hepatitis B virus) carriers and 1.41 (95% CI: 0.06–1.87) in past exposure to HBV.¹¹⁰ Hepatitis B surface antigen (HBsAg) has been detected in pancreatic and bile juice,¹¹¹ and there is evidence of HBV replication in pancreatic cells. HBV results in damage to pancreatic exocrine and endocrine epithelial cells via an inflammatory response.^{112, 113}

Dietary factors

Various dietary factors have been suspected to play a role in the development of pancreatic cancer. Generally, high intakes of fat or meat increase the risk; whereas high intakes of fruits and vegetables reduce the risk.⁵ Less is known about which type of fatty acids pose the greatest risk.¹¹⁴ Several studies suggest that the method of meat preparation (deep fried, grilled, or barbequed), and subsequent intake of food mutagens may contribute to the development of pancreatic cancer.^{115–117}

The associations of dietary carbohydrates, refined sugars, and glycemic index or load with pancreatic cancer have been investigated in many studies but the results are inconsistent. A recent meta-analysis of data from eight prospective cohort studies concluded that there was no association among diets high in glycemic index, glycemic load, total carbohydrates or sucrose, and pancreatic cancer risk.¹¹⁸

Decreased pancreatic cancer rates have been associated with the high consumption of vegetables, citrus fruits, fiber, and vitamin C.⁵ It remains uncertain whether vitamin D has a protective effect on PDAC.¹¹⁴

Occupational exposures

The role of occupational or industrial factors in pancreatic cancer has been investigated extensively. Increased risk of pancreatic cancer has been associated with exposures to some chemicals (e.g., organochlorines, chlorinated hydrocarbons, and formaldehyde) or some specific occupations (e.g., stone miners, cement workers, gardeners, and textile workers).^{4, 88} The strongest and most consistent occupational risk factors associated with pancreatic cancer to date are chlorinated hydrocarbons and polycyclic aromatic hydrocarbons.⁸⁸

In summary, cigarette smoking and obesity may each be responsible for as many as 25% of the cases of pancreatic cancer implying that half of pancreatic cancer cases may be preventable.^{119, 120} Conversely, the proportion of pancreatic cancer cases attributable to known inherited pancreatic cancer syndromes is small. Identification of individuals with excessively high risk of pancreatic cancer may allow for focused screening.^{121–123} Thus far, proved benefit to screening remains elusive, except in highly selective populations such as high-risk familial pancreatic cancer kindreds.¹²⁴ Currently, for those individuals determined to have structural,¹²⁴ or blood-based abnormalities,¹²⁵ suggesting premalignancy or early stage neoplasm, management remains extremely controversial. Current options range from close observation to aggressive surgical intervention with a variety of approaches in evolution.^{126–128}

Prevention of pancreatic cancer

The epidemiology of PDAC described earlier provides strong evidence for the prevention of pancreatic cancer; possibly resulting in a substantial reduction in global pancreatic cancer mortality. Primary prevention strategies expected to significantly reduce the risk of developing pancreatic cancer likely require lifestyle and dietary modifications. In addition, a number of available over the counter agents and widely prescribed medications have potential to reduce the risk of pancreatic cancer ([Table 2](#)).^{129–132}

Table 2 Interventions that may reduce pancreatic cancer risk

<i>Lifestyle and nutritional factors</i>
Cessation/avoidance of tobacco smoking and smokeless tobacco
Regular exercise
Weight control and weight reduction if needed to BMI < 25 kg/m ²
Healthy diet high in fruits and vegetables
<i>Potential chemopreventive agents</i>
Metformin
Aspirin
Curcumin
Celecoxib
Atorvastatin and other HMG-coenzyme reductase inhibitors
β-Carotene
Vitamins C, D, and E

Histopathology of exocrine pancreatic neoplasms

PDAC accounts for approximately 95% of all neoplasms arising in the pancreas.¹³³ On histological examination of surgically resected tumors, it is not uncommon to find neoplastic cells infiltrating into lymphatic structures or into the many nerve endings enervating the pancreatic bed, which may explain the pain associated with PDAC. Another defining histological feature of PDAC is an exuberant host stromal reaction to the cancer (desmoplasia), wherein smooth muscle actin expressing myofibroblasts generate abundant extracellular collagen that surrounds infiltrating neoplastic glands ([Figure 2](#)).¹³⁴ Other components of this host desmoplastic response include secreted glycosaminoglycans (e.g., hyaluronan) that contribute to high interstitial pressures and impede the passive efflux of chemotherapeutics from the circulation into the peritumoral milieu.¹³⁵

Figure 2 Stromal desmoplasia in pancreatic ductal adenocarcinoma. Infiltrating neoplastic glands (white arrows) are surrounded by a florid host response, comprised spindle-shaped cancer-associated fibroblasts and myofibroblasts (red arrowheads) and extracellular matrix, including collagen 1 (black arrow).

PDAC arises through a stepwise histological progression of well-recognized precursor lesions. The most common precursor lesions are microscopic, and known as *pancreatic intraepithelial neoplasia* or PanIN, which are almost always present in the pancreatic parenchyma surrounding an invasive cancer. PanINs vary from innocuous low-grade PanIN-1 lesions to the ominous highest grade PanIN-3 (previously known as carcinoma *in situ*), wherein the constituent cells morphologically resemble PDAC, except for their containment within a basement membrane. PanIN-3 lesions share many of the genetic aberrations found in infiltrating cancer. Of note, while PanIN-1 and -2 lesions can occur incidentally (with autopsy studies reporting as many as 50% of elderly individuals with low-grade PanINs in their pancreas),¹³⁶ PanIN-3 is essentially never found in the absence of a synchronous PDAC.¹³⁷ Thus, the emergence of high-grade PanIN-3 lesions likely represents the critical inflection point in the multistep progression of PDAC. By definition, and in contrast to cystic precursor lesions of PDAC (see below), isolated PanINs are not seen on abdominal imaging, although individuals with germ line mutations or a familial predisposition may

have structural pancreatic changes discernible on endoscopic ultrasound (EUS).¹²⁸

Cystic precursor lesions of PDAC comprised two distinct entities—intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs).¹³⁸ IPMNs arise in either the main duct or one of the side branches of the pancreas and are characterized by broad “finger-like” papillae and secretion of abundant extracellular mucin. MCNs are less common and occur in women with significantly greater propensity than men (9 : 1 ratio). In contrast to IPMNs, MCNs have no communication with the ductal system. Akin to PanINs, the epithelial lining of cystic precursor lesions also demonstrates histological progression from low-grade (adenoma) through high-grade (carcinoma *in situ*) to invasive cancer. Approximately 25–33% of surgically resected cystic lesions are associated with an invasive adenocarcinoma, and the onset of invasion is associated with a significant reduction in median OS.^{139, 140} The precise timeline of progression from noninvasive cyst to invasive carcinoma is not known, although the median age of presentation for cystic lesions is about a decade earlier than the median age for PDAC, suggesting that this might reflect the period required for progression. Of note, the explosion in the use of abdominal imaging for symptoms not related to the pancreas has led to a veritable “man-made” epidemic of incidentally discovered cystic lesions of the pancreas. As the overwhelming majority of these asymptomatic cysts are not likely to progress to invasive cancer, radiological criteria have been proposed that help distinguish “high risk” from “indolent” cysts.^{141, 142} Intensive efforts are underway to identify molecular markers from cyst fluid or blood that would further refine this distinction and help prevent unnecessary surgeries and frequent monitoring.¹²³

Other uncommon exocrine tumors include (1) acinar cell carcinoma, which bears morphological resemblance to pancreatic acini, wherein the neoplastic cells express acinar enzymes, such as trypsin and chymotrypsin;¹⁴³ (2) solid pseudopapillary neoplasm, a cystic tumor of uncertain histogenesis that often arises in the tail of the pancreas in young adults, and typically has a favorable prognosis;¹²² (3) serous cystic neoplasm, a cystic tumor characterized by serous (watery) secretion, in contrast to the mucinous contents of IPMN and MCN, and which does not harbor a risk of progression to PDAC;¹⁴⁴ and (4) pancreatoblastoma, the most common pancreatic tumor in children.¹⁴⁵

Approximately 2% of primary tumors arise from the endocrine compartment (islets of Langerhans) and are known as pancreatic neuroendocrine tumors or PanNETs or “islet cell tumors.”¹⁴⁶ PanNETs can be nonfunctional in up to a quarter of cases, or they can express a variety of islet cell hormones such as insulin or glucagon, which may lead to characteristic syndromes owing to systemic hormonal excess. PanNETs do not form glandular structures and are typically not associated with an exuberant host desmoplastic reaction. PanNETs can be readily identified based on expression of neuroendocrine markers such as chromogranin or synaptophysin in tissue sections.

Molecular pathology of exocrine pancreatic neoplasms

The advent of next-generation sequencing technology has enabled considerable advances over the last 5 years in elucidating the genomic landscape of PDAC,¹⁴⁷ as well as that of other variant neoplasms of the exocrine and endocrine pancreas.^{148, 149} The International Cancer Genome Consortium (ICGC) has sequenced hundreds of PDAC, where the sequencing data is publicly available.¹⁵⁰

By far, the most common genetic abnormality in the multistep pathogenesis of PDAC happens to be oncogenic mutation of *KRAS*, located on chromosome 12p, which encodes for Ras, a membrane-bound small GTPase.¹⁵¹ Somatic mutations of *KRAS* are reported in >90% of PDAC cell lines and patient-derived xenografts, although the frequency is somewhat lower (75–90%) in primary tumor samples. The

majority of *KRAS* mutations cluster at codon 12, with mutations also found at codons 13 or 61, respectively. Somatic *KRAS* mutations result in constitutive activation of the GTPase activity of the encoded Ras protein, which, in turn, activates multiple downstream effector pathways.¹⁵² Somatic *KRAS* mutations are present even in the lowest grade PanIN lesions, underscoring its status as an early genetic “hit.”¹⁵³ In genetically engineered mouse models (GEMMs), expression of a mutant *KRAS* in the pancreas results in preinvasive neoplasia closely recapitulating human PanINs, with a minority of animals progressing to full-fledged invasive cancer.¹⁵⁴ Additional genetic events, such as expression of mutant *p53* or biallelic deletion of the *Ink4a/Arf* locus, significantly accelerate the natural history of Ras-induced pancreatic neoplasia.^{155, 156} Conversely, in GEMMs with an inducible mutant *KRAS* allele, turning off Ras expression in established PDAC, leads to variable tumor regression.^{157, 158} Not surprisingly, a multitude of avenues have been explored toward pharmacological inhibition of aberrant Ras activity in PDAC and other *KRAS*-mutant tumors,^{159–161} but the clinical results overall have been disappointing. Nonetheless, Ras remains an attractive target, and a large federally funded “RAS Initiative” is currently underway at the National Cancer Institute to identify strategies to block Ras in PDAC and other cancers (<http://www.cancer.gov/researchandfunding/priorities/ras>).

Somatic inactivation of the *CDKN2A/INK4A* gene, which encodes for the cell cycle regulator p16, is another early genetic event in the multistep progression of PDAC. The p16 protein inhibits the cyclin D1/Cdk-4 complex that normally acts to constrain the retinoblastoma (Rb) protein via phosphorylation.¹⁶² In approximately 95% of PDAC, the *CDKN2A/INK4A* gene is inactivated by one of several mechanisms, including homozygous deletion, the loss of one allele combined with an intragenic mutation in the other allele, or epigenetic inactivation via promoter methylation. A potential therapeutic vulnerability that emerges in the setting of p16 loss pertains to the dependence on Cdk4 activity for unregulated proliferation, which can be targeted using small molecule inhibitors of Cdk4 function.¹⁶³

In the multistep progression model of PDAC, loss of the *TP53*, *SMAD4/DPC4*, and *BRCA2* tumor suppressor genes are considered later genetic events.¹⁶⁴ Somatic mutations of *TP53* are found in approximately 75% of human PDAC, while nuclear accumulation of p53 protein on immunohistochemistry, indicative of an underlying mutation, occurs in the majority of PanIN-3 lesions.¹⁶⁵ The *SMAD4/DPC4* tumor suppressor gene on chromosome 18q21 encodes for an intracellular transducer of the transforming growth factor- β signaling pathway that inhibits cell growth under physiological conditions. The *SMAD4/DPC4* gene is inactivated in approximately 55% of human PDAC through either homozygous deletions or the loss of one allele coupled with an intragenic mutation in the second allele.¹⁶⁶ Epithelial Dpc4 expression is nearly always retained in low-grade PanIN lesions and in noninvasive cystic precursor lesions of PDAC, reiterating that *SMAD4/DPC4* abnormalities generally occur concomitant with progression to invasive cancer.^{167, 168} Overall, *KRAS*, *CDKN2A/INK4A*, *TP53*, and *SMAD4/DPC4* are the “big four” peaks in the genomic landscape of PDAC, each mutated in over 50% of cases. Patients that harbor in all four genes tend to have a significantly worse OS than those with mutations in 1 or 2 of these genes, underscoring their role in prognosis.¹⁶⁹

The *BRCA2* gene, which has been discussed in the context of familial predisposition to PDAC, is also somatically mutated in approximately 5% of cancers. The *BRCA2* protein plays a critical role in homologous recombination-mediated repair (HRR), and neoplastic cells with *BRCA2* or related gene defects in the HRR pathway are exquisitely sensitive to double-strand breaks induced by agents such as cisplatin or mitomycin C.¹⁷⁰ Another newer class of agents that is being selectively evaluated in tumors with *BRCA2* mutations is PARP ([poly (ADP-ribose) polymerase]) inhibitors, which inhibits a second mechanism of DNA repair in cells already compromised in HRR. The concurrent PARP inhibition in

BRCA2-mutant PDAC is expected to create a “synthetic lethality” vis-à-vis DNA repair that can be exploited toward a therapeutic advantage.¹⁷¹

Although a comprehensive tabulation of genetic abnormalities in PDAC is beyond the scope of this book, significant molecular aberrations are observed within every interrogated cellular component, including DNA methylation, histone marks, coding and noncoding RNAs (latter incorporating both long noncoding RNA and microRNAs), and protein. Many of these abnormalities, such as DNA mutations, aberrant DNA methylation, or deregulated microRNAs, are considered candidate biomarkers for the diagnosis of PDAC in surrogate biospecimens such as blood or pancreatic juice.^{172–175} Newly emerging areas of biomarker discovery for early diagnosis of PDAC, and in monitoring for recurrence postresection, include circulating cell-free mutant DNA (cfDNA) and DNA contained within extracellular microvesicles (exosomes),^{176, 177} which can be detected using ultra-sensitive PCR techniques.¹⁷⁸

Molecular biology of exocrine pancreatic neoplasms: Translational implications

Below are a few selected examples of recent advances made in understanding the tumor biology of PDAC that have translational relevance within the field of cancer medicine.

A genetic timeline for PDAC progression: The overwhelming majority of PDAC patients present with advanced disease, and early detection remains one of the most promising avenues for improving OS. In a seminal report of PDAC autopsy cases that compared the genomic aberrations present in primary versus synchronous metastatic lesions, investigators calculated that almost two decades might be required for progression from the initial mutant clone(s) to terminal metastatic disease.¹⁷⁹ No more than 2 years of this prolonged genetic timeline occurs during the symptomatic phase of disease, reiterating the importance of elucidating clinically applicable biomarkers that can identify emerging PDAC at a preclinical stage.

PDAC stroma: friend or foe? Traditionally, the cancer-associated myofibroblasts within the exuberant desmoplastic stroma in PDAC have been considered an ally of the invasive cancer.^{180, 181} One pathway that emerged as particularly relevant in facilitating tumor-stroma crosstalk is the Hedgehog signaling pathway,¹⁸² and depletion of stromal myofibroblasts in PDAC GEMMs using short-term therapy with Hedgehog inhibitors was shown to enhance chemotherapy delivery in preclinical studies.¹⁸³ This prompted a randomized clinical trial of an inhibitor of Hedgehog signaling in combination with gemcitabine, but rather unexpectedly, the inhibitor to paradoxical disease progression (www.businesswire.com/news/home/20120127005146/en/Infinity-Reports-Update-Phase-2-Study-Saridegib). A more recent series of studies using both genetic and pharmacological ablation of myofibroblasts in PDAC GEMMs have been instrumental in implicating a tumor-constraining role for stroma.^{184–186} Specifically, stromal depletion led to tumor dedifferentiation and increased metastases, with reduced median survival of mice, mimicking the clinical findings. These paradigm-shifting reports have led to a reassessment of the role of stroma in PDAC. One approach that has been proposed in preclinical models is a shift away from stromal ablation to stromal “reprogramming,” wherein myofibroblasts are still retained *in situ*, but pharmacological strategies are used to revert their transcriptional profiles to a basal, resting state.¹⁸⁷

Overcoming immune tolerance in PDAC: Cancer immunotherapy has emerged as one of the most promising therapeutic strategies over the last 5 years with agents known as checkpoint inhibitors resulting in dramatic improvements in survival for patients with melanoma.¹⁸⁸ To date, these successes have not translated to PDAC.^{189, 190} Some of these failures have been attributed to the unique tumor

microenvironment of PDAC. In contrast to certain “immunogenic” cancers such as melanoma, the immunological infiltrate in the PDAC microenvironment is sparse in effector T cells, and populated by cells that dampen tumor rejection, including regulatory T cells, macrophages, and suppressor cells of myeloid origin.^{191–193} This immunosuppressive milieu contributes to a state of immune tolerance and facilitates tumor progression. As immunotherapy of PDAC continues to evolve, there is increasing recognition of the importance of combination regimens, such as vaccines to induce an antigen-specific T-cell response in conjunction with blockade of checkpoints,¹⁹⁴ or adoptive therapy using antigen-specific engineered T cells in conjunction with checkpoint inhibitors.¹⁹⁵

Metabolic vulnerabilities in PDAC: As proposed by Otto Warburg nearly a century ago,¹⁹⁶ cancer cells are known to mostly rely on aerobic glycolysis of exogenous glucose for their energy needs. In addition to glucose, exogenous glutamine is a key elemental fuel for PDAC survival and proliferation.¹⁹⁷ Upon uptake, glutamine is converted by the enzyme glutaminase into glutamate. Not surprisingly, mutant Ras appears to be a critical orchestrator of the intracellular reprogramming. Mutant Ras rewires the metabolic machinery such that glutamate is oxidized via a noncanonical pathway distinct from normal cells, without increasing deleterious intracellular reactive oxygen species levels.¹⁹⁸ In preclinical models, this unique glutamine utilization mechanism is essential for cancer cell survival and has generated enthusiasm about targeting glutaminase or other enzymes of this pathway in PDAC. Second, mutant Ras has been shown to promote dependence on autophagy, a nutrient recycling mechanism wherein lysosomal degradation of damaged proteins, macromolecules, and organelles, generates key intermediates for bioenergetics.¹⁹⁹ Autophagy can be blocked using agents such as chloroquine and has shown promising results in preclinical settings.²⁰⁰ Finally, mutant Ras leads to profound increase in macropinocytosis, a primitive nutrient uptake mechanism that functions via endocytosis of extracellular fluid and nutrients via the so-called macropinocytic vesicles originating from the cell membrane.²⁰¹ Macropinocytosis in PDAC cells enhances uptake of albumin and other extracellular proteins that are catabolized into essential amino acids channeled into various anabolic pathways. Thus, inhibition of macropinocytosis can be leveraged as potential therapeutic avenue. Alternatively, the propensity of PDAC cells to uptake extracellular albumin can be used as a “Trojan horse” strategy, by conjugating therapeutic agents with albumin. In fact, there is some evidence to suggest that the enhanced efficacy of nano-albumin-conjugated paclitaxel might be, at least in part, due to the macropinocytosis-induced uptake of the drug within *KRAS*-mutant cancer cells.

Taken together, these results provide greater understanding of the complexity of PDAC's underlying biology with protracted genomic evolution, a dynamic microenvironment, and distinct differences in metabolism between normal and malignant cells. These insights suggest strategies to modulate the tumor's cellular and extracellular defense mechanisms. A few specific examples translating these recent laboratory-based discoveries to the clinical arena will be discussed in the section titled “Future Directions” at the end of this chapter.

Diagnostic evaluation

The diagnostic work-up of patients ultimately found to have pancreatic cancer can be fragmented and inefficient. Surgeons or subspecialty oncologists may be asked to evaluate a patient at any point in the diagnostic process to include evaluation of abdominal pain, suspicion of a pancreatic mass, or biopsy-confirmed pancreatic cancer with or without complete staging evaluation. Essential clinical information which may have important therapeutic implications can be obtained from a thorough history and physical examination. Some of this information cannot be obtained from imaging studies and includes the assessment of performance status (PS), cardiopulmonary function, evaluation for left supraclavicular or

periumbilical adenopathy, or evidence for venous thromboembolism (VTE).

Classification of clinical stage

It is critically important to use standardized, objective radiologic criteria for clinical staging. Modern imaging techniques have revolutionized the clinical staging of pancreatic cancer. Precise and objective anatomic radiographic criteria are used to determine the extent of the tumor–vascular relationship and to categorize clinical staging. The clinical stage of pancreatic cancer can be broadly divided into patients with inoperable disease (metastatic or locally advanced) and localized disease (borderline resectable or resectable); see [Table 3](#) for specific radiographic criteria. The majority of patients will present with metastatic disease, as evidenced by ascites/peritoneal implants, liver, or lung metastases. Confirmation of metastatic disease can be achieved with percutaneous biopsy of the metastatic lesion (preferred) or at the time of endoscopy (**EUS-FNA** (fine needle aspiration)). In the absence of metastatic disease, the clinical stage is determined by the relationship of the primary tumor to adjacent vasculature. Radiographic findings of a potentially resectable pancreatic cancer (AJCC stages I or II) are (1) the absence of tumor-arterial abutment or encasement and (2) <50% involvement of the superior mesenteric vein (SMV)/portal vein (PV) ([Figure 3](#)). As a general rule, any tumor abutment ($\leq 180^\circ$ tumor-vessel interface) or encasement ($>180^\circ$) of the celiac axis, common hepatic artery, or superior mesenteric artery (SMA) should be considered a contraindication to immediate surgery. A patient is deemed to have locally advanced, unresectable disease (AJCC stage III) when (1) the tumor encases the SMA or celiac axis, as defined by $>180^\circ$ of the circumference of the vessel ([Figure 4](#)), or (2) there is occlusion of the SMPV (superior mesenteric-portal vein) confluence without the possibility for venous reconstruction. Patients who have tumor abutment, without encasement, of the SMA or celiac axis, or short segment encasement of the hepatic artery are considered to have borderline resectable pancreatic cancer. In addition, patients with tumors that cause >50% narrowing or short segment occlusion of the SMV/PV that may be amenable to reconstruction are also considered to be borderline resectable. There is emerging consensus that even more subtle tumor-vein abutment may be best considered borderline resectable (especially as neoadjuvant therapy becomes more widely accepted).

Table 3 Radiographic criteria for clinical staging of pancreatic cancer

<i>Resectable</i>	
Tumor–artery relationship	No radiographic evidence of arterial abutment (celiac, SMA, or hepatic artery)
Tumor–vein relationship	Tumor-induced narrowing ≤50% of SMV, PV, or SMV-PV
<i>Borderline resectable</i>	
Artery	Tumor abutment (≤180°) of SMA or celiac artery. Tumor abutment or short segment encasement (>180°) of the hepatic artery
Vein	Tumor-induced narrowing of >50% of SMV, PV, or SMV-PV confluence. Short segment occlusion of SMV, PV, and SMV-PV with suitable PV (above) and SMV (below) to allow for safe vascular reconstruction
Extrapancreatic disease	CT scan findings suspicious, but not diagnostic of, metastatic disease (e.g., small indeterminate liver lesions which are too small to characterize)
<i>Locally advanced</i>	
Artery	Tumor encasement (>180°) of SMA or celiac artery
Vein	Occlusion of SMV, PV, or SMV-PV without suitable vessels above and below the tumor to allow for reconstruction (no distal or proximal target for vascular reconstruction)
Extrapancreatic disease	No evidence of peritoneal, hepatic, and extra-abdominal metastases
<i>Metastatic</i>	
Evidence of peritoneal or distant metastases	

Figure 3 Contrast-enhanced computed tomography scan demonstrating a resectable adenocarcinoma of the pancreatic head. The low-density tumor is easily seen in the pancreatic head. Note the absence of tumor extension to the superior mesenteric artery (SMA) (small arrow); there is a normal fat plane between the low-density tumor and the SMA. However, the tumor (area of low density) does extend to the superior mesenteric vein (SMV) just inferior to the tip of the large arrow. This patient may require venous resection and reconstruction at the time of pancreaticoduodenectomy. This subtle finding would not be apparent on a lesser quality scan. The intrapancreatic portion of the common bile duct contains a stent that was endoscopically placed for biliary drainage.

Figure 4 Contrast-enhanced computed tomography scan demonstrating an unresectable adenocarcinoma of the pancreatic head and uncinate process. The low-density tumor is inseparable from the posterior wall of the SMA (small arrow). Direct intraoperative assessment of the extent of retroperitoneal tumor growth in relation to the SMA is not possible until after gastric and pancreatic transection, at which point the surgeon has committed to resection; accurate preoperative imaging of this vital tumor–vessel relationship is thus critical. The large arrow identifies the SMV.

Imaging

As accurate characterization of tumor–vascular relationship is critical for clinical staging, interventions such as EUS and ERCP (endoscopic retrograde cholangiopancreatography, which can induce pancreatitis and interfere with accurate assessment of the extent of disease) should be deferred briefly until high-quality imaging is obtained. The single most important imaging tool for the detection and staging of pancreatic cancer is computed tomography (CT).^{202, 203} Current multidetector protocols utilize dual-phase technique. A rapid injection of intravenous contrast allows for the maximal enhancement of the pancreas and mesenteric vasculature.²⁰⁴ The first (arterial) phase is used for visualization of the primary tumor and optimal assessment of the tumor–arterial relationship. The second (venous) phase aids definition of the relationship of the tumor to the surrounding venous structures (SMV, PV, and splenic vein) and may uncover metastases to locoregional lymph nodes and distant organs (particularly to the liver).

If a low-density mass is not seen on CT, the presence of biliary or pancreatic duct obstruction remains concerning for malignancy. Additional imaging with magnetic resonance imaging (MRI) can be considered. Several studies have demonstrated that small pancreatic lesions (<2 cm) are more conspicuous on MRI relative to CT.^{205, 206} As in CT imaging, the hypovascular nature of pancreatic cancer may make tumors best seen on early phase (arterial) sequences.²⁰⁴ Ultimately, patients with suspicion of pancreatic cancer without evidence of a mass should undergo EUS. In addition, EUS combined with FNA may provide tissue confirmation of malignancy. Rarely, patients may present with radiographic features concerning for pancreatic cancer without an identifiable mass on CT, MRI, or EUS. If the patient is jaundiced, an ERCP may provide additional radiographic information to include evidence for a double

duct sign or smooth tapering more suggestive of sequelae of pancreatitis ([Figure 5](#)). In these settings, biliary brushings can provide material for cytologic evaluation. Importantly, pancreatic cancer remains the major diagnostic consideration in patients (without a history of recurrent pancreatitis or alcohol abuse) who have a malignant-appearing stricture of the intrapancreatic portion of the common bile duct or the presence of pancreatic duct dilation without radiographic evidence of a mass. In the presence of an elevated CA 19-9 level, repeat EUS should be considered and if a cytologic diagnosis cannot be confirmed, upfront surgery would be the obvious next step assuming that the patient is otherwise healthy with no contraindications for major abdominal surgery.

Figure 5 Endoscopic retrograde cholangiopancreatography demonstrating the smooth tapering common bile duct stricture (arrowhead) seen with biliary obstruction secondary to chronic pancreatitis.

Tissue acquisition

Confirmation of malignancy is required in all patients with locally advanced or metastatic disease before treatment with systemic therapy or radiotherapy. For patients with radiographic evidence of metastatic disease, percutaneous biopsies of the metastatic site can usually be obtained with either US- or CT guidance. For patients with localized disease that may be amenable to surgical resection, we prefer EUS-guided FNA biopsy to minimize the risk of tumor seeding. Furthermore, EUS-guided biopsy is much safer and more accurate than percutaneous CT-guided biopsy for tumors that are smaller or difficult to access using CT guidance.²⁰⁷ A negative cytology from EUS-guided FNA should not be considered proof that a malignancy does not exist, and repeat EUS-guided FNA may improve diagnostic accuracy.²⁰⁸ Of note, FNA biopsy should only be performed if a mass is visualized; blind biopsy of the pancreas is inappropriate.

Laparoscopic staging

In the past, laparoscopy was performed in patients who had radiologic evidence of localized pancreatic cancer.²⁰⁹ However, with the advent of high-quality contrast-enhanced CT, the role of laparoscopy in

staging (when performed under a separate anesthesia induction) appears to be decreasing. Moreover, the yield of staging laparoscopy may be improved in those patients with very high levels of serum carbohydrate antigen (CA) 19-9, and acquisition of preoperative CA 19-9 levels is recommended.^{210, 211} If the suspicion of extra-pancreatic disease is high, or if the patient is a marginal surgical candidate based on medical comorbidities, laparoscopy as a stand-alone procedure may be appropriate.

Biliary drainage

In patients with localized pancreatic cancer, placement of endobiliary stents before surgery relieves the symptoms of biliary obstruction and facilitates the normalization of liver function. The latter is particularly important for patients who will be treated with neoadjuvant therapy, as hyperbilirubinemia prevents the safe delivery of systemic therapy. If neoadjuvant therapy is planned, biliary complications, including stent occlusion and cholangitis, can be minimized with insertion of a short metal stent after cytologic confirmation of cancer.²¹² For patients with locally advanced or metastatic pancreatic cancer, an endobiliary self-expandable metal stent has superior long-term patency compared with plastic stents.^{213, 214}

Certain groups of patients with symptomatic distal bile duct obstruction should not undergo endobiliary metal stent placement. Although covered metal stents can also be removed endoscopically,²¹⁵ they should rarely be used to provide temporary biliary decompression in a patient without a tissue diagnosis of malignancy.

Treatment of localized, potentially resectable disease

Surgical considerations

If the primary tumor cannot be resected completely (gross complete resection), surgery for pancreatic cancer (pancreaticoduodenectomy) offers no survival advantage. Patients who undergo a gross incomplete resection have an expected median survival of <1 year.²¹⁶ Even microscopically positive surgical margins have a negative impact on OS and the ability to obtain a margin negative resection should be viewed as necessary for long-term survival.²¹⁷

Upfront surgery and adjuvant therapy

Currently, the standard of care for early-stage, resectable disease is surgery followed by adjuvant therapy. Owing to recent advances in operative technique, anesthesia, and critical care, the 30-day in-hospital mortality rate is 2% or less in patients who undergo pancreaticoduodenectomy performed by experienced surgeons.^{218–220} Data have also demonstrated that higher hospital volume is associated with lower surgery-related mortality.²²¹ Upfront surgical resection followed by adjuvant therapy is potentially curative. However, median survival times of 22–24 months have remained stagnant for the last 30 years using this approach.^{222, 223}

Pancreaticoduodenectomy

The standard surgical procedure for neoplasms of the pancreatic head and perampullary region is pancreaticoduodenectomy. The current technique of pancreaticoduodenectomy has evolved from the procedure first described by Whipple and colleagues in 1935.²²⁴ and incorporates selected aspects of the traditional Whipple procedure and emphasizes the importance of removing all soft tissue to the right of

the SMA. The surgical resection is divided into six clearly defined steps ([Figure 6](#)); the most oncologically important and difficult part of the operation is step six, during which the pancreas is divided and the specimen is removed from the SMPV confluence and the right lateral border of the SMA.²²⁵

Figure 6 Six surgical steps of pancreaticoduodenectomy.

The high incidence of local recurrence after standard pancreaticoduodenectomy requires particular attention to the SMA margin, the soft tissue margin along the right lateral border of the proximal SMA ([Figure 7a](#)).²²⁶ It is critical that this margin be identified for the pathologist and assessed histologically; the residual disease status (termed “R” factor) cannot be determined if the retroperitoneal margin is not assessed histologically.^{220, 227}

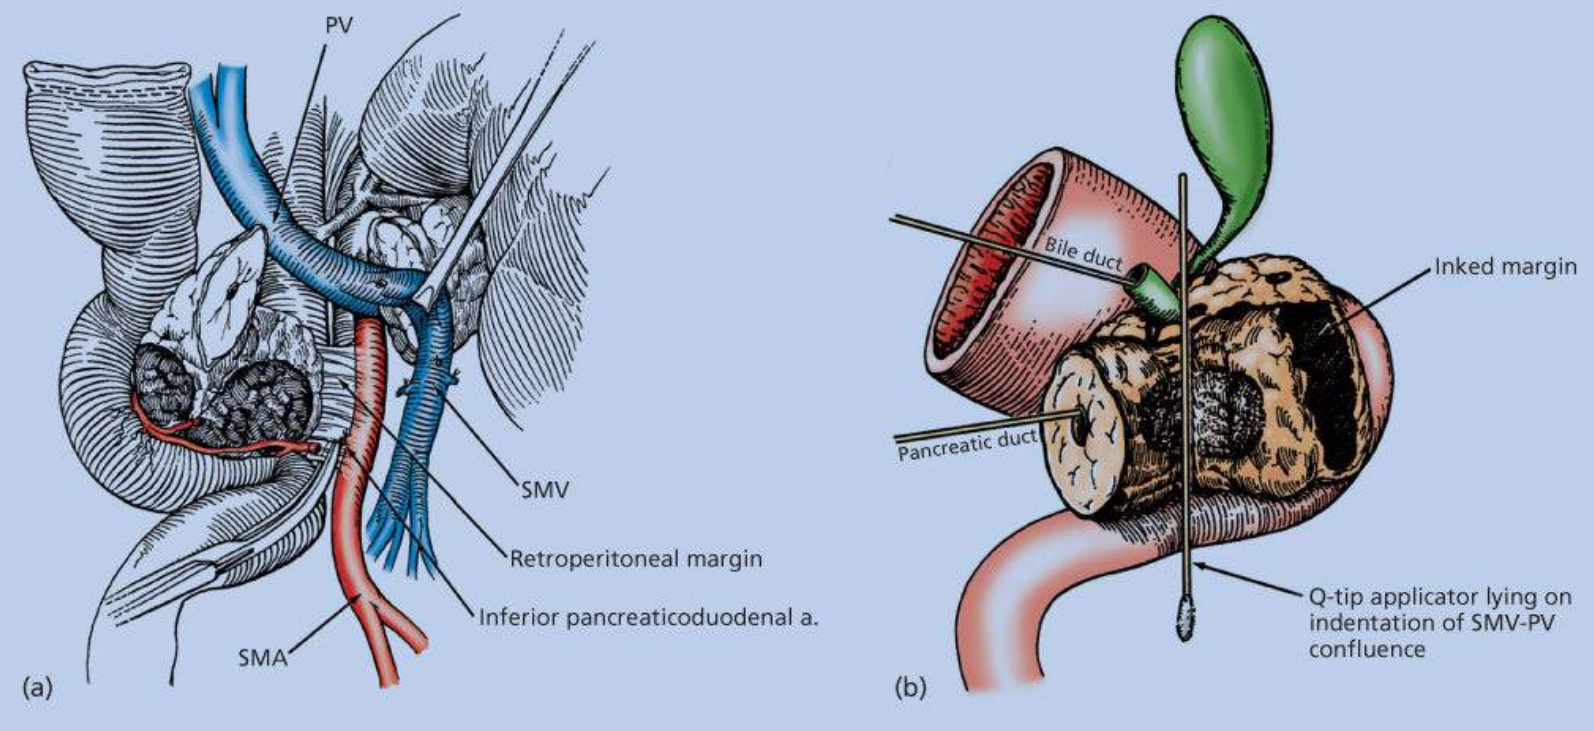

Figure 7 Illustration of the retroperitoneal margin as defined at the time of tumor resection (a). Medial retraction of the SMV and superior mesenteric-portal vein (SMPV) confluence facilitates dissection of the soft tissues adjacent to the lateral wall of the proximal SMA; this site represents the retroperitoneal margin. Complete permanent-section analysis of the pancreaticoduodenectomy specimen requires that it be oriented for the pathologist to enable accurate assessment of the retroperitoneal margin of excision and other standard pathologic variables. The retroperitoneal margin must be identified and inked with the pathologist (b); it cannot be assessed retrospectively. As shown here, a probe is in both the pancreatic duct and the bile duct, and a Q-tip applicator lies on the indentation of the SMPV confluence. One can then ink (for final pathologic assessment) the soft-tissue margin adjacent to the proximal SMA; this represents the retroperitoneal (or mesenteric) margin of excision.

Vascular resection

The goal of vascular resection is to obtain an R0 resection, which requires complete removal of the tumor from the SMV/PV, and exposure of the SMA to allow sharp dissection of the tumor off this artery. Venous resection and reconstruction should be performed for tumors adherent to the SMV or SMPV confluence (Figure 8) or in the presence of short segment occlusion of the SMV/PV with no tumor encasement of the SMA or celiac axis.^{220, 225}

Figure 8 Venous resection/reconstruction. Illustration of resection of the SMV with splenic vein preservation. The intact splenic vein tethers the portal vein (PV), making a primary anastomosis impossible in most cases. Our preferred method of reconstruction of the SMV is to use an internal jugular vein interposition graft. With the splenic vein intact, exposure is inadequate to separate the specimen from the lateral aspect of the proximal SMA. Therefore, the graft can be placed before specimen removal, thereby allowing medial retraction of the reconstructed SMPV confluence, or after separation of the specimen from the SMA posteriorly. Segmental resection of the SMV with splenic vein preservation adds significant complexity to this operation.

A very select proportion of patients with locally advanced disease (as currently defined) may be considered for surgery (after neoadjuvant therapy) if (1) tumor encasement of the celiac axis or common hepatic artery can be removed with an Appleby procedure (extended distal pancreatectomy with celiac resection) and (2) there is evidence of radiographic, biochemical (CA 19-9), and physiologic response (improved PS) to preoperative therapy. In these patients, neoadjuvant chemoradiation is recommended and surgical candidacy is reassessed upon the completion of therapy. The most common operation performed for such patients has been a distal pancreatectomy, splenectomy, and en bloc resection of the celiac axis (Appleby procedure). In the small series of patients where resection and arterial reconstruction has been performed, results have been encouraging.^{228, 229}

Pylorus preservation

Currently, available findings from randomized trials suggest no difference in perioperative factors or patient outcome between standard and pylorus-preserving pancreaticoduodenectomy.^{230–232} Most investigators would agree that pylorus preservation should not be performed in patients who have bulky tumors of the pancreatic head or duodenal tumors involving the first or second portions of the duodenum.

Minimally invasive pancreatectomy

Interest in applying minimally invasive techniques to pancreatic resection stems from the hypothesis that open surgical resection is associated with substantial physiologic stress and morbidity. While the advantages and appropriateness of minimally invasive approaches are still controversial, from 1998 to 2009, the rates of minimally invasive pancreatectomy have risen from 2.4% to 7.3%.²³³ Minimally invasive procedures include both laparoscopic and robotically assisted procedures.

Laparoscopic distal pancreatectomy is the most common minimally invasive pancreatic operation performed as there is no requirement for anatomic reconstruction after the tumor is removed. Although no prospective trials have been performed comparing open versus laparoscopic distal pancreatectomy, multiple retrospective studies have reported favorable perioperative outcomes, with decreased blood loss, complications rates, and shorter hospital stays associated with the laparoscopic approach.^{234, 235} The oncologic impact of open versus laparoscopic surgery has been less rigorously reported. Only three studies have described the oncologic outcomes of patients undergoing laparoscopic distal pancreatectomy.^{236–238} The largest study was a multicenter, retrospective matched cohort analysis; no differences in R0 resection status (74% vs 66%), lymph nodes examined (14 vs 12), or median OS (16 months vs 16 months) were observed between open and laparoscopic distal pancreatectomy.

In contrast to laparoscopic distal pancreatectomy, which is offered in most major centers, minimally invasive approaches to pancreaticoduodenectomy for pancreatic cancer have not yet achieved widespread acceptance. Few centers have a reported experience with 30 or more patients.^{239, 240} Among these studies, conversion to an open procedure occurred in approximately 6–10% of cases.

Robotic-assisted pancreaticoduodenectomy has also been reported with perioperative complication rates that appear comparable to the laparoscopic approach.^{241–243} Similar to distal pancreatectomy, the oncologic outcomes for minimally invasive pancreaticoduodenectomy are limited. In one of the largest series of minimally invasive pancreaticoduodenectomy for cancer, 108 patients were reported and their survival duration was no different than the larger cohort of patients who underwent an open pancreaticoduodenectomy. The authors suggested that with a minimally invasive approach, more patients may receive adjuvant therapy and in a more timely manner. However, time to the receipt of adjuvant therapy (duration of time from the date of surgery to the start of systemic therapy) has recently been shown to be less important than whether or not the patient receives all intended postoperative therapy.²⁴⁴

Pathologic (surgical) staging

The staging system of the AJCC and International Union Against Cancer is given in [Table 4](#). The modifications to the TNM staging system in the sixth edition allow for the accurate staging of patients even if they do not undergo pancreatic resection. The T4 (and stage III) designation is reserved for locally advanced unresectable primary tumors in the absence of distant metastases.²²⁶

Table 4 TNM staging system

<i>Definitions</i>			
<i>Primary tumor (T)</i>			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	<i>In situ</i> carcinoma		
T1	Tumor limited to pancreas and 2 cm or less in greatest dimension		
T2	Tumor limited to pancreas and more than 2 cm in greatest dimension		
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery		
T4	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)		
<i>Regional lymph nodes (N)</i>			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
<i>Distant metastasis (M)</i>			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
<i>Stage grouping</i>			
Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1–3	N1	M0
Stage III	T4	N0/1	M0
Stage IV	T1–4	N0/1	M1

When the (pathologic) pancreaticoduodenectomy specimen is evaluated, the surgeon and pathologist should first evaluate frozen sections of the common bile duct transection margin and the pancreatic transection margin. The SMA margin (the soft tissue margin directly adjacent to the proximal 3–4 cm of the SMA—[Figure 7b](#)) is then evaluated on permanent sections by inking the margin and sectioning the

tumor perpendicular to the margin.²²⁰ The R status of resection cannot be determined if the SMA margin is not assessed histologically. Most importantly, the surgeon and pathologist should classify this margin after integrating the operative findings and the histologic assessment of this margin. All pancreatic resections should be classified according to the R status: R0, no gross or microscopic residual disease; R1, microscopically positive surgical margins with no gross residual disease; and R2, grossly evident residual disease. The R designation should appear in the final operative report and should be consistent with the pathology report. The final pathologic evaluation of the permanent sections should include a description of the tumor histology and differentiation, gross and microscopic evaluation of the tissue of origin (pancreas, bile duct, ampulla of Vater, or duodenum), and a measurement of the maximum transverse tumor diameter, involved lymph nodes and total lymph nodes examined, and the presence or absence of perineural, lymphatic, and vascular invasion.

Prognostic factors

Investigators have examined pathologic factors of the resected tumor in an effort to establish reliable prognostic variables associated with decreased survival.^{218, 245} Regional lymph node metastases, poorly differentiated histology, and increased size of primary tumors have all been associated with decreased survival duration. Nevertheless, heterogeneity in patient outcomes remains. For example, in one study of 45 patients with pancreatic adenocarcinoma who underwent complete resection with both negative resection margins and negative regional lymph nodes, median survival was 32 months with a 5-year survival of 40%.²⁴⁶ However, another group reported on 12 five-year survivors (following complete resection); 4 had poorly differentiated histology, 5 had metastatic disease in regional lymph nodes, 9 had histologic evidence of malignant extrapancreatic soft tissue extension, and 10 had evidence of perineural invasion.²⁴⁷ Similarly, in a report of actual 5-year survivors, 36% were node positive, and 20% of all node positive patients survived 5 years; this last report utilized preoperative therapy before surgical resection.²⁴⁸

Adjuvant (postoperative) therapy

The first report of the beneficial adjuvant therapy was published in 1985 by the Gastrointestinal Tumor Study Group (GITSG).²⁴⁹ Since that time, several other prospective randomized trials have been conducted and published ([Table 5](#)).^{250–254}

Table 5 Summary of randomized trials of adjuvant therapy in resected pancreatic cancer

Study (year)	Number of enrolled patients	Patients with R1 resection (%)	Treatment assignment Median survival (months)	Treatment assignment Median survival (months)	p-Value	Local failure rate (%)
GITSG ²⁴⁹ (1985)	49	0	5-FU chemoradiation 21.0	Observation 10.9	0.035	NR
EORTC ²⁵⁰ (1999)	114	19	5-FU chemoradiation 17.1	Observation 12.6	0.09	34
ESPAC-1 ²⁵¹ (2004)	289	18	5-FU chemotherapy 20.1	No chemotherapy 15.5	0.09	60
			5-FU chemoradiation 15.9	No chemoradiation 17.9	0.009	
RTOG 9704 ²⁵² (2011)	388 (Head lesions)	≥35	Gemcitabinethen5-FU chemoradiationthen5-FU 20.5	5-FUthen5-FU chemoradiationthen5-FU 16.9	0.09	26
CONKO 001 ²⁵³ (2007)	368	19	Gemcitabine 22.8	Observation 20.2	0.005	>35%
ESPAC-3 ²⁵⁴	1088	35	Gemcitabine 23.6	5-FU/Folinic acid 23.0	0.42	NR

Abbreviation: NR, not reported.

These assorted trials have posed various questions: whether chemoradiation is better than observation after surgery, whether regimens that contain chemoradiation are superior to those that deliver chemotherapy alone or nothing, whether gemcitabine is superior to 5-FU-based therapy (either as systemic therapy alone, or with additional 5-FU-based chemoradiation).

Two of these studies deserve special mention. CONKO-001, a large, multinational European randomized trial compared gemcitabine with observation after surgery and showed a distinct survival advantage for those patients randomized to receive gemcitabine.²⁵³ In this trial, patients were randomized to receive six cycles of postoperative gemcitabine or observation alone after curative intent surgery. Although the median survival advantage was quite modest for patients randomized to receive gemcitabine (22.8 months vs 20.2 months, $p = 0.005$), the 3- and 5-year survival rates showed the clear superiority of treatment with gemcitabine over observation (26% vs 18% and 20% vs 9%, respectively). This trial provided the best level one evidence that chemotherapy alone improved disease-free and OS compared with surgery alone. ESPAC-3, the largest trial of adjuvant therapy ever conducted, provided additional information.²⁵⁴ This study enrolled 1088 patients from 159 pancreatic centers in Europe, Australasia, Japan, and Canada. Patients were randomized to receive either 5-FU 425 mg/m² and folinic acid (leucovorin) 20 mg/m² intravenously × 5 days every 28 days or gemcitabine 1000 mg/m² over 30 min weekly × 3 every 28 days. There was no difference in median OS between patients randomized to receive gemcitabine and those randomized to receive 5-FU/folinic acid (23.6 months vs 23.0 months, respectively, $p = 0.42$). However,

there was more toxicity leading to serious adverse events caused by 5-FU-based therapy compared with gemcitabine (14% vs 7.5%).

Taken together, CONKO-01 and ESPAC-3 support the use of systemic therapy alone as adjuvant therapy for pancreatic cancer and ESPAC-3 provides further evidence for the use of gemcitabine over 5-FU/folinic acid (based on differences in toxicity, not efficacy). Thus, at present, the standard adjuvant therapy after surgical resection with curative intent is six cycles of gemcitabine, given as three weekly injections every 28 days.

Radiotherapy in adjuvant therapy for pancreatic cancer: No role?

Despite years of investigation, questions still remain as to the possible additional benefits of radiotherapy as a component of adjuvant therapy. Proponents of radiation as a component of adjuvant therapy point to the initial results from the GITSG, single institution reports and data from SEER all showing that postoperative chemoradiation leads to median survival durations similar to those reported in ESPAC-3.²⁵⁵

In an effort to definitely answer the question about the role of radiotherapy in adjuvant therapy, the Radiation Therapy Oncology Group (RTOG) is conducting a large randomized trial (RTOG 0848), which delivers gemcitabine (with or without erlotinib) to all enrolled patients, and then restages these patients for interval development of metastatic disease.²⁵² For the subset of patients who do not develop metastatic disease, randomization assigns patients to either two more cycles of gemcitabine alone or one more cycle of gemcitabine followed by 5-FU-based chemoradiation to a total dose of 50.4 Gy to the surgical bed.

Other approaches to adjuvant therapy

Despite negative results using radiation as a component of adjuvant therapy, 5-FU-based chemoradiation remains a cornerstone of completed phase II adjuvant therapy trials. In one study, an intense course of chemoradiation consisting of external-beam radiation therapy (EBRT) at a dose of 45–54 Gy and three-drug chemotherapy: continuous infusion 5-FU, weekly intravenous bolus cisplatin, and subcutaneous interferon alpha (IFN α) reported encouraging survival.²⁵⁶ With a median follow-up of 31 months, median survival was not reached at the time of the initial report. A subsequent larger study had somewhat less impressive results with a median survival of 24.7 months and significant therapy-related toxicity.²⁵⁷

Another novel approach to adjuvant therapy was studied at the Johns Hopkins Hospital (JHH) with a focus on immunotherapy as one component.²⁵⁸ Investigators there treated a group of 60 patients who had undergone surgical resection of PDAC with an allogeneic pancreatic tumor cell vaccine genetically manipulated to express granulocyte-macrophage colony-stimulating factor (GM-CSF). The first vaccination was administered 8–10 weeks after surgical resection. Subsequently, patients received 5-FU-based chemoradiation. Patients who remained disease free after completion of chemoradiotherapy received further vaccinations. The median OS was 24.8 months. While these results are provocative, larger randomized phase II or III trials will be required to support the incorporation of immunotherapy into standard adjuvant therapy.

Adjuvant therapy for resectable pancreatic cancer: Is this the right strategy?

Adjuvant therapy has been investigated for 30 years; during that time, adjuvant therapy has been refined,

not improved. By definition, efforts to advance adjuvant therapy rely on a surgery-first approach. However, upfront surgery for resectable disease has significant drawbacks. First, even when the primary tumor appears technically resectable, positive surgical margins are common and from numerous reports in the literature to include ESPAC-3 show that positive surgical margins are associated with poor survival.^{222, 254, 259–262} Second, pancreatic cancer is a systemic disease, with metastases ultimately present in over 80% of patients who undergo surgical resection. Data from several sources show that approximately 15% of patients who receive preoperative therapy for resectable pancreatic cancer will develop radiographically evident metastases within 6–12 weeks of beginning anticancer therapy.^{263–269} It is therefore estimated that in patients who undergo surgery first, the likelihood of having metastatic disease seen on subsequent postoperative imaging is probably at least 20%. Finally, pancreatic cancer surgery is associated with significant morbidity and, in small-volume centers, mortality. Currently, about half of patients who undergo surgery first for pancreatic cancer ultimately receive adjuvant therapy, the other half does not.^{270–272}

Given the locally invasive and metastatic properties of PDAC, delivery of multimodal therapy in addition to surgery is required to increase the chances of long-term survival. However, if surgical resection is performed upfront and results in a margin positive resection, any meaningful chance for cure vanishes. Thus preoperative, or neoadjuvant therapy is gaining greater attention as a potentially superior approach to localized disease compared with upfront surgery and postoperative treatment.

Preoperative (neoadjuvant) therapy

There are many practical and theoretical advantages to preoperative treatment of patients with localized pancreatic cancer. Most compelling is the ability to provide immediate systemic therapy for a disease that is systemic at diagnosis in virtually all patients. Moreover, results from a number of institutions suggest that the delivery of chemoradiation as a component of neoadjuvant therapy may aid in the achievement of negative surgical margins at the time of attempted resection.²⁷³ Another important advantage of neoadjuvant therapy is improved patient selection for pancreatic surgery. Using a preoperative strategy, patients with rapidly progressive systemic disease are identified as part of the restaging evaluation performed following neoadjuvant treatment (before planned surgery).

Since 1988, five prospective preoperative trials have been completed at UTMDACC.^{263, 264, 267–269} These trials have had identical eligibility criteria using a CT-based definition of resectable disease (as previously described), a uniform surgical technique for the performance of pancreaticoduodenectomy, and a standardized system for pathologic evaluation of surgical specimens. Our two most recent trials have used a gemcitabine-based preoperative approach. The first trial used rapid-fractionation chemoradiation with seven weekly infusions of gemcitabine. A total of 86 patients were enrolled in this trial.²⁶⁸ In this trial, 74% of patients underwent successful pancreaticoduodenectomy. Overall, median survival for all 86 patients was 23 months with an actual 5-year survival of 27%. Median survival was 34 months for the 64 patients who completed all therapy to include surgical resection in the form of pancreaticoduodenectomy and 7 months for the 22 patients who did not undergo pancreatic resection (due to disease progression or evolving medical comorbidities). The actual 5-year survival for those who did and did not complete all therapy was 36% and 0%, respectively. In our subsequent gemcitabine-based neoadjuvant trial, we delivered additional systemic therapy before chemoradiation and planned surgery. Preoperative gemcitabine and cisplatin was given every 2 weeks for four doses followed by chemoradiation consisting of four weekly infusions of gemcitabine combined with radiation therapy (30 Gy in 10 fractions over 2 weeks).²⁶⁹ The study enrolled 90 patients and 79 (88%) completed chemo-chemoradiation. Sixty-two

(78%) of 79 patients were taken to surgery and 52 (66%) of 79 underwent pancreaticoduodenectomy. Median survival for the 79 patients who completed Gem-Cis-XRT was 19 months, with a median survival of 31 months for the 52 patients who received all therapy to include surgery and 10.5 months for those patients who did not undergo resection due to disease progression ($p < 0.001$). These results were essentially equivalent to those observed with preoperative gemcitabine-based chemoradiation without induction chemotherapy. Nevertheless, the results from these two preoperative gemcitabine-based chemoradiation trials are sufficiently compelling to justify broader investigation of neoadjuvant treatment for localized stage I/II pancreatic cancer.

Critics have been concerned that the delivery of neoadjuvant therapy may result in local tumor progression, precluding potentially curative surgery. In our studies, local tumor progression has occurred during preoperative therapy, but with rare exception, is accompanied by concurrent metastatic disease. Isolated local tumor progression occurred in <4% of all enrolled patients.

As previously stated, the standard of care in patients with resectable pancreatic cancer is upfront surgery. This strategy results in high rates of R1 resection, rapid onset of metastatic disease in an estimated 20% of patients, and inability to deliver postoperative therapy in almost half the patients. Thus, while neoadjuvant therapy for resectable disease remains investigational, more studies of neoadjuvant therapy are fully justified.

Neoadjuvant therapy in borderline resectable disease

With the advent of MDCT, and better understanding of the implications of positive surgical margins at surgery, tumors that are neither clearly resectable nor clearly unresectable have become increasingly recognized. These tumors are now being described as borderline resectable. While definitions vary, borderline resectable tumors can be broadly defined as tumors which abut but do not encase critical arterial structures such as the SMA, hepatic artery, or celiac axis, or tumors with varying degrees of involvement of the SMV, PV, and SMPV confluence.^{274, 275} As such, a borderline resectable tumor puts the patient at high risk for a margin-positive resection (R1 or R2) with upfront surgery, an independent predictor of poor survival.^{218, 259–262} On the basis of results in resectable disease, neoadjuvant chemoradiation leads to low R1 resection rates^{267–269} and reduces the risk of an R1 resection compared with upfront surgery.²⁷³ Further support for preoperative chemoradiation comes from our experience showing that approximately 40% of patients with borderline resectable disease can ultimately undergo surgical resection, with a median OS for the subset undergoing surgical resection equal to 40 months. Moreover, an R0 resection was achieved in 96% of resected patients.²⁷⁶

Given these lines of evidence, upfront surgery should be discouraged in patients with borderline resectable disease. Preoperative chemotherapy, chemoradiation, or both should be considered as sufficient tumor destruction, particularly at the tumor's periphery, could render a tumor resectable with curative intent (i.e., negative surgical margins).

Current practice guidelines now recommend initial nonoperative (neoadjuvant) multimodality treatment (followed by eventual surgery) for patients with borderline resectable pancreatic cancer.^{277–279}

Prospective trials of neoadjuvant therapy for borderline resectable pancreatic cancer are now being reported. Three basic strategies are being investigated: systemic therapy followed by surgical resection, chemoradiation followed by surgery, and induction chemotherapy, subsequent chemoradiation, with surgical resection performed last.^{280–282}

The role of radiation in borderline resectable disease

In comparison with adjuvant therapy, radiotherapy may have a better defined role in the preoperative treatment of potentially resectable disease, and as a component of neoadjuvant therapy for those patients who are considered to have borderline resectable disease. Results using preoperative radiation in resectable and borderline resectable PDAC are discussed earlier, with data regarding the role of radiation in borderline resectable cancer beginning to emerge.

Tumors of the pancreatic body and tail

Because adenocarcinomas of the pancreatic body and tail do not obstruct the intrapancreatic portion of the common bile duct, early diagnosis is rare, and most patients present with locally advanced or metastatic disease. The celiac axis or SMA is encased in most patients. Furthermore, peritoneal metastases are more frequent and laparoscopy before laparotomy is advised.^{283, 284}

Locally advanced pancreatic cancer

In the early 1980s, the delivery of chemoradiation was shown to improve survival compared with radiation alone for patients with locally advanced (unresectable) pancreatic cancer.²⁸⁵ For over 20 years thereafter, upfront chemoradiation was generally recommended to patients with locally advanced disease. This approach may be partly explained by the lack of active systemic agents for treatment of advanced PDAC at the time. However, after the approval of gemcitabine in 1997 for PDAC, trials that compared gemcitabine alone to chemoradiation showed conflicting results ([Table 6](#)). In a French study, patients with LAPC (locally advanced pancreatic cancer) were randomized to receive gemcitabine alone or radiation (total dose 60 Gy) with concurrent 5-FU and cisplatin, followed by gemcitabine.²⁸⁶ The median OS was higher in the gemcitabine alone arm compared with chemoradiation: 13.0 versus 8.6 months ($p = 0.03$), respectively. Of note, the trial was stopped prematurely owing to poor compliance and toxicity of the chemoradiation regimen.

Table 6 Select trials of chemotherapy, radiation, and chemoradiation in patients with locally advanced pancreatic cancer

Study (year)	Number of patients	Control arm Median survival (months)	Experimental arm Median survival (months)	p-Value
GITSG ²⁸⁵ (1981)	194	XRT 40 Gy (only) 5.5	5-FU + XRT 40–60 Gy 10	<0.01
FFCD/SFRO ²⁸⁶ (2008)	119	Gem alone 13.0	5-FU/Cisplatin + XRT 60 Gy then gem 8.6	0.03
ECOG 4021 ²⁸⁷ (2011)	74	Gem alone 9.2	Gemcitabine + XRT 50.4 Gy then gem 11.1	0.017
LAP07 ²⁹¹ (2013)	442 (269 in R2)	Induction gem ± erlotinib (R1) × 4 months if no progression then: gem × 2 months 16.5	Induction gem ± erlotinib (R1) × 4 months if no progression then Capecitabine + XRT 54 Gy 15.3	0.83

Abbreviation: Gem, gemcitabine; XRT, radiation; R1, first randomization; R2, second randomization.

In contrast, ECOG 4201 showed superiority of gemcitabine-based chemoradiation compared with gemcitabine alone. It compared upfront gemcitabine-based chemoradiation, followed by weekly gemcitabine with standard treatment using gemcitabine alone. Although it closed prematurely after accruing only 74 of a planned 316 patients, a statistically significant median survival benefit was seen in the patients randomized to receive chemoradiation compared with those who received chemotherapy alone, 11.0 months versus 9.2 months, $p = 0.034$. This benefit came at the cost of increased gastrointestinal toxicity (grade 3 or greater gastrointestinal toxicity 38% vs 14% $p = 0.03$) and fatigue, 32% versus 6%.²⁸⁷ Thus, the addition of radiation to standard chemotherapy resulted in a modest prolongation of median survival at the cost of a modest increase in toxicity that remained manageable.

During this same time period, a shift in the management of LAPC began to occur. In a retrospective analysis conducted at UTMDACC, patients with LAPC who were initially treated with systemic therapy followed by chemoradiation had longer survival times compared with patients who were initially treated with upfront chemoradiation (median survival 11.9 months vs 8.5 months).²⁸⁸ The authors suggested that systemic therapy acted as a selection mechanism to identify patients with rapidly progressing disease. This was supported by reports from two prospective trials^{289, 290} that suggested induction chemotherapy followed by chemoradiation led to favorable median OS (15–17 months). Of note, in both trials, approximately 30% of patients progressed on induction systemic therapy delivered for 3–6 months; these patients did not go on to receive subsequent chemoradiation.

Most recently, the trial with the greatest impact on clinical practice is the LAP 07 trial, a multinational trial conducted in Europe. Preliminary data from the LAP 07 trial reveal no clear benefit with the addition of conventional chemoradiation following gemcitabine chemotherapy.²⁹¹ Using a 2×2 randomized design, patients received initial gemcitabine with or without erlotinib for 4 months and for those patients who did not develop metastatic disease, a second randomization assigned patients to receive 2 additional months of gemcitabine or capecitabine-based chemoradiation (54 Gy to the gross tumor alone). After a median follow-up of 36 months, there was no difference in median OS between the chemotherapy and chemoradiation groups (15 months vs 14 months, respectively, $p = 0.083$). Further details in regard to the results of LAP 07 are awaited when the manuscript is published.

Chemotherapy alone versus chemotherapy and subsequent chemoradiation: How to select patients?

Similar to the delivery of preoperative therapy before surgical intervention, induction chemotherapy allows an interval of time to uncover unfavorable tumor biology manifest by onset of metastatic disease. Just as resectable patients who develop metastatic disease during preoperative therapy will not benefit from surgery, LAPC patients with aggressive disease that quickly disseminates will not benefit from local therapy in the form of chemoradiation. While LAP 07 did provide a mechanism for identifying patients with aggressive tumor biology with the delivery of 4 months of systemic gemcitabine, it does not provide a mechanism to identify a subset of patients who may benefit from consolidative chemoradiation.

In the future, SMAD4 may be useful to select patients for systemic therapy, of for standard dose or dose-intensified radiation therapy. Currently, the only active clinical trial in the United States for this population has been designed to evaluate the role of radiation after induction chemotherapy with gemcitabine and nab-paclitaxel (RTOG 1201). SMAD4 expression status is a stratification variable and patients are randomized to receive six cycles of chemotherapy alone in the standard arm, four cycles of chemotherapy followed by 50.4 Gy in 28 fractions or four cycles of chemotherapy followed by 63 Gy in 28 fractions using intensity-modulated radiation therapy (IMRT). Concurrent capecitabine will be given with radiation. This trial will evaluate the value of SMAD4 as a predictive marker for chemoradiation

decision making and provide further data evaluating the role of chemoradiation in the context of more active chemotherapy.

Gemcitabine-based versus fluoropyrimidine-based chemoradiation

The introduction of gemcitabine was a modest step forward in the treatment of pancreatic cancer. Its value as a systemic agent in pancreatic cancer and discovery of its potent radiosensitizing properties,²⁹² stimulated the study of combinations of gemcitabine with EBRT for patients with localized pancreatic cancer.^{293–297} Most of these studies suggested gastrointestinal toxicity as a dose-limiting factor, but hematologic toxicity has also been observed. At the present time, there is no standard approach for combining gemcitabine and radiation, but several variables appear to be important in predicting the maximum tolerated dose (MTD). These include variations in the size of the radiation portal, the total radiation dose, possibly the dose of radiation per fraction, and whether gemcitabine is administered once or twice weekly.²⁹⁸

The best data available comparing concurrent chemotherapeutic agents in the setting of LAPC come from the SCALOP trial. In a randomized phase II design of 114 patients with locally advanced PDAC, a course of gemcitabine and capecitabine for 12 weeks was followed by chemoradiation with either gemcitabine (300 mg/m² weekly) or capecitabine (830 mg/m² twice daily on days of radiation). A longer median OS with less toxicity was reported with the use of capecitabine compared to gemcitabine (15.2 months vs 13.4 months, $p = 0.012$).²⁹⁹

Radiotherapy technique for patients with locally advanced PDAC

Patients with locally advanced tumors probably do not benefit from regional lymph node irradiation; radiotherapy fields should therefore be confined to the gross tumor. This strategy reduces the gastrointestinal toxicity of chemoradiation. Thus, it is important to identify the pancreatic tumor correctly. On contrast-enhanced CT, pancreatic tumors are typically hypodense compared with the surrounding pancreatic parenchyma. When there is doubt about the location of the primary tumor, CT images should be reviewed with an experienced radiologist. Administration of an oral contrast agent at the time of simulation illuminates the duodenal “c-loop.” Endobiliary biliary stents can also be visualized, which facilitates identifying the common bile duct.

The pancreas and duodenum move a median of 1 cm with respiratory excursion.³⁰⁰ If the gross tumor alone is to be treated, respiratory motion must be either controlled or accounted for in radiotherapy planning. This is commonly accomplished by simply adding an additional margin to the planned radiation fields in the cranial and caudal directions. However, because axial tumor motion is negligible, an additional margin for motion in the axial directions is not necessary. Radiation treatment that is gated to the respiratory cycle (respiratory gating)³⁰¹ is a necessary component of radiation dose escalation studies that seek to deliver >60 Gy to the primary tumor while sparing the duodenum. Thus, radiation fields designed to spare the duodenum that are tightly confined to the primary tumor without correction for organ motion could lead to under-dosing of the tumor target, or “marginal miss.” A four-field technique is recommended with equally weighted anterior, posterior, and opposed lateral fields. A 2-cm block margin is used in the radial directions, and a 3-cm margin is used in the cranial and caudal directions.

Novel approaches to chemoradiation

Molecular agents as radiosensitizers

Just as molecular agents have been combined with cytotoxic chemotherapy, targeted drugs are being actively investigated as radiosensitizers in solid tumors.³⁰² In LAPC, none of the currently available inhibitors (gefitinib, erlotinib, panitumumab, or cetuximab) have been evaluated in multi-institutional trials in combination with radiation for pancreatic cancer. Nevertheless, small clinical trials using molecular radiosensitizers have demonstrated encouraging results, particularly those which combine EGFR inhibitors with radiation.^{303–305} Unfortunately, as EGFR inhibitors have not significantly improved clinical outcomes for patients with advanced pancreatic cancer when combined with chemotherapy,^{306, 307} investigation of EGFR inhibition as radiosensitization has stopped as well.

Stereotactic radiation body therapy (SBRT) for pancreatic cancer

Stereotactic body radiotherapy (SBRT) is capable of precisely delivering high doses of radiation to small tumor volumes. The feasibility of SBRT as a pancreatic cancer treatment has been investigated in a phase I and phase II trials of a single fraction of radiation therapy in patients with LAPC.^{308, 309} On the basis of limited efficacy and significant toxicity, investigation shifted in favor of a five fraction regimen. A multi-institutional trial evaluating SBRT (33 Gy in five fractions in 1 week) has been reported.³¹⁰ Results indicate good tolerability and median survivals comparable to chemoradiation at standard fractionation. Thus, it appears that SBRT given in five fractions is perhaps better tolerated and more convenient than standard chemoradiation, with similar efficacy. If long-term survival is the goal, better local tumor control is needed.

Irreversible electroporation in locally advanced pancreatic cancer

Although not a radiotherapeutic intervention, irreversible electroporation (IRE) is being investigated as a local ablative technique receiving increasing attention in oncology.³¹¹ IRE involves the delivery of pulses of high-voltage energy through the placement of electrodes into a solid tumor mass. These pulses lead to the formation of pores in the phospholipid cell membrane, which changes cellular permeability and results in apoptotic cell death. The advantage of IRE over other ablative techniques is the absence of thermal injury to surrounding tissues, specifically vascular and ductal structures.³¹² Early experience has been reported using IRE in 27 patients with LAPC.³¹³ In eight patients, IRE was combined with surgical resection (four head lesions and four left-sided resections) for the purpose of margin accentuation. In the remaining 19, IRE was performed *in situ*. All 27 patients developed elevation of their amylase and lipase, which peaked at 48 h and returned to normal at 72 h postprocedure. Other centers are beginning to report on their experience with IRE to include percutaneous, image-guided localization of the electrodes.³¹⁴

On the basis of current literature, there appears to be growing enthusiasm for this technique, particularly for patients with borderline resectable and locally advanced disease.³¹⁵ However, broader multi-institutional experience will be required to develop more refined criteria to select patients and appropriate sequencing of this technique with other therapeutic modalities. As previously emphasized given the systemic nature of PDAC, systemic therapies should precede any local therapeutic intervention (IRE, surgery, or chemoradiation).

Approach to patient with locally advanced pancreatic cancer

Whenever possible, patients with locally advanced disease having a good PS should be treated in the context of a clinical trial. This may involve a predefined course of chemotherapy followed by chemoradiation, or alternatively a program of chemoradiation with a targeted agent, followed by further

systemic therapy.

Outside of a clinical trial, systemic therapy may improve both pain control and PS,³¹⁶ and avoids the gastrointestinal toxicity associated with chemoradiation.

The role of systemic therapy in pancreatic cancer

While surgery and radiotherapy have important roles in the treatment of pancreatic cancer, these modalities are generally limited to the subset of patients with localized disease. Furthermore, as described earlier in this chapter, radiation therapy may have additional benefits for select patients with locally advanced PDAC. In contrast, systemic therapy has proved benefit as adjuvant therapy after potentially curative surgery,²⁵³ in the treatment of locally advanced PDAC,²⁹¹ and as the primary therapy for metastatic disease.³¹⁷ Until recently, the mainstay of systemic therapy has been gemcitabine which remains the standard of care as adjuvant therapy and for the treatment of locally advanced PDAC. However, with the advent of FOLFIRINOX and gemcitabine plus nab-paclitaxel (both of which are superior to gemcitabine monotherapy in metastatic disease),^{318, 319} further investigation of these regimens in earlier stages of disease is certain, with the goal of (1) improving cure rates and survival for those undergoing surgery with curative intent, (2) increasing the proportion of patients with borderline resectable disease undergoing subsequent surgery with curative intent, (3) prolonging survival of patients with borderline resectable disease who are not ultimately surgical candidates, and (4) improving survival for those with locally advanced PDAC.

The evolution of systemic therapy

A history of systemic therapy for pancreatic cancer is beyond the scope of this chapter and is well summarized in a number of review articles published on this subject.

On the basis of the early and more recent trials of systemic cytotoxic agents, several conclusions can be drawn. First, bolus 5-FU has virtually no activity in the setting of advanced PDAC.^{316, 320} However, both infusional 5-FU and capecitabine have very modest single agent activity in pancreatic cancer of 7–8%.^{321, 322} Second, gemcitabine monotherapy leads to an objective response rates (RR) of approximately 10%; this has been consistent across studies and time. Third, several gemcitabine doublets lead to improved objective rates compared to gemcitabine alone. However, with the exception of gemcitabine plus nab-paclitaxel, combining gemcitabine with oxaliplatin, cisplatin, bolus 5-FU, or capecitabine has demonstrated no statistically significant improvement in survival compared with delivery of gemcitabine alone ([Table 7](#)).^{319, 323–331} Most importantly, PS remains an important predictor of OS. As early as 1985, PS was observed to have impact on patient survival for patients with all stages of pancreatic cancer.³³² This observation has been supported in the modern era by findings from CALGB 80803³³³ and the randomized trial of gemcitabine versus gemcitabine plus nab-paclitaxel.³³⁴

Table 7 Summary of completed randomized trials of gemcitabine versus a cytotoxic gemcitabine doublet in the treatment of advanced PDAC

Principal investigator (year)	Number of patients	Patients with metastatic disease (%)	Control arm Median overall survival (months)	Experimental arm Median overall survival (months)	p-Value

New regimens in metastatic disease: FOLFIRINOX and gemcitabine/nab-paclitaxel

Since the last edition of this text, two new combination regimens have been proved to extend survival of patients with metastatic disease compared with gemcitabine alone (Table 8). FOLFIRINOX was initially shown in a phase 2 trial with 47 patients to generate an objective RR of 26% and a median survival of 10.2 months.³³⁵ It was then investigated in a large randomized phase 3 trial comparing FOLFIRINOX to gemcitabine alone.³¹⁸ FOLFIRINOX was superior to gemcitabine in terms of RR (32% vs 9%), progression-free survival (PFS) (6.4 months vs 3.3 months), and OS (11.1 months vs 6.8 months). The hazard ratio for death favored FOLFIRINOX at 0.57, $p < 0.001$. Of note, this trial limited enrollment to chemo-naïve patients with metastatic disease and having an ECOG PS 0 or 1.

Table 8 Summary of randomized trials of cytotoxic drugs or drug combinations for advanced or metastatic pancreatic cancer

	Burris 1996 ³¹⁶		Conroy 2011 ³¹⁸ (ACCORD)		Von Hoff 2013 ³¹⁹ (MPACT)	
Treatment	Bolus 5-FU	Gem	Gem	FOLFIRINOX	Gem	Gem/nab-P
PS	Karnovsky PS ≥ 50%		ECOG PS 0 or 1		Karnovsky PS ≥ 70%	
Patients with Met Dz (%)	70		100		100	
RR (%)	0	10	9	32	7	23
MS (months)	4.5	5.7	6.8	11.1	6.7	8.5
1-Year survival (%)	2	18	21	48	22	35
Neutropenia (%)	5	25	21	46	27	38

Diarrhea (Grades 3–4)	6	2	2	13	1	6
Neuropathy	NS	NS	0	9	7	17

Abbreviations: PS, performance status; Gem, gemcitabine; nab-P, nanoparticle-albumin-bound paclitaxel; MS, median survival; NS, not stated; RR, response rate.

Slightly later, nanoparticle, albumin-bound (nab)-paclitaxel was also investigated in pancreatic cancer. At the maximum tolerated dose of nab-paclitaxel (125 mg/m²) combined with gemcitabine (1000 mg/m²) administered weekly × 3 weeks followed by 1 week off and repeated, the objective RR was 48%, with a median survival of 12.2 months.³³⁶ This impressive result prompted a larger randomized phase 3 trial comparing gemcitabine plus nab-paclitaxel with gemcitabine alone.³¹⁹ The eligibility criteria for this trial allowed for the enrollment of chemo-naïve patients with metastatic disease having a KPS ≥ 70% (roughly equivalent to ECOG PS 0-2). The trial enrolled 861 patients and demonstrated gemcitabine/nab-paclitaxel was superior to gemcitabine alone in RR (23% vs 7%), PFS (5.5 months vs 3.7 months), and survival. Median OS was superior for the doublet at 8.5 months versus 6.7 months for gemcitabine (HR for death, 0.72; *p* < 0.001). Not surprisingly, as seen in prior clinical trials, subsequent analysis revealed that patients with KPS 70–80% had inferior survival compared with those having a KPS 90–100%.³³⁴

On the basis of these large well-designed clinical trials, both FOLFIRINOX and gemcitabine/nab-paclitaxel represent significant advances in the systemic treatment of metastatic pancreatic cancer. Moreover, the availability of both regimens provides clinical oncologists with some flexibility in choosing frontline therapy as there are differences in the toxicity profiles for these regimens with both regimens sharing a sizable risk for neutropenia.³³⁷

Molecular agents in pancreatic cancer: Virtually no added value

Attempts to improve pancreatic cancer therapy using modern molecular therapeutics have been disappointing although molecular agents have changed the face of cancer therapy in other gastrointestinal tumors to include hepatocellular carcinoma,³³⁸ advanced colorectal cancer,³³⁹ and more recently gastric cancer.³⁴⁰ A number of randomized trials have compared the efficacy of gemcitabine or a gemcitabine combination to the same regimen with the addition of a targeted agent.^{306, 307, 333, 341–345} Only the

combination of gemcitabine and erlotinib has led to a small, statistically significant survival advantage over gemcitabine alone.³⁰⁶ In a large placebo-controlled, double-blind, phase III trial conducted by the National Cancer Institute of Canada, 569 patients were randomized to receive gemcitabine and erlotinib or gemcitabine plus placebo. The median survival for patients randomized to receive gemcitabine/erlotinib was 6.24 months versus 5.91 months for gemcitabine/placebo; hazard ratio for death 0.82, $p = 0.038$).

More recently, provocative preclinical experiments showed that hedgehog pathway inhibition could modulate the PDAC tumor microenvironment and facilitate enhanced delivery of cytotoxic agents to the tumor mass.¹⁸³ This led to the conduct of a placebo-controlled, double-blind, randomized phase 2 trial comparing gemcitabine plus saridegib (a hedgehog inhibitor) with gemcitabine plus placebo in 122 previously untreated patients with metastatic pancreatic cancer. The trial was terminated early based on an interim analysis showing that patients who were randomized to receive the gemcitabine/saridegib arm had inferior survival compared with patients receiving gemcitabine/placebo (www.businesswire.com/news/home/20120127005146/en/Infinity-Reports-Update-Phase-2-Study-Saridegib). Future successful clinical testing of molecular therapeutics for treatment of PDAC will require rigorous and compelling preclinical data, in addition to disciplined clinical trial design. This will be discussed in more detail in section titled “Future Directions.”

Systemic therapy for “BRCAness”

Clinicians have recognized for some time that patients with PDAC are heterogeneous and a subset will have a protracted course of disease and survival that significantly exceeds median survival times reported in the literature (for all stages of disease). In addition, the objective responses to chemotherapy can occasionally be quite striking. Such patients likely have underlying germ line or somatic mutations that render the tumors more susceptible to the cytotoxic effects of chemotherapy, particularly DNA damaging agents (oxaliplatin, cisplatin, and mitomycin C) and possibly topoisomerase inhibitors. Genetic testing for germ line mutations in *BRAC1*, *2*, and *PALB2* is often negative and cannot explain exquisite sensitivity to these agents. Nevertheless, there appear to be poorly defined subsets of sporadic cancers that may have characteristics suggesting defects in DNA repair pathways with greater sensitivity to treatment with specific cytotoxic agents. Some authors have described these sporadic cancers as having a “BRCAness” phenotype, likely explained by mutations, amplifications, or methylation of the genes regulating DNA repair.³⁴⁶ There are hints from the clinic to support this notion. A retrospective analysis of patients from JHH who had received cytotoxic therapy with or without a platinum analog suggested that patients with a family history of pancreatic, breast, or ovarian cancer were more likely to benefit from a platinum containing regimen, compared with patients having no such history. Importantly, somatic mutations in *BRCA2* in pancreatic cancer are now being reported in PDAC,³⁴⁷ and these tumors may also be quite sensitive to DNA damaging chemotherapeutic agents.

In the future, better characterization of BRCAness may identify a broader subset of patients who may benefit from treatment with platinum, mitomycin C, and possibly topoisomerase inhibitors. Of further note, PARP inhibitors, now entering clinical trials in PDAC, may be particularly useful in germ line *BRCA*-mutated patients and/or sporadic tumors considered to have BRCAness.

Approach to the patient with metastatic disease

Options for systemic treatment

On the basis of the data presented earlier regarding the role of cytotoxic therapy in metastatic PDAC, an accurate assessment of a patient's PS is critical to decision making and recommendations for treatment. Systemic therapy for metastatic disease should be actively discouraged in patients with poor PS (ECOG > 2, KPS < 70%) or if significant metastatic tumor burden is present. Whenever possible, patients with good PS should be encouraged to enroll in a clinical trial. When enrollment in a trial is not possible or desired, for ECOG PS 0-1 patients, therapy with FOLFIRINOX or gemcitabine/nab-paclitaxel is appropriate frontline options. In patients with ECOG PS 2 or KPS 70%, gemcitabine/nab-paclitaxel is a valid choice, but should be administered cautiously, with close follow-up and low-threshold for dose/schedule adjustments. For patients who are equivocal candidates for systemic therapy, gemcitabine monotherapy may be considered. The addition of erlotinib in this setting is also reasonable; the anticipated benefits of this drug should not be overstated and it may have decreasing relevance as a component of systemic therapy in the future.³⁰⁶

At present, second line therapy should be limited to those patients who are maintaining adequate PS in the face of disease progression and is obviously dependent on prior first line therapy. Supportive care as an alternative to continued anticancer therapy should be thoroughly discussed.

Supportive care and palliation

Metastatic pancreatic cancer is characterized by anorexia, cachexia, and pain. Jaundice may result from the primary tumor or intrahepatic metastases. Local tumor progression can lead to worsening pain, gastric outlet obstruction, or gastroparesis, and patients with peritoneal carcinomatosis may suffer from intractable ascites, intestinal dysmotility, or mechanical obstruction. Constipation is also very common. Patients are also at risk of VTE, but the risk is not clearly higher than that associated with other gastrointestinal tumors.³⁴⁸ Palliation must always be the primary goal and is facilitated by a multidisciplinary team. Symptomatic relief of biliary obstruction and pain should be addressed before initiation of systemic therapy. For most patients, adequate pain control can be obtained with the use of long- or short-acting narcotics, without excessive sedation.³⁴⁹ However, if pain is not well controlled with oral or transdermal narcotics or if these agents are poorly tolerated, patients should be evaluated for celiac plexus or splanchnic plexus ablation. Whether EUS-guided neurolytic blocks are superior to fluoroscopic- or CT-guided blocks remains an open question, but EUS-guided neurolysis has been shown to be superior to CT-guided blockade in patients with chronic pancreatitis.³⁵⁰

Given the poor prognosis for patients with metastatic disease, biliary obstruction should be relieved with nonsurgical means whenever possible. The use of duodenal stents in patients with mechanical gastric outlet obstruction and poor prognosis is becoming more widely accepted.³⁵¹ For patients with intractable symptomatic ascites, paracentesis is generally perceived as most efficacious,³⁵² but it is not an intervention with durable benefits. Insertion of an intraperitoneal catheter to control ascites is a preferred alternative to frequent paracenteses, and the overall risk of infection is low.³⁵³

Prophylactic treatment with low-molecular-weight heparin can reduce the risk of VTE in patients with advanced disease receiving chemotherapy.³⁵⁴ However, impact on OS with this intervention has yet to be demonstrated.

Future directions

On the basis of evidence presented in other sections of this chapter, progress in the treatment of pancreatic cancer is obviously slow and incremental. With a greater understanding of PDAC tumor biology and

microenvironment, coupled with the availability of a broader range of agents designed to kill tumor cells, modulate the tumor microenvironment, or augment the host immune response, better treatment of pancreatic cancer is anticipated. At present, the thrust of ongoing efforts can be partitioned into three categories: (1) improvement in nonimmune killing of tumor cells directly, (2) modulation of the tumor microenvironment to promote cancer cell death, and (3) enhancing immune destruction of PDAC.

Nonimmune killing of tumor cells

Combination cytotoxic chemotherapy

One of the most important lessons from early experience with FOLFIRINOX may be that combination cytotoxic therapy can be more effective than monotherapy or even doublet therapy.³⁵⁵ Thus, investigation of other triplet combinations is currently underway and includes studies with combinations of gemcitabine, cisplatin and nab-paclitaxel (GAC), and 5-FU, leucovorin, oxaliplatin, and nab-paclitaxel (FOLFOX-A) (www.clinicaltrials.gov).

New cytotoxic drugs: Irinotecan reformulated

MM 398 is a nanoliposomal encapsulation of irinotecan (nal-IRI), which has been reported to have improved pharmacokinetics and tumor biodistribution compared with the parent compound. This drug has been investigated as a single agent in 40 patients with gemcitabine-refractory pancreatic cancer and yielded a RR of 7.5% and median OS of 5.2 months.³⁵⁶ Subsequently, Napoli-1, a three-armed randomized study comparing nal-IRI alone with nal-IRI plus 5-FU/leucovorin or 5-FU/leucovorin alone, has generated some preliminary results. Nal-IRI plus 5-FU/leucovorin was superior to 5-FU/leucovorin alone in gemcitabine-refractory advanced pancreatic cancer patients (median survival 6.1 months vs 4.2 months, $p = 0.012$).³⁵⁷ Final results are awaited.

Ruxolitinib

The Janus kinase/signal transducer and transcriptional activator (JAK/Stat)-3 pathway has been reported to be constitutively activated in pancreatic cancer, with inhibition of this pathway abrogating growth of tumor cells *in vitro*.³⁵⁸ Ruxolitinib is a JAK2 inhibitor recently approved for the treatment of myelofibrosis and other myeloproliferative disorders.³⁵⁹ This agent has been studied in a group of patients with gemcitabine-refractory pancreatic cancer in a placebo-controlled trial assigning patients to ruxolitinib plus capecitabine or placebo/capecitabine.³⁶⁰ In a prespecified analysis of enrolled patients with C reactive protein (CRP) levels >13, ruxolitinib/capecitabine prolonged PFS and OS compared with placebo/capecitabine. A larger phase 3 trial of ruxolitinib or placebo with capecitabine is now underway and enrolling patients with CRP levels >10 (www.clinicaltrials.gov).

PARP inhibitors

As discussed previously, a small subset of patients with PDAC harbor germ line mutations of *BRCA1*, *BRCA2*, or *PALB2*. A larger proportion may have somatic mutations of *BRCA1* or *BRCA2* in their tumor cells.³⁴⁷ These pancreatic tumors are theoretically more susceptible to the effects of PARP inhibition, resulting in synthetic lethality.³⁶¹ Investigations of several PARP inhibitors to include olaparib, veliparib, rucaparib, and BMN-673 are now underway in patients with PDAC.³⁶²

Drugs to modulate the tumor microenvironment

Hyaluronidase

Hyaluronic acid is an important component of the extracellular matrix in which PDAC thrives.³⁶³ Variants of CD44, a transmembrane glycoprotein expressed on the surface of tumor cells, are capable of binding hyaluronic acid, leading to enhanced proliferation and invasion. On the basis of more recent studies, there has been renewed interest in degradation of hyaluronic acid as a means to modulate the tumor stroma and enhance the delivery of cytotoxic chemotherapy.^{135, 364, 365} Early phase clinical investigation of PEGPH20 (PEGylated recombinant human hyaluronidase) has shown promise when combined with single agent gemcitabine.³⁶⁶ Therefore, a multicenter study is now investigating the addition of hyaluronidase to conventional cytotoxic therapy in an effort to improve the cytotoxic effect of chemotherapy. This trial is currently enrolling patients with previously untreated metastatic disease with the results anticipated in the next 1–2 years (www.clinicaltrials.gov).

Drugs designed to modulate the cellular constituents of PDAC microenvironment

In addition to efforts aimed at manipulating the extracellular matrix of pancreatic cancer, there are now agents becoming available that may modulate the cellular component of PDAC's microenvironment. These include CD40 agonists, which have the capability to release bone marrow-derived elements from primary pancreatic adenocarcinoma tumors based on murine models and clinical investigation.³⁶⁷ One of these agents, CP-870,893, a monoclonal antibody, is entering clinical investigation and the delivery of such an agent in combination with chemotherapy appears to be safe.³⁶⁸ However, a clear efficacy signal to suggest augmentation of the cytotoxic effects of chemotherapy or radiation has yet to be established.

Another interesting compound is PF-04136309, a chemokine receptor type 2 (CCR2) antagonist. Activation of CCR2 mobilizes monocytes and macrophages from the bone marrow to infiltrate malignant tumors. These inflammatory monocytes appear to have tumor-promoting properties. Preclinical models have demonstrated that the delivery of PF-04136309 decreases circulating monocytes and reduces the monocytic infiltration of pancreatic adenocarcinomas grown in mice.³⁶⁹ Furthermore, inhibition of CCR2 resulted in enhanced antitumor immunity, decreased tumor growth, and reduced metastasis. There has been some early clinical investigation of this compound in conjunction with FOLFIRINOX. The drug appears to be safe when delivered in combination with FOLFIRINOX, with early results suggesting improved anticancer effect.³⁷⁰

Another approach to modulate PDAC stroma has been proposed by investigators at the Salk Institute. They showed that vitamin D receptor (VDR) is expressed in malignant pancreatic stroma and is associated with markers of inflammation and fibrosis. Treatment with a ligand to the VDR led to transcriptional changes, stromal remodeling, and decreases in markers of inflammation and fibrosis. When calcipotriol (a vitamin D analog) was delivered in conjunction with gemcitabine, they observed increased intratumoral gemcitabine levels and improved survival in a murine model of pancreatic cancer.¹⁸⁷ Clinical investigation is now adding paricalcitol (a commercially available VDR agonist) to chemotherapy in a neoadjuvant trial (www.ctrc.net/documents/pdf/VonHoff_2015.pdf).

Augmentation of immune response to pancreatic cancer

The entire discipline of immunotherapy in cancer is rapidly changing. Efforts have included the development of more sophisticated and specific vaccination strategies, the delivery of checkpoint inhibitors, the isolation and expansion of T cell subsets from patients for reinfusion, and the molecular manipulation of T cells to enhance cancer cell recognition and immune destruction. Detailed description of such efforts can be found elsewhere in the textbook. Nevertheless, some specific examples of novel

immunologic approaches are described in the following sections.

Vaccine therapy

Efforts to enhance the immunologic response to pancreatic cancer using vaccine strategies have been going on for years. The group at JHH has continuously worked to explore the benefit of injecting GM-CSF-secreting allogeneic pancreatic tumor cells (now named GVAX) into patients with pancreatic cancer.³⁷¹ Early trials administering GVAX to patients with pancreatic cancer demonstrated the development of specific immune responses and suggested clinically relevant activity.³⁷² Most recently, in an effort to improve the efficacy of GVAX, a combination of low-dose cyclophosphamide (used to inhibit regulatory T cells) with GVAX and CRS 207 (live-attenuated *Listeria monocytogenes*-expressing mesothelin) was compared with treatment using low-dose cyclophosphamide (Cy) and GVAX alone in a 2 : 1 randomized phase 2 trial.³⁷³ The trial enrolled 90 patients with metastatic pancreatic cancer (97% previously treated). Patients who received Cy, GVAX, and CRS 207 had longer PFS and OS compared with patients who received only Cy and GVAX. OS was 6.1 months in the Cy/GVAX/CRS 207 arm versus 3.9 months in the Cy/GVAX arm (hazard ratio 0.59; $p = 0.02$). Of further note, in a prespecified per-protocol analysis of patients who received at least three doses (two doses of Cy/GVAX plus one of CRS-207 or three of Cy/GVAX), OS was 9.7 versus 4.6 months in favor of those who received CRS 207. These results are provocative and provide the first strong evidence of a clinical benefit to immune therapy in advanced pancreatic cancer.

Check point inhibition

With the development of checkpoint inhibitors, to include ipilimumab and nivolumab,¹⁸⁸ there has been great interest in the potential for immunotherapy to dramatically augment the current armamentarium of systemic agents used in pancreatic cancer. Unfortunately, early trials of ipilimumab as a single agent in advanced pancreatic cancer have been disappointing.¹⁸⁹ Other checkpoint inhibitors are now being investigated to include nivolumab and MEDI-4736, an anti-PD1 monoclonal antibody.³⁷⁴ These agents are unlikely to be sufficiently active as single agents to alter the course of pancreatic cancer for most patients, and it can be expected that their future investigation in PDAC will likely involve the delivery of vaccines, cytotoxic drugs, radiotherapy, other molecular agents, or modulated T cells.³⁷⁵

Another potentially important target in PDAC is CD47, a cell surface protein expressed by cancer cells. CD47 acts signals macrophages and cytotoxic T cells as a “don't eat me” command. Investigators have synthesized anti-CD47 monoclonal antibodies that can prevent the inhibitory signal of CD47 and promote phagocytosis and subsequent priming of T cells to both recognize and kill cancer cells *in vitro* and in *in vivo* models.³⁷⁶

T cells directed against PDAC

A number of groups are intensively working to both decrease the inhibitory signals of regulatory T cells and to amplify the very potent cytotoxic capabilities of tumor-infiltrating lymphocytes (TILs). Much work needs to be done in the fundamental biology and immunology of pancreatic adenocarcinoma, but preclinical and clinical studies are suggesting that these approaches will have the potential to modulate the tumor microenvironment and add to our weaponry in pancreatic cancer.³⁷⁷

Discipline, discipline, discipline

Since clinical trials in the treatment of pancreatic cancer began about 50 years ago, some hard lessons

have been learned as to the need for greater discipline in clinical trial design and clinical practice for patients with PDAC.

First, as recognized from prior trials in pancreatic cancer, criteria for trial enrollment should include careful assessment of PS, limiting enrollment of patients to those having KPS of at least 70% or ECOG PS > 2. Second, we must use more stringent criteria for protocol entry to segregate patients with distinct clinical stages of PDAC: resectable, borderline resectable, locally advanced, and metastatic disease. Failure to do so hampers rapid-learning and progress in any given disease stage.

Third, we need to be more rigorous in assessing the validity of preclinical models to predict clinical benefit of any given drug or drug combination. Lastly, translational research using innovative imaging, blood-, or tissue-based analyses should be incorporated into virtually every early phase trial seeking to demonstrate tumor cell killing, stromal modification, or other biologic changes deemed relevant for clinical benefit. If we merge our understanding of the fundamental tumor biology with a disciplined approach to preclinical and clinical testing of novel agents and approaches, we are certain to make more significant progress for our pancreatic patients in the near future.

Chapter 94

Neoplasms of the small intestine, vermiform appendix, and peritoneum and carcinoma of the colon and rectum

Georgia M. Beasley, MD ■ Zhifei Sun, MD ■ Daniel P. Nussbaum, MD ■ Douglas S. Tyler, MD

Overview

Cancers of the small bowel, large bowel, and appendix compromise a multitude of distinct pathologic entities and clinical presentations. While tumors of the small bowel are uncommon with <3% of all alimentary tract tumors and 0.4% of all malignancies arise in the small bowel, colon cancer is the third most common malignant tumor and the fourth most common cause of cancer death worldwide. Although adenocarcinoma remains the common pathology, many advances have been made regarding our diagnoses and management of carcinoid tumors and even to a larger degree in gastrointestinal stromal tumors. Additional advances include our understanding of genetics, new imaging modalities, and minimally invasive surgeries. This chapter will provide a comprehensive review of the management and treatment of cancers of the small bowel, large bowel, and appendix.

Tumors of the small intestine

The estimated number of new small bowel malignancies in the United States was 9160 in 2014. The small intestine represents 75% of the total length of the gastrointestinal (GI) tract and comprises 90% of its mucosal surface area, yet rarely does this region develop malignant tumors.¹ Recent figures show that <3% of all alimentary tract tumors and 0.4% of all malignancies arise in the small bowel.²

Several mechanisms have been postulated to explain the low incidence of neoplastic transformation within the small intestine. The most important of these are the rapid transit of content through the small bowel, which provides a shorter exposure of its mucosa to carcinogens, increased lymphoid tissue in the small intestine with a high level of immunoglobulin A (IgA) expression, and a lower bacterial load in the small bowel that results in a decreased conversion of bile acids into potential carcinogens by anaerobic microorganisms.^{3, 4} In addition, the liquid contents of the small bowel may cause less mucosal irritation than the more solid contents of the large intestine, and there is the presence in the small intestine of mucosal detoxifying enzymes such as benzopyrene hydroxylase.⁵

Adenocarcinomas comprise 30% to 50% of small bowel malignant tumors, followed by carcinoids (25–30%), lymphomas (15–20%), and, to a lesser extent, sarcomas. Leiomyomas account for 25% of all benign tumors, while others include adenomas and lipomas and rarer neoplasms such as fibromas, fibromyxomas, neurofibromas, ganglioneuromas, hemangiomas, and lymphangiomas.⁶

Clinical presentation

Because the small intestine is relatively inaccessible to routine endoscopy, diagnosis of small intestinal neoplasms is often delayed for months after onset of symptoms. Many small bowel tumors are asymptomatic until late in their course because of their relatively slow growth and the ease with which

the liquid contents of the small bowel can pass even a partially obstructing lesion.⁶ The remainder are usually found as a result of the symptoms of partial obstruction: nausea and vomiting if the lesion is proximal, as well as crampy abdominal pain, or other nonspecific findings such as weight loss. Hemorrhage is frequently found in those tumors that penetrate beyond the submucosa, but almost always is occult, presenting as microcytic anemia or stool that is positive on guaiac testing. Certain small bowel tumors have more specific presenting symptoms, such as jaundice (ampullary carcinoma) and fever, diarrhea, and weight loss (lymphoma). Endocrine tumors of the gut, the most common of which are carcinoid tumors, may present with their own set of classic symptoms, such as flushing, diarrhea, cyanosis, and intermittent respiratory distress. Only a small proportion of patients with carcinoid tumors have these symptoms, the vast majority being asymptomatic or having symptoms secondary to mass lesion effects.

Eventually, malignant tumors cause enough symptoms for the ensuing medical work-up to reveal the tumor. Unfortunately, some time may pass between the first symptom and diagnosis. In one series, almost one-third of the patients had symptoms for 5 years or more prior to definitive diagnosis.⁷ Another study demonstrated a mean duration of symptoms of 7 months prior to diagnosis.⁸ Many patients eventually diagnosed with small bowel tumors present as an emergency with either bowel obstruction or perforation.

Diagnostic imaging

Radiographic studies often aid in the diagnosis of these lesions, especially in advanced disease. However, such studies, on many occasions, are not useful for early diagnosis of curable malignancy. Small bowel radiology has undergone dramatic changes in the past 2 decades. Plain films, the small bowel follow-through, and double-contrast modality of enteroclysis may be useful in certain situations but have largely been replaced by cross-sectional imaging techniques (computed tomography (CT) and magnetic resonance imaging (MRI)), which can be used to investigate both extraluminal abnormalities and intraluminal changes. CT scanning with oral contrast has led to nearly 100% recognition of small bowel tumors in some series, although it has limited ability to differentiate among tumor types.⁹ This modality appears to be most useful for preoperative staging and metastatic evaluation.¹⁰ In one series, the sensitivity for CT in determining T (tumor) stage was 57%, compared with 61% and 42% for colon and gastric cancers, respectively.^{11, 12} MRI techniques clearly highlight endoluminal, mural, and extramural enteric details and provide vascular and functional information, thereby enhancing the diagnostic value of these techniques in small bowel diseases. MRI offers detailed morphologic information and functional data of small bowel diseases and provides reliable evidence of normalcy, thereby allowing the diagnosis of early or subtle structural abnormalities and guiding treatment and decisions in patient care. MRI has many properties that make it ideal for imaging of the small bowel: the ability to perform real-time imaging, functional imaging, the lack of ionizing radiation, and the improved tissue contrast that can be achieved by using a variety of pulse sequences.^{13–15} Magnetic resonance (MR) enteroclysis has yielded a 96.6% accuracy in the detection of small bowel neoplasms.^{16, 17} In addition to CT and MR, angiography and nuclear scanning may be useful in the case of a bleeding tumor or a suspected hemangioma. Endoscopic ultrasonography (EUS) is used to detect and stage small bowel tumors and allows real-time interventional diagnostic procedures, mainly in the periampullary region. EUS has been shown to be superior to CT and MRI in predicting vascular invasion and overall assessment of T stage of ampullary neoplasms.^{18, 19} In the past decade, small bowel endoscopy has become increasingly useful as a diagnostic tool. There are three main types of small bowel endoscopy: push enteroscopy, intraoperative or laparoscopically assisted enteroscopy, and, most recently, double-balloon enteroscopy. Push enteroscopy involves an intestinal intubation of a 220- to 250-cm instrument, usually with fluoroscopic

assistance, and can be used to examine the jejunum for mean lengths of 120 cm beyond the ligament of Treitz.²⁰ During intraoperative endoscopy, the surgeon manually manipulates through the small bowel wall with either a push endoscope (anterograde) or a colonoscope (retrograde) to examine the entire small bowel. The surgeon can mark the lesions of interest, usually by suture, and resect at the completion of the enteroscopy. These techniques are particularly useful in prophylactic polypectomy of small bowel large polyps (>15 mm) for conservative approach in management of PJS patients.²¹ The recent addition of laparoscopically assisted enteroscopy provides a less invasive technique than interoperative enteroscopy but still requires general anesthesia and both a surgeon and endoscopist.²² In double-balloon enteroscopy, an endoscope and a soft flexible overtube, each of which has an inflatable balloon attached to its distal end, are employed together. The two tubes are advanced over one another repeatedly using alternating inflation of the balloons to hold position, allowing deep advancement into the small intestine. The entire small intestine can be examined using this method with less discomfort than experienced with the push method.²³ After receiving the Federal Drug Administration (FDA) approval in 2001, a small, swallowable imaging capsule was introduced by Swain and colleagues that is propelled by peristalsis through the intestinal tract and transmits data to a receiver that captures video images.²⁴ However, the use of capsule endoscopy to evaluate small bowel tumors, particularly submucosal forms, has several limitations.^{25, 26} Indeed, capsule endoscopy may fail to depict neoplastic disease in as many as 18.9% of cases,²⁷ and capsule retention occurs in 10–25% of small bowel tumor cases.^{27, 28}

Treatment

The treatment of small bowel tumors is generally surgical, with simple resection for benign lesions and an aggressive approach for malignant lesions. Overall, the survival for adenocarcinomas, carcinoids, lymphomas, and sarcomas was better in 328 cases from a population-based registry than that for all other organs, except the breast, colon, prostate, and uterus.²⁹ In rare cases, radiation or chemotherapy may precede surgery. Duodenal tumors may require pancreaticoduodenectomy if malignant, whereas tumors of the terminal ileum may require right hemicolectomy to ensure complete resection and adequate margins.

Malignant neoplasms of the small bowel

Adenocarcinomas

Adenocarcinomas are the most common malignant tumors in the small bowel, accounting for approximately 30–50% of all malignant small bowel tumors.^{30, 31} They most commonly arise in the seventh decade of life and are seen slightly more often in men than in women.³² Cohort studies suggest that increased body mass index and alcohol use may increase risk of small bowel cancer.³³ While primary tumors arise most often in the duodenum (48–52%) and jejunum (23–25%) and less commonly in the ileum (13–16%), the reason for this distribution is unclear.^{34, 35} Some have postulated that the richness of IgA-secreting cells in the ileum accounts for its relative sparing from adenocarcinoma by neutralizing luminal carcinogens.⁴ Others have noted that the abundance of the enzyme benzopyrene hydroxylase may play a protective role by detoxifying potential carcinogens.³⁶ Adenocarcinoma is staged using the American Joint Committee on Cancer (AJCC) TNM system, and as expected small bowel carcinomas that are well differentiated with only local invasion and no lymph node metastasis tend to have the best prognosis. Unfortunately, little progress has been made in the treatment of small bowel adenocarcinoma. There have been improvements in diagnostic modalities and insights into the molecular basis, but the prognosis is still generally poor.

The histogenesis of small bowel adenocarcinoma most likely follows the adenoma–carcinoma sequence described initially for large bowel cancer.³⁷ As a result, the single most important risk factor for small bowel adenocarcinoma is preexisting adenoma, either single or multiple, as associated with multiple polyposis syndromes.³⁸ Small bowel adenocarcinomas have also been associated with alcohol (but not tobacco), nontropical sprue, regional enteritis, celiac disease, and urinary diversion procedures such as ileal conduit.^{39–43}

Familial adenomatous polyposis (FAP) is known to be a powerful risk factor for adenocarcinoma, with small bowel cancer being the most common cancer after colon cancer itself.⁴⁴ The relative risk (RR) of small bowel carcinoma in these patients has been described as being greater than 100.⁴⁵ Other hereditary syndromes associated with small bowel tumors include Peutz–Jeghers (PJ) syndrome (increased incidence of hamartomatous polyps in the jejunum and ileum), Gardner syndrome (adenoma and adenocarcinoma), and von Recklinghausen disease (paraganglioma). Small bowel inflammatory disorders are associated with increased malignancy, including, most notably, Crohn's disease.⁴⁶ Crohn's disease is a risk factor for future small bowel adenocarcinoma. An RR of 33 (95% CI: 15.9–60.9) was reported in a 2006 meta-analysis.⁴⁷ As with ulcerative colitis (UC) and tumors of the colon, the diagnosis of Crohn's disease precedes small bowel tumors by about 10 years. Several risk factors have been identified in patients with Crohn's disease who develop adenocarcinoma of the small bowel: duration of Crohn's disease, male gender, fistulization, presence of strictures, and surgical creation of blind excluded loops of intestines.^{48, 49} Other disorders associated with increased risk of malignancy are celiac disease (lymphoma and adenocarcinoma) and immunoproliferative disease (diffuse intestinal lymphoma and immunoproliferative small intestinal disease).⁵

Celiac sprue, while well known to predispose to intestinal lymphoma, is also associated with adenocarcinoma of the small bowel.⁴⁰ The numbers cited in case reports are few, but the presence of disease in otherwise noncharacteristic locations seems to lend credence to the theory that gluten-mediated jejunoileitis is also an independent risk factor for the development of adenocarcinoma of the small bowel as well as lymphomas.³¹ Adenocarcinoma of the small intestine, often aggressive, can affect children and is usually associated with degeneration of a PJ hamartoma.³⁸

The genetic mechanisms involved in the carcinogenesis of the small bowel remain unknown, most likely because of the small number of cases. Blaker and colleagues from Germany showed that although small intestinal carcinomas reveal complex genetic changes, a significant number of tumors share karyotypic instability and losses of chromosome 18q21–q22. 18q deletions often target the SMAD4 gene and disrupt tumor suppression through TGF β -signaling.⁵⁰ Svrcek and colleagues, using tissue microarray analysis, determined that inactivation of the SMAD4/DPC4 gene is involved in small intestinal adenocarcinoma tumorigenesis and that overexpression of TP53 and abnormal expression of β -catenin are two common events in small intestinal adenocarcinoma.⁵¹ Other pathways include Notch3 signaling associated with MUC5AC expression.⁵² There is also recent evidence suggesting DNA mismatch repair genes are involved; the frequency of the dMMR phenotype is variable, ranging from 5% to 35% of cases.⁵³

Symptoms of adenocarcinoma of the small bowel range from obstructive symptoms, such as vomiting and jaundice for those with duodenal tumors, to indistinct abdominal pain, weight loss, and anemia for more distal lesions. Weight loss is also common, occurring in more than 50% of patients. Obstruction is found in 40% to 70% of patients prior to presentation. In the collected Mayo series, 71% of patients had either overt or clinical evidence of blood loss.⁵⁴ Adenocarcinomas, especially duodenal tumors, usually become symptomatic earlier than other small bowel tumors, allowing for earlier diagnosis and intervention. Despite this, 30–35% of small bowel adenocarcinomas are metastatic at the time of

diagnosis.^{34, 35}

In a recent study conducted by the American College of Surgeons on 5000 small bowel adenocarcinomas, the overall 5-year disease-free survival (DFS) was 30.5%.⁵⁵ The median survival in this series was 19.7 months. The primary treatment of adenocarcinomas is wide surgical resection, with removal of lymph nodes and the vascular pedicle. Margins of 5 cm are considered acceptable. Recent reports indicate that even this treatment does not yield good survival rates for node-positive patients. In a recent study examining 217 patients with small bowel adenocarcinoma followed over a 10-year period at MD Anderson Cancer Center, patients with stage IV disease had a shorter 5-year overall survival (OS) than those with I–III disease (5% vs 36%).³⁵ The 5-year survival was significantly shorter if the positive lymph node ratio (number of positive lymph nodes/number of total lymph nodes) was greater than 75% versus <75% (12% vs 51%).

All attempts should be made to resect the primary lesion to prevent mucosal bleeding. For patients deemed unresectable at the time of laparotomy, some have advocated the use of intraoperative radiation therapy.^{56–58} The lack of clinical trials makes this therapy difficult to recommend in a setting other than specialized centers. Data regarding the role of adjuvant chemotherapy are limited, with no evidence of significant benefit in survival in patients with adenocarcinoma of the small intestine treated with adjuvant chemotherapy. An attempted Cochrane review in 2007 failed to find any studies eligible for meta-analysis.⁵⁹ Despite this, adjuvant chemotherapy is frequently used because small bowel cancer tends to recur systemically, similar to CRC, and because colon cancers respond to adjuvant therapy. A 2009 retrospective multicenter study suggested that an adjuvant folinic acid, 5-FU, and oxaliplatin (FOLFOX) regimen prolonged OS by around 5 months compared to patients treated with other regimens, but the findings of this small study were not statistically significant.⁵³ For advanced unresectable disease, a recent phase II study of modified FOLFOX as first-line chemotherapy in advanced small bowel adenocarcinoma reported an objective response rate of 48.5% [95% confidence interval (95% CI): 31–67%], with one complete response in patients with advanced small bowel adenocarcinomas.⁶⁰

Carcinoid tumors

Carcinoid tumors represent approximately 25–30% of malignant tumors of the small bowel.^{58, 61} Obendorfer used the term “karzinoide” in 1907, but the exact nature of the tumor was not determined until 1928 when Masson described its origin as the chromaffin cell.^{62, 63} The frequency of carcinoid in large autopsy series, before the era of increased detection by CT and endoscopy, indicated that about 85% were undiagnosed during life.⁶⁴ US data show that the incidence of GI carcinoid has increased at a rate of 3%–10% per year over the past three decades.^{64, 65} The most frequent sites for carcinoids were the GI tract (54.5%) and the bronchopulmonary system (30.1%). Within the GI tract, most occurred in the small bowel (44.7%), rectum (19.6%), and appendix (16.7%). In contradistinction to adenocarcinoma, the carcinoid tends to arise in the distal small intestine rather than in more proximal sites. In the series reported by Moertel, all surgically confirmed, 3% were in the duodenum, 5% in the jejunum, 32% in the proximal ileum, and 60% in the distal ileum.⁶⁶ The median age at discovery is 60.9 years, and females constitute 54.2% of patients.⁶⁷ The overall 5-year survival rate for patients with GI carcinoid is about 58%, with little change over the past 30 years.⁶⁴ However, in the subgroup of patients with well-differentiated carcinoid with distant spread, the 5-year survival rate has improved from 15% to 52% over this time period.⁶⁴

The most useful marker of neuroendocrine cells in tissue sections is chromogranin A (CgA), a glycoprotein stored in secretory granules of neuroendocrine cells. Plasma CgA levels correlate with

tumor burden and may be useful for monitoring treatment.⁶⁸ Twenty-four-hour measurement of urinary 5-hydroxyindole-3-acetic acid (5-HIAA), the degradation product of serotonin, can also aid in diagnosis. The specificity of 5-HIAA as a marker for these carcinoids is 88%, although tryptophan/serotonin-rich foods (bananas, avocados, plums, eggplants, tomatoes, plantains, pineapples, and walnuts) can provide false elevations, and several drugs can result in increased or decreased 5-HIAA levels.⁶⁹ Higher concentrations of 5-HIAA in urine are consistent with a worse prognosis, while persistently low levels predict a more favorable outcome in disseminated disease.⁶⁸ Mitotic count and Ki-67 index [a marker of cell proliferation] provide some indication of prognosis.⁶⁸

A unique feature of carcinoid tumors is their ability to produce a variety of protein and peptide products, the most characteristic of which is serotonin. Systemic serotonin is thought to cause most of the symptoms of the carcinoid syndrome, including diarrhea, flushing, wheezing, and right-sided heart disease. Carcinoid syndrome is seen in 5–7% of patients with large tumor burdens and metastatic disease.⁵⁴ It is believed that the metastatic component is necessary to ensure drainage of the compounds involved in the syndrome into the systemic circulation and to provide an adequate tumor mass to produce large amounts of peptidergic products.

The clinical manifestations of carcinoid are often vague or absent, and the definitive diagnosis is often not made prior to surgery. Patients with small intestine carcinoid often present at a late stage, and the prognosis is poor once tumors have spread beyond the intestine. In a series of 145 patients with GI carcinoid tumors, only 12 had a proper diagnosis before surgery, and those 12 had definite symptoms of carcinoid syndrome.^{54, 70} Most often, patients are operated on for signs of bowel obstruction, not by the tumor itself but by a desmoplastic reaction that leads to shrinking of the mesentery as a result of fibrosis and kinking of the bowel.⁷¹ Scintigraphy with radiolabeled octreotide has been successfully used to localize undetected primary and metastatic lesions.⁷² Two large European studies show carcinoid lesion detection with a sensitivity of 89% by using this diagnostic tool.⁷³

The metastatic potential of a carcinoid tumor correlates closely with its size. In the Moertel series, there were no metastases in tumors <0.5 cm in diameter, 15% in tumors 0.5 to 0.9 cm in diameter, 72% in tumors 1.0 to 1.9 cm in diameter, and 95% metastases in tumors larger than 2 cm.⁶⁶ However, small bowel carcinoids may still metastasize when <1 cm. Recent evidence based on 5-HIAA levels suggests that most cases of metastatic carcinoid of unknown primary probably arise from small ileal tumors.^{74, 75} Extent of disease, which mainly comprises either lymph node (regional) or liver (metastatic) involvement, is a definite predictor of outcome. In Maggard's analysis of 11,427 carcinoids, 5-year survival for localized, regional, and distant disease of the small intestine was 70.4%, 64.1%, and 32.4%, respectively.⁶⁵

Primary surgical resection of the tumor and regional lymph nodes is the only curative treatment for GI NETs; this is usually possible in about 20% of patients. Surgery remains the only approach that allows definitive histopathologic staging, resection of occult lymph node metastasis, and prevention of local complications caused by a desmoplastic resection.⁷⁶ Referral for surgical management should not be influenced by the inability to localize the primary tumor. As midgut tumors are difficult to localize on imaging, one study found the primary tumor could be identified intraoperatively in a majority of patients with metastatic NETs, irrespective of preoperative localization status.⁷⁷ Careful intraoperative examination is mandatory, because most series report that 30% of these tumors are multicentric.⁶⁶ Primary duodenal carcinoids account for only 2.6% of carcinoid tumors in the United States; although they are increasingly recognized with the more widespread use of upper GI endoscopy.⁷⁸ Because of the rarity of this disease, management recommendations for duodenal carcinoids have been extrapolated from the

experience with midgut and hindgut carcinoids. A recent study by Mullen and colleagues however demonstrated successful margin negative endoscopic resection in six patients with tumors <1.5 cm.⁷⁸ Interestingly, this study found lymph node metastases to be present in 54% of patients with duodenal carcinoid, including two patients with tumors smaller than 1 cm and limited to the submucosa. The impact of lymph node metastasis in duodenal carcinoids is uncertain, however, in that no patient developed distant metastases or carcinoid syndrome in this series. In the case of advanced disease, there may be some benefit to debulking procedures, but this remains controversial, because the absolute size of the tumor does not correspond well with the degree of symptoms.^{54, 79, 80} Some authors recommend aggressive treatment even in patients with widely metastatic disease, including resection of all intra-abdominal tumor deposits, segmental liver resection as needed, and hepatic arterial embolization. Cholecystectomy also has been performed to prevent gallbladder necrosis during hepatic embolization. Although it has not been proven whether this aggressive surgical approach increases survival, it has yielded biochemical remission in up to 25% of patients and regression of hepatic metastases for long periods.^{69, 81} In the MD Anderson experience of 81 patients with carcinoid disease metastatic to the liver who underwent hepatic artery embolization or chemoembolization, 67% experienced a partial response with a mean duration of response of 17 months. Overall, 63% of patients had reduction in their tumor-related symptoms and the OS time was 31 months.⁸² Importantly, many patients diagnosed with carcinoid have other malignancies. Using the surveillance, epidemiology, and end results (SEER) database to identify patients diagnosed with small intestine carcinoids between 1973 and 2007, almost one-third of patients with small bowel carcinoid had an associated metachronous primary tumor. The most common sites were prostate (26.2%), breast (14.3%), colon (9.1%), lung/bronchus (6.3%), and bladder (5.3%).⁸³

Medical therapy in the form of somatostatin analogues is effective in relieving symptoms of the carcinoid syndrome, though demonstrated tumor regression is rare. Octreotide is an eight amino acid, long-acting somatostatin analogue that binds to receptor subtypes 2, 3, and 5 and has been widely used for both detection and treatment of carcinoid tumors.⁸⁴ The currently available SSAs—Sandostatin LAR (octreotide; Novartis) and Somatuline Autogel (lanreotide; Ipsen)—display high-affinity binding for receptor subtypes 2 and 5, low affinity for subtypes 1 and 4, and medium affinity for subtype 3. SOM230 (pasireotide; Novartis), a more recently developed SSA, now in phase III trials, has a wider range of activity against somatostatin receptors and may offer a therapeutic advantage, especially in resistant disease.⁸⁵ In one study, octreotide was delivered subcutaneously at a dosage of 150 µg three times a day, showing improved symptoms in 88% of patients and decreased urinary 5-HIAA in 72% of patients.⁸⁶

Advances in the understanding of the mechanisms underlying tumor progression have led to the identification of several potential therapeutic targets (including the vascular endothelial growth factor (VEGF) and mammalian target of rapamycin (mTOR) signaling pathways). In a randomized phase 3 trial of everolimus plus octreotide LAR compared with placebo plus octreotide LAR improved progression-free survival in patients with advanced neuroendocrine tumors. However, progression-free survival was still poor at 16.4 (95% CI 13.7–21.2) months in the everolimus plus octreotide LAR group and 11.3 (8.4–14.6) months in the placebo plus octreotide LAR group.⁸⁷ Several other agents are being studied, including the use of novel SSTa, VEGF and mTOR inhibitors, and agents that interfere with insulin growth factor 1 receptor and AKT signaling. Another treatment modality is peptide receptor radionuclide therapy. Peptide receptor radionuclide therapy delivers tumoricidal doses of radiation to carcinoid cells highly selectively, with few adverse effects (nausea and occasional bone marrow and renal toxicity). By linking a radioactive isotope (¹¹¹Indium, ⁹⁰Yttrium, or ¹⁷⁷Lutetium) to a somatostatin analogue, carcinoid cells, with their often high density of somatostatin receptors, may be specifically targeted. Tumor regression rates of up to 50%, with a disease-free response approaching 3 years, have been reported in some studies.⁸⁸

Prognosis of patients with carcinoid disease varies according to several factors. Size of the primary tumor is an important predictor of metastasis and survival. Carcinoid tumors >2 cm in diameter portend a worse prognosis than those <2 cm.⁸⁹ In a recent series of 603 patients, lymph node metastasis was also not surprisingly prognostic.⁹⁰ In the Maggard series, increased tumor size was associated with a greater likelihood of lymph node involvement.⁶⁷ In the carcinoid series at Duke University, a direct correlation was found between size of the primary tumor and extent of disease at presentation.⁹¹ In addition, after controlling for stage of disease, region of origin of primary tumor predicted prognosis in this series of patients. In patients with distant metastases at presentation, those with midgut tumors had markedly better prognosis than did patients with foregut or hindgut tumors. In addition to traditional pathologic determinants, expression of cocaine- and amphetamine-regulated transcript (CART) in small bowel carcinoid tumors is associated with worse survival.⁹²

Composite tumors, those that display characteristics of both carcinoid tumors and adenocarcinomas, are well described in the appendix but are less well known in the small intestine. These tumors are relatively rare, with most reports to date encompassing only one or two cases. They are aggressive tumors with a metastatic potential similar to that of adenocarcinoma and should be treated as adenocarcinomas. Lymphatic metastasis appeared histologically to be adenocarcinoma in two cases and carcinoid in one; thus, it seems that these tumors may arise from cells with pluripotential patterns of differentiation.⁹³

Gastrointestinal stromal tumors

Gastrointestinal stromal tumor (GIST) is the current nomenclature for a diverse group of benign or malignant GI neoplasms derived from embryonic mesoderm. There are three histologic subtypes of GIST. The spindle cell form is the most common (70%) and consists of uniform, intersecting fascicles with eosinophilic cytoplasm. The epithelioid (20%) and the rare mixed type (10%) forms show more rounded cells with nuclear atypia.⁹⁴ Malignant GISTs constitute 15–20% of the malignant tumors found in the small bowel.⁹⁵ The annual incidence in the United States is reported to be approximately 5000 cases per year which seems to be rising due to increased awareness and histopathologic diagnosis.^{96, 97} GISTs affect men and women equally.⁹⁸ Most patients diagnosed with GIST are between 40–80 years old with a median age at diagnosis of 60.⁹⁹ The most commonly encountered GIST is the sporadic form. Familial GISTs occur and result from a germline mutation in either the KIT or platelet-derived growth factor receptor alpha (PDGFR α) proto-oncogenes.^{100, 101} The cellular origin of GIST is proposed to be the interstitial cell of Cajal, an intestinal pacemaker cell.⁹⁵ GISTs are characterized by mutations in the proto-oncogene C-kit that lead to constitutive activation of its glycoprotein product KIT and the subsequent tyrosine kinase activity.¹⁰² The tyrosine kinase inhibitor, imatinib, has revolutionized the treatment of GIST tumors. More than 95% of GISTs express KIT and biochemical evidence of KIT can be found in almost all GISTs.¹⁰³ The most common sites of KIT mutation include exon 11 (70%) and exon 9 (10%) although other regions have been described.^{104, 105} Other commonly expressed markers include CD34 (70%), smooth muscle actin (30%), and desmin (<5%).¹⁰⁶ Because other malignancies can stain positive for KIT include metastatic melanoma, angiosarcoma, and Ewing's sarcoma, IHC alone is not sufficient for diagnosis.⁹⁴ The diagnosis of GIST is based on both morphology and IHC. GIST can also occur in patients with neurofibromatosis type-1 (NF1) and in young women as part of a syndrome that includes, paragangliomas, pulmonary chondromas, and gastric GISTs.^{107, 108}

GISTs can occur anywhere in the GI tract from the esophagus to the rectum. Stomach represents the most common site (60%), followed by the small bowel (30%), rectum (~5%), and esophagus (~5%).⁹⁹ Up to

50% of patients will present with metastatic disease at the time of diagnosis, with the liver and peritoneum being the two most common sites.¹⁰⁹ Most GISTs present as an abdominal mass causing bowel obstruction evidenced as nausea, vomiting and abdominal pain, or as GI bleeding. GISTs usually grow rapidly, with masses 5 cm in diameter or greater being common.¹¹⁰ This rapid rate of growth explains the propensity for GI blood loss, because these tumors may outgrow their blood supply, become necrotic, and ulcerate. Blood loss is usually chronic, with laboratory studies revealing a microcytic anemia.¹¹⁰ Fistulas and abscesses are also caused by tumor necrosis. The primary mode of diagnosis and assessment of extent of disease is by contrast-enhanced CT scan of the abdomen and pelvis. Characteristic findings on CT scan include an enhancing, exophytic mass in close association with the stomach or bowel wall. Like other sarcomas, GISTs tend to displace rather than invade adjacent structures. While positron emission tomography (PET) is not used to diagnose GIST, it can be used to assess the response to tyrosine kinase therapy. GIST appears as a submucosal mass on endoscopic evaluation. Endoscopic or percutaneous biopsy is recommended in cases in which neoadjuvant therapy is planned or metastasis is suspected.¹¹¹

The primary treatment of GIST is surgical resection with wide margins. However, there is current debate about the management of tumors <2 cm. Current National Comprehensive Cancer Network (NCCN) guidelines for the management of gastric GISTs <2 cm without high-risk features on EUS include surveillance endoscopy every 6–12 months.¹¹² For tumors >2 cm, surgical resection included en bloc resection when other organs are involved is advocated. Because lymph node involvement is not common, extensive lymphadenectomy appears to provide no added survival benefit. The role of laparoscopy in the management of patients with GIST continues to expand. Those undergoing laparoscopic resection of GIST up to 8 cm at MSKCC had equivalent perioperative and oncologic outcomes when compared with case-matched controls undergoing open resection.¹¹³ With a median follow-up of 34 months, oncologic outcomes were similar with no positive microscopic margins and one recurrence in each group. Bischof et al. also reported that a minimally invasive approach for gastric GIST was associated with low morbidity, and a high rate of R0 resection, based on their review of nearly 400 patients undergoing surgical resection for GIST.¹¹⁴ Periampullary GIST tumors of the duodenum represent a more challenging surgical approach. A meta-analysis demonstrated that local resection should be the procedure of choice for duodenal GIST whenever technically feasible, because it is associated with good oncologic outcomes and lower morbidity compared with pancreaticoduodenectomy (PD). The use of imatinib in patients with duodenal GIST may potentially allow a proportion of patients who would otherwise require a PD to undergo local resection instead.¹¹⁵

Even after surgical resection, many tumors recur. One study analyzing 200 cases of GIST over a 16-year period found that in patients with primary disease who underwent complete resection of gross disease, the 5-year actuarial survival rate was 54%.⁹⁹ Even with complete surgical resection, the majority of tumors recurred, often involving the liver and peritoneal surface. In the largest series of GIST recurrences, the group from Memorial Sloan Kettering Cancer Center retrospectively analyzed 69 such patients.⁹⁹ Local recurrence was seen in 76% of patients, of which half had synchronous liver lesions. Surgical resection for recurrent disease was completed in one-third of cases with median survival of 15 months. The advent of tyrosine kinase inhibitors has revolutionized treatment of GIST. Although the mechanism of tumor response was believed to be predominantly inhibition of KIT-driven cells, recent data suggest the immune system contributes substantially to the antitumor effect. Imatinib therapy was shown to induce regulatory T cell apoptosis within the tumor by reducing tumor cell expression of the immunosuppressive enzyme indoleamine 2,3-dioxygenase.¹¹⁶ This data is critical to devising future treatment strategies that may involve immune modulators to increase response.

Due to high recurrence rates, adjuvant imatinib has been explored in several trials. There have been two American College of Surgeons Oncology Group (ACOSOG) trials looking at the role of adjuvant imatinib mesylate after resection for those patients at intermediate or high risk of recurrence. ACOSOG Z9000 was the first phase II trial studying the efficacy of adjuvant imatinib following complete resection of GIST at high risk of recurrence.¹¹⁷ Patients underwent complete gross resection of a KIT-expressing primary GIST that was at high risk of recurrence (tumor size >10 cm, tumor rupture, or <5 peritoneal metastases). Following resection, patients received oral imatinib 400 mg/day for 1 year. At a median follow-up of 4 years, the 1-, 2-, and 3-year OS rates were 99%, 97%, and 97%, respectively. The 1, 2, and 3-year recurrence-free survival rates were 94%, 73%, and 61%, respectively. These results compared favorably with historical controls for both recurrence-free survival and OS. ACOSOG Z79001 was a follow-up phase III trial in which patients were randomized to 1 year of oral imatinib or placebo following resection.¹¹⁸ Imatinib taken once a day for 1 year following surgery for localized, primary GIST (≥ 3 cm) was compared with placebo in 713 patients. Recurrence-free survival was significantly higher in the imatinib arm (98%) when compared with the control group (83%) while there was no difference in OS. Subsequently, disease survival was found to be longer with 3 years versus 1 year of adjuvant imatinib.¹¹⁹ However, only a few percent of low-risk patients developed recurrence, and more than 70% of patients appeared to be cured by surgery alone based on recurrence-free survival in the placebo arm. Thus, the value of adjuvant imatinib in patients with resected primary GIST 3 cm should be considered carefully. Risk stratification systems can be used to identify patients who have a low likelihood of recurrence in whom adjuvant therapy is not indicated; risk stratification can also identify patients who should get therapy.¹²⁰ For example, patients with KIT exon 11 deletions assigned to 1 year of adjuvant imatinib had a longer regression-free survival.¹²¹ Furthermore, specific mutations have been found to be resistant to imatinib; patients with PDGFRA D842V mutations do not respond to imatinib. Another risk stratification score showed that patients with nongastric GIST with a high mitotic count are at a particularly high risk for recurrence.¹²¹

The future focus of research for the use of adjuvant imatinib is which patients should be treated and what is the optimal duration.¹²² The PERSIST5 trial is an ongoing phase II trial testing 5 years of adjuvant imatinib therapy in patients at moderate to high risk of recurrence (NCT00867113). Expert opinion suggests that currently mutation testing of the tumor should be performed to exclude patients with a PDGFRA D842V mutation or wild-type tumor. In the remaining patients, a discussion should ensue about the goals and current results of adjuvant therapy.¹²³

The role of neoadjuvant imatinib in the setting of locally advanced disease has been investigated. Neoadjuvant imatinib mesylate holds much promise because it can lead to marked shrinkage in tumor size, which can frequently be predicted within 2 to 4 weeks of initiating therapy using PET scans. The cytoreductive potential of imatinib in the preoperative setting may enable surgeons to obtain R0 resections with less extensive resections. This is most applicable to GIST tumors near the gastroesophageal junction, ampulla, and in the rectum. Recent results from a phase II trial led by the Radiation Therapy Oncology Group (RTOG) revealed that imatinib is well tolerated in the neoadjuvant setting.¹²⁴ The groups were divided into whether disease was locally advanced and >5 cm (Group A) or recurrent/metastatic and >2 cm (Group B). Imatinib administered at 600 mg per day for 8 weeks preoperatively was followed by surgery and an additional 2 years of imatinib. Response rates after 8 weeks of preoperative imatinib were similar between groups A and B (4–7% partial response, 83–90% stable disease, and 4–5% progressive disease).¹²⁴ Another phase II trial from MD Anderson Cancer Center investigated either 3, 5, or 7 days of neoadjuvant imatinib in 19 patients.¹²⁵ This regimen was tolerated well and response rates by FDG-PET were 69%. The duration of neoadjuvant therapy and

patient selection remain to be defined. Current NCCN guidelines suggest that in patients on neoadjuvant imatinib, once two successive CT scans fail to show any radiographic response, surgical resection should be considered.¹¹²

In the metastatic setting, there is strong evidence of the effectiveness of imatinib mesylate. Up to 80% of patients with metastatic GIST attain a partial or complete response with imatinib.¹¹⁸ A recent meta-analysis of two, large, randomized studies^{126, 127} comparing the efficacy of imatinib given either once (400 mg) or twice daily revealed that the higher dose confers a progression-free survival advantage among patients with exon 9 mutations.¹²⁸ The second-line agent for patients with imatinib-resistant disease is sunitinib.¹²⁹ Sunitinib targets KIT and PDGFR α , as well as the vascular endothelial cell growth factor receptor (VEGFR). In patients with advanced disease resistant to imatinib, sunitinib is a safe and effective second-line agent.¹³⁰ Molecular studies suggest that imatinib is most effective in patients with exon 11 C-kit tyrosine kinase mutations, and sunitinib may be more effective in patients with exon 9 mutations.¹²⁸ Other studies have recently been completed examining third-line agents. Regorafenib was shown to significantly improve progression-free survival compared with placebo in patients with metastatic GIST after progression on standard treatments.¹³¹ Although a relatively rare clinical entity, the treatment of GIST is continually evolving and represents an area of active developments.

Lymphoma

Lymphoma accounts for 15–20% of all malignant small bowel tumors.¹³² The stomach is the most common site of GI lymphoma (>60%), followed by an equal distribution between the large and small intestines.¹³³ There is a slight male predominance of approximately 1.5 : 1, and the median age is lower than that of persons with other small bowel tumors (49 years in one large series).^{134, 135} Lymphomas are the most frequent malignant neoplasms in transplant recipients, appearing on average 20 months after the initiation of cyclosporine.¹³⁵ Prognosis is better than for other forms of intestinal lymphomas with two-thirds cured with resection, radiotherapy, acyclovir, and reduction of immunosuppression.^{136, 137} Small bowel lymphomas also occur in AIDS. Virtually all lesions are B lymphocyte in origin. The prognosis is poor but is dominated by the HIV-related disease such that life expectancy for these patients is not significantly inferior to similar HIV-positive patients without lymphoma.¹³⁶

The clinical presentation of GI lymphoma includes abdominal pain, nausea, vomiting, fatigue, weight loss, and GI bleeding, which may be occult. A mass with bulky adenopathy on CT scan is highly suggestive of abdominal lymphoma.¹³⁸ Multiple staging systems have been proposed for GI lymphomas, including the Ann Arbor, Musshoff, and the European–American classification system. Each of these major staging systems recognizes four major stages of small bowel lymphoma: stage I for local disease, stage II for regional involvement, and stages III and IV for advanced disease with metastasis. Imaging is also now included in some staging systems after the 11th International Conference on Malignant Lymphomas (ICML) in 2011.¹³⁹

Resection of small bowel lymphoma is important for local control but rarely eradicates the disease. Disease is often advanced so that fewer than 30% of intestinal tumors are amenable to primary curative resection.¹⁴⁰ Adjuvant therapy is an essential part of the treatment. Surgical resection should be attempted for localized disease and should involve removal of the bowel segments, with wide margins, and the involved mesenteric lymph nodes, if possible. Margins need to be completely clear of tumor since lymphomas may spread for long distances in the submucosal plane. Adjuvant chemotherapy in patients after potential curative resection is advocated.¹⁴¹ In patients with unresectable lymphoma, radiation therapy and chemotherapy are recommended.¹⁴² Additionally, rituximab, the chimeric monoclonal

antibody against the protein CD20, has also shown some promise in B cell lymphomas.¹⁴³

Forty years ago, an unusual immunoproliferative small intestinal disease was reported to be particularly common in the Middle East, especially in southern Iran. This Mediterranean lymphoma is found in children and young adults and carried a poor prognosis.¹⁴⁴ Patients tend to be from lower socioeconomic groups with a background of malnutrition. The tumor progenitor cell is believed to be the perifollicular B cell, which produces IgA. The tumor releases an excess of alpha heavy chains, which are detectable in the serum.¹⁴⁵ However, recent epidemiologic reports from southern Iran suggest that distribution of NHL in the GI tract is similar to Western countries.¹⁴⁶

Metastatic neoplasms

Metastatic neoplasm involvement of the small bowel is more frequent than primary small intestinal neoplasia. Primary tumors of the colon, ovary, uterus, and stomach involve the small bowel, most often by direct invasion or peritoneal spread. Primaries from the breast, lung, and melanoma metastasize to the small intestine hematogenously. A large review of autopsies from Memorial Sloan Kettering Cancer Center previously found the incidence of GI metastases from metastatic melanoma was 58% small bowel.¹⁴⁷ Within the GI tract, the small bowel is the most frequent site of metastasis of melanoma most likely because of its rich blood supply. A retrospective study of 103 cases of malignant melanoma performed by the Armed Forces Institute of Pathology stated that small bowel involvement by melanoma, even in the absence of a known primary, is usually metastatic.¹⁴⁸ If possible, surgery to remove disease should be offered. Ollila et al. reported on a retrospective review of 124 of 6509 melanoma patients who had GI tract metastases at the John Wayne Cancer Institute from 1971 through 1994.¹⁴⁹ Of these 124 patients, 69 (56%) underwent surgical exploration of the abdomen, of which 46 (67%) had curative resection and 23 (33%) had a palliative procedure only. Almost all (97%) of the 69 surgical patients experienced symptomatic relief postoperatively. The median survival of patients undergoing curative resection was 48.9 months compared with only 5.4 months in patients undergoing palliative procedures and 5.7 months in patients undergoing nonsurgical interventions. Metastatic lesions to the small bowel can be treated with resection in selected cases and/or tumor-specific systemic therapy.

Tumors of the appendix

Neoplasms of the appendix are found in as high as 5% of specimens obtained by appendectomy for acute appendicitis.¹⁵⁰ Most of these lesions are benign, including mucosal hyperplasia or metaplasia, leiomyomas, lipomas, neuromas, and angiomas. Malignancies of the appendix are rare, making up less than 0.5% of all intestinal neoplasms.¹⁵¹ Among 71,000 appendectomy specimens taken over a 40-year period, Collins found 958 malignant tumors, with an overall incidence of 1.35%.¹⁵⁰

Broadly, appendiceal malignancies are divided into those of neuroendocrine origin (carcinoid) or epithelial origin. Malignancies of epithelial origin include mucocoeles, pseudomyxoma peritonei (PMP), goblet cell carcinomas, and primary adenocarcinomas. In a large series of 5655 appendiceal tumors observed from the SEER database of the National Cancer Institute between 1973 and 2007, malignant carcinoid comprised of 11% of specimen but had the best 5-year disease-specific survival of 93%.¹⁵²

Tumors of the appendix often present in the setting of appendicitis, which may lead to a pathological diagnoses after appendectomy. However, in the setting of perforated appendicitis complicated by phlegmon or abscess, the paradigm of management has shifted from interval appendectomy towards nonsurgical management. This trend is important because in 2% of patients where nonsurgical

management is undertaken, there is an associated underlying cancer diagnoses or Crohn's disease, especially in patients over 40 years old.¹⁵³

Carcinoids

Carcinoids are the most common appendiceal tumors, comprising 32% to 85% of all appendiceal neoplasms, which include both benign and malignant types.^{154, 155} Malignant carcinoids comprised of 11% of appendiceal malignancies, derived from the SEER study. The SEER study also revealed a sex predominance for appendiceal carcinoids, with tumors from females comprising 68% of the cases. This female predominance may reflect the increased number of pelvic procedures performed in women, leading to more incidental findings, including carcinoids of the appendix. Peak incidence occurs in the third to fourth decades of life, averaging 32 to 42 years in the literature.^{156, 157}

Most of carcinoids occur in the distal 1/3 of the appendix, where they are unlikely to cause obstruction.¹⁵⁸ Symptoms are more likely with larger tumors and with metastases beyond the regional lymph nodes. Approximately 10% of appendiceal carcinoids are located at the base of the appendix, where they can cause obstruction, leading to appendicitis.¹⁵⁵ Similar to other intestinal carcinoids, appendiceal carcinoids can be vasoactive substances, which are responsible for carcinoid syndrome. Carcinoid syndrome symptoms are rare but indicate metastatic disease, typically to the liver.¹⁵⁹

In general, metastases from appendiceal carcinoids <2 cm in diameter are uncommon. Moertel and colleagues, in their evaluation of 150 appendiceal carcinoids over a period of 51 years, noted that 4.7% of the cases metastasized but none of the tumors <2 cm exhibited metastatic spread.¹⁶⁰ Extension into the mesoappendix, if present, correlates with nodal metastases and tumor size, and those with high mitoses and Ki67 positivity correlate with tumor aggressiveness.^{161, 162}

Small (<2 cm) carcinoids at the tip of appendix may be treated with a simple appendectomy.¹⁶³ At laparotomy, these tumors appear as small yellow nodules, usually in the distal third of the appendix. Histologically, the cells are small and uniform, and contain a central nucleus with few mitoses. Almost all carcinoids show invasion of the muscular layer of the wall of the appendix, and involvement of lymphatic vessels adjacent to the tumor is essentially universal.¹⁶³ Despite this microscopic finding, few patients have regional or distant dissemination of disease. Large (>2 cm) carcinoids and those at the base of appendix require a right colectomy, which removes the draining lymph nodes and any residual disease that might remain at the base of the appendix or in the mesoappendix.

Based on consensus guidelines in 2010 and 2012 from the North American Neuroendocrine Tumor Society (NANETS) and European Neuroendocrine Tumor Society (ENETS), completion colectomy is also recommended for tumors between 1 and 2 cm that also have mesoappendiceal invasion, positive or unclear margins, higher proliferate rate, angioinvasion, and mixed histology consistent with goblet cell carcinoid or adenocarcinoid.^{164, 165}

In 2010, the AJCC included a TNM staging for appendiceal carcinoid for the first time, which is different from TNM staging systems for carcinoids arising from other intestinal sites and lung. Overall outcomes for early-stage appendiceal carcinoids are optimistic. Based on analysis of 900 appendiceal carcinoid tumors observed from the SEER database, five-year disease-specific survival rates for appendiceal carcinoids were 100% if tumor size <3 cm without regional nodal or distant metastases, 78% if tumor size between 2 and 3 cm with regional nodal metastases or tumor size >3 cm with or without nodal or distant metastases, and 32% if there is distant metastases.¹⁶⁶

Mucocele

An appendiceal mucocele is any one of a number of lesions that are characterized by dilation of the appendiceal lumen, alteration of the mucosal lining, hypersecretion of mucus, and occasional extension outside of the appendix.¹⁶⁷ The underlying pathology may be a hyperplastic polyp; a benign neoplasm, such as cystadenoma; or a malignant tumor, such as cystadenocarcinoma. Many authors support the use of a system based on histologic findings rather than on the presence of a cystic lesion.¹⁶⁷ In this system, mucocèles of the appendix are classified into simple (obstructive) and mucocèles with proliferative epithelial changes. Benign neoplastic proliferative changes may be localized, as in adenoma of colonic type, or diffuse, as in mucinous adenoma or mucinous cystadenoma. Malignant proliferative groups may be classified as colonic-type adenocarcinoma, mucinous cystadenocarcinoma, and mixed carcinoidadenocarcinoma.¹⁶⁸ The preneoplastic potential of hyperplastic epithelium and the premalignant nature of adenomatous epithelium are seen by the coexistence of hyperplastic, adenomatous, and carcinomatous epithelia all in the same lesion.¹⁶⁸ A consequence of mucocèles of the appendix (cystadenomas and cystadenocarcinomas) is PMP. This lesion, characterized by large quantities of mucus-like material in the peritoneal cavity, is considered to represent dissemination of mucinous cystadenocarcinoma within the peritoneal cavity (see the section on PMP).¹⁶⁹

Though the diagnosis of appendiceal mucocele is usually an incidental finding at celiotomy, mucinous cystadenomas and cystadenocarcinomas are among the few appendiceal tumors that may be diagnosed preoperatively.¹⁶³ CT strongly suggests a mucinous tumor if a mass is present in the right lower quadrant with near water density. Ultrasound shows a diagnostic variable sonographic echogenicity because of the combination of mucin with more anechoic fluid. Although both imaging techniques may be helpful in diagnosing a mucocele, other cystic lesions of the peritoneal cavity, such as ovarian cysts, duplication cysts, mesenteric and omental cysts, or an abscess, may have a similar appearance.¹⁷⁰

Surgical resection should be pursued, even for a benign-appearing appendiceal mucocele, since lesions that appear to be benign on imaging studies may harbor a cystadenocarcinoma. The extent of resection is dependent on the underlying histology. In the case of hyperplastic polyps or cystadenoma, a simple appendectomy is considered curative. In the series reported by Higa and colleagues, 36 of the 46 patients with mucinous cystadenomas were treated with appendectomy alone with no recurrence.¹⁶⁷ In patients with mucinous cystadenocarcinoma, a substantial number will present with extensive abdominal metastases or PMP. Treatment of the primary lesion includes a formal right hemicolectomy with removal of draining lymph nodes.¹⁷¹ Stephenson and Brief reviewed 53 appendiceal mucinous cystadenocarcinomas treated by either simple appendectomy or right hemicolectomy. At 10 years, survival was 65% among patients treated with hemicolectomy in contrast to a 37% rate among patients who had received an appendectomy alone.¹⁷² Surgical debulking of metastatic deposits and evacuation of mucus collections are also recommended.

Pseudomyxoma peritonei

PMP is a condition characterized by diffuse collections of gelatinous material in the abdomen and pelvis and mucinous implants on the peritoneal surfaces, originating from ruptured mucinous neoplasms. As the primary tumor grows and occludes the lumen, mucus accumulates leading to appendiceal rupture. The peritoneum is then seeded with mucus-producing cells, which continue to proliferate and produce mucus.¹⁷³ Accumulation of intraperitoneal mucus eventually progresses to intestinal obstruction, nausea, vomiting, and starvation, which is fatal. Over the years, the term PMP has begun to be used more generally by clinicians to signify not only intraperitoneal mucinous dissemination from rupture of a benign

cystadenoma, but also peritoneal dissemination of mucus-producing adenocarcinomas of the appendix, large and small bowel, as well as lung, breast, pancreas, stomach, bile ducts, gallbladder, and fallopian tubes/ovary.^{174, 175}

PMP is found incidentally in approximately 2 of 10,000 laparotomies, with a female predominance.¹⁷⁴ The most common presenting symptom in both men and women is increasing abdominal girth; in men the second most common symptom is an inguinal hernia, while for women it is an ovarian mass palpated at the time of a routine pelvic examination.¹⁷³ On CT scan, the mucinous material is similar in density to fat and appears heterogeneous. Scalloping of the liver, spleen, and mesentery is found, and calcifications are common. The undersurface of the diaphragm may be greatly thickened by large cystic masses of mucinous tumor. A striking early finding is the characteristic peripheral location of tumor within the abdomen and pelvis and relative sparing and central displacement of the small bowel and mesentery.¹⁷³

Traditionally, treatment for PMP is repeated surgical debulking for symptomatic disease.¹⁷⁴ Debulking is not curative but aims to limit the buildup of mucus and its pressure effect. Invariably, disease recurrence requires repeated and progressively more difficult surgery due to adhesions and fibrosis, with five-year survival of 50%.¹⁷⁶ Cytoreduction and intraperitoneal chemotherapy is a more aggressive approach that includes radical surgical removal of all intra-abdominal and pelvic disease and the administration of intraperitoneal heated chemotherapy. Drug penetration is enhanced by heating the perfusate containing chemotherapy, an approach termed intraperitoneal hyperthermic chemotherapy (IPHC).^{177–180} This approach is best suited to patients with minimal residual disease (deposits smaller than 2–2.5 mm) after surgical cytoreduction. It is unlikely that even a heated solution of chemotherapy could penetrate large tumor deposits.

Sugarbaker et al. have written most extensively about treatment of peritoneal surface malignancy with aggressive surgical debulking and IPHC.¹⁷⁹ His group uses four clinical assessments to select patients who are most likely to benefit from combined treatment. First, histopathologic assessment in which noninvasive malignancies such as true PMP or cystic mesothelioma are more likely to be made visibly disease-free through a peritonectomy procedure and are less likely than other invasive histologies to have spread to regional nodes, liver, or other systemic sites. Second, preoperative contrast-enhanced CT of the chest, abdomen, and pelvis not only to exclude liver or other systemic metastases but also to determine if small bowel obstruction or tumor nodules greater than 5 cm are present, which portends a poor prognosis. Two other clinical indices, the peritoneal cancer index (PCI, a quantitative indicator of prognosis derived from the size and distribution of nodules on the peritoneal surface) and the completeness of cytoreduction score (the size of persisting tumor nodules after maximal cytoreduction), are derived intraoperatively. A 2001 report by Sugarbaker and colleagues included 108 patients with PMP treated over a 10-year period (1983–1993) with surgical debulking and intraoperative intraperitoneal heated mitomycin followed by intraperitoneal 5-FU during postoperative days 1 to 6 and three subsequent courses of adjuvant intravenous mitomycin and intraperitoneal 5-FU.¹⁸¹ Of the 65 patients with true PMP, 5-year survival was 75% and 10-year survival was 68%. Those with carcinomatosis had a poorer outcome with 5- and 10-year survival rates of 26% and 9%, respectively. Morbidity associated with combination of cytoreductive surgery and IPEC is high (37.75%).¹⁸² However, studies have shown that this rate is still acceptable in terms of cost–benefit ratio to patients.¹⁷⁶

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm, accounting for 4–6% of primary appendiceal neoplasms, arising in preexisting adenomas.¹⁸³ The mean age of presentation is 50 years, and a male

predominance is noted of anywhere from 4 : 1 to 2.8 : 1.^{184–186} The clinical presentation in the majority of patients in the literature is acute appendicitis or an abdominal mass, though the diagnosis is rarely made preoperatively. Perforation may complicate the clinical picture, occurring in up to 40% of cases, but perforation alone has little effect on OS.¹⁸⁷

Histologically, primary adenocarcinoma is distinguished from an adenoma by invasion of the wall of the appendix by the neoplastic tissue. Lymph node metastases are noted in 25% of cases at presentation.¹⁸⁸ Adenocarcinoma of the appendix has a metastatic potential between that of appendiceal carcinoid and colonic adenocarcinoma, with metastases developing in 20% of patients, often to the ovary.¹⁸³ The degree of metastatic involvement varies with the histologic grade; about 30% of the well-differentiated tumors are found to have metastasized, whereas nearly 70% of the poorly differentiated tumors are metastatic at the time of laparotomy.^{184, 185} The overall 5-year survival rate is 55% and varies with Dukes stage (A 100%, B 67%, C 50%, D 6%).¹⁸⁹

The literature suggests that surgical treatment of adenocarcinomas should involve more than just an appendectomy. Hesketh reported that the 5-year survival rate was 20% with appendectomy alone compared to 63% with right hemicolectomy.¹⁸⁶ Hopkins et al. reported rates of 20 and 45%, respectively.¹⁹⁰

Carcinoma of the colon and rectum

Epidemiology

Colorectal cancer (CRC) remains an important global health issue. It is the third most common malignant tumor and the fourth most common cause of cancer death worldwide.¹⁹¹ CRC is most common in developed nations. In the United States alone, an estimated 130,000 people were diagnosed with CRC in 2014, and approximately 50,000 died from the disease.¹⁹² It is thought that dietary and lifestyle habits, in conjunction with genetic factors, account for the increased incidence in developed countries. Research shows that individuals who migrate from regions where CRC is less common to regions of high incidence will inherit the risk of the host country.¹⁹³

There are disparities in CRC incidence and mortality among genders, races, and ethnic groups. While CRC is the third most common malignancy in the United States for both men and women, and the incidence of colon cancers is similar between the sexes, rectal cancer is more common in men. Right-sided/proximal colon cancers are more common among women compared to distal tumors in men.¹⁹¹ Moreover, mortality is approximately one-third higher in men.¹⁹⁴ African-Americans have the highest rates of both incidence and mortality when compared to the White, Asian-American, American Indian, and Hispanic populations.¹⁹⁵ The reasons for the disparities are not entirely known; however it has been postulated that differences in access to high-quality regular screening, timely diagnosis and treatment, dietary and lifestyle factors, and socioeconomic status could play a role.^{195, 196}

Despite the high prevalence of CRC in the United States, both the incidence and overall mortality from CRC have been declining over several decades. These declines have accelerated recently; as for both males and females, the incidence rates decreased at a rate of approximately 4% between 2008 and 2010, and mortality rates decreased by about 3% over the same time period.¹⁹⁷ Studies have shown that increased screening and detection can reduce the chance of developing or dying from CRC by 10–75%, depending on which screening tests are used and how often they are performed.¹⁹⁸ This increased

screening could also be a reason for the shift in anatomic distribution of CRC from rectum and left-sided cancers to more right-sided cancers. Data from the National Cancer Data Base from the years 1988 and 1993 show an increase from 51% to 55% of all CRC to be proximal to the splenic flexure.¹⁹⁹ Multiple studies have confirmed a higher rate of proximal colon cancer rates compared to distal colon or rectal carcinoma rates, both in the United States and globally.^{199–202}

Risk factors

Age and racial background

Age is a known risk factor for CRC. The vast majority of cases of CRC occur in people over age 50, with incidence continuing to increase thereafter.¹⁹⁸ In fact, fewer than 10% of all new CRC diagnoses and deaths occur in patients younger than 50.¹⁹² As discussed previously, African-American individuals have a higher incidence and mortality rate of CRC compared to other racial and ethnic populations.^{195, 198, 199.}

Personal or family history

Patients with a personal history of adenomatous polyps or previous CRC have an increased risk of developing colon cancer in the future. Size, number, and histology of polyps are important prognostic factors, with size >1 cm, villous or tubulovillous histology, and multiple polyps conferring a greater risk for CRC.²⁰³ Patients with an isolated tubular adenoma of <1 cm do not appear to be at an increased risk of developing CRC.²⁰³ In patients with previous CRC, the incidence of metachronous CRC is 6%, and the incidence of metachronous adenomas is 25%.²⁰⁴

Family history of CRC in a first-degree relative increases the risk of developing CRC two- to threefold, while cancer in a second-degree relative increases the risk of CRC by 25–50%.^{205, 206} In addition, risk increases if there are more than one first-degree relative with colon cancer or if they are diagnosed before age 55.²⁰⁷ Family history of colonic adenoma also increases the risk of CRC, especially if the adenoma is diagnosed early.

Inflammatory bowel disease

UC and Crohn's disease are well-known risk factors for colorectal carcinoma. For UC, the extent of disease and the duration of disease are the primary prognostic factors. Patients with pancolitis have a 5- to 15-fold increased risk of developing CRC compared to a threefold increased risk with colitis limited to the left colon.²⁰⁸ The risk also increases the longer the disease is present.²⁰⁹ Similar characteristics and incidence of CRC have been reported in Crohn's disease.^{210–212}

Diet and lifestyle

Westernized dietary habits, including an increased consumption of red meat and fat with a decreased consumption of fruits and vegetables, are associated with CRC. There is conflicting evidence regarding the effect of diets high in fruits and vegetables, but the general consensus is that while there may not be a protection associated with increased consumption, very low consumption does increase risk of developing CRC.^{213–215} A high-fat diet containing mixed lipids and saturated fat has been shown to promote colon carcinogenesis.^{216, 217} Alternatively, high intake of poultry and fish appears to be protective.²¹⁸

Obesity has been associated with an increased risk of CRC in both men and women, and people with a

BMI ≥ 30 kg/m² appear to have nearly a 20% increased risk of CRC compared to nonobese patients.^{219, 220} In contrast, physical activity and exercise are correlated with a decreased risk of CRC.²²¹

Diabetes mellitus and hyperinsulinemia

There is increasing evidence that diabetes mellitus and insulin resistance are risk factors for CRC. A meta-analysis of 15 studies found the estimated risk of CRC in diabetics was 30% higher than nondiabetics.^{222, 223} A possible explanation is the hyperinsulinemia associated with diabetes or even chronic insulin treatment for diabetes, resulting in growth signals to colonic mucosal cells via insulin-like growth factor 1.^{223, 224}

Alcohol and tobacco

Heavy alcohol consumption is correlated with a moderately increased risk of CRC. The association is dose dependent and is irrespective of the type of alcoholic beverage consumed.^{225, 226} The association between smoking and CRC is not as straightforward, and cigarette smoking may have a greater impact depending on specific somatic polymorphisms.²²⁷

Genetics

Colorectal tumorigenesis follows a distinct genetic pattern, with accumulation of genomic alterations and progressive waves of clonal expansion of cells that have a growth advantage over their progenitors. Three major categories of genes have been implicated in the development of CRC, namely, oncogenes such as *K-ras*; tumor suppressor genes such as adenomatous polyposis coli (*APC*), deleted in colorectal carcinoma (*DCC*), *p53*, and mutated in colon cancer (*MCC*); and the mismatch repair genes *hMSH2*, *hMLH1*, *hPMS1*, and *hPMS2*.

CRC develops from a multistep gene mutation sequence termed loss of heterozygosity (LOH) that can be observed in inherited and sporadic CRC. Fearon and Vogelstein first postulated in 1990 that at least five genes had to be mutated in order to progress in the adenoma to carcinoma sequence.²²⁸ Further studies showed that at least seven genetic alterations take place before the development of cancer. Important genes in the LOH model include *APC*, *K-ras*, *DCC*, and *p53*. An entirely different pathway of cancer development is initiated by defects within the mismatch repair genes. In this case, replication errors (RERs) increase, leading to microsatellite instability and malfunction of the gene. This pathway is referred to as RER and occurs in 20% of all colorectal tumors.²²⁹

APC gene

The *APC* gene is located on the long arm of chromosome 5 (5q). It is mutated in FAP and Gardner syndrome and in most cases of Turcot syndrome. A mutated *APC* gene is detected in 63% of adenoma and carcinoma, but not in the surrounding tissues, indicating that this is a somatic mutation. Because *APC* is a tumor suppressor gene, inactivation of the second allele must occur for the cell to lose the tumor-suppressing activity of the APC protein. There is considerable evidence that *APC* mutations occur early and may be the first event in sporadic colorectal mutagenesis.

DCC gene

The *DCC* gene is located on the long arm of chromosome 18 (18q). The gene product is involved in cell–cell adhesion and cell–matrix interactions, which may be important in preventing tumor growth, invasion, and metastasis. In sporadic CRC, *DCC* seems to play a critical role in the ability of a tumor to

metastasize.

p53 gene

The *p53* is located on the short arm of chromosome 17 (17p). *p53* seems to be the most important determinant of malignancy during colorectal tumorigenesis. As a tetramer, *p53* binds sequences of DNA in the promoter region of other genes to enhance their transcription.²³⁰ Most genes activated by *p53* are thought to be involved in the inhibition of growth. Mutations of *p53* can be found in more than half of all human cancers.²³¹

K-ras proto-oncogene

K-ras is an oncogene, which acts in a classic dominant fashion and is located on the short arm of chromosome 12 (12p). The *K-ras* protein interacts with putative effector molecules, conveying a growth response. The signal transduction process is perturbed with a mutant *K-ras* protein leading to tumor formation. In sporadic colorectal tumors, *K-ras* mutations have been found in approximately 50% of carcinomas and large adenomas.²³²

Mismatch repair gene

Mismatch repair genes are needed for cells to repair DNA RERs and spontaneous base repair loss. The four DNA mismatch repair genes found in humans are *hMSH2* (chromosome 2p), *hMSH6* (chromosome 2p), *hMLH1* (chromosome 3p), *hPMS1* (chromosome 2q), and *hPMS2* (chromosome 7p). They are regarded to contribute to hereditary nonpolyposis syndrome in various percentages.²³³

Inherited syndromes

Even though the vast majority of cases of CRC are sporadic rather than familial, inherited susceptibility results in a dramatic increase in risk of developing CRC. The genetic syndromes are typically inherited in an autosomal dominant fashion and are associated with a very high risk of developing CRC.

FAP is an autosomal dominant process characterized by numerous colonic adenomas which appear during childhood. This syndrome has penetrance approaching 100% with the onset of symptoms and diagnosis generally around age 15 years.²³⁴ If left untreated, FAP will invariably become CRC with a mean age of diagnosis and death of 39 and 42 years, respectively.²³⁵ An attenuated form of APC (AAPC) is a milder variant of FAP with a similar risk for developing CRC. AAPC is characterized by fewer adenomatous polyps and an older average age of diagnosis (usually in the early 50s). Both of these inherited syndromes are caused by different germline mutations in the same *APC* gene, which is located on chromosome 5.²³⁶

Hereditary nonpolyposis colorectal cancer (HNPCC) is another autosomal dominant inherited syndrome which accounts for 1–5% of all colorectal carcinomas. Also known as Lynch syndrome, this disease is characterized by an early age of onset (some patients can present in their 20s, while the mean age of diagnosis is 48 years), right-sided predominance, multiple synchronous or metachronous colonic tumors, and extracolonic manifestations. The extracolonic neoplasms can include endometrial cancer, renal pelvis and ureter cancer, bladder cancer, small bowel cancer, and skin lesions.²³⁷ As described above, HNPCC is caused by a mutation in one of the mismatch repair genes.²³⁸

MYH-associated polyposis (MAP) is a recently described autosomal recessive polyposis syndrome associated with a somewhat attenuated phenotype compared to other familial polyposis syndromes.²³⁹ Mutations in *MYH*, a base excision repair gene, are associated with an increased risk of multiple

adenomas or polyposis coli.²⁴⁰ In patients where no *APC* gene mutation is found, especially in those patients with 10–15 or more adenomas, work-up for an *MYH* gene mutation is indicated for diagnosis.^{240, 241} In addition, these patients are at high risk for synchronous GI cancers.

PJ syndrome is an inherited hamartomatous polyposis syndrome that predisposes to CRC. The two major manifestations of PJ are pigmented mucocutaneous lesions and multiple colonic polyps which have the ability to undergo malignant transformation. PJ is associated with an increased risk of both GI and non-GI malignancies including ovarian, breast, pancreatic, uterine, Sertoli cell, and cervical neoplasms.^{242–244} Juvenile polyposis (JP) is another inherited hamartomatous polyposis syndrome that can predispose to CRC. Patients with JP are also at increased risk for gastric, duodenal, and pancreatic cancers.^{245, 246}

Polymorphisms

Numerous genetic polymorphisms (normal variations in genes) have been found to be associated with developing CRC. Changes in genes such as carcinogen metabolism genes, methylation genes, and tumor suppressor genes can lead to either an increase or decrease in cancer risk. Cytochrome P450 genes, Glutathione-S transferase genes, N-acetyltransferase genes, and tumor suppressor genes have all been implicated in CRC. Cytochrome P450A1 (CYP1A1) is a phase I enzyme which acts on carcinogens found in tobacco smoke.²⁴⁷ Polymorphisms such as A→G at Ile462Val, exon 7 in the gene for CYP1A1 puts patients at an increased risk for developing CRC.²⁴⁸ Patients who smoke cigarettes are especially at risk when they carry a polymorphism in this gene.

Glutathione-S-transferases are phase II enzymes responsible for the detoxification of mutagenic electrophiles, including polyaromatic hydrocarbons.²⁴⁷ Glutathione-S-transferase Mu (GSTM1) and Theta (GSTT1) have both been discussed in relationship to CRC. In addition, N-acetyltransferases are phase II enzymes involved in detoxifying arylamines, which are found in cooked meat.²⁴⁷ Both GSTT1 and NAT2 rapid acetylator phenotype have been identified as causing an increased risk for CRC.²⁴⁹

The most common tumor repressor gene associated with CRC is the *APC* gene. A polymorphism at I1307K, found predominantly in the Ashkenazi Jewish population, confers a twofold increase in CRC risk.²⁵⁰ Another polymorphism in the *APC* gene, I1317Q, also increases the risk of CRC.²⁵¹

Some polymorphisms have been shown to be protective against CRC. Patients who eat a low-fat diet and who are homozygous for a variant *APC* gene at codon 1822 have a reduced risk of colon cancer compared to those patients who are wild type and eat a high-fat diet.²⁵² In addition, variations in a methylation gene for methylenetetrahydrofolate reductase (MTHFR) have been shown to influence CRC risk. Patients who carry the MTHFR 677TT genotype have a reduced risk of CRC.²⁵³

Presentation, screening, and surveillance

Signs and symptoms

The presentation of large bowel malignancy generally falls into three categories: insidious onset of chronic symptoms, acute onset of intestinal obstruction, or acute perforation. The most common presentation is that of an insidious onset of chronic symptoms (77–92%), followed by obstruction (6–16%), and then perforation (2–7%).^{254–256}

Bleeding is the most common symptom of colorectal malignancy.²⁵⁷ Unfortunately, patient and physician alike often attribute the bleeding to benign conditions. Bleeding may be occult or it may be seen as stool that is black, maroon, or bright red depending on the location of the malignancy.

Change in bowel habits is the second most common complaint, with patients noting either diarrhea or constipation.^{257, 258} Constipation is more often associated with left-sided lesions because the diameter of the colon is smaller and the stool is more formed than on the right side. Patients may report a gradual change in the caliber of the stool or may have diarrhea if the narrowing has progressed sufficiently to cause obstruction. Carcinomas of the right side of the colon do not typically present with changes in bowel habits, but large amounts of mucus generated by a tumor may cause diarrhea, and large right-sided lesions or lesions involving the ileocecal valve may cause obstruction.

Abdominal pain is as common a presentation as change in bowel habits.²⁵⁹ Left-sided obstructing lesions may present with cramping abdominal pain, associated with nausea and vomiting, and relieved with bowel movements. Right-sided malignancies may result in vague pain that is difficult to localize. Rectal lesions may present with tenesmus, but pelvic pain is generally associated with advanced disease after the tumor has involved the sacral or sciatic nerves. Less common symptoms include weight loss, malaise, fever, abdominal mass, and symptoms of urinary tract involvement. Bacteremia with *Streptococcus bovis* is highly suggestive of colorectal malignancy.^{260, 261}

Physical exam is often unrevealing because the abdomen is distended, and masses, primary or metastatic, are not palpable. Tympany, ascites, and distention may be all that is noted on abdominal exam. Rectal exam will only rarely reveal an obstructing tumor. Colorectal malignancy should always be considered when patients present with large bowel obstruction. The diagnosis may be confirmed with contrast enema, rigid or flexible endoscopy, or CT scans of the abdomen and pelvis.

Perforation may result in localized or generalized peritonitis or, if walled off, it may present with obstruction or fistula to an adjacent structure such as the bladder. Perforation occurs in 12–19% of patients with obstruction due to CRC.^{262, 263} When the perforation occurs proximal to the obstructing lesion, the patients present with diffuse peritonitis and sepsis. Emergent surgical intervention after adequate fluid resuscitation is clearly indicated. However, perforation at the tumor, possibly secondary to tumor necrosis, may follow a more indolent course, and thus may be confused with alternative diagnoses such as appendicitis, diverticulitis, or Crohn's disease.

Screening and surveillance

Cancer screening refers to the testing of a population of apparently asymptomatic individuals to determine the risk of developing CRC. Surveillance refers to the ongoing monitoring of individuals who have an increased risk for the development of the disease. For CRC, surveillance is reserved for patients with inflammatory bowel disease, family cancer syndromes, and those with a previous history of CRC or colorectal adenomas. Various screening and surveillance modalities are available to detect CRCs and adenomatous polyps. Current screening and surveillance recommendations are listed below ([Table 1](#)).

Table 1 Screening recommendations, National Comprehensive Cancer Network

Risk category	Screening and surveillance recommendations
<i>Average risk:</i> Asymptomatic, age 50 or greater; no history of adenoma, sessile serrated polyp, or colorectal cancer	Starting at age 50, colonoscopy every 10 years <i>or</i> flexible sigmoidoscopy every 5 years (with interval stool-based testing at 3 years) <i>or</i> yearly stool-based testing (guaiac or immunochemical based)
<i>Increased risk without personal history:</i> First-degree relative with CRC or adenomatous polyps at age 60 or greater, two second-degree relatives affected with CRC, or one second-degree relative with CRC at age younger than 50	Colonoscopy every 5 years starting at age 50 or 10 years younger than earliest family diagnosis
First-degree relative with CRC or adenomatous polyps at age younger than 60 or two or more first-degree relative with CRC	Colonoscopy every 3–5 years starting at age 40 or 10 years younger than earliest family diagnosis
Gene carrier or at risk for familial adenomatous polyposis	Flexible sigmoidoscopy or colonoscopy every year beginning at age 10–15
Gene carrier or at risk for hereditary nonpolyposis colorectal cancer	Colonoscopy every 1–2 years beginning at age 25–30 or 2–5 years younger than earliest family diagnosis

Stool-based screening methods

The advantage of fecal occult blood testing includes availability, convenience, and low cost. Limitations include low sensitivity, low specificity, low compliance, and inability to detect adenomas. Sensitivity is affected by slide storage, ascorbic acid, lesions not bleeding at the time of testing, and degradation of hemoglobin by colonic bacteria. Specificity is adversely affected by exogenous peroxidase activity by red meat and uncooked vegetables and medications that may induce bleeding from noncolonic sources such as aspirin and other nonsteroidal anti-inflammatory drugs. In five large controlled studies including more than 300,000 patients, an increased detection of CRC at earlier stages was demonstrated with the proper use of stool-based screening,^{264, 265} and testing was also associated with a significant reduction in mortality.^{264–268} Stool-based screening techniques include high-sensitivity guaiac-based testing, immunochemical-based testing, and most recently stool DNA tests. DNA testing detects the presence of genomic alterations that are known to occur in CRC oncogenesis; the best tests have demonstrated sensitivities as high as 95%.²⁶⁹ Currently, DNA tests have not yet been FDA approved, and thus they do not represent a first-line option for screening. As of 2014, high-sensitivity guaiac-based and immunochemical-based stool testing as standalone screening methods are considered appropriate so long as they are performed annually by a healthcare provider and a prescribed diet is followed. Any abnormal test requires follow-up invasive screening. Recently, immunochemical-based testing has proven to have increased sensitivity compared to guaiac-based tests.²⁷⁰ Stool-based screening is a particularly good option for those who refuse more invasive options.²⁷¹

Flexible sigmoidoscopy

Both rigid and flexible sigmoidoscopies are inexpensive, require no conscious sedation, and afford direct visualization and biopsy of polyps and cancers.²⁷² The advantage of the flexible sigmoidoscope over the

rigid is that it can reach the descending colon and even the splenic flexure. The disadvantage of sigmoidoscopy is that the entire colon is not visualized, and lesions may be missed in the proximal colon. Current National Comprehensive Cancer Network and American Cancer Society Guidelines recommend sigmoidoscopy with or without stool-based screening every 5 years, with subsequent full colonoscopy if adenomatous disease is found.²⁷³

Barium enema

Barium enema combined with sigmoidoscopy allows for evaluation of the entire colon and rectum. Single-contrast barium enema is significantly less sensitive and specific than double-contrast barium enema (DCBE) and should not be used as a screening tool. DCBE has a sensitivity of 50–80% for polyps <1 cm, 70–90% for polyps >1 cm, and 55–85% for stage I and II carcinomas.^{274–276} When combined with sigmoidoscopy, the sensitivity reaches 98% and 99% for carcinomas and adenomas, respectively.²⁷⁷ Perforation as a result of DCBE has been reported at a rate of 1 per 25,000 studies.²⁷⁸ Current ACS screening recommendations are for a barium enema every 5 years with subsequent colonoscopy if test results are positive. The NCCN does not include barium enema as a screening option.²⁷³

Colonoscopy

Examination of the entire colon by colonoscopy is the gold standard screening method. When performed by trained endoscopists, colonoscopy with polypectomy is a safe procedure with a perforation incidence of 0.1%, hemorrhage incidence of 0.3%, and a mortality of 0.01–0.03%. The cecum is visualized in up to 98.6% of patients, and a DCBE may be performed when the cecum is not reached.^{279–284} Studies have shown that detecting and removing polyps reduce the incidence of colorectal malignancy, that detecting earlier lesions decreases disease-related mortality, and that fewer carcinomas develop in patients who have colonoscopy and polypectomy.^{285, 286} Colonoscopy is better than DCBE in detecting lesions <1 cm.²⁷⁶ Furthermore, a tissue diagnosis or therapeutic intervention may be made at the time of initial evaluation. Colonoscopy also compares favorably with sigmoidoscopy because the entire colon may be directly visualized. In one study, a prevalence of 24% of new adenomas was found when 226 patients underwent colonoscopy within 1 year of flexible sigmoidoscopy. Advanced lesions proximal to the descending colon were found in 6% of these patients.²⁸⁷ Current ACS screening recommendations are for a colonoscopy every 10 years.

CT colonography

CT colonography (virtual colonoscopy) is an emerging technique that uses three-dimensional reconstruction of the air-distended colon. At the National Naval Medical Center, in 1223 average-risk adults who underwent CT colonography followed by conventional colonoscopy, virtual colonoscopy was as good or better at detecting relevant lesions.²⁸⁸ However, it may be less accurate in surveillance populations, and subsequent multi-institutional studies have failed to confirm the excellent results from this series. The major limitations include uncertain accuracy, need for full bowel preparation, and follow-up colonoscopy for tissue diagnosis of radiographic abnormalities. CT colonography as the primary method of screening also results in repeated radiation exposure to the patient. Because virtual colonoscopy is considerably time and labor intensive from the standpoint of the radiologist, active investigations into methods of automating the evaluation process are ongoing. Current ACS screening recommendations are for a virtual colonoscopy every 5 years with subsequent colonoscopy if a lesion is found. The NCCN does not include CT colonography as a screening option.²⁷³

Preoperative work-up and staging

The general physical examination remains a cornerstone in assessing a patient preoperatively to determine the extent of local disease, disclosing distant metastases, and appraising the general operative risk. Special interest should be paid to weight loss, pallor as a sign of anemia, and signs of portal hypertension. In addition, a complete work-up should include routine lab work, colonoscopy, chest X-ray, CT of the abdomen and pelvis, and transrectal ultrasound (TRUS) for those with rectal cancer.

Routine laboratory work

A complete blood count (CBC) may reveal the presence of anemia. Liver function tests (LFTs) may be abnormal in the case of liver metastases. Carcinoembryonic antigen (CEA) levels should be obtained as a baseline against which further values may be compared. Metastatic disease to the liver is often accompanied with very high levels of CEA, and levels surpassing 10 to 20 ng/mL are associated with increased chances of treatment failure.²⁸⁹

Colonoscopy

Colonoscopy remains the single most important investigation in the evaluation of colonic diseases. It allows assessment of tumor size, but not depth of invasion, as well as localization in the colon. Further histology from the tumor can be obtained, synchronous tumors are detected, and synchronous polyps may be removed. Synchronous carcinomas occur in 2–7% of patients and synchronous polyps 29.7% of the time.²⁹⁰ It has been suggested that preoperative colonoscopy alters the operative procedure in 30% of patients.²⁹¹

Radiologic evaluation

A chest X-ray evaluates for pulmonary lesions and serves as a rough guideline for cardiac as well as pulmonary status. The use of CT of the abdomen and pelvis in the preoperative evaluation of patients with colon cancer is controversial. It is our practice to obtain a CT in order to detect involvement of contiguous organs, paraaortic lymph nodes, and the liver. Abnormal LFT's are present in only 15% of patients with liver metastases and may be elevated without liver metastases in up to 40%.²⁹² Therefore, we do not believe LFT's are a useful screening tool for determining the need for obtaining a CT scan. Abdominal ultrasound can be used in select patient to identify liver metastases, ascites, and gross adenopathy.

PET, and now PET-CT, have emerged as potentially important imaging modalities for CRC. Using the glucose analog fluorodeoxyglucose, metabolically active tissues are visualized. The standardized uptake value can provide a semiquantitative determination to help discriminate benign from malignant disease. Although potentially useful in recurrent cancer, it has not been helpful in the primary evaluation of patients with colon cancer due to false positive rates and high costs.

TRUS has become an important component of preoperative assessment in patients with rectal cancer. The layers of the rectal wall can be identified and the depth of penetration determined. Sensitivity ranges from 55% to 100% and specificity from 24% to 100% in different studies. The status of lymph nodes also can be predicted in 73–85%.²⁹³ The depth of invasion and lymph node status is especially important if local excision is considered.

More recently, MRI has been utilized for the evaluation of rectal cancers, particularly for preoperative staging purposes. Compared to TRUS, MRI has similar sensitivity in determining depth of invasion within the rectal layers; however, ultrasound is superior in detecting local invasion into perirectal tissues and

adjacent organs.²⁹⁴ MRI and TRUS have highly similar sensitivities in detecting perirectal lymph node metastases, both of which are superior modalities compared to CT.²⁹⁴ An advantage of MRI, however, is that it can be utilized to evaluate iliac, mesenteric, and retroperitoneal lymph nodes as well.

In addition, MRI has an emerging role in the prognostic risk stratification of patients preoperatively based on the likelihood of having involvement of the circumferential resection margin (CRM). The MERCURY study utilized preoperative MRI to assess the relationship of the primary rectal tumor to the mesorectal fascia, choosing a distance of <1 mm to signify potentially involved margins.²⁹⁵ Patients with potentially involved margins were found to have substantially shorter 5-year OS, DFS, and likelihood of developing local recurrence following resection. In fact, preoperative MRI evaluation of the CRM was found to have superior prognostic ability compared to AJCC TNM staging. Thus, MRI will likely continue to have an increasing role in the preoperative assessment of patients with rectal cancer. In the future, it may also become an integral part of neoadjuvant treatment strategies as a way to evaluate the response to preoperative chemotherapy or chemoradiation therapy.²⁹⁶

Staging

Staging systems are important for predicting outcomes, selecting patients for various therapies, and comparing therapies for patients across institutions. For a tumor to be considered as an invasive cancer and staged, it must penetrate through the muscularis mucosa. Malignant cells superficial to this layer are considered carcinoma *in situ*. In 1932, Dukes proposed a classification based on the degree of direct extension along with the presence or absence of regional lymphatic metastases for the staging of rectal cancer. The TNM classification was proposed by the American College of Surgeons' Commission on Cancer to incorporate findings at laparotomy, and over multiple iterations, it has largely replaced Dukes' classification in clinical use ([Table 2](#)).

Table 2 AJCC 7th edition TNM staging system for colorectal cancer

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i> , intraepithelial or tumor invades into lamina propria
T1	Tumor invades into submucosa
T2	Tumor invades into muscularis propria
T3	Tumor invades through muscularis propria
T4a	Tumor perforates visceral peritoneum
T4b	Tumor directly invades other structures
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes
N1	1–3 lymph nodes
N1a	1 regional lymph node
N1b	2–3 regional lymph nodes
N1c	Tumor deposits in subserosa, mesentery, or nonperitonealized regional tissue without nodal metastasis
N2	4 or more lymph nodes

N2a	4–6 regional lymph nodes		
N2b	7 or more regional lymph nodes		
M0	No distant metastases		
M1	Distant metastases		
M1a	Metastasis confined to one organ or site		
M1b	Metastasis in more than one organ or site or within the peritoneal surface		
<i>Stage</i>	<i>Depth</i>	<i>Nodal status</i>	<i>Distant metastasis</i>
Stage 0	Tis	N0	M0
Stage I	T1, T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T4	N0	M0
Stage IIC	T4b	N0	M0
Stage IIIA	T1–T2	N1/N1c	M0
	T1	N2a	M0
Stage IIIB	T3–T4a	N1/N1c	M0
	T2–T3	N2a	M0
	T1–T2	N2b	M0
Stage IIIC	T4a	N2a	M0
	T3–T4a	N2b	M0
	T4b	N1–N2	M0
Stage IVA	Any T	Any N	M1a
Stage IVB	Any T	Any N	M1b

The AJCC has settled on two grading classifications, low grade (well and moderately differentiated) and high grade (poorly and undifferentiated). DNA ploidy assessment is the measurement of the quantum amount of DNA in cells. Diploidy is correlated with good prognosis, while aneuploidy is correlated with poor prognosis. Bowel perforation and elevated preoperative CEA are associated with poorer prognosis. Lastly, as the genetic determinants of colon cancer become more thoroughly understood, there has been increasing interest in profiling the disease at the genomic level for prognostic purposes. Initially, studies evaluating particular genetic alterations, typically focusing on p53 expression and K-ras mutation status, produced conflicting results and were thus unable to add significantly to conventional staging systems.²⁹⁶ More recently, focus has shifted toward assays that profile many different genes in parallel. Oncotype DX®, for example, is a multigene assay that utilizes polymerase chain reaction (PCR) to quantify the gene expression of 12 genes from an individual tumor to predict disease recurrence following resection.²⁹⁸ These genes were selected based on an analysis of over 1800 colon cancers (stage II and III) as part of the National Surgical Adjuvant Breast and Bowel Project.²⁹⁹ Subsequently, two prospective studies have validated the prognostic ability of this platform to predict recurrence risk in patients with stage II and III colon cancer; although they were unable to validate its usefulness in predicting response to

chemotherapy.^{300, 301} As these assays improve, gene profiling will almost certainly become an important part of cancer staging in the near future. Although the role of multigene assays is yet to be determined, a 2014 prospective multicenter study evaluating the effect of providing an Oncotype DX® recurrence score on physician behavior (decision to use adjuvant chemotherapy among patients with stage IIa colon cancer) demonstrated that the score altered the treatment plan in over 40% of the cases.³⁰² While these results do not confirm any benefit to Oncotype DX in making treatment decisions, they do suggest that there is confidence in the medical oncology community that multigene profiling can provide useful, objective information that may ultimately help guide the need for certain therapies.

Surgical management of CRC

Management of carcinoma in a polyp

Colon cancers that appear to be confined to an adenomatous polyp (“malignant polyps”) have their invasion limited to the submucosa. Their propensity for lymph node metastasis appears to be related to a number of histopathologic features, including grade, presence of perineural/perivascular invasion, and overall gross morphology (i.e., sessile vs. pedunculated).

The Haggitt classification system is used to define the depth of involvement of carcinoma into a polyp (Table 3). The risk of lymph node metastasis in Haggitt level 1, 2, and 3 lesions is <1%, and these lesions can usually be managed with complete endoscopic excision and India ink tattooing of the polypectomy site.³⁰³ In these cases, careful colonoscopic surveillance of the polypectomy site is recommended. However, lymphovascular invasion, poor differentiation, or cancer close to the polypectomy resection margin (<2 mm) are usually an indication for a colectomy because of the increased risk of lymph node metastasis. Haggitt level 4 lesions have an increased incidence of lymph node metastasis (12–25%) and should be managed with a colectomy.³⁰³ In general, sessile polyps of the colon containing cancer should be managed with a colectomy as they are by definition Haggitt level 4.

Table 3 Haggitt classification of malignant polyps

Haggitt level	Characteristics
0	Carcinoma <i>in situ</i>
1	Carcinoma invading into submucosa but limited to head of polyp
2	Carcinoma invading level of neck of polyp
3	Carcinoma invading stalk
4	Carcinoma invading submucosa below the stalk (above the muscularis propria)

Most polyps throughout the colon can be removed through the colonoscope using the snare polypectomy technique. The polyp is visualized through the colonoscope and the snare wire is looped around the polyp and gently tightened while the electric current is applied. Whenever possible the polyp is retrieved for histology. When performed by trained endoscopists, colonoscopy with polypectomy is a safe procedure, with a perforation incidence of 0.3–1% and a hemorrhage incidence of 0.7–2.5%.³⁰⁴

Standard resection margins and techniques

Bowel preparation

Despite recent evidence challenging the benefit of mechanical bowel preparation, it remains a

cornerstone in modern colorectal surgery. Mechanical cleansing may be accomplished by the use of vigorous laxatives along with repeated enemas until clearing. Until recently, an oral lavage with a polyethylene glycol hypertonic electrolyte solution such as GoLYTELY was used extensively. More recently, oral phospho-soda preparations have become increasingly popular, but their use can be associated with fluid and electrolyte abnormalities.

Antibiotic administration

Perioperative antibiotics can be delivered both orally and intravenously, the former typically employed in combination with mechanical bowel preparation. Intravenous antibiotics are utilized to prevent surgical site infections, which are particularly common among patients undergoing colorectal surgery. Although the exact antibiotic regimen remains debated, it should cover both aerobic and anaerobic bacteria. The enhanced recovery after surgery (ERAS) group recommends a single dose of antibiotics within one hour of surgery, and there is level 1 evidence to support this guideline.³⁰⁵ While an initial single dose provides equivalent prophylaxis compared to multidose regimens, subsequent dosing may be required in prolonged cases.³⁰⁵ Oral antibiotics have traditionally been used for two purposes: to act as a cathartic alongside mechanical bowel preparation and to eradicate potentially pathologic intraluminal bacteria. A 2014 Cochrane Review concluded that combined oral and intravenous antibiotic prophylaxis is superior to either intravenous antibiotics alone (HR 0.56) or oral antibiotics alone (HR 0.56). It remains uncertain whether oral antibiotic prophylaxis is necessary if the colon is emptied (complete bowel preparation) prior to surgery.³⁰⁶

Right-sided colon cancers

Cancers of the right colon account for up to 30% of primary CRCs.³⁰⁷ Patients with adenocarcinoma involving the cecum or ascending colon who do not have HNPCC or other synchronous lesions should be treated with a right hemicolectomy ([Figure 1a](#)). The ileocolic, right colic, and right branch of the middle colic vessels should be ligated near their origins to assure adequate lymphadenectomy. Approximately 5 to 10 cm of distal small intestine should be resected in continuity with the right colon to assure adequate blood supply at the stapled edge of the small intestine.

Figure 1 Extent of resection for colon carcinoma: (a) Cecal or ascending colon cancer; (b) transverse colon cancer; (c) splenic flexure colon cancer; (d) sigmoid colon cancer. Abbreviations: ICA, ileocolic artery; IMA, inferior mesenteric artery; LCA, left colic artery; MCA, middle colic artery; RCA, right colic artery; SA, sigmoidal arteries; SHA, superior hemorrhoidal (rectal) artery.

Transverse colon cancers

Transverse colon cancers are relatively uncommon, accounting for only 10% of colorectal primaries.³⁰⁷ Lesions of the proximal and midtransverse colon are usually best managed with an extended right hemicolectomy involving ligation of the ileocolic, right colic, and middle colic vessels ([Figure 1b](#)). The ascending colon, hepatic flexure, transverse colon, and splenic flexures are removed with anastomosis of the ileum to the descending colon. It is advisable to avoid an anastomosis between the hepatic and splenic flexure because of concerns over adequacy of blood supply and tension at the anastomosis.

Left-sided colon cancers

Lesions of the splenic flexure and descending colon are also uncommon, accounting for 15% of colorectal primaries.³⁰⁷ Splenic flexure cancers may be managed with an extended right or left hemicolectomy ([Figure 1c](#)). Cancers in the descending colon may be managed with a left hemicolectomy involving division of the left colic artery, preservation of the left branch of the middle colic artery, and anastomosis of the distal transverse colon to the distal sigmoid colon. Alternatively, a left hemicolectomy may be performed with ligation of the inferior mesenteric vessels and an anastomosis between the transverse colon and the upper rectum.

Sigmoid colon cancers

Tumors of the sigmoid colon account for 25% of colorectal primaries.³⁰⁷ These tumors are usually removed by means of an anterior sigmoid colectomy, which usually involves division of the inferior mesenteric artery either above or below the left colic artery and the superior rectal arteries within the upper mesorectum with anastomosis of the descending colon to the upper rectum ([Figure 1d](#)). Large, bulky sigmoid cancers located above the peritoneal reflection but at the level of the pelvic inlet present a unique challenge as their posterolateral borders abut the ureters, hypogastric nerves, and iliac vessels. Proper preoperative planning based on optimal imaging and consideration of ureteral stent placement is essential.

Subtotal colectomy

This resection involves the removal of the entire colon to the rectum with an ileorectal anastomosis (IRA). This procedure is indicated for multiple synchronous colonic tumors that are not confined to a single anatomical distribution for selected patients with FAP with minimal rectal involvement (discussed below) or for selected patients with HNPCC and colon cancer.

Total proctocolectomy

The surgical treatment of FAP depends on the age of the patient and the polyp density in the rectum. Surgical options include proctocolectomy with Brooke ileostomy, total abdominal colectomy with IRA, or restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA). Proctocolectomy with continent ileostomy is rarely performed today. Total abdominal colectomy with IRA has a low complication rate, provides good functional results, and is a viable option for patients with fewer than 20 adenomas in the rectum. These patients must be observed with 6-month proctoscopic examinations to remove polyps and detect signs of cancer. If rectal polyps become too numerous, completion proctectomy, when technically possible, is warranted. The Cleveland Clinic has recently evaluated their registry of patients with FAP who were treated with IRA or IPAA. Prior to the use of IPAA for patients with high rectal polyp burdens, the risk of cancer in the retained rectum was 12.9% at a median follow-up of over 17 years.³⁰⁸ Alternatively, for patients treated with IPAA or the selected use of IRA (for those with small rectal polyp burdens), none developed rectal cancer in the remaining rectum at a median follow-up of 5 years. Restorative proctocolectomy with IPAA has the advantage of removing all or nearly all large intestine mucosa at risk of cancer while preserving transanal defecation. Complication rates are low when the procedure is done in large centers, but morbidity includes incontinence, multiple loose stools, impotence, retrograde ejaculation, dyspareunia, and pouchitis. Approximately 7% of patients have to be converted to permanent ileostomy due to complications from the procedure.³⁰⁸

Rectal cancers

The surgical approach to rectal tumors depends upon depth of invasion and distance from the anal verge.

The four categories include transanal approaches, transsacral approaches, LAR with total mesorectal excision (TME), and APR.

Local excision

Early studies of local excision have shown up to a 97% local control rate and 80% DFS for properly selected individuals.³⁰⁹ Local treatment is best applied to T1 rectal cancers within 10 cm of the anal verge, tumors <3 cm in diameter involving less than one-fourth of the circumference of the rectal wall, highly mobile exophytic tumors, and tumors of low histologic grade. The decision to use local excision alone or to employ adjuvant therapy after local excision is based on the pathological characteristics of the primary cancer and the potential for micrometastases in draining lymph nodes. T1 lesions have positive lymph nodes in up to 18% of cases, whereas the rate for T2 and T3 lesions is up to 38% and 70%, respectively. T2 tumors treated with local resection alone can have recurrence rates of 15% to 44%.³⁰⁹ It is therefore our practice to treat T1 lesions with poor prognostic features and all T2 tumors with radical surgery.

Local excision of distal rectal cancers can be accomplished by transanal excision, posterior proctectomy (Kraske procedure), or transanal endoscopic microsurgery. Transanal excision is the most straightforward approach and involves using the perirectal fat as the deep plane of dissection to achieve adequate circumferential margins of 1 cm. The Kraske procedure can be used for tumors in the middle and upper rectum and is more suitable for larger rectal lesions than transanal excision. In this procedure, a perineal incision is made just above the anus, the coccyx is removed, fascia divided, and a proctectomy performed. The disadvantage of this procedure is fistula formation and potential to seed the posterior wound with malignant cells. Transanal endoscopic microsurgery provides accessibility to tumors of the middle and upper rectum that would otherwise require a laparotomy or transsacral approach. This approach can be used for selected lesions up to 15 cm from the anal verge. The procedure is technically demanding and requires special equipment, which is expensive and therefore has limited its acceptance in the United States.

Low anterior resection

As surgical treatment for rectal cancer has improved over the past 2 decades, it has become evident that sphincter preservation is feasible without sacrificing oncologic outcomes. The procedure involves removal of the sigmoid colon and the involved rectum, with ligation of the inferior mesenteric artery at its origin. The splenic flexure is routinely mobilized and the reconstruction is performed using the descending colon. The use of the sigmoid colon is discouraged, as the thickened and hypertrophic muscle of the sigmoid is less compliant than the descending colon. The technical feasibility of the LAR was increased with the advent of circular stapling devices, lighted retractors, and the knowledge that distal mucosal margins of resection of 2 cm were adequate. The mesorectal margin, however, should be at least 5 cm distal to the inferior aspect of the tumor or to the end of the mesorectum at the pelvic floor. The technique of TME, which involves sharp excision and extirpation of the mesorectum by dissecting outside the investing fascia of the mesorectum, optimizes the oncologic operation by not only removing draining lymph nodes but also maximizing lateral resection margins around the tumor. Neoadjuvant therapy in properly selected patients is effective in converting probable APRs into sphincter-preserving operations.³¹⁰

Abdominal perineal resection

For patients who have cancers that overlap or abut the sphincter or who are incontinent of stool

preoperatively, a combined approach of transabdominal and transperineal dissection is performed to remove the rectal specimen en bloc. Once the rectal specimen is removed via the perineal opening, the perineum is sutured closed and a permanent colostomy is created.

Synchronous and metachronous lesions

The incidence of synchronous colon cancers ranges from 2% to 11%, and incidence of synchronous adenomatous polyps may exceed 30%.³⁰⁷ For lesions that are widely separated, preservation of colonic length via more than one anastomosis is desirable as long as the adequacy of the required individual cancer resections is not compromised. An alternative to multiple anastomoses is a subtotal colectomy with an ileorectal or ileosigmoid anastomosis. Metachronous colon cancers, defined as those detected more than 6 months following the management of the index lesion, may be managed with either partial or subtotal colectomy as dictated by the location of the lesions.

Lymphadenectomy

An appropriate lymph node dissection should extend to the origin of the primary vessel draining the portion of the colon incorporating the cancer. Resection of a lesion located near two major vessels should involve removal of the two major vessels along with the associated lymph nodes in an en bloc fashion. Apical lymph nodes at the origin of a primary vessel should be removed when feasible and tagged for pathologic analysis. Suspicious lymph nodes outside the field of resection should be sampled and resected when positive. Although not always feasible, efforts should be made by the pathologist to examine a minimum of 12 lymph nodes.^{311, 312} This allows for the most accurate staging, which can be used to appropriately select patients for adjuvant therapies.³¹³ In addition, the absolute number of lymph nodes examined has itself been shown to be associated with survival.³¹³ Although several series have demonstrated that sentinel node mapping and biopsy is feasible in patients with colon cancer, its true clinical utility in the management of patients with colon cancer awaits further investigation.³¹⁴

Laparoscopic colectomy

Laparoscopic resection of the colon was first described in 1990.³¹⁵ The proposed benefits to laparoscopic colectomy include a shorter recovery time and less narcotic use than the traditional open procedure. The technique of a laparoscopically assisted colon resection consists of an intracorporeal approach to explore the abdomen and mobilize the colon. The bowel is then exteriorized through a small incision for extracorporeal resection and anastomosis. There was some initial concerns regarding the ability to achieve an adequate oncologic resection and the frequency of port-site recurrences using the laparoscopic technique for colon cancer.³¹⁶ However, the results of several large studies have provided solid evidence demonstrating laparoscopic colectomy in patients with colon cancer provides equivalent oncologic outcomes and superior short-term perioperative morbidity compared to open colectomy.^{317–326}

Five prospective randomized trials, Barcelona, Australasian, Clinical Outcomes of Surgical Therapy Study Group (COST), Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASICC), and Colon Cancer Laparoscopic or Open Resection (COLOR), have reported long-term follow-up data on the equivalence of laparoscopic colectomy to open colectomy for colon cancer.^{317–322, 324, 325} The first long-term cancer data from the single-center Barcelona study showed cancer-related survival was significantly higher in the laparoscopically assisted group than in the open surgery group.³¹⁷ This was accounted for by the significant improvement in cancer-related survival observed in patients with stage III colon cancer, while there were no differences in patients with stage I or II disease.

However, the COST and CLASICC trials showed no such differences between the two groups.^{318, 319} In a recent follow-up report of the COST trial, 5-year OS, 5-year DFS, recurrence rates, and sites of first recurrence were similar between groups.³²⁴ Similarly, in a recent follow-up report from the CLASICC trial (which also included patients who underwent laparoscopically assisted excision of rectal cancer), there were no differences at 3 years in OS, DFS, or local recurrence between the laparoscopic-assisted surgery group and the conventionally treated (open) group.³²⁵ The COLOR trial demonstrated similar rates of positive surgical margins and number of regional lymph nodes retrieved, as well as equivalent 3-year DFS and OS. Short-term postoperative benefits for laparoscopy included earlier recovery of bowel function, need for fewer analgesics, and shorter hospital stay.³²² The Australasia trial demonstrated similar rates of 5-year OS and DFS.³²³ In all five studies, hospital stay was shorter while operating time for laparoscopically assisted colectomy was longer. The length of ileus was significantly less with laparoscopic colectomy in both the CLASICC and COST trials, while the COST trial also observed significantly less time of use of oral analgesics with laparoscopic colectomy.^{318, 319} While these short-term patient benefits have been observed, it is unclear if long-term patient benefits exist. In the CLASICC trial, no significant difference in the quality of life (QOL) at 3 years for all scales was observed between the two groups.³²⁵ In a meta-analysis of the four trials which included over 1500 patients, 3-year DFS and OS after laparoscopically assisted or open resection were similar, and disease-free OS rates for stages I, II, and III evaluated separately did not differ between the two treatments.³²⁶ Laparoscopic-assisted colectomy when performed by experienced surgeons has proven to be an equivalent oncologic operation compared to open colectomy for patients with colon cancer.³²⁷

Future directions in the study of the laparoscopic technique include maturation of more long-term data, appropriate patient selection for laparoscopic versus open procedures, and evaluating the cost-effectiveness of the laparoscopic technique. The rates of conversion to an open procedure from the COLOR, COST, and CLASICC trial were 17%, 21%, and 29%, respectively.³¹⁸⁻³²⁰ Patients in the CLASICC trial treated with a converted procedure had higher complication rates making the selection of appropriate patients for laparoscopic surgery important.³¹⁹ The cost-effectiveness of the laparoscopic technique given the longer operating time and the advanced surgical training required also requires further evaluation.

The investigational experience with laparoscopic rectal cancer resection is not as complete as the data for laparoscopic colectomy. Surgical resection is an extremely important treatment modality for rectal cancer. The standard for middle and low rectal cancers is precise TME as described by Heald.³²⁸ TME and adequacy of resection margins are associated with low recurrence and optimal survival.³²⁹ Laparoscopic resection of rectal cancer must be able to achieve the same oncologic outcomes. The laparoscopic technique for rectal cancer involves transection of the distal bowel and mesorectum intracorporeally and the division of the remaining mesentery and proximal bowel done extracorporeally. An intracorporeal end-to-end anastomosis is performed by positioning the anvil of the stapler in the descending colon and inserting the circular stapler through the rectum.^{330, 331} For low rectal cancers requiring laparoscopically assisted APR, the mobilized rectum with mesorectum is retrieved through the perineal incision in the traditional fashion and the perineal wound is closed primarily.³³¹ Currently, laparoscopically assisted resection of rectal cancer has not been definitely proven to be as oncologically effective as open surgery although currently available data strongly favors such a conclusion.

Several single-center case series of laparoscopically assisted resection of rectal cancer have reported on the safety and feasibility of using the laparoscopic approach.³³¹⁻³³⁴ There have been several prospective randomized trials comparing laparoscopic and open techniques for resection of rectal and rectosigmoid

cancers including the subset of patients in the CLASICC trial.^{319, 325, 330, 335} An initial observation in the CLASICC trial was a nonsignificant increase in the rate of positive CRM in patients undergoing laparoscopically assisted anterior resection compared to those undergoing standard open LAR. This difference was not seen in patients undergoing APR. However, in a follow-up report, the higher positivity of CRM did not translate into an increased incidence of local recurrence.³²⁵ This finding may have been a result of small numbers of patients and needs further investigation. Other results from this trial were discussed above in the laparoscopic colectomy section. A 2004 trial of patients with rectosigmoid carcinomas randomized patients to either laparoscopic-assisted or open LAR (APR was not included).³³⁰ Results included no significant differences in 5-year survival, 5-year DFS, or tumor recurrence.³³⁰ Postoperative recovery was significantly better for the laparoscopic group, while the operative time was significantly longer and the cost higher in the laparoscopic group.³³⁰ Most recently and definitively, the Laparoscopic Versus Open Surgery for Rectal Cancer (COLOR II) Trial was a multicenter, randomized, intention-to-treat-based trial comparing short-term perioperative and oncologic outcomes for laparoscopic and open resection for rectal cancers.³³⁵ The trial included over 1100 patients and demonstrated improvements in operative blood loss, return of bowel function, and hospital length of stay. In addition, the two groups had similar rates of complete resection, including CRM positivity. Long-term survival is not yet available from this study, but short-term findings are encouraging that laparoscopic resection of rectal cancers, in appropriately selected patients and among experienced surgeons, can provide equivalent oncologic outcomes compared to traditional open techniques. Two meta-analyses have also been performed.^{336, 337} Aziz et al. analyzed a total of over 2000 patients and found no significant differences in the proportion of patients with positive radial margins or the number of lymph nodes harvested when considering the laparoscopic rectal cancer surgery, open rectal cancer, laparoscopic APR, and open APR groups.³³⁶ Time to stoma function, first bowel movement, and length of hospital stay were significantly reduced after laparoscopic surgery. In the set of patients undergoing laparoscopically assisted APR, a reduced rate of postoperative wound infection was observed.³³⁶ In the other meta-analysis, short-term outcomes reported included a significantly lower morbidity but longer operating times in the laparoscopically resected group.³³⁷ In addition, there was no difference in wound healing, leakage rates, or positive margins between the two groups.³³⁷ Thus, increasing evidence supports the equality of laparoscopically assisted resection of rectal cancer to traditional open surgery.

In order to establish that laparoscopically assisted resection of rectal cancer is not inferior to open resection, more long-term data on cancer recurrence and survival are needed. Furthermore, similar issues of cost-effectiveness of appropriate patient selection also apply to laparoscopic resection of rectal cancer as conversion rates from the two randomized trials were reported to be 23% and 34%. The laparoscopic procedure also requires longer operating time and advanced technical skill.^{325, 326} In order to further address concerns about the use of laparoscopically assisted resection of rectal cancer, the American College of Surgery Oncology Group has developed a prospective, randomized phase III trial to determine if laparoscopic surgery is a technically and oncologically safe approach to the resection of rectal cancer (ACSOG-Z6051).³³⁸ The trial has recently been completed, and short-term results are expected soon. As long-term data from this trial become available, a more definitive evaluation of the technique will be established, which can more clearly elucidate the role of laparoscopic surgery for rectal cancer.

Robotic colectomy

There are limited data regarding robotic colorectal surgery, either in comparison to laparoscopic or traditional open surgery. The only randomized data have come from a small study comparing robotic right colectomy to standard laparoscopic right colectomy,³³⁹ which demonstrated equivalent lymph node

harvest, margin positivity rate, and need for conversion to open surgery between the two groups. Most other data have come from small, single-institution studies. With regard to retrospective comparative effectiveness studies evaluating robotic versus open colectomy, robotic resections—like laparoscopic resections—have been associated with improvements in perioperative morbidity and other short-term outcomes such as return of bowel function, wound complications, and hospital length of stay.^{340–343} However, robotic colectomy has been associated with longer operative times in nearly all studies to date, as well as increased costs of care.³⁴⁰ These latter two shortcomings may improve as centers develop more experience with the complexities of the robotic system. In comparison to laparoscopic colectomy, robotic resections have been associated with similar lymph node harvest, specimen length, and need for conversion to open surgery.³⁴⁴ Even compared to laparoscopy, studies to date indicate that robotic colectomy is associated with increased operative room time and increased operating room costs.^{344, 345} The increase in OR time may be the result of more intracorporeal anastomoses being performed in robotic colectomies, as well as time associated with set-up of the laparoscopic system.³⁴⁵ Although there is a near complete lack of randomized data, studies to date indicate that there is no difference in short-term oncologic outcomes for robotic colon resections between either laparoscopic or open surgery.

Robotic rectal surgery has several theoretical advantages compared to both traditional open and laparoscopic techniques. In comparison to open surgery, these include a better morbidity profile, as well as improvements in short-term quality metrics such as hospital length of stay and readmission rates. In comparison to laparoscopic rectal resections, robotics may offer lower rates of conversion to open surgery. While there are no randomized studies to date, several single-institutional reviews have demonstrated that robotic rectal resections can be performed safely among experienced surgeons in appropriately selected patients.^{342, 343, 346} In the largest retrospective comparative effectiveness study, robotic LAR has resulted in lower conversion rates and serious complication rates as compared to laparoscopic LAR.³⁴² Improvements were also appreciated in completeness of the TME. Given the retrospective nature of this study, however, these improvements may be the result of patient selection bias. Currently, the Robotic Versus Laparoscopic Resection for Rectal Cancer (ROLARR) Trial is ongoing, which will provide level 1 evidence as to the perioperative complications, short-term mortality, and 3-year DFS and OS, as well as sexual function assessment for robotic versus laparoscopic rectal resections.³⁴⁷ Study results are expected in 2016. In the interim, robotic rectal resections should be considered only a technique under investigation, best left to centers and surgeons with experience in advanced minimally invasive surgery.

Perforated colon cancers

Patients with perforated colon cancers often present with peritonitis. In this setting, the goals of surgical management are to remove the diseased segment of colon and prevent ongoing peritoneal contamination. Following resection and thorough irrigation of the peritoneal cavity, options for subsequent management include proximal diversion with creation of a mucous fistula/Hartmann pouch or primary anastomosis with proximal diversion via loop ileostomy. Perforated colon cancer is associated with a high rate of local recurrence and low rate of OS.³⁴⁸

Obstructing colon cancers

Cancer is the most common cause of large bowel obstruction.³⁴⁹ Obstructing right and transverse colon cancers are generally managed with a right hemicolectomy and primary anastomosis. Left-sided colon cancers can be managed with either a single operation or a two-stage procedure.³⁴⁹ The options for single-stage management include segmental resection or subtotal colectomy with IRA. Subtotal colectomy

is attractive because it removes the remaining of the potentially compromised colon, but it is a more extensive operation and may be associated with five to six bowel movements per day. On-table lavage has been used in the setting of segmental resection for obstruction, but postoperative complication rates remain a concern. A two-stage procedure involves first resection of the primary tumor with proximal diversion and then creation of a mucous fistula or Hartmann's pouch. The second stage, performed at a later time, involves reanastomosis of the colon. An alternative two-stage approach in select patients with an obstructing left colon lesion is resection with primary anastomosis and proximal fecal diversion with a loop ileostomy.³⁴⁹

Colonic stenting has recently been established as an option for patients with malignant colon obstruction.^{350, 351} Although it does not represent a long-term solution to the malignant colonic obstruction, stenting is useful in those whose prognosis is limited by the presence of metastatic disease or comorbidities. Stenting has also been used to allow transient relief of obstruction and bowel preparation with or without colonoscopic evaluation of the proximal colon before planned resection.^{350, 351}

Synchronous distant metastases

The liver is the most common site for colon cancer metastasis, and approximately 17% of patients will present with synchronous liver metastasis.³⁰⁷ Concomitant resection of colon and liver lesions may be undertaken safely in selected patients. Alternatively, management of liver metastasis may be dealt with at a subsequent operation. Systemic chemotherapy is also an essential component of therapy in these patients and will be discussed below.

Surveillance following resection

The goal of postoperative surveillance following resection of colon adenocarcinoma is identification of asymptomatic recurrences or new primaries that will allow for subsequent early treatment and lead to an improvement in survival. An expert panel assembled by the American Society of Clinical Oncology (ASCO) examined the evidence of supporting the role of various screening tests following resection of CRC ([Table 4](#)).³⁵² Interestingly, CBC, LFTs, FOBT, and CT scanning were not considered essential components of surveillance. With these guidelines in mind, surveillance should be individualized depending on factors unique to a given case, including comorbidities and patient anxiety.

Table 4 ASCO guidelines for surveillance following resection of stage II/III colorectal cancer

Test	Recommendation
History and physical	Every 3–6 months for 5 years; then annually
Serum CEA	Every 3–6 for 5 years
Colonoscopy	Perform 1 year after resection, followed by every 5 years if the first is normal. For patients with rectal cancer who have not received radiation, a rectosigmoidoscopy should be performed every 6 months for 2–5 years
Computed tomography	Annually for 3 years or every 6–12 months in high risk (must include pelvis in patients with rectal cancer)

Local recurrence

Local recurrence following resection of colonic adenocarcinoma occurs in approximately 4% of cases

with the highest rates in advanced-stage tumors.³⁵³ Although these patients generally have a poor survival, surgical resection of locoregional recurrence can result in long-term survival in up to 15% of patients.³⁵³ Best results are obtained in patients with isolated small recurrences (<5 cm) that can be resected with negative margins.

Adjuvant therapy for CRC

5-Fluorouracil-based regimens

The antifolate 5-FU has been the cornerstone of chemotherapy for CRC since the 1960s. A metabolite of 5-FU, fluorodeoxyuridine monophosphate (FdUMP), inhibits thymidylate synthase (TS) and thus interferes with DNA synthesis.³⁵⁴ 5-FU is also incorporated into RNA, which disrupts protein synthesis.³⁵⁴ Studies, however, did not show a survival advantage for adjuvant 5-FU until it was combined with a biomodulator. Leucovorin (LV) (folinic acid), levamisole (an antihelminthic agent), and methotrexate were all explored as modulators of 5-FU.^{355–359} LV has been accepted as the standard biomodulator and increases cytotoxicity by stabilizing the FdUMP/TS complex and increasing the intracellular pool of reduced folate.

Multiple prospective trials have shown the clinical benefit of postoperative 5-FU in combination with either LV or levamisole.^{355, 356, 358, 359} The National Surgical Adjuvant Breast and Bowel Project C-03 trial showed that 6 months of 5-FU and LV each given weekly at 500 mg/m² for 6 of 8 weeks (Roswell Park regimen) were superior to combination therapy with methyl 1-[2-chloroethyl-3-(4methyl-cyclohexyl)] (CCNU), vincristine, and 5-FU.³⁵⁹ The incremental increases in DFS from 64% to 73% and in OS from 77% to 84% were proportionally similar to other randomized trials with 5-FU and LV.³⁵⁹

There are numerous 5-FU dosing schedules. In the adjuvant setting, these include bolus daily for 5 days every 4 weeks, the so-called Mayo Clinic regimen; weekly for 6 of every 8 weeks, or Roswell Park regimen; and infusional schedules. Unlike the metastatic setting, continuous infusion 5-FU (CIFU) has not shown superiority over bolus-type adjuvant regimens. There was no difference in DFS or OS, but there was a suggestion that it may have an improved toxicity profile.^{360, 361}

The convenience of oral therapy and the prospect of avoiding long-term intravenous access complications, such as thrombosis and infection, have stimulated development of oral fluoropyrimidines. Capecitabine is a fluoropyrimidine carbamate that is converted to 5-FU in a three-step enzymatic cascade. Preclinical studies had shown that capecitabine exhibits selectivity for neoplastic cells because the final enzymatic conversion involves thymidine phosphorylase, which is preferentially expressed in tumor as opposed to normal tissues.^{362, 363} Twice-daily oral administration simulates continuous infusion of 5-FU without the costs and inconvenience of a pump.

The X-ACT trial showed that capecitabine was at least equivalent to bolus 5-FU in the adjuvant setting.³⁶² This noninferiority trial randomized 1987 patients with resected stage III colon cancer to 6 months of adjuvant capecitabine 1250 mg/m² twice daily for 2 weeks of a 3-week schedule or to bolus 5-FU 425 mg/m² and LV 20 mg/m² daily days 1 through 5 of a 28-day cycle (Mayo regimen). The 3-year DFS was 64.2% in the capecitabine arm compared with 60.6% in the bolus 5-FU arm. With a hazard ratio of 0.87% and a $p < 0.001$, this study met its primary endpoint of equivalent DFS. The side-effect profiles are slightly different, with capecitabine having an increased risk for hand–foot syndrome but markedly improved reductions in neutropenia and stomatitis seen in the bolus regimen.³⁶²

Oxaliplatin-based regimens

Oxaliplatin is a third-generation platinum compound that cross-links DNA and induces apoptosis. Oxaliplatin has properties that are distinct from other platinum compounds such as cisplatin and carboplatin. The preclinical models showed both activity in cisplatin-resistant CRC cell lines and synergism when combined with 5-FU.³⁶⁴ Oxaliplatin causes little nephrotoxicity, ototoxicity, and alopecia but shares bone marrow suppressive properties and has its own sensory neuropathy that is typically reversible, cumulative, and exacerbated by exposure to cold.^{364–367}

Oxaliplatin was quickly moved to the adjuvant setting after initial studies showed its efficacy in the metastatic setting. The MOSAIC trial randomized 2246 stage II (node negative) and stage III patients to receive either oxaliplatin, folinic acid, and 5-FU (FOLFOX-4) combination or infusional 5-FU/LV.^{364, 366, 367} The infusional 5-FU was given every 2 weeks on a 28-day cycle as LV 200 mg/m² over 2 h followed by bolus 5-FU 400 mg/m² and then a 22-h infusion of 5-FU at 600 mg/m² on days 1 and 2. FOLFOX-4 included the same regimen of 5-FU/LV with addition of oxaliplatin at 85 mg/m² over 2 h every 2 weeks of a 28-day cycle.³⁶⁴ The probability of being free of disease at three years was 78.2% in the FOLFOX-4 arm compared with 72.9% in the infusional 5-FU/LV arm. Subgroup analysis revealed that stage III patients derived more benefit as evidenced by 3-year DFS (72% receiving FOLFOX-4 vs. 65% receiving 5-FU/LV, $p = 0.0002$) than stage II patients (87% receiving FOLFOX-4 vs 84% receiving 5-FU/LV, $p = \text{ns}$). Oxaliplatin regimens are still restricted by its dose-limiting toxicity of neuropathy, which seriously affected 12% of patients during the trial but the percentage of patients affected dropped to 0.5% after 18 months.^{364, 366} In 2009, long-term results from the MOSAIC trial were published, which demonstrated statistically significant improvements in 5-year DFS (73.3 vs 67.4%).³⁶⁸ Among patients with stage III disease, there was a corresponding improvement in 6-year OS (72.9 vs 68.7%); however, there was no statistically significant difference in OS for patients with stage II disease. Furthermore, a subgroup analysis of the MOSAIC trial demonstrated that elderly patients (70–75 years old) with both stage II and III disease did not benefit from the addition of oxaliplatin to 5-FU/LV (hazard ratio 1.1 for OS).³⁶⁹ The benefit of oxaliplatin does not appear to be dependent on the schedule of 5-FU/LV. NSABP C-07 randomized 2407 patients with stage II/III colon cancer to bolus weekly 5-FU/LV (Roswell Park regimen) or to FLOX (the same 5-FU/LV regimen with biweekly oxaliplatin).³⁶⁵ The improvement in the hazard ratios and DFS was similar to that seen in the MOSAIC trial. The probability of being alive and free of disease at 3 years was 76.5% in the oxaliplatin arm compared with 71.6% in the control arm.³⁶⁵ Although the efficacy of FLOX looked similar to the infusional 5-FU used in the MOSAIC trial, it does appear to be slightly more toxic, with increased diarrhea and dehydration.

Irinotecan-based regimens

Irinotecan is a camptothecin derivative that inhibits topoisomerase I by stabilizing DNA breaks that arise in DNA uncoiling for transcription and replication.³⁷⁰ Two randomized controlled trials showed improved survival in patients receiving irinotecan along with 5-FU/LV, compared with 5-FU/LV alone, as first-line therapy in metastatic disease.^{371, 372} Despite the proven benefit in advanced disease, preliminary results from three large trials do not support the use of irinotecan in the adjuvant setting. CALGB C89803 compared a bolus version of irinotecan with 5-FU/LV (IFL) with 5-FU/LV alone and found an increase in grade III–IV toxicities (neutropenia, neutropenic fever, and death on treatment) without an improvement in DFS.³⁷³ PETACC-3 and Accord02/FFCD9802 compared the addition of irinotecan with infusional 5-FU and also found increased toxicities in the experimental arm with no improvement in DFS in patients with stage III cancer.³⁷⁴ On the basis of these trials, irinotecan-based regimens cannot be recommended in the adjuvant setting.^{373, 374}

Irinotecan is hydrolyzed in the liver to its active metabolite, SN-38, which in turn is glucuronidated to an inactive form by uridine diphosphate glucuronosyltransferase isoform 1A1 (UGT1A1).³⁷⁰ The adverse events associated with irinotecan, including diarrhea, bone marrow suppression, and nausea or vomiting, have been shown in retrospective studies to correlate with polymorphisms of UGT1A1.³⁷⁰ A diagnostic test has been approved by the FDA, and several current trials include adjustment of irinotecan dosages on the basis of genetic profiles (pharmacogenomics) of these metabolic enzymes.³⁷⁰

Biologic agents

The two most recent FDA-approved therapies in metastatic colon cancer are “targeted,” “biologic” agents rather than standard cytotoxic drugs. Both agents are monoclonal antibodies. Bevacizumab targets the VEGF pathway and cetuximab is directed against the epidermal growth factor receptor (EGFR) pathway.

Bevacizumab is a humanized recombinant monoclonal antibody directed against VEGF. By binding ligand and preventing signaling of the VEGF receptor, bevacizumab is thought to interfere with the recruitment and growth of tumor-feeding blood vessels. Two phase III trials have shown an improvement in both DFS and OS after the addition of bevacizumab to 5-FU-based regimens combined with either oxaliplatin or irinotecan in the metastatic setting.^{375, 376} Side effects seen in these trials thought to be due to the addition of bevacizumab included reversible hypertension and proteinuria, as well as rare serious, but not statistically significant, side effects including GI perforation, wound dehiscence, bleeding, and clotting.^{375, 376} The AVANT trial compared FOLFOX4, FOLFOX4 plus bevacizumab, and XELOX plus bevacizumab in patients with stage III or high-risk stage II colon cancers.³⁷⁷ This trial found that the addition of bevacizumab to oxaliplatin-based adjuvant chemotherapy did not improve DFS and suggested that its addition may in fact result in decreased OS. The NSABP C-08 trial compared the addition of bevacizumab to modified FOLFOX6 versus modified FOLFOX6 alone in patients with resected stage II and III colon cancers and also found that the addition of bevacizumab did not increase 3-year DFS.³⁷⁸

Cetuximab is a monoclonal antibody directed against EGFR, which is involved with multiple growth signaling pathways. Cetuximab received FDA approval for treatment of irinotecan-resistant metastatic disease in 2004. In irinotecan refractory disease, a 22% response rate was reached in patients treated with cetuximab/irinotecan compared with an 11% response rate with cetuximab as a single agent in a randomized phase II trial.³⁷⁹ The side effects of cetuximab are relative mild, with an acneiform rash over the face, chest, and back occurring in most patients.³⁷⁹ Allergic reactions also occur as cetuximab, unlike bevacizumab, is not fully humanized.³⁷⁹ The US Intergroup N0147 trial comparing FOLFOX-4 with and without cetuximab for patients with resected stage III colon cancer found no difference in 3-year DFS for either patients with wild-type or mutant KRAS.³⁸⁰ Moreover, grade 3 adverse events and failure to complete 12 cycles of therapy were significantly higher in patients treated with cetuximab.

Summary recommendations

The magnitude of benefit from adjuvant therapy appears to be proportional to the risk of relapse on the basis of pathologic stage. For stage III (node positive) patients, the evidence supports the use of adjuvant chemotherapy for 6 months following resection.^{381, 382} FOLFOX-4 has the most convincing efficacy data but is associated with increased toxicities compared with 5-FU/LV alone. Capecitabine is a reasonable alternative to intravenous 5-FU/LV. Irinotecan-based regimens cannot be recommended in the adjuvant setting nor can the addition of bevacizumab and cetuximab to established adjuvant regimens. For stage II (node negative) patients, the absolute benefit appears to be real but much smaller. The current trials were

not powered to see a difference in this subgroup, so the role of adjuvant treatment for stage II patients is controversial.^{381, 382} Following the NCCN practice guidelines, FOLFOX-4 or 5-FU is often considered if the pathology displays high-risk features such as poor differentiation, lymphatic or vascular invasion, bowel obstruction, inadequate staging (<12 lymph nodes removed), perforation, or direct extension into other organs.³⁸² For stage II patients with no high-risk features, observation or enrollment in a clinical trial is recommended.³⁸²

The role of adjuvant chemotherapy in older patients remains controversial, particularly regarding the addition of oxaliplatin to 5-FU-based therapies. While the MOSAIC trial failed to demonstrate a benefit in adding oxaliplatin to 5-FU/LV,³⁶⁹ pooled analysis of three randomized clinical trials suggested that efficacy of adjuvant 5-FU-based chemotherapy was maintained in the elderly (defined as 70 years of age and older), and that toxicity was similar to younger patients except for an increase in leucopenia in one study.^{383, 384}

Neoadjuvant and adjuvant therapy for rectal cancer

As in colon cancer, surgical resection remains the cornerstone of the curative approach. However, unlike colon cancer, there is significant tendency for local failure after potentially curative resection. Improvements in the initial surgical procedure by performing a TME have reduced but not eliminated the risk of local recurrence. Salvage surgical procedures are technically difficult, often unsuccessful and fraught with morbidity. Therefore the major difference in the adjuvant treatment paradigm for rectal as compared with colon cancer is the addition of radiation therapy to reduce the risk of local failure.

Adjuvant chemotherapy and radiation

Studies in the 1980s and 1990s solidified the superiority of postoperative chemoradiation over surgery alone and surgery followed by radiation without chemotherapy. Chemoradiation reduced the risk of local failure, distant failure, and the risk of death.^{385–387} In these studies, chemoradiation involved the use of semustine (methyl-CCNU) in addition to 5-FU. Semustine carries a small but real risk of acute myeloid leukemia and is no longer used in adjuvant regimens for rectal cancer.³⁸⁸ The North American Intergroup trial confirmed the lack of additional benefit of semustine in addition to 5-FU and has established the role of continuous infusion 5-FU with radiation.³⁸⁹ Comparing continuous infusion 5-FU (225 mg/m² per day for 5 weeks) to bolus 5-FU (500 mg/m² days 1–3 and days 36–39) at 4 years, the time to relapse was improved from 53% to 63%, and survival was improved from 60% to 70%. Unlike colon cancer, biomodulation with LV or levamisole has not increased the efficacy of 5-FU in rectal cancer. Intergroup study 0144 compared continued systemic therapy with infusional 5-FU during radiation, bolus 5-FU 4 weeks before and after radiation, and combined bolus and continued infusional 5-FU during radiation. The study found no difference in relapse-free survival or OS between the three groups.³⁹⁰ A 2012 trial comparing capecitabine-based chemoradiotherapy (2500 mg/m² days 1–14, repeated day 22, followed by 50.4 Gy plus capecitabine 1650 mg/m² days 1–38, followed by three cycles of capecitabine) with 5-FU-based radiotherapy (two cycles of bolus 5-FU 500 mg/m² days 1–5, 29, followed by chemoradiation with 50.4 Gy and infusional 5-FU, followed by two additional bolus cycles of 5-FU) in patients with stage II–III rectal cancer found that capecitabine was noninferior to 5-FU in terms of 5-year OS, 3-year DFS, and local recurrence.³⁹¹ Distant metastasis was less common in the capecitabine group. Adverse reactions differed between the two arms, with leukopenia more common in patients receiving 5-FU and hand–foot skin reactions, fatigue, and proctitis more common in the capecitabine group. Capecitabine is thus a reasonable alternative to 5-FU in adjuvant chemoradiation regimens. In general, adjuvant therapy is

recommended for any tumor that is T3 or greater in size or is node positive. Radiation therapy should be directed at the tumor bed, including a 2–5 cm margin as well as the presacral nodes and the internal iliac nodes. If an APR was performed, the perineal wound should be included in the radiation field.³⁹²

Neoadjuvant chemotherapy and radiation

The neoadjuvant approach is particularly attractive in rectal cancer because downstaging may increase ease and rates of respectability, allow potential sphincter preservation, and increase compliance by avoiding long postoperative recoveries. The Swedish Rectal Cancer Trial was the first to show that a short-term regimen of high-dose preoperative radiotherapy decreased the rate of local recurrence and improved survival compared with surgery alone.³⁹³ The German phase III EORTC 22921 study was the first study to complete accrual in comparing neoadjuvant therapy with combined 5-FU/radiation to postoperative adjuvant 5-FU/radiation.³⁹⁴ Patients with tumor extending through the muscle wall (T3) or with positive nodes (N1) were randomized to preoperative or postoperative chemoradiation. In both arms, the radiation (5040 GY in 28 fractions) was combined with 5-FU (1000 mg/m² over 120 h during the first and fifth week). All patients received additional systemic 5-FU for 4 months. The study failed to see an improvement in OS, but preoperative therapy was associated with an improved rate of local control at 5 years (6% failure compared to 13%), reduced acute and chronic toxicity, increased compliance, and an increased rate of sphincter preservation in patients with low-lying tumors.³⁹⁴ Interestingly, posttreatment pathology results proved to be highly prognostic with patients who showed marked regression or negative nodes having improved DFS.³⁹⁴ In 2012, long-term results from the German trial became available. At 10 years, preoperative chemoradiation therapy was associated with improved local control compared to postoperative therapy; however, there remained no difference in OS.³⁹⁵ There are several theoretical benefits of neoadjuvant as opposed to adjuvant chemoradiation therapy. First, there is the increased possibility of ultimately performing a sphincter-sparing resection. While two studies have demonstrated higher rates of sphincter preservation,^{394, 396} other large meta-analyses have disputed these findings.^{397, 398} During resection, adhesions can result in bowel that becomes fixed in the pelvis. By administering radiation in the preoperative versus postoperative period, daily radiation to the same segment of fixed bowel can be avoided. A third hypothetical benefit is the presence of intact vasculature prior to resection, which may result in greater tissue oxygenation and better response to radiation.

Short-course radiation

Short-course radiation (e.g., Swedish or European approach) refers to 25 Gy of radiation without chemotherapy over a 5-day time period. Initially, the Swedish Rectal Cancer Trial demonstrated improved rates of local recurrence and OS for short-course preoperative radiotherapy compared to surgery alone.³⁹³ However, a later analysis of this study population demonstrated that patients treated with short-course radiation had higher rates of GI morbidity following surgery, most notably, bowel obstructions.³⁹⁹ In a large randomized trial of more than 1,300 patients, short-course preoperative radiation without any adjuvant therapy was compared to postoperative chemoradiation therapy in patients with a positive circumferential margin.⁴⁰⁰ Short-course radiation was associated with improved local recurrence rates and DFS, although there was no detectable difference in OS. More recently, the TME trial comparing patients treated with short-course radiation to patients who underwent TME alone demonstrated improvements in local recurrence (5 vs 11%) without a corresponding increase in OS.⁴⁰¹ While OS was significantly improved among stage III patients treated with short-course RT who had a negative circumferential margin, among node-negative patients with negative margins, the improvement in

CRC-specific mortality was countered by an increase in other causes of death. Only one randomized trial has directly compared short-course high-dose radiotherapy to conventional preoperative chemoradiation, which showed no improvement in local recurrence, RFS, or OS.⁴⁰² Short-course radiation therapy appears to result in equivalent local control compared with traditional long-course chemoradiation therapy; however, improvements in OS have not been appreciated, and concerns about increased perioperative toxicity remain.

Summary recommendations

Neoadjuvant chemoradiation therapy has been shown to result in tumor downstaging in approximately half of patients, with a pathologic complete response in up to 20%.⁴⁰³ Thus, although no survival benefit has been proven with preoperative compared to postoperative chemoradiotherapy, it is suggested that preoperative chemoradiotherapy be the preferred treatment for patients with locally advanced rectal cancer, given that it is associated with a superior overall compliance rate, an improved rate of local control, reduced toxicity, improved function, and perhaps an increased rate of sphincter preservation in patients with low-lying tumors.³⁸² Although no trial has demonstrated conclusively that additional postoperative adjuvant 5-FU-based chemotherapy improves outcomes in patients who have undergone neoadjuvant chemoradiotherapy, guidelines from the National Comprehensive Cancer Network recommend that all such patients receive 5-FU-containing chemotherapy even if they have a pathologic complete response to neoadjuvant therapy.³⁸²

Chemotherapy for hepatic metastasis

Conversion therapy

Selected patients with initially unresectable liver metastases may become eligible for resection if the response to chemotherapy is sufficient. This approach has been termed “conversion therapy” to distinguish it from “neoadjuvant therapy” which applies to preoperative chemotherapy given to patients who present upfront with apparently resectable disease. The key parameter for selecting the specific regimen in this scenario is not survival or improved QOL but instead response rate. The NCCN currently recommends any chemotherapeutic regimen that is active in the metastatic setting, as the goal of conversion therapy is not to treat occult disease but rather to obtain the tumor regression necessary to convert unresectable metastases to a resectable state.⁴⁰⁴ Regimens studied include FOLFIRI,⁴⁰⁵ FOLFOX,⁴⁰⁶ FOLFOXIRI.^{407, 408} Between 12% and 40% of patients with isolated but initially unresectable CRC liver metastases have a sufficient downstaging response to permit a subsequent complete resection.^{404–408} Following resection, 5-year survival rates average 30–35%, results that are substantially better than expected using chemotherapy alone. In the largest study, 138 (12.5%) of 1104 patients with initially unresectable CRC liver metastases were able to undergo resection after induction chemotherapy that consisted mainly of 5-FU/LV combined with either oxaliplatin (705), irinotecan (7%), or both (4%).⁴⁰⁹ Overall 5- and 10-year survival was 33% and 23%, respectively. Targeted and biologic agents have been tested in combination with established chemotherapy regimens in the conversion setting. The addition of cetuximab (an EGFR inhibitor) may substantially increase resectability in patients with wild-type *KRAS*; however, the effect on OS remains controversial.^{410–412} Most recently, bevacizumab has been tested in combination with established chemotherapies in the setting of unresectable disease.^{413–415} While there may be a modest improvement in conversion rates using bevacizumab in combination with irinotecan-based therapies,^{413, 414} the same benefit has not been observed with oxaliplatin-based therapies.⁴¹⁵ In summary, chemotherapy alone is not curative in this setting with the majority of

radiographic completely responding lesions containing viable tumor. Thus, even in the setting of a complete clinical response, resection is still needed.

Neoadjuvant therapy for hepatic metastasis

There is evidence that perioperative chemotherapy improves both progression-free survival and DFS among patients with initially resectable hepatic metastases; however, its effect on OS remains unproven.⁴¹⁶ Whether patients benefit most from pre- or postoperative therapy remains unclear. The theoretical benefits of neoadjuvant chemotherapy for patients with resectable hepatic metastases include the guarantee that these patients will receive systemic therapy (vs patients who are unable to tolerate postoperative therapy), as well as an earlier initiation of systemic therapy compared to those who receive adjuvant chemotherapy. The EORTC trial randomly assigned 364 patients with up to four metastases without prior exposure to oxaliplatin to liver resection with or without perioperative FOLFOX-4 chemotherapy.⁴¹⁷ Six cycles of chemotherapy were administered prior to surgery, and six cycles were administered postoperatively. Sixty-seven of the 182 patients assigned to chemotherapy had an objective response, while 11 progressed, eight of whom were no longer considered resectable. Overall, 83% of patients were successfully resected, similar to the number who were successfully resected in the surgery alone group, 84%. The postoperative complication rate, however, was significantly higher in the chemotherapy group (25% vs 16%). Patients receiving perioperative chemotherapy had higher rates of hepatic failure, biliary fistulas, and intra-abdominal infection. Postoperative mortality was similar between groups. There is increasing evidence that for patients with resectable hepatic metastases, the use of preoperative chemotherapy is associated with hepatic steatosis, vascular injury, and nodular regenerative hyperplasia, particularly among patients treated with irinotecan or oxaliplatin-containing regimens.^{409, 418, 419} Moreover, there is evidence that among patients who have complete radiographic responses to neoadjuvant therapy, most sites of metastasis nonetheless harbor viable cancer cells.⁴²⁰ This presents a substantial challenge with regard to operative planning following the cessation of neoadjuvant therapy.

Adjuvant therapy after hepatic resection

Adjuvant chemotherapy is commonly recommended following resection of hepatic colorectal metastasis despite the lack of data to support its use. There are many unknowns, including the timing of resection, optimal drug combination, schedule, and duration of therapy. Because the presence of hepatic metastasis confers stage IV disease, either FOLFOX-4 or folinic acid, 5-FU, and irinotecan (FOLFIRI) for 4 to 6 months is often used.⁴²¹ A targeted biologic agent may be considered despite the lack of data supporting use in stage II/III disease. Because of the risk of wound complications and other issues, it is recommended that bevacizumab be discontinued 8 weeks before or after major surgical procedures.⁴²²

Summary recommendations

There are no widely accepted guidelines for determining which patients with CRC liver metastases should undergo immediate surgery and when neoadjuvant chemotherapy is indicated. However, the increasing reports of liver injury following neoadjuvant chemotherapy have prompted most physicians to recommend initial surgery for low-risk (medically fit with four or fewer lesions), potentially resectable patients, followed by adjuvant chemotherapy.⁴²³ On the other hand, neoadjuvant chemotherapy is reasonable for those who are higher risk or have borderline resectable or unresectable liver metastases. However, the duration should be limited, radiographic response assessment performed frequently, and surgery undertaken as soon as the metastases become clearly resectable.

Metastatic CRC

The last two decades have seen unprecedented advances in the treatment of metastatic CRC, and these improvements serve as a model for the treatment of many additional solid tumors for which progress has been less rapid. In the era when 5-FU was the sole active agent, OS was approximately 11 to 12 months. Currently, the average median survival duration has doubled, with patients routinely living longer than 2 years. This increase has been mainly driven by the availability of new active agents. There are now three different classes of primary chemotherapies with significant antitumor activity (fluoropyrimidines, irinotecan, and oxaliplatin), as well as multiple targeted and biologic therapies with an emerging role in the treatment of CRC (e.g., cetuximab, bevacizumab, panitumumab, and regorafenib). For most patients, the goal of treatment will be palliative and not curative, with the treatment goals being to prolong OS and maintain QOL for as long as possible. For the vast majority of patients with noncurable metastatic CRC, rationally designed doublet combinations, such as FOLFOX or FOLFIRI should be considered the standard chemotherapy backbone for first-line palliative therapy. These regimens have well-documented activity and a tolerable toxicity profile. Other appropriate therapies include XELOX, 5-FU/LV, capecitabine, and FOLFOXIRI.

FOLFOX

The first large size, randomized phase III trial comparing 5-FU and LV versus FOLFOX-4 included 420 patients.³⁶⁷ Patients received exactly the same regimen of a 2-h infusion of 200 mg/m² of LV followed by a bolus of 400 mg/m² and a 22-h infusion of 600 mg/m² of 5-FU. All drugs were repeated for 2 consecutive days every 2 weeks. Half of the patients were assigned to receive 85 mg/m² of oxaliplatin as a 2-h infusion on day 1 only.³⁶⁷ Patients allocated to receive FOLFOX-4 had significantly longer PFS (median 9.0 vs 6.2 months; $p = 0.0003$) and better response rate (50.7% vs 22.3%; $p = 0.0001$) when compared with the control arm. However, although a trend could be seen, the improvement in OS did not reach statistical significance (median, 16.2 vs 14.7 months, $p = 0.12$).³⁶⁷ The lack of survival benefit in this European trial delayed FOLFOX acceptance in the United States. Shortly after, the NCCTG and the American Intergroup conducted the N9741, a phase III trial with three arms.⁴²⁴ The control arm received IFL regimen, and oxaliplatin was included in the two experimental arms. It was combined at 85 mg/m² with 200 mg/m² of irinotecan in the irinotecan and oxaliplatin (IROX) regimen, or with 5-FU and LV, following the FOLFOX-4 regimen described above.⁴²⁴ The final results showed a median time to progression of 8.7 months, response rate of 45%, and median survival time of 19.5 months for those patients assigned to FOLFOX-4. These results were significantly superior to those observed for IFL (6.9 months, 31%, and 15.0 months, respectively) or for IROX (6.5 months, 35%, and 1.4 months, respectively).⁴²⁴ FOLFOX-4 was generally well tolerated but it was associated with a significantly higher rate of sensory neuropathy as described above. More recently, modified FOLFOX6 has emerged as the preferred dosing schedule for the FOLFOX regimen.⁴²⁵

Capecitabine/XELOX

Capecitabine, an orally active fluoropyrimidine, allows for the attractiveness of oral dosing and the potential for eliminating the need for a central venous catheter and ambulatory infusion pump. At least five randomized phase III trials have directly compared XELOX (capecitabine, oxaliplatin) versus FOLFOX for first-line or second-line chemotherapy in metastatic CRC.^{426, 427} None showed that XELOX was inferior to FOLFOX-type regimens in terms of response rate, PFS, or OS. However, in nearly all cases, the PFS and OS curves for XELOX trailed beneath the curves for FOLFOX. In no case was this effect statistically significant or clinically meaningful. Thus, the available evidence supports the view that

XELOX can be considered as a noninferior substitute for FOLFOX in palliative therapy.

FOLFIRI

The effectiveness of irinotecan was initially demonstrated in a randomized phase III trial conducted to evaluate irinotecan with or without standard bolus 5-FU and LV versus a standard regimen of bolus 5-FU and LV.³⁷² The combination regimen became known as the IFL regimen and included 5-FU 500 mg/m², LV 20 mg/m², and irinotecan 125 mg/m² given weekly for 4 weeks every 6 weeks. Irinotecan alone was given at 125 mg/m² weekly for 4 weeks every 6 weeks, and the 5-FU/LV was given using the standard Mayo regimen as described above.³⁷² The three drug regimen was superior to either 5-FU and LV or to irinotecan alone, and the latter produced similar results as the 5-FU/LV regimen. In a comparison of IFL and the Mayo regimens, the median PFS improved from 4.3 months to 7.0 months, and the median OS improved from 12.6 months to 14.8 months.³⁷² FOLFIRI is a variation of IFL using infusional 5-FU, LV, and irinotecan. There are several variations of FOLFIRI, but one of the favored regimens combines 180 mg/m² of irinotecan given on day 1 weekly, 400 mg/m² bolus LV weekly, 400 mg/m² bolus 5-FU weekly, and followed by a 46 h infusion of 2400 mg/m² of 5-FU. The entire cycle is repeated every 14 days. A European trial compared the use of FOLFIRI versus FOLFOX as a first-line therapy for metastatic CRC.⁴²⁵ Although it has been criticized for its relatively small size, this trial was important because it showed similar response rates and median survivals for FOLFOX and FOLFIRI. However, these data are supported further by the 2005 multicenter trial from the Gruppo Oncologico Dell'Italia Meridionale, in which 360 patients were randomized to FOLFIRI versus FOLFOX4.⁴²⁸ There were no differences in response rates, time to progression, duration of response, or OS between arms.

While XELOX may be regarded as a valid substitute for FOLFOX, the situation is different for combinations of capecitabine with irinotecan (XELIRI) as an alternative to FOLFIRI. Capecitabine and irinotecan have partially overlapping toxicity profiles, particularly with regard to diarrhea. The potential for greater toxicity reduces the therapeutic advantage of an irinotecan/capecitabine combination and makes the selection of appropriate doses and schedules for this combination difficult.⁴⁰³

FOLFOXIRI

There have been two recent trials comparing FOLFOXIRI to FOLFIRI among patients with metastatic CRC.^{407, 429} The GONO trial randomized 244 treatment-naïve patients with metastatic, unresectable CRC to receive either FOLFOXIRI or FOLFIRI.⁴⁰⁷ FOLFOXIRI was dosed every two weeks, with irinotecan (165 mg/m²), oxaliplatin (85 mg/m²), and LV (200 mg/m²) given on day one and 5-FU administered as a 48-h continuous infusion starting on day 1. Partial response rates were higher in the FOLFIRI arm (44 vs 66%); however, there was no difference in complete response. Patients in the FOLFOXIRI arm were more likely to undergo a complete resection of their hepatic metastases (12 vs 36%). Most importantly, both PFS and OS were significantly improved in the FOLFOXIRI arm (7 vs 10 months and 17 vs 23 months, respectively). The HORG trial also compared FOLFOXIRI to FOLFIRI, although the FOLFOXIRI dosing regimen was slightly different.⁴²⁹ In this trial, no differences in OS, time to disease progression, or response rates were appreciated between groups. Moreover, FOLFOXIRI was associated with a higher rate of treatment toxicity, including alopecia, diarrhea, and neurotoxicity.

Bevacizumab

CRC was the first malignancy for which clear evidence for efficacy of an anti-VEGF strategy was obtained in randomized trials. In a pivotal early trial, the addition of bevacizumab to the bolus IFL

regimen significantly improved response rates from 35% to 45%; PFS was extended from 7.1 months to 10.4 months, and more importantly, the OS improved from 15.6 to 20.3 months.³⁷⁵ The adverse events in this trial were similar among the treatment with some notable exceptions. Patients receiving bevacizumab had an 11% incidence of grade 3 hypertension and a 1.5% incidence of bowel perforations. No patients in the IFL arm presented with such problems.³⁷⁵ The ECOG 3200 trial compared the use of FOLFOX to combination therapy of bevacizumab and FOLFOX.³⁷⁶ The median survival for combination therapy was 12.5 months versus 10.7 months for FOLFOX alone. This confirmed that bevacizumab does significantly add potency to oxaliplatin-based regimens. Since 2004, the majority of patients with metastatic CRC have received bevacizumab as a component of first-line therapy regardless of the specific regimen chosen for chemotherapy backbone (FOLFOX, XELOX, FOLFIRI). With regard to the addition of bevacizumab to established regimens in the advanced setting, FOLFOXIRI/bevacizumab appears to have increased progression-free survival and response rates compared to FOLFIRI/bevacizumab among patients who have not received prior adjuvant therapy.⁴³⁰ FOLFOXIRI/bevacizumab was also found to be superior to FOLFOX/bevacizumab in the conversion setting for patients with hepatic metastases (rate of R0 resection 49 vs 23%).⁴³¹

Anti-EGFR monoclonal antibodies

The benefit of cetuximab added to first-line or second-line irinotecan-containing therapy has been addressed in the CRYSTAL trial and CALGB 80203.^{432, 433} In the CRYSTAL trial, 1198 previously untreated patients were randomly assigned to FOLFIRI with or without cetuximab.⁴³³ Although the addition of cetuximab significantly improved PFS, the incremental gain was only 0.9 months. The addition of cetuximab also improved the response rate but only by 8%.⁴³³ Early results from the phase II CALGB 80203 trial, which randomly assigned 283 patients to FOLFOX or FOLFIRI with or without cetuximab as first-line therapy, provided confirmatory data supporting the results of the CRYSTAL trial.⁴³² In a preliminary report, there was a clear demonstration of increased response rate with cetuximab in conjunction with both FOLFOX and FOLFIRI, while the impact on PFS was inconclusive.⁴³² Furthermore, a retrospective analysis of the CRYSTAL trial investigating the role of KRAS mutation status on PFS and response rate showed that in the KRAS wild-type population, the 1 year PFS rate for those who received cetuximab and FOLFIRI was 43% versus 25% for those who received FOLFIRI alone, and the risk of progression was decreased by 32% in the combination treatment arm.⁴³⁴ In the KRAS mutant population, however, there was no difference in PFS between the two arms. Long-term results from this study should be available shortly. Most recently, a meta-analysis of 14 trials comparing standard therapies with or without the use of anti-EGFR monoclonal antibodies was performed, which found an increase in progression-free survival only among patients with wild-type KRAS.⁴³⁵ In this analysis, patients with KRAS mutations demonstrated no clinical benefit from anti-EGFR therapies. KRAS genotyping is now recommended among all patients with metastatic CRC.⁴⁰⁴ Other trials evaluating both cetuximab and panitumumab have confirmed a clear benefit for anti-EGFR therapy among patients with wild-type KRAS.^{436–438} It is recommended that anti-EGFR therapies not be used among patients with KRAS mutations. Finally, several randomized trials have compared the addition of bevacizumab versus anti-EGFR therapy to established chemotherapies among patients with metastatic wild-type KRAS CRC.^{438–440} These data remain inconclusive as to a superiority benefit for either combination. At present, either anti-EGFR therapy or bevacizumab as an addition to a first-line regimen is an acceptable choice of therapy for patients with metastatic CRC with wild-type KRAS.

Summary recommendations

Initial combination therapy is preferred for patients with nonoperable metastatic CRC, in whom the palliative treatment strategy should aim to maximize the number of patients exposed to all active agents. This is best achieved by using well-established combination doublets (i.e., FOLFOX, XELOX, or FOLFIRI) as the chemotherapy backbone, which would then only require one additional step to have all three active agents included in the treatment algorithm for second-line therapy (e.g., FOLFOX followed by FOLFIRI, or FOLFIRI followed by FOLFOX, or FOLFOXIRI). Bevacizumab should be considered a component of first-line therapy regardless of which regimen is chosen. Cetuximab in patients with wild-type KRAS is a reasonable alternative to bevacizumab in combination with established chemotherapy regimens.

Chapter 95

Neoplasms of the anus

Bruce D. Minsky, MD ■ Jose G. Guillem, MD

Overview

Although an uncommon tumor, the incidence of anal cancer has increased over the past few decades. This increase may be due to sexual transmission of human papillomavirus virus as well as the impact of human immunodeficiency virus. Chemoradiation therapy (CMT) involving pelvic radiation and concurrent chemotherapy (5-FU combined with either mitomycin-C or cisplatin) has resulted in 5-year survival rates of approximately 80% while maintaining sphincter preservation for most patients. Surgery is reserved for selected patients with T1M0 disease who can undergo resection with acceptable functional outcomes or an abdominoperineal resection (APR) for salvage following CMT.

Gross anatomy

There are three regions where anal cancers occur; the perianal skin or anal margin, the anal canal, and the lower rectum. The anal canal is 3–4 cm long and extends from the anal verge to the pelvic floor.¹ Cancers of the anal canal and the anal margin have different natural histories. The literature is confusing because of the various definitions of the anal canal and the anal margin. For example, some define the distal limit of the anal canal as the dentate line and all tumors below this as anal margin cancers,^{2,3} others consider the distal extent of the anal canal as the anal verge,^{4,5} while another definition of anal margin tumors are those tumors that arise within 5 cm of the anal verge.⁶

The incidence of anal margin and anal canal cancers is dependent on the anatomical boundaries. When the anal verge is defined as the distal margin of the anal canal, 15% of tumors arise from the anal margin, but this number increases to 30% when the dentate line is used as the distal limit. To clarify this issue, the American Joint Committee on Cancer (AJCC) and the Union Internationale Contra le Cancer (UICC) formed a consensus that the anal canal extends from the anorectal ring (dentate line) to the anal verge.^{7,8} These two organizations agree that anal margin tumors behave in a similar manner to skin cancers and therefore are classified and treated as skin tumors.

There is an extensive lymphatic system for the anus with many connections. The three main pathways include (1) superiorly from the rectum along the superior hemorrhoidal vessels to the inferior mesenteric lymph nodes, (2) from the upper anal canal and superior to the dentate line along the inferior and middle hemorrhoid vessels to the hypogastric lymph nodes, and (3) inferior from the anal margin and anal canal to the superficial inguinal lymph nodes.

Epidemiology

In the United States, cancers of the anal region account for 1–2% of all large bowel cancers and 4% of all anorectal carcinomas. Since 1997, the incidence of carcinoma *in situ* (CIS) and squamous cell cancer

(SCC) anus have dramatically increased. However, more men are more likely to be diagnosed with CIS.⁹ In 2014, a total of 7210 cases of cancers of the anal region are estimated to occur in the United States, including 2660 men and 4550 women.¹⁰ It is estimated that there will be 950 deaths.

Etiology

HPV infection

Squamous cell carcinoma is closely correlated with HPV (human papillomavirus), most commonly types 16 and 18. In a population-based case–control study from Scandinavia of 417 patients with anal canal cancers, a variety of behavioral factors such as sexual activity and venereal infection, tobacco consumption, and anal inflammatory lesions were examined.¹¹ A positive correlation was found by both univariate and multivariate analysis for the number of sexual partners and the risk of anal cancer. An association between venereal infection in both men and women was also noted.

Anal intraepithelial neoplasia (AIN) is rare in heterosexual men, whereas the incidence is 5–30% in men who have sex with men (MSM) who are HIV-negative (human immunodeficiency virus). These changes are rare among HIV-negative women. AIN is linked to HPV and is common in MSM and immunosuppressed patients, especially those who are HIV positive.^{12, 13} In a report from Surawicz et al.¹⁴ of 90 MSM to anal cancer with an abnormal examination of the anal canal, 89% had HPV-associated changes. A recent metatanalysis of 53 trials examining the relationship of HPV infection in MSM revealed that anal HPV and anal SCC precursors were very common.¹⁵ The pooled prevalence of HPV-16 was 35% in HIV positive versus 13% in HIV negative patients. However, the rate of progression to cancer was substantially lower than that reported for cervical precancerous lesions.

HIV (human immunodeficiency virus)

There is a clear association between HIV and anal canal cancer. Cross-referencing US databases for AIDS with those for cancer, the relative risk of anal cancer in homosexual men compared to men in the general population at the time of or after AIDS diagnosis was 84.1.¹⁶ The relative risk of anal cancer for up to 5 years before AIDS diagnosis was 13.9.

Anal canal carcinoma and AIN are associated with condylomata.¹³ HPV-16 infection has a strong association with high-grade AIN and a risk of anogenital malignancy. However, HPV infection alone may be insufficient for malignant transformation, as many patients with HPV-positive cytology do not develop either AIN or anal cancer.¹⁷

Molecular factors

Overexpression of p53 protein has been studied in patients receiving CMT. In an analysis involving approximately 20% of patients entered on both arms of the Radiation Therapy Oncology Group (RTOG) protocol 87-04, there was a trend toward adverse outcome (decreased local control and survival) in patients over expressing p53.¹⁸ In one study of 55 patients, MIB-1 murine monoclonal antibody measurement of Ki 67 failed to predict outcome for patients treated with radiation, with or without chemotherapy.¹⁹ Patel et al proposed that activation of AKT, possibly through the PI3K-AKT pathway, is a component of the development of SCCs.²⁰ In a cohort of 142 Danish patients with SCC of the anal canal treated with CMT, p16 positivity was an independent prognostic factor for disease specific and overall survival.²¹ Williams et al reported that elevated serum SCC antigen in 174 patients with SCC of the anal

margin and canal were associated with a decreased chance of achieving a clinical complete response (cCR), local control, or longer survival.²² Fraunholz reported that EGFR expression correlates with outcome.²³ A systematic review of 29 biomarkers in 21 published trials reported that p53 and p21 were the only markers found to be prognostic in more than one trial.²⁴

Other factors

The relationship between anal cancer and fistulas is conflicting. In one study, 41% of anal canal carcinomas were preceded by benign anorectal disease for at least 5 years.²⁵ However, two studies reveal only a temporal relationship but no evidence of causation.^{26, 27} In a separate study, homosexual males with a history of anal fissure or fistula had an elevated risk of anorectal squamous cell carcinoma (RR, 9.1).²⁸ Overall, the incidence of anal canal cancers in patients with Crohn's disease is low.²⁹ Immunosuppressed renal transplant patients have a 100-fold increase in anogenital tumors compared with the general population.³⁰ In a series of 3595 patients undergoing a solid organ transplant, the incidence of anal cancer was 0.11%.³¹

Pathology

A variety of histologic cell types may occur in the anal area.³² The majority of these (75–80%) are squamous cell carcinomas³³ and 15% are adenocarcinomas. In addition to the more common types seen in [Table 1](#), other rare histologic entities can arise, such as small cell carcinomas³⁵ and lymphoma. Melanomas constitute 1–2% of all anal cancers.³⁶

Table 1 Histologic types of anal cancer

Type	%
Squamous cell	63
Transitional (cloacogenic)	23
Adenocarcinoma	7
Basal cell	2
Melanoma	2
Pagets disease	2

Source: Peters 1983,³⁴ Reproduced with permission of MacMillan Publishing Group.

Squamous tumors may arise from the entire length of the anal canal as well as from the anal margin. Basaloid carcinomas, which are a variant of squamous carcinoma, are commonly referred to as cloacogenic carcinomas. Adenocarcinomas arise from the glands at the dentate line. Small cell carcinomas are of neuroendocrine origin and are rare.

Tumors of the anal margin include squamous carcinoma, basal cell carcinoma, Bowen's disease (squamous CIS), Paget's disease (adenocarcinoma *in situ*), verrucous carcinoma, and Kaposi's sarcoma. Malignant melanomas may arise from either location but more commonly from below the dentate line.

Squamous cell tumors are divided into those with and without keratinization,³⁷ and nonkeratinizing tumors are further subdivided into basosquamous, basaloid, and cloacogenic carcinomas. With the exception of melanoma and sarcoma, most clinicians conclude that prognosis is more dependent on stage rather than

histology and treat all histologic varieties the same.^{38, 39} In contrast, using a multivariate analysis, Das and associates reported a higher distant metastasis rate for patients with basaloid histologies.⁴⁰

Studies of flow cytometric analysis are conflicting and have reported both high proliferative index but near-diploid peaks⁴¹ as well as an aneuploid pattern.⁴² In a multivariate analysis by Shepard et al, the depth of penetration, inguinal node involvement, and DNA ploidy were of independent prognostic significance.⁴³

Natural history

The most common route of spread is by local extension proximally to involve other organs in the pelvis. Hematogenous spread occurs more often from tumors that arise at or above the dentate line.⁴⁴ This pattern of spread allows tumor cells into the portal system resulting in liver and lung metastases in 5–8% of patients⁴⁴ and bone in 2%.⁴⁵ Distant metastases occur with equal frequency independent of the histologic cell type involved. Distant metastases are rarely seen with anal margin tumors.

Lymphatic spread is common and involves the inguinal, pelvic, and mesenteric nodes. Inguinal lymph nodes are positive in 15–63% of cases.^{46, 47} The incidence of synchronous positive inguinal nodes is 15%.^{44, 48} In a series of 96 patients, Metachronous positive inguinal nodes appeared in 25% with a median time to presentation of 12 months. Pelvic nodes are less commonly involved and mesenteric nodes are more likely to be involved if the tumors are proximal (50%) than distal (14%).⁴⁹ Positive mesenteric nodes in anal margin tumors are rare.

Historic surgical series report survivals of 0–20% following lymph node dissection with synchronous positive nodes.^{50, 51} Modern CMT has substantially improved this. Patients who undergo lymph node dissection for metachronous lesions have more favorable survivals with rates as high as 83%.^{50, 52} The majority of these recurrences occur by 2 years but may present as late as 8 years.⁴⁹

Diagnosis

The initial and most common symptom is bleeding, which occurs in over 50% of patients. Other common symptoms include pain, tenesmus, pruritus, change in bowel habits, abnormal discharge, and less commonly, inguinal lymphadenopathy.^{49, 53, 54} Most of these symptoms are associated with benign conditions of the anus including fissure, fistula-in-ano, hemorrhoids, anal pruritus, and anal condyloma. Benign perianal conditions may coexist in 60% of anal margin tumors and in 6% of anal canal tumors.⁵⁵

The most common physical finding is an intraluminal mass that can be misdiagnosed as a hemorrhoid.^{45, 46} Endoscopically, the tumors may appear as flat or slightly raised lesions, as raised lesions with indurated borders, or as polypoid lesions ([Figure 1](#)). The use of transrectal ultrasound is required and allows for the determination of depth of penetration and involvement of adjacent organs.⁵⁶

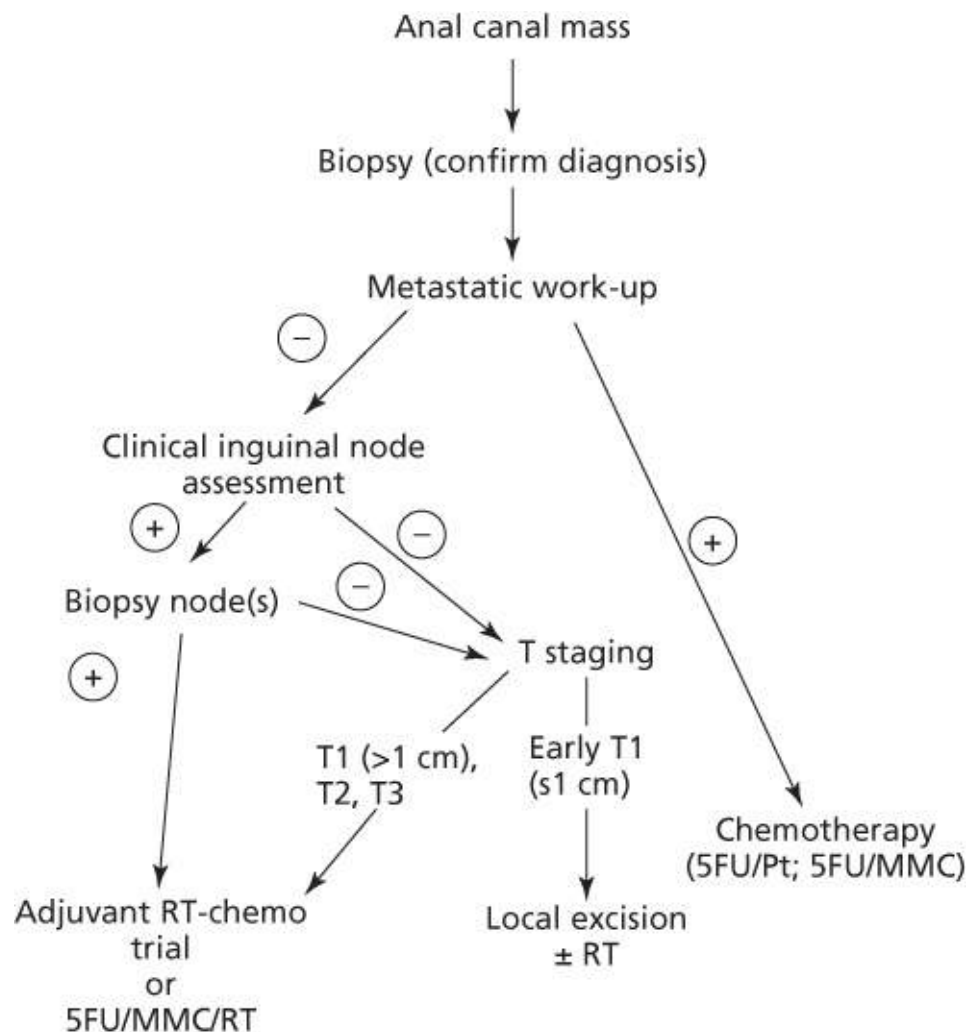

Figure 1 Treatment schema for squamous cell cancer of the anal canal.

An incisional biopsy is recommended for diagnosis. Excisional biopsies should be limited to small superficial lesions. Clinically palpable inguinal lymphadenopathy should be aspirated for cytological examination. A formal inguinal lymph node dissection is not recommended owing to the associated morbidity, failure to have an impact on outcome, and the high control rates with CMT. In a report by Garcia and associates of 46 HIV+ patients, anal brush cytology was more sensitive and specific for external compared with internal lesions.⁵⁷ High-resolution anoscopy is helpful in detecting both high-grade intraepithelial and invasive lesions in HIV+⁵⁸ and HIV− patients.⁵⁹

Although a metastatic work-up is commonly negative, it includes computed tomography (CT) of the abdomen and pelvis to evaluate the primary tumor and exclude liver metastases. A chest X-ray or chest CT is required.

Most studies reveal a benefit of positron emission tomography (PET) for staging.^{60–63} In a series of 41 patients, ¹⁸flourodeoxyuridine glucose positron emission tomography (¹⁸FDG-PET) detected 91% of nonexcised primaries compared with 59% with CT alone.⁶⁴ In addition, 17% of inguinal nodes negative by CT and physical exam were positive by PET. Sveistrup et al.⁶² performed a retrospective analysis of 28 patients with SCC and found that compared with transrectal ultrasound, PET/CT upstaged disease in 14% and changed the treatment plan in 17%. Bannas et al.⁶⁵ reported that compared with either PET or CT alone, radiation field design was changed in 23% of patient who underwent a combined PET-CT.

Although feasible, the benefit of sentinel inguinal lymph node biopsy is variable and its role remains controversial.^{66–68}

Staging

A common staging system was developed in 1997 by the AJCC and the UICC. This staging system accounts for the fact that anal canal carcinoma is primarily treated by CMT and abdominoperineal resection (APR) is reserved for treatment failure. The TNM classification is clinical. The primary tumor is assessed for size and for invasion of local structures such as the vagina, urethra, or bladder. The seventh edition of the AJCC staging system is seen in [Table 2](#).⁶⁹

Table 2 AJCC TNM staging system for anal canal cancer (seventh edition)

Primary tumor (T)			
TX	Primary tumor cannot be assessed		
T ₀	No evidence of primary tumor		
T _{is}	Carcinoma <i>in situ</i>		
T ₁	Tumor ≤ 2 cm in maximum diameter		
T ₂	Tumor > 2 cm but ≤ 5 cm in maximum diameter		
T ₃	Tumor > 5 cm in maximum diameter		
T ₄	Tumor of any size, which invades an adjacent structure(s) (involvement of the sphincter muscle(s) alone is not classified as T4)		
Regional lymph nodes (N)			
N _X	Regional lymph nodes cannot be assessed		
N ₀	No regional lymph node metastasis		
N ₁	Perirectal lymph node metastasis		
N ₂	Unilateral internal iliac and/or inguinal node metastasis		
N ₃	Perirectal and inguinal node, and/or bilateral internal iliac and/or inguinal node metastasis		
Distant metastasis (M)			
M _X	Distant metastasis cannot be assessed		
M ₀	No distant metastasis		
M ₁	Distant metastasis		
Stage groupings			
Stage			
0	T _{is}	N ₀	M ₀
I	T ₁	N ₀	M ₀
II	T _{2–3}	N ₀	M ₀
IIIA	T ₄	N ₀	M ₀
	T _{1–3}	N ₁	M ₀
IIIB	T ₄	N ₁	M ₀
	T _{1–4}	N _{2–3}	M ₀
IV	T _{1–4}	N _{0–3}	M ₁

Note: Anal margin cancers are classified as skin cancers.

Note: Additional descriptors: Although they do not impact the stage grouping, additional prefixes are used, which indicate the need for additional analysis:

Suffix	Reason
m	The presence of multiple primary tumors in a single site and is recorded in parenthesis: pT(m)NM
y	When classification is performed during or following initial radiation and/or chemotherapy and is based on the amount of tumor present at the time of the examination, and not an estimate of tumor before therapy: ycTNM or ypTNM
r	Indicates recurrent tumor: rTNM
a	Indicates the stage at autopsy: aTNM

Lymphatic vessel invasion (L)

Lx	Cannot be assessed
L0	No lymphatic vessel invasion
L1	Lymphatic vessel invasion present

Venous invasion (V)

Vx	Cannot be assessed
V0	No venous Invasion
V1	Microscopic venous Invasion present
V2	Macroscopic venous invasion present

Prognostic factors

As with most gastrointestinal cancers, the most important prognostic factors in anal cancer are T and N stage. In patients treated with radiation with or without chemotherapy, the most striking difference in results is seen when comparing T1-2 primary cancers (≤5 cm) versus T3-4 primary cancers (>5 cm). The local failure rates with T3-4 primary cancers are approximately 50% following CMT. When a complete response is achieved, the local failure rate is 25%.

Peiffert et al.⁷⁰ reported an increase in local failure with T-stage (T1: 11%, T2: 24%, T3: 45%, and T4: 43%) and a corresponding decrease in 5-year survival (T1: 94%, T2: 79%, T3: 53%, and T4: 19%). A similar decrease in 5-year colostomy-free survival with T1-2 tumors versus T3-4 tumors was reported by Gerard et al.⁷¹ (T1: 83% and T2: 89% vs T3: 50% and T4: 54%).

In contrast to T stage, the impact of positive lymph nodes is less clear. Unlike rectal cancer, inguinal lymph nodes in anal cancer are considered nodal (N) metastasis rather than distant (M) metastasis and patients should be treated in a potentially curative manner. Cummings et al reported that patients with negative nodes who received CMT had a higher 5-year cause specific survival compared with those with positive nodes (81% vs 57%).⁷²

The RTOG 87-04 trial ([Table 3](#)) reported a higher colostomy rate (which is an indirect measurement of local failure) in N1 versus N0 patients (28% vs 13%).⁷³ In node negative and possibly node positive patients, the addition of mitomycin-C decreased the overall colostomy rates. The EORTC randomized

trial ([Table 3](#)) of 45 Gy ± 5-FU/mitomycin-C also reported that patients with positive nodes experienced significantly higher local failure ($p = 0.035$) and lower survival ($p = 0.038$) rates compared to those with negative nodes.⁷⁶

CFS, Colostomy free survival; *, statistically significant ($p \leq 0.05$); MMC, Mitomycin-C; CDDP, cisplatin; LN+, lymph node positive; CR, complete response; PFS, progression free survival; EBRT, external beam radiation therapy. The ACT I trial included 23% anal margin cancers.

^a Biopsy at 6 weeks.

^b Biopsy at 8 weeks.

Allal et al. reported that, by multivariate analysis, the only variable for which there was a possible impact was overall treatment time ($p = 0.09$).⁸⁰ In the EORTC randomized trial, multivariate analysis identified that positive nodes, skin ulceration, and male gender were independent negative prognostic factors for local control and survival.⁷⁶ Goldman et al.⁸¹ also found that women had a more favorable outcome than men. The multivariate analysis of 167 patients by Das et al.⁴⁰ revealed that higher T and N stage correlated with increased local failure, N stage, and basaloid histology was associated with distant failure and N stage and HIV+ predicted for lower survival. Other authors have reported that T stage, radiation dose, and percent hemoglobin were significant. In the Intergroup RTOG 98-11 trial ([Table 3](#)), multivariate analysis revealed that male gender ($p = 0.04$), clinically N+ ($p < 0.0001$), and tumor size >5 cm (0.005) were independent prognostic factors for disease free survival.⁷⁷

The histologic cell type for squamous cancers of the anal canal (squamous versus cloacogenic) has not

been found to be of major prognostic significance. In some series, cloacogenic carcinomas have been considered to have a slightly better prognosis.^{38, 82} However, in a series of 243 patients with resectable anal canal tumors, there was a worse prognosis for nonkeratinizing and basaloid carcinoma versus keratinizing lesions.⁸³ Small cell carcinomas of the anus are rare and, similar to extra pulmonary small cell cancers in other parts of the body, appear to have a worse prognosis and a high incidence of metastatic disease.^{35, 84} Location has modest prognostic importance with anal margin tumors having a better outcome than those in the anal canal.

Three studies have examined DNA content (diploid vs nondiploid). Two found no prognostic impact of this factor,^{42, 43} while in one multivariate analysis of 184 patients,⁸⁴ DNA ploidy was an independent prognostic factor for survival. In a separate study,⁴² grade was a significant prognostic factor, with low-grade tumors resulting in a 5-year survival of 75% compared with only 24% for high-grade tumors. Data from the Princess Margaret Hospital suggest that the DT-diaphorase mutation is not a strong determinant of treatment outcome in patients who fail CMT.⁸⁵

Tanum and Holm⁸⁶ reported p53 expression in 34% of patients with anal cancer. Pretreatment biopsies from 80 patients treated on the CMT arm of the Intergroup RTOG 87-04 randomized trial were examined by immunohistochemistry for p53 expression.⁸⁷ For the total group, p53 protein was overexpressed in 47% of tumors. By multivariate analysis, the 4-year local disease-free survival was significantly decreased in those patients whose tumors overexpressed p53 (64% vs 88%, $p = 0.027$). However, significant differences were not seen in overall disease free or overall survival.

In a retrospective analysis from the Princess Margaret Hospital, p53 was measured by immunohistochemistry in 49 patients who received CMT.⁸⁸ The incidence of p53 expression was 82%. By univariate analysis, p53 expression $\geq 5\%$ was a poor prognostic factor for 5-year survival (78% vs 90%) compared with $< 5\%$. It was an independent poor prognostic factor for disease-free survival ($p = 0.01$).

Treatment for primary disease

General principles

Local excision

Local excision has been used in selected patients with tumors that are < 2 cm, well differentiated, or tumors found incidentally at the time of hemorrhoidectomy. Of 188 patients with anal canal carcinoma treated at the Mayo Clinic, a subset of 19 were treated with local excision.³⁵ For the 12 patients with tumors confined to the epithelium and subepithelial connective tissues, 11 had tumors < 2 cm and 1 patient had two lesions. The survival was 100%. One of 12 patients recurred, and this patient was without evidence of disease 5 years after salvage APR. Patients with tumors penetrating into muscle who refused a colostomy had a higher recurrence rate. These patients often can be salvaged with an APR or CMT.

In summary, local excision alone is reasonable for those cancers found incidentally following hemorrhoidectomy for T1 tumors, which can be excised while maintaining sphincter continence. They require close follow-up and local recurrences can subsequently be treated with CMT.

Brachytherapy

In contrast with treatment programs in North America where patients receive CMT, patients treated in

selected European centers, most commonly France, receive external beam radiation therapy alone, with or without brachytherapy. The nonrandomized data suggest that the results of radiation therapy alone are comparable to CMT; however, the radiation-related toxicity is higher.⁸⁹ Brachytherapy techniques commonly involve afterloading ¹⁹²Ir. A frequent treatment approach is external beam for the first 45 Gy followed by an additional 15–20 Gy with a perineal boost or brachytherapy.

Ortholan and associates treated 66 patients with T1/TIS tumors with brachytherapy with or without small field external beam radiation.⁹⁰ With a median follow-up of 50 months, there were only six local failures of which four occurred outside of the radiation field.

Abdominoperineal resection

APR is reserved for salvage in patients who have failed radiation or in patients who have received prior pelvic radiation therapy. The results will be discussed later.

Chemoradiation therapy

The conventional treatment for anal canal cancer was APR until the late 1970s. This standard was challenged by Nigro et al in his initial report of three patients with SCC of the anal canal who, following preoperative treatment with 30 Gy plus concurrent 5-FU and mitomycin-C, were found to have a pathologic complete response at the time of surgery.⁹¹

Since that time, many single-arm phase II studies have indicated that initial CMT yields an 80–90% complete response rate with APR reserved for salvage. Even in patients with large (≥ 5 cm) primary cancers, although the complete response rates are lower (50–75%), the majority of patients may be spared a colostomy and have an excellent overall survival.

Chemotherapy

Results of two prospective randomized trials ([Table 3](#)) from Europe of CMT versus radiation alone (EORTC⁷⁶ and UKCCCR ACT 1⁷⁴) support the use of CMT. With 13-year follow-up of the UKCCCR ACT 1 trial, patients who received CMT versus radiation alone had a significant improvement in both local control (59% vs 34%) and colostomy free survival (30% vs 20%). However, the improvement in overall survival (33% vs 28%) did not reach statistical significance.⁷⁴ In the EORTC trial, CMT resulted in a higher complete response rate (80% vs 54%) and a significantly higher 5-year actuarial local control rate (68% vs 50%) and colostomy-free survival rate (72% vs. 40%) but no significant difference in survival 57% vs 52%).⁷⁶ Although neither trial revealed a significant overall survival advantage, given the improvement in local control and colostomy-free survival, they helped to establish CMT as the standard of care.

Results and controversies

In the North America, CMT has been well established and randomized trials have focused on defining the ideal regimen. The role of mitomycin-C as a necessary component of CMT was confirmed by the Intergroup trial RTOG 87-04.⁷³ Patients were randomized to 45 Gy plus continuous infusion 5-FU with or without mitomycin-C. At 6 weeks following the completion of treatment patients with less than a complete response had an additional 9 Gy to the primary tumor plus concurrent 5-FU/cisplatin as salvage therapy. If there was still less than a complete response 6 weeks after the completion of this salvage therapy, an APR was performed. Patients who received mitomycin-C had a higher complete response rate (92% vs 85%) and a significantly lower colostomy rate (9% vs 22%) and a corresponding significant increase in

colostomy-free survival (71% vs 59%) ([Table 3](#)). There was little difference in overall 4-year survival (75% vs 70%). Early grade 4+ toxicity was significantly increased in the mitomycin-C arm (23% vs 7%). Although overall survival was not significantly increased given the advantage in colostomy-free survival, mitomycin-C is considered a necessary component of CMT.

Mitomycin-C versus cisplatin

For patients who receive mitomycin-C-based regimens, rates of complete response are 84% (81–87%), local control is 73% (64–86%), and 5-year survival rate is 77% (66–92%). For patients with T1-2 disease, the complete response rates are >90% with ultimate local control rates following surgical salvage of 80–90%. In patients with T3-4 disease, approximately 50% of patients will require a salvage APR. If they achieve a complete response following the completion of CMT, then only 25% will require salvage APR.

Although the results of 5-FU, mitomycin-C, and concurrent 45 Gy are impressive, there is room for improvement, especially in patients with T3-4 disease. A variety of treatment approaches have been tested. These include the use of 5-FU and cisplatin (as induction therapy and/or concurrently with radiation) and intensifying the radiation dose beyond 45 Gy using external beam or brachytherapy. The combination of 5-FU plus cisplatin is an attractive regimen: (1) patients who have failed 5-FU/mitomycin-C still respond to 5-FU/cisplatin and (2) cisplatin is a radiation sensitizer.

The Intergroup randomized trial RTOG 98-11 was developed to compare conventional CMT with 5-FU/mitomycin-C versus induction 5-FU/cisplatin chemotherapy followed by CMT with 5-FU/cisplatin ([Table 3](#)).⁷⁸ A total of 682 patients with stages T2-4 squamous (86%), basaloid, or cloacogenic carcinoma of the anal canal were randomized. Patients were stratified by gender, clinical node status, and tumor size and the primary endpoint was disease-free survival. Overall, 27% had tumors >5 cm, 35% had T3-4 tumors, and 26% were clinically node positive.

Treatment details by arm were as follows. Conventional CMT arm: 5-FU (1000 mg/m² days 1–4 and 29–32) plus mitomycin (10 mg/m² days 1 and 29) and radiation (45–59 Gy). Induction arm: 5-FU (1000 mg/m² days 1–4, 29–32, 57–60, and 85–88) plus cisplatin (75 mg/m² on days 1, 29, 57, and 85) and radiation (45–59 Gy beginning day 57).

Radiation doses and techniques were the same for both arms. The whole pelvis received 30.6 Gy (1.8 Gy/fx) followed by a 14.4 Gy cone down to the true pelvis. For N0 patients, the inguinal nodes were excluded after 36 Gy. For patients with T3-4 and/or N+ disease or for those T2 lesions with residual disease after 45 Gy, a second cone down of 10–14 Gy to the gross disease or nodal disease was performed.

Palpable inguinal nodes were biopsied before treatment, and a full thickness biopsy was optional 8 weeks following completion of CMT if any palpable residual abnormality was present in the inguinal node region. Local regional failure was defined as the present of disease in the radiation field at the 8-week follow-up.

With long-term follow-up, patient who received mitomycin-C-based treatment had a significant improvement in 5-year disease-free survival (68% vs 58%, $p = 0.006$), 5-year colostomy-free survival (72% vs 65%, $p = 0.05$), and overall survival (78% vs 71%, $p = 0.026$). Although local-regional failure was lower (20% vs 26%), it did not reach statistical significance. There was no difference in Grade 3+ long-term toxicity (13% vs 11%). Consistent with other reports, a separate analysis revealed that higher T and N category had a significant negative impact on outcomes including local regional failure, distant

metastasis, colostomy-free survival, disease-free survival, and overall survival.⁹²

Similar results were reported in the UKCCR ACT II trial. This four-arm trial compared cisplatin versus mitomycin-C-based CMT (50.4 Gy) with a secondary randomization to maintenance 5-FU/cisplatin versus observation.⁷⁹ A total of 940 patients (81% anal canal, 15% anal margin, 43% T3-4, and 62% N+) were randomized. Compared with mitomycin-C-based CMT, patients who received cisplatin-based CMT had no significant differences in the CR rate at 6 months (90% vs 91%), grade 3+ toxicity (72% vs 71%), or 3-year progression-free survival with maintenance (72% vs 73%) or without maintenance chemotherapy (74% vs 73%).

In summary, mitomycin-C-based conventional CMT remains the standard of care. Despite these results, a number of investigators still advocate the use of cisplatin-based CMT based on single institution series.⁹³ New CMT approaches including the use of cytotoxic agents such as capecitabine, oxaliplatin, and cetuximab have been investigated.^{94, 95} To date, these approaches, as well as the use of 3 drug regimens,⁹⁶ have not shown benefits compared with 5-FU/Mitomycin-C-based CMT.

Dose intensification

Conventional external beam

In an attempt to improve local control and survival, two parallel pilot trials of radiation dose intensification were performed. In both trials, patients received 36 Gy to the pelvis (30.6 whole pelvis plus 5.4 Gy to the true pelvis) and following a 2-week break, received an additional 23.4 Gy to the primary tumor with a 2–3 cm margin for a total dose of 59.4 Gy. The main differences between the two trials were the type of chemotherapy. The RTOG 9208 trial⁹⁷ used 5-FU and mitomycin-C, whereas the ECOG 4292 trial(2297) used 5-FU and cisplatin.

The RTOG 9208 trial reported similar results to the standard regimen of 45 Gy plus 5-FU/mitomycin-C used in RTOG 87-04 except for a higher 2-year colostomy rate (30% vs 7%). Similarly, the ECOG 4292 trial did not reveal a benefit compared with conventional treatment.⁹⁸ Long-term follow-up of the ECOG 4292 trial revealed a 5-year PFS of 55% and a 5-year overall survival of 69%, which is consistent with other cisplatin-based trials.⁹⁹ One retrospective series revealed improved local control and survival with doses >60Gy.¹⁰⁰ The RTOG 98-11 trial allowed a boost of 10–14 Gy; however, a dose–response analysis has not been presented.⁷⁷

The four-arm UNICANCER ACCORD 03 randomized trial examined the role of both induction chemotherapy and dose escalation. A total of 307 patients received 5-Fu/cisplatin CMT + 45 Gy with or without induction 5-FU/cisplatin. This was followed by a brachytherapy or external beam boost of wither 15 or 25 Gy.¹⁰¹ Neither induction chemotherapy (77% vs 75%) nor the boost (78% vs 74%) had a significant improvement in 5-year colostomy-free survival.

Brachytherapy

Brachytherapy is an ideal method by which to deliver conformal radiation while sparing the surrounding normal structures. In most series, patients received 30–55 Gy of pelvic radiation with or without chemotherapy followed by a 15–25 Gy boost with Ir192 afterloading catheters. Most use low dose rate, but some investigators have advocated high dose rate.^{102–104}

Combining the series, the mean results include a complete response rate of 83% (73–91%), local control rates of 81% (73–89%), and a 5-year survival rate of 70% (60–84%). The primary concern is anal

necrosis and reports vary from 2% to as high as 76%¹⁰³ with an average of 5–15%. Although a retrospective analysis from Hannoun-Levi et al.¹⁰⁵ revealed an improvement in local control with a brachytherapy versus external beam boost and in another series from France revealed a toxicity benefit from a brachytherapy boost versus no boost,¹⁰⁶ the randomized UNICANCER ACCORD 03 trial discussed earlier did not confirm a local control benefit.¹⁰¹

Intensity-modulated radiation therapy

IMRT is a method to deliver pelvic radiation therapy with lower acute and long-term toxicity. By identification of the dose-limiting tissues surrounding the primary tumor and pelvic nodes and using multiple radiation fields to avoid them, IMRT allows for dose escalation with less toxicity. Salama and associates treated 53 patients with IMRT-based CMT.¹⁰⁷ Patients received 45 Gy whole pelvis followed by a boost to a median of 51.5 Gy. Acute grade 3 toxicities were 15% GI and 28% skin. Acute grade 4 toxicities included 30% leucopenia and 34% neutropenia. With a median follow-up of 15 months, freedom from failure included local (84%) and distant (93%) and survivals were colostomy free: 84% and overall: 93%. Other investigators have reported similar reductions in acute toxicity.^{108–110}

The RTOG 0529 phase II trial examined IMRT in a cooperative group setting.¹¹¹ A total of 63 patients were treated with 5-FU/mitomycin-C plus IMRT based on stage (T2N0: 50.4 Gy primary PTV and 42 Gy nodal PTV, T3-4N0-3: 54 Gy primary PTV and 45 Gy nodal PTV). Compared with RTOG 98-11, patients who received IMRT had fewer treatment breaks (49% vs 62%) and lower acute toxicity (grade 2+ heme [73 vs 85, $p = 0.032$], grade 3+ GI [21% vs 36%, $p = 0.0082$], and grade 3+ skin [23% vs 49%, $p < 0.0001$]). Another finding was the steep learning curve for IMRT planning. Although institutions were required to be IMRT certified, 81% of the plans required initial modification and 46% required a second revision. Contouring guides are now routinely available.¹¹² On the basis of both single institution and RTOG data, IMRT has become the standard of care for CMT treatment of anal cancer.

Radiation therapy alone

Radiation therapy alone with either external beam or combined with brachytherapy may yield comparable local control and survival rates to CMT. However, as it is associated with an increase in anal necrosis even in experienced hands, it should be used with caution.

Is biopsy necessary at 6 weeks?

There is considerable controversy as to the need for the first biopsy at 6 weeks following initial treatment. Data from the Princess Margaret Hospital suggest that SCCs regress slowly and continue to decrease in size for 3–12 months after the completion of CMT.⁷² The ACT II trial reported a clinical CR rate of 66% at 11 weeks following CMT, which increased to 84% at 26 weeks.

On the basis of these data, an increasing number of investigators advocate a more conservative approach and do not recommend a posttreatment biopsy. In the RTOG 87-04 trial, of the 25 patients with biopsy proven residual disease after 45 Gy and 5-FU/mitomycin-C who then received salvage therapy with 9 Gy plus 5-FU/cisplatin, 55% achieved a complete response 6 weeks later (a total of 12 weeks following the completion of the initial 45 Gy).⁷³ It is unclear if the complete response was a result of the “salvage” therapy or was due to an additional 6 weeks of tumor regression following initial therapy.

At many institutions, if there is residual disease at the 6 week posttreatment evaluation, patients do not receive the 1 week of “salvage” therapy. The patients are examined every 6 weeks and providing the tumor continues to decrease in size, no salvage therapy is performed. However, if there is progression of

disease or no response at 6 weeks following initial therapy, APR is necessary. In addition to careful physical exam, anal ultrasound may be helpful in following the tumor. In the Intergroup phase III anal canal cancer protocol RTOG 98-11, biopsy at 6 weeks following the initial 45 Gy was optional.

Treatment of the HIV-positive patient

In general, HIV+ patients have received lower doses of radiation and chemotherapy owing to a concern that standard therapy may not be tolerated.¹⁶ With a better understanding of the immunological deficiencies seen in HIV-positive patients, more recent reports have recommended therapy based on clinical and immunological parameters such as a history of prior opportunistic infections and CD4 counts.^{113–115} Patients with a CD4 count $>200 \mu\text{L}$ who receive effective doses of antiviral therapy have outcomes similar to non-HIV patients and should be treated as aggressively.¹¹⁶ CMT can result in prolonged decreased CD4 counts one series reports an increase in late deaths,¹¹⁷ whereas another series report no increased HIV-related morbidity up to 6 years following CMT.¹¹⁸ For those patients with a CD4 count $<200 \mu\text{L}$ or who have signs or symptoms of other HIV-related diseases, attenuated doses of radiation and/or chemotherapy are recommended.

Toxicity of treatment

As seen with other cancer therapies, pelvic radiation is associated with acute and long-term toxicity. The acute toxicity is due to a combination of chemotherapy and radiation therapy. These include leukopenia, thrombocytopenia, proctitis, diarrhea, cystitis, and perineal erythema. Long-term toxicity is primarily increased urgency and fecal incontinence.^{119, 120} This is due to both the impact of radiation on the sphincter and the fact that when the tumor responds it is replaced by fibrotic tissue rather than new sphincter muscle. Acute toxicity is lower with IMRT versus conventional 3D radiation^{107–111, 121}; however, long-term toxicity data are not yet available.

There are limited reports of functional outcome in the anal cancer literature. One series reports that full function was maintained in 93% of patients¹²² and a second series, which used anorectal manometry, reported complete continence in 56%.¹²³ Another reported good to excellent function in 93% of patients with a minimum of 1-year follow-up.¹²⁴

Treatment of anal margin cancer

Anal margin cancers are considered to be skin cancers. In brief, a reasonable approach is to recommend a local excision for smaller tumors ($\leq 4 \text{ cm}$), which are not in direct contact with the anal verge. If the patient would require an APR due to anatomic constraints, or if a local excision would compromise sphincter function, or if the tumor is $>4 \text{ cm}$ and/or node positive, then nonoperative treatment is an appropriate alternative. On the basis of the randomized trial from the UKCCCR (which included 23% of patients with anal margin cancers), CMT is recommended. In a report from Erlangen, 5-year colostomy-free (69%) and overall survival (54%) rates of anal margin tumors treated with CMT were lower than anal canal tumors. However, this may have been due to the higher T stages.¹²⁵

Follow-up after treatment

Patients treated for anal cancer need to be followed carefully as those with local failure are amenable to

salvage APR and can achieve long-term survival. Patients should be examined by physical exam and anoscopy every 6 weeks until a complete response is achieved then every 3 months for a total of 2 years. Follow-up examinations can then be decreased to every 6 months for the next 3 years and then yearly after 5 years. When failure of CMT occurs, 95% of the time it occurs within 3 years.¹²⁶

The usefulness of CT of the abdomen and pelvis or FDG-PET for follow-up is unclear. Christensen and colleagues reported that sensitivity for detecting recurrences was 1.0 for 3D ultrasound combined with physical exam versus 0.86 for 3D ultrasound alone versus 0.57 for 2D ultrasound.¹²⁷ Goh et al examined MRI in 35 patients 6–8 weeks after CMT and found that it was not helpful in predicting future clinical outcome.¹²⁸ As the most common site of failure is at the primary tumor site, there is no substitute for physical exam.

Management of inguinal nodes

When examining the impact of positive lymph nodes on local control and survival, it is important to identify the site of nodal disease and differentiate synchronous versus metachronous nodal disease. Unfortunately, most series do not separate N1 versus N2 versus N3 disease. However, there are data examining synchronous versus metachronous nodal disease.

There are conflicting reports as to the prognosis of patients with synchronous nodal disease who are treated with CMT. Compared with node negative patients, Allal et al report a higher rate of local failure (N1-3: 36% vs N0:19%),¹²⁹ and the Intergroup RTOG 87-04 trial reported a higher colostomy rate (N1: 28% vs N0: 13%).⁷⁰ Although Cummings and associates reported a local failure rate of only 13% in node positive patients, 5-year cause-specific survival was lower (N1-3: 57% vs N0: 81%).⁷² By multivariate analysis, the EORTC randomized trial reported that positive nodes were an independent negative prognostic factor for local failure and survival.⁷⁶

In contrast, in the CMT plus brachytherapy series from Gerard et al.,⁷¹ patients with N1 versus N0 disease had similar 5-year disease specific and overall survival rates. Similarly, complete response rates in the primary tumor are not affected by the presence of nodal disease. Doci and associates report similar rates in patients receiving cisplatin-based therapy (N1-3: 92% vs N0: 100%)¹³⁰ and in a separate series of patients receiving mitomycin-C-based therapy, all eight patients with N1-3 disease achieved a complete response.¹³¹ Overall, external beam radiation alone^{1, 132–134} can control positive nodes in 65% of patients, and CMT^{1, 73, 75, 76} can achieve nodal control in approximately 90%.

Patients with T2N0 disease should receive prophylactic radiation. In a retrospective review of patients with stages T1N0 and T2 N0 disease in whom the inguinal nodes were excluded from the radiation field, the inguinal failure rate was 2% and 13%, respectively.¹³⁵

The current treatment recommendations for patients with suspicious positive inguinal nodes include needle aspiration or at the most limited surgical sampling for confirmation of cancer followed by CMT with a boost of 45–50.4 Gy to the involved groin. Although inguinal node dissection should not be performed as part of the initial therapy, it may be done for isolated inguinal recurrence in carefully selected patients as the morbidity from such an approach is significant.

The development of unilateral metachronous inguinal lymph nodes is not associated with such an ominous prognosis. After therapeutic groin dissection, the 5- to 7-year survival rates exceed 50% in two series,⁴⁸ but there were no long-term survivors in a small series reported from the Mayo Clinic.⁶ Current strategies in patients with metachronous isolated inguinal node metastases after CMT include a formal groin

dissection followed by chemotherapy. The use of radiation in this setting depends on prior dose and fields.

Residual or recurrent cancer

1. Anal margin: Locally recurrent anal margin cancers are more successfully controlled by local excision than are recurrences of anal canal cancer.^{136, 137} A series of recurrent tumors included 16 of 48 patients who, following a local excision, recurred locally,¹¹ in the inguinal nodes,⁴ or both.^{1, 138} There were no visceral failures. The median time to recurrence was 26 months. Ten of the patients with local recurrences underwent repeat local excision and only one required an APR. Nine of these patients survived more than 5 years. All four patients with inguinal node recurrences had inguinal lymphadenectomies, and two were long-term survivors. Although there is little reported experience with radiation therapy or CMT for patients with local recurrence after a local excision, it is a reasonable option for those who would otherwise require an APR, dependent on prior radiation dose, if any.
2. Anal canal. The standard treatment is APR.

Treatment of metastatic disease

Given the low incidence of anal cancer and the high success of CMT, the number of patients who develop metastatic disease is small. Single agent trials of doxorubicin (adriamycin) and cisplatin resulting in limited responses have been reported by several investigators.^{139, 140} Combination chemotherapy with cisplatin and 5-FU has a response rate of approximately 50% using both systemic and regional (hepatic-arterial) routes.^{141–143} Retreatment with 5-FU/mitomycin-C is an alternative. There is limited experience with newer agents such as irinotecan and cetuximab.¹⁴⁴

A small series of six patients with metastatic disease limited to the para-aortic nodes recommends CMT with an extended radiation field to include the nodes.¹⁴⁵

Other histologies

Melanoma

Anorectal melanomas are relatively rare, accounting for less than 1% of all anal canal tumors. The presenting stage, defined by the tumor thickness and nodal status, is the primary determinant of survival. Distant metastasis is common.^{146–151}

Despite a better local control rate with APR, most series have not shown a clear survival advantage for patients who have had an APR compared with patients having wide local excision.^{146, 147, 152–154}

A retrospective analysis of the SEER database of 126 patients treated from 1973 to 2001 with a variety of therapies was reported by Podnos et al.¹⁵⁵ The 5-year survival based on disease status at presentation included local (32%), local/regional (17%), and distant (0%).

The inability to show a survival benefit for APR compared with wide local excision can be attributed to the small numbers of patients involved in the studies, selection bias, and the lack of randomized data. Any relative advantage of adjuvant immunotherapies, chemotherapy, and radiation therapy is similarly

obscured and difficult to interpret. A histologic margin of at least 3 mm should be obtained if local excision is to be used. In view of possible higher local control rates, APR is still a reasonable option.^{147–150, 156, 157}

Adenocarcinoma

Primary adenocarcinoma of the anal canal arising from the anal glands is rare. Most adenocarcinomas in the canal represent rectal cancer with distal spread. In general, they should be treated like adenocarcinomas of the rectum. If T3 and or N+, then preoperative CMT followed by surgery and 4 months of postoperative adjuvant therapy is appropriate. However, the radiation fields should include the inguinal nodes. In a series of 13 patients, Beal and associates recommended the combination of CMT and APR and reported a 2-year actuarial survival of 62%.¹⁵⁸ Adenosquamous cancers of the anus are also rare and have a poor prognosis.¹⁵⁹ Given the squamous component, it is reasonable to treat these patients with combined 5-FU/mitomycin-C and concurrent radiation therapy with APR for salvage.

Sarcoma

Few cases of leiomyosarcoma of the anus have been reported. The optimal treatment for this neoplasm is not known. The standard surgical approach is APR. Using a technique well established for management for sarcomas of the extremities, one approach is local excision and Iridium-192 brachytherapy in an attempt to preserve the anal sphincter.^{160–162} This technique may be an alternative to APR in selected patients.

Others

Bowen's disease, Paget's disease, and Kaposi's sarcoma are commonly treated with surgery. In settings where this could compromise sphincter function there are rare reports of treatment with CMT.

Chapter 96

Renal cell carcinoma

Earle F. Burgess, MD ■ Stephen B. Riggs, MD ■ Brian I. Rini, MD, FACP ■ Derek Raghavan, MD, PhD, FACP, FRACP, FASCO

Overview

Renal cell carcinoma occurs in 64,000 new patients each year in the United States and results in about 14,000 deaths. For localized disease, cure is achieved by nephrectomy. Meticulous surgical staging is crucial. With improved imaging techniques, active surveillance has become an option for small, asymptomatic renal masses. Modifications in surgical technique, including laparoscopic and robotic approaches, have contributed to reduced morbidity. In more advanced disease, with locoregional or metastatic spread, immune response is a governor of outcome and survival, and immune modulation via interleukin-2 or PDL-1 inhibition results in sustained responses. Cytotoxic chemotherapy has negligible activity, but targeted therapies, such as tyrosine kinase and mammalian target of rapamycin inhibitors, often cause dramatic regressions. Uncommon cancers of the kidney represent about 10% of incident cases, and a general approach to their management is reviewed in this chapter.

Introduction

The incidence of renal cell carcinoma (RCC) is estimated at approximately 64,000 cases with 14,000 deaths in the United States annually.¹ The reported incidence of RCC has increased over time, largely but not entirely owing to an increase in the number of asymptomatic tumors incidentally detected with abdominal imaging obtained for other indications.^{2,3}

Many advances in RCC have been made in recent years. Novel approaches to treating localized renal masses that emphasize less invasive and nephron-sparing approaches have been developed. Further, the biology underlying RCC has been elucidated, and agents targeting relevant biologic pathways have demonstrated robust clinical effect in the metastatic setting. This chapter details these advances and summarizes the epidemiology, pathology, staging, and treatment of RCC.

Epidemiology

RCC commonly presents in the sixth to seventh decade of life and develops in men twice as frequently as in women. Tobacco exposure is an established risk factor for RCC with a relative risk of approximately two- to threefold.⁴ Obesity is also a risk factor although specific dietary associations are not well defined.⁵ Hypertension, but not likely antihypertensive medicine, is associated with RCC development.⁶ Acquired polycystic disease also predisposes to the development of RCC.⁷ A small percentage of patients (2–3%) will have one of several autosomal dominant syndromes that predispose patients to various RCC histologic subtypes that are detailed subsequently. One Australian study suggested that analgesic abuse is associated with RCC, although more commonly this association is found for cancer of the renal pelvis.

Clinical presentation

In contemporary series, more than 50% of RCC patients present without initial symptoms as a result of abdominal CT scans or ultrasounds performed for an unrelated indication.^{8–11} This has changed over the years as evidenced by the fact that in the 1970s, 10% of RCCs were discovered incidentally, compared to 60% in 1998.^{3, 12}

The most common local symptoms of RCC include hematuria, flank pain and a palpable mass, although this classic triad is currently observed infrequently. Other local presentations include left scrotal varicoceles that may be observed in up to 11% of men because of obstruction of the gonadal vein by tumor in the left renal vein to which it directly empties. Venous involvement can also cause lower extremity edema, ascites, hepatic dysfunction, and pulmonary emboli. Pain or dysfunction of specific organs may be the presenting feature of the patient with metastatic disease.

Systemic symptoms of paraneoplastic syndromes may also be an initial manifestation of RCC. Hypercalcemia is the most common paraneoplastic syndrome in RCC manifesting in 13–20% of patients. This is mediated by tumor production of parathyroid hormone (PTH) or PTH-related peptide. Polycythemia occurs in 1–8% of cases and is postulated to be mediated by elevated erythropoietin levels; anemia is far more common and can be quite severe. Iron studies are suggestive of anemia of chronic disease. Stauffer's syndrome is hepatic dysfunction in the setting of RCC without liver metastases. Corticosteroid-insensitive polymyalgia rheumatica can occasionally occur and often resolves following nephrectomy. Endocrine abnormalities including elevated HCG and ACTH have also been reported. Other systemic manifestations including constitutional symptoms such as fever, weight loss, and fatigue are common.

Pathology

The World Health Organization classification of renal neoplasms published in 2004 categorized malignant parenchymal renal cell neoplasms into three main and several other rare subtypes.¹³ The most common RCC histology is the conventional clear cell subtype accounting for 75–80% of all RCCs. The remaining subtypes including papillary (10–15%), chromophobe (5–10%), medullary (<1%), and collecting duct carcinoma (CDC) (<1%). Recently, several new entities, including RCC associated with Xp11.2/TFE3 translocation and mucinous tubular and spindle cell carcinoma, have also been described, in addition to less common variants beyond the scope of this review.

Conventional clear cell renal cell carcinoma (ccRCC) arises from the proximal convoluted tubule and has clear cytoplasm on routine microscopic sections. The most common genetic alteration in ccRCC is a highly specific abnormality involving silencing of chromosome 3p [the von Hippel Lindau (*VHL*) gene] that occurs in approximately 35–50% of sporadic cases.¹³ Noninherited ccRCC tends to present with larger, unilateral tumors. The inherited *VHL* syndrome (1/36,000 births) is a highly penetrant autosomal dominant disorder in which patients inherit a *VHL* gene defect on chromosome 3p25 and develop ccRCC and/or a constellation of cysts and tumors in the central nervous system and abdominal viscera.¹⁴ CNS lesions include retinal hemangioblastomas, endolymphatic sac tumors, and craniospinal hemangioblastomas. The visceral lesions in these patients include ccRCCs, pheochromocytomas, pancreatic neuroendocrine tumors, epididymal cystadenomas, and broad ligament cystadenomas. In addition to *VHL* genetic aberrations, comprehensive genomic analysis of more than 400 ccRCC specimens by The Cancer Genome Atlas research network revealed that mutations in components of the PI3K/Akt pathway are common, in addition to chromatin remodeling genes, implicating epigenetic

dysregulation in ccRCC tumorigenesis.¹⁵ Well-defined intratumoral heterogeneity,^{16, 17} suggests that molecular characterization may require a multiplicitous effort, especially when performed for clinical purposes.

Papillary RCCs arise from the distal convoluted tubule and are composed of tubulopapillary structures with hemosiderin deposition and foamy histiocytes within the fibrovascular cores. They are subdivided into type 1 and type 2 papillary RCCs based on the morphology of the tumor cells lining the papillary structures.¹³ Papillary carcinomas do not have *VHL* gene inactivation but have trisomy of chromosomes 7, 17 and loss of Y chromosome as the most frequent genetic alterations. Papillary tumors tend to have a multifocal nature and may present with bilateral kidney involvement. Hereditary papillary renal carcinoma (HRPC) is characterized by c-Met proto-oncogene activation (chromosome 7q31-34) and the development of type 1 papillary RCC. Hereditary leiomyomatosis renal cell carcinoma (HLRCC) involves abnormalities of the fumarate hydratase gene (chromosome 1q42-43) and development of type 2 papillary RCC, leiomyomas of skin and uterine leiomyomas and leiomyosarcomas.¹⁸

Chromophobe RCC arises from the intercalated cells of the kidney and is characterized by large solid sheets of cells with pale or eosinophilic cytoplasm, a thick and distinct cell membrane, and pleomorphic nuclei with an irregular nuclear membrane and perinuclear clearing.¹³ The most frequent genetic alterations are a combination of loss of heterozygosity in chromosomes 1, 2, 6, 10, 13, 17, 21 and hypodiploidy. Patients with chromophobe histology tend to present with early stage disease with <5% of patients presenting with metastases.^{19, 20} Patients with Birt–Hogg–Dube syndrome have a high proportion of RCCs with chromophobe-predominant histology. They possess loss of function mutations in the BHD gene on chromosome 17p, have prominent cutaneous manifestations (fibrofolliculomas), and are predisposed to pneumothoraces from rupture of pulmonary cysts.²¹ More recently, comprehensive whole-genome analysis has identified prevalent genomic rearrangements within the promoter region of the *TERT* gene, the catalytic subunit of telomerase, leading to increased *TERT* expression.²² Thus, enhanced telomerase expression via structural promoter rearrangements may be an early pathogenic event in the development of chromophobe RCC.

Prognostic features

Grade

In patients with localized RCC, nuclear Fuhrman grade and TNM stage are consistently the most important prognostic factors.²³ The Fuhrman grading system scores the nuclear grade of RCCs on a scale of 1 (least aggressive) to 4 (most aggressive) based on nuclear and nucleolar size, shape, and content.²⁴ Higher nuclear grade is associated with a worse 5-year overall survival. Five-year cancer-specific survival rates for localized grade 1, grade 2, and grade 3 or 4 tumors after nephrectomy are 89%, 65%, and 46%, respectively.²³ Fuhrman grading is not useful for chromophobe RCC.²⁴

Staging

In a patient with a suspected RCC, staging investigations including a CT of the chest and CT of the abdomen and pelvis are required to define the extent of the disease. The most common sites of metastases include the lungs, abdominal and mediastinal lymph nodes, liver, and bone. Unless a patient has symptoms suggestive of bone or brain metastases, initial bone scans and brain imaging tend to produce relatively low yield.

The 2010 American Joint Committee on Cancer (AJCC) and TNM staging system has been reported in detail previously²⁵ and reflects the extent of tumor (T), lymph node involvement (N), and presence of metastases (M).

Treatment of localized RCC

A number of treatment options exist for small (<4 cm) renal masses. These include surgical excision, radiofrequency ablation (RFA) or cryotherapy (collectively called thermal ablation), or active surveillance with delayed intervention in very select populations. Surgical resection remains the cornerstone of the treatment of localized stage I and II RCC and usually obviates the need for a renal biopsy. Partial nephrectomy is preferred whenever feasible, especially in a patient with limited renal function, bilateral tumors and/or a patient with a solitary kidney. Although nephron sparing is currently recommended as treatment for small renal masses, its absolute benefit compared to radical nephrectomy (in the elective setting) has come into question.²⁶ Laparoscopic partial nephrectomy is less invasive and appears to have similar outcomes to that of an open approach. Often the laparoscopic approach is performed with robotic assistance helping to overcome some of the inherent technical demands.²⁷

The preferred treatment of large tumors (>7 cm) and locally advanced tumors is a radical nephrectomy, either with a laparoscopic or open procedure. This involves ligation of the renal vasculature, excision of the kidney, Gerota's fascia, and the ipsilateral adrenal gland if it appears involved by tumor on preoperative imaging. Laparoscopic radical nephrectomy is currently widely performed and has decreased postoperative pain to allow for shorter hospitalization and quicker recovery.

Thermal ablative options such as cryoablation and RFA are additional options for selected patients, often being performed in a percutaneous manner. Recent retrospective data, with limited follow-up from a cohort of more than 1400 patients, suggests that the use of percutaneous ablative therapies may result in similar local recurrence-free survival as compared to partial nephrectomy.²⁸ Unfortunately, randomized controlled trials comparing these noninvasive approaches to traditional surgical treatment are not available, and partial nephrectomy has the perceived advantage of complete pathologic evaluation as well as reduced follow-up with contrasted studies. In general, percutaneous ablation is favored in patients with smaller tumors (<4 cm) desiring an option other than surgery or who are not candidates for invasive operations.

Active surveillance is an emerging approach to small renal masses understanding that 50–60% will be indolent based on size and grade. Mean growth rate is around 0.3 cm per year with a 1–3% metastatic rate.^{29–32} However, it should be emphasized that data from published series has been limited with regards to follow-up, so firm conclusions are lacking.³³ Importantly, utilization of percutaneous renal biopsies is evolving. Historically fraught with inconclusive results, more contemporary studies suggest nondiagnostic biopsies to occur less than 10% of the time.³⁴ Unfortunately, grade accuracy remains intermediate (50–70%).^{34–37}

Stage III disease involves the, perinephric tissues, lymph nodes and/or invasion of the renal vein or inferior vena cava. The procedure of choice for these individuals is an open radical nephrectomy for curative intent. Lymph node dissection should be carried out in patients with evidence of enlarged lymph nodes. In patients with no suspected nodal metastases, a routine extended lymph node dissection is controversial.³⁸

Although preoperative treatment with targeted molecular therapies may be safe,³⁹ a role for these agents in the nonmetastatic setting has not been established. Retrospective case series suggest that use of

currently available targeted agents before nephrectomy does not result in frequent down-sizing of primary tumors^{40, 41} and exposes patients to the risk of progression⁴² and increased complexity of ensuing surgical management. In patients with inferior vena cava tumor thrombi, neoadjuvant-targeted therapies have also failed to show significant cytoreductive effect on tumor thrombus burden and should not be routinely utilized to influence surgical decision making.^{43, 44}

Therapeutic intervention for local and/or oligometastatic recurrences may improve patient outcomes, underscoring the importance of detecting recurrences early. An ideal surveillance strategy following definitive management of primary renal tumors should balance the risk of recurrence against the desire to avoid unnecessary diagnostic testing. Individual risk-based surveillance guidelines have been proposed,^{45, 46} although an optimal surveillance strategy remains to be defined.

Metastatic disease

Prognostic factors

The most widely used prognostic factors for metastatic renal cell carcinoma (mRCC) were developed in the era when patients with mRCC were treated primarily with immunotherapy. The Memorial Sloan Kettering Cancer Center (MSKCC) criteria were developed via multivariable analysis in patients being treated for mRCC.⁴⁷ A clinical scoring system was developed and classifies patients into favorable, intermediate, and poor prognosis categories based on the number of adverse risk features present. Significant treatment heterogeneity existed in patients from the original cohort is used to establish these criteria, so updated analysis of additional patients treated with IFN only defined the median overall survival for each prognostic category as 30, 14, and 5 months, respectively ([Table 1](#)).⁴⁸

Table 1 Prognostic criteria for metastatic RCC

Memorial Sloan Kettering Cancer Center (MSKCC) criteria. Data from Ref. ⁴⁸
<i>Adverse prognostic factors</i> <ul style="list-style-type: none">• Karnofsky performance status < 80%• Diagnosis to treatment interval < 1 year• Hemoglobin < lower limit of normal• Serum corrected calcium > 10 g/dL• LDH > 1.5x upper limit of normal
<i>Risk categories and clinical outcome</i> <ul style="list-style-type: none">• 0 prognostic factors (good risk): PFS: 8.3 m OS: 30 m• 1–2 prognostic factors (intermediate risk): PFS: 5.1 m OS: 14 m• 3–5 prognostic factors (poor risk): PFS: 2.5 m OS: 5 m
International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) criteria. Data from Ref. ⁴⁹
<i>Adverse prognostic factors</i> <ul style="list-style-type: none">• Karnofsky performance status < 80%• Diagnosis to treatment interval <1 year• Hemoglobin < lower limit of normal• Serum corrected calcium > upper limit of normal• Neutrophil count > upper limit of normal• Platelet count > upper limit of normal
<i>Risk categories and clinical outcome</i> <ul style="list-style-type: none">• 0 prognostic factors (good risk): OS: 43 m• 1–2 prognostic factors (intermediate risk): OS: 23 m• 3–6 prognostic factors (poor risk): OS: 8 m

Abbreviations: OS, overall survival; PFS, progression-free survival.

New prognostic factors have been developed for contemporary patients being treated with molecular-targeted therapy described below. Retrospective, multicenter analysis of 645 patients with mRCC treated with sunitinib, sorafenib, or bevacizumab led to the development of a revised prognostic model consisting of three risk groups ([Table 1](#)).⁵⁰ External validation by an international mRCC database consortium (IMDC) supports the routine use of this prognostic model with current standard therapies and illustrates survival improvements that have resulted from the evolution of treatment paradigms, as the observed median overall survival for patients in the favorable, intermediate, and poor risk groups, respectively, was 43, 23, and 8 months, respectively.⁴⁹ IMDC risk stratification also has prognostic value in patients

with metastatic non-ccRCC⁵¹ and may facilitate decision making regarding cytoreductive nephrectomy⁵² as discussed in the following section.

Surgery in patients with metastatic disease

Radical nephrectomy is also indicated in many patients with mRCC. Results from two phase III studies demonstrated that cytoreductive nephrectomy before IFN improved overall survival. In a combined analysis of these trials, median survival was 7.8 months in patients treated with interferon-alpha alone versus 13.6 months for patients who underwent cytoreductive nephrectomy initially.^{53–55} A greater survival advantage was observed in patients with better performance status. The cytoreductive paradigm remains predominant even though supporting data are primarily empiric and have not been proven in combination with the newer targeted agents. A phase III trial assessing the benefit of nephrectomy before sunitinib in patients with clear cell mRCC is ongoing, although retrospective analysis of the IMDC prognostic criteria in a cohort of 1658 patients has suggested that cytoreductive nephrectomy may benefit patients with at least a 12-month life expectancy and less than four IMDC risk factors.⁵² The role for cytoreductive nephrectomy in patients with nonclear cell mRCC remains unproven.⁵⁶

While cytoreductive nephrectomy appears to benefit many patients with clear cell mRCC, it is not curative and should not be performed indiscriminately. Patients who are most likely to benefit from cytoreduction include those with (1) substantial tumor burden (e.g., >75%) in the involved kidney, (2) good performance status, and (3) no central nervous system or liver metastases (with rare exceptions).⁵⁷ Other considerations pertain to surgical resectability, particularly, the potential for morbidity if there is proximity to vital structures, encasement of the renal hilum or other complicating factors.

Patients with mRCC with solitary metastases may be considered for metastasectomy, although they represent only 2–3% of cases. Favorable prognostic factors include a long interval between initial diagnosis and development of metastases, solitary metastatic site and ability to achieve a complete resection of known metastatic disease.⁵⁸ Patients with favorable features can anticipate up to a 40% 5-year survival with metastasectomy, and thus surgical resection of metastases should be considered in highly selected RCC patients.

Systemic therapy for metastatic disease

Immunotherapy

As early trials employing chemotherapy did not produce any significant benefit,^{59, 60} immunotherapy had long been the standard of care for the treatment of mRCC in an attempt to harness the innate immune response of RCC tumors based on occasional spontaneous regression of metastatic lesions.⁶¹ IFN and high-dose IL-2 have produced response rates of 10–20% with modest prolongation of overall survival.^{62, 63} Of note, there were significant side effects including capillary leak syndrome, which necessitated intensive monitoring and occasional vasopressor support. Phase III trials of high-dose IL-2 failed to demonstrate significant benefits for the cohort versus alternative, low-dose cytokine regimens.^{64, 65} Thus, cytokine-based immunotherapy remains relevant in mRCC owing to the small percentage of patients who may dramatically benefit with a complete response, although attempts to predict the responding group have been uniformly unsuccessful.

Combination of the autologous tumor cell vaccine AGS-003 with sunitinib resulted in possibly prolonged survival relative to historical control in patients with unfavorable risk factors in a small phase II trial,⁶⁶ serving as the basis for the ongoing ADAPT phase III randomized trial. Cytotoxic T cell activation

through modulation of the inhibitory PD-1/PD-L1 axis has also demonstrated striking antitumor activity.^{67–69} Results from ongoing phase III trials of these new immunomodulatory agents are eagerly anticipated.

Targeted therapy

New treatment approaches have resulted from a better understanding of the biology and genetics of RCC. As noted previously, most ccRCCs demonstrate an abnormality of the *VHL* gene ([Figure 1](#)). When inactivated, the *VHL* gene product cannot regulate the degradation of the transcription factor hypoxia inducible factor (HIF) alpha, thus resulting in the transcription of numerous hypoxia-regulated genes including vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF). These growth factors promote angiogenesis and tumor growth through binding with their respective receptor tyrosine kinases (RTKs).¹⁴ Activation of RTKs can induce signaling through the PI3K/Akt pathway and further downstream through the mammalian target of rapamycin (mTOR) pathway promoting cell proliferation and survival through regulation of mRNA translation. These intricate pathways have been identified as key therapeutic targets for the treatment of mRCC ([Table 2](#)).

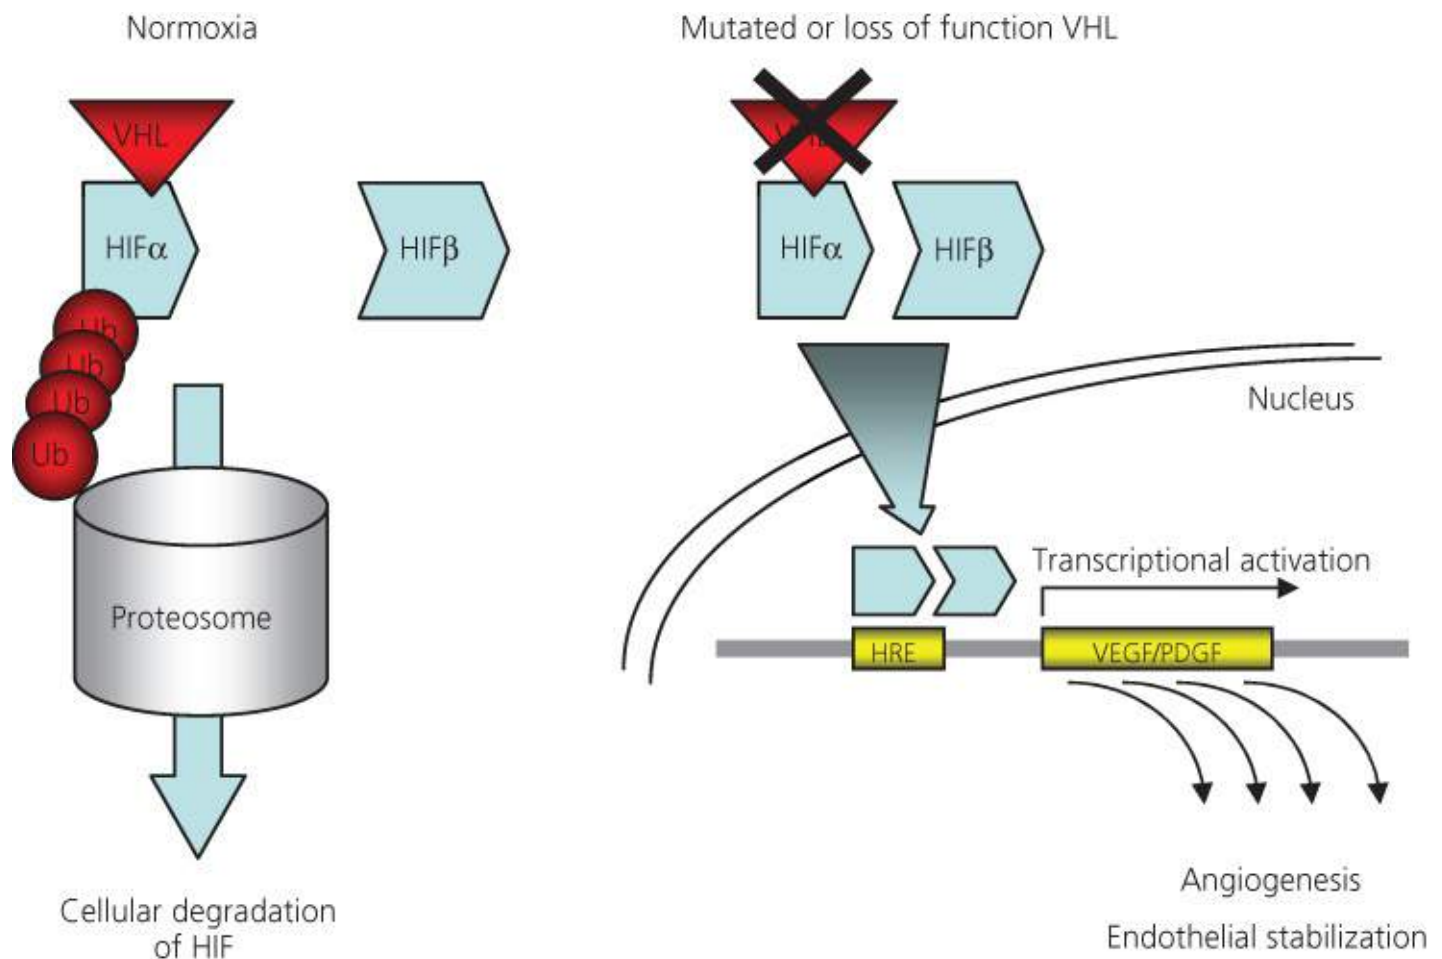

Figure 1 Normal function of VHL in the normoxic state compared to the aberrant VHL state/hypoxia. Under normal conditions, VHL binds to HIFα and polyubiquitinates it to mark it for destruction in the cellular proteasome. In conditions of hypoxia or when VHL function is lost, HIFα binds HIFβ and then translocates into the nucleus to activate HIF responsive elements (HRE). This results in transcriptional activation of genes important in angiogenesis and endothelial stabilization such as VEGF and PDGF.

Table 2 Selected clinical trials of targeted agents in metastatic renal cell carcinoma

Agent	Mechanism	Efficacy						
				Population and trial arms	RR	PFS (months)	OS (months)	
Sunitinib ^{70, 71}	Tyrosine kinase inhibitor of VEGF and related receptors	First line <i>sunitinib</i> versus <i>IFN</i>	47%	11	26.4			
						12% <i>p</i> < 0.001	5 <i>p</i> < 0.001	21.8 <i>p</i> = 0.051
Pazopanib ^{72, 73}	Tyrosine kinase inhibitor of VEGF and related receptors	First line <i>pazopanib</i> versus <i>sunitinib</i>	31%	8.4	28.3			
						25% <i>p</i> = 0.03	9.5	29.1 NS
Sorafenib ^{74, 75}	Tyrosine kinase inhibitor of VEGF and related receptors	Treatment refractory, second line <i>sorafenib</i> versus <i>placebo</i>	10%	5.5	17.8			
						2% <i>p</i> < 0.001	2.8 <i>p</i> < 0.01	15.2 <i>p</i> = 0.146
Axitinib ⁷⁶	Tyrosine kinase inhibitor of VEGF and related receptors	Treatment refractory, second line <i>axitinib</i> versus <i>sorafenib</i>	19%	8.3	20.1			
						11% <i>p</i> = 0.0007	5.7 <i>p</i> < 0.0001	19.2 NS
Temsirolimus ⁷⁷	mTOR inhibitor	Poor risk, first line <i>temsirolimus</i> versus <i>IFN</i>	8.6%	N/A	10.9			
						4.8% NS	N/A	7.3 <i>p</i> < 0.008
Everolimus ⁷⁸	mTOR inhibitor	Treatment refractory, second line <i>everolimus</i> versus <i>placebo</i>	1.8%	4.9	14.8			
						0%	1.9 <i>p</i> < 0.001	14.4 NS
Bevacizumab ^{79 80^a}	VEGF ligand-binding antibody	First line <i>bevacizumab</i> + <i>IFN</i> vs <i>placebo</i> + <i>IFN</i>	31%, 25%	10.2, 8.5	23.3, 18.3			
						13%, 13% <i>p</i> < 0.0001	5.4, 5.2 <i>p</i> < 0.0001	21.3, 17.4 NS

IFN, interferon; N/A, not available or data not yet mature; NS, not statistically significant; *p* values for PFS are based on hazard ratios.

^a The results of two phase III bevacizumab trials are shown.

VEGF ligand-directed therapy

Bevacizumab is a recombinant monoclonal antibody that binds and neutralizes circulating VEGF. The activity of this agent in the first-line setting for advanced RCC has been established by two randomized phase III clinical trials. The AVOREN study randomized untreated patients with clear cell mRCC and prior nephrectomy to receive the combination of IFN (three times per week at a dose of 9 MIU for up to 1 year) plus bevacizumab (10 mg/kg IV every 2 weeks) or placebo until disease progression.⁸¹ The addition of bevacizumab to IFN significantly increased PFS (10.2 vs 5.4 mo) (HR = 0.63; $p = 0.0001$) and objective tumor response rate (31% vs 13%; $p = 0.0001$). A trend toward improved OS was observed with the addition of bevacizumab.⁷⁹ A CALGB phase III trial of similar design confirmed a PFS benefit (8.5 vs 5.2 months $p < 0.0001$) and ORR benefit (25% vs 13%, $p < 0.0001$) with the addition of bevacizumab to IFN.⁸² OS also trended toward improvement in the bevacizumab arm,⁸⁰ although high rates of second-line therapy confounded survival analysis in both trials. Common toxicities included hypertension and proteinuria with rare but serious toxicity including bowel perforation, arterial ischemic events, and bleeding. It is unknown whether bevacizumab must be given in combination with interferon owing to the absence of a bevacizumab monotherapy arm in the phase III trials. Combined use with mTOR inhibition does not improve efficacy,⁸³ whereas concurrent use with additional VEGF targeted agents is associated with unacceptable risk of thrombotic microangiopathy.⁸⁴ Use in patients after prior treatment with other targeted agents remains unproven.

VEGF receptor tyrosine kinase inhibitors

RTKs play an integral role in the signaling cascade of VEGF and PDGF.⁸⁵ RTKs have an extracellular domain that binds their respective ligand, which activates oncogenic intracellular signaling cascades through protein phosphorylation events regulated by a cytoplasmic kinase domain. Targeting RTKs with small molecule inhibitors has proven to be an effective therapeutic strategy in mRCC and has led to regulatory approval of multiple agents in this class as detailed below.

Sunitinib is an oral multikinase inhibitor that blocks VEGFR-1, 2 and 3, PDGFR-B, and related RTKs.⁸⁶ A pivotal phase III randomized trial⁷⁰ in untreated mRCC patients compared first-line sunitinib (50 mg daily four out of 6 weeks) with interferon and demonstrated a significant advantage in objective response rate (ORR) (47% vs 12%; $p < 0.001$), PFS (11 vs 5 months, HR = 0.54; $p < 0.001$), and OS (26.4 vs 21.8 months, HR = 0.82; $p = 0.051$).⁷¹ Of note, most patients enrolled (94%) had favorable or intermediate risk MSKCC prognostic criteria. Common toxicities included fatigue, hand-foot syndrome, diarrhea, mucositis, and hypertension. This agent has become a standard of care for the first-line treatment of mRCC on the basis of these results. Efforts to improve the toxicity profile by altering dose and schedule of administration have been unsuccessful or remain investigational.^{87, 88}

Pazopanib is a second-generation oral TKI that inhibits VEGFR-1, -2 and -3, PDGFR-A and -B, and c-kit.⁸⁹ A randomized phase III trial comparing pazopanib to placebo in patients with mRCC previously untreated or following cytokine failure demonstrated that pazopanib improved PFS (9.2 vs 4.2 months, HR = 0.46; $p < 0.0001$) and ORR (30% vs 3%, $p < 0.001$).⁹⁰ Common toxicities included hypertension, diarrhea, nausea, anorexia, and hair depigmentation. Hepatic toxicity is more frequently observed with this agent than others in the class and may be associated with UGT1A1 gene polymorphisms.⁹¹ A large, noninferiority randomized phase III trial compared outcomes and tolerability of pazopanib and sunitinib in previously untreated patients with mRCC with a clear cell component and found that pazopanib resulted in a similar PFS (8.4 vs 9.5 months, HR = 1.05; 95% CI 0.90–1.22), higher ORR (31% vs 25%, $p = 0.03$), and similar OS (28.3 vs 29.1 months, $p = 0.24$).^{72, 73} Similar drug discontinuation rates were observed, although patients receiving pazopanib reported better quality of life scores including fatigue

and hand-foot syndrome. Improved tolerability of pazopanib compared to sunitinib was also demonstrated in the PISCES trial in which patients were randomized in a double-blind manner to receive treatment with one agent for 10 weeks followed by cross-over.⁹²

Sorafenib inhibits a broad repertoire of kinases including BRAF, CRAF, VEGFR-2, -3, PDGFB, Flt-3, p38, and c-kit.⁹³ In the treatment naïve setting, sorafenib has not demonstrated superior antitumor activity compared to IFN and therefore does not have a proven role in this setting.⁹⁴ However, in previously treated patients, sorafenib is superior to placebo. The treatment approaches in renal cancer global evaluation trial (TARGET) enrolled 903 patients with previously treated metastatic ccRCC and randomized patients to oral sorafenib 400 mg twice daily versus placebo.^{74, 75} All patients enrolled had favorable or intermediate risk MSKCC prognostic criteria and over 80% had been previously treated with cytokine therapy. PFS was prolonged in the sorafenib group (5.5 vs 2.8 months, $p < 0.01$). ORR was minimal (10% investigator assessed), and OS was similar to the placebo group (17.8 vs 15.2 months, $p = 0.146$), although an OS benefit could have been obscured from placebo patients being allowed to cross-over and receive sorafenib at progression.

Subsequent development of axitinib, a second-generation inhibitor of VEGFR-1, -2 and -3 of greater potency than earlier agents,⁹⁵ resulted in this newer agent largely supplanting sorafenib as a standard second-line choice. In the AXIS trial, over 700 patients with clear cell mRCC previously treated with one line of systemic therapy [cytokines (35%), sunitinib (54%), bevacizumab (8%), or temsirolimus (3%)] were randomized to receive axitinib (5 mg twice daily) or sorafenib (400 mg twice daily).⁹⁶ Notably, one-third of enrolled patients had MSKCC poor risk criteria. Median PFS favored the axitinib group (8.3 vs 5.7 months, $p < 0.0001$), although OS (20.1 vs 19.2 months, $p = 0.3744$) and patient reported outcomes were similar between arms.⁷⁶ On the basis of these results, many consider axitinib preferable to sorafenib in patients who have failed one prior line of therapy. Axitinib has not been proven superior to sorafenib in the first-line setting.⁹⁷ Results from a first-line dose escalation study suggest a possible role for axitinib dose titration, especially in normotensive patients, although the optimal approach remains investigational.⁹⁸

mTOR inhibition

The “mTOR” kinase is regulated by Akt and PI3 Kinase, both downstream of VEGFR, and promotes tumor growth and proliferation through regulation of mRNA translation. Temsirolimus is an FDA-approved mTOR inhibitor that binds to FKBP-12 to create a complex that directly inhibits mTOR. A phase III trial⁷⁷ included 626 previously untreated patients with poor prognostic criteria and randomized them to temsirolimus 25 mg IV weekly, interferon alpha 18 MU 3x/week or temsirolimus 15 mg IV weekly + IFN 6 MU 3x/week. Patients were required to have three or more of the following adverse risk features: Karnofsky performance status $< 80\%$, lactate dehydrogenase $> 1.5\times$ laboratory upper limit of normal, hemoglobin $<$ laboratory lower limit of normal, serum calcium corrected for albumin > 10 mg/dL, time from first diagnosis of RCC to start of therapy of < 1 year and three or more metastatic sites. Of note, 19% of enrolled patients had nonclear cell histology. Temsirolimus monotherapy demonstrated an overall survival advantage compared to interferon alpha (10.9 vs 7.3 months, $p = 0.008$). On the basis of these results, temsirolimus has become a first-line standard of care for patients with poor risk mRCC. In the second-line setting following progression with sunitinib, results of the INTORSECT phase III study⁹⁹ showed that temsirolimus confers a similar PFS as sorafenib though inferior OS (12.3 vs 16.6 months, $p = 0.01$) and thus should not be used in VEGF TKI eligible patients this setting.

Everolimus is an oral mTOR inhibitor with US FDA approval for use in patients with mRCC after

sunitinib or sorafenib failure on the basis of results from the RECORD-1 randomized phase III trial comparing everolimus to placebo.^{78, 100} Everolimus demonstrated an improved PFS (4.9 vs 1.9 months, $p < 0.001$) although no OS benefit, owing in part to the high cross-over rate of patients in the placebo arm. Whether the findings of the INTORSECT trial described above are applicable to the use of everolimus is unknown, as studies comparing everolimus to a VEGFR TKI in the second-line setting have not been reported, and the use of a placebo comparator in the RECORD-1 trial is no longer considered an appropriate control arm given the efficacy of axitinib and sorafenib in this setting. The optimal sequencing of everolimus with a VEGFR TKI has been studied in the RECORD-3 trial.¹⁰¹ In this randomized phase II noninferiority trial, treatment naïve patients received either everolimus followed by sunitinib at progression or the reverse sequence. The median PFS and OS for first-line everolimus were inferior to first-line sunitinib, providing further support that everolimus should not be used before a VEGFR TKI.

Uncommon cancers of the kidney

A detailed discussion of the biology and management of uncommon variants is beyond the scope of this truncated chapter, in accordance with editorial directions, but has been covered in detail elsewhere.^{102, 103} However, we will address one variant that appears to have been reported more frequently in the recent past and for which there have been changes in systemic care.

Collecting duct carcinoma

CDC represents less than 1% of kidney cancer,^{103–105} although there has been an increasing proliferation of case reports in the past few years. It was originally thought to derive from distal tubular epithelium, but more recently has been shown to arise in the collecting ducts.^{102, 104} CDC, which is usually found in the renal medulla, ranges in size from small to greater than 10 cm and often has an irregular margin with evidence of local infiltration. Often surrounded by desmoplastic stroma, CDC has a variable tubular-papillary pattern of growth, with high-grade nuclei and high mitotic activity. Mucin and sarcomatoid changes may be seen. There is no classical immunohistochemical appearance.

CDC is an aggressive tumor, often presenting at advanced stage.^{102, 104, 105} Common features include hematuria, flank pain, or abdominal pain, and there are frequently metastases at first presentation, including lung, liver, bone, adrenals, or lymph nodes. There is a 2:1 male predominance, with a broad age range of presentation. The appearance on CT scan is not specific and consists mainly of a centrally arising infiltrative lesion without much contrast enhancement.

The diagnosis of CDC is usually made at surgery, which remains the definitive treatment for localized disease. However, this is one of the aggressive variants of renal cancer and thus is often associated with early metastasis. There is little evidence that immunotherapy has any significant utility, and thus most reports of treatment of metastatic disease have involved the use of systemic chemotherapy, mostly predicated on cisplatin-containing regimens.^{106, 107} Unfortunately, remissions are relatively infrequent and of short duration. It has been suggested that the combination of cisplatin and gemcitabine has sustained activity.¹⁰⁶ More recently, a small series from France reported substantially sustained and long-term remissions from the combination of bevacizumab, gemcitabine, and cisplatin,¹⁰⁷ although it is important to note that the added impact of bevacizumab has not been proven. This work suggests that there may be an additive effect from the combination of chemotherapy and targeted therapy in this disease, and confirmatory evidence will be required before this can be viewed as a standard.

Conclusion

RCC incidence is increasing worldwide. Surgery remains a mainstay of treatment for localized tumors and is part of multimodality therapy in the metastatic setting. An enhanced understanding of the biology of RCC has led to the clinical development of a number of targeted therapies that have substantially altered the therapeutic landscape. Future investigative endeavors include further refinement of the approach to the small renal mass, a better understanding of the biology of response and resistance to targeted therapy, clinical testing of combinations and sequences of targeted therapy in mRCC and the development of novel immunotherapeutic approaches.

Chapter 97

Urothelial cancer

Derek Raghavan, MD, PhD, FACP, FRACP, FASCO ■ Richard Cote, MD, FRCPath, FCAP ■ Earle F. Burgess, MD ■ Stephen B. Riggs, MD ■ Michael Haake, MD

Overview

Urothelial malignancy is one of the most common cancers in Western society and involves the bladder, urethra, ureters, and renal calyces. It is predominantly associated with smoking, industrial dyes, schistosomiasis, radiation exposure, and certain geographical locations. Well-defined molecular prognosticators have been identified and, in combination with improved staging techniques, have led to improved outcomes. Patients with nonmuscle invasive urothelial malignancy are best managed by surgical resection, often in combination with intravesical immunotherapy or chemotherapy. Muscle invasive disease is best managed by neoadjuvant cisplatin-based chemotherapy followed by cystectomy; less robust patients are often effectively treated by cisplatin-based chemoradiation. Patients with metastatic disease achieve response rates of up to 70% with MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin) or GC combination chemotherapy but are infrequently cured. New approaches to the management of systemic disease are predicated on recent data reflecting the importance of unblocking checkpoints for immune function and correlate with expression of PD-L1 (programmed death-ligand 1).

Introduction and epidemiology

Bladder cancer is one of the most common malignancies in Western society, with an annual incidence of about 16 cases/100,000 males per year and 5 cases/100,000 females.¹ In the United States, this translates into about 75,000 new cases per year, with approximately 16,000 deaths per year.² An additional 3000 cases of upper tract malignancy present each year, and additional cases are found throughout the urothelial lining. This is one of the malignancies for which the incidence and mortality figures have not changed significantly in the past 50 years, although possibly the incidence figures in males are beginning to plateau, reflecting the reduction in cigarette smoking. This is predominantly a disease of older aged males, with a median age at presentation of 60–65 years. There are geographical variations in incidence with increased rates in the Great Lakes region of the United States, in the littoral basin of the Middle East, and in regions with an increased incidence of schistosomiasis (most often squamous carcinoma). In the Balkan region, endemic familial interstitial nephropathy is associated with a 100- to 200-fold increase in upper tract tumors. Urothelial cancer occurs more often in Caucasians than in Asian or African American populations.²

The etiology is well-defined, with the most common association being cigarette smoking, and other factors including exposure to dyes and industrial reagents, motor exhaust, reduced intake of fluids (controversial), and analgesic (phenacetin) abuse.¹ Other associations include prior treatment with cyclophosphamide and other oxazophosphorine cytotoxics, high fat diet, chronic urinary infection, paraplegia, and prior pelvic irradiation. Family history is also relevant, especially for patients with

Lynch syndrome, and for upper tract tumors.

Pathobiology and molecular determinants

Bladder cancer consists predominantly of urothelial carcinoma (UC), formerly known as transitional cell cancer.^{1, 3} This type of cancer can occur anywhere along the urothelial tract and may be multifocal in origin, with identical tumor histology irrespective of site of origin. About 90% of incident cases are UC, with about 5–10% being squamous cell carcinoma, 4–5% being adenocarcinoma, and the remainder consisting of rare cancers, such as small cell anaplastic cancer, sarcoma, melanoma, or lymphoma. Occasionally, other tumors metastasize to the bladder.

Increasingly, bladder cancer is believed to arise from cancer stem cells⁴ and that the cancer stem cells have the ability to differentiate along different pathways. Thus, not surprisingly, intermixed histological patterns will be found, although usually UC predominates in such situations. These tumors are associated with a field defect of the urinary mucosa, probably due to antecedent carcinogenic stimuli, and thus can occur at multiple sites.

UC presents as either noninvasive or invasive disease. In the former pattern, two distinct histological subtypes are known, papillary versus flat carcinoma *in situ* (CIS). Noninvasive papillary carcinoma is the single most common presentation for bladder cancer, comprising more than 60% of incident cases. This can be classified according to grade of disease, ranging from tumors generally considered benign (papilloma) to high-grade tumors with a high risk of developing invasion (grades 3 and 4). Grading systems are generally restricted to noninvasive papillary neoplasms, as CIS is high grade by definition, and virtually all invasive tumors are high grade as well.³

Grade 1 (well-differentiated) papillary neoplasms show a well-organized pattern similar to the organization of normal urothelium, including polarity of the urothelial cells and the presence of an umbrella cell layer. A fibrovascular stalk is often seen. In grade 2 tumors, there is a higher nuclear to cytoplasmic ratio, and prominent nucleoli, with loss of urothelial orientation and at least partial loss of the umbrella cell layer. Grade 3 (high grade) disease is characterized by poorly differentiated or undifferentiated tissues that are increasingly disorganized and manifest a high mitotic index, with complete loss of the umbrella cell layer. The latest WHO (World Health Organization) nomenclature combines tumor differentiation into only low and high grades, based on the finding that tumor behavior is more accurately reflected in a dichotomized system.^{3, 5} Although the bladder is heavily invested by fat and muscle, this is not the case in the upper tracts, and thus, the barriers to spread, and patterns of spread, are somewhat different.

Because the different morphologic subtypes of bladder cancer have long been recognized to have different biologic behavior, these subtypes became the focus of molecular analysis.⁵ The earliest cytogenetic studies in bladder cancer demonstrated alterations in chromosomes 9, 11, and 17, reflecting the possible presence of tumor suppressor genes in these areas.^{5, 6} On the basis of consistent and frequent genetic defects in bladder tumors, it has become clear that there are at least two distinct molecular pathways involved in bladder cancer tumorigenesis and progression ([Figure 1](#)), as reviewed elsewhere.^{5, 6} Papillary tumors frequently show alterations in chromosome 9, particularly at the INK4a/p16 locus. Further, these tumors frequently show constitutive activation of the receptor tyrosine kinase–Ras pathway, exhibiting activating mutations in the HRAS and fibroblast growth factor receptor 3 (FGFR 3) genes. In contrast, flat CIS and invasive tumors frequently show alterations in the p53 gene and protein (TP53) and the retinoblastoma (RB) gene. Similar molecular changes are found in upper tract tumors, and added

abnormalities in chromosomes 5q, 1p, 14q, and 8p have been identified.

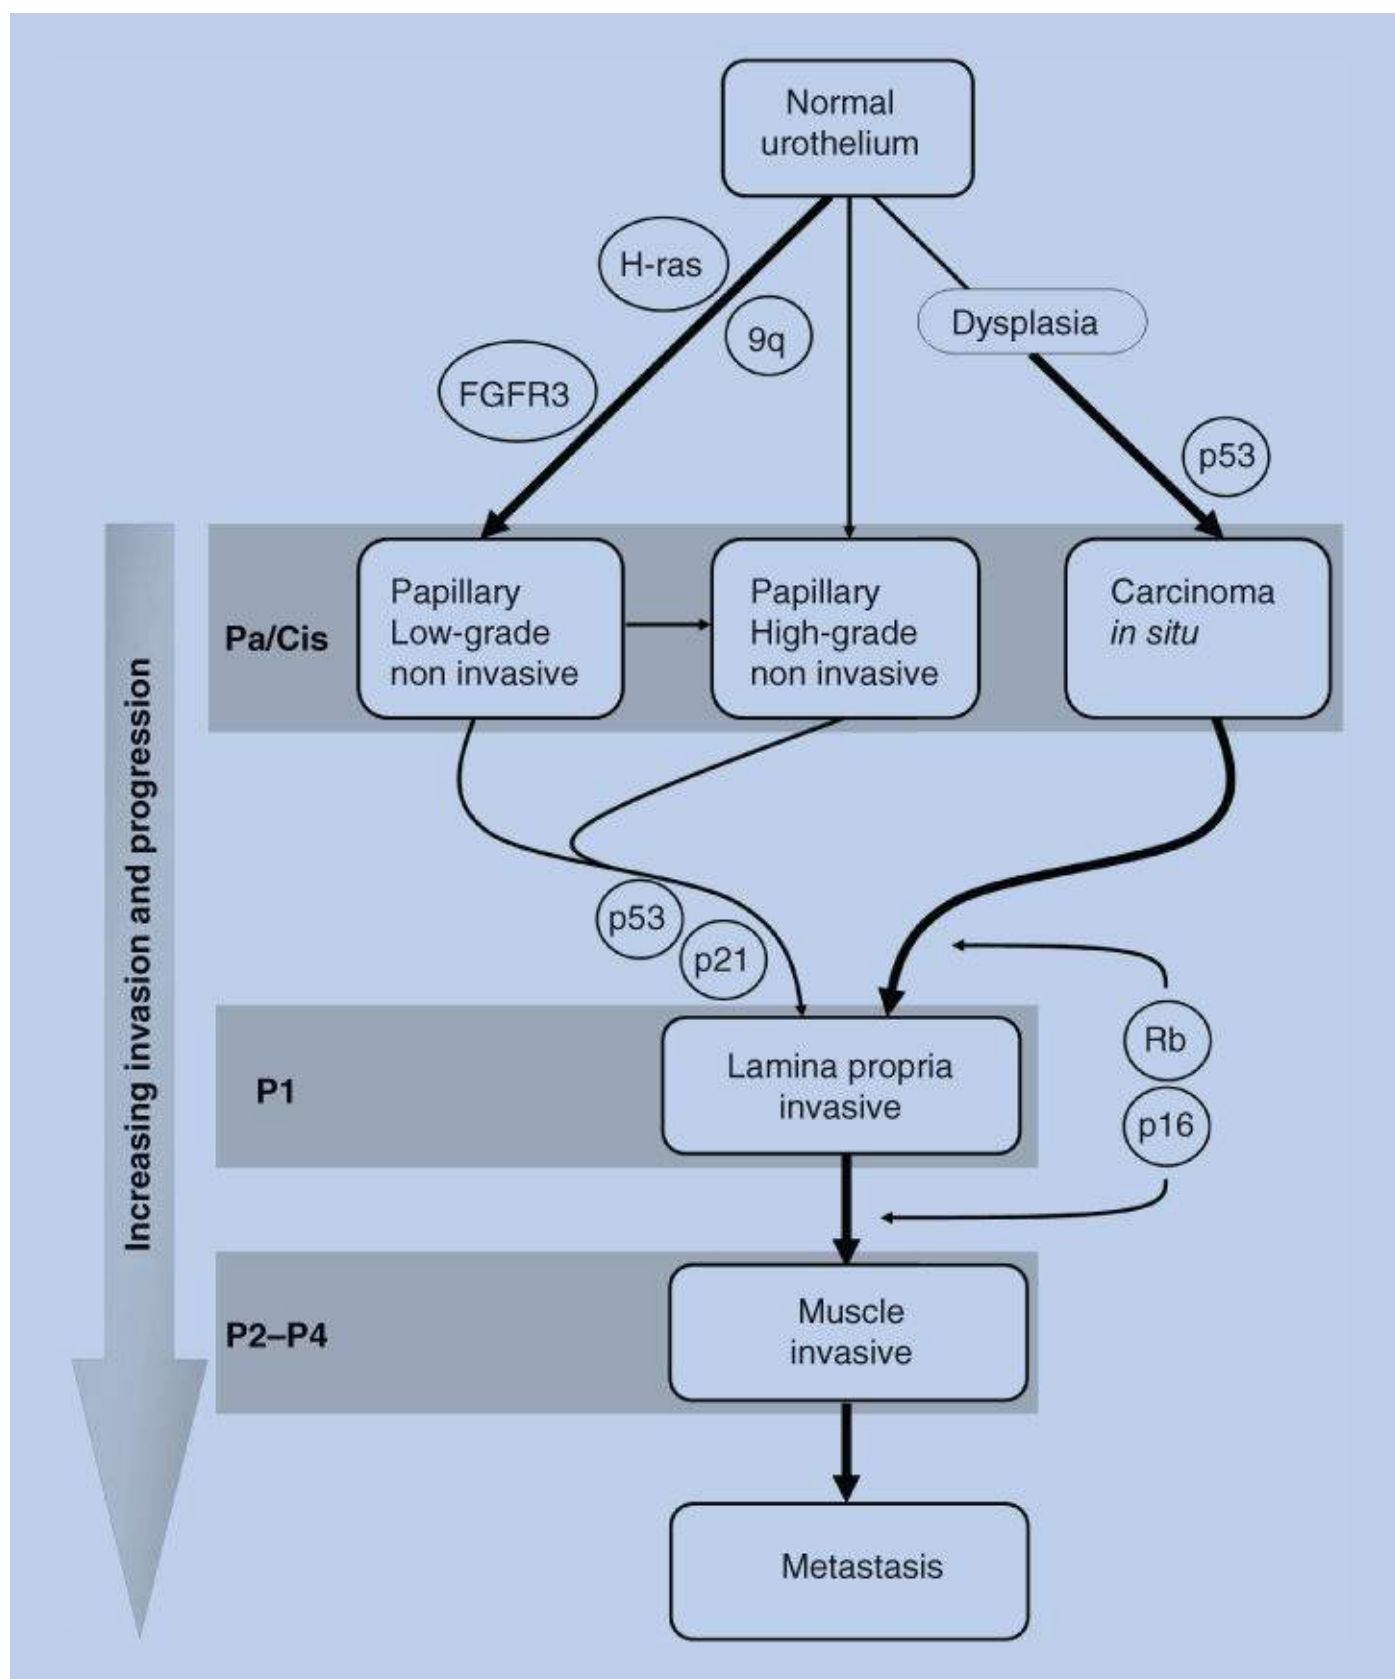

Figure 1 Proposed model for urothelial tumorigenesis and progression. Superficial and invasive tumors have unique molecular profiles and arise from distinct pathways. The locations of molecules indicate events that pose a risk for progression of a particular phenotype. The rare papillary carcinomas that invade are more likely to have genetic alterations at crucial loci. The thickness of arrows represents the relative frequency of occurrence.

The RAS–MAPK signal transduction pathway is also important in noninvasive papillary tumors. Most noninvasive papillary UC's show activation of this pathway, generally through the activation of FGFR3, and potentially presenting a target for novel therapies. Other receptor tyrosine kinases are also involved, such as epidermal growth factor receptor (EGFR) and Her2-neu, as reviewed previously.⁵

Cell cycle regulation has clearly been shown to be a critical pathway in flat CIS and invasive UC. A central molecule in this pathway is the p53 tumor suppressor protein, encoded by the *p53* gene. Patients showing alterations in two or three out of the three critical genes (p53, p21, RB) in this pathway have much poorer outcomes than patients with tumors showing alterations in none or only one of these determinants ([Figure 1](#)).

Tumor angiogenesis and epigenetic alterations are also important in the genesis and control of UC. Comprehensive whole genome sequencing efforts have now confirmed the prevalence of mutations in chromatin remodeling genes, underscoring the potential importance of epigenetic dysregulation in UC carcinogenesis. Genes known to be affected by methylation in UC include RASSF1A, DAPK, and INK4A.⁵

Multiplex genome-wide expression analysis has become increasingly important in the analysis of UC and other cancers, leading to more detailed molecular profiles with histogenetic, prognostic, therapeutic targeting, and predictive implications ([Figure 2](#)).^{5, 6}

Figure 2 Probability of recurrence-free survival in 164 bladder cancer patients, who underwent radical cystectomy, based on alterations in p53, p21, and/or RB expression. The combined analysis shows an increased risk of recurrence with increasing number of deregulated molecules (logrank $p < 0.001$).

Clinical presentation

The presentation of bladder cancer usually reflects the extent of disease, with somewhat different patterns

associated with non-muscle-invasive tumor, invasive disease, metastases, and the nonmetastatic manifestations of malignancy.^{1, 8} Patients with noninvasive tumors may present with asymptomatic hematuria (diagnosed on urinalysis), visible hematuria, and irritative patterns such as frequency, dysuria, burning, or nocturia. In patients with a prior history of non-muscle-invasive bladder cancer and prior transurethral resections (TURs), irritative bladder symptoms may be more prominent. Invasive tumors have a similar pattern of presentation, although more advanced tumors may be associated with pelvic pain, slowing of urinary stream, dyspareunia, and occasionally pneumaturia or fecal incontinence. Occasionally, tumors involving the trigone will cause obstruction of ureters, with concomitant flank pain. Flank pain or more generalized abdominal pain occasionally reflects the presence of an upper tract tumor, although usually such features are associated with more advanced local disease.

The presenting features of metastatic disease usually reflect the site(s) of involvement. Common sites include distant lymph nodes, lung, liver and bone, and less commonly brain, skin, other viscera. In the present era of aggressive imaging, many metastases will first be detected upon routine follow-up scans. Pulmonary involvement will classically be associated with cough and dyspnea and occasionally with hemoptysis or chest pain. Liver involvement may present with right upper quadrant pain or shoulder tip pain, and occasionally disruption of function, most commonly manifested by jaundice. Osseous metastases are often associated with bone pain, and less commonly with pathologic fracture, with common sites of involvement including spine, ribs, pelvis, and skull. Brain metastases may be suggested by the development of headache, confusion, or other motor features. A computed tomography (CT) or magnetic resonance imaging (MRI) brain scan will usually reveal the problem, although rarely a spinal tap will be required to diagnose carcinomatous meningitis in a patient with a normal scan (especially in a patient with suspicious symptoms who has received extensive prior chemotherapy for metastatic disease). Skin metastases are uncommon but usually are manifest by an infiltrative pattern or isolated cutaneous or subcutaneous nodules.

The nonmetastatic manifestations of malignancy consist predominantly of serological syndromes, although occasional patients will present with the thromboembolic syndromes classically associated with advanced adenocarcinomas of the gastrointestinal (GI) tract. Bladder cancer is occasionally associated with the production of granulocyte-macrophage colony-stimulating factors or other cytokines, and a greatly elevated white blood cell count may reflect this phenomenon, rather than underlying infection. Tumors with squamous differentiation may sometimes be associated with hypercalcemia, owing to excess production of immunoreactive parathyroid hormone (PTH)-like substance. In general, these syndromes should be taken in context and generally do not require specific management unless causing clinical problems—for example, severe hypercalcemia and significant thrombotic episodes.

Investigation and staging

The specifics of the presentation will usually govern the nature of the investigations. Presentation with hematuria or other urinary symptoms will usually lead to urinalysis and assessment of possible infection or urinary calculi. The absence of these conditions or the presence of sterile pyuria is usually grounds for assessing urinary cytology and/or progressing to cystoscopic examination. In some clinical practices, to improve upon the sensitivity of urine cytology and to reduce the need for periodic cystoscopy in the follow-up of patients with non-muscle-invasive bladder cancer, novel biomarker dipstick assays have been developed, based on soluble bladder tumor antigens or cell-based markers (NMP22, BTA-TRAK, BLCA-4, and Immunocyt).⁹ Molecular analysis (Urovysion) allows detection of aneuploidy reflecting changes in chromosomes 3, 7, and 17, which are associated with high-grade tumors, and loss of the 9p21 site that is characteristic of low-grade disease. Case-control and cohort studies have suggested that

several of these markers may have higher sensitivity than urine cytology, and some have been approved by the FDA (Food and Drug Administration) for use in screening (UroVysion and NMP-22) and in combination with cystoscopy for the diagnosis of recurrence.⁹ False positives can occur in cystitis, urolithiasis, bowel interposition, or in the presence of foreign bodies. Urinary cytology is said to be more than 95% specific, and a positive reading mandates further investigation; however, negative findings are less helpful. A more recently introduced approach that will require further validation is the use of microfiltration devices for capture and characterization of bladder cancer cells in the urine.¹⁰ The technology of endoscopic examination has improved in recent years with the introduction of more sophisticated endoscopic cameras, high-resolution videography, fluorescence cystoscopy, and narrow banding imaging cystoscopy, leading to improved specificity and sensitivity.^{11, 12} This has also facilitated instrumentation of the upper tracts.

There is no specific serological workup for bladder cancer. Routine hematological and biochemical testing may reveal chronic anemia of chronic disease or from blood loss, renal dysfunction (from obstruction or the underlying cause of the cancer), and occasionally evidence of metastases, such as raised alkaline phosphatase or liver function tests. No tumor markers have been shown to be specific to bladder cancer, although occasional elevation of HCG, CEA, CA 19-9, or CA125 will be seen, the latter particularly in the presence of elements of adenocarcinoma.

Imaging of the urinary tract may be carried out before or after cystoscopy. A relatively standard approach is to obtain an excretory urogram to delineate the anatomy of the urinary tract, including the presence of tumors of the bladder and upper tracts or hydronephrosis.⁸ CT urography is more commonly used in the current era, based on its ability to evaluate the renal parenchyma in addition to the urothelium, and it is performed more rapidly than excretory urography. MRI may also be helpful to define the local anatomy and the extent of an invasive tumor, while also providing staging information about involvement of lymph nodes and distant sites. However, the sensitivity and specificity of non-muscle-invasive pelvic imaging are somewhat limited. Also of importance, CT and MRI scans performed soon after transurethral resection of bladder tumor (TURBT) will often suffer from the artifact of apparently increased depth and invasion owing to the impact of postresection inflammatory infiltrate. The role of the positron emission tomography (PET) scan is limited, although we occasionally use this modality to assist in defining potential metastatic sites for further investigation, with a “positive” result being investigated further and a negative result having limited implications.

Definitive investigation involves TUR with the usual goals of complete tumor eradication and accurate staging. Bimanual examination at the time of TUR allows assessment of tumor stage and the presence of extravesical disease. In the setting of high-grade cancer, the existence of detrusor muscle invasion is important to determine. Unless cystectomy is planned, repeat TUR (in patients with non-muscle-invasive disease) within 4–6 weeks shows upstaging in 30% of patients with muscle identified in the original specimen and 60% of patients in whom no muscle was present initially.

Prognosis

The prognosis of bladder cancer largely reflects several of the factors already discussed, including stage and grade of the tumor, multifocality, the presence of lymphovascular invasion, association with CIS, morphology, pattern of gene mutation, and the presence of anemia or hydronephrosis. Similar factors govern the prognosis of upper tract tumors, including grade, stage, the presence of lymphovascular invasion, aneuploidy, EGFR expression, location of tumor (ureters with worse prognosis than renal pelvis), and the presence of residual disease after surgery.¹

The AJCC (American Joint Committee on Cancer) Staging Classification¹³ generally correlates well with outcome. Although the bladder is heavily invested by fat and muscle, this is not the case in the upper tracts, and thus the barriers to spread and patterns of metastasis are somewhat different from tumors in the bladder.

In addition, Bajorin et al.¹⁴ have developed an algorithm for estimating risk and prognosis for patients with advanced disease, focused on the presence of visceral metastases, performance status, and anemia; this has recently been focused and updated to increase the precision of prediction.¹⁵ Several modifications have been proposed, including prognostic criteria for second line and salvage chemotherapy, but they have not led to improved survival figures, although they may have contributed to avoidance of futile chemotherapy ([Table 1](#)).

Table 1 Risk factors in metastatic bladder cancer

Variable	Statistical significance (p)	Risk ratio
<i>Three variables</i>		
Visceral metastases (yes/no)	0.0001	1.99
Karnofsky PS (</≥80%)	0.0001	2.05
Hemoglobin (normal/abnormal)	0.0103	1.41
<i>Two variables</i>		
Visceral metastases (yes/no)	0.0001	2.10
Karnofsky PS (</≥80%)	0.0001	2.20

Management of non-muscle-invasive bladder cancer

The key to effective management of non-muscle-invasive bladder cancer involves cystoscopy and resection of visible bladder tumor(s),^{16, 17} sometimes followed by postoperative use of intravesical therapy (immunological or cytotoxic reagents) to reduce the risk of recurrence.^{8, 16, 17} As bladder cancer is associated with a field defect, multiple random biopsies of apparently normal urothelium should be performed to identify occult CIS if urine cytology is positive or in the presence of high-grade disease when bladder conservation is contemplated. Usually, endoscopic resection is repeated within 4 weeks of the initial resection in patients with high-grade disease and/or T1 tumors, as up to 50% will have evidence of invasive bladder cancer into muscularis propria on rebiopsy.

The grade and stage of the tumor will dictate subsequent management. Patients with non-muscle-invasive, low-grade papillary bladder cancer are at low risk of progression to invasive disease, although the risk of recurrence may be as high as 60–80%. Patients at increased risk for recurrence on the basis of tumor size, multifocal tumors, or prior recurrent tumors are often given adjuvant intravesical therapy (usually weekly instillations for 6–8 weeks) following resection, mostly with bacillus Calmette Guerin (BCG), which reduces the risk of recurrence by up to around 40%.¹⁴ The mechanism of action of BCG is based on local immunological stimulation, perhaps with alteration of suppressor-helper T cell ratios. Effectively, such treatment allows the bladder to “reject” implantation and recurrence of bladder cancer. This may be a harbinger of the apparent utility of PD-1 targeting, which releases the brake on T cell function, for invasive and metastatic disease.

Randomized trials suggest that BCG is superior to other intravesical agents at preventing tumor progression,¹⁷ and an initial bladder preservation strategy involving intravesical BCG is associated with long-term outcomes similar to early cystectomy for low-grade tumors.¹⁷ Maintenance BCG is associated with a reduction in tumor recurrence and reduced requirement for cystectomy, compared to a single 6-week induction regimen. The optimal schedule of BCG administration has not been defined, and, similarly, the optimal commercial preparations and the ideal duration of administration remain controversial.

The side effects of all the intravesical agents in common use include irritative symptoms and hematuria. BCG may also cause a flu-like syndrome and, because it is an attenuated mycobacterium, it can produce local, regional and systemic TB (tuberculosis)-like infections. Granulomatous infections can occur at extravesical sites, including the prostate, epididymis, testes, kidney, liver, and lungs. BCG sepsis is the most serious complication, and can be life threatening, and should usually be treated with triple-antituberculous therapy.

In some centers, cytotoxic agents such as mitomycin C or gemcitabine¹⁸ are preferred because of purportedly reduced toxicity, although the certainty of this is not substantiated. For patients who refuse cystectomy for relapsed non-muscle-invasive disease, several lines of immunological or cytotoxic intravesical therapy may be feasible and may delay recurrence and progression.

After completion of treatment, patients should be monitored closely with periodic cystoscopy and selective urine cytology and/or tumor marker evaluation at 3–6 months intervals to detect recurrence early. Patients with high-risk non-muscle-invasive bladder cancer (high-grade Ta, T1, or CIS) have at least a 50% risk of developing invasive bladder cancer and a 35% risk of dying from bladder cancer. Moreover, those with persistent or recurrent high-grade disease after one or two courses of intravesical therapy will develop muscle invasion and progression in 80% of cases. Thus, we advocate timely radical cystectomy with urinary diversion for relapsed high-risk disease, particularly for patients with long life expectancy.^{19, 20} Cure rates approach 90% in this setting, but when cystectomy is delayed, deeply invasive disease may develop and is associated with diminished survival.¹⁹

Management of invasive bladder cancer

Definitive surgery

Over the past 20 years, radical cystectomy with bilateral pelvic lymphadenectomy has been viewed as the standard treatment for clinically localized invasive bladder cancer.^{1, 8, 20, 21} Traditionally, this requires the en bloc removal of the anterior pelvic organs, which include the bladder, prostate, and seminal vesicles in men and the bladder, urethra, uterus, ovaries, and vaginal cuff plus anterior vaginal wall in women.²⁰ A urinary diversion is formed by the connection of the ureters to detubularized intestinal reservoir. Continent reservoirs, such as the Indiana pouch and orthotopic neobladder, are now standard approaches because they offer improved continence without the need for an external collecting bag. The orthotopic neobladder involves creation of an intestinal reservoir that is attached to the urethra and enables the patient to void normally without self-catheterization.

Radical cystectomy, without adjuvant therapy, is curative in up to 60% of patients with invasive bladder cancer,^{20, 21} depending on stage and other prognostic factors. The 5-year overall survival rates in large series of patients with T2–T3 disease range from 40% to 65%. Relapse rates reflect stage, grade, the presence of lymphovascular invasion, and expression of adverse molecular prognosticators. Radical

cystectomy alone has been reported to be curative in 20–40% of patients with regional metastasis to pelvic lymph nodes, and the outcome is influenced by the primary tumor stage, number of involved lymph nodes, and the presence of extranodal extension.^{1, 8, 20, 21} Extended template node dissection may improve cure rates.^{20, 21} However, this may reflect the case selection bias, surgical skill, or support and salvage techniques available in centers of excellence.

Advances in instrumentation

Laparoscopic radical cystectomy, with or without robotic assistance, has been reported in modest series from centers experienced in laparoscopic surgery.^{22, 23} The cystectomy and lymph node dissection are commonly performed laparoscopically and the urinary diversion is carried out through a midline incision smaller than is usual for conventional surgery. The potential advantages include reduced blood loss, less postoperative pain, and shorter convalescence, although most of the data have been derived from nonrandomized series, carried out by technically superb surgeons, with careful case selection and relatively short follow-up. More recently, Bochner et al.²⁴ have reported preliminary outcomes of a randomized trial, which suggested much higher cost for laparoscopic cystectomy, with equivalent toxicities. As this was an early report focused on acute morbidity, long-term outcomes are not yet available.

Another innovation has been the use of prostate-sparing cystectomy, with the intent of ameliorating the extent of mutilation and late effects, although this has not yet been validated by randomized trials. This approach is not useful for patients with extension of tumor into the prostate or with incidental prostate adenocarcinoma.

Role of radiotherapy

For patients with invasive, clinically nonmetastatic bladder cancer who are not surgical candidates, by their choice, technical considerations, or physical fitness, radiation is the treatment of choice.^{25–27} There have been no well-designed, randomized studies comparing radiation with surgery in patients with similar characteristics. The optimal technique of dose delivery, either conformal or IMRT (intensity-modulated radiotherapy), remains controversial.²⁵ Favorable prognostic features for use of radiotherapy include small, localized, T2 tumors, absence of hydronephrosis, normal renal function, maximum debulking by TUR, and absence of anemia.^{1, 26, 27}

A relatively standard radiotherapy approach is to deliver more than 65–70 Gy over 6–7 weeks, with 40 Gy delivered to the bladder, and the highest doses confined to the tumor plus a reasonable margin, as defined by diagnostic scans. Mapping is done at the time of TURBT with CT simulation films in the prone position.^{26, 27} It is less common today for radiotherapy to be delivered in isolation than for it to be administered in combination with systemic chemotherapy, based largely on the studies of the RTOG (Radiation Therapy Oncology Group) and a randomized trial conducted by the National Cancer Institute of Canada.²⁸ These studies have shown significantly improved local control from chemoradiation, although a statistically significant survival benefit remains unproved. In the United Kingdom, a randomized trial of chemoradiation with 5-fluorouracil and mitomycin C versus radiation alone showed a significant increase in local control and a strong trend toward a survival benefit from the combination.²⁹

Toxicities of radiation include cutaneous inflammation, proctitis occasionally complicated by bleeding and/or obstruction, cystitis or bladder fibrosis, impotence, incontinence, and development of secondary malignancies in the region surrounding the radiation field. Importantly, if radiotherapy fails, salvage surgery is much more complex because of the formation of fibrosis in the irradiated field.

Several innovations in radiation planning and treatment have been introduced in recent years, including devices for tracking physiological movement of the tumor tissue and adjusting the radiation beam, and particle therapy, such as proton beam, with more focused beams and potentially less normal tissue toxicity. No level 1 evidence supports the use of proton beam therapy for bladder cancer, which remains investigational.

Combined modality strategies

Neoadjuvant (preemptive) chemotherapy

We first studied pre-emptive or neoadjuvant systemic chemotherapy plus local treatment more than 30 years ago,³⁰ based on the rationale that chemotherapy might reduce the extent of local tumor while controlling occult metastases. Our preliminary studies showed that this can shrink primary bladder cancers and result in downstaging, sometimes achieving a complete clinical and pathological remission.³⁰ However, initial randomized trials did not confirm a survival benefit for single agent regimens. The introduction of multidrug chemotherapy regimens, such as methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC), and cisplatin, methotrexate, and vinblastine (CMV), adapted from use in metastatic disease into neoadjuvant protocols yielded survival benefit, confirmed by randomized clinical trials (Table 2).^{31–33}

Table 2 Results of clinical randomized trials of neoadjuvant chemotherapy for invasive bladder cancer, stages T1–T4

Series	Neoadjuvant regimen	Definitive therapy	Median survival with/without neoadjuvant therapy (months)	Actuarial long-term survival with/without neoadjuvant therapy
Neoadjuvant				
MRC-EORTC	CMV	RT/cystectomy	44/37.5	35%/30% at 10 years
Intergroup	MVDC	Cystectomy	77/46	42%/35% at 10 years
Nordic 1 trial	DC	Cystectomy	Not reached/72	59%/51% at 5 years
Adjuvant				
EORTC	MVDC	Cystectomy	81/55	44%/39% at 5 years
Stanford	CMV	Cystectomy	63/36	42%/38% at 5 years
USC	CDCy	Cystectomy	52/30	44%/39% at 5 years
Cognetti	GC	Cystectomy	38/58	44%/44% at 6.5 years

Abbreviations: C, cisplatin; D, doxorubicin; M, methotrexate; Cy, cyclophosphamide; V, vinblastine; G, gemcitabine; MRC-EORTC, Medical Research Council/European Organization for Research and Treatment of Cancer; RT, radiotherapy.

Thus, the consensus is now that neoadjuvant MVAC or equivalent chemotherapy affords an absolute survival benefit of 7–8%, with an increase in median survival of up to 3 years, when added to radical cystectomy. A statistically significant survival benefit has not been proved when the primary treatment is radiotherapy. Recent national surveys of patterns of practice have indicated that most patients do not receive such treatment, suggesting that change has come slowly in this area of clinical work.^{34, 35}

To date, no multidrug cytotoxic regimen has been shown to be superior or even equivalent to the MVAC or CMV regimens for neoadjuvant chemotherapy. However, the newer gentle regimens, such as gemcitabine-cisplatin or gemcitabine-carboplatin, are being used increasingly for neoadjuvant therapy. This may be reasonable for the older or frail patients, but may lead to a greater risk of death from cancer for the more robust patient without intercurrent medical disorders. Ideally, a well-powered, randomized clinical trial would be needed to resolve this issue.

The importance of dose-dense MVAC, as initially developed and tested by the European Organization for Research and Treatment of Cancer (EORTC) in the metastatic setting, remains unclear and controversial. Toxicity may be reduced by this approach, but whether long-term results are equivalent is unclear, despite the imprimatur of the NCCN (National Comprehensive Cancer Network) guidelines.

Adjuvant chemotherapy

Chemotherapy administered after radical cystectomy for patients with T3–T4 tumors and/or lymph node involvement improves *disease-free* survival, as one would expect for any effective chemotherapy.^{36–41} However, in the randomized trials reported to date, most of which have been flawed by poor design, a disease-free statistical target, or inadequate sample size, a statistically significant improvement in total survival has never been demonstrated, as previously discussed.⁴² An Italian group tested the use of adjuvant gemcitabine-cisplatin and demonstrated a statistically nonsignificant inferior survival in the chemotherapy arm.⁴¹ An attempt was made to address these problems in the EORTC international randomized trial that had been in progress for several years, and which suffered from poor accrual, leading to premature closure. This study confirmed a disease-free survival benefit, the largest benefit counterintuitively in patients without node metastases, but no overall survival benefit.⁴³ This suggests that the adjuvant chemotherapy may have compensated for inadequate definitive surgery.

Although meta-analysis can sometimes help to resolve the failure of small trials to resolve an issue, the study published by the Cochrane group was flawed.⁴⁴ It grouped a heterogeneous set of small trials that were poorly designed, poorly executed, or which did not actually compare adjuvant chemotherapy with chemotherapy at relapse and thus confused the issue. However, understanding the significant limitations of historical controls and poorly executed randomized trials, our group has concluded that a survival benefit from adjuvant chemotherapy is still possible, and a survival deficit is unlikely; thus, we sometimes offer this approach to carefully selected otherwise healthy, postcystectomy patients with high-risk disease. A well-powered randomized chemotherapy trial is unlikely to ever answer this question.

Metastatic bladder cancer

Chemotherapy is the first-line treatment of choice for patients with metastatic bladder cancer. The single agent activity of 5-fluoruracil, methotrexate, the vinca alkaloids, doxorubicin, and cisplatin was demonstrated between the 1960s and early 1980s.⁴⁵ The combination of methotrexate, vinblastine, and cisplatin, with⁴⁶ or without⁴⁷ doxorubicin, first produced objective responses in more than 60% of cases, with a median survival of 1 year. Investigators in the United States, Canada, and Australia proved the utility of the MVAC regimen in a randomized trial against single agent cisplatin and confirmed that the benefit persisted with a median follow-up beyond 6 years.⁴⁸ The major limitation of the MVAC regimen was substantial toxicity, including grade 3–4 GI effects, stomatitis, and myelosuppression, as well as occasional cases of renal dysfunction and cardiotoxicity.^{46, 48} Attempts were made to improve the regimen, and Sternberg et al.⁴⁹ demonstrated, in a randomized trial, that a dose-intense variant of MVAC

yielded higher response rates and reduced toxicity compared to the original regimen, but without achieving a major increment in median survival. However, at 5 years, the number of surviving patients was greater than for standard-dose MVAC but did not reach statistical significance.

Single agent response rates of around 20–30% have been reported for paclitaxel, gemcitabine, docetaxel, ifosfamide, and pemetrexed.⁴⁵ The combination of these agents with other standard or investigational drugs has resulted in response rates of 50–80%, sometimes with less toxicity than the conventional-combination MVAC regimen, but median survival figures have remained in the range of 12–20 months, and cure rates for patients with visceral metastases have not exceeded 10–15%.⁴⁵ After initial studies with the combination of gemcitabine and cisplatin revealed apparently equivalent response rates and substantially less toxicity than the MVAC regimen,⁵⁰ a randomized trial comparing gemcitabine-cisplatin versus MVAC confirmed these observations and showed that survival was similar.⁵¹ Consequently, an international consortium added paclitaxel to this doublet for patients with previously untreated metastatic UCs in an effort to improve cure rates, but without major survival impact in a randomized trial.⁵² Several other doublets and triplets have been assessed in phase I–II trials, but none has emerged as a major advance.

An important caveat in interpreting modern clinical trial data is that stage migration has occurred in the management of advanced bladder cancer, largely due to the increased use of aggressive postsurgical imaging via CT, MRI, and PET scans, and there has been increased use of systemic chemotherapy to treat patients with small volume, asymptomatic metastases. This should be borne in mind when considering the utility of novel combinations, such as the ITP regimen (ifosfamide, paclitaxel, and cisplatin), which yields a median survival of about 18 months, which is similar to outcomes in the current use of the MVAC regimen. Before novel regimens can be accepted into routine clinical practice, their safety and efficacy should be defined in randomized trials against accepted current standards. Despite modest progress in the past two decades, the majority of patients with metastases still die of progressive tumor. It is particularly important, in an era of increasing cost awareness and focus on the value proposition, that the aims of chemotherapy are detailed clearly, and that patients unlikely to secure life prolongation or improved quality of life are referred either into Hospice programs or, if still sufficiently fit, into clinical trials of novel approaches. Focal radiotherapy for symptomatic local or metastatic disease may also confer a palliative benefit for such patients.

Because cytotoxic chemotherapy regimens have not improved the cure rate dramatically, alternative approaches are being investigated. In the past decade, we have focused on novel compounds that target the genes and proteins that control cellular growth, differentiation, and apoptosis. Agents that modulate the function of EGFR and other tyrosine kinase inhibitors have been studied as monotherapy and in combination with chemotherapy. The ability to identify expression of the *HER-2/neu* oncogene, EGFR, and other molecular predictors of response allows some tailoring of treatment. Hussain et al.⁵³ have assessed herceptin, in combination with a regimen of chemotherapy, against bladder cancers expressing the *HER 2/neu* gene, and showed a response rate of 70%; however, the median survival of 14 months did not suggest that this was a major advance; in this study, a higher response rate was seen in tumors expressing EGFR.

The tyrosine kinase inhibitor, sunitinib (see [Chapter 97](#)), can cause partial remissions in heavily pretreated bladder cancer but of only relatively short duration.⁵⁴ Although this suggests some utility of the targeting of anti-angiogenesis pathways in bladder cancer, other studies have shown lack of activity of this group of agents against bladder cancer, and this approach is not gaining traction.

However, two novel approaches appear more promising. Recent data indicate that the MET gene is

heavily expressed in urothelial cancer and prostatic adenocarcinoma. Early trials showed significant activity against prostate cancer, and a more recent study has suggested similar anti-cancer efficacy against advanced urothelial cancer.⁵⁵

Preliminary studies have shown substantial expression of programmed death-ligand 1 (PD-L1) in urothelial malignancy, and phase I trials have suggested substantial anti-tumor effect from PD-L1 inhibitors, such as MPDL3280A.⁵⁶ Phase II trials are in progress. Despite early promise, such agents, because of their uncertain long-term impact and very high cost, should be validated against established standards before introduction into routine clinical practice.

Another approach that is being investigated anew is the use of surgery to consolidate remissions achieved from chemotherapy.⁵⁷ This approach was pioneered in bladder cancer by Alan Yagoda more than 20 years ago. The rationale is based on the high relapse rate observed at responding sites of disease and is supported by the 33% incidence of viable cancer found within resected specimens after complete clinical response. Five-year survival rates, as high as 30–40%, have been reported in patients following complete resection of metastatic sites after cisplatin-based chemotherapy, these represent very heavily selected cases, dominated by single metastases.

Uncommon histologic variants

A detailed discussion of the management of adenocarcinoma, squamous carcinoma, small cell carcinoma, and sarcoma of the bladder is beyond the scope of this brief review and has been detailed elsewhere.^{58, 59} However, certain principles of management can be noted.⁶⁰ All of the uncommon variants tend to be more resistant to chemotherapy than are the pure UCs, and thus a greater emphasis is placed on surgical resection or definitive radiotherapy when possible. Where unusual histologic patterns are noted, it is also important to ensure that the diagnosis is confirmed by an expert tumor pathologist and also to exclude the diagnosis of a metastatic second primary cancer. In general, we recommend referral to a center of excellence at least for confirmation of the diagnosis and a second opinion regarding management.⁶⁰

The prognosis of metastatic tumors of non-transitional type reflects the sites of involvement, growth characteristics, and bulk of disease. As the yield from chemotherapy is less impressive than for urothelial cancer,^{48, 58, 59} consideration of context (age, anticipated active life expectancy, intercurrent disease, sites of metastases) is important when planning the approach to chemotherapy.⁶⁰

As a general rule, squamous carcinomas are sensitive to combinations that include a platinum complex, paclitaxel, and gemcitabine, and occasional responses have been reported after treatment with methotrexate, bleomycin, and ifosfamide. We have shown that the MVAC regimen is not especially useful for squamous carcinoma of the bladder.⁴⁸ Patterns of practice vary with the combinations of gemcitabine, ifosfamide, and cisplatin or paclitaxel, gemcitabine, and cisplatin, occasionally producing long-term survival for metastatic disease. Adenocarcinomas tend to respond transiently to regimens used for cancers of the GI tract, such as combinations involving oxaliplatin, irinotecan, and fluoropyrimidines, such as 5-fluorouracil or capecitabine, although there is a paucity of data from well-structured phase II or phase III clinical trial data.

Investigators at the MD Anderson Cancer Center have reported a substantial experience with metastatic small cell anaplastic cancer of the bladder, revealing anticancer efficacy but few cures.⁵⁹ The regimens with most utility resemble those used for small cell cancers of the lung and generally involve combinations that include a platinum complex, etoposide, doxorubicin, a taxane, and an oxazophorine. However, there is a general consensus that these tumors are more resistant to chemotherapy than are

bronchogenic small cell tumors, and there is thus a greater emphasis on the role of surgical extirpation in the control of the primary tumor. In the metastatic setting, this is less relevant. In addition, there is good level-2 evidence that chemotherapy adds to the survival impact of surgical resection for clinically nonmetastatic disease.

Upper tract tumors

The approach to upper tract urothelial cancers is very similar to that employed for cancers of the bladder, with the caveat that the extent of surrounding fat and muscle is less, thus constituting less obstruction to metastasis. In addition, the phenomenon of “drop metastasis” may occur, in which tumor deposits from the upper tract(s) may seed to the urothelium of the bladder; whether this is the only mechanism of metachronous tumors, or whether this reflects the presence of field defect remains unclear. Details regarding etiology, epidemiology, clinical presentation, and investigation have been addressed in the relevant sections earlier.^{61–63}

Surgical treatment

The surgical approach to upper tract tumors is quite different from that employed for the bladder.^{64–67} The standard treatment for localized upper tract UC is radical nephroureterectomy, with complete removal of the kidney, surrounding fat and Gerota's fascia, removal of the affected ureter, and the en bloc resection of a bladder cuff. We believe that ipsilateral node dissection or extensive sampling should be performed for prognostication purposes, although there is no level 1 evidence to prove a therapeutic impact from the procedure.

Increasingly, laparoscopic radical nephroureterectomy is being considered as a viable alternative to open surgery, although long-term outcome equivalence has yet to be proven. Nonrandomized series appear to indicate that the results are comparable with respect to tumor control and possibly with less operative morbidity.^{65, 66}

Nephron-sparing surgery is considered for settings such as bilateral disease, solitary kidney, impaired renal function, or significant comorbid medical conditions. This can be achieved by partial nephrectomy, partial ureterectomy, partial resection of renal pelvis, and percutaneous resection of a renal pelvic tumor. The decision to take this approach is essentially a cost-effectiveness choice, and one which must take into consideration the likely outcome of tumor management versus the morbidity of treatment and its impact on the comorbid state. Low grade tumors, in particular, may be treated safely and effectively by endoscopic means.⁶⁷ Case selection is of critical importance, and recurrence rates reflect surgical experience and technique, instrumentation employed, and the prognostic determinants of the tumors being treated.

Radiotherapy and chemotherapy

There is remarkably scanty levels 1–2 information to support the use of radiotherapy for upper tract tumors, beyond palliation for inoperable cases. Dosing is limited by the sensitivity of the normal tissues to the impact of radiotherapy. Furthermore, those tumors with sufficiently poor prognosis to require consideration of radiotherapy for local control actually have a high chance of synchronous or metachronous distant nodal or metastatic involvement, thus vitiating the true role of radiotherapy. In structured trials, adjuvant radiotherapy has not been shown to have a major survival impact for upper tract tumors.^{68, 69}

The efficacy of intravesical therapy for bladder cancer led investigators to use these agents in upper

urinary tract tumors. The most common approach has been to place bilateral ureteral stents followed by instillation of cytotoxic agents (usually BCG) via a urinary catheter, as for bladder cancer; however, uncertainty remains as to how well the agents are being delivered upstream. Alternatively, there have been reports of transcutaneous insertion of flexible catheters into the ureters, followed by infusion of agents. Anecdotal data suggest that tumor regression occurs in response to topical delivery of chemotherapy or immunotherapy.

The use of adjuvant intravesical instillation of BCG, doxorubicin, and mitomycin C after endoscopic treatment has been reported, with evidence of anti-cancer effect on tumors in the upper tracts.⁷⁰ These agents have also been delivered via nephrostomy tube after percutaneous treatment. The quality of the data, including length of follow-up, has been variable, but the overall consensus is that relapse and progression can be reduced by this type of treatment. Approximately 30% of patients with upper tract urothelial cancer will develop a recurrence in the bladder, thus requiring long-term cystoscopic surveillance of the bladder for patients with upper tract UC.⁷¹

The considerations for systemic chemotherapy for upper tract urothelial cancers are essentially identical to those pertaining to urothelial bladder cancer.^{45–52} In the past, upper tract tumors were considered to be less responsive than those arising in the bladder. However, there is little evidence to support this, and the international randomized study of MVAC versus cisplatin confirmed similar response rates and survival.⁴⁸ Thus, systemic chemotherapy is covered in detail in the section on chemotherapy for bladder cancer.

Summary

Significant progress has been made in the management of bladder cancer over the past 30 years, with refinement of our understanding of the underlying biology, relevance of gene expression and stem cell function, molecular prognostication, improvement in the nature of surgery, reduction in morbidity of surgery, and rationalization of the role of chemotherapy for advanced disease. There is also a place for bladder conservation via chemoradiation. Despite progress, many patients with metastatic disease die of their disease, and this has led to the search for new systemic therapies, including novel cytotoxics and the assessment of targeted therapies, with agents targeting the MET gene and PD-L1 currently appearing most promising. New agents should be compared against standard regimens in well-structured trials before introduction into routine clinical practice.

Overview

Cancer of the prostate is the most commonly diagnosed nonskin neoplasm and the second leading cause of cancer-related mortality in men in the United States. Considerable advances have been made in screening, diagnosis, and therapy options, particularly in advanced disease, but controversies about the diagnosis and management of prostate cancer, especially in the areas of screening and choice of therapy, continue to evolve. Controversies in advanced disease states have shifted from prognostication to prediction, and current treatment considerations are focused on optimization of sequence or combinations of therapy, determining the role of local control and bone targeting. It is anticipated that addressing these knowledge gaps will lead to an integrated and more effective treatment strategies. Further advances in therapy can be achieved by development of new agents with unique mechanisms of action and rational integration into combination therapies.

Prostate cancer awareness, clinical application of improved biopsy schemes, and advances in imaging combined with the widespread use of prostate-specific antigen (PSA) have resulted in increased detection of prostate cancer. The evolving use of the serum PSA concentration and its change over time have not been paralleled by studies that tested the relevance of those findings until the results of the European Randomized Study of Screening for Prostate Cancer (ERSPC) and the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial were first published in 2009.¹ Though many of the apparent discrepancies between these trials can be accounted for by trial design and patient cross-contamination, they brought to the forefront the dilemma of overdiagnosis and overtreatment and the urgent need to improve the accuracy of clinically significant prostate cancer. It is hoped that replacement of the current morphologic and anatomic classification of prostate cancer with one based on improved understanding of biology will lead to molecular classification and bring closer a personalized management of this complex disease.

Salient features that distinguish prostate cancer from other malignancies and that frame the dilemmas surrounding it are its striking age-dependent incidence, with progressively increasing frequency with increasing age; the variable lethality of morphologically identified cancers; the central role of androgen signaling; and the preponderance of bone-forming metastases on its lethal progression. The important advances made in each of these areas will, in the near future, modify the approaches currently used to prevent, prognosticate, and treat prostate cancer.

Biology of prostate cancer

Normal anatomic and histologic features of the prostate

The prostate gland sits in the pelvis, surrounded by the rectum posteriorly and the bladder superiorly, and

it is anchored to the bladder pelvic floor; the urethra communicates between the bladder and the prostate into the penis ([Figure 1](#)). The prostate is composed of stromal, ductal, and luminal epithelial cells and is organized around branching ducts and individual glands lined with secretory epithelial cells and basal cells.² The secretory epithelial cell is the major cell type in the gland. These androgen-regulated cells produce PSA and prostatic acid phosphatase (PAP). The central role of androgen signaling in prostate cancer biology likely accounts for the utility of PSA and PAP in determining disease status clinically. The vast majority of prostate cancers have cells that share properties with the secretory epithelial cells. Unlike the epithelial cells, the basal cell layer is not directly controlled by androgen signaling. Investigators have suggested that the basal cell population contains the prostate stem cells from which the epithelial cells develop. If correct, this view has obvious implications for the prevention and treatment of all stages of prostate cancer.

Figure 1 Normal prostate anatomy.

As in other human tissues, cells belonging to the neuroendocrine system are also present within the prostate. Neuroendocrine cells contain secretory granules and extend dendrite-like processes between adjacent epithelial cells or toward the acinar or urethral lumina.^{3, 4} A variety of secretory products can be found within the granules, including serotonin, calcitonin, gastrin-releasing peptide, and somatostatin.^{3, 4} Neuroendocrine cells are commonly identified immunohistochemically by the presence of markers such as chromogranin A or synaptophysin in the cytoplasm. They are terminally differentiated cells that are thought to regulate the growth, differentiation, and function of coexisting prostatic cells, but their exact role remains to be fully understood.

The view that the prostate has a lobar pattern has been challenged. McNeal et al.⁵ conducted detailed studies of the normal and pathologic anatomy of the prostate and introduced the transforming concept of anatomic zones rather than lobes to describe the gland. There are four major zones within the normal

prostate: peripheral, central, transition (constituting 70%, 20%, and 5% of the glandular tissue, respectively), and anterior fibromuscular stroma ([Figure 2](#)). The peripheral zone, which extends posterolaterally around the gland from the apex to the base, is the most common site for the development of prostate carcinomas. The central zone surrounds the ejaculatory duct apparatus and makes up the majority of the prostatic base. The transition zone constitutes two small lobules that abut the prostatic urethra and is the region where benign prostatic hypertrophy (BPH) primarily originates. Some reports suggest that transition zone cancers have a lower malignant potential, but other studies report no difference in outcome compared with those originating in the peripheral zone, when controlled for grade and stage.^{6, 7}

Figure 2 Zonal anatomy of the prostate: the three glandular zones of the prostate and the anterior fibromuscular stroma.

Surrounding the gland is stroma, which includes fibroblasts, smooth muscle, nerves, and lymphatic tissue. The roles of stromal–epithelial interactions in prostate physiology and cancer development are being elucidated. Recent insights suggest that these interactions are critical in normal function, and increasing evidence implicates them in prostate carcinogenesis as well. The stromal–epithelial interactions may exert both tumor-promoting and carcinogenesis—and progression—inhibitory effects. Furthermore, the stromal–epithelial interacting pathways implicated in the development of the tumor microenvironment in

prostate cancer progression may be those that are shared by the prostate and bone in their normal development and function.⁸

There are varying distinct anatomic barriers surrounding the prostate. The smooth muscle of the prostatic stroma gradually extends into fibrous tissue that then ends in loose connective and adipose tissue. Of particular relevance is the absence of any semblance of a capsule at the gland's apex and anteriorly. This understanding of anatomic detail allows clinicians to determine the adequacy of prostate surgery by accurately defining the surgical margin with increasing confidence. It also allows the surgical delineation of disease as “organ confined” or “specimen confined.” The organ-confined cancers do not extend beyond the confines of the prostate, whereas specimen confined indicates that the cancer does not extend beyond the cut margins. The distinction between these two terms is important because they are used to determine the adequacy of surgery and inform the use of postoperative radiation therapy in selected patients.

A final anatomic note about the prostate is that Walsh and Donker⁹ described the presence of two neurovascular bundles that pass adjacent to the gland posterolaterally. The neurovascular bundles are essential for normal erectile function, and defining their presence outside of the posterior–lateral prostatic fascia allowed Walsh to develop a “nerve-sparing” radical retropubic prostatectomy procedure that improves the odds of preserving potency.¹⁰

Premalignant prostatic lesions

Paradigms that are used to explain the progression of other solid tumors may not apply to prostate cancer.¹¹ Extensive information about the genetic and epigenetic phenomena associated with prostate cancer progression has been developed recently but has yet to pass the threshold of clinical utility to be truly useful. Many clinicians accept that premalignant lesions existing in the prostate may precede the development of cancer by many years. But given the lack of knowledge about the nature or rate of their progression, the morphologic identification of premalignant lesions on biopsy specimens only serves to provide rationale for close monitoring of patients.

Morphologically heterogeneous lesions are included under the single term prostatic intraepithelial neoplasia (PIN) ([Figure 3](#)).¹² PIN is defined as the presence of cytologically atypical or dysplastic epithelial cells within architecturally benign-appearing glands and acini. Although three different grades have been described, 1 (mild), 2 (moderate), and 3 (severe), grades 2 and 3 PIN are often combined as “high grade” and worthy of note. PIN is presumed to be a premalignant lesion because it is commonly present adjacent to prostate adenocarcinomas.¹³ The finding of PIN is associated with the existence of cancer in sites not sampled on biopsy and implies increased risk of developing a morphologic cancer although the risk of progression has not been established or quantified.

Figure 3 Photomicrograph of high-grade prostatic intraepithelial neoplasia (PIN) with basal cell layer (open arrows) with budding microacinus lacking basal cells (curved solid arrows). A microacinus of invasive Gleason pattern 3 adenocarcinoma is seen in the adjacent stroma (straight solid arrow). Hematoxylin and eosin $\times 160$.

Source: Courtesy of Thomas M. Wheeler, MD.

Prospective studies have been small but have reinforced the hypothesis that PIN is the morphologic manifestation of a precursor lesion to morphologic prostate cancer. The data have suggested that the presence of high-grade PIN predicts the subsequent development of cancer, perhaps through a multistep carcinogenesis process. However, close clinical follow-up remains the standard of care after diagnosis of high-grade PIN alone.

Another lesion that may represent a premalignant change is atypical adenomatous hyperplasia (AAH), although existing data on this are scantier than they are for PIN. The characteristic appearance with AAH is the fulfillment of the architectural criteria for malignancy, with disruption of the basal cell layer, mainly in the transition zone, but without the cytologic changes diagnostic of cancer.¹⁴ Some authors have suggested that a prostatic lesion composed of focal areas of epithelial atrophy associated with chronic inflammation (called proliferative inflammatory atrophy, or PIA) is a precursor of PIN and eventually prostate cancer.¹⁵ Evidence for this hypothesis includes the observation that PIA often occurs adjacent to areas of PIN and prostate cancer¹⁶ and that somatic genetic abnormalities seen in PIA often resemble those seen in prostate carcinoma.¹⁷ Of particular relevance is that PIA implicates inflammation in the progression of prostate cancer.¹⁸ If this hypothesis is confirmed and causally implicated with greater confidence in prostate cancer progression, that finding may lead to more effective prevention strategies.

Histologic features of prostate cancer

Cancers that arise in the epithelium account for >95% of prostate cancers ([Figure 4](#)).¹⁹ The reported low frequency of histologic variants may reflect the fact that frequency determinations of variants are principally derived by the examination of primary cancers, among which the more common forms may be overrepresented. However, less common histologic varieties have been described, including mucinous or signet ring tumors, adenoid cystic carcinomas, carcinoid, large prostatic duct carcinomas (including the endometrial type), adenocarcinomas, and small-cell undifferentiated cancers. These unusual subtypes are reported to occur in low frequencies. Because the histologic variants often present with advanced disease clinically, they are not subjected to surgery as often as the more common forms of prostate cancer. In addition, they occasionally manifest only in metastases during progression, thus in sites not often sampled. As a consequence, we may be underestimating their frequency because of their manifestation. This fact may be particularly important when attempting to estimate the true frequency of small-cell carcinomas of the prostate, which have been reported with increasing frequency.²⁰ Nonetheless, it is important to recognize these unusual variants of prostate cancer because standard hormonal therapies may be less effective in their treatment while they may be more responsive to chemotherapy than the more common type.^{17, 21}

Figure 4 (a) Microscopic histologic appearance of prostate adenocarcinoma. (b) Gross histologic appearance of prostate adenocarcinoma.

Tumors with a neuroendocrine appearance (i.e., carcinoid and small-cell undifferentiated types) may arise from Kulchitsky cells, which are found in the basal regions of the prostatic epithelium.²² Small-cell carcinomas of the prostate share histologic and clinical features with other extrapulmonary small-cell carcinomas. These cancers have been described as a histologic continuum, perhaps in some instances reflecting progression of acinar adenocarcinomas.²³ Thus, these “neuroendocrine” cancers of the prostate are likely to be a mechanistically and clinically heterogeneous grouping. Of importance is that they

predict a specific pattern of anatomic progression: nonosseous visceral spread with lytic bone metastases and the probability of responsiveness to chemotherapy. These are recognized as a unique and aggressive variant of prostate cancer that account for a significant portion of far advanced prostate cancers.

Transitional cell carcinomas involving the substance of the prostate may also be mistaken for prostate adenocarcinoma. It may be difficult to distinguish a transitional cell carcinoma arising in the transitional epithelium of the distal prostatic ducts from a tumor arising in the bladder epithelium and spreading into the contiguous prostatic ducts.

Study findings have confirmed the primary prognostic importance of the degree of histologic differentiation of prostate adenocarcinoma. The degree of this differentiation is typically determined by patterns of gland formation and, less importantly, by cytologic detail. The most widely accepted grading scheme for adenocarcinoma of the prostate is that developed by Gleason ([Figure 5](#)).²⁵ Gleason created a system for classifying prostate tumors based on two levels of scoring that recognize the heterogeneous nature of prostate carcinomas. The primary pattern of differentiation is assigned a Gleason grade of 1 to 5 according to the dominant morphologic features of the specimen and its departure from normal appearance; the next most common pattern is also assigned a grade. This results in a two-digit score; for example, $3 + 4 = 7$. The Gleason system has been criticized for inadequately recognizing the proportion of the tumor that is composed of the secondary pattern as well as for lacking adequate distinction between good and poor prognoses in patients whose cancers have Gleason scores of 5–7 (most patients). However, the reproducibility and reliability of Gleason grading between pathologists have consistently been shown to be excellent. Gleason's original work demonstrated a clear association between a higher score and a higher mortality rate, which others have since confirmed.²⁶ Many other predictors of the clinical behavior of prostate cancer have been explored, but the Gleason score still remains the most broadly applicable and prognostically useful histologic grading system.

Molecular pathogenesis

Unlike the case of breast cancers, in which clinically relevant subsets of cancer have been identified on the basis of molecular profiles, the morphologic characterization of prostate cancer remains the standard.²⁷ Prostate cancer cells harbor a number of somatic mutations, and in advanced disease, additional alterations accumulate. Alterations that affect the development and progression of prostate cancer include those in the hormonal and growth factor milieu, in hormonal and growth factor receptors, in intracellular signaling pathways, and in cell cycle regulation and apoptosis. The identification of chromosome 8q24 as a susceptibility locus supports the hypothesis that a significant portion of prostate cancers have genetic origins.²⁸

Technological advances in genome sequencing made possible to identify germline mutations that have been linked to increased risk of prostate cancer. The *HOXB13 G84E* variant is the first *bona fide* prostate cancer susceptibility gene to be identified. In a study of 94 unrelated patients, the *HOXB13 G84E* variant was associated with a significant risk of early-onset hereditary prostate cancer.²⁹ Additionally, germline *BRCA1* and *BRCA2* mutations confer high risk of prostate cancer and prognostic of more aggressive

prostate cancer.³⁰ However, these germline mutations have not yet translated into therapeutic relevance. The hormonal and growth factor milieu to which the prostate is exposed has been consistently associated with the pathogenesis of cancer. In population-based studies, two hormones have been implicated: testosterone and insulin-like growth factor I (IGF-I). The association between testosterone and prostate cancer progression is well known. Several lines of evidence also suggest that IGF may be important in prostate cancer growth. First, several prostate cancer cell lines and prostate xenograft models express both IGFs I and II and their receptors.^{31, 32} Second, Chan et al.³³ reported on the relationship between plasma IGF-I concentration and prostate cancer, citing a relative risk of 4.3 for men in the highest quartile, compared with men in the lowest quartile. Moreover, a higher incidence of prostate cancer has been noted in patients who had relatively high IGF-I concentrations in plasma samples that had been obtained 5 years prior to the cancer diagnosis,³⁴ supporting the concept that IGF-I may be important early in the development of prostate cancer. Although this observation has yet to be confirmed, it does implicate IGF-I signaling in prostate cancer progression. It is likely that growth factor and other stromal–epithelial interacting pathways cooperate in prostate cancer progression. Thus, a simple model centered on a single pathway is unlikely to lead to the understanding of human prostate cancer. Other growth factors—including epidermal growth factor, vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor beta (TGF- β)—may also be dysregulated in the development of prostate cancer ([Table 1](#)).³⁵

Table 1 Growth factors implicated in prostate cancer

Transforming growth factor beta
Fibroblast growth factor
Epidermal growth factor
Insulin-like growth factor
Platelet-derived growth factor
Vascular endothelial growth factor
Neurotensin
Endothelins
Colony-stimulating factors

The central role of androgen signaling in an endocrine fashion has dominated the understanding of the pathway in prostate cancer. It is clear that androgens are a major mediator of progression, though their role in prostate cancer susceptibility remains poorly understood. In fact, several hormonal receptors are altered in prostate cancer cells. Perhaps the best example is alterations in the androgen receptor (AR). In early cancer, AR mutations are relatively uncommon,³⁶ but germline variation (CAG repeats) in the AR gene has been shown to be a predictor of cancer aggressiveness³⁷ and may play a role in the frequency and aggressiveness of prostate cancer in African-Americans.³⁸ It is interesting that AR mutations are more commonly seen in androgen-independent (castrate-resistant) prostate cancer,^{36, 39} arguing that the AR gene remains central in the growth and survival of prostate cancer even after the need for the ligand (androgens) has been mitigated. Several theoretical frameworks have been proposed for the development of androgen independence, most of which still postulate a cancer cell that depends on a functional AR but one that is amplified, oversensitive, promiscuous, or activated by upregulated coactivators or downregulated by corepressors.⁴⁰ For example, in LNCaP prostate cancer cells, an AR mutation, T877A,

which is a substitution of alanine for threonine at position 877, results in an AR that is activated by other steroid hormones and by the androgen antagonist flutamide.⁴¹ This AR mutation could help explain the “antiandrogen withdrawal syndrome.” However, AR mutations occur too infrequently to account for the eventual evolution of most metastatic prostate cancers to a castrate-resistant state.

AR splice variants have been identified in prostate cancer. AR splice variants lacking the ligand-binding domain (ARVs), originally isolated from prostate cancer cell lines derived from a single patient, are detected in normal and malignant human prostate tissue, with the highest levels observed in the late stage, castrate-resistant prostate cancer (CRPC). Approximately 20 AR splice variants have been identified to date, and they are not exclusively found on prostate tissue. The first AR splice variant was identified in the placenta. “The most studied variant (called AR-V7 or AR3) activates AR reporter genes in the absence of ligand and therefore, could play a role in castration resistance.” Correlative studies have associated the presence of ARV7 in prostate cancer-infiltrated bone marrow biopsies and circulating tumor cells from patients with metastatic CRPC who have primary resistance to novel androgen signaling inhibitors abiraterone acetate (CYP17 inhibitor) and enzalutamide (second-generation antiandrogen).^{42, 43}

Recent observations support the view that “intracrine” production of androgens acting in both autocrine and paracrine fashion are implicated in the progression of prostate cancer. Several lines of evidence support the concept that CYP17 lyase is implicated in remodeling the prostate cancer tumor microenvironment: androgens in the microenvironment are at a higher concentration than they are in the serum, CYP17 expression occurs in stage-dependent cancer progression, and tumor regression occurs clinically in castrate-resistant cancers. These data support the hypothesis that androgen signaling can be considered a stromal–epithelial interacting pathway. Difficulty in measuring the concentration of androgens in the local microenvironment continues to plague this concept, and although it is appealing, it remains unproven.

True androgen independence is likely to arise from alternative stromal–epithelial interacting or other signaling pathways. Several bone and prostate development pathways have been noted to be involved in prostate cancer progression and to be associated with higher-grade cancers.⁴⁴ This attractive hypothesis could account for the bone-homing and bone-forming phenotype of prostate cancer and for its resistance to therapy in an organ-specific manner.

Molecules that alter intracellular signaling pathways also may be important in the pathogenesis and progression of prostate cancer to a castrate-resistant state. The clearest example to date is the tumor suppressor gene *PTEN*. This gene encodes for a phosphatase that is important in modulating the signal generated by activated growth factor receptors. Somatic mutations in *PTEN* occur at high frequency in prostate carcinoma cells, suggesting this as a frequent target for inactivation. One study documented a 60% rate of *PTEN* mutations; most of these were found in cell lines from metastatic disease, although mutations were also seen in primary cancers.⁴⁵ In fact, another group demonstrated higher rates of *PTEN* loss or mutation in tumors of advanced stage and grade.⁴⁶ Another pathway that may be inappropriately activated in prostate cancer is the hedgehog pathway. Normal hedgehog signaling is important in early development and patterning of the prostate epithelium. Recent work by Karhadkar et al.⁴⁷ demonstrated that activation of the hedgehog pathway distinguishes prostate cancer from normal prostate cells and, further, metastatic prostate cancer from localized cancer. Moreover, they demonstrated that hedgehog pathway inhibition results in PC3 xenograft regression. Both the *PTEN* and hedgehog pathways are therefore attractive targets for drug development.

Small-cell prostate carcinomas, which often emerge during the progression of CRPC, have garnered much attention in recent times as a model of primary and possibly secondary resistance to AR-directed

therapies. Most small-cell prostate carcinomas lack markers of prostatic luminal differentiation such as AR, PSA, PSAP, PSMA, and p501s.^{48–56} Instead of these, they often express markers that are characteristic of neural progenitor cells, such as ASCL1, POU4F2, and MYCN.^{50, 57, 58, 59} A decrease in the expression of RE-1-silencing transcription factor (REST), a master repressor of neuronal differentiation, has been proposed as a mechanism involved in this transdifferentiation.^{60, 61} In addition, small-cell prostate carcinomas are characterized by high Ki67 staining and high levels of expression of genes involved in cell cycle and mitosis, including AURKA, AURKB, PLK1, and UBE2C.^{58, 60, 62} It is noteworthy that concordant AURKA and MYCN amplification has been found in approximately 40% of small-cell prostate carcinomas⁵⁸ and that REST knockdown resulted in a derepression of cell cycle genes in prostate cancer models⁶¹ supporting a connection between the aberrant neural development and mitotic programs. Finally, small-cell prostate carcinomas have also been shown to bear frequent Tp53 mutations^{49, 50, 51, 63, 64, 65} as well as RB1 and PTEN losses and a high rate of copy number alterations.^{50, 58, 62, 63, 65, 66}

Finally, alterations in molecules that regulate the cell cycle and apoptosis offer promising avenues for further investigation. TP53, p27, p21, and Rb have been studied, and the results have provided variable levels of evidence that they participate in the pathogenesis of prostate cancer.⁶⁷ Of particular relevance is that each of these molecules has been reported by some investigators to serve as prognosticators. The utility of these molecules as independent prognosticators or as part of a signature has yet to be prospectively validated. Signatures that predict disease recurrence after surgery have yet to find a role in the clinic.⁶⁸

Early detection of prostate cancer

Early detection of prostate cancer, when it remains confined to the prostate, brings patients and their physicians face to face with the controversial question of how localized disease may best be managed, that is, how patients can avoid overtreatment and preserve quality of life while simultaneously escaping from life-threatening disease.

Prostate cancer screening and early detection themselves are controversial because for every 18 cases detected, only 3 will result in death. The cost of radical prostatectomy, which removes the threat of disease if there is no metastasis, may be the risk of impotence and urinary incontinence, which might affect these disease-specific quality-of-life domains.⁶⁹ To determine whether screening for prostate cancer and three other cancers reduces mortality, the National Cancer Institute's (NCI's) Division of Cancer Prevention undertook the randomized, controlled PLCO Screening Trial at 10 sites in 1993. The prostate screening arms have been published with commentary.^{1, 70} Participants underwent annual PSA screening examinations for 6 years and follow-up of 13 years for the latter publication.^{71, 388}

With a sample size of 76,685 men allocated to intervention (38,340) or control (38,345), the extended follow-up diagnosed 4250 cancers in the intervention arm and 3815 in the control. These events corresponded to 158 deaths in the intervention arm and 145 in the controls. The key conclusion was that PSA screening increased detection but did not affect mortality. A common critique of this study as echoed by Smith⁷⁰ was significant contamination in the arms in the form of noncompliant screening in the intervention arm and opportunistic screening in the control arm.

Also launched in the 1990s was the ERSPC, which is also testing whether screening saves lives. It was published along with the PLCO trial in 2009. Updated results truncated at 11 years and at 13 years.^{71, 72} In this trial, there was significantly less contamination of the arms. The ERSPC's results showed a

significant relative reduction in prostate cancer mortality by 21% and 29% after adjustment for noncompliance.³⁸² To prevent one death, the number needed to be screened was 1055 and to detect was 37. The additional follow-up time improved the screening metrics as expected. The authors caution that all-cause mortality was not affected and that overdiagnosis/overtreatment remains a problem with PSA screening.³⁹⁸ The trial is often criticized in its design as not a unified multicenter study but rather a merger of several screening studies with differences in methodology and outcomes. As a result, the US Preventive Services Task Force (USPSTF) has issued a “D” rating for PSA screening (discourage the use of this service), yet this remains highly controversial.^{73, 74}

Identifying early disease using PSA and PSAV

Strategies to manage the diagnosis of localized prostate cancer include watchful waiting, radical prostatectomy, and radiotherapy and will result in superior recurrence-free outcomes at earlier stages of intervention. The early detection of prostate cancer debate has centered around using absolute PSA cutoffs versus prostate-specific antigen velocity (PSAV) or PSA isomers. The PSAV, one measure used in monitoring patients with localized disease, has been scrutinized as a tool for use in the diagnosis and prediction of outcomes. It is calculated using the log slope of at least three PSA values calculated over at least 2 years with no less than 6 months between measures.⁷⁵ Conceived as a way to capture the variability of prostate cancer or its progression, PSAV measures are used preoperatively and postoperatively. Researchers sometimes rely on measures taken closer together, consider fewer than three measures, and reduce the longitudinal period to less than 2 years.

Prostate cancer screening can be oversimplified into an algorithm in which all patients with a certain threshold of PSA (e.g., 2.5 or 4.0 ng/mL) or abnormal digital rectal exam (DRE) findings are referred to a urologist for evaluation and possible biopsy. However, patients' overall interests are better served if a more comprehensive evaluation takes place that considers whether they are at increased risk of having prostate cancer because of ethnicity (e.g., African-Americans are at increased risk), age, and/or family history and whether a prostate cancer diagnosis would be likely to affect their overall survival because of a younger age and fewer competing comorbid conditions. A comprehensive PSA history may be beneficial for calculating PSAV, and the complexed PSA test may be useful as a frontline screening tool because it has slightly better specificity than total PSA in the total PSA range of 2.5–4.0 ng/mL.⁷⁶

The PSA blood test has been described as a test that “neither excludes benign disease nor wholly predicts meaningful malignancies.”⁷⁵ Ian Thompson, principal investigator of the Prostate Cancer Prevention Trial (PCPT), and his colleagues studied 8575 men from the study's placebo group to estimate the receiver operating characteristic (ROC) curve for PSA and concluded that no absolute cutoff value had the high degree of sensitivity and specificity simultaneously required for identification of a risk-free value.⁷⁷ Instead, they endorsed viewing all PSA values as a continuum of risk for prostate cancer.⁷⁷

Single measures of PSA performed on blood samples taken decades before a patient's diagnosis have been statistically associated with levels of risk and have garnered great attention because of their apparent simplicity and efficiency and their ability to stratify patients for screening, but their reliability awaits verification.^{78, 79} These studies relied on blood samples drawn from 21,277 men in Sweden from 1974 to 1986 and on Sweden's cancer registry. From among these samples, prostate cancer diagnoses and blood samples were ascertained for 462, who were matched to controls. The median PSA level was about 0.6 ng/mL in the low-risk group. These investigators' most recent work bases prediction of cancer risk on a single PSA test before age 40.⁷⁹ Although the USPSTF recommended against PSA-based screening for prostate cancer in 2012, under the Affordable Care Act, for men over age 50 with Medicare

PSA, the test is covered every 12 months.

More widely investigated have been measures of PSAV, a calculation of rising PSA level that was introduced in the early 1990s as a marker of prostate cancer development, a means to reduce unnecessary biopsies, and a way to improve the specificity of PSA testing. However, current standards that shorten the minimum longitudinal monitoring period for calculating PSAV and push ever lower the levels of PSAV considered worrisome (now 3.5 ng/mL/year in men with a PSA <4 ng/mL in one algorithm) actually increase the likelihood of biopsy.^{80–83} Cautious investigators⁸² argue that to use PSAV to monitor men with a PSA <4 ng/mL, it is necessary to have evidence that such measures ensure that enough cases will be detected within the “window of curability” to make them worthwhile and that the financial and emotional costs of overdiagnosis will not undermine other advances. They also point out that relying on findings about PSAV in undiagnosed cases, which have been largely lacking, would be very different from relying on posttreatment PSAV findings and applying them to the detection setting. They and others have said that prospective studies are needed.^{82, 84}

An early study on the PSAV was one of men enrolled in a geriatric trial. Carter et al.⁸⁰ concluded that in men with PSA values <4 ng/mL, a PSAV <0.75 µg/mL/year indicated absence of prostate cancer and a PSAV ≥0.75 µg/mL/year indicated its presence. In a work published 15 years later, Krejcarek et al.⁸⁵ reported that in the undiagnosed patients they studied who had PSAV values <1.0 ng/mL/year, only 6% of those younger than 70 years with cT1c disease had high-grade cancer; however, they found that a median PSAV value of 2.71 ng/mL/year, age, and clinical T stage were significantly related to high-risk disease (Gleason score 4 + 3). Because these subjects had undergone radiotherapy, the findings are not generalizable to patients treated with other therapeutic modalities. The study by Krejcarek et al. was a retrospective evaluation in 358 men to identify those at higher risk, so they could improve outcomes by adding androgen-suppression therapy to radiotherapy and by improving the selection of radiotherapy fields.

A prospective trial conducted at the Royal Marsden Hospital and reported in 2008 studied 237 patients enrolled in an active surveillance trial who had a median PSA level of 6.5 ng/mL at the outset and a median pretreatment PSAV of 0.44 ng/mL/year.⁸⁶ The investigators determined that PSA density was a statistically significant independent determinant of PSAV in untreated patients: those with a PSA density measure >0.185 ng/mL had a median PSAV of 0.92 ng/mL/year, and those with a PSA density measure <0.185 ng/mL had a median PSAV of 0.35 ng/mL/year. Because PSA density is a measure available at the outset of diagnosis and does not require longitudinal data collection, it will be a more efficient marker than PSAV is if others confirm this finding.

As a recent commentary by Vickers et al.⁸⁷ points out, the use of PSAV in prostate cancer early detection and management of clinically localized disease is questioned. The main arguments against PSAV are lack of clinical utility that it does not add to established predictors of prostate cancer diagnosis, methodologic variability, and it being a poor prognosticator for mortality after conservative management and after prostatectomy.

Staging of prostate cancer

Staging of cancer, which is integral to the treatment decisions that follow, comprises initial clinical staging based on findings from physical examination of the patient and diagnostic tests and pathologic staging based on findings at surgery and on subsequent pathologic study of the removed prostate gland and other tissues. Less definitive than pathologic staging, clinical staging relies on palpation of the prostate;

imaging studies, which for patients at low and intermediate risk are sometimes omitted; and needle biopsy results. Physicians can combine the clinical staging with two other significant prognostic factors, the Gleason score and the preoperative PSA value, to classify the case according to the D'Amico system, as low, intermediate, or high risk.⁸⁸ This system was first described in 1998 in the report of a retrospective study in which D'Amico et al. evaluated 1872 men with prostate cancer who had been treated with radical prostatectomy, external beam radiotherapy, or radioactive implant with or without neoadjuvant androgen-deprivation therapy. In that study, clinical staging was based on DRE findings alone (American Joint Committee on Cancer tumor stage⁸⁹). The researchers found that with that system, men who had been classified as being at low or intermediate risk had outcomes that were not statistically significantly different from others within their class. Most of this reliability is probably attributable to the Gleason score and the PSA level.

In the staging of prostate cancer, physicians rely on the tumor, node, and metastasis (TNM) system of the American Joint Committee on Cancer to classify cases⁸⁹ ([Table 2](#)). It reports the extent of the tumor (T), the presence or absence of disease in the regional lymph nodes (N), and the extent of metastasis (M). In a second step of the staging process, the Gleason score is combined with the TNM classification, and cases are identified as stage I, II, III, or IV, progressively representing advances in the extent of disease⁸⁹ ([Table 3](#)).

Table 2 TNM clinical and pathologic staging of prostate cancer

	Clinical stage		Pathologic stage
<i>Primary tumor</i>			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Clinically inapparent tumor neither palpable nor visible by imaging		
T1a	Tumor incidental histologic finding in 5% or less of tissue resected		
T1b	Tumor incidental histologic finding in more than 5% of tissue resected		
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)		
T2	Tumor confined within prostate ^a	pT2 ^b	Organ confined
T2a	Tumor involves one half of one lobe or less	pT2a	Unilateral, involving one-half of one lobe or less
T2b	Tumor involves more than one-half of one lobe but not both lobes	pT2b	Unilateral, involving more than one-half of one lobe but not both lobes
T2c	Tumor involves both lobes	pT2c	Bilateral disease
T3	Tumor extends through the prostate capsule ^c	pT3	Extraprostatic extension
T3a	Extracapsular extension (unilateral or bilateral)	pT3a	Extraprostatic extension ^d
T3b	Tumor invades seminal vesicle(s)	pT3b	Seminal vesicle invasion

T4	Tumor is fixed or invades adjacent structures other than seminal vesicles: bladder neck, external sphincter, rectum, levator muscles, and/or pelvic wall	pT4	Invasion of bladder, rectum
<i>Regional lymph nodes</i>			
NX	Regional lymph nodes were not assessed	pNX	Regional nodes not sampled
N0	No regional lymph node metastasis	pN0	No positive regional nodes
N1	Metastasis in regional lymph node(s)	pN1	Metastasis in regional nodes
<i>Distant metastasis^e</i>			
MX	Distant metastasis cannot be assessed (not evaluated by any modality)		
M0	No distant metastasis		
M1	Distant metastasis		
M1a	Nonregional lymph nodes		
M1b	Bone(s)		
M1c	Other site(s) with or without bone disease		

^a Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c.

^b There is no pathologic T1 classification.

^c Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.

^d Positive surgical margin should be indicated by an R1 descriptor (residual microscopic disease).

^e When more than one site of metastasis is present, the most advanced category (pM1c) is used.

Table 3 Prostate cancer stages

Stage	TNM classification and Gleason score
I	T1a, N0, M0, Gleason score 1
II	T1a, N0, M0, Gleason score 2, 3–4
	T1, T1b–T2, N0, M0, any Gleason score
III	T3, N0, M0, any Gleason score
IV	T4, N0, M0, any Gleason score
	Any T, N1, M0, any Gleason score
	Any T, any N, M1, any Gleason score

Prostate cancer is the most commonly diagnosed cancer in US men, with the exception of skin cancers and in situ cancers.⁹¹ About 3/4 of US men report having been screened at least once, and early prostate cancer, because it has no symptoms, is often diagnosed in outpatient settings. Distinguishing between high-

and low-risk localized prostate cancer, maximizing disease control and survival, and avoiding overtreatment, especially in men likely to die of comorbidities, are challenges physicians who treat these men face daily.⁹²

The American Urological Association has characterized localized disease into three risk categories⁹³ (Table 4). Low-risk disease is generally characterized by a PSA value ≤ 10 ng/mL, a Gleason score ≤ 6 , a lack of symptoms, and absence of both diseases in the lymph nodes and metastases (i.e., clinical stage T1c or T2). Disease is nonpalpable on DRE, but evidence of tumor may be detected by a transurethral resection of the prostate (TURP) performed because of what was thought to be BPH or by needle biopsy prompted by a high PSA level. PSA values >10 ng/mL but ≤ 20 ng/mL and/or a Gleason score of 7 (3 + 4 or 4 + 3) are associated with intermediate risk. PSA values >20 ng/mL and/or Gleason scores of 8–10 indicate high-risk cases.

Table 4 Risk stratification for localized prostate cancer

Risk level	PSA level (ng/mL)		Gleason score		Clinical stage
Low	≤ 10	and	≤ 6	and	T1c or T2a
Intermediate	>10 –20	or	7	or	T2b but not qualifying for high risk
High	>20	or	8–10	or	T2c

It is noteworthy that there is intense interest in further staging prostate cancer with endorectal coil magnetic resonance imaging (MRI) with multiparametric (mp) techniques.⁹⁴ Studies have shown that a suspicious lesion on MRI is an independent risk factor for adverse pathology after radical prostatectomy.⁹⁵ On the other hand, a normal lesion or one of low suspicion on mpMRI has a high negative predictive value for clinically insignificant disease.⁹⁶ Neither MRI nor any other imaging modality is incorporated into the clinical risk groups for localized disease, nor staging of the primary tumor.

Validated pretreatment nomograms that combine PSA, Gleason score, and clinical stage have been developed to give estimates of pathologic stage, which may be valuable to clinicians planning treatment.^{97–100} In a 2007 update of the Partin tables, Makarov et al.¹⁰⁰ analyzed 5730 men who had undergone prostatectomy between 2000 and 2005 at Johns Hopkins Hospital and confirmed that, as these researchers had previously shown, clinical stage contributes significantly to the prediction, as do PSA level and Gleason score, and that cumulatively they are better predictors than any one alone. No patient's disease was clinically staged higher than T2c, and at prostatectomy, almost 75% had disease confined to the prostate. None of the 123 of 164 patients with a clinical Gleason score ≥ 8 who had a workup was found to have metastatic disease. In their series, as in others, the proportion of men presenting with organ-confined disease has been increasing: 54% in 1993,⁹⁷ 48% in 1997,⁹⁸ 64% in 2001,⁹⁹ and 73% in 2007 (year of publication).¹⁰⁰ New in this series was the absence of Gleason scores of 2 to 4, reflecting pathologists' belief that such scores represent sampling error.¹⁰¹ Among patients with higher clinical stage, the authors reported a trend toward more accurate staging in their 2007 report over that in 2001 and perhaps indicating a broader need for surgery in those patients with higher clinical stage and Gleason scores. A 2013 update to the tables confirms a similar distribution of pathologic stage, updated Gleason scoring, and a more contemporary prognosis.^{67, 68}

Following up on previous work to improve the accuracy of identifying cases of low-volume, low-grade

disease,^{102, 103} researchers at The University of Texas M.D. Anderson Cancer Center have refined a nomogram specifically for identifying men for active surveillance.¹⁰⁴ This nomogram includes age, PSA density, and tumor length in a biopsy core. The low number of factors, the ease in ascertaining their values with only laboratory tests and extended biopsy, and their nonsubjective nature combined with an area under the curve (AUC) measure indicating good discriminatory power (i.e., 0.727) make this nomogram attractive. The authors admitted that they cannot explain why their analysis indicates that older age would reduce the probability of low-volume, low-grade cancer and that younger men with values appropriately low in the other categories would be good candidates for surveillance. Nonetheless, their work offers for validation a new, practical tool for identifying these low-risk men.

Including a molecular marker as a predictor is another way investigators have attempted to improve a nomogram's accuracy. PCA3, a prostate-specific noncoding mRNA, is readily detected in urine when prostate cancer is present because it is overexpressed 60- to 100-fold 90% of the time.¹⁰⁵ Deras et al.¹⁰⁵ undertook a prospective, multisite study of 570 men immediately before they underwent prostate biopsy and found PCA3 to be reliably sensitive and specific across PSA values <4 and >10 ng/mL and across various values of prostate volume and number of prior biopsies. Overall, PCA3 sensitivity was 54% (95% CI 0.49–0.59) and specificity was 74% (95% CI 0.71–0.77).

Staging is meant to refine the risk of oncologic end points and can be augmented with commercialized genomic prognostic biomarkers taken from biopsy specimens. Cuzick et al.¹⁰⁶ reported a panel of cell cycle progression (CCP) genes known from breast cancer studies and validated them in a cohort of patients managed conservatively. The CCP score, a numerical representation of average CCP gene expression compared to a housekeeping gene panel, was statistically superior in predicting 10-year mortality rates compared to clinical features. Another panel of genes was validated by Klein et al.¹⁰⁷ that mixed several pathways (stromal response, androgen signaling, proliferation, and organization) and linked elements in a small sample of a prostate biopsy with long-term radical prostatectomy outcomes. The development and validation efforts have created a genomic score that estimates adverse pathology (Gleason $\geq 4 + 3$ and/or pT3 stage) at radical prostatectomy, from patients with favorable biopsy findings (Gleason 3 + 3 to 3 + 4). Both biomarkers have strong statistical validation but need additional studies on clinical utility impact such as changing recommendations between active surveillance and immediate treatment and correlating such decisions with superior oncologic and quality-of-life outcomes. The theme of disease prognosis from genomics can continue into the postradical prostatectomy space, CCP score in this setting will predict for biochemical recurrence rates along with clinical features, and another genomic classifier (commercialized as Decipher, GenomeDx, San Diego, CA) specifically estimates early metastatic progression from patients with known high-risk pathology. [Table 5](#) compares key clinical end points, clinical utility, and cost.

Table 5 Comparison of key features of three commercialized genomic tests for prostate cancer.¹⁰⁸

	Decipher	Oncotype DX	Prolaris
Tissues tested	RP for high risk—pT3, positive margin, PSA rise	Biopsy—for NCCN very low to intermediate risk	Biopsy or RP
Clinical end points	Early regional nodes or bone metastasis	Risk of unfavorable pathology—pT3 and/or ≥ Gleason 4 + 3	Biopsy—10-year mortality with conservative management RP—biochemical recurrence risk
Clinical utility	Adjuvant/salvage therapy	Active surveillance or immediate therapy	Biopsy—active surveillance or immediate therapy RP—adjuvant/salvage therapy
Cost (USD)	4250	3825	3400

RP, radical prostatectomy; pT3, pathologic stage with extraprostatic extension and/or seminal vesicle invasion; PSA, prostate-specific antigen; NCCN, National Comprehensive Cancer Network; USD, United States Dollar equivalent.

Imaging of prostate cancer

Although bone and CT scan are standard imaging tools to establish metastatic disease, the staging and detection tasks have been only modestly assisted with T2 weighted MRI. Recently, the addition of novel imaging sequences such as diffusion weighted imaging and dynamic contrast-enhanced imaging together with the T2 weighted images can combine to form an “mp” sequence. There is renewed interest in the MRI for the purposes of either advanced screening (i.e., prior negative biopsy with rising PSA) or enhanced staging (i.e., estimating if a patient with low-volume/low-grade disease is likely to be harboring undiagnosed higher-grade/volumes of disease).¹⁰⁹

Novel software/hardware packages are commercially available that allow the biopsying physician to “fuse” MRI suspicious lesions with the otherwise normal ultrasound images.¹¹⁰ These additional “targeted” biopsies lead to novel metrics in prostate detection such as increase in tumor upgrading and/or volume measurement per core of tissue. MRI/fusion biopsies, however, do not appear sensitive enough to omit standard extended core biopsies, consisting of random sampling by zone: right and left apex, mid, base, and lateral horns for at least 10–12 cores. Although these systematic biopsies appear necessary to detect some MRI invisible lesions, the targeted cores are more likely to detect higher-grade tumor and omit low-grade detection. In a recent prospective cohort study of 1003 men undergoing both MR/fusion biopsy and standard (sextant) biopsy, targeted biopsy detected 30% more high-risk (Gleason score ≥4 + 3) and 17% fewer low-risk prostate cancer.¹¹¹

Although these conclusions are exciting in the field, the technique and standardization of the imaging have a way to go before being standard. As Emberton¹¹² commented more than a million biopsies are performed annually in Europe, and if each one would be MRI driven, there would be significant logistical needs to build out proper equipment, technique, and training. In addition, the standardization of reporting is newly reported and ongoing in clinical adoption.^{113, 114} The current state-of-the art programs are selecting patients for active surveillance or prior negative biopsy/rising PSA for MRI/fusion biopsy and combining teams of dedicated urologist and urologists to advance this exciting new field. The significance will be fewer patients with false negative biopsies and few patients incorrectly selected for active surveillance. Additionally, further prospective studies are needed to evaluate predictive value of

this technology for clinical outcomes (e.g., disease reclassification in active surveillance, prostate cancer specific mortality).

Therapy options and applications

Active surveillance

In the pre-PSA era, “watchful waiting” implied an alternative to active treatment and described a period when patients were monitored but not treated until the disease progressed and/or symptoms developed. With the advent of PSA testing, a paradigm shift occurred, in which we now diagnose considerably more early prostate cancers, including those destined to remain clinically insignificant. New strategies are needed for managing select cases of low-risk prostate cancer without imposing immediate therapy. Such an approach has been called different terms, including “watchful observation with selective delayed intervention”¹¹⁵ and “active surveillance.”¹¹⁶ This new strategy is to forego immediate treatment but closely follow patients with low-risk prostate cancer, pursuing early detection of tumor progression when the disease is still curable and initiating definitive therapy appropriately. For this strategy to fulfill its promise, two clinical tools are mandatory: a method of identifying a priori patients harboring small low-grade, indolent tumors and a surveillance strategy that reliably detects tumor progression when the disease is still curable. Data supporting conservative management of cases with clinically localized prostate cancer can be gleaned from population-based studies^{117, 118} and a meta-analysis.¹¹⁹ These pre-PSA era studies had a preponderance of older patients and patients with clinically evident cancers; therefore, their results cannot be directly extrapolated to the PSA-screened population. Other problems included the way patients had been diagnosed—many had not undergone a full workup for metastasis, and for many, diagnosis was based on fine-needle biopsy results¹¹⁸—and the fact that the researchers did not centralize pathology review.¹¹⁷ Despite their limitations, these observational studies showed that men with low-grade prostate cancer have a protracted course of indolent disease and a very small risk of disease-specific death, even after 20 years of follow-up.¹²⁰

In contrast, the risk of death from disease progression is higher for men with Gleason scores of 7–10. Watchful waiting and prostatectomy were compared prospectively in an important study by Swedish investigators who followed up their initial report with further analyses 3 years later and an estimated 15-year results.^{78, 121, 122} The researchers studied 695 men with T0d, T1b, T1c, or T2 disease who were randomly assigned to undergo radical prostatectomy ($n = 347$) or watchful waiting ($n = 348$). Two-thirds had palpable tumors, but fewer than half in each group—43.8% of those undergoing prostatectomy and 39.7% of those assigned to watchful waiting—had symptoms. In the recently reported extended 23.2 years of follow-up analysis,⁷⁹ the investigators observed statistically significant differences at 18 years of follow-up between those who underwent prostatectomy and those who were not treated until androgen-deprivation therapy was used [42.5% vs 67.4%, RR 0.49 (95% CI 0.39 to 0.60; $P < 0.001$)], distant metastasis developed [26% vs 38.3%, RR 0.57 (95% CI 0.44 to 0.75; $P < 0.001$)], and disease-specific mortality occurred [17.7% vs 28.7%, RR 0.56 (95% CI 0.41 to 0.77; $P = 0.001$)]. The benefit from prostatectomy was confined to men younger than 65 years of age. Also, it is important to note that a large proportion of men in the watchful waiting arm did not require any palliative treatment. Whether these findings would be replicable in a US study population is unknown because prostate cancer is typically diagnosed earlier here than it is in Sweden.¹²³ The Prostate Cancer Intervention versus Observation Trial¹²⁴ conducted in the United States compared prostatectomy with watchful waiting in 731 of mostly screened men with localized prostate cancer and life expectancy of at least 10 years. At median follow-up of 10 years, there was no significant statistical difference in all-cause mortality and prostate cancer-

specific mortality between the two groups. There was trend toward lower prostate cancer-specific mortality with surgery among men with PSA levels >10 ng/mL and subgroups with higher-risk cancers. In fact, for men with low-risk prostate cancer, there was nonstatistically significant increase in prostate cancer-specific mortality by 15%. Two of the longest-running prospective cohort studies have examined the feasibility of active surveillance, or expectant management. Additionally, there are other large cohort prospective studies underway.¹²⁵ Carter et al.¹²⁶ studied 81 men believed to have T1c low-volume prostate cancer for a median of 23 months (range 12–58 months). Their median age was 65 years (range 52–73 years). At baseline, all men had a PSA density ≤ 0.15 ng/mL/cm³ and a Gleason score of <7 . Free PSA in the men was a median of 17% (range 4.3–37%). Every 6 months, subjects underwent PSA measurement (both free and total) and DRE. Every 12 months, patients underwent transrectal ultrasound-directed biopsy, including evaluation of at least 12 cores. After at least 1 year in the study, 56 (69%) of the men were free of progression and still on surveillance. The other 25 men (31%) met the criteria of progression, which were adverse findings on prostate needle biopsy, including a Gleason score ≥ 7 , any Gleason pattern of 4 or 5, more than two cores with cancer involvement, or 50% cancer involvement in any core. Their median time to disease progression was 14 months (range 12–52 months). The researchers found that in men who experienced progression by their definition, the PSA density was statistically significantly higher and the free PSA value statistically significantly lower than those values in men who did not experience progression.

In a larger phase II study, Klotz¹²⁷ reported findings on 299 men who at baseline had prostate cancer of grade T2b or lower, a PSA of <15 ng/mL, and a Gleason score ≤ 7 . All subjects were older than 70 years. Surveillance included PSA measures, serial bone scans, transrectal sonography (every 6 months for first 2 years and then annually thereafter), and biopsy within 1.5 or 2 years of entering the trial. Criteria for progression were that patients demonstrate PSA, clinical, and histologic disease progression. PSA progression was defined as having a PSA doubling time of <2 years (measured at least three times during a minimum of 6 months), a final PSA of >8 ng/mL, and a regression analysis of $\ln(\text{PSA})$ on time $P < 0.05$. Clinical progression was defined as one of the following: doubling of the product of the maximum perpendicular diameters of the primary lesion (measured digitally), TURP necessitated by local progression, ureteral obstruction, or clinical or radiologic evidence of distant metastasis. Histologic progression was defined as a Gleason score ≥ 8 at subsequent biopsy. At 55 months, 60% remained on surveillance; at 96 months, disease-specific survival was 99%, and overall survival was 85%. Thirty-five percent had a PSA doubling time of >10 years (median doubling time 7.0 years). Reasons for abandoning surveillance included patient preference (16%), rapid biochemical progression (12%), clinical progression (8%), and histologic progression (4%). In a recently published update of the study with the median follow-up time of 6.4 years from the first biopsy (range 0.2–19.8 years), Klotz et al.¹²⁸ reported the prostate cancer-specific mortality in AS of 1.5%. The risk of dying of another cause was 9.2 times greater than the likelihood of dying from prostate cancer. As AS methods move toward integration of novel imaging and biomarkers, investigators are challenged with including more men with early prostate cancer, minimizing risk of cancer progression, and maximizing quality of life.

Prostate Testing for Cancer and Treatment (ProtecT) will compare active surveillance with active therapies.¹²⁹ Investigators of ProtecT, begun in 2001, expect to enroll more than 1500 men in the United Kingdom and to randomize them to treatment with conformal radiotherapy, prostatectomy, or active surveillance. Results are expected in 2016. This trial should offer investigators more information about localized disease detected through PSA screening, helping physicians and patients understand the risks and benefits better and collaborate better in decision-making.

Curative therapy: an anatomic discussion of the challenges of disease control and minimizing side effects

The patient with early disease has the option to pursue one of a number of definitive therapeutic options, each with its own variations in technique. Fundamentally, the options are a radical prostatectomy or dose-escalated radiation therapy. Both treatment categories aim to treat the entire gland by surgical removal or radiation-based destruction. Alternative treatments have also emerged, such as cryotherapy and high-intensity focused ultrasound, that treat all or a portion of the gland. All treatments are associated with a risk of treatment recurrence and varying degrees of quality-of-life side effects specific to prostate cancer treatments: erectile dysfunction, urinary incontinence, urinary irritation and/or obstruction, and bowel dysfunction. The desire to diminish side effects and treatment recurrences has left the field with numerous updates in technique, entirely new technologies, and numerous comparisons. For each question involving treatment efficacy and side effects, the patient and practitioner want to know both the average results expected and any contributing features that help predict whether an individual patient will experience the favorable or unfavorable end of the range of results. In addition, studies have shed light on whether a particular procedure is reproducible across the range of treatment centers.^{130–132} Most patients diagnosed today are very much aware of the potential for side effects and the concept that a practitioner's experience may affect outcomes.

The selection of patients for treatment is often derived by considering the slow natural history of prostate cancer, the life expectancy of the aging man, and the personal wishes of the patient. The most commonly accepted recommendation is that a patient may benefit from treatment if he has 10 or more years of life expectancy. However, this estimation may be a moving target because death from cardiac disease is declining with better treatments. Men should not be denied treatment on the basis of age alone,¹³³ but the study by Albertsen et al.¹¹⁸ demonstrated significantly reduced prostate cancer-related death when the disease was diagnosed at age 70 and higher, especially for men with Gleason scores <7. The recent update of the Bill-Axelson study that randomized radical prostatectomy and watchful waiting has been highly beneficial in decision-making.⁷⁹ The majority of survival benefit in the radical prostatectomy cohort was observed in men < age 65; however men ages 65–75 had secondary benefits in reduced hormonal therapy, palliative therapy, and metastatic progression.

Radical prostatectomy: a model for the treatment dilemmas concerning therapy for early prostate cancer

The challenges of treating early prostate cancer can be illustrated by an anatomic tour of a radical prostatectomy operation and by using the steps of the operation to highlight what the surgeon and radiotherapist must consider in achieving cancer control with minimal side effects. Refer to [Figure 6](#) as we narrate our way through the intricate anatomy surrounding the prostate gland.

Figure 6 Surgical anatomy of the prostate in relationship to the deep dorsal vein complex, neurovascular bundle (NVB), and other surrounding periprostatic structures (lateral view).

The radical prostatectomy operation involves complete removal of the prostate gland, seminal vesicles, and distal vas deferens. Conceptually, the prostate gland can be thought of as a conical structure with open ends—the bladder neck and the urethra. The sides of the cone have a capsular structure (although not a true histologic capsule) and are surrounded by endopelvic fascia laterally and by Denonvilliers fascia posteriorly. At its apex, the prostate is surrounded by the rhabdosphincter muscle and the dorsal vein complex, which is narrow over the urethra and then spreads into an apron-like structure as it traverses over the midprostate, base of the prostate, and then over the bladder. Regardless of approach and technique, the removal of the prostate requires an intimate understanding of the intricate anatomic structures to be encountered, and a set of allowed surgical motions can be defined.

Access to the prostate

The prostate gland is among the more difficult structures to access for surgery. It is covered anteriorly by the pubic arch, distally by the dorsal vein complex and rhabdosphincter, inferiorly by the rectum, inferolaterally by the nerve bundles, and superiorly by the bladder. The prostate can be exposed with a lower midline abdominal incision from the pubic bone to the umbilicus, and the exposure progresses

through extraperitoneal spaces. Alternative approaches include minilaparotomy, laparoscopic access via 5 or 6 ports in the lower abdomen (extraperitoneal or transperitoneal), and perineal access. The minilaparotomy incision is generally 8–10 cm rather than the 15–20 cm long needed for the standard laparotomy. Visualization of the prostate is similar in the two open abdominal approaches, but in the minilaparotomy, the surgeon will rely more on instrument dissection than on manual dissection. The laparoscopic approach has become increasingly popular with the availability of robotic surgical systems to increase the laparoscopic surgeon's dexterity with instruments, with seven degrees of motion and three-dimensional camera view.

The choice of surgical approach depends on both the surgeon's training and the patient's characteristics. The retropubic approach has been taught in most residency programs worldwide; it provides access to the prostate and lymph nodes and entails a familiar transabdominal orientation. The perineal approach may be associated with less pain, and the scar is certainly less visible. There may be an advantage to this procedure in the circumstances of morbid obesity. However, the lymph nodes are not accessible, and this approach may be difficult for larger prostates, for example, those >60 g. The laparoscopic approach requires a steep learning curve of more than 100 cases, whereas the robot-assisted laparoscopic approach requires fewer.^{134–136} Differences in postoperative pain and hospital discharge are not reliably seen between open retropubic and laparoscopic approaches^{137, 138} but may be decreased with the perineal approach.¹³⁹ Both perineal and laparoscopic approaches are associated with less bleeding, but in expert hands the transfusion rates are probably not significantly different.¹⁴⁰ Results from nonrandomized comparisons show increased transfusion rates in retropubic prostatectomy if the rates for this group are more than 10–15%.¹⁴¹

Moving forward with this discussion, we will discuss only the open retropubic and laparoscopic (both manual and robot-assisted types) operations. However, it is worth noting that although historic discussions on the perineal operation suggest that the outcomes may increase positive margin rates, decrease potency rates, and cause de novo rectal incontinence,¹⁴² several high-volume centers have published very competitive outcomes,^{139, 143} and there is arguably a cost savings relative to the use of robotic approaches.^{144, 145}

Alternative treatments must also consider access to the prostate in their application. Brachytherapy is a form of whole-gland radiation treatment in which radioactively labeled seeds are inserted into the prostate by transperineal access using transrectal ultrasound for guidance. In cases of BPH, the anterior portion of the prostate may extend around the pubic bone's arch, creating a form of interference to needle placement. Thus, in the application of brachytherapy and cryotherapy (another transperineal access ablative therapy), the prostate must be of a certain size (generally <60 g) and shape to allow for access. In contrast, modern external beam radiation treatments can handle a broader range of prostate sizes and shapes. The intensity-modulated radiation therapy (IMRT) technique, for example, uses multiple beams from different angles to boost the dose to the prostate while limiting the dose to surrounding organs such as the bladder and the rectum. Proton beam radiation has recently become popular as another way to limit the dose to normal tissue.

Exposure and dissection of the apex

The anterior and lateral surfaces of the prostate are covered by endopelvic fascia. This fascia can be cut sharply or by using cautery, with care to avoid or ligate varying networks of veins that course along the prostate and often penetrate the apex at 11 and 1 o'clock. The pubovesical ligaments are cut by most surgeons to allow distal ligation of the dorsal vein complex. Mistakes in this region can cause significant

blood loss in the open operation, although less so in the laparoscopic and/or robotic approaches because of the positive pressure of the CO₂ pneumoperitoneum.

The rhabdosphincter surrounds the urethra distally, and the apex of the prostate has no capsule-like structure. Therefore, there is tremendous potential for mistakes in this region, and this may be the step of the operation that improves the most with experience. In essence, the surgeon must control the dorsal vein complex with proximal and distal sutures and then make a tangential cut that is as close to the apex as possible to avoid damaging the rhabdosphincter complex yet avoid a positive apical margin. Numerous technique descriptions are available and cannot be fully catalogued, but the objectives of cancer control (i.e., negative surgical margins) and urinary control are strongly influenced by this step.

Alternatives to surgery must also completely treat the apical region while avoiding side effects. Dose-escalated external beam and brachytherapy will inevitably reach both the apex and surrounding rhabdosphincter. However, because those structures are not specifically disrupted, stress incontinence results significantly less often than with surgery. Cryotherapy techniques include temperature monitors at the sphincter to avoid freezing outside of the apex.

Exposure and dissection of the bladder neck

Dissection of the bladder neck is by comparison much easier than that of the apex in the open operation. The Foley catheter can be used as a guide, and electrocautery can be used safely. Care must be taken to preserve the posterior plate of the bladder neck and divide it away from the ureteral orifices. The bladder neck-sparing technique has been reported as possibly beneficial in avoiding urinary continence but is possibly associated with an increased incidence of positive margins.¹⁴⁶ A nonbladder neck-sparing plane can be reconstructed with sutures to match the urethral size for the anastomosis.

Alternatives to surgery must completely treat the base of the prostate while avoiding damage to the bladder. In conventional-dose radiation to the pelvis, the surrounding dose to the bladder and rectum was always a dose-limiting factor. Dose-escalation techniques, however, whether IMRT, proton therapy, or brachytherapy, effectively increase the dose to the prostate while holding down the dose to the bladder. Nevertheless, some of the dose does affect the bladder, accounting for the differing distribution of urinary side effects, including irritation, frequency, and hematuria.

Exposure and dissection of the seminal vesicles

The seminal vesicles present their own surgical challenges. These structures lie immediately posterior to the bladder, with their tips coursing laterally. The vesicles are surrounded by several small arterial branches that must be controlled with clips or sutures. If uncontrolled, these branches may cause significant postoperative bleeding, which may require a second surgery. However, electrocautery must be avoided if possible because the tips of the vesicles lie immediately medial to the neurovascular bundles. Some researchers have reported the concept of leaving the tips intact to avoid nerve damage.¹⁴⁷ Laparoscopic surgeons may address this challenge by dissecting the seminal vesicles posterior to the bladder through the pouch of Douglas. For the radiotherapist, the seminal vesicles cannot be adequately treated by implant therapy but can be targeted by external technique. MRI with an endorectal coil can be used to stage the seminal vesicles for deciding whether to include them in the treatment plan—the trade-off being increased bladder toxicity.

Neurovascular bundle dissection

The technique for neurovascular bundle dissections is usually retrograde (apex to base) for open surgery

and anterograde (base to apex) for laparoscopic surgery. For the retrograde approach, the dorsal vein and urethral division steps are completed, and the plane posterior to the Denonvilliers fascia is developed with blunt finger dissection. The bundles on each side can then be palpated. Visually, the neurovascular bundles blend well into the sides of the prostate through a series of lateral fascial layers. A triangle of fascia exists, with its borders being the prostatic fascia medially, the endopelvic fascia laterally, and the Denonvilliers fascia posteriorly. Regardless of the technique, the nerve bundle must be released at two junctions: the anterolateral junction of the prostatic fascia and levator fascia and the medial posterior junction of the Denonvilliers fascia.

During the course of neurovascular bundle dissection, the use of electrocautery must be avoided or the thermal transmission may produce irreparable nerve damage. The portion of the bundle from middle to apex has mostly parallel vessels and a few perforating veins that can be controlled with clips or just transected and left to clot. In contrast, the portion of the bundles near the base gives off perforating arteries to the prostate that must be controlled with clips to avoid hemorrhage. Alternative coagulation devices have been described that produce less thermal discharge, but the nerve bundles are very sensitive to heat, and an athermal technique is preferable. Two different planes of nerve-sparing dissection have been described: intrafascial and interfascial. Surgeons must use judgment in this area because although the closer margin obtained from the intrafascial approach may improve postoperative potency, it moves the inked margin of the resection closer to the prostate gland.¹⁴⁸

Surgeons may choose to sacrifice the nerve bundles depending on the estimated risk of extraprostatic extension, as determined from pretreatment parameters such as PSA, clinical stage, biopsy Gleason score, number of biopsies with cancer, and volume of cancer on biopsies, and possibly by imaging with sonography or endorectal coil MRI. Nomograms may assist with arriving at this estimate,^{100, 149, 150} but the surgeon's intuition and experience always play a role that is difficult to measure. In general, most patients prefer to have a nerve-sparing operation as long as cancer control can be maintained.

The proximity of the nerve bundle and the prostate capsule also relates to radiotherapy planning. With brachytherapy, the dose delivered can be quite high within the peripheral zone of the prostate but will steeply drop off outside the gland. As a result, intermediate- to high-risk disease may not be adequately treated when there is higher risk of microscopic extraprostatic extension. Many centers will recommend either radiotherapy, as the dose planning can be driven outside of the capsule, or a combination of brachytherapy and radiotherapy. Cryotherapists can also customize treatment in this region by either driving the ice ball extraprostatically if there is a concern or warming the neurovascular bundle region and thus protect it from the ice ball if no cancer is present on a given side.

Urethral division

The urethra must be divided close to the prostate apex, essentially right near the verumontanum. The surrounding rhabdosphincter should be preserved, and excessive trauma from urethral dilators and catheters should be avoided.

Anastomosis

Both running and interrupted suture lines have been described, the latter more popular and feasible with the laparoscopic approaches. The objective is to approximate the bladder to the urethra so that the anastomosis is watertight and the mucosal surfaces are in contact. Excessively large urethral bites that may shorten the functional urethral length should be avoided. Anastomoses that leak or separate may lead to a higher rate of scarring and contracture.¹⁵¹

Technical modifications for high-risk disease

A shift has been observed toward selecting more surgical patients with higher-risk disease.¹⁵² This requires additional surgical skill to obtain negative margins while maximizing feasible neurovascular bundle preservation and adding additional staging information with an extended pelvic lymph node dissection. As reviewed by Yuh et al.,¹⁵³ the incidence of nerve sparing in high risk varies, and positive lymph nodes may be observed in one-third of patients.

Outcomes of treatment for early disease

Cancer control

Most modern studies use PSA recurrence-free survival as an end point because the data can be collected in a 5- to 10-year time frame rather than the 15- to 20-year time frame needed for longer end points such as disease-specific and overall survival rates. However, as the AUA guidelines⁹³ stress, PSA recurrence is inconsistently defined and does not directly correlate with longer survival. The most commonly used definition of PSA failure for surgery is a PSA level >0.2 ng/mL, and for radiation, the updated American Society for Therapeutic Radiology and Oncology (ASTRO) recommendation is PSA nadir plus 2 ng/mL.¹⁵⁴ Definitions of risk stratification also vary in different studies. The AUA guidelines recommend the D'Amico criteria and the options for each⁸⁸:

- Low risk: PSA ≤ 10 ng/mL, a Gleason score ≤ 6 , and clinical stage cT1c–cT2a.
- Intermediate risk: PSA > 10 –20 ng/mL or a Gleason score ≤ 7 or clinical stage T2b.
- High risk: PSA > 20 ng/mL or a Gleason score ≤ 8 –10 or clinical stage T2c.

According to these risk groupings, the expected cancer control outcomes of brachytherapy, external beam radiotherapy, and radical prostatectomy in terms of PSA recurrence-free survival are seen in [Figure 7](#).⁹³ For each modality, the 5-year range of outcomes are low risk, 75–95%; intermediate risk, 70–90%; and high risk, 30–80%. At 10 years, the ranges are low risk, 60–90%; intermediate risk, 40–80%; and high risk, 20–60%. On the basis of the limitations of lack of standardized reporting, different definitions of failure, and lack of head-to-head randomized controlled trials, the AUA panel stated that there are insufficient data to conclude that one treatment is superior to another. For patients choosing radiation therapy, the panel cited two randomized controlled clinical trials showing that higher-dose radiation may decrease the risk of a PSA recurrence.^{155, 156}

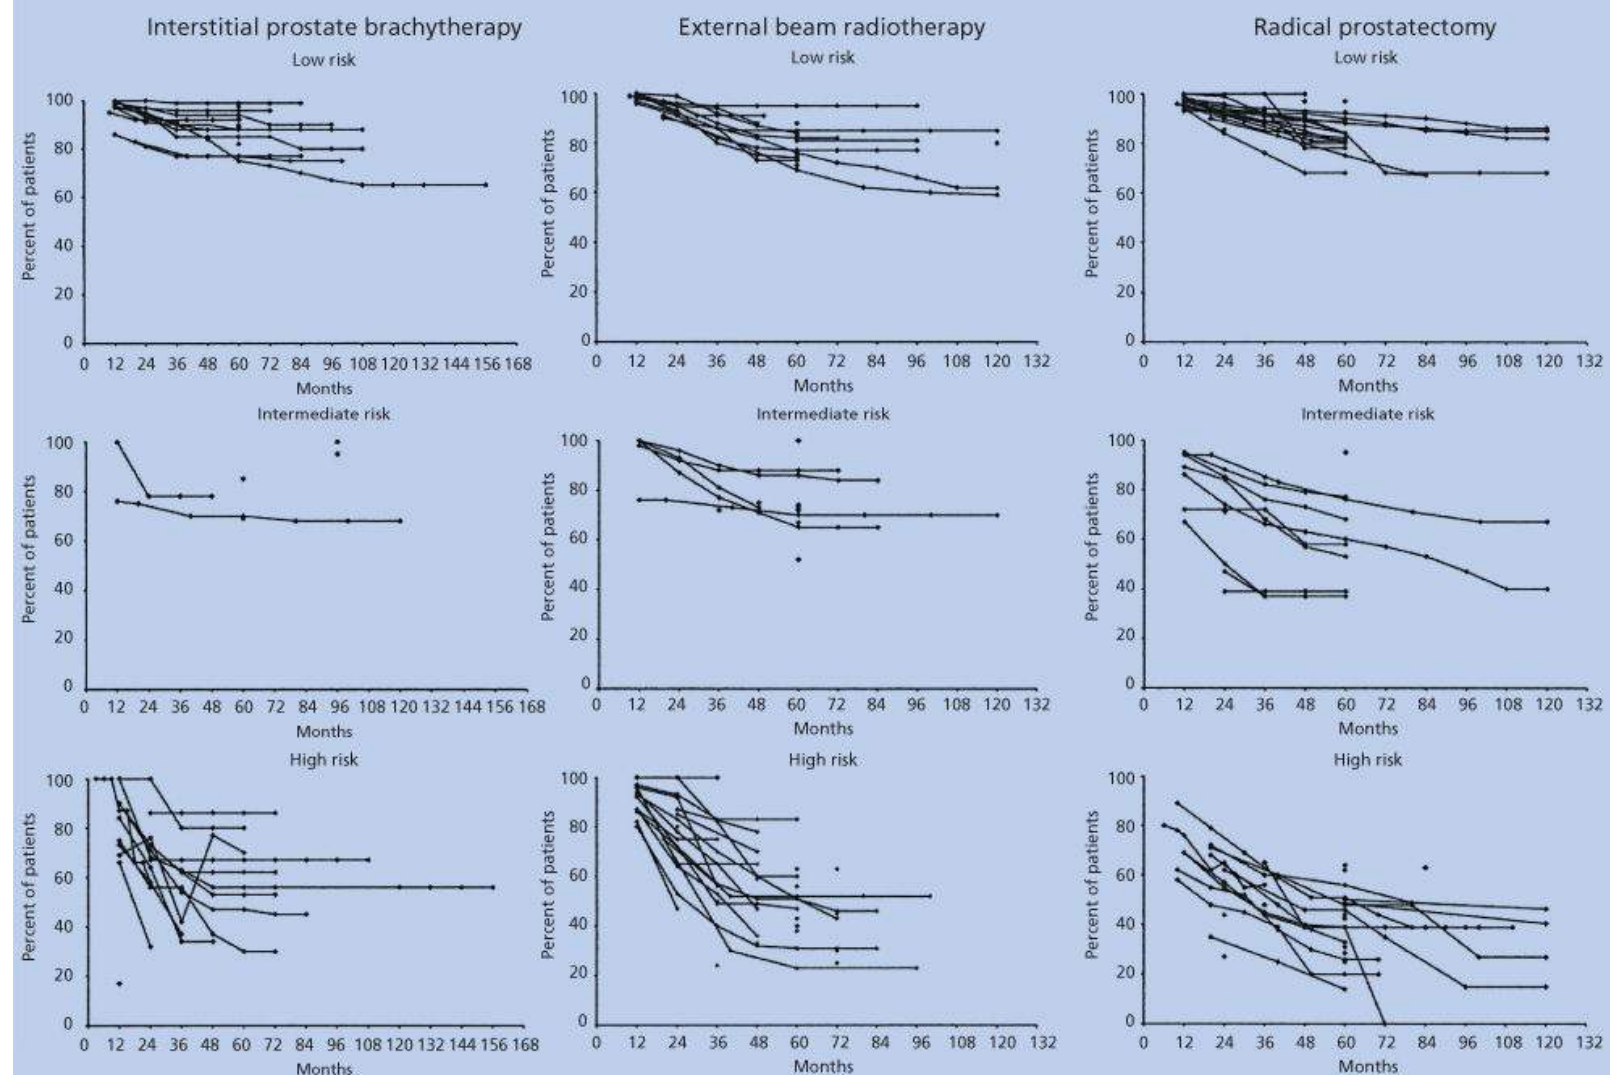

Figure 7 Prostate-specific antigen (PSA) recurrence-free survival in patients with low-, intermediate-, and high-risk prostate cancer treated with interstitial prostate brachytherapy, external beam radiotherapy, or radical prostatectomy.

The topic of neoadjuvant and/or adjuvant androgen deprivation was also addressed by the AUA panel. Randomized clinical trials of neoadjuvant androgen deprivation plus radical prostatectomy showed no benefit in terms of PSA recurrence-free survival.^{157, 158} However, for intermediate-risk patients treated with radiotherapy, one trial showed that neoadjuvant and concurrent androgen deprivation for 6 months may prolong survival after radiotherapy.¹⁵⁹ For high-risk patients treated with radiotherapy, trials demonstrated a survival benefit for a longer duration of adjuvant androgen deprivation,¹⁶⁰ in the 2- to 3-year range. However, it is noteworthy that the radiotherapy used in these trials was conventional and not dose escalated.

In summary, the AUA guidelines list active surveillance, brachytherapy, radiotherapy, and radical prostatectomy as treatment options for low-, intermediate-, and high-risk disease. For radiotherapy, randomized controlled trials are cited regarding dosages and androgen deprivation use. For the high-risk patient, it is noted that recurrence rates are high and that patients should consider “clinical trials examining new forms of therapy, including combination therapies, with the goal of improved outcomes.” It is also worth noting that the AUA panel concluded that first-line hormonal therapy is “seldom indicated in the patients with localized prostate cancer.”¹⁶¹

The European Association of Urology has also issued a guideline statement on prostate cancer, in which it cites many of the same randomized clinical trials regarding watchful waiting, surgery, and

radiotherapy.¹⁶² Additional recommendations based on lower levels of evidence are also cited. Some selected recommendations regarding early disease are as follows:

- Brachytherapy “may be proposed to patients cT1-T2a, Gleason score <7 (or 3 + 4), PSA ≤ 10 ng/mL, prostate volume ≤ 50 mL, without a previous TURP and with a good IPSS (International Prostate Symptom Score) (level of evidence: 2b).”
- Cryotherapy “has evolved from an investigational therapy to a possible alternative treatment method for CaP (prostate cancer) in patients unfit for surgery or in those with a life expectancy <10 years (grade C recommendation).”
- “All other minimally invasive treatment options, such as HIFU (high-intensity focused ultrasound), RITA (radiofrequency interstitial tumor ablation), microwaves, and electrosurgery, are still experimental or investigational. For all of these procedures, a longer follow-up is mandatory to assess their true role in the management of CaP (grade C recommendation).”

Another large-scale effort to summarize the state of the literature was prepared for the Agency for Healthcare Research and Quality and published in the *Annals of Internal Medicine*.¹⁶³ Again, the researchers met with difficulties because of variations in reporting and definitions, and only three randomized controlled trials compared the effectiveness between primary treatments (none with patients “primarily detected with PSA testing”), so, essentially stated, no conclusions could be drawn.

Complications of treatment

General

As a general statement, radical prostatectomy results in more urinary incontinence than radiotherapy or active surveillance do.¹⁶³ Brachytherapy and radiotherapy are associated with more bladder irritation and/or hematuria side effects and less incontinence. Radiotherapy has the higher risk of bowel urgency. All treatments have sexual side effects: although the pattern with radical prostatectomy is one of early loss with gradual improvement, the pattern with brachytherapy or radiotherapy is one of more gradual and delayed loss of function. Younger age and better preexisting function will predict better outcomes from all treatments.

However, there are numerous sources of bias and variability in comparisons, and there is no evidence that any one therapy “has a more significant cumulative overall risk of complications.”¹⁶¹ Although patients often request a single statistic, such as an incontinence rate or potency rate, it is accepted that more accurate quality-of-life research will result from the use of (1) validated instruments that ask multiple questions and offer a range of potential answers; (2) an instrument that is administered by someone other than the treating practitioner; (3) a prospective longitudinal design, including a pretreatment baseline measurement; and (4) an instrument that maintains response rates at >70% throughout the study period. The recent multicenter study by Ferrer et al.¹⁶⁴ evaluated the three standard treatments (radical prostatectomy, brachytherapy, and radiotherapy) with such an ideal method (except for treatment randomization). In the absence of comparisons of side effects in randomized controlled trials, various categories of studies can assist with our understanding of side effects: (1) results from multicenter community or academic series (i.e., voluntary reporting of what goes on in the community), (2) single-surgeon high-volume series (i.e., idealistic results), and (3) Medicare- or claims-based studies (i.e., involuntary outcome reporting).

Multicenter studies

Penson et al.¹⁶⁵ reported the results from the Prostate Cancer Outcomes Study, which is a community-based cohort study conducted at six centers where men underwent radical prostatectomy in 1994 and 1995. In this study, the only relevant predictive information was that the men underwent a radical prostatectomy in the community, that is, no description of technique or quality analysis of the surgeon and/or surgery was given. Among the 1288 patients studied, frequent urinary leakage occurred in 3% at baseline, in 19% at 6 months, in 13% at 1 year, in 9% at 2 years, and in 11% at 5 years. At 5 years, the urinary control level was described as having total control in 35%, occasional leakage in 51%, frequent leakage in 11%, and no control in 3%.

Additional data were presented regarding pad use, irritative symptoms, and bother. Urinary bother started as no problem in 87% at baseline; at 5 years, 45% reported no problem, 42% reported a slight problem, and 13% reported a moderate to great problem. The percentages of patients who reported experiencing erections sufficient for intercourse were 81% at baseline, 9% at 6 months, 17% at 1 year, 22% at 2 years, and 28% at 5 years. Although urinary function and bother scores improved between 2 and 5 years, the percentages of men with no sexual activity were 15% at baseline, 44% at 1 year, and 46% at 5 years. Bilateral nerve sparing predicted a better return of erections at 5 years: 40% for bilateral compared with 23% for unilateral and 23% for nonnerve sparing. Age was also a predictor: in the most favorable group, 61% of men 39–54 years old reported erections.

Sanda et al.⁶⁹ reported on a multi-institutional cohort from nine university-affiliated centers, with surgery completed with open, laparoscopic, and robotic-assisted techniques. In theory, this group of surgeons has a high volume, but again, specific technique was not reported. Using the 100-point Expanded Prostate Cancer Index Composite (EPIC) scale, patients who underwent radical prostatectomy had a baseline score for urinary continence of just 90; the score dropped to 50 at 2 months, improved to 70 at 6 months, and plateaued at 80 at 12–24 months.

However, as the results from these two large studies demonstrate, the literature contains varying definitions of incontinence. Sexual function was adversely affected by both radical prostatectomy and radiotherapy. Among patients who underwent radical prostatectomy, potency was better preserved with nerve-sparing techniques. Among patients who underwent radiotherapy, however, potency was better preserved in patients treated with monotherapy than in those given a combination with hormonal therapy (even after a short duration of 6 months). Bowel function was most affected by radiotherapy and brachytherapy even after 1 year—9% with distress related to bowel function.

The AUA guideline panel review^{93, 161} reported a range of 3–74% for urinary incontinence and suggested that there are insufficient data to provide an overall assessment of urinary outcomes. Those AUA guidelines also provide a large-scale review of published results of erectile dysfunction after radical prostatectomy without details of surgical technique and experience. Rates of erectile dysfunction after 1 year are as high as 90%, and nerve-sparing techniques are helpful.

Expert series

The nerve-sparing operation was initially described by Walsh et al. in the early 1980s,¹⁶⁶ and it became increasingly popular and oncologically safe after the introduction of PSA screening. As one can imagine, patient demand for Walsh's services and the services of other surgeons dedicated full time to this operation became quite high. Walsh et al. published a validated quality-of-life survey study that demonstrated the return of urinary control at 1 year in 93% of patients and a potency rate of 86% at 18 months.¹⁶⁷ A high-volume robot-assisted prostatectomy series also demonstrated excellent results: 1032 of 1110 patients (93%) wore one or no pads per day at 1 year, and potency was reported in 79.2%.¹⁶⁸

Although other studies have looked closely at factors affecting urinary control or potency rates, a recent trend has been to estimate the odds of achieving the “trifecta” of desired outcomes: cancer control, urinary control, and potency. The group from Memorial Sloan Kettering Cancer Center has published the concept as a nomogram.¹⁶⁹

Expert comparisons have extended across technique choices. Touijer et al.¹⁷⁰ performed a single-institution study involving two high-volume surgeons, one of whom performed laparoscopic and the other, open surgeries. There was an unexpected finding of better return of continence (defined as patient reports of no leakage or not requiring a pad) in the open-surgery group: at 12 months, 75% versus 48%. Descriptions of the surgical techniques were cited, but the true difference that affected outcomes was not described. Those authors suspected the result was due to the apical dissection in the laparoscopic approach and stated that further prospective analysis is needed.

Thus, a clear need in outcomes research in early disease is to better link technique to outcome. An example is seen in the study by Masterson et al.¹⁷¹ which demonstrated that a specific technical improvement in nerve sparing can be described and the results measured. In the standard technique, the apex is dissected starting with the dorsal vein complex, cutting the urethra and then bluntly mobilizing the posterior plane before releasing the posterolateral neurovascular bundles. In the modified technique, the sequence starts with dissection of the entire neurovascular bundle off the lateral aspect of the prostate from apex to seminal vesicle before the urethra is cut and posterior dissection performed. This avoids excessive traction applied to the neurovascular bundles. The 6-month recovery of erections improved from 40% with the standard technique to 67% with the modification. Such analogies can be seen in the literature on brachytherapy, in which the D90 analysis of the implant quality is a significant predictor of long-term biochemical disease-free interval.¹⁷²

Variations in outcomes and Medicare databases

In multicenter studies and expert series, researchers voluntarily submit their own results and therefore have the ability to decide whether to participate. In the case of other studies, accessible data are used without such a decision to participate from each physician. Even among expert surgeons, complications vary.¹³² The Medicare database and the Surveillance, Epidemiology, and End Results (SEER) registries are common sources for data from studies such as these. The advantages of these studies include their large numbers of patients and the opportunity they offer for studying a more average community cohort of patients. Their limitations include sampling only patients over age 65 and that their data end points are designed for billing purposes more than for research and can be incomplete in their assessment of the outcomes.

Quality-of-life data seen in such databases appear quite different from those in expert series. Benoit et al.¹⁷³ found urethral stricture in 19.5%, urinary incontinence in 21.7%, and erectile dysfunction in 21.5%. Begg et al.¹⁷⁴ looked at morbidity after radical prostatectomy in the SEER–Medicare Linked Database and found significant trends in the association between surgeon volume and complications and between hospital volume and complications. Recently, Hu et al.¹⁷⁵ analyzed a Medicare sample of patients who underwent minimally invasive radical prostatectomy versus open radical prostatectomy. The trends demonstrated fewer perioperative complications and shorter hospital stay for those who had a minimally invasive radical prostatectomy, although they had higher rates of salvage therapy and anastomotic strictures. However, the unfavorable outcomes with the minimally invasive radical prostatectomy procedure decreased significantly with increasing surgeon volume.

PSAV as a predictor after diagnosis

Researchers have also relied on PSAV to predict disease progression, relapse, and outcomes. In a retrospective study of 102 men who underwent radical prostatectomy,¹⁷⁶ researchers found a statistically significant association between a PSAV of 2 ng/mL/year in the year before diagnosis and tumor volume, which was 2.55 cm³ in men with biochemical recurrence and 0.94 cm³ in men who were disease free 5 years postsurgery ($P < 0.05$). The median PSAV in the men who experienced relapse was almost twice that of men who did not (1.98 ng/mL/year vs 1.05 ng/mL/year). Although these results help identify those at high risk, they may also help physicians identify patients whose tumors are more likely eradicable.

The results of two studies published in 2005 revealed associations between PSAV and outcomes. D'Amico et al.¹⁷⁷ studied PSAV in the year before diagnosis in 1095 men with localized prostate cancer to identify those most at risk of death from prostate cancer. They determined that a PSAV of >2.0 ng/mL/year was related to a statistically significantly shorter time to death from prostate cancer ($P < 0.001$) and to death from any cause ($P = 0.01$); those outcomes were also influenced by PSA level, tumor stage, and Gleason score at diagnosis. Factors that predicted time to death from prostate cancer were a clinical tumor stage of T2; a Gleason score of 8, 9, or 10; and an increasing PSA level at diagnosis.

In an even larger study with a follow-up of more than 7 years, Sengupta et al.¹⁷⁸ also found a significant association between increased risk of death from prostate cancer and both preoperative PSAV and PSA doubling time. In 2290 men who underwent radical prostatectomy, 460 with a PSAV of >3.4 ng/mL/year had a greater than sixfold increase in risk of prostate cancer death [hazard ratio (HR) 6.54; 95% CI 3.51–12.91] compared with those with lower PSAV values. In addition, the 506 men whose PSA doubling time was <18 months had a similar increased risk (HR 6.22; 95% CI 3.33–11.61) compared with those with lower PSA doubling times. The authors said that their findings that PSAV is a better predictor than PSA doubling time of biochemical progression while PSA doubling time is a better predictor than PSAV of clinical progression and death conform to the notion that prostate cancer growth follows an exponential rather than a linear model.¹⁷⁸

In a study in a group of 379 men with prostate cancer who experienced biochemical recurrence after radical prostatectomy, Freedland and colleagues found that PSA doubling time along with pathologic Gleason score and time from surgery to recurrence were statistically significant risk factors for prostate cancer-specific mortality¹⁷⁹; in a separate study in a cohort with a PSA doubling time of <15 months, the same investigators found that 90% of deaths could be attributed to prostate cancer.¹⁸⁰ In studies of PSAV and PSA doubling time, those same investigators found no relationship between those variables and adverse pathologic findings or biochemical recurrence after radical prostatectomy.¹⁸¹

Furthermore, though African-American men are at higher risk for prostate cancer than men of other races, researchers found no relationship between PSAV or PSA doubling time and race among whites, blacks, Hispanics, and Asians. As might be predicted, no relationship was found between PSAV and prostate volume.¹⁷⁶

Prostate cancer chemoprevention: Large trials

The PCPT involved 18,882 men randomized to treatment with finasteride (a 5 α -reductase inhibitor) or placebo.¹⁸² PCPT ended more than a year earlier than planned because its Data Safety and Monitoring Committee determined that the trial had met its primary objective. Prostate cancer prevalence during the 7-year treatment period was 24.8% lower in men taking finasteride than in men taking placebo (95% CI 18.6–30.6; $P < 0.001$). This good news was tempered, however, by the finding that tumors detected in those taking finasteride were 1.67 times more likely to be of a higher grade (Gleason score 7–10) than

were those in subjects taking placebo (37.0% of graded tumors vs 22.2%; $P < 0.001$).

Newer studies of the PCPT data have reassured physicians that finasteride's ability to reduce cancer is clinically significant, explained why the initial results found high-grade disease more frequently in the finasteride arm, and endorsed its use. Taken together, the new results ease the concern that finasteride caused the rate of aggressive cancers to rise in the treated group and encourage physicians to offer finasteride to more men.¹⁸³

According to other reevaluations of the PCPT data, a continuum of risk began at a PSA of even <4.0 ng/mL,¹⁸⁴ and new pathologic studies were undertaken of the PCPT prostate biopsy specimens on which data were available (finasteride, 519 patients; placebo, 716 patients) after results were initially reported to determine whether these tumors were clinically insignificant.¹⁸⁵ Results confirmed that the risk of clinically significant tumors rises with increasing PSA value and that of insignificant tumors falls ([Table 6](#)); nonetheless, 62% of cancers in men with Gleason scores ≤ 6 were deemed clinically significant, as were 75% of all cancers detected.¹⁸⁵

Table 6 PSA and identification of significant and insignificant tumors

	PSA value (ng/mL)			
Tumor type for which at risk	0–1.0	1.1–2.5	2.6–4.0	4.1–10.0
Significant tumors	15.6%	37.9%	49.1%	52.4%
Insignificant tumors	51.7%	33.7%	17.8%	11.7%

In another reevaluation of the PCPT findings, Pinsky et al.¹⁸⁷ used a statistical model to tackle the problem of determining misclassification rates among the pathology findings in each arm and identifying a “true” relative risk for high-grade disease. They determined that misclassification from low- to high-grade disease from specimens at biopsy to those at radical prostatectomy is a function of the true ratio of low- to high-grade disease and misclassification rates. Although the results were not statistically significant in comparison with those for the placebo arm, the true rate of high-grade disease was lower in the finasteride arm (RR 0.84; 95% CI 0.68–1.05); also in the finasteride arm, the true rate of low-grade disease was both lower and significant (RR 0.61; 95% CI 0.51–0.71) compared with that in the placebo arm. The authors explained this paradox of similarly upgraded rates in both arms despite the finasteride group's having less misclassification as being the result of finasteride's decreasing the ratio of true low-grade to high-grade disease.

In response to evidence reported after the initial analysis of the PCPT^{184, 186} and to understand the effect of uncovered biases affecting that analysis, Redman and her colleagues¹⁸⁸ undertook a reanalysis, including evaluable patients omitted from the final analysis, estimating the true prevalence of cancer grade using the highest standard (radical prostatectomy), and studying the sensitivity of biopsy for prostate cancer. These reanalyses included one for selection bias and another that included grading information on radical prostatectomy in 500 cancer-diagnosed participants. Both produced greater risk-reduction estimates than the original study analysis had and attributed to finasteride no increased risk of high-grade cancer. In the first of those reanalyses, risk reduction was increased to 30% (RR 0.70; 95% CI 0.64–0.76; $P < 0.0001$), and prostate cancer rates were 21.1% in the placebo group (4.2% high-grade disease) and 14.7% (4.8% high-grade disease) in the finasteride group, with the 14% increase in high-grade disease nonsignificant (RR 1.14; 95% CI 0.96–1.35; $P = 0.12$). In the second reanalysis by Redman, risk reduction was increased to 27% (RR 0.73; 95% CI 0.56–0.96; $P = 0.02$), and risk of high-

grade disease was lower in the finasteride group (placebo 8.2%; finasteride 6.0%). A third reanalysis found that biopsy sensitivity could significantly affect risk ratio estimates. The authors' conclusion was that men had no reason to worry about increased risk of high-grade cancer when they are treated with finasteride.¹⁸⁸

Earlier reevaluations of the PCPT data helped to explain how detection bias introduced by finasteride increased the sensitivity of PSA level for the end points of prostate cancer and high-grade disease (Gleason score 7–10) and how finasteride increased the sensitivity of the DRE (finasteride 21.3%; placebo 16.7%; $P = 0.015$).^{184, 186} Detection of high-grade disease by DRE was also found to be more sensitive than the PSA, but the difference was not statistically significant.¹⁸⁶

Before these new analyses were published, principal investigator of the PCPT Ian Thompson et al.¹⁸⁴ had answered in part the question their own research had posed when they demonstrated that finasteride's ability to increase the sensitivity of the PSA for prostate cancer and high-grade prostate cancer introduced detection bias for these end points. When their end-of-study biopsy findings failed to demonstrate the increased detection of high-grade tumors in the finasteride arm that had been shown in the for-cause biopsies prompted by high PSA values or abnormal DRE findings, the researchers had a reason to suspect that finasteride might not have caused the changes. Thus, Thompson et al.¹⁸⁴ used AUC studies to demonstrate that the AUC for finasteride was significantly greater than that for placebo for cancer detection overall and for high-grade disease, whether the Gleason score was ≥ 7 or ≥ 8 . Additionally, the 18-year long-term follow-up of the PCPT study confirmed that finasteride has no significant effect on the overall survival or survival after the prostate cancer diagnosis.¹⁸⁹

Thompson et al.¹⁸⁴ performed another analysis of PSA in the PCPT data, estimating the ROC curve for PSA, and found that there was no cut point for PSA with both high sensitivity and specificity for monitoring healthy men for prostate cancer; rather, there was a continuum of prostate cancer risk at all PSA levels. The ROC curve was better for high-grade than for overall prostate cancer risk, but as subsequent analysis showed, there is a substantial risk of biopsy-detected prostate cancer and high-grade disease in men with PSA levels <4 ng/mL, which is generally thought to be in the normal range. Although PSA values <4 ng/mL are related to prostate cancer risk, it is not clear how this information should be applied to clinical decision-making. These data illustrate (1) the need for improved biomarkers of risk and prognosis of prostate cancer and (2) the value of biopsy-proven negative controls for assessing prostate cancer risk, biology, and prevention.

Another important NCI-supported chemopreventive randomized, placebo-controlled trial is called Selenium and Vitamin E Cancer Prevention Trial (SELECT). The study evaluated the effects of selenium and vitamin E, separately and combined, against those of placebo in preventing prostate cancer.¹⁹⁰ Paradoxically, the investigators reported a statistically nonsignificant increase in prostate cancer risk in the vitamin E alone group in their first report, which became significant with longer follow-up and more prostate cancer events.^{191, 192} The serial collection of biospecimens from all SELECT study participants will enable the construction of risk models to help determine which men are most likely to develop prostate cancer and to help identify those most likely to benefit from selenium and vitamin E chemopreventive therapy.

Specimens from the other landmark NCI initiative for prostate cancer prevention, the PCPT, were recently released, making them available to researchers whether they are supported by NCI grants or not.¹⁹³

Putative chemopreventive agents other than finasteride that have been studied or are in development include celecoxib, sulindac, toremifene, soy isoflavones, lycopene, and doxercalciferol. Additionally,

novel preventive strategies such as immunotherapy and mechanistically based drug combinations are being explored.¹⁹⁴ Currently under way are molecular epidemiologic studies of diet and prostate cancer risk as well as basic research into the carcinogenicity of specific diet-derived compounds such as heterocyclic amines. Statins have also been of interest. In 2003, the NCI's Division of Cancer Prevention awarded \$42 million to fund a consortium made up of six programs headed by experienced cancer prevention principal investigators at six major institutions. Members were charged with becoming national leaders in prevention research and in initiating trials on agents of interest, including some of the agents named earlier.

Algorithm for therapy: future directions

Future studies will affect therapy most dramatically if they address limitations reported in current reviews of the literature. These studies must (1) use a randomized design, including an untreated control group, (2) use standard definitions of cancer control and quality-of-life outcomes, (3) link specific techniques to outcome, and (4) demonstrate that a specific technique can be reproduced by multiple practitioners and produce an effect that is similar across settings in the same way that prescribing a drug produces similar effects across patient groups in different settings. After scientific standards are met, the study design should incorporate measures that will make progress possible by resolving questions, both large and small, posed by other works or by producing data that eliminate potential explanations that could undercut conclusions.

Using current knowledge, investigators can outline an algorithm for patients with localized disease as follows: make a determination about treatment, follow an evidence-based guideline or enroll the patient in a clinical trial if treatment is the option of choice, and incorporate molecular signatures to address tumor heterogeneity. First, patients and their physicians must cooperatively decide whether to pursue treatment. As described earlier, expectant management, also called watchful waiting or active surveillance, permits patients with localized disease to forgo treatment, and national organizations, including the National Comprehensive Cancer Network, have created guidelines for management¹³⁵; however, in some active surveillance studies, as many as 75% of men electing expectant management have been found to pursue therapy within 5 years, mostly because of rising PSA values.¹⁹⁵ Advances in better identification of low-risk cases with refined arrays of prognostic factors, including molecular markers, and closer surveillance may change that trend.

Critical to efforts in the future to spare patients with localized disease the side effects of unnecessary definitive therapy will be better tools for differentiating aggressive from indolent disease. Such tools, some of which are in development, may take the form of nomograms such as those described earlier, of a combination of one or more molecular markers added to PSA values, of genetic variants, or of discriminating molecular signatures.^{196–198} With these combinations, we may be inspecting findings not for one specific value but for patterns of values within each collection of factors, and we may be able to obtain this information not only preoperatively but also before biopsy. Furthermore, predictions achieved this way may encompass not only therapeutic response but also natural disease progression.¹⁹⁷

Locally advanced disease

Clinical presentation

Locally advanced prostate cancer is heralded by disease extension outside the prostate capsule (T3a) or

into the seminal vesicles (T3b). The tumor may grow laterally into the pelvic sidewall, centrally into the urethra, superiorly into the bladder neck and trigone, inferiorly into the base of the penis, or posteriorly into the rectum. Although patients may be relatively asymptomatic when they are first seen, complaints are related to the direction of spread.

Common symptoms can be similar to those seen with BPH and vesicle outlet obstruction, such as urinary urgency, frequency, and hesitancy, nocturia, dysuria, and decreased stream. Invasion of the bladder or urethra can produce hematuria, and ureteral obstruction can lead to renal impairment. hematospermia can be seen as well. Although Denonvilliers fascia is usually an effective barrier to tumor spread, rectal invasion produces symptoms similar to those seen in primary rectal cancer, such as hematochezia, constipation and obstruction, reduced stool caliber, and pelvic pain. Tumor extension inferiorly into the urogenital diaphragm or corporal bodies may result in perineal pain, priapism, or impotence.

In addition to DRE, the use of pelvic CT scanning or MRI, transrectal ultrasonography, cystoscopy, and rectosigmoidoscopy can help to better define the extent of disease and the adjacent organs involved. The PSA level is usually high in these patients, sometimes markedly so, although very high tumor grade, anaplastic tumors, and ductal variants may produce little PSA, and in these cases, the PSA level is disproportionate to the amount of disease present. In PSA-producing tumors, the PSAV is an important consideration because it is a measure of the growth rate and aggressiveness of the disease. A PSAV >2 ng/mL/year before treatment (prostatectomy or radiation) has been shown to relate to a higher rate of cancer-specific death.¹⁹⁹ A rapid PSA doubling time can also be an early indication of metastatic disease. Laboratory work related to the local extent of the tumor may show a low red blood cell count secondary to chronic bleeding or elevated blood urea nitrogen and creatinine values secondary to ureteral obstruction and renal impairment.

To assess potential disease outside the pelvis, abdominal CT or MRI, bone scanning, and chest X-ray are also indicated.

Therapy options and applications

According to the results of a patient care evaluation completed by the American College of Surgeons in 1990, the most common treatment for locally advanced prostate cancer at that time was radiation or hormone therapy. Combination treatment was used in just 12% of patients.²⁰⁰ Poor outcomes and subsequent reports of superior results achieved with combined radiation and androgen-deprivation therapy^{160, 201, 202, 203} led to a planned multimodality approach as the mainstay of treatment for these patients. Although surgery may be used selectively for locally advanced disease, it is usually combined with postoperative adjuvant radiation or with chemohormonal therapy or molecular targeting agents in a clinical trial.

Radiation and hormone therapy

Because radiation alone does not successfully eradicate the bulky local disease burden in patients with locally advanced disease (<50% chance) and this modality does not address the significant risk for metastasis in these patients, combined radiation and androgen deprivation has become the standard of care. The results of four randomized clinical trials—RTOG 85-31, EORTC 22863, RTOG 86-10, and RTOG 92-02—with 10 years of follow-up provide compelling supportive evidence for the use of combined therapy.²⁰⁴ Patients with locally advanced tumors comprised the study group in the Radiation Therapy Oncology Group (RTOG) trials, and the European Organisation for Research on the Treatment of Cancer (EORTC) trial patients had either T3 or T4 tumors or high-grade disease. The radiation dose in

all of these trials was low by today's standards, 65–70 Gy. In all of those trials, the main drug was a luteinizing hormone-releasing hormone (LHRH) agonist.

In RTOG 85-31, hormone therapy was given indefinitely beginning after radiation, and in the EORTC trial, it was given concomitantly with radiation and then continued for 3 years. The results from both of these trials revealed a significant benefit in biochemical and clinical end points (local recurrence, distant metastasis, and disease-free survival) as well as in disease-specific and overall survival rates for the patients who received radiation and hormone therapy, as compared with those who received radiation alone.^{160, 201} In RTOG 85-31, subset analysis showed that this advantage was largely driven by patients with Gleason scores of 7 or higher.²⁰¹

RTOG 86-10 compared the effects of 4 months of hormone therapy, started 2 months before radiation, with those of radiation therapy alone. Patients benefited more from the combined radiation and hormone therapy in the end points of biochemical failure, distant metastasis, and disease-free and disease-specific survival.^{202, 205} The latest report revealed that just 4 months of adjuvant androgen-deprivation therapy had a profound effect on disease-specific survival²⁰⁵: one-third of the patients treated with radiation alone died as a result of prostate cancer within 9 years, whereas it took an additional 9 years for the same number of patients to die of their disease when hormone therapy had been added. However, there still was no significant difference in the overall survival rate.

RTOG 92-02 compared 4 months of hormonal therapy plus radiation (as in the combined treatment arm in RTOG 86-10) with radiation plus 28 months of hormone therapy (hormone therapy for 2 months before and 2 months during radiation followed by 24 more months). Similar to the results from the other studies, there was a between-group difference in all end points except overall survival, for which only patients with Gleason scores of 8–10 benefited from the longer duration of hormone therapy.^{203, 206}

These study results taken in conglomerate suggest that a longer duration of hormone therapy in conjunction with radiation better addresses not only local disease but also distant dissemination in patients who have a significant local tumor burden, especially in patients with high Gleason scores.

A study by D'Amico et al.²⁰⁷ included a mixture of patients at intermediate and high risk (T1b–T2b or low risk with T3 by endorectal MRI, PSA 10–40 ng/mL, or Gleason score 7–10). Patients were randomized to receive 70 Gy to the prostate and seminal vesicles alone or 70 Gy combined with 6 months of total androgen blockade starting 2 months before radiation treatment began. This study also showed an advantage in prostate cancer-specific mortality in patients receiving the combination therapy: 2% versus 8% at 8 years after treatment. Additionally, overall survival was 74% versus 61% in favor of the group treated with combination therapy. Of note, however, is that although the survival benefit was of even greater magnitude in patients who had no or minimal comorbidity (90% vs 64%), there was no benefit in patients with moderate or severe comorbidity. In the group with moderate or severe comorbidity, the survival rate was higher than it was in the group treated with radiation alone, although the difference was not statistically significant. D'Amico et al.²⁰⁸ suggested that hormone therapy increases the risk of myocardial infarction in this cohort.

In another randomized trial in men with locally advanced (T2b–T4) disease, that of the Trans Tasman Radiation Oncology Group (96.01), the addition of 6 months of total androgen blockade begun 5 months before radiation to a dose of 66 Gy significantly reduced biochemical, local, and distant failure and improved prostate cancer-specific survival.²⁰⁹ The benefit of adding hormone therapy appeared to increase as the PSA and Gleason score became indicative of higher-risk disease. Although the current trend is to try to decrease the use of hormone therapy or at least limit its duration, because of the recent

reports of cardiac morbidity, metabolic syndrome, and bone density effects,^{208, 210} the ideal duration of hormone therapy has yet to be determined on the basis of a maximal therapeutic ratio.²¹⁰

A follow-up EORTC trial, 22961, was designed to prove the noninferiority of 6 months of hormone therapy and radiation compared with 3 years of hormone therapy and radiation in men with locally advanced prostate cancer (T2c–T4) and those with T1c–T2b N1–2 disease. The trial closed early after accrual of 990 patients, however, because an interim analysis showed the futility of trying to prove this hypothesis. Five-year PSA and clinical progression-free survival as well as overall survival rates were all lower in the patients who received 6 months of hormone therapy: 78% versus 59%, 82% versus 69%, and 85% versus 81%, respectively.²¹¹ The most recently reported trial (PCS IV) compared 18 months to 36 months of androgen deprivation with moderate-dose radiation. With a median follow-up of 6.5 years, no statistically significant differences were seen in overall and disease-specific survival.²¹² Additionally of note is the fact that current standard radiation doses are higher than those used previously, and this has been shown to both decrease local failure and subsequently affect distant metastasis.^{213, 214} Thus, we must continue to test the most therapeutically beneficial combinations of androgen deprivation and radiation.

Radiation and chemotherapy

Because the results of combined hormone therapy and radiation leave ample room for improvement, combinations with chemotherapy are being tested in clinical trials. In RTOG 99-02, patients with high-risk disease were randomized to treatment with radiation plus 2 years of androgen ablation or to treatment with the same combination followed by treatment with paclitaxel, estramustine, and etoposide for four cycles beginning 8 weeks after radiation.²¹⁵ This study was closed prematurely because of excessive thromboembolic toxicity. A follow-up study, RTOG 05-21, has completed accrual and has the same design as RTOG 99-02 but uses docetaxel and prednisone for six cycles after radiation as the adjuvant agents. Future analysis will give some indication as to the efficacy of these agents delivered adjuvantly with radiation. Similar to trials for metastatic disease, attention has turned to the newer targeted agents and the possible combination with radiation.

Radical prostatectomy

Although prostatectomy has been used to treat patients with locally advanced prostate cancer, the reported studies are usually qualified by including patients with less-extensive, resectable disease and lower-grade tumors than have been included in radiation trials. With prostatectomy, PSA disease-free outcome has been in the 50–60% range 5–10 years after treatment, and 60–80% of patients have required adjuvant and/or salvage radiation or hormone ablative therapy postoperatively.^{216–219} Unlike the combined approach with radiation, the use of short-course androgen deprivation has not resulted in significant improvement in PSA disease-free progression when combined neoadjuvantly with prostatectomy.^{158, 220}

To date, surgery has not yielded results superior to those obtained with radiation plus hormonal therapy. A randomized trial comparing 8 weeks of treatment with diethylstilbestrol (DES) and either radiation or radical prostatectomy in patients with T2b–T3 tumors showed similar results with regard to biochemical, clinical progression-free, and cause-specific survival.²²¹ The dose of radiation used was only in the 60–70 Gy range, and the treatment-related morbidity was treatment specific, as might be expected.

Although several phase II studies have proven that various chemotherapeutic agents and hormonal therapy can be combined neoadjuvantly with surgery with an acceptable level of toxicity, a significant decrease in cancer progression or improvement in survival has yet to be seen.^{222–224} The recently opened Cancer and Leukemia Group B (CALGB) 90203 trial randomizes patients to receive either six cycles of neoadjuvant

docetaxel plus prednisone and androgen deprivation followed by radical prostatectomy or radical prostatectomy alone.

A series of studies conducted at M.D. Anderson Cancer Center expanded the concept of local control with surgery to more advanced disease states as part of an integrated treatment strategy for patients with more advanced cancers. Although the patients did not meet accepted criteria for prostatectomy, they were at risk for pelvic and urinary outlet obstructive symptoms. No attempt has been made to date to establish the efficacy of this approach in large patient groups. A benefit of this approach is that it has provided relevant human prostate cancer to generate or test new hypotheses. The preoperative platform adds to the evidence that sonic hedgehog signaling is a therapy target for prostate cancer and can be therapeutically modulated in vivo.²²⁵ These findings have prompted the further study of agents that inhibit sonic hedgehog signaling in the therapy of prostate cancer. In addition, we suggest that stromal–epithelial interacting pathways implicated in prostate cancer progression within the primary tumor are also those central to its progression in the bone.⁸ The clinical reasoning used to integrate surgery in patients with locally advanced cancers has been extended to patients with castrate-sensitive disease, primarily in the case of prostates with “oligometastatic” cancer.²²⁶ Taken together, these clinical observations establish feasibility.

Several population-based studies have analyzed the effect of local therapy in the metastatic setting and have demonstrated improved survivals for those men receiving radiation or surgery to the primary.^{227, 228} This influence may be directly related to symptomatic local progression and subsequent complications, but more interestingly local therapy may disrupt the process of metastases and therefore alter tumor biology. The feasibility of radical prostatectomy in the metastatic setting was demonstrated by one study, which showed acceptable morbidity with surgery.²²⁹ Concomitantly, two clinical trials are evaluating the role of local therapy in M1, castrate-sensitive patients. The STAMPEDE trial in Europe has included evaluating the use of radiation to the primary tumor in M1 patients.²³⁰ Meanwhile, a trial out of M.D. Anderson Cancer Center is assessing the integration of best systemic therapy with or without local therapy (surgery or radiation) in castrate-sensitive disease (NCT10751438). While the concept of local therapy in metastatic disease is intriguing, widespread adoption of this practice should not occur until we have more definitive data. These trials will help to identify the subset of patients likely to benefit from an integrative strategy incorporating local therapy in the metastatic setting.

Postprostatectomy radiation

The results of three randomized trials have shown similar benefit for adjuvant radiation after prostatectomy for the indications of extracapsular extension, seminal vesicle involvement, and positive surgical margins, the latter being the most significant predictor of the benefit of radiation.^{231–233} All three of these studies have now demonstrated a benefit of at least 20% points in PSA disease-free survival with 10 years of follow-up. The EORTC and the SWOG trials also a reported decrease in local recurrence rates and clinical progression.²³⁴ At the latest update, with a median follow-up of 11.5 years, the SWOG trial has now shown a statistically significant difference in metastasis-free survival, which was the primary study end point.²³² At 15 years after treatment, 54% of the men treated with adjuvant radiation had developed metastatic disease or died, compared with 62% treated with prostatectomy alone; this is a hazard reduction of 25% in favor of the use of adjuvant radiation. Significant improvement in overall survival in the irradiated group was also seen.²³²

As the radiation dose is increased, targeting is improved, and candidates for prostatectomy are chosen more carefully by using newer imaging techniques to rule out metastatic disease, it is likely that the

benefit of adjuvant radiation will only increase in the future.

Castrate-resistant locally advanced disease

Bulky tumor located within the prostate is especially problematic in patients with castrate-resistant disease. An evaluation of men progressing to castrate-resistant disease identified patients with an untreated primary tumor as having a significantly increased risk of subsequent local symptoms (20% post-RP vs 46.7% EBRT vs 54.3% with an intact prostate).²³⁵ In men with retained primaries, hormonal therapy will often not debulk the tumor to achieve the desired response with radiation. Additionally, recent data would suggest that androgen deprivation is coupled to DNA repair enzymes and that tumors which demonstrate early androgen insensitivity may be less susceptible to radiation therapy.²³⁶ In patients with metastatic disease, radiation alone can serve the purpose of palliation, relieving symptoms such as hematuria or recurrent urinary obstruction. In patients with greater expected longevity, chemotherapy may be used as a debulking agent prior to or in conjunction with radiation, although the duration and degree of response has not been well documented. Alternatively, prostatectomy may be feasible and will provide symptomatic relief in many of these patients.²³⁷

Recently, “anaplastic features” identified as clinical features that portend a poor prognosis, but increased chemotherapy responsiveness, have been identified. Of these seven clinical features, the authors found that bulky primary tumors were a significant predictor of worse survival, while neuroendocrine features were not predictive of survival or response to systemic chemotherapy.²³⁸ While late palliative local therapy is possible for retained primaries, it is often in the form of aggressive surgical procedures (cystoprostatectomy and pelvic exenteration).²³⁹ While providing relief for many patients, these procedures are often fraught with significant risk of complications and necessary reoperations making these late interventions less appealing. Clinical trials at M.D. Anderson Cancer Center have incorporated further evaluation of early progressors on initial systemic androgen ablation in an attempt to identify “anaplastic” carcinomas at a time when local therapy is possible to further evaluate its potential impact on disease progression (NCT10751438).

Algorithm for therapy: future directions

To apply the most appropriate treatment strategy, it is critical that physicians use diagnostic imaging, pathology review, PSA kinetics, and tumor markers to their fullest extent in assessing the tumor and individualizing therapy. The current emphasis is on exploring combined therapies that will not only eradicate local disease but will prevent or treat distant micrometastases as well. Trials using molecular targeting agents such as tyrosine kinase inhibitors and antiangiogenic agents in combination with radiation or prostatectomy are currently under way. The doses and toxic effects of these agents must be explored, along with their molecular effects in tissue. Ideally, in the future, molecular markers will enable more precise individualized therapy, predicting tumor growth and dissemination patterns (locoregional vs distant) so that treatment can be designed to effect the best response. The molecular targets of new agents and their effects on tissue—both tumor and stroma—must be defined in detail so that therapy can be matched to the tumor's molecular characteristics. It is in this manner that an individualized, multidisciplinary approach will provide the best strategies for both local and distant disease controls as we move forward.

Metastatic prostate cancer

Among the leading causes of cancer-related deaths worldwide, metastases from adenocarcinoma of the

prostate possess a highly conserved clinical phenotype, characterized by osteoblastic bone metastases. Although morbidity and mortality from advanced disease correlate with the volume of bone metastases, notable phenotypic variants observed in approximately 10% of patients include lymph node-dominant metastases, visceral-dominant (liver or lung) metastases, and locally advanced manifestations without bone metastases. Outgrowth of neuroendocrine or small-cell carcinoma is a particular phenomenon associated with prostate cancer at the initial visit or, more commonly, after lengthy periods of hormonal therapy.

At the time of diagnosis of prostate cancer, overt radiologic evidence of metastatic disease varies from 10% to 15% of men from populations among which screening for the disease is commonplace to $\geq 70\%$ of men from unscreened populations. After therapy directed toward localized disease, the earliest presentation of *micrometastatic disease* is most commonly a rising PSA serum level. Given that approximately $\frac{1}{3}$ of patients treated for localized prostate cancer will experience treatment failure, it has been estimated that nearly 70,000 men are diagnosed yearly with the *rising PSA disease state*, and the prevalence in the United States may be as high as 1 million.²⁴⁰

Biochemical recurrence of prostate cancer may be defined variably after surgery,²⁴¹ that is, time to PSA ≥ 0.2 ng/mL with the confirmatory value of >0.2 ng/mL, or radiation therapy,²⁴² that is, time to PSA nadir + 2 ng/mL. Such working definitions can assist in annotating and harmonizing reportable outcomes from therapy. It is important to recognize that a rise in PSA is not an absolute indicator of malignancy, an absolute indication for therapy, or fully predictive of disease progression or disease-specific mortality. The reasons for this are as follows: (1) benign explanations for PSA rise include incomplete prostatectomy or PSA bounces after radiation therapy, (2) the disease is capable of exceptional indolence, (3) early therapy has no established efficacy in improving overall survival or quality of life, and (4) comorbidities are common in aging men (the median age at diagnosis of the rising PSA disease state is 70 years), and alternative causes of death are incrementally dominant among lower-risk rising PSA disease states.

The *long natural history* of the disease after radical prostatectomy for localized adenocarcinoma of the prostate has been described as a median time to metastases of 8 years and a median life expectancy of 13 years.²⁴³ The investigators of one randomized study of radical prostatectomy versus watchful waiting in 695 men reported a 19% cumulative incidence of metastases at 12 years in men with clinically localized disease who had undergone surgery at the time of diagnosis, compared with a 26% incidence of metastases in men who had undergone watchful waiting, without an observable plateau.²⁴⁴ Foci of disseminated but apparently dormant cancer cells may persist for long periods in suitable microenvironmental niches such as within the bone marrow. These clones are thought to remain clinically undetectable in dormant nonproliferative states or in balanced proliferative–apoptotic states before emerging from a dormant state as clinically detectable metastases.²⁴⁵

Using PSA doubling time, time to biochemical failure from surgery, and the histologic Gleason grade, for instance, different metastasis-free and overall survival outcomes can be estimated. For example, men with high-grade disease (Gleason score 8–10) and evidence of biochemical failure within 2 years of surgery have a 70% probability of developing metastases in 5 years,²⁴³ and those with PSA doubling times of <3 months have a probability of prostate cancer-specific mortality of nearly 50% within 5 years.¹⁷⁹ In contrast, men with very long PSA doubling times (≥ 15 months) have prostate cancer-specific mortality rates of no greater than 10% at 10 years.¹⁷⁹ The PSA doubling time are a useful tool to estimate time to meaningful progression and the knowledge deploy therapy in a “risk-adapted manner” and design clinical trials.

The median age at diagnosis of men who have the rising PSA and comorbidities influences timing of therapeutic intervention. Standardized approaches that integrate prognostic markers with age and medical comorbidity will need to be developed to guide future therapy.^{246, 247} Biomarkers that can link the heterogeneous phenotype of metastatic disease to specific therapeutic strategies are required.

Diagnosis

A diagnosis of metastatic prostate cancer may be suspected with the emergence of symptoms or signs of the disease or with a rapidly rising and/or markedly elevated PSA concentration.

Symptoms and signs of metastatic disease

The emergence of bone pain is perhaps the most common symptom of metastatic prostate cancer. Correctly diagnosing the cause of the pain is critical. A change in the character, location, and severity of preexisting “arthritis” pain, for example, should arouse suspicion. Malignant bone pain is usually unremitting and worsens over time. Base-of-skull syndromes can manifest as occipital pain or cranial nerve palsy; the sixth and twelfth nerves are frequently affected. Mental neuropathy presents as chin numbness related to unilateral or bilateral mandibular infiltration and compression of the vulnerable inferior alveolar nerve. A concomitant finding of exquisite sternal tenderness caused by replacement of the bone marrow with high-volume disease is reminiscent of acute leukemia. Referred pain from malignant nerve-root impingements can mimic benign disease; for example, L2 pain can be mistaken for degenerative disease of the hips and lower thoracic root impingement, as an acute abdomen. The Lhermitte sign may signal spinal cord impingement. Back pain can result from bulky retroperitoneal adenopathy rather than from spinal metastases. On bone scans, benign disease such as vertebral compression fractures from osteoporosis, severe degenerative disease, and Paget's disease of the bone can mimic malignant progression.

The emergence of cough, shortness of breath, and interstitial perihilar infiltrates on chest X-ray suggests lymphangitic spread of disease; infection caused by *Pneumocystis carinii* is rare in men with prostate cancer, even those with long-term steroid exposure. Lung metastases are rarely the sole manifestation of distant disease; lung nodules and pleural effusions are other pulmonary manifestations. High-volume lung metastases, although unusual, should raise the suspicion of concomitant brain metastases. Liver metastases usually remain asymptomatic. High-volume liver metastases, lytic bone disease, and brain metastases can imply the presence of neuroendocrine or small-cell carcinoma.

Local progression in the intact or irradiated prostate may be the dominant manifestation of advancing disease, and DRE is a surprisingly neglected diagnostic tool. Late emergence of irritative or obstructive urinary symptoms after radiation, rectal urgency, a change in stool caliber, or perineal pain suggests failure of local control and invasion of local structures. Lymphedema results from infiltration of regional lymphatics and can be particularly debilitating. Invasion of the base of the bladder can result in obstruction of the bladder outlet or ureter (with resultant hydronephrosis and renal failure), hematuria, and recurrent infections. Penile and scrotal metastases are less common.

Radiologic studies

Radiologic studies that are most useful for staging metastatic disease include radionuclide bone scanning and CT of the abdomen and pelvis. A chest X-ray can identify less common pulmonary manifestations, and CT of the chest is occasionally useful to further characterize small pulmonary nodules, the presence of mediastinal lymphadenopathy, or lymphangitic disease. CT-guided needle biopsies are occasionally required to diagnose indeterminate lesions, but sampling errors and false negatives such as with small

bone lesions remain a problem; follow-up is usually required to properly resolve the diagnostic question. MRI is useful for defining the presence of metastatic disease in bony lesions that are indeterminate on bone scans or plain X-rays, screening for suspected spinal cord compression or brain metastases, and evaluating the extent of infiltrative locally advanced disease in the pelvis. Positron emission tomography and indium-labeled capromab pendetide (ProstaScint, Cytogen Corporation, Princeton, NJ) imaging require further development with respect to sensitivity and specificity for metastatic disease and cannot be routinely recommended at this time.

Pathologic studies

Pathologic studies to confirm a diagnosis of metastatic disease may include immunohistochemical testing for PSA and PAP expression; for example, PSA expression may be lost with androgen-deprivation therapy. In the future, molecular evidence of characteristic fusion genes may help resolve indeterminate cases. Men who have a markedly elevated serum PSA concentration (e.g., >100 ng/mL) and a typical metastatic phenotype such as osteoblastic bone metastases at diagnosis rarely require a biopsy to confirm the presence of metastatic disease.

Currently used therapies

Hormonal therapy

Since the discovery of the hormonal biology of prostate cancer,²⁴⁸ hormonal therapy has been the mainstay in the control of advanced disease. Current therapies are directed toward lowering the concentrations of circulating androgens by surgical or medical castration therapy or by pharmacologic blockade of the binding of androgens to their receptor in target tissue²⁴⁹ ([Figure 8](#)). A combination of surgical and medical castration and AR blockade, referred to as combined androgen blockade, may yield additional benefits²⁵⁰ in subsets of patients still to be defined. Data supporting the integration of 5 α -reductase inhibitors, which inhibit the conversion of testosterone to dihydrotestosterone, with combined androgen blockade, referred to as triple androgen blockade, are similarly limited. More effective antagonism of the AR such as with an avidly binding antagonist lacking partial agonist activity (e.g., MDV3100) or more selective and potent inhibitors of androgen synthesis (e.g., abiraterone acetate) is an example of novel hormonal approaches currently being investigated in phase I–III clinical trials.

Figure 8 Hormonal axis and therapeutic agents in prostate cancer. Abbreviations: LHRH, luteinizing hormone-releasing hormone; LH, luteinizing hormone; ACTH, adrenocorticotropin; AR, androgen receptor; DHT, dihydrotestosterone; 5α-R, 5-alpha-reductase.

In men with the rising PSA disease state, there is no evidence that the early application of hormonal therapy—before the emergence of metastases—improves overall survival or quality of life. The demonstration of improved survival with the integration of hormonal therapy and radiation therapy for high-risk localized disease^{160, 251} likely relates to improved local control and a decrease in a late wave of metastases from the primary²⁵² tumor rather than to the control of micrometastatic disease. In contrast, in a small study of immediate adjuvant versus deferred hormonal therapy for node-positive disease after radical prostatectomy, poorer than expected outcomes with hormonal therapy in the deferred therapy arm²⁵³ suggested that as in the antecedent Medical Research Council trial of immediate versus deferred

hormonal therapy in metastatic disease,²⁵⁴ late application of hormonal therapy results in inferior outcomes in some studies. There is a critical dearth of high-quality studies examining the role of hormonal therapy in the high-risk postoperative adjuvant setting or the rising PSA disease state in the overall survival and quality-of-life end points.

Complications of hormonal therapy²⁵⁵ include hot flashes, weight gain, diminished libido and energy level, insomnia, mood and intellectual impairment, osteoporosis, sarcopenia, and acceleration of the metabolic syndrome or cardiovascular disease. Some parts of these complications attributed to hormonal therapy, such as neurocognitive effects, may also relate to aging and the debilitating effects of advanced disease.²⁵⁶ Monotherapy with nonsteroidal antiandrogens (e.g., high-dose bicalutamide) may yield survival outcomes equivalent to those produced by medical castration in low-risk disease²⁵⁷ but with lesser effects on bone mass, muscle strength, and libido.²⁵⁸ Intermittent castration therapy with LHRH agonists reduces the cost and morbidity of therapy with no known adverse (or beneficial) effects in terms of duration of disease control; mature results from several randomized phase III trials are awaited.²⁵⁹

In men with either the rising PSA disease state or metastatic disease, the decline in PSA with castration therapy yields a nadir value that may be prognostically useful.^{260, 261} A nadir PSA >4 ng/mL in men with metastatic disease after 7 months of hormonal therapy was associated with a median overall survival of 13 months in contrast to a median survival of 75 months with a nadir PSA of ≤0.2 ng/mL.²⁶¹ These data suggest that a lethal phenotype can be identified in this manner for early intervention with experimental strategies.

To date, randomized studies in newly diagnosed metastatic disease have not identified a survival or quality-of-life benefit for early versus deferred introduction of chemotherapy combined with hormonal therapy.²⁶² Thus, the use of chemohormonal therapy in this setting remains experimental.

Nonhormonal therapy

No convincing evidence supports the value of chemotherapy in treating hormone-naïve prostate cancer. A range of nonhormonal therapeutic agents, including vaccines, immunomodulators, angiogenesis and signal-transduction inhibitors, and differentiation agents have been legitimately studied in the rising PSA disease state and in asymptomatic metastatic disease. These settings have particular trial design challenges, including the lack of validated early surrogate end points for survival. To date, there is no evidence that a nonhormonal therapy has a major influence on the natural history of the disease.

Castrate-resistant disease

Durations of hormonal control vary from 6 years in men without metastases²⁶² to 18 months in men with metastatic disease.²⁶³ When evidence of progressive disease emerges in the context of low serum concentrations of testosterone, by consensus <50 ng/dL,²⁶⁴ the term *CRPC* may be preferable to “hormone-refractory” or “androgen-independent” prostate cancer.²⁶⁵ These tumors are often responsive to alternative hormonal therapeutic agents and hence are not strictly hormone refractory. Because persistent signaling via a “supersensitive” AR may occur despite the serum levels of testosterone after castration, they are often not truly androgen independent, either.

Prognosis

Few study reports have described the prognosis for men with CRPC defined by a rising PSA concentration alone. Observations from the placebo arm of a randomized controlled trial of zoledronic

acid (201 men with castrate levels of serum testosterone, rising PSA values, and no evidence of bone metastases) demonstrated the potentially lengthy time to the development of bone metastases, particularly in men with low PSA values and long PSA doubling times.²⁶⁶ Overall, the risk of bone metastases in this cohort was 33% at 2 years, and the median bone metastasis-free interval was 30 months. More than 50% of the men with PSA doubling times of <6 months developed bone metastases within 18 months, whereas only 40% of those with PSA doubling times of >18 months had developed bone metastases within 3 years.

Although the median overall survival time in asymptomatic CRPC without metastases is 4 years, the prognosis of men with metastatic CRPC varies between symptomatic^{267, 268} and asymptomatic²⁶⁹ disease and ranges from 9 to 23 months, respectively. Several predictive nomograms incorporate a range of easily determined clinical and biochemical parameters to predict 12- and 24-month overall survival rates.^{270–272} A model that incorporated PSA doubling time, time to PSA progression after initiation of castration therapy, and presence of metastatic disease at the time of CRPC transition defined three prognostic groups to predict clinical progression or event-free survival (EFS)²⁷²: a low-risk group defined solely by a PSA doubling time of >10 months (median EFS 96 months); an intermediate-risk group with a PSA doubling time of <10 months and a time to PSA progression of >13 months (median EFS 33 months); and a high-risk group defined by a PSA doubling time of ≤10 months, the presence of metastatic disease at progression from androgen-dependent prostate cancer to CRPC transition, and a time to PSA progression of ≤13 months (median EFS 6 months).

Given these evident variations in the natural history of CRPC, there is clearly a need for reliable prognostic models both for routine clinical practice and for accrual stratification and reporting in clinical trials. Interpretations of differences in survival outcomes in clinical trials must take into account the potential effect of such variations, which may be incompletely accounted for by strategies of randomization and prognostic stratification.

Management of CRPC

A key principle in the management of CRPC is to balance the limitations of benefit of therapies and the variable threat of the disease. Current therapies can serve to control the disease by improving symptoms, reducing specific morbidity, and improving quality of life as well as overall survival time. The burden of androgen-deprivation syndrome, medical comorbidities, influences therapeutic choices. The prevailing approach is to apply therapeutics sequentially based on prognostication and predicted tolerance. Future direction will be leveraging advances in biology to apply more effective combinations in select patient identified by predictive markers. Strides have been made in molecularly classifying patients likely to be androgen responsive^{42, 43, 273} or have aggressive variants.²³⁸ These observation and associations are the foundational studies to transition from the prevailing prognostic model for allocation of therapies²⁷⁴ to a biologically based predictive model.²⁷⁵

Secondary hormonal therapy

Responses to secondary hormonal therapies are explained by the incompletely defined endocrine mechanisms that drive the progression of CRPC via the persistently expressed AR or AR bypass pathways. In general, the median duration of progression-free survival for an unselected population treated with secondary hormonal therapy is <6 months with first-generation androgen signaling inhibitors.^{276, 277} Men with short durations of primary hormonal control and with suboptimal PSA nadir response and rapid PSA doubling times are less likely to experience a prolonged response to secondary hormonal therapies. On a practical level, the choice of a secondary hormonal therapy in CRPC is influenced by details of prior hormonal therapy, comorbidity, and the risk of drug interactions.

A small but significant fraction of men with progressive CRPC given concurrent antiandrogen therapy will experience a 50% drop in PSA and objective regression of disease with *antiandrogen withdrawal* alone; this phenomenon has been described across the broad spectrum of steroidal and nonsteroidal antiandrogen agents. Estimates of the frequency and duration of the antiandrogen withdrawal response (AAWR) have varied, but the single largest prospective study of nonsteroidal antiandrogen agent (bicalutamide, flutamide, or nilutamide) withdrawal ($n = 132$) demonstrated a PSA decline by half in 11%, an objective response in 2%, and a median time to PSA progression of 6 months.²⁷⁸ In the main they are modest benefit and the interest has been supplanted with the new evidence of efficacy for the improved androgen signaling targeting the AR (enzalutamide) or androgen biosynthesis inhibition (abiraterone acetate). The retained interest is based principally due the biologic significance of AAWR. The finding points to the clinical relevance of the emerging knowledge of the alterations in AR alteration and androgen biosynthesis in prostate cancer progression.²⁷⁹ Mutations of the AR were found in 10% of bone metastases, and these did not correlate with the AAWR.²⁸⁰ Withdrawal responses have also been described with steroidal antiandrogens, including the progestins and glucocorticoids. These data suggest that the AAWR observation has yet to be fully elucidated and may be more complex than initially anticipated. Recently presence of AR splice variants and more specifically ARV7 has been strongly associated with primary resistance to novel androgen signaling inhibitors, namely, the irreversible inhibitor abiraterone acetate and the second-generation antiandrogen enzalutamide. However it is not clear whether splice variant presence is mechanistically linked to resistance.^{42, 43, 281}

Approved novel androgen signaling inhibitors in mCRPC

Abiraterone is a steroidogenesis CYP17 inhibitor that selectively and potently inhibits adrenal androgen synthesis by inhibiting 17- α hydroxylase and C17,20 lyase.²⁸² Following two positive phase III studies in chemotreated and chemonaive mCRPC, abiraterone acetate is currently indicated in mCRPC.^{283, 284} Hypertension and hypokalemia that result from upstream accumulation of pregnenolone and adrenocorticotrophic hormone as a result of the 17 α hydroxylase inhibition can be suppressed with prednisone supplementation.

Enzalutamide is a second-generation antiandrogen that has approximately fivefold higher binding affinity for the AR compared to the antiandrogen bicalutamide. Enzalutamide blocks translocation of AR to the nucleus and in addition prevents binding of AR to DNA and AR to coactivator proteins. Enzalutamide is currently indicated in mCRPC following two positive phase III studies in chemotherapy-treated and chemotherapy-naive mCRPC. Fatigue is the most common adverse events. In the chemotherapy-naive mCRPC trial²⁸⁵ (PREVAIL), increased incidence of hypertension was reported. Enzalutamide administration has been associated with rare events of seizure disorder.

Alternative androgen signaling inhibitors

High doses of the azole antifungal agent *ketoconazole* (400 mg, 3 times daily) may function to enhance the effects of castration by ablating synthesis of adrenal androgens, themselves weak ligands of the AR but also a source of testosterone. Glucocorticoid replacement is required for ketoconazole-induced adrenal insufficiency. Adverse effects and complications include fatigue, nausea, hepatotoxicity, and drug interactions with agents metabolized by the cytochrome P450 system. This agent has largely been replaced by the more effective and less toxic irreversible CYP17 inhibitor abiraterone acetate.

Estrogens possess some activity in prostate cancer, due at least in part to their castration effects. In the control of advanced disease, DES has demonstrated efficacy equal to that of LHRH agonist therapy, but DES has come into disrepute because of its well-documented thrombotic and cardiac complications,

particularly with daily doses >3 mg. The efficacy of oral DES 1 to 3 mg daily in mCRPC^{286, 287} has been described without clear evidence of a dose–response relationship. The mechanism of action of DES has not been fully established. Thrombotic complications of DES persist even with low doses; concomitant therapy with low-dose warfarin and enteric-coated aspirin or low molecular weight heparin may offer prophylactic benefit. DES-related gynecomastia can be particularly troublesome, and prophylactic breast irradiation is recommended prior to initiation of therapy.

Glucocorticoids as single agents have modest activity in CRPC. The different glucocorticoids have not been compared directly, but low-dose dexamethasone has arguably the highest single-agent activity reported.²⁸⁸ Many mechanisms may account for the effects of glucocorticoids such as suppression of the hypothalamic–pituitary axis, direct effects via steroid receptors, or modulation of the tumor microenvironment. Cushingoid side effects, weight gain, hyperglycemia, osteoporosis, sarcopenia, insomnia, and mood disturbance are all important considerations with prolonged use of glucocorticoids.

The rationale for *continued castration therapy* in men treated with an LHRH agonist is unsettled. Although select retrospective data suggest the potential for inferior survival outcomes without persistent castration,²⁸⁹ no randomized prospective data demonstrate an advantage to this approach. A consensus statement from the Prostate-Specific Antigen Working Group for the purpose of harmonizing the conduct of clinical trials in CRPC recommended maintenance of a castrate level of testosterone of <50 ng/dL.²⁶⁴ The role of more complete suppression of androgen signaling in prostate cancer progression is no longer debated given the efficacy of androgen signaling inhibition in the context of castrate-resistant progression.^{283, 284}

Serum testosterone levels of >50 ng/dL in men treated with optimal doses of LHRH agonist therapy or after orchiectomy are usually associated with low levels of free serum testosterone. However, rare instances of acquired LHRH agonist resistance have been described, likely related to immunologic mechanisms; these cases emphasize the need for periodic monitoring of serum testosterone concentration. Recent studies have applied methodologies that determine lower concentration of testosterone and establish the clinical relevance of “paracrine/intracrine” concentration of androgens (<50 ng/dL of testosterone).²⁹⁰

In contrast to these considerations, PSA decreases and objective responses to *testosterone therapy* in prostate cancer have been described, a further reminder that a deeper understanding of the steroid-regulated biology of prostate cancer is necessary.²⁹¹

Nonhormonal therapy

As is the case with hormone-naïve metastatic disease, various nonhormonal therapeutic agents are being evaluated in clinical trials for use in asymptomatic or lower-risk CRPC in lieu of secondary hormonal therapy or chemotherapy. Experimental therapeutic agents in lower-risk settings are justified given the demonstrably limited benefits of standard chemotherapy.

Chemotherapy

Although there has been long-standing nihilism with regard to the role of chemotherapy in CRPC,¹¹ in the last few years, the results of randomized controlled clinical trials have demonstrated the *overall-survival*^{292–294} and/or *quality-of-life*^{268, 293} advantages of chemotherapy in men with metastatic CRPC.

Mitoxantrone plus prednisone (MP) therapy with 12 mg/m² of mitoxantrone at 3-week intervals and 5 mg of prednisone given twice daily was approved for use in the United States by the Food and Drug

Association on the basis of greater pain relief with that regimen than with that achieved using prednisone monotherapy in symptomatic CRPC; however, a survival advantage for MP therapy was not shown in this 160-patient randomized trial.^{267, 268} In a 770-patient study, the SWOG used treatment with 60 mg/m² of docetaxel given every 21 days plus 280 mg of estramustine given three times daily for 5 consecutive days and compared that regimen with treatment with MP; the results demonstrated an increase in progression-free survival from 3 to 6 months and an improvement in median survival by 2 months with the docetaxel–estramustine regimen.²⁹² However, the toxic effects attributed to estramustine were clinically significant, and the patients' quality of life was not improved.

In the multinational 1006-patient TAX 327 trial, a regimen of 10 mg of prednisone daily plus 30 mg/m² of docetaxel given weekly for 5 of 6 weeks and a regimen of 10 mg of prednisone daily plus 75 mg/m² of docetaxel given every 3 weeks were compared with a regimen of 10 mg of prednisone daily plus 12 mg of mitoxantrone given every 3 weeks.²⁹³ A statistically significant improvement in median survival time similar to that in the SWOG trial (i.e., 2 months) was described for the every 3-week schedule of docetaxel compared with the MP regimen²⁹⁵ (Figure 9). Similar improvement in PSA decline rates, pain response, and global quality of life were reported for the two dosing schedules of docetaxel compared with those resulting from the MP regimen; in contrast, objective responses were infrequent and no different in the three groups. Progression-free survival outcomes for the individual arms were not described.

Figure 9 Updated results from TAX 327. Survival benefits are modest with docetaxel chemotherapy: median survival remains under 2 years, and an understanding of biologic subsets that benefit from therapy is required.

Source: Eble 2004.²⁹⁶ Reproduced with permission of World Health Organization.

The results from these studies prompted the US Food and Drug Administration to approve a regimen of daily prednisone plus 75 mg/m² of docetaxel given every 3 weeks for the treatment of CRPC.

More recently, cabazitaxel, a novel tubulin-binding taxane with activity in preclinical models resistant to paclitaxel and docetaxel,²⁹⁷ was compared to MP for the treatment of men with metastatic CRPC whose

disease had progressed during or after treatment with a docetaxel-containing regimen.²⁹⁴ In this 775-patient randomized clinical trial, 25 mg/m² of cabazitaxel given intravenously every 3 weeks resulted in an improvement of 2.4 months in median overall survival, compared to the MP regimen. Pain palliation was similar in both groups.²⁹⁸ These findings provided the necessary impetus for the further development of systemic chemotherapeutic regimens for CRPC to affect patients' overall survival time and quality of life.

When should patients with CRPC be offered chemotherapy? The optimum timing of initiation of chemotherapy in men with CRPC is still undetermined. Given its relative ease of administration and cost, secondary hormonal therapy is a reasonable choice for use in asymptomatic or minimally symptomatic patients, those with low burdens of metastatic disease, and those with rising PSA concentrations with adverse kinetics. Observation alone is reasonable for men with indolent PSA kinetics and/or no evidence of metastatic disease. In men with symptomatic CRPC, though, docetaxel or cabazitaxel chemotherapy is preferable to existing secondary hormonal therapeutic agents, given the data demonstrating the survival and quality-of-life benefits of docetaxel. When a single site of disease is dominant and symptomatic in a threatened area such as the spinal column or weight-bearing bone, the use of palliative radiation therapy is reasonable to secure this area before the initiation of chemotherapy. Asymptomatic patients with widespread disease should also be considered for taxane-based chemotherapy.

The *optimal duration* of chemotherapy in CRPC is also undetermined. Continued treatment to two cycles beyond the best response followed by observation is reasonable and commonly used because cumulative fatigue is common with docetaxel-based therapy. Intermittent chemotherapy with a view toward retaining control and providing interrupted therapy for quality-of-life purposes has been described,²⁹⁹ but the drug holidays become progressively shorter as drug resistance invariably emerges. In addition, the role of maintenance chemotherapy in patients with a stable response is uncertain, and its use must be balanced against emergent toxicity.

The *limits of benefit* of chemotherapy are clear with docetaxel, cabazitaxel, and with all other cytotoxic agents reported to date. Improvements in survival are tangible, but though comparable to those obtained in breast cancer, they remain modest. Another limitation is that therapeutic agents can be expensive and toxic, and the disease is still incurable, with few long-term survivors beyond 5 years.

Third-line therapy, used after treatment with cabazitaxel failures, has not been standardized, and for such patients, participation in a clinical trial should be strongly considered.³⁰⁰ When assessing therapeutic options for a patient whose disease is taxane resistant, unexplored secondary hormonal maneuvers should be considered.

Consistent with the data that the *microtubule* is an important target in CRPC, *paclitaxel* has also demonstrated significant activity when given weekly as a single agent as well as in several estramustine-containing combinations.^{301–303} MP therapy was considered the de facto standard after docetaxel failures, prior to the approval of cabazitaxel, but the results observed were discouraging, with 50% PSA decreases of approximately 20%.^{304, 305} Data for the role of MP following cabazitaxel have not been published to date. Oral cyclophosphamide given in chronic schedules has demonstrable activity in CRPC and is an alkylator-based approach, distinct from the approaches with the taxanes and anthracyclines described to date.^{306, 307}

In an effort to build on the taxane experience and the increased understanding of the biology of the disease, a number of randomized phase III clinical trials were conducted in the last decade to test the contribution of various targeted agents (including the endothelin receptor antagonist atrasentan,³⁰⁸ the

multitargeted antiangiogenic receptor tyrosine kinase inhibitor sunitinib,³⁰⁹ the Src-kinase inhibitor dasatinib,³¹⁰ the VEGF inhibitors bevacizumab³¹¹ and aflibercept,³¹² the endothelina A receptor antagonist zibotentan,³¹³ and high-dose calcitriol³¹⁴). Although many of these combinations resulted in a prolongation of progression-free survival over single-agent docetaxel, none resulted in improvements in overall survival.

Carboplatin³¹⁵ has also been evaluated in various combination regimens in phase II studies in CRPC^{303, 316, 317, 318, 319} more recently with an emphasis on the treatment of aggressive variants of the disease sharing clinical and phenotypic features with the small-cell neuroendocrine carcinomas of the prostate^{238, 320} based on the hypothesis that the shared clinical features should predict for shared sensitivity to platinum-based chemotherapy.²⁰ It has been proposed that platinum sensitivity may be a distinguishing feature of a biologically distinct subset of CRPC and prospective studies are ongoing to test this hypothesis.

Bone-targeting therapy

The specific epithelial–stromal interactions that define the typical metastatic phenotype of prostate cancer are of critical interest. A mechanistic definition of the pathways to bone metastases, including epithelial–stromal interactions³²¹ ([Figure 10](#)) may yield a therapeutic approach that can successfully modulate the natural history of the disease. Given that the dominant morbidity and mortality from the disease can be traced to bone metastases, an organ-targeting strategy has long been of interest to the field. The hallmark pathologic feature of advanced disease in bone is carcinoma cells nested in woven bone with adjacent functionally active osteoblasts. These morphologic features correspond to the characteristic feature of bone-forming metastases that dominate clinical picture of men with advanced prostate cancer. There is intense research interest in modeling the early events of disease progression, including understanding the components and determinant physiologic characteristics of a putative metastatic niche in bone.

Figure 10 The multistage process of metastases: the pathophysiology of early events in the metastatic cascade, undetected dormant micrometastatic disease, and proliferative disease in the bone microenvironment are likely regulated by distinctive events with differing implications for therapy.

Source: Chung 2001.³²¹ Reproduced with permission of Springer.

The principles of selective uptake in bone and prolonged retention of radiopharmaceutical agents at sites of increased bone mineral turnover guided initial studies of bone targeting in advanced prostate cancer. The natural affinity of the *radioisotope* strontium chloride Sr 89 (half-life 50 days) for the bone, on the basis of its strong homology with calcium, and the phosphonate-coupled samarium Sm 153 (half-life 1.9 days) permit delivery of medium-energy β emitters to the tumor–bone matrix interface.³²² These agents offer a palliative option,³²³ and observations of a survival benefit in CRPC with consolidative radioisotope therapy after the initial response to chemotherapy³²⁴ have sparked further interest in an organ-directed approach. A more effective radioisotope with favorable toxicity profile has been developed. RAD 223, an alpha-emitting and bone-homing radiopharmaceutical, has been approved for use in men with symptomatic prostate cancer bone metastases because it demonstrated relief of symptoms and prolongation of survival in men with CRPC.³²⁵ Ongoing studies will determine its role in combination with newer antiandrogens or chemotherapy. RAD 223 has largely replaced strontium 89 and samarium in the United States and European countries.

Evidence of increased markers of bone resorption in cases of CRPC with bone metastases has justified the study of osteoclast-inhibitory bisphosphonates.³²⁶ A large randomized phase III trial evaluating zoledronic acid in men with CRPC receiving concomitant chemotherapy demonstrated a reduction in bone pain and “skeletal-related events” with the use of this highly potent bisphosphonate.³²⁷ The receptor

activator of nuclear factor κ B (RANK) ligand antibody denosumab has demonstrated promising activity in reducing bone lysis markers in men with progressive CRPC treated with zoledronic acid. In a phase III study of 1904 patients comparing zoledronic acid and denosumab in CRPC, denosumab was superior in preventing skeletal-related events.³²⁸ A prospective study of denosumab in men with nonmetastatic CRPC did not meaningfully delay the onset of bone metastases in men at high risk for bone progression.^{329, 330}

Several lines of evidence implicate the platelet-derived growth factor receptor (PDGFR) in the progression of disease in the bone. Preclinical studies with the PDGFR inhibitor imatinib mesylate in combination with taxane chemotherapy yielded promising results in an orthotopic lytic-dominant model of prostate cancer bone metastases.³³¹ However, the results from a randomized study of docetaxel with and without imatinib suggested potent inhibition of bone lysis markers without detectable clinical benefit.³³² Cabozantinib, a potent c-Met/VEGFR2, demonstrated striking efficacy in men with bone metastatic CRPC.³³³ Surprisingly the efficacy in the phase II setting did not translate into a survival benefit in men with treatment refractory CRPC in the phase III setting. The failure of these phase III studies points to the challenges faced by investigators to prioritize and apply laboratory observation(s) clinically and transition from phase II to phase III.

Future directions

The substantial limits of the efficacy of contemporary cytotoxic or available bone-targeting therapies in CRPC are known or predictable. It is highly unlikely that novel combinations, doses, or schedules of these agents will meaningfully transform the outcome of prostate cancer in patients. A deeper understanding of the molecular pathways involved in disease progression is now the necessary basis for reassessing our perspectives about the disease and for advancing the exploration of novel therapeutic approaches. In this regard, novel strategies need to exploit the unique biology of the malignant epithelial cell—its angiogenic, inflammatory, and immunologic microenvironment—and the physical and chemical components of the inorganic matrix that determine survival and progression of disease.

Current perspectives targeting the epithelial cell are centered on androgen dependent pathways that may activate downstream androgen signaling independent of the androgen receptor or entirely independent of the androgen signaling.⁴⁰ Evidence that tissue androgens exist and AR signaling occurs despite medical castration³³⁴ has justified continued AR targeting in castrate-resistant disease.³³⁵ AR inactivation, whether by reducing or eliminating ligand synthesis, blocking the ligand–receptor interaction, enhancing degradation of the receptor, inhibiting AR nuclear translocation, or interfering with the interaction between the AR and androgen-response elements,³⁰⁷ may spare putative AR-negative stem cells that perpetuate the disease.⁴⁰ Autopsy series have demonstrated the heterogeneity of AR expression with 40% of metastatic sites expressing <10% AR by immunohistochemistry.³³⁶ The frequent inactivation of the PTEN tumor suppressor in high-grade disease with activation of the *PI3-kinase/Akt signaling and downstream cell survival and proliferation pathways* is currently a dominant theme in the framework of defining the lethal molecular phenotype.³³⁷ Therapeutic agents targeting the AR and PI3-kinase/Akt signaling pathways are currently in trials. A high frequency of *novel gene fusions* in primary prostate cancer specimens was reported in 2005.³³⁸ A 5' untranslated region of a TMPRSS2 gene is fused to a 3' ETS-1 family member in most specimens studied to date. These and other novel fusion genes have thus far been found only in malignant epithelial cells across all Gleason grades. The fusions appear nonrandom and are largely exclusive within each individual tumor across all tumor foci. The 5' TMPRSS2 region contains an androgen-responsive promoter element, which also suggests that this gene fusion is a central biologic event in the progression of the disease.

The broad scope of *immunotherapeutic* strategies in CRPC includes efforts to integrate the innate and adaptive immune response using vaccine strategies and immune adjuvant. The use of agents that can block negative regulatory components of the physiologic immune response, tumor-associated angiogenesis, may modulate the host response to the therapeutic benefit of patients. Although current vaccine approaches have not yielded major antitumor activity in phase II settings, the results of phase III trials indicate a survival advantage that led to the approval of Provenge, a prostate cancer vaccine.^{339, 340} The lengthening of overall survival was greatest in the subset with more favorable (less volume) cancers. The perplexing finding was lengthening of overall survival with no observed tumor regression or prolongation of progression free survival. This outcome has made it difficult to identify the individual patients who derive benefit. This limitation has made it difficult to develop predictive markers that can be used to apply vaccines with greater precision. Immune checkpoint blockade has demonstrated effectiveness in selectmen with mCRPC. This finding led to a phase III study³⁴¹ demonstrating lengthening of survival that did not meet statistical significance. A post hoc subset analysis that men with favorable features had a prolongation of survival whereas as the with unfavorable features did not.³⁴¹ The lower-volume, more favorable patients not exposed to chemotherapy are the subject of an ongoing prospective randomized study. Overall vaccines and immune checkpoint blockade have demonstrated benefit in subsets of men in the more favorable groups with metastatic CRPC and show great promise for the future.

Summary perspectives

Advances in the understanding of the biology of prostate cancer in general and including CRPC has increased dramatically; we have access to technologies that allow us to characterize clinical prostate cancer in great detail; model systems that reflect the complexities of prostate cancer have been characterized, and multiple new therapies have been added to our clinical armamentarium.³⁴² These advances have created optimism and elevated the expectations of patients, physicians, and researchers. *The heterogeneity of virtually all known therapeutic targets* indicates that assessing biologic subsets with disproportionate benefit to specific interventions and understanding subsequent emergent resistance remain a preeminent challenge in experimental design. Progress toward achieving these goals has been made; for example, predictors of benefit or resistance to androgen inhibition have been proposed, and the characterization of variants that may benefit most for chemotherapy has been accomplished. These two groups may account for up to sixty percent of men with advanced prostate cancer and therefore serve as the solid foundation for the reclassification of prostate cancer. Acquisition of informative biomarkers is difficult, given the unique distribution of heterogeneous disease to bone; the phenotype of circulating tumor cells may vary substantially from those embedded in a metastatic environment under distinctive paracrine influences. The development of new methods to acquire relevant specimens and apply technologies to characterize them has demonstrated the potential of these strategies. These include enumeration or characterization of circulating tumor cells, bone marrow tumor cells, organoids, cytokine profile, and steroid metabolome.^{290, 343}

Palliative care

At no time in the management of CRPC is a focus on symptom control inappropriate. The selective and strategic use of external beam *radiation therapy* for palliation of bone pain, spinal cord compression, and prevention of fracture is critical in the management of CRPC. Early in the course of CRPC, external beam radiation or radioisotope therapy must be used sparingly, however, because bone marrow reserve critical for support of systemic therapy may be significantly compromised. *Palliative surgery* on the spine or long bones to prevent or manage pathologic fractures is less commonly required in CRPC than in breast cancer

or myeloma. Surgical extirpation of progressive symptomatic localized CRPC can prevent the grievous burden of pelvic floor invasion. The services of a *palliative care specialist* skilled in analgesic pharmacy and the management of a range of symptoms of advanced disease such as anorexia, nausea, constipation, depression, weight loss, insomnia, and delirium can be very valuable. The rediscovery of methadone as an effective and inexpensive opioid with a well-defined safety margin has been influential on patterns of care, and it is the rare patient for whom indwelling devices such as epidural pumps are necessary for maintaining effective analgesia. Finally, facilitation of end-of-life discussions and transition to hospice care at the appropriate time is of major benefit for patients and their families.

Histologic variants

Markers

The WHO histological classification of tumors of the prostate²⁹⁶ lists more than 30 histologic variants of tumors besides acinar adenocarcinoma that can affect the prostate ([Table 7](#)). This section describes the three most common of those variants.

[Table 7](#) WHO histologic classification of tumors of the prostate

Tumor class	Tumor type	Tumor subtype
Epithelial	Glandular neoplasms	Adenocarcinoma (acinar)
		Atrophic
		Pseudohyperplastic
		Foamy
		Colloid
		Signet ring
		Oncocytic
		Lymphoepithelioma-like
		Carcinoma with spindle cell differentiation (carcinosarcoma, sarcomatoid carcinoma)
		Prostatic intraepithelial neoplasia (PIN)
		PIN, grade III (PIN III)
		Ductal adenocarcinoma
		Cribriform
		Papillary
		Solid
	Urothelial tumors	Urothelial carcinoma
	Squamous tumors	Adenosquamous carcinoma
		Squamous cell carcinoma

	Basal cell tumors	Basal cell adenoma
		Basal cell carcinoma
Neuroendocrine tumors		Endocrine differentiation within adenocarcinoma
		Carcinoid tumor
		Small-cell carcinoma
		Paraganglioma
		Neuroblastoma
Prostatic stromal tumors		Stromal tumor of uncertain malignant potential
		Stromal sarcoma
Mesenchymal tumors		Leiomyosarcoma
		Rhabdomyosarcoma
		Chondrosarcoma
		Angiosarcoma
		Malignant fibrous histiocytoma
		Malignant peripheral nerve sheath tumor
		Hemangioma
		Chondroma
		Leiomyoma
		Granular cell tumor
		Hemangiopericytoma
		Solitary fibrous tumor

Ductal adenocarcinomas

Of the epithelial tumor variants, the most common are the ductal adenocarcinomas, originally described by Melicow and Pachter³⁴⁴ as endometrial carcinoma of the prostatic utricle. Once thought to arise from the verumontanum, a müllerian duct remnant, their prostatic origin has been firmly established, but the more recent controversy is centered on whether they truly represent a separate category of prostatic adenocarcinomas with a distinct biology, as opposed to a “mere morphological variant of prostatic adenocarcinoma.”^{345, 346} Ductal adenocarcinomas of the prostate have been reported to constitute 0.13%³⁴⁷ to 6.3%³⁴⁸ of all prostate carcinomas. They are characterized by duct-like structures lined by single layer or pseudostratified tall columnar cells with abundant eosinophilic to amphophilic cytoplasm displaying a papillary, cribriform, solid, or glandular architecture.³⁴⁶ Up to 20% present as pure ductal adenocarcinomas, but most cases are mixed with elements of acinar adenocarcinomas.^{348–350} Ductal adenocarcinomas do not express any specific markers that differentiate them from acinar adenocarcinomas. They are strongly positive for PSA and PAP and often express alpha-methylacyl coenzyme A racemase (AMACR) and occasionally carcinoembryonic antigen (CEA).^{351–353}

Approximately 30% of these tumors demonstrate residual basal cells, as demonstrated by positive staining for high molecular weight cytokeratin (HMWCK or 34betaE12) and p63.³⁵³

Sarcomatoid carcinomas

Carcinomas of the prostate with spindle cell differentiation, also known as carcinosarcomas or sarcomatoid carcinomas, are rare tumors (with only approximately 100 cases described in the literature³⁵⁴) that are characterized by the presence of both malignant high-grade epithelial and mesenchymal components. The epithelial component consists most commonly of acinar adenocarcinoma but may consist of ductal adenocarcinoma or contain elements of small-cell or squamous cell carcinoma.^{355–357} In approximately two-thirds of the cases, the mesenchymal component is a nonspecific malignant spindle cell proliferation, but in one-third, it displays specific mesenchymal elements such as those of osteosarcoma, chondrosarcoma, or rhabdomyosarcoma.³⁵⁶ The adenocarcinoma components are positive for keratin, and the sarcomatoid elements are positive for vimentin. The adenocarcinoma components are also positive for PSA in approximately 75% of the cases.³⁵⁵

Neuroendocrine tumors

Of the nonepithelial variants of prostate cancers, neuroendocrine tumors are the most frequently encountered. The WHO classification includes focal neuroendocrine differentiation, carcinoid tumors, and small-cell neuroendocrine carcinoma under this name.²⁹⁶ Focal neuroendocrine differentiation, when defined as immunohistochemical staining for neurosecretory products such as chromogranin A, serotonin, or synaptophysin, is encountered to some extent in almost all cases of acinar adenocarcinoma³⁵⁸ and appears to increase during treatment with androgen deprivation.^{359, 360}

Small-cell carcinomas

Only 0.5–2% of clinical prostate tumor specimens contain small-cell carcinomas, but 12–20% of cases in autopsy series have revealed small-cell carcinoma in the context of acinar adenocarcinoma.^{336, 361, 362} Between 42% and 75% of the clinical cases are preceded by a diagnosis of acinar adenocarcinoma, and mixed elements of high-grade acinar adenocarcinoma are present in 33–74% of the cases.^{20, 53, 54, 363, 364}

Small-cell carcinomas of the prostate are characterized by small round to spindle-shaped malignant cells displaying scanty cytoplasm, with hyperchromatic nuclei, coarse (salt-and-pepper) chromatin, nuclear molding, and absent or inconspicuous nucleoli. These cells are arranged in sheets with frequent necrosis and a high mitotic rate.³⁶⁵ Most but not all small-cell carcinomas stain positively for cytokeratin AE1/AE3 and CAM 5.2 (with a characteristic cytoplasmic dot-like pattern), as well as for neuroendocrine markers such as synaptophysin, chromogranin A, neuron-specific enolase, bombesin, and CD56.^{52, 53, 364, 365, 366} They are also often positive for TTF-1 and P504S, occasionally positive for CEA, but rarely positive for PSA, PAP, or AR.^{365, 367}

Clinical presentations

Ductal adenocarcinomas

Ductal adenocarcinomas commonly manifest with symptoms of urinary obstruction and/or hematuria. Cystoscopic examination frequently reveals infiltration of the prostatic urethra and occasional polypoid or villous intraurethral projections arising at or near the verumontanum.^{348, 351} These tumors are typically

high volume and locally advanced at diagnosis, with a 55–93% incidence of extraprostatic extension and a 20–47% incidence of positive margins reported in radical prostatectomy series.^{349, 350} In most instances, PSA levels are relatively high in patients with advanced disease,^{349, 368} although some cases manifest with serum PSA levels that are low relative to the tumor burden: in one series of 23 patients with metastatic disease, three patients (13%) had values <4 ng/mL.³⁶⁹ Most prostatic ductal adenocarcinomas metastasize to the bone and lymph nodes, as acinar adenocarcinomas do, but they have also been found to metastasize to unusual sites such as the penis, testis, and visceral organs.^{369, 370}

Sarcomatoid carcinomas

Sarcomatoid carcinomas of the prostate typically manifest as large prostatic masses with local invasion, resulting in pelvic or perineal pain, lower abdominal mass, and symptoms of urinary obstruction with low serum PSA levels.^{355, 357, 371} In more than half the cases, the diagnosis is preceded by a history of acinar adenocarcinoma treated with androgen-deprivation or radiation therapy, with the time between the original diagnosis of acinar adenocarcinoma and the diagnosis of sarcomatoid carcinoma ranging from 2 months to 16 years.^{355, 356, 372, 373} Both the carcinomatous and sarcomatous elements can metastasize, and metastatic disease is often present at the time of diagnosis, with the most common sites of nonlymph node metastases being the lung, bone, and brain.³⁵⁵

Small-cell carcinomas

Most patients with primary small-cell carcinomas have advanced-stage disease at their first visit, with large primary masses leading to lower urinary tract symptoms, bladder outlet obstruction, pelvic pain, ureteral obstruction, and/or hematuria.^{54, 363} Metastases are present in 75% of patients at the time of diagnosis of small-cell carcinoma.⁵⁴ When preceded by a diagnosis of acinar adenocarcinoma of the prostate, the time between that original diagnosis and the diagnosis of small-cell carcinoma can range between 1.5 months and 10 years.^{20, 54, 363, 364} Metastases are most often located in pelvic lymph nodes, liver, lungs, and bones,^{54, 363} although bony metastases are often osteolytic instead of osteoblastic, as would be typical for acinar adenocarcinoma.^{52, 364} Metastases to uncommon sites, such as the epididymis,³⁶⁶ subcutaneous tissue,²⁰ pericardium,⁵² or omentum,³⁶³ have been described. Brain metastases occur in up to 20% of patients during the course of the disease, so MRI of the brain or contrast-enhanced CT should be performed as part of the staging workup.^{54, 364} Serum PSA and PAP levels are often within normal ranges, but serum CEA and lactic acid dehydrogenase levels have been found to be higher than normal in 53–65% and 39–76% of patients, respectively.^{20, 364} Elevated levels of circulating bombesin, calcitonin, adrenocorticotrophic hormone, and somatostatin have also been observed.³⁶⁴ As is the case for small-cell carcinomas of the lung, a number of paraneoplastic syndromes have been described in association with small-cell carcinomas of the prostate, including hypercalcemia,³⁶⁶ elevated adrenocorticotrophic hormone,³⁷⁴ syndrome of inappropriate antidiuretic hormone,⁵² myasthenic syndrome,³⁶³ and hyperglucagonemia.³⁷⁵

Therapy options and applications

Ductal adenocarcinomas

The natural history of ductal adenocarcinomas is debated. Some series describe cases with indolent courses and prolonged survival,^{368, 370, 376, 377} whereas others describe cases with aggressive courses and relatively low 5-year survival rates.^{348–351} Some authors have proposed that the pure ductal

adenocarcinomas have a more indolent behavior, and the prognosis of the more common mixed ductal adenocarcinomas is dictated by the acinar component, which is frequently high grade.³⁶⁸ Much like acinar adenocarcinomas, most ductal adenocarcinomas are sensitive to both radiation and hormone-deprivation therapies.³⁴⁷ No published data support the use of chemotherapeutic treatments in this disease other than standard regimens for acinar adenocarcinomas.

Sarcomatoid carcinomas

The prognosis of prostatic sarcomatoid carcinomas is poor, regardless of the histologic type of the sarcomatous elements.^{355, 356, 371} In a 21-patient series with a median follow-up of 10 months (range 1–107 months), 18 patients died of their tumor within the follow-up period,³⁵⁵ and in a more recent 32-patient series, the actuarial risk of death at 1 year was estimated at 20%.³⁵⁶ Androgen-deprivation therapy is usually administered to target the malignant epithelial component, and the use of chemotherapy drugs typically administered for the treatment of sarcomas, such as ifosfamide and doxorubicin, has been reported.^{357, 371} However, among the nine patients given chemotherapy containing docetaxel, estramustine, carboplatinum, or cisplatin in the series of Hansel et al.,³⁵⁵ three died within 1 year of the diagnosis, and in five the cancer was unresponsive to chemotherapy. Given the morbidity caused by the local invasion of the primary tumors, palliative surgery (which often will need to involve anterior exenterations with urinary diversion) with or without adjuvant radiation may be appropriate. It is noteworthy that the only long-term survivor described by Dundore et al.³⁵⁴ was treated by pelvic exenteration and resection of lung metastases. Two other patients in their series, who survived 89 and 107 months, were treated with intratumoral iodine 125 (¹²⁵I) before dying of carcinosarcoma.

Small-cell carcinomas

Although chemotherapeutic agents are active in the treatment of small-cell carcinomas of the prostate, the prognosis remains poor, with reported median survival times ranging from 5 to 17.5 months.^{20, 52, 363, 364} In a recent 83-patient retrospective series, patients with nonmetastatic disease at their initial visit appeared to do slightly better (median disease-specific survival 17.1 months vs 12.5 months in patients with metastatic disease at the initial visit), although only 20% of the patients with nonmetastatic disease received local therapy in addition to systemic therapy.⁵⁴ Since these are radiosensitive tumors³⁷⁸ and at least one patient was apparently cured by surgical excision,³⁷⁹ it is clear that the role of local therapies deserves further investigation in this patient population. In a 21-patient series described by Amato et al.,³⁶³ four of eight patients responded to a combination of vincristine, doxorubicin, and cyclophosphamide. In a 38-patient phase II study of doxorubicin, etoposide, and cisplatin in patients with histologically proven small-cell carcinoma of the prostate (either pure or mixed with adenocarcinoma), the response rate in patients with measurable disease was 61%, and 84% of symptomatic patients experienced pain reduction.³⁶⁴ However, there were no complete responses, and the median time to progression and median overall survival were short, at 5.8 months and 10.5 months, respectively. It was concluded that the addition of doxorubicin to the standard etoposide–cisplatin regimen increased the toxic effects without any apparent increase in efficacy. It is also noteworthy that none of the 13 patients subjected to antiandrogen withdrawal in this study responded to that maneuver.³⁶⁴ It should be noted that even though small-cell carcinomas do not appear to respond to androgen-deprivation therapies, a large proportion of cases have shown coexisting components of acinar adenocarcinoma, so it is recommended that hormonal therapy accompany chemotherapy in the treatment of this disease.^{20, 52}

Algorithm for therapy: future directions

The main question about these histologic variants is whether they represent true biologic variants with different responses to standard treatments for prostate acinar adenocarcinomas that would require different therapeutic approaches, although differences in prognosis as treatment response profiles between the extremes of morphologic groupings (small-cell vs acinar adenocarcinoma) are obvious. However these are rare subsets and are often insufficient discriminators to make decisions in the majority of patients. Aparicio et al. noted that a group of men with CRPC and clinical features of small-cell cancers had heterogeneous morphologies but shared chemotherapy response profiles, prognosis, and shared biology in experimental model systems. These clinicopathologically identified variant prostate cancers with aggressive feature were dubbed “anaplastic prostate cancer.” The report highlights to the inadequacy of morphological characterization in predicting benefit to specific therapies and the urgent need to add molecular classification that reflects “driver biology.”

For all three variants, the role of local therapies remains to be determined, and in the case of small-cell carcinoma, it is reasonable to ask whether prophylactic brain irradiation should be offered to patients whose systemic disease is otherwise controlled.

Chapter 99

Tumors of the penis and the urethra

James F. Holland, MD, ScD (hc) ■ Raymond S. Lance, MD ■ Donald F. Lynch, Jr. MD

Overview

Carcinoma of the penis, predominantly squamous, some related to human papilloma virus, is rare in the developed world and among circumcised men, but of major importance elsewhere. Surgery early can be curative. Other modalities are less robust. Voluntary adult circumcision to diminish susceptibility to human immunodeficiency virus infection is being observed as possibly preventive. Urethral cancer, rare, usually of transitional epithelium, is often detected too late for cure.

Squamous carcinoma of the penis is a largely preventable disease, dependent on early circumcision, personal hygiene, access to healthcare, and avoidance of human papilloma virus (HPV). Because the disease is rare in the developed world, the efficacy of HPV immunization will likely be determined in the developing world. Early recognition of tumor lesions correlates with lower staging and more effective treatment with better organ sparing and lower mortality.

Cancer of the penis is an unusual disease in the United States (<2000/year) and Europe, but is a major health problem in Africa, Asia, and South America. Approximately 95% of primary penile cancers are squamous cell carcinomas (SCCs) ([Figure 1](#)). Other cancers involving the penis are verrucous carcinoma, alternatively known as giant condyloma or Buschke-Lowenstein tumor, a variant of squamous carcinoma which does not metastasize, but which spreads aggressively by local extension and destroys surrounding tissue ([Figure 2](#)).¹ Epidemic Kaposi's sarcoma associated with acquired immunodeficiency syndrome (AIDS) is now uncommon ([Figure 3](#)). Melanoma and basal cell carcinoma very rarely involve the penis. A scaly red clearly demarked intraepithelial squamous carcinoma *in situ* (CIS) is denominated Bowen's disease when it involves the base of the penis and the scrotum. When CIS involves the glans or prepuce, it appears as shiny red velvet and is known as erythroplasia of Queyrat ([Figure 4](#)). Carcinomas *in situ* have the potential to develop into invasive squamous carcinoma in about 20%. Biopsy is required to establish a diagnosis. Leukemias and lymphomas can present as priapism. Diagnosis and therapy for them are systemic.

Figure 1 Microscopic squamous cell carcinoma, moderately well differentiated, with characteristic keratin pearl formation.

Figure 2 Verrucous carcinoma (Buschke-Lowenstein tumor).

Figure 4 Erythroplasia of Queyrat of glans.

Epidemiology and etiology

In countries where infant circumcision is common, such as Israel and the United States, the incidence of squamous carcinoma of the penis is low. Circumcision later in life has not conferred protection, perhaps because it was done for cause such as phimosis and balanitis.² Proper hygiene is made difficult by phimosis, perpetuating chronic inflammation of the glans penis and preputial tissue. Inexpensive adult circumcision as a protective measure against human immunodeficiency virus (HIV) infection, recently practiced in Africa, may alter this information.²

An association between cervical cancer in women whose partners have penile cancer has been observed, and squamous carcinoma of the penis and of the cervix has been associated with human papilloma viruses (HPV [16,18,31]).³ The foreskin of 9% of uncircumcised preadolescent boys contained HPV, attesting to the ubiquity of this virus.⁴ Uncircumcised men are three times more likely to harbor HPV than circumcised men, and female partners of circumcised men are less likely to develop cervical cancer.^{5, 6} HPV shedding may occur in asymptomatic carriers, in those with unrecognized intraurethral lesions, or men with condyloma accuminata, exposing their partners of either sex. Tobacco smoking is correlated with increased HPV infection and cancer of the penis and cervix.⁵

Diagnosis

Early invasive tumors may be small and largely unremarkable, sometimes resembling small abrasions (hair cuts) or calloused thickenings of penile skin. The initial lesion of squamous carcinoma most commonly presents on the glans or prepuce. It varies from a small, velvety, reddened, raised maculopapule to an ulcer, hyperkeratotic area, or exophytic papillary tumor. Biopsy is required to make the diagnosis and should include contiguous normal skin for comparison.¹ More advanced lesions may be exophytic or ulcerated, and very advanced cancers may completely destroy the penile shaft. Metastases to the inguinal lymph nodes may produce large ulcerations in the groin late in the course of the disease. Well-differentiated tumors tend to metastasize infrequently, while more poorly differentiated tumors have a high propensity for early metastasis. Several studies have confirmed that higher tumor grade increases the likelihood of inguinal nodal metastases.⁷

Metastasis

Invasive squamous carcinoma of the penis follows a predictable pattern of metastasis. Lesions of the glans, coronal sulcus, prepuce, and distal shaft spread to the deep inguinal nodes, while lesions of the proximal shaft and base of the penis spread to the more lateral and superficial inguinal nodes. Subsequent spread to the external iliac, obturator, and iliac chains follows.⁸ Metastases to distant sites are infrequent and occur late in the course of disease. Left untreated, penile cancer progresses, causing the deaths of the majority of those untreated within 3 years.

Because primary lesions may be infected or chronically inflamed, secondary inflammation of the inguinal nodes is often present which may be difficult to distinguish from metastatic disease. Careful re-examination of the inguinal nodes following a 4–6-week course of broad-spectrum antibiotic therapy may help to differentiate inflammation from cancer.

Tumor staging

Once the diagnosis of squamous carcinoma is established, complete staging is undertaken. Inguinal nodes are carefully palpated. Additional studies should include chest X-ray, computerized tomography (CT) of the pelvis and inguinal regions, and possibly magnetic resonance imaging (MRI).⁹ Positron emission tomography-computerized tomography (PET-CT) and MRI are superior to palpation for detection of suspicious nodal enlargement. Lymph angiography is no longer used as a staging procedure. MRI provides good discrimination of penile structures and may identify corpora cavernosal or spongiosal invasion.

The American Joint Committee on Cancer (AJCC) Tumor, Nodes, Metastases (TNM) system, seventh edition, is the accepted staging system for penile cancer ([Table 1](#)).

Table 1 AJCC (2010) TNM staging of penile cancer

Primary tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma <i>in situ</i>		
Ta	Noninvasive verrucous carcinoma ^a		
T1a	Tumor invades subepithelial connective tissue without lymph vascular invasion and is not poorly differentiated (i.e., grades 3–4)		
T1b	Tumor invades subepithelial connective tissue with lymph vascular invasion or is poorly differentiated		
T2	Tumor invades corpus spongiosum or cavernosum		
T3	Tumor invades urethra		
T4	Tumor invades other adjacent structures		
Regional lymph nodes (N)			
Clinical stage definition ^a			
cNX	Regional lymph nodes cannot be assessed		
cN0	No palpable or visibly enlarged inguinal lymph nodes		
cN1	Palpable mobile unilateral inguinal lymph node		
cN2	Palpable mobile multiple or bilateral inguinal lymph nodes		
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral		
Anatomic stage/prognostic groups			
Stage 0	Tis	N0	M0

Surgical treatment

Treatment of penile cancer is based on the extent of the primary tumor and its tumor grade, established by biopsy of the lesion. Antibiotic therapy is begun before biopsy and continued throughout surgical treatment and from 4 to 6 weeks afterward. Lymph node metastasis is assessed. Once the tissue diagnosis is confirmed, small superficial tumors may be treated successfully with local surgical excision, LASER surgery,¹¹ Mohs' micrographic surgery,¹² or superficial radiation therapy.

Larger tumors with invasion may sometimes be managed with organ-sparing surgery or radiotherapy (RT), but deeply invasive cancers, particularly those that deform the glans or that involve the shaft structures, may not be amenable to conservative measures. These lesions, which involve the distal shaft or glans, are usually managed by partial penectomy providing that a 2-cm margin can be achieved and still leave enough penile length to allow voiding while standing and to permit intercourse.^{13, 14} More advanced cancers that involve the base of the penis are best managed by total penectomy with creation of a perineal urethrostomy.¹⁴ Extensive lesions that involve the base of the penis and the bulbar urethral portion may require cystoprostatectomy or even anterior or total pelvic exenteration with urinary diversion.

Inguinal or pelvic lymph node metastasis constitutes an important factor predicting survival in men with SCC of the penis. The superficial inguinal lymph nodes receive lymphatic drainage from the penile shaft and base. The deep inguinal lymph nodes receive drainage from the glans, prepuce, and distal shaft. There is crossover of the lymphatic channels at the base of the penis so that a lesion on one side of the penis may metastasize to the contralateral inguinal nodes. The deep inguinal nodes drain to the external iliac and obturator chains and, subsequently, to the common iliac nodes and the retroperitoneal nodes surrounding the aorta and inferior vena cava.¹⁵

A meticulous inguinal node dissection is curative in 40–60% of cases. Traditional node dissection carries with it a high likelihood of morbidity: flap necrosis, wound infection, chronic lymphangitis, lymphocele, and chronic lower limb edema. A modified, less extensive dissection has been adopted by many surgeons, which has reduced some of the adverse sequelae of groin dissection.¹⁶ Nonetheless, inguinal node dissection should not be undertaken lightly, and clinical and imaging assessment should be made. Inguinal lymph nodes are palpable in 50–82% of patients at initial diagnosis. In only about half these cases is cancer found on lymph node dissection.¹⁷ Lymphadenectomy may be indicated if palpable nodes remain after 4–6 weeks of antibiotic therapy. PET-CT and MRI should be done at that time. Sentinel node biopsy may be helpful. About 25% of patients with impalpable nodes have metastatic disease and should undergo

a node resection.¹⁸ For those with impalpable nodes and negative imaging studies, close and continued follow-up is essential with repeated imaging and examination.^{19, 20} Patients with metastases to the groin who do not undergo appropriate node dissection usually die of their disease within 3 years.

Tumor grade

Tumor grade as well as stage is important in assessing the risk of nodal metastases. Patients with grade I well-differentiated tumors that are limited to the skin and superficial tissues of the penis are unlikely to have tumor metastases to inguinal nodes. Patients with moderately or poorly differentiated lesions with any degree of invasion of the deeper penile structures are at significant risk of groin metastasis.¹⁹ Contemporary practice supports early surgery if higher grade tumor and more than superficial invasion are documented on biopsy.

Pelvic lymphadenectomy

Patients found to have inguinal node metastases should undergo pelvic lymphadenectomy on the affected side.²¹ This can be done extraperitoneally via a midline incision or through a modified groin incision at the time of inguinal node dissection, although at some centers the procedure is staged several weeks later. Patients with three or less lymph nodes below the bifurcation of the external and internal iliac vessels often do well, but metastases above the bifurcation have usually been fatal.

Radiotherapy

Primary RT of penile cancer is used more widely in Europe than in the United States but may be appropriate for small superficial lesions or for selected larger lesions when organ preservation is the goal, or when patients refuse surgery.²² Tissue preservation may not be feasible in more advanced lesions, however. Concurrent chemotherapy may enhance the effectiveness of RT. RT can be delivered either as external beam administered with wax block delivery or as brachytherapy with a mold or with Iridium¹⁹² wires. Iridium¹⁹² or Cesium¹³⁷ may be used to boost dosages in bulky or extremely cornified tumors. The normal dose is 30–50 Gy given over 3–5 weeks. Boosts to 65–70 Gy utilizing various brachytherapy techniques may follow if clinically indicated. RT is often the treatment of choice in symptomatic lesions of Kaposi's sarcoma. RT may be used as primary therapy in a select group of men presenting with localized penile cancer.²³ This group is small but includes young men with small superficial noninvasive lesions located on the distal penis and those who refuse to have surgery as initial treatment. In addition, RT is used for men with inoperable tumors.

Acute radiation reactions—edema, tissue inflammation, skin irritation, tenderness, and dysuria—are common. Such symptoms usually subside promptly when therapy is completed. Long-term effects of radiation may include telangiectasia, hyperpigmentation, diminished sensation, scarring, and atrophy of the treated tissues. Fibrotic change and fistulization may occur in large lesions where significant tissue damage has occurred before the RT. Late recurrences in radiated sites may occur up to a decade after definitive treatment, affirming that close follow-up is essential.

Randomized trials comparing RT to surgery have not been reported. In one study of clinically localized penile cancer, local regional relapse occurred in 56% of those treated with definitive primary radiation therapy compared to 13% of those treated by surgery. Of the RT failures, 73% were salvaged with surgery.²⁴

RT to the groin following inguinal surgery increases complications. Some studies have suggested benefit from such treatment, while others show no improvement when compared with patients treated by surgery alone. RT to bulky unresectable lymph node metastases is rarely effective, except as a palliative measure, usually in concert with systemic chemotherapy.

Chemotherapy

Chemotherapy is used in treating penile cancer as an adjuvant to definitive surgical or radiation therapy or as a radiosensitizer. Experience with various treatment protocols is limited by the relative rarity of the disease. Combination chemotherapy with vincristine, bleomycin, and methotrexate (VBM) has been successful in rendering patients with fixed nodal metastases resectable.²⁵ Extensive experience with cisplatin or carboplatin in combination with fluorouracil, paclitaxel, or docetaxel has caused regression in SCCs of esophagus, head and neck, and anus. Many of these cancers are also related to HPV. The recognition that the molecular characteristics of SCCs are more relevant than their organs of origin supports the use of these agents in SCC of the penis. Neoadjuvant chemotherapy can reduce tumor burden under direct observation.²⁶ Postoperative adjuvant chemotherapy requires a randomized series to establish its definitive value. Although used simultaneously with radiation, adjuvant chemotherapy has been used after surgery on the presumption of its importance by analogy with proven effectiveness in other sites. Where positive nodes have been excised, there are many data to support adjuvant chemotherapy. In patients where SCCs of the penis have been totally removed, who do not have inguinal metastases on biopsy, or even on the basis of clinical and imaging negativity, the use of adjuvant chemotherapy is still controversial.

Prognosis

Left untreated, squamous carcinoma of the penis is invariably lethal, killing most of those afflicted within 3 years. Outcome is directly related to the extent of the disease at diagnosis and the presence or absence of inguinal metastases. Disease-related survival for localized tumor is approximately 80%, for regional nodal disease about 50%, and for pelvic metastases about 10%. In a retrospective study of men with positive pelvic lymph nodes, adjuvant chemotherapy resulted in a median survival of 22 months versus 10 months in its absence.²⁷ In a prospective study of cisplatin, fluorouracil, and a taxane for men with N2 or N3 M0 disease, disease-free survival at 2 years was only 37%.²⁶

Carcinoma of the urethra

Male urethral carcinoma

The male urethra averages some 18 cm in length and is subdivided into the penile urethra, the membranous urethra, and the prostatic urethra. Beginning distally, the penile urethra is composed of the meatus and fossa navicularis, which is lined with stratified squamous epithelium. The pendulous urethra extends from the proximal fossa navicularis to the suspensory ligament of the penis, where it then becomes the bulbar urethra between the ligament and the urogenital membrane. These areas are lined with stratified or pseudo-stratified columnar epithelium as is the short (1.5 cm) membranous urethra. This contains the external sphincter, which is composed of striated muscle fibers. The prostatic urethra passes through the prostate and is lined with transitional cell epithelium.

From 50% to 75% of male urethral cancers arise in the bulbar urethra ([Figure 5](#)). The remainder occurs predominantly in the fossa navicularis. About 90% of male urethral tumors demonstrate SCC histology.²⁸ Stricture of the urethra is often a result of the cancer. Transitional cell or undifferentiated carcinomas usually predominate at the bladder neck and within the prostatic urethra. Poorly differentiated transitional cell carcinomas often exhibit squamous characteristics. Adenocarcinoma can arise in the glands of Littre or the prostatic utricle but are rare. Metastasis to the penis from other organ sites is also rare.

Figure 5 Retrograde urethrogram demonstrating squamous cell carcinoma of bulbous urethra associated with a stricture.

Obstructive symptoms are common in proximal lesions, while urethral bleeding and a palpable mass characterize cancers of the penile urethra. In general, the more proximal a tumor, and the longer its delay in diagnosis, the higher the stage is.

If the urethra is retained following cystectomy for bladder cancer, urethral tumors if they develop are usually transitional cell carcinomas. If urethrectomy is a component of cystectomy for bladder cancer, the entire structure, including the fossa navicularis, must be excised.²⁹

Lymphatic draining of the distal urethra is similar to that of penile tumors. Tumors of the fossa and pendulous urethra drain to the superficial inguinal lymph nodes, whereas tumors of the bulbar, membranous, and prostatic urethral segments drain to the iliac obturator and presacral node groups. Crossover metastasis may occur at the prepubic lymphatic plexus.

Staging

The AJCC staging system for urethral carcinoma is given in [Table 2](#). In the older terminology, anterior and posterior tumors were delineated at the suspensory ligament.

Table 2 AJCC (2010) TNM staging of urethral cancer

Primary tumor (T) (male and female)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma <i>in situ</i>

T1	Tumor invades subepithelial connective tissue		
T2	Tumor invades any of the following: corpus spongiosum, prostate, and periurethral muscle		
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, and anterior vagina bladder neck		
T4	Tumor invades other adjacent organs		
Regional lymph nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single lymph node 2 cm or less in greatest dimension		
N2	Metastasis in a single node more than 2 cm in greatest dimension or in multiple nodes		
Anatomic stage/prognostic groups			
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
	Tis pu	N0	M0
	Tis pd	N0	M0

Surgical management

Low-grade, low-stage tumors of the urethra are uncommon but can be managed by transurethral resection or laser fulguration. Biopsy is essential to establish histopathology and the depth of the neoplasm. Partial penectomy with at least a 2 cm margin may be adequate if the tumor does not involve the corpus

spungiosum or the corpora cavernosa.³⁰ Advanced or more proximal lesions usually require total penectomy and creation of a perineal urethrostomy. Anterior exenteration and radical cystoprostatourethrectomy may be required for carcinomas of the membranous or prostatic urethra.

Metastases to superficial or deep inguinal lymph nodes often lead to pelvic and systemic metastases.³¹ Attentive clinical and imaging assessment is crucial in the follow-up of urethral cancer. Inguinal node dissection is critical if metastatic adenopathy is suspected based on MRI, PET/CT, or clinical examination. Deep pelvic adenectomy is also indicated for positive nodes, although the success of such surgery in extending survival is uncommon.

Adjuvant therapy

Because most urethral cancers carry a poor prognosis from surgery alone, if they are not superficial and local, chemotherapeutic regimens appropriate for the tumor type have been used as adjuvant treatment. Radiation therapy is also used. Clinical reports endorse these efforts, although prospective studies with controls have not been reported. Neoadjuvant chemotherapy or chemoradiotherapy for patients with T3 disease or clinically positive inguinal adenopathy had superior surgical outcome compared to those who underwent primary surgery without adjuvant participation.³²

Female urethral carcinoma

The female urethra is largely contained within the anterior vaginal wall. In the adult, it is 2–4 cm in length. It is lined distally with stratified squamous epithelium changing to columnar epithelium proximally. At the bladder neck, transitional cell epithelium is found. A urethral diverticulum in the distal urethra may be a remnant of Wolffian or ectopic cloacal epithelium.

The histopathology of female urethral cancer depends on the cell of origin. Squamous carcinoma is the most frequent, comprising about 50% of tumors. Transitional cell carcinoma and adenocarcinoma are about 25% each. Tumor grade apparently does not influence metastasis and prognosis as much as in men. Mixed tumors, undifferentiated carcinomas, melanoma, cloacogenic carcinoma, and clear cell adenocarcinomas are rare but do occur.

Urethral carcinomas spread first by local extension and then metastasize by lymphatic channels and hematogenously. Lymphatic drainage of the distal urethra and the labia leads to the superficial and deep inguinal nodes. Proximal urethral drainage leads to iliac, obturator, presacral, and preaortic nodes. Palpable adenopathy is present at presentation in up to half the patients and almost always represents metastatic cancer.³³ Adenocarcinomas more commonly metastasize to distant sites hematogenously, including liver, lung, brain, and skeleton.

Staging

The AJCC TNM staging system is presented in [Table 2](#). The entire length of the female urethra is often involved.

Surgical management

Most urethral tumors in women present with bleeding or dysuria because of a urethral mass. Distal urethral lesions generally are diagnosed early at a low stage. Local excision, partial urethrectomy, RT, and laser ablation have all been employed with some success. Higher stage more extensive urethral carcinomas can be managed with cystourethrectomy and an ileal pouch, or when bladder preservation is possible, interposition of the amputated vermiform appendix as a conduit to the surface (the Mitrofanoff

procedure). Proximal lesions present later and at higher stage than distal lesions. Obstructive symptomology is the hallmark of proximal urethral lesions. Extensive lesions that involve the bladder or the vaginal wall may necessitate cystectomy or even anterior exenteration with urinary diversion. Local recurrence is common. Positive inguinal nodes by clinical or imaging techniques and proximal urethral carcinomas require deep pelvic node adenectomy.

Chapter 100

Testis cancer

Christian Kollmannsberger, MD, FRCPC ■ Craig R. Nichols, MD ■ Siamak Daneshmand, MD ■ Eric K. Hansen, MD ■ Christopher L. Corless, MD, PhD ■ Bruce J. Roth, MD ■ Lawrence Einhorn, MD

Overview

Cancer of the testis is a relatively uncommon disease, accounting for approximately 1% of all cancers in males. However, it represents a highly curable neoplasm, the incidence of which is focused on young patients at their peak of productivity. Curative treatment of disseminated nonseminomatous germ cell tumors often combines surgery and chemotherapy. The goal of initial therapy is never palliation or prolongation of survival, but cure.

Epidemiology

Incidence

Age-related incidence of testicular cancer reveals a bimodal distribution.¹ The major peak occurs between ages 15 and 35 years, owing almost exclusively to tumors of germ cell origin, which account for approximately 95% of all testicular cancer. Embryonal carcinoma represents the predominant histopathologic diagnosis up to the age of 35 years, after which seminoma is more common. From 2001 to 2005, the median age at diagnosis for cancer of the testis was 34 years of age.²

The incidence of testicular cancer varies based on geographic distribution. The incidence is highest in northern Europe and North America and lowest in Asia and Africa. There is also a striking influence of race, with the incidence among black and Hispanic males worldwide far less than that for their white counterparts.^{3, 4} In the United States, estimates of the incidence ratio between white and African-American patients range from 4 to 5 : 1. Testicular cancer appears to be increasing among young white males in the Scandinavian countries, the United Kingdom, and the United States.⁵ Standardized incidence rates increased annually 2–5%, with marginal differences between seminomas and nonseminomas. In the United States, the annual percentage change from 1989 to 2005 was 0.8%. It is estimated that 8090 cases of testicular cancer were diagnosed in the United States in 2008, with approximately 380 persons dying of the disease.⁶

Risk factors

Cryptorchidism is the major identifiable risk factor associated with the development of testicular cancer, with a risk ratio reported between 2.5 and 14 in case–control studies.⁷ The location of the maldescended testicle appears to be an important cofactor, because those patients with intra-abdominal retention have a fourfold higher incidence of malignancy than those with the testicle retained in the inguinal canal. It seems unlikely that maldescent alone represents the initiating event in the development of germ cell tumors (GCTs): Only 10% of testicular tumors are associated with cryptorchidism, whereas 10–20% of the

malignancies in patients with cryptorchidism occur in the contralateral, normally descended testicle; prepubertal orchiopexy fails to prevent the subsequent development of malignancy in the undescended testicle; and first-degree male relatives of patients with testicular cancer exhibit an increased incidence of cryptorchidism, hydroceles, and inguinal hernias, as well as testicular cancer.^{8,9} These data suggest that some genetic predisposition and/or in utero environmental event may result in several genitourinary developmental abnormalities, including maldescent and germ cell neoplasia. An increase in the frequency of cryptorchidism has been observed and appears to parallel the timing and magnitude of the increase in incidence of testicular cancer. Brothers of men with testicular germ cell tumors (TGCTs) have an 8-fold to 10-fold risk of developing TGCT, whereas the relative risk to fathers and sons is approximately fourfold. This familial relative risk is much higher than that for most other types of cancer. A genome-wide linkage search yielded evidence for a testicular cancer susceptibility gene on chromosome Xq27 that may also predispose to undescended testes.¹⁰

TGCTs occur at increased frequency in men with human immunodeficiency virus (HIV). In one multicenter study, 35 patients with HIV-related GCTs were identified. The median age at GCT diagnosis was 34 years (range, 27–64 years). The median CD4 cell count was 315/mm³ (range, 90–960/mm³). There were seminoma in 26 patients (74%) and nonseminomatous germ cell tumor (NSGCT) in nine patients (26%). Twenty-one patients (60%) had stage I disease and 14 patients had metastatic disease. Overall, six patients relapsed, three died from GCT, and seven died from HIV, resulting in a 2-year overall survival rate of 81%. HIV-related seminoma occurred more frequently than in the age-matched and sex-matched HIV-negative population, with a relative risk of 5.4 (95% confidence interval [CI] = 3.35–8.10); however, NSGCT did not occur more frequently, and there was no change in the incidence of GCT since the introduction of highly active antiretroviral therapy. The authors concluded that testicular seminoma occurs significantly more frequently in HIV-positive men than in the control population. Patients with HIV-related GCTs present and should be treated in a similar manner to those in the HIV-negative population. Most of the mortality relates to HIV infection.¹¹

An additional predisposition is the association of mediastinal NSGCTs with Klinefelter's syndrome. Approximately 10% of all patients with mediastinal nonseminoma have Klinefelter's syndrome, and there does not appear to be an increased incidence in patients with testicular or retroperitoneal primary tumors.¹²

An association of dysplastic nevus syndrome and testicular cancer has been observed.¹³ A twofold higher incidence of multiple atypical nevi, and the attendant risk of melanoma, has been noted.

Patients with a history of unilateral testicular cancer are at risk of developing cancer in the other testicle. In a large series, 2.7% of 2338 patients developed a contralateral testicular tumor during the period of follow-up.^{14–16} Investigators at the Royal Marsden Hospital reported a similar rate of 2.75% for developing contralateral tumors among 760 men in an interval as long as 15 years.¹⁷

Between 1950 and 2001, 3984 patients with testicular cancer were treated at Memorial Sloan Kettering for GCT. A total of 58 patients with bilateral TGCTs were identified. Median follow-up was 60 months. Ten of the 58 patients (17%) had synchronous tumors, while the other 48 (83%) had metachronous tumors. Overall, seminoma was the most common histology of the synchronous and metachronous tumors. Most patients in the synchronous and metachronous tumor groups presented with low-stage disease. Of the 58 patients, 52 (89%) had no evidence of disease, and 6 (11%) were dead of disease at the last follow-up. Treatment of the second tumor appeared to be influenced by therapy for the first tumor in 16.7% of cases.¹⁸

Some clinicians recommend routine biopsy of the contralateral testis for patients diagnosed with unilateral testicular cancer. Fossa and colleagues evaluated the risk of contralateral testicular cancer and survival in a large population-based cohort of men diagnosed with testicular cancer before age 55 years using Surveillance, Epidemiology, and End Results (SEER) data. From 29,515 testicular cancer cases reported to the SEER Program of the National Cancer Institute (NCI), from 1973 through 2001, estimates of prevalence of synchronous contralateral testicular cancer, the observed-to-expected ratio (O/E), 15-year cumulative risk of metachronous contralateral testicular cancer, and the 10-year overall survival rate of both synchronous and metachronous contralateral testicular cancer were made. A total of 175 men presented with synchronous contralateral testicular cancer; 287 men developed metachronous contralateral testicular cancer (O/E = 12.4 [95% CI = 11.0–13.9%]; 15-year cumulative risk = 1.9% [95% CI = 1.7–2.1%]). In the multivariable analysis, only nonseminomatous histology of the first testicular cancer was associated with a statistically significantly decreased risk of metachronous contralateral testicular cancer (hazard ratio [HR] = 0.60; 95% CI = 0.46–0.79%; $p < 0.001$). Increasing age at first testicular cancer diagnosis was associated with decreasing risk of nonseminomatous metachronous contralateral testicular cancer (odds ratio (OR) = 0.90; 95% CI = 0.86–0.94%). The 10-year overall survival rate after metachronous contralateral testicular cancer diagnosis was 93% (95% CI = 88–96%), and that after synchronous contralateral testicular cancer was 85% (95% CI = 78–90%). The low cumulative risk of metachronous contralateral testicular cancer and favorable overall survival of patients diagnosed with metachronous contralateral testicular cancer is in accordance with the current US approach of not performing a biopsy on the contralateral testis.

These observations underscore the importance of continued long-term follow-up of patients with TGCTs.

Pathology

Origin and molecular genetics

Testicular tumors fall into several broad groups ([Table 1](#)). Classification of the GCTs has been based on morphology, but recent molecular studies have yielded a more ontological scheme consisting of five distinct subtypes that differ in their proposed cell of origin.¹⁹ Accordingly, teratomas and yolk sac tumors arising in neonates and young children derive from primordial germ cells or very early gonocytes distributed along the gonadal ridge or in the testis/ovary. These tumors retain most of the genomic imprinting from both parental genomes. The teratomas remain diploid, while the yolk sac tumors show gains of chromosomes 1q, 12p13–14, and 20q, and losses of 1p, 4, and 6q.¹⁹

Table 1 Primary tumors of the testis

Type	Relative frequency	Genotype/comments
<i>Germ cell tumors</i>		
Infants and children	~1% of all testis tumors	
Yolk sac tumor	65–80% of prepubertal	Aneuploid
Teratoma	20–35% of prepubertal	Diploid; mature elements; benign
Adolescents and adults	95% of all testis tumors	
ITGCNU	>90% of postpubertal	Aneuploid (near triploid)
Seminoma	~45% of postpubertal	Aneuploid (near triploid); iso12p
Nonseminomatous (NSGCT)	~55% of postpubertal	Aneuploid (near triploid); iso12p
Embryonal carcinoma	~75% of NSGCT	
Yolk sac tumor	~50% of NSGCT	
Teratoma	~50% of NSGCT	Malignant (even mature elements)
Choriocarcinoma	~10% of NSGCT	
Adults (usually >50 years)		
Spermatocytic seminoma	<1% of postpubertal	Variable ploidy; gain of chromosome 9
Spermatocytic seminoma with sarcoma	Very rare	
<i>Sex cord-stromal tumors</i>		
Leydig cell tumor	~3% of all testis tumors	7–10% metastasis (postpubertal)
Sertoli cell tumor	<1% of all testis tumors	
Granulosa cell tumor		
Adult type	Very rare	
Juvenile type	Uncommon	Infants <6 months
Mixed/indeterminate	Rare	
<i>Mixed germ cell/sex cord-stromal tumors</i>		
Gonadoblastoma	Very rare	

Spermatocytic seminoma is a second, distinct subtype of GCT thought to derive from postpubertal spermatogonia/spermatocytes. Accordingly, these tumors have a paternal pattern of genomic imprinting and show variable ploidy, sometimes with a gain of chromosome.¹⁰

Two of the other five proposed subtypes of GCT do not occur in the testis. Dermoid cysts of the ovary, which are thought to arise from oogonia/oocytes, are diploid/tetraploid and show maternal genomic imprinting. Hydatidiform mole (gestational trophoblastic disease) is a placental-derived neoplasm that

contains a purely paternal genome as a result of fertilization of an empty ovum.

The fifth subtype of GCT consists of seminoma and the NSGCT patterns that, together, account for 95% of primary testicular neoplasms (Table 1). Variants of this GCT subtype also occur in the ovary (dysgerminoma), anterior mediastinum, and midline brain (germinoma). It is suggested that seminoma and NSGCT are derived from gonocytes that have lost their genomic imprinting as a result of being later in their development than those that give rise to infantile teratomas and yolk sac tumors. These gonocytes are polyploid (triploid or tetraploid), probably because of meiotic arrest. Depending on exactly when this arrest occurs during fetal development, the affected cells may be distributed to one or both testes, accounting for the bilateral GCTs observed in 2–3% of patients.

Seminomas and NSGCT share a common precursor lesion called intratubular germ cell neoplasia, unclassified (ITGCNU). Growing *in situ* within seminiferous tubules, ITGCNU cells express markers shared with embryonic stem cells, including the transcription factors OCT3/4 and NANOG.^{20, 21} These factors are essential to the development of embryonic stem cells in mice, but are not expressed in normal spermatogonia in mice or humans. Their presence in ITGCNU supports the theory that a pluripotent gonocyte is the cell of origin for both seminoma and NSGCT. In addition, OCT3/4 serves as a highly specific immunohistochemical marker in the diagnosis of extra-TGCTs (Table 2).^{20, 22}

Table 2 Markers of testicular germ cell tumors

Morphologic subtype	Serum	Immunohistochemistry	FISH
ITGCNU		PLAP, KIT, OCT3/4	
Seminoma	HCG (low)	PLAP, KIT, OCT3/4	Excess 12p
Embryonal carcinoma	HCG (low)	CD30, OCT3/4, PLAP	Excess 12p
Yolk sac tumor	AFP	AFP, PLAP	Excess 12p
Choriocarcinoma	HCG (high)	HCG	Excess 12p
Teratoma			Excess 12p

Abbreviations: AFP, α-fetoprotein; FISH, fluorescence *in situ* hybridization; HCG, human chorionic gonadotropin; PLAP, placental/germ cell alkaline phosphatase.

Progression of ITGCNU to an invasive GCT is accompanied by a number of common events.²³ One is the acquisition of excess genetic material from the short arm of chromosome 12. In 80% of cases, this is accomplished through loss of 12q and reduplication of 12p (isochromosome 12p), while in 20%, the additional 12p sequences are distributed among other derivative chromosomes. Interestingly, the embryonic stem cell gene *NANOG* is on 12p. Fluorescence *in situ* hybridization (FISH) for 12p is used in paraffin sections as a diagnostic marker for GCTs and also for nongerm cell derivatives.

Additional events associated with malignant progression of ITGCNU include loss of expression of the homeobox gene *NKX3.1*,²⁴ loss of the tumor suppressor *PTEN*,²⁵ and decreased expression of the cell cycle regulator p21.²⁶ Mutations of *TP53* are rare in postpubertal GCTs, but the effects of this important tumor suppressor may be by *MDM2* overexpression²⁶ or downregulation of *LATS2* by microRNAs mi-R372 and mi-R373. A genetic screen implicates miRNA-372 and miRNA-373 as oncogenes in TGCTs.²⁷

Although seminoma and NSGCT share a common origin, they are clinicopathologically distinct cancers. Little is known of what determines their differences, but oncogenic mutations in *KIT* (a receptor tyrosine kinase) are found in 25% of seminomas and are essentially absent in NSGCT. These mutations may occur very early in seminoma tumorigenesis, as they are present in ITGCNU,²⁸ and in dysgerminoma/germinoma

of the ovary, mediastinum, and brain. Based on studies in mice, *KIT* gene function is essential to the development of primordial germ cells and to normal spermatogenesis; therefore, constitutive activation of this kinase may favor the seminoma pathway. Unfortunately, KIT kinase inhibitors such as imatinib are not likely to be of benefit to seminoma patients harboring *KIT*-mutant tumors, because most of the published mutations are inherently resistant to the available drugs.

Seminoma

Approximately 45% of all postpubertal TGCTs are pure seminoma (“classic” seminoma). The incidence is increased to 60% in cryptorchid testes. On gross examination, such tumors are generally homogeneous and well demarcated. Distinct lobulation may be apparent, with the nodules separated by dense fibrous bands. Areas of necrosis and hemorrhage are usually discrete. Microscopically, there is a monotonous distribution of uniform, rounded cells with large, centralized nuclei and nucleoli. The cytoplasm may be either clear or granular and will frequently stain for glycogen, lipid, and/or placental/germ cell alkaline phosphatase (PLAP). Stromal elements include an infiltrate rich in T lymphocytes and containing occasional granulomas ([Figure 1](#)). These features may mimic granulomatous orchitis.

Figure 1 Small nests of seminoma are separated by a lymphoid infiltrate and a focal granulomatous reaction.

Seminoma presents most commonly in the fourth and fifth decades, usually as an enlarging, painless testicular mass. Approximately 70% of patients present with stage I disease, 20% with stage II, and only rarely with disease above the diaphragm. Lymphatic spread is to the para-aortic (PA) lymph nodes and then to the mediastinal or supraclavicular lymph nodes. Hematogenous dissemination to the lung, liver, bone, or adrenal is a late occurrence. Seminomas contain syncytiotrophoblastic giant cells that stain for human chorionic gonadotropin (HCG). Low-level HCG elevation is seen in 5–10% of patients with pure seminoma and likely reflects syncytiotrophoblastic elements present within the tumor ([Table 2](#)). Seminoma does not secrete α -fetoprotein (AFP).

Nonseminomatous germ cell tumors

The most common postpubertal GCTs of the testis are composed of one or more elements that are collectively known as “nonseminomatous.” Four morphologic patterns are recognized among this group. In most cases, these patterns are intermixed in varying proportions, often subtly merging from one to the next. Areas of seminoma may be included (termed “mixed GCTs” by some), but the prognosis is determined by the presence of the other elements and is less favorable, overall, than for pure seminomas.

Embryonal carcinoma

Embryonal carcinoma is present in up to 90% of NSGCT cases. Macroscopically, it forms a soft, fleshy, inhomogeneous mass with areas of necrosis and hemorrhage. Direct invasion of the spermatic cord, epididymis, and tunica albuginea occurs.

The microscopic appearance is extremely variable and may include papillary, solid, tubular, and glandular patterns, frequently interrupted by geographic necrosis ([Figure 2](#)). Large polygonal cells with indistinct cytoplasmic borders (unlike seminoma) are the rule, with pale granular cytoplasm, large nuclei, and one or more centrally placed nucleoli. Mitotic figures and multinucleated cells are common. Clinically, these are aggressive tumors with lymph node metastases present in two-thirds of patients.

Figure 2 Yolk sac tumor. Numerous microcysts occur in the most common pattern of yolk sac tumor.

Yolk sac tumor

Yolk sac tumor, formerly called endodermal sinus tumor, is present in approximately half of NSGCT cases, but is rare in pure form in the postpubertal patient.²⁹ The most readily recognized pattern consists of a cluster of tumor cells surrounding a small central blood vessel (Schiller–Duval body) ([Figure 3](#)). The morphologic spectrum is broad, including microcystic (lacelike), micropapillary, solid, and hepatoid patterns. The tumor cell nuclei are smaller than those of embryonal carcinoma. Cytoplasmic globules are common and stain for AFP, which accounts for the serum elevations characteristically present in patients with this tumor ([Table 2](#)).

Figure 3 Choriocarcinoma. Syncytiotrophoblastic cells “cap” islands of mononucleated cytotrophoblast. Note the hemorrhagic background.

In its pure form, yolk sac tumor is the most common testicular neoplasm in infants and young children ([Table 1](#)). Despite morphologic similarity to the subtype observed in postpubertal NSGCT, the pediatric

tumor is an oncogenetically distinct entity and carries a better prognosis.

Choriocarcinoma

Choriocarcinoma is an uncommon element in NSGCT (15%) and is rare as a pure tumor. On gross examination, areas of choriocarcinoma are characteristically hemorrhagic. Microscopically, the diagnosis requires a combination of cytotrophoblasts and syncytiotrophoblasts ([Figure 4](#)). Stroma is sparse but tends to be highly vascular. Choriocarcinoma of the testis represents the most aggressive subtype of NSGCT, often presenting with large-volume visceral metastases and/or brain metastases. Extreme elevations of serum HCG levels are characteristic.

Figure 4 Embryonal carcinoma. Irregularly shaped glands and papillae are lined by pleomorphic cells with vesicular, crowded nuclei and poorly defined cytoplasmic membranes.

Teratoma

Teratoma is defined as a tumor that contains elements of all three germ layers present with varying degrees of differentiation. Teratomatous elements are recognized in approximately half of NSGCT cases, but are not usually pure. Macroscopically, teratomas tend to be large and have multiloculated cysts containing serosanguineous fluid as well as cartilaginous solid areas. Microscopically, all manner of tissue elements may be present, including cysts with squamous, respiratory, or intestinal-type linings, mature cartilage, muscle, and fibroblastic stroma ([Figure 5](#)). Areas that are less well differentiated (“immature teratoma”) are often intermixed ([Figure 6](#)). Regardless of the degree of differentiation, all teratomas in the postpubertal setting are regarded as malignant. In postchemotherapy specimens teratoma is the most common residual element. The presence of nonteratomatous NSGCT may be an indication for additional therapy.

Figure 5 Mature teratoma. There are mature-appearing small glands, a portion of a pilosebaceous unit, and bundles of smooth muscle.

Figure 6 Immature teratoma. An island of immature neuroepithelium is present adjacent to a nodule of hyaline cartilage.

A pure form of mature teratoma is common among pediatric patients under the age of 4 years. Although morphologically similar to mature areas of teratoma within NSGCT, these lesions arise through a different pathway and are essentially benign³⁰ ([Table 1](#)). Rarely, a nonteratomatous element is identified and may give rise to metastases.

Nongerm cell cancers arising from germ cell tumors

Given the pluripotent nature of the gonocytes from which seminomas and NSGCT are thought to arise, a nongerm cell element may emerge and become the dominant pattern in advanced cases of postpubertal testicular cancer. Among these are cancers morphologically resembling embryonal rhabdomyosarcoma, adenosquamous carcinoma, leiomyosarcoma, Wilms' tumor, glioblastoma multiforme, and primitive neuroectodermal tumor (PNET), all of which are associated with resistance to chemotherapy.³¹ Myelodysplasia and leukemia may also evolve from NSGCT.³²

Spermatocytic seminoma

Spermatocytic seminoma accounts for 1–2% of TGCTs. On gross examination, it has a grayish appearance and tends to be softer than classic seminoma. Microscopically, these tumors tend to form tubular clusters and are composed of round cells of highly variable size that bear resemblance to the cellular stages of normal spermatogenesis ([Figure 7](#)). In contrast to classic seminoma, stromal lymphocytic infiltration is not a feature of spermatocytic seminoma. This tumor tends to occur over the

age of 50, with a median age of 65 years. The prognosis following surgery is excellent, as there are only anecdotal reports of metastases.

Figure 7 Spermatocytic seminoma. There is a diffuse sheetlike arrangement of neoplastic cells that vary in size.

Sex cord-stromal tumors

Tumors arising from stromal tissue account for only 4% of all adult testicular tumors but represent almost 20% of childhood testicular tumors. These tumors are thought to arise from primitive gonadal mesenchyme and are subcategorized as Leydig cell tumor, Sertoli cell tumor, gonadoblastoma, granulosa cell tumor, and mixed/indeterminate types ([Table 1](#)).

Leydig cell tumor

Leydig cell tumor represents about 3% of all testicular tumors, and although they may be seen in children, the median age of appearance is 60 years. Histologically, they are typified by cells with abundant oncocytic cytoplasm and round, regular nuclei. Clinical symptoms are usually related to the production of both androgens and estrogens by tumor cells, leading to precocious puberty in a child and gynecomastia in the adult. Approximately 10% of Leydig cell tumors metastasize, but this occurs only in the postpubertal patient. In patients with metastatic disease, treatment with radiation or chemotherapeutic agents has generally been ineffective. Retroperitoneal lymph node dissection (RPLND) is an important staging procedure. The therapeutic role of RPLND in low-volume metastatic retroperitoneal disease is unclear, but waiting to resect higher-volume tumor is ineffective. A prophylactic RPLND should, therefore, be considered in patients with clinical stage I tumors.

Sertoli cell tumor

Sertoli cell tumor shows no age predilection, presenting as a testicular mass that may be accompanied by gynecomastia or impotence secondary to estrogen production. Microscopically, these lesions are composed of rounded cells growing in cords and sheets in a fibrous background. Therapy is primarily directed at resection of the primary lesion, with a staging work-up to include abdominal computed tomography (CT) scan and chest radiography. RPLND is controversial in clinical stage I disease. Large primary tumors with frequent mitoses or necrosis may prompt an RPLND. Sertoli cell tumors can respond to platinum combination chemotherapy.

Clinical presentation

Most patients seek medical attention because of a swollen testis. Accompanying symptoms include a sensation of heaviness or aching in the affected gonad. Severe pain is rare, unless there is associated epididymitis or bleeding in the tumor. Because testicular cancer is commonly associated with low sperm counts, patients may present during an infertility work-up.

Approximately 25% of patients with disseminated disease present with symptoms from metastatic disease.³³ Severe back pain from metastasis to the retroperitoneum is the most frequent and is the presenting symptom in patients with primary retroperitoneal GCTs. Shortness of breath, chest pain, and hemoptysis are usually manifestations of advanced lung metastases. Primary mediastinal GCTs are an exception, in that these tumors (if malignant) present with symptoms of mediastinal compression with pain, dysphagia, shortness of breath, and superior vena cava syndrome. Teratomas of the mediastinum produce few symptoms and are commonly discovered on routine chest film obtained for minor chest complaints.

Diagnosis

Understanding the diagnosis and staging of TGCTs depends on understanding the anatomy of the vascular and lymphatic drainage of the testis as well as the likely sites of metastatic spread of the disease. The spermatic cord contains the lymphatic and vascular supply of the testis. The lymphatic and vascular supply diverges medially when the spermatic vessels cross ventral to the ureter. The landing zones for the lymphatic drainage of the right testis are the interaortocaval nodes below the renal vasculature and the ipsilateral distribution of nodes, especially the paracaval and preaortic nodes. The primary landing zone for a left-sided primary tumor includes in the PA nodes below the left renal vessels and the PA and preaortic nodes. Ipsilateral common iliac nodes are uncommonly involved unless large-volume disease is present.

Unusual patterns of disease can be seen (or created) in patients who have had prior pelvic surgeries including herniorrhaphy, abdominal orchiopexy, or scrotal violations.³⁴ The proper and only diagnostic procedure in this setting is a radical inguinal orchiectomy. Transscrotal procedures can disrupt predictable patterns of lymphatic metastases and should not be done.

Tumors of the testis can present with a discrete nodular density or as diffuse infiltration of the entire testis (particularly seminoma and lymphoma). The other testis serves as a useful reference standard. If a testicular mass is suspected, transscrotal ultrasonography should be performed. The presence of a hypoechoic mass represents a testicular neoplasm, and a radical inguinal orchiectomy is required to make a diagnosis and to ensure local control of a primary testicular cancer.

Extragenital germ cell tumors (EGCTs) arising within the retroperitoneum or mediastinum require specialized management. A diagnosis may be made on the basis of significantly elevated tumor markers in a patient with a mass in the anterior mediastinum or retroperitoneum. If there is no marker elevation, tissue confirmation is required. Chemotherapy is the primary treatment; attempts at debulking or total removal of mediastinal GCTs as initial management are inappropriate. Primary retroperitoneal GCTs may be associated with an occult testicular primary. Such patients should have a thorough evaluation of the gonads, including the use of testicular ultrasonography. If a previously unsuspected testicular tumor is found, orchiectomy can serve as the diagnostic procedure. Otherwise, fine-needle aspiration of the abdominal mass or exploratory laparotomy is required. In addition, an i(12p) chromosomal abnormality is diagnostic for GCT in a patient who presents with undifferentiated cancer.

A transscrotal biopsy should never be performed. If, at the time of scrotal orchiectomy, the surgeon identified the tumor and removed the testis in toto, then the inguinal portion of the spermatic cord must be

removed. If a testicular biopsy was performed, management of the hemiscrotum depends on the primary treatment modality. Patients who are receiving primary chemotherapy do not need hemiscrotectomy. Inguinal lymphadenectomy is reserved for patients with palpable inguinal lymphadenopathy. For patients with early-stage seminoma who have had a scrotal violation, approximately 5–10% will experience local failure. Extending the field to include the groin and scrotum diminishes these prospects but is associated with increased infertility.

Tumor markers

Serum HCG and AFP have significant value in the diagnosis, prognosis, and management of patients with GCTs. AFP is derived from the yolk sac or embryonal carcinoma elements of germ cell cancers. Elevation of AFP is not seen in normal adults. The half-life of this protein in the serum is approximately 5 days. In germ cell cancers, syncytiotrophoblastic components elaborate HCG. The protein comprises an alpha subunit and a beta subunit, each of which is antigenically distinct. The serum half-life of the entire protein is 18–30 h.

Serum HCG and AFP are elevated in 85% of patients with disseminated NSGCTs. AFP alone is elevated in 40% of patients, and HCG alone is elevated in 50–60% of patients with disseminated nonseminomatous testicular cancer. Elevated lactic acid dehydrogenase (LDH) is less specific and is mainly a correlate of disease bulk.

Pure seminoma is most frequently associated with normal AFP and HCG, but approximately 10% of all cases, and up to 30% of patients with advanced disease, may have low levels (usually <100 mIU/mL).³⁵ Any elevation of AFP in patients with seminoma must be viewed as evidence of nonseminomatous disease, and management should proceed accordingly.

AFP and HCG should be determined before and after orchiectomy, but the absence of marker elevation should not influence the decision to undertake the procedure. Likewise, normalization of serum markers after orchiectomy does not ensure that all disease has been removed, although persistence of marker elevation implies residual disease.

The rate of disappearance of elevated tumor markers is very useful in determining response to chemotherapy. HCG is the most useful in this regard; a 10-fold decrease in the HCG level over a 3-week period is consistent with potentially curative chemotherapy. Less steep declines of HCG levels may correlate with the emergence of drug resistance. Likewise, the reappearance of markers often predates the radiographic appearance of recurrent disease.

The presence of tumor markers also can lead to errors in clinical management. First, HCG determination can be nonspecific, and there is some cross-reactivity in the radioimmunoassay with luteinizing hormone. Also, HCG can be falsely elevated in patients who use marijuana. HCG determination should be repeated to ensure that the elevation is not a laboratory error. If the level is still high, the patient should be queried regarding drug usage. Testosterone should be given in a dose of 300 mg intramuscularly to ensure that a hypogonadal state with resultant high levels of luteinizing hormone is not interfering with the determination of HCG. If the level remains increased, restaging procedures and investigation of sanctuary sites (brain and contralateral testis) are in order. A retrospective review by Zon and colleagues evaluated management problems in patients with very high HCG levels.³⁶ Forty-one patients with an HCG >50,000 mIU/mL were included. All patients received cisplatin-based chemotherapy. Two of these 41 patients had normal HCG levels at the time of the fourth course of chemotherapy. Eight additional patients had normalized the HCG within 1 month of completion of the fourth course of therapy. Of these ten patients, seven remain continuously free of disease, and three are currently disease-free with salvage therapy.

Thirty-one patients still had an abnormal HCG more than 1 month after completing the fourth course of primary chemotherapy. Fifteen of these patients are continuously disease-free, despite no further treatment. A subset of patients with very high HCG levels do not have a consistent predictable decline of HCG with treatment. Absolute dependence on predicted patterns of decline in these patients would have resulted in overtreatment. Our strategy has been to wait for a rising serum HCG before considering salvage therapy.

False-positive elevation of AFP is quite rare. Differential considerations include laboratory error, other tumor types (such as hepatocellular carcinoma), and liver inflammation from cirrhosis or hepatitis. An occasional patient may have baseline elevation of AFP (usually <100 ng/mL) that remains static over time and does not reflect active disease. Some individuals have familial, hereditary, mildly elevated serum AFP levels in the range of 15–30 ng/mL. Patients with clinical stage I disease, normal imaging, normal contralateral testicle, and a minimally elevated AFP level (<25 ng/mL) should be observed and only be treated if there is a clear AFP increase and/or development of metastases.³⁷

Staging

GCTs are typically categorized as stage I, referring to tumors confined to the testis; stage II, indicating metastatic disease to the nodes of the periaortic or vena caval zone without pulmonary or visceral involvement; and stage III, which denotes metastasis above the diaphragm or involving other viscera. The AJCC and World Health Organization (WHO) classification is the international standard classification ([Table 3](#)).³⁹

[Table 3](#) AJCC staging

TNM clinical classification	
T:	<i>Primary tumor:</i> The extent of the primary tumor is classified after radical orchiectomy (see pT). If no radical orchiectomy has been performed, TX is used
N:	<i>Regional lymph nodes</i>
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass ≤2 cm in greatest dimension or multiple lymph nodes, not >2 cm in greatest dimension
N2	Metastasis with a lymph node mass >2 cm but not >5 cm in greatest dimension, or multiple lymph nodes, any one mass >2 cm but not >5 cm in greatest dimension
N3	Metastasis with a lymph node mass >5 cm in greatest dimension
M:	<i>Distant metastasis</i>
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional lymph node or pulmonary metastasis
M1b	Distant metastasis other than to nonregional lymph node and lungs
pTNM pathologic classification	

pT:	<i>Primary tumor</i>
pTX	Primary tumor cannot be assessed (if no radical orchiectomy has been performed, TX is used)
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma <i>in situ</i>)
pT1	Tumor limited to testis and epididymis without vascular/lymphatic invasion; tumor may invade tunica albuginea, but not tunica vaginalis
pT2	Tumor limited to testis and epididymis with vascular/lymphatic invasion, or tumor extending through tunica albuginea with involvement of tunica vaginalis
pT3	Tumor invades spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades scrotum with or without vascular/lymphatic invasion
pN:	<i>Regional lymph nodes</i>
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension and ≤ 5 positive nodes, none > 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass > 2 cm but not > 5 cm in greatest dimension; or > 5 nodes positive, not > 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass > 5 cm in greatest dimension
pM:	<i>Distant metastasis</i>
	The pM category corresponds to the M category
S:	<i>Serum tumor markers</i>
SX	Serum marker studies not available or not performed
S0	Serum marker study levels within normal limits LDH, HCG, and α -fetoprotein
S1	$< 1.5 \times \text{N}$ and < 5000 and 1000
S2	$1.5\text{--}10 \times \text{N}$ or $5000\text{--}50,000$ or $1000\text{--}10,000$
S3	$> 10 \times \text{N}$ or $> 50,000$ or $> 10,000$

N, the upper limit of normal for the lactate dehydrogenase assay.

Standard procedures to establish clinical stage include physical examination, abdominal and chest CT scans, and serum levels of AFP, β HCG, and LDH. Brain imaging and bone scans should be performed only when clinically indicated (e.g., clinical symptoms and/or poor-risk disease). The role of positron emission tomography (PET) remains investigational in the initial staging of patients with GCTs and is not considered a standard staging procedure. PET scan will not reliably detect teratoma or microscopic carcinoma. PET scan has been investigated in patients with residual masses after chemotherapy for seminoma, and the persistence of PET avidity is associated with risk of recurrence, but a PET scan cannot differentiate between residual teratoma and necrosis.⁴⁰

Therapy

Carcinoma *in situ*

Carcinoma *in situ* (CIS) or tubular intraepithelial neoplasia (TIN) is a true premalignant condition leading to both seminomatous and nonseminomatous invasive GCTs in up to 50% of untreated cases (Figures 8 and 9).⁴¹ Management is controversial. Observation after diagnosis of TIN offers the best chance of retained fertility but requires a compliant patient and risks the possible requirement for more intensive treatment of invasive disease. Low-dose radiotherapy (18–20 Gy in 1.5–2.0 Gy fractions) will eradicate the TIN with high probability of decreased or eliminated fertility without affecting potency.^{41, 42} Total orchiectomy will obviously eliminate TIN in the effected testicle, as well as all germ cells and Leydig cells within that testicle. It may be the favored option in some patients with TIN in one testicle and a normal contralateral testicle. Partial orchiectomy alone is ill advised because TIN is typically a diffuse process within the effected testicle. Chemotherapy is not indicated for TIN.⁴³

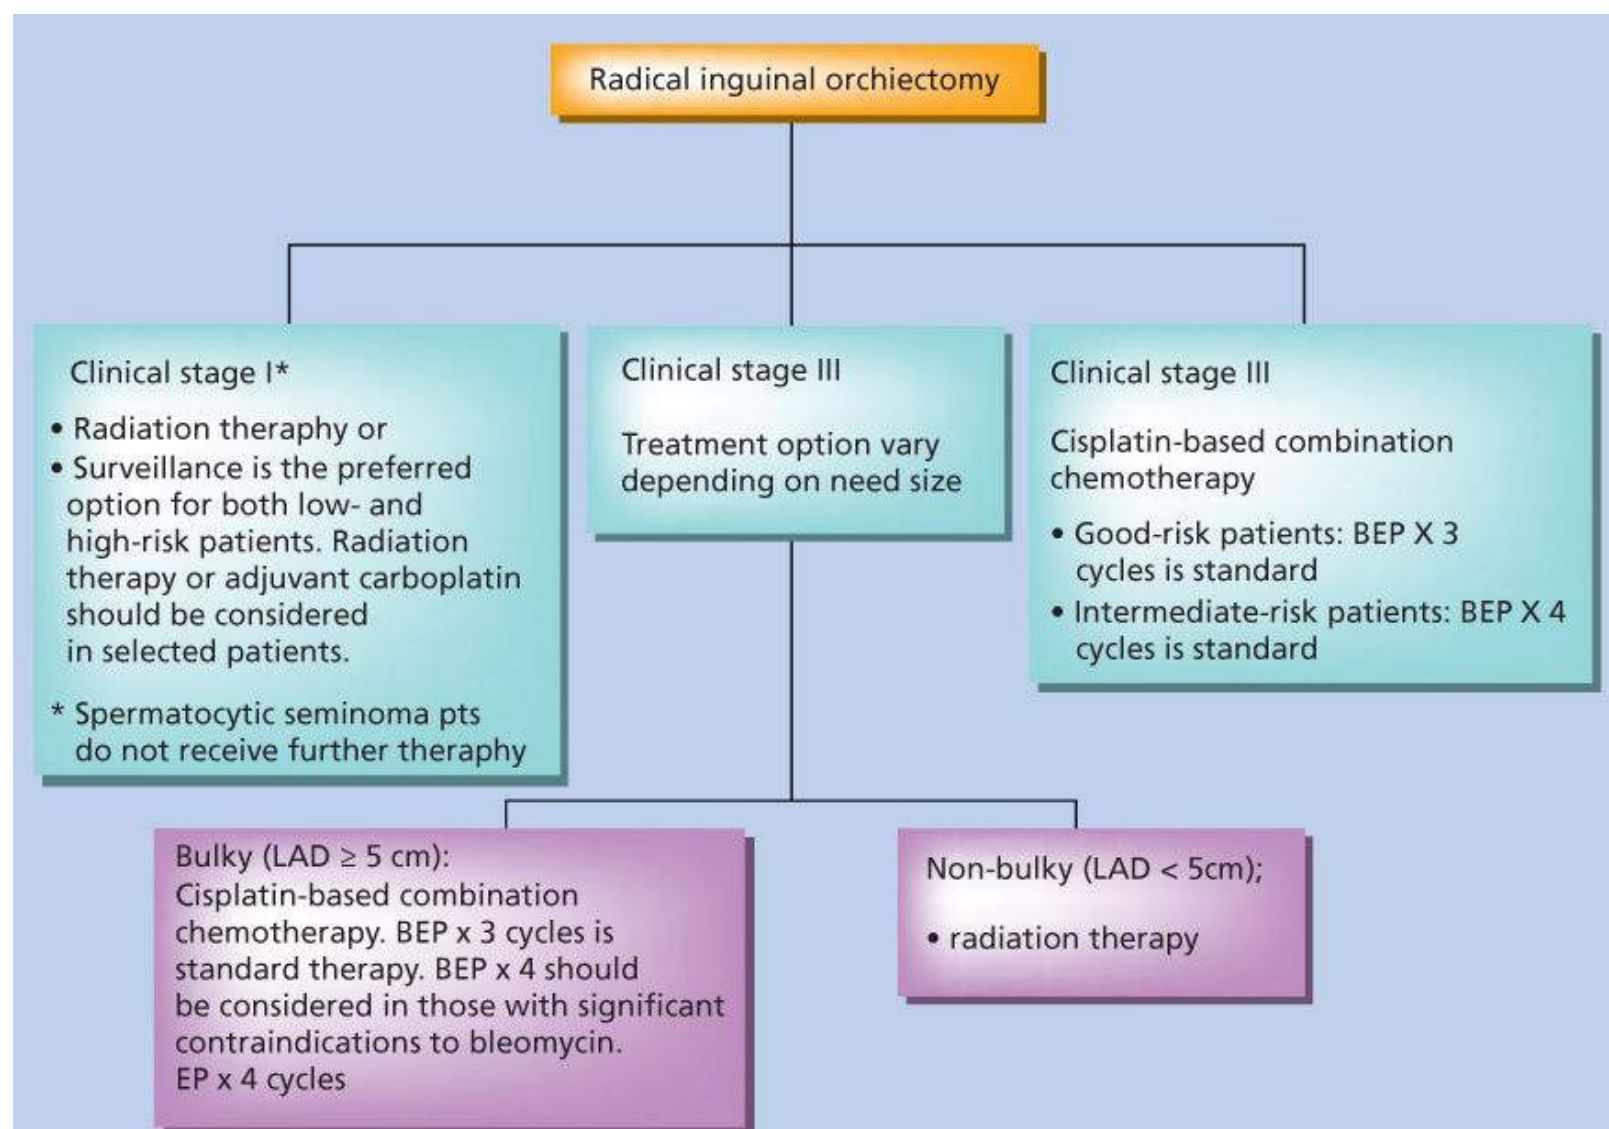

Figure 8 Treatment of seminoma.

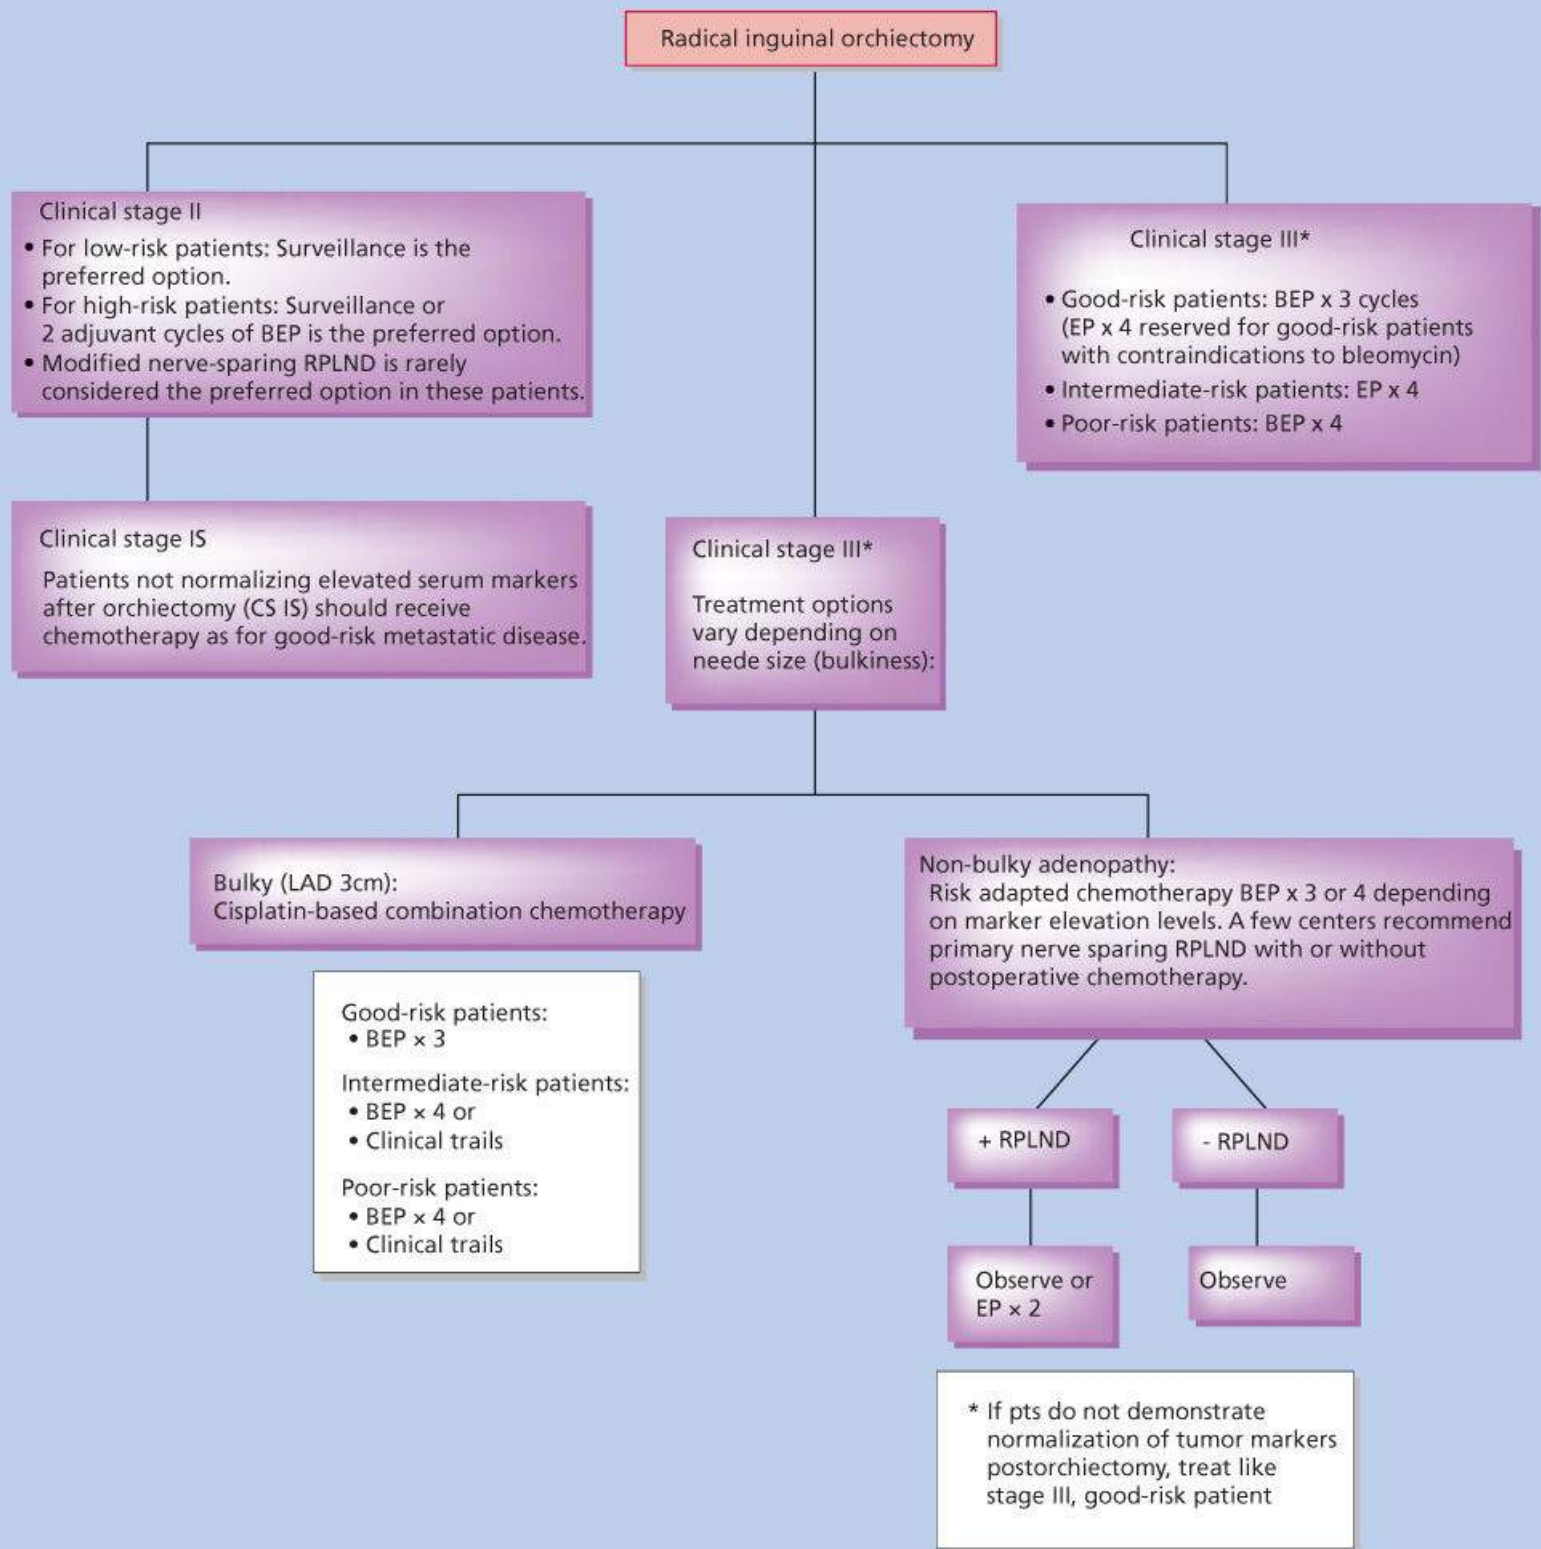

Figure 9 Treatment of nonseminoma.

Nonseminoma: Early stage

Knowledge of the natural history of testicular primary lesions and their lymphatic drainage patterns is key to understanding the therapeutic options. Testicular lymphatics arise in proximity to the embryonic origin of the testicle, in the genital ridge in the high lumbar region. Although the afferent lymphatic channels accompany testicular descent into the scrotum, draining lymph nodes remain in the retroperitoneum.

In 1910, Jamieson and Dobson demonstrated that the drainage pattern for testis tumors differed according to the side of the primary lesion, with right-sided lesions draining to the paracaval, interaortocaval, and preaortic nodes and left-sided lesions to the PA and preaortic nodes.⁴⁴

Stage I nonseminoma

The cure for patients with stage I nonseminoma is close to 100%. Three therapeutic options exist—primary RPLND, adjuvant chemotherapy, and active surveillance—all of which result in a similarly excellent outcome. Attention has therefore been focused on the reduction in toxicity. The accurate diagnosis of clinical stage I disease is critical. Following inguinal orchiectomy and the diagnosis of nonseminoma, serum levels of β -HCG and AFP must return to normal (if elevated before orchiectomy), and abdominal CT, chest radiography, and/or chest CT must all be negative before a patient can be labeled as having clinical stage I disease. In this clinical setting, approximately 30% of patients will suffer a relapse if no other therapy is administered, with the retroperitoneum remaining as the area at highest risk. Approximately 8–10% of patients will develop metastases outside of the retroperitoneum, mostly in the lungs.⁴⁵

Freedman and colleagues developed a mathematical model on the basis of the four identified prognostic factors and were able to identify a subset of patients with a 58% relapse rate at 2 years.⁴⁶ These four factors included invasion of testicular veins, invasion of testicular lymphatics, absence of yolk sac elements, and presence of undifferentiated tumor. Pathologic T-stage higher than 1, the presence of components of embryonal carcinoma, and percent of the primary tumor occupied by teratoma have also been described.^{46–48} The importance of vascular invasion as the most dominating independent risk factor has been emphasized. Clinically, the presence of vascular invasion in the primary tumor specimen discriminates the “high-risk” patients with a risk of relapse of approximately 50% from the “low-risk” patients without lymphovascular invasion and an approximately 15–20% risk of relapse.

There is an ongoing controversy regarding the optimal management of patients with clinical stage I nonseminoma. All three options—RPLND, adjuvant chemotherapy, and active surveillance—are discussed later.

Retroperitoneal lymph node dissection

Based on a predictable lymphatic pattern of spread of testicular tumors, RPLND emerged as a treatment option for testicular cancer as early as 1907.^{49–51} In the United States, primary RPLND became the conventional approach for patients with clinical stage I NSGCTs. In Europe and Canada, consensus guidelines do not currently advocate primary RPLND in early-stage disease.^{52, 53} Nevertheless, RPLND does provide the most accurate method of detecting retroperitoneal nodal disease, which account for more than 90% of the first site of metastatic spread. RPLND alone can be curative in 50–80% of clinical stage I disease who are found to have limited nodal disease at surgery (pN1). More than five metastatic lymph nodes, diseased nodes measuring more than 2 cm, and any extranodal extension (pN2–pN23) are virtually all cured following two cycles of adjuvant chemotherapy.⁵⁴ Primary RPLND also has the advantage of removing retroperitoneal teratoma, which is chemoresistant, virtually eliminating the risk of late relapse of teratoma.⁵⁵ However even in pure teratomas, only 20% of patients will harbor occult retroperitoneal lymph node metastases at the time of diagnosis.⁵⁶ Relapses in the retroperitoneum are exceedingly rare in patients who undergo RPLND by experienced surgeons. The overall relapse rate for patients with disease limited to the testicle is approximately 10%, with the great majority of relapses occurring in the lungs.

Radical lymphadenectomy via a thoracoabdominal (extraperitoneal) approach was described in 1950⁵⁷ and popularized by Skinner in the 1980s,⁵⁸ while reports of pure abdominal (anterior) approaches dominated the 1970s,^{59, 60} with each approach having intrinsic advantages. The thoracoabdominal approach is associated with significantly higher morbidity including pain and chest complications albeit lower rates of small bowel obstruction.⁵⁸ To reduce morbidity Donohue and colleagues described the

midline anterior approach, and since the incidence of suprahilar metastases in clinical stage I disease was shown to be rare, the technique evolved to include only infrahilar RPLND.⁶¹ The thoracoabdominal incision has largely been replaced by the anterior midline approach.

In experienced hands, the classic bilateral RPLND is associated with minimal perioperative morbidity and virtually no mortality.⁶² A major side effect is the loss of antegrade ejaculation, with resultant need for assisted reproductive technology in over 90% of patients. An improved understanding of the nerves and pathways responsible for seminal emission and ejaculation along with meticulous anatomic studies of the distribution of right-sided and left-sided tumors led to further modification of the surgical “templates” for RPLND.^{63, 64} Several nerve-sparing modifications of the classic node dissection have now been described.^{65–67} Any template used must adhere to strict principles of thoroughly resecting all interaortocaval lymph nodes and ipsilateral lymph nodes from the level of the renal hilum down to the bifurcation of the ipsilateral common iliac artery. Dissection is minimized on the contralateral side particularly below the level of the inferior mesenteric artery (IMA). To minimize retroperitoneal recurrence, some advocate bilateral infrahilar dissections only sparing the contralateral nodes below the IMA.⁶⁸ Modified template nerve-sparing RPLND is now considered standard for patients undergoing surgery for clinical stage I disease. Meticulous preservation of the postganglionic sympathetic fibers arising from the sympathetic chain and the hypogastric plexus results in uniformly high rates of preservation of ejaculatory function (96–100%) while maintaining more than 99% cure rate.^{59, 66, 69}

To further reduce the morbidity of surgery, laparoscopic techniques for RPLND have been used.⁷⁰ Although operating room times are longer, long-term follow-up in over 550 patients has shown no difference in relapse rates compared with traditional open RPLND. However, the vast majority (>90%) of the patients with positive nodes have received adjuvant chemotherapy raising the question of the true efficacy of this approach.

Radiotherapy

Although previously utilized in stage I nonseminoma, radiotherapy is no longer used based on the overwhelming success of combination chemotherapy, the safety of active surveillance, as well as the limited efficacy of radiotherapy in nonseminomas.

Adjuvant chemotherapy

The definition of a high-risk group by vascular invasion, the efficacy and safety of chemotherapy for good-risk metastatic disease, and the near-perfect results of two cycles of chemotherapy in the setting of fully resected stage II disease have prompted investigators to consider the use of primary chemotherapy in high-risk stage I disease.

Based on data from stage II trials suggesting that two cycles of bleomycin, etoposide, and cisplatin (BEP) may be sufficient adjuvant treatment, the MRC designed a prospective study offering two cycles of BEP to patients with high-risk stage 1 NSGCTT⁷¹ to evaluate the efficacy and long-term toxicity of adjuvant chemotherapy. One hundred and fourteen patients were treated and followed up for a median of 4 years. The 2-year recurrence-free survival was 98%. The 95% CI excluded a true recurrence rate of more than 5%. Of the two patients who recurred, one was found to have adenocarcinoma of the rete testis rather than a germ cell tumor. No major clinically significant long-term toxicities were observed, although the median follow-up was only 4 years. Adjuvant chemotherapy with two cycles of BEP achieves a near-universal cure in patients with stage I disease with relapse rates in various studies ranging from 0% to 2%.

Two cycles of adjuvant BEP were subsequently adopted as the standard approach to patients with vascular invasion for the European consensus guidelines, whereas patients with low-risk disease are candidates for active surveillance.⁵²

Recent data suggest that 1 cycle of BEP results in similar outcome and 1 cycle of BEP is now recommended as the adjuvant chemotherapy of choice.^{72, 73}

Active surveillance

The main rationale for active surveillance is that systemic chemotherapy is highly effective and thus patients who are cured by orchiectomy alone can be spared the treatment-related toxicity of a primary RPLND or adjuvant chemotherapy.

An early large prospective study of surveillance included 373 patients with a median follow-up of 5 years.⁷⁴ The recurrence rate was 27% and of these 80% recurred within the first year. Overall cure rate for the entire cohort of patients exceeded 98%. Vascular invasion was confirmed as the most important prognostic factor. A large data set including 1139 stage I nonseminoma patients recently confirmed active surveillance as an excellent and safe management modality. With a recurrence rate of 19% (44% in lymphovascular invasion-positive patients and 14% in negative patients) and a disease-specific survival of 99.7% on long-term follow-up, this series of surveillance underlines the efficacy of the approach.⁷⁵

There are now reports of more than 3000 patients worldwide with clinical stage I disease who have had no other therapy administered following orchiectomy with relapse rates and survival remarkably similar between trials, regardless of the size of the study or country of origin.⁷⁶ Almost all patients on active surveillance relapse within 2 years after diagnosis with IGCCCG good-prognosis disease.^{74, 77} Only 2–3% of relapses occur beyond 2 years.⁷⁵ Thus careful surveillance plus chemotherapy at the earliest sign of recurrence is an effective management approach to patients with stage 1 NSGCTT. Active surveillance has been adopted as the standard of care for patients with low-risk disease by the European consensus guidelines and for patients with both low-risk and high-risk disease by the Canadian consensus guidelines.⁵²

Based on a randomized prospective trial, a sufficient follow-up schedule for vascular invasion-negative patients consists of tumor markers and clinical examination every 2 months for the first 2 years and every 4–6 months for years 3–5. Chest X-rays are done every 4 months for the first 2 years and then every 6 months thereafter until year 5.⁷⁸ CT scans are performed at 3, 12, 24, and 56 months. Various surveillance schedules with closer follow-up and more frequent imaging exist for high-risk patients.

Management preferences in stage 1 NSGCTT

Patients with stage 1 NSGCTT, especially those at high risk of recurrence, have a choice of management options. All options, when carried out meticulously, result in the same excellent survival prospects but with different shortcomings.

Arguments for retaining primary surgery are that when done in one of the few high-volume centers in the United States or elsewhere, results are excellent, infertility and complication rates are very low, and essentially such procedure eliminates the abdomen as a source of relapse. However, even in excellent centers, preoperative evaluations routinely fail to reliably identify the seventy percent of patients who are pathological stage I, thus subjecting the majority of patients to major surgery without therapeutic benefit. In addition, 25–35% of patients will require additional two cycles of BEP due to extensive retroperitoneal disease. Most importantly, RPLND does not eliminate the risk of recurrence outside the

retroperitoneum (8–10%). The results of community-level primary surgical management of stage I nonseminoma have demonstrated not only a numerically greater relapse rate as compared to adjuvant chemotherapy but also an increased number of patients experiencing both scrotal and abdominal relapses, strongly suggesting that primary RPLNDs performed by less experienced urologists result in inadequate cancer operations.⁷²

Adjuvant chemotherapy, in particular for high-risk disease, is considered the standard of care in many countries. While the recurrence rate is decreased to 2–4%, adjuvant chemotherapy will also result in overtreatment in at least 50% of patients.⁷⁶ All of these patients will experience hair loss; a significant disruption from work, school, and life; exposure to significant neutropenia with the rare risk of fatal complications; risk of vascular complications; rare acute chemotherapy reactions; at least temporary effects on fertility; and the anxiety and fears that all patients receiving chemotherapy face. The potential long-term complications are currently unknown and relapses can still occur. Thus, patients treated with adjuvant chemotherapy are not fully spared the fear of relapse or the inconvenience of ongoing imaging. Expert groups are now recommending one cycle of adjuvant BEP for high-risk stage I nonseminoma.^{73, 79}

Concerns regarding the lack of compliance are an argument against surveillance, in particular in high-risk CSI nonseminoma.⁷⁶ There is no evidence that the level of compliance across varying geographies materially impacts survival.^{76, 80, 81} Survival rates consistently approach 100% even in series with reported “unsatisfactory” compliance. Educating patients is crucial and emphasizing that later identification of disease might well lead to more complicated and complex therapies is fully warranted. Concerns about the undissected retroperitoneum leading to a significant number of late refractory cancer or late recurrence of teratoma have not been realized in this and other studies.^{76, 80, 82, 83}

On surveillance, only patients who relapse will receive treatment. Treatment of these patients will be slightly longer than adjuvant BEP (6 vs. 9 weeks).⁸⁴ In our opinion, there is only a small difference in toxicity between two and three courses of chemotherapy. However, there is a major difference between no chemotherapy and two courses. Active surveillance completely spares 70–75% of patients the burden of any active treatment.

Clinical stage II

Tumor marker-positive disease and/or large-volume abdominal disease (>2 cm on abdominal CT, stage IIB) should be treated with primary chemotherapy. Standard treatment is three cycles of BEP for IGCCCG good-prognosis disease.⁸⁴ Only in the case of significant contraindication to bleomycin four cycles of etoposide and cisplatin (EP) can be considered.⁸⁵ Most patients with stage IIA/B will achieve a clinical complete remission with resolution of all lymph node metastases and normalization of tumor markers (80–90% in stage IIA and 65–85% in stage IIB).^{84, 85} Only patients with persistent retroperitoneal residual disease on the postchemotherapy CT scan should undergo RPLND. The relapse rate with this strategy is 4–9% for stage IIA and 11–15% for stage IIB.^{86–88} Tumor marker-negative stage IIA (lymph nodes ≤2 cm) represents a particular problem. Some of these patients will have benign lymph node enlargement; however, some will have teratoma, pure embryonal carcinoma, or mixed tumors. There is currently no diagnostic tool to determine the nature of these masses reliably. Management options include primary RPLND or a surveillance period with repeat imaging after 6–8 weeks. If the lesions shrink, no further therapy is required; for stable or growing lesions, most centers would consider primary chemotherapy, with a few selected centers considering primary RPLND.

Seminoma: Early stage

Orchiectomy and postoperative radiation therapy constituted the standard of care for early-stage seminoma patients during most of the twentieth century.^{89–91} A radical orchiectomy by an inguinal approach is highly effective therapy for controlling disease at the primary tumor site. Occult or gross PA lymphatic tumor deposits can be eradicated with high probability after low doses of radiation therapy (20–25 Gy), owing to the extreme radiosensitivity of seminoma. Trials have investigated surveillance in stage I seminoma. With a large majority of patients experiencing prolonged disease-free survival in early-stage seminoma, long-term quality of life will assume, increasing significance in evaluating management options.

Stage I seminoma: Primary and adjuvant therapy

Stage I disease comprises 85% of all seminoma cases.⁹² Surveillance studies demonstrated that an orchiectomy is curative approximately 80–85% of the time. Chemotherapy and/or radiation can be given as salvage therapy or as prophylaxis. Regardless of the elected management method, disease-specific survival at 5 years is over 99%.^{93–96} The treatment of relapsed treatment-naïve disease appears to be as curable as it is at first presentation.

Four major series demonstrated that surveillance is a viable option.^{93–95, 97–100} Their combined experience was pooled to better identify candidates for treatment or surveillance.⁹⁴ In the entire group of 638 patients, six patients (0.9%) died of disease or complications of treatment or relapse. The overall 5-year and 10-year relapse-free rates were 82.3% and 78.7%, respectively. The majority (68.6%) of relapses occurred within 2 years, but still 7% of recurrences occur after 6 years. The two most important prognostic factors were tumor size and rete testis invasion. Patients with tumors >4 cm in diameter were twice as likely to relapse as those with smaller tumors. The rete testis is a communicating network of seminal channels traversing the mediastinum (or hilum) of the testis. Rete testis invasion was seen in 37% and defined as extension of the tumor into the testicular mediastinum without necessarily involving the tubular lumens. For patients with large tumor size and rete testis invasion, the rates of recurrence were as high as 33%. For patients without these factors, the recurrence rates were as low as 13%. This analysis could not be validated in a subsequent, recently published analysis from the two groups using an independent data set, although tumor size as a linear variable is associated with risk.^{101, 102}

The schedule for surveillance testing is in flux and in general the previous intense schedules are being revised downward.⁷⁵ Many centers concentrate observations into the highest period of risk and use progressively less CT scans in follow-up. Many schedules in seminoma are recommending a 3–2–1 with 3 abdominal/pelvic CTs the first year, 2 the second, and 1 the third with no CTs thereafter. Thus, although surveillance is a very attractive option, the frequency of follow-up imaging and tests cannot be reduced in any given patient. Therefore, patients who elect surveillance need to be compliant and reliable.

Patients with stage I seminoma have been successfully treated with orchiectomy and adjuvant radiation for over 60 years with overall survival rates now above 99%. Adjuvant PA radiation results in a 3–4% rate of relapse with most of those being salvageable with additional radiation and/or chemotherapy. Analogous to the movement for surveillance is a simultaneous drive to reduce the toxicity of initial adjuvant therapy by reducing radiation dose and volume treated.

Radiation dose has been gradually reduced to 20–25.5 Gy in 1.5–2 Gy fractions in current practice. The MRC TE18/EORTC 30942 trial addressed whether the radiation dose could be safely lowered from 30 to 20 Gy.¹⁰³ Most patients received only radiation to the PA nodes, and they were randomized to 30 Gy in 15 fractions versus 20 Gy in 10 fractions. The 0.7% absolute difference in relapse rates was statistically insignificant, and the lower dose was associated with less lethargy and inability to carry out normal work

at 1 month.

Similarly, radiotherapy volume has been reduced.¹⁰⁴ Ipsilateral pelvic lymph node irradiation did not significantly improve the 96% relapse-free survival at 3 years obtained with PA node field only radiation. However, four of nine of the patients who had been treated with PA node radiation had pelvic node involvement as a component of their relapse. Thus, patients who receive PA node radiation alone must still be followed with CT scans of the pelvis. Current practice is to treat the PA nodes from the top of T11 or T12 to the bottom of L5. Ipsilateral pelvic lymph node irradiation is still recommended, however, for patients who have had prior pelvic or inguinal surgery as this can disrupt normal lymphatic flow. PA node radiation alone is sufficient for patients with an undisturbed testicular lymphatic drainage.

Postorchiectomy chemotherapy

A large randomized trial was conducted by the EORTC/MRC in which patients with well-staged clinical stage I seminoma were randomly allocated to standard prophylactic radiation therapy (primarily PA radiation at 20–30 Gy) or treatment with single-course single-agent carboplatin (AUC 7).^{105, 106} This trial was designed to exclude an absolute increase in relapse at 2 years of 3%. In a 1 : 2 randomization scheme, 560 patients were assigned to single-agent carboplatin, and 885 were assigned to standard radiation therapy. With median 4-year follow-up, the 3-year relapse-free survival rate was 95.9% for radiation compared with 94.8% for carboplatin ($p = 0.31$), the majority of relapses on the carboplatin arm occurring in the abdomen and almost all of the recurrences in the radiation arm occurring outside the radiation portal. There were fewer new second primary TGCTs with carboplatin (two patients) versus radiotherapy (10 patients). The authors' conclusions were that single-agent carboplatin was a safe and effective adjuvant treatment of clinical stage I seminoma, but follow-up longer than 4 years is necessary. Criticisms of the study were that the pattern of abdominal relapse with the carboplatin-treated patients may necessitate abdominal imaging in follow-up and that short follow-up may underestimate the true incidence of relapse. This trial was updated,¹⁰⁶ and with median 6.5 year follow-up, there remains no significant difference in 5-year relapse-free survival between carboplatin (95%) and radiotherapy (96%). The rate of new second primary GCTs was lower with carboplatin (two patients) versus radiotherapy (15 patients).

Consensus guidelines in Europe and in Canada reflect the collected work of experienced radiation oncologists, medical oncologists, and urologists. The European consensus statement favors surveillance for all patients independent of the individual risk for relapse. Only if surveillance is not applicable, the equally effective alternatives are either adjuvant radiation or adjuvant carboplatin. A risk-adapted strategy with selection of adjuvant treatment according to individual risk is currently being investigated and is still experimental.¹⁰⁷

Stage II seminoma

Several different staging systems have defined stage II seminoma, depending on how the distinctions are made for nodal size. Regardless of the specific staging system used, the potential for supradiaphragmatic involvement increases with the size of the subdiaphragmatic disease. At most centers, the arbitrary cutoff for systemic chemotherapy is 5 cm, while patients with nodal masses <5 cm can be treated with radiation alone. Unlike with stage I, surveillance is not an option, and the expected 5-year relapse-free survival drops to 89–95% for patients treated with radiation alone.^{108–110} The overall survival still remains around 97–99% because of the effectiveness of salvage therapy. For patients with stage II seminoma, the standard radiation field incorporates the PA and ipsilateral pelvic lymph nodes. The treatment of stage II seminoma with radiation has also evolved. Historically for a patient with stage II seminoma, radiation

was delivered to the PA nodes, to the pelvic lymph nodes, and prophylactically to the mediastinum. This practice, although effective at limiting supradiaphragmatic failures, became associated with cardiac morbidity. Chemotherapy is now favored for patients who are at significant risk of supradiaphragmatic involvement.

There is also an increasing experience with chemotherapy as primary management of small- to moderate-volume stage II seminoma.¹¹¹ A Spanish collaborative study entered 72 patients at 26 participating centers. Eighteen patients had stage IIA disease, and 54 patients had stage IIB disease. Eighty-three percent of patients achieved complete response (CR), and 17% achieved partial response (PR) with residual mass. After a median follow-up of 71.5 months, six patients with stage IIB disease experienced relapse, and one of these died of seminoma. Three patients experienced nonseminoma-related deaths. The estimated 5-year progression-free survival rates for patients with stage IIA or IIB disease were 100% and 87% (95% CI, 77.5–97%), respectively. Five-year progression-free and overall survival rates for the whole group were 90% (95% CI, 82–98%) and 95% (95% CI, 89–100%), respectively; mild to moderate emesis, stomatitis, and diarrhea were the most common nonhematologic effects. Such experiences strongly suggest that primary chemotherapy may be an effective alternative to abdominal radiation.

Therapy for disseminated disease

Chemotherapy: pre-cisplatin

A broad spectrum of chemotherapeutic agents were tested from 1952 to 1972 in disseminated GCTs. In the early 1960s, the vinca alkaloids were tested. Vinblastine induced complete remissions in 4 of 30 treated patients.¹⁰⁹ Although these were of short duration, they provided investigators with a rational component of subsequent combination regimens.

Several antitumor antibiotics were also found to have single-agent activity, including actinomycin D. In 1970, bleomycin was reported to induce complete remissions.^{112, 113}

An early combination regimen described in 1960, which contained methotrexate, actinomycin D, and chlorambucil, remained popular throughout the rest of the decade.¹¹⁴ Li reported an objective response rate of 52%, with more than half of those being CR. These were the first durable remissions, with five patients alive at 9–39 months after treatment.

A further advance occurred when vinblastine and bleomycin were used in combination.¹¹⁵ This regimen resulted in 65% of patients achieving a complete remission, including some durable responses.

The most important event in the development of curative therapy for disseminated disease was the 1965 report by Rosenberg and colleagues of the antibacterial effect of platinum coordination compounds.¹¹⁶ One of these compounds, cis-diamminedichloroplatinum (II) (cisplatin) was found also to have significant antitumor activity. Preclinical studies revealed testicular atrophy as a side effect in the dog model, prompting some investigators to predict activity for this compound against human testicular malignancies in the clinical setting. Cisplatin was soon reported to be the single most active agent against TGCTs, with response rates of 70% and complete remission rates of 50%.¹¹⁴ Thirty years later, it remains the most active drug in GCTs.

Indiana University studies

In 1974, investigators at Indiana University began studies using vinblastine (PVB) in patients with

disseminated testicular cancer. The initial study remains a landmark study in modern oncology.¹¹⁷ This study incorporated principles of combination chemotherapy, as well as the concept of surgically resecting residual disease after the completion of chemotherapy. Induction chemotherapy was brief (three to four courses), and maintenance chemotherapy was given for 2 years after induction therapy. Thirty-three of 47 patients (70%) obtained a complete remission with chemotherapy. Of the remaining 14 patients, five obtained a complete remission with resection of residual disease. Six of the patients attaining remission relapsed.

The initial study proved that PVB was remarkably effective, and yet there was substantial toxicity. The next study was designed to compare the original PVB program with a similar regimen with a lower dose of vinblastine (0.3 mg/kg vs. 0.4 mg/kg).¹¹⁸ Seventy-eight patients were entered into this study, with 70% of all patients remaining continuously free of disease with equivalent results with the different vinblastine dosages. As expected, however, the reduction in the vinblastine dose led to less sepsis and granulocytopenic fever. Thus, the lower dose of vinblastine, along with cisplatin and bleomycin, became the standard regimen for PVB.

Confirmation of the results of these trials was obtained in a large EORTC trial.¹¹⁹ This trial tested the contribution of high-dose vinblastine (0.4 mg/kg) versus lower-dose vinblastine (0.3 mg/kg) and the value of maintenance vinblastine. The trial of 214 patients failed to demonstrate any advantage for patients assigned to high-dose vinblastine therapy or for those assigned to maintenance vinblastine.

A third-generation study was begun at Indiana University in 1978 in conjunction with the Southeastern Cancer Study Group (SECSG).¹²⁰ The previous studies had used maintenance therapy with monthly vinblastine for 2 years after the completion of induction therapy. This trial tested the contribution of maintenance chemotherapy. Patients with disseminated testicular cancer received four courses of induction chemotherapy with PVB. Patients obtaining a complete remission with chemotherapy, or after resection of teratoma, were randomized to receive maintenance vinblastine or no further therapy. This study failed to demonstrate an advantage to the maintenance therapy arm.

The next study was a randomized trial comparing cisplatin plus bleomycin and either PVBs or etoposide (BEP).¹²¹ Two hundred sixty-one patients with disseminated germ cell cancer were entered, and 244 were evaluable for response. Of these, 123 were randomly allocated to receive BEP, and 83% achieved a disease-free status. One hundred twenty-one patients were assigned to receive PVB, and 74% attained a disease-free status. In the combined subgroups of patients with minimal or moderate disease by the Indiana classification system, 90% achieved a disease-free status, with no difference between the two treatment arms. However, PVB patients experienced significantly more paresthesias, myalgias, and abdominal cramping. Because BEP had substantially less neuromuscular toxicity with equal or superior therapeutic results, cisplatin, etoposide, and bleomycin became and remain a standard regimen.

Prognostic classifications

An international consortium collected clinical data on patients receiving platinum-based therapy for metastatic GCT to develop a new prognostic model for disseminated disease.¹²² Data on 5202 patients with NSGCT and 660 patients with seminoma were analyzed. Independent predictors of outcome in univariate analysis were mediastinal primary site for nonseminomatous tumors, degree of AFP, HCG, and LDH elevation, and the presence of nonpulmonary visceral metastasis. Good-risk patients with nonseminomatous disease were those with testicular or retroperitoneal primary, favorable markers, and no nonpulmonary visceral metastases (anticipated progression-free survival 90%). Poor prognosis included those patients with mediastinal primary nonseminoma, those with nonpulmonary visceral

metastases, or those with unfavorable elevation of tumor markers (anticipated progression-free survival 40%). An intermediate group had an anticipated progression-free survival rate of 75%. For seminoma, only good-risk and intermediate-risk groups were identified by the absence or presence of nonpulmonary visceral metastases ([Table 4](#)). This classification should be the standard classification system for comparing results of clinical studies done at various institutions.

Table 4 International germ cell consensus classification

Good prognosis
Nonseminoma testis or retroperitoneal primary and no nonpulmonary visceral metastases and α -fetoprotein <1000 ng/mL, β HCG <5000 IU/L, and LDH <1.5 upper limit of normal
Seminoma of any primary site and no nonpulmonary visceral metastases and normal α -fetoprotein, any β HCG, and any LDH
Intermediate prognosis
Nonseminoma testis or retroperitoneal primary and no nonpulmonary visceral metastases and α -fetoprotein >1000 ng/mL and <10,000 ng/mL or β HCG >5000 IU/L and <50,000 IU/L or LDH >1.5 normal and <10 normal
Seminoma of any primary site and nonpulmonary visceral metastases and normal α -fetoprotein, any β HCG, and any LDH
Poor prognosis
Nonseminoma with mediastinal primary, nonpulmonary visceral metastases, or α -fetoprotein >10,000 ng/mL or β HCG >50,000 IU/L, or LDH >10 upper limit of normal

Abbreviations: LDH, lactate dehydrogenase; β HCG, β -human chorionic gonadotropin.

Treatment of good-risk disseminated germ cell tumors

Patients with good-risk disease constitute approximately 56% of patients presenting with disseminated disease. The IGCCC for good-risk disease suggests that more than 90% of patients in this category enjoy long-term disease-free survival.

Because virtually all these patients achieve complete remission with standard chemotherapy, additional trials addressed the possibility of reducing the amount of chemotherapy (thus decreasing acute and chronic toxicity) while maintaining the excellent cure rate. Approaches included shortening of the duration of therapy, use of chemotherapeutic agents with less single-agent toxicity, and a reduction in the number of agents.

The SECSG performed a trial in which patients with good-risk disease were randomized to receive either three or four courses of BEP.¹²³ There was no difference in the percent of patients achieving complete remission, and 92% of patients on both arms were disease-free with a median follow-up of 19 months. On the basis of these results, three courses of BEP (cisplatin 20 mg/m² plus etoposide 100 mg/m² intravenously [IV] days 1–5, repeated every 3 weeks, with bleomycin 30 units IV weekly) are the standard therapy at Indiana University for patients with good-risk disease.

ECOG completed a trial randomizing patients with minimal or moderate disease to receive three courses of either BEP or EP alone to eliminate the inconvenience (and possible pulmonary toxicity) of weekly bleomycin.¹²⁴ However, patients receiving bleomycin had superior survival. EORTC conducted a trial

comparing four cycles of EP with or without bleomycin in patients with good-risk NSGCT.¹²⁵ Complete remission rate (95% vs. 89%) favored the bleomycin-containing arm, but relapse rates were similar. Another trial randomized good-risk patients to receive VP-16 (etoposide), combined with either cisplatin for four cycles (standard arm) or carboplatin.¹²⁶ In addition, the MRC/EORTC compared etoposide and bleomycin with either cisplatin or carboplatin in good-risk patients.^{127, 128} The advantages of carboplatin are its relative lack of nephrotoxicity and neurotoxicity and the ability to administer on an outpatient basis without aggressive prehydration. However, inferior survival was seen in patients receiving carboplatin in these trials. Toner and colleagues reported inferior survival with four cycles of a dose-reduced version of BEP in comparison with standard BEP for three cycles.¹²⁹ In summary, analysis of all trials attempting to further reduce toxicity by the elimination of bleomycin or the substitution of carboplatin for cisplatin has shown therapeutic inferiority.

A final attempt to eliminate bleomycin from chemotherapy for good-risk regimens comes from the French collaborative study.¹³⁰ The trial enrolled 257 patients who were randomly allocated to three cycles of BEP or four cycles of EP (both regimens used 5-day schedules with 500 mg/m² of etoposide per cycle). At the time of trial initiation, an older prognostic classification was used. The trial was underpowered for survival, but using the original prognostic classification system and when patients were reclassified by the IGCCCC system, there were more unfavorable outcomes and more deaths in the EP. A definitive trial would require a very large patient population to prove equivalence of the two regimens. Toxicity was not substantially different between the two arms with the exception of more skin and neurologic toxicity in the BEP arm and more neutropenia and thrombocytopenia in the EP arm. There were no therapy-related deaths in either arm and no difference in pulmonary toxicity. The authors concluded that BEP at standard “American” BEP represented standard therapy for good-risk disseminated GCTs. They also concluded that further testing of this concept was not likely to be fruitful and that there was very little chance that four cycles of EP could be proven superior. European and Canadian consensus statements also endorse BEP × 3 as the standard regimen for IGCCC good-risk disseminated disease.

Further reductions in the amount of therapy are unlikely to reduce toxicity significantly, but have the potential to reduce the cure rate in this stage of disease. Alternative schedules of BEP have also been reported. De Wit and colleagues report the results of a study from the EORTC and the MRC in which patients received either three cycles of BEP with etoposide given as 100 mg/m² days 1–5 or 165 mg/m² days 1–3, cisplatin given as either 20 mg/m² days 1–5 or 50 mg/m² on days 1 and 2 only, and weekly bleomycin. There was some mild increase in ototoxicity and gastrointestinal side effects with the 3-day schedule, and long-term quality of life parameters and late toxicities are not available. These two versions of the BEP regimen yielded no significant difference in 2-year overall survival, with a 98% cure rate in patients with HCG < 1000.¹³¹

Treatment of patients with “intermediate-risk” disseminated disease

Intermediate-risk disease was defined by the IGCCCG classification in 1995; very few studies are available. An EORTC randomized study comparing EP plus either bleomycin (BEP) or ifosfamide (VIP) in an intermediate prognosis group found comparable response rates as well as similar long-term survival rates of 83% in the BEP and 85% in the VIP arm.¹³² The VIP regimen was associated with more acute hematologic toxicity. The study was prematurely discontinued when data became available from a competing study in poor-risk patients that showed no improvement in outcomes with VIP but rather very similar results to BEP.¹³³ In a subsequent study a combination of paclitaxel plus BEP (T-BEP) was compared to BEP alone.¹³⁴ The study was closed early due to slow accrual and failed to show an overall survival benefit. No other large studies are currently available in the intermediate-risk group, and four

cycles of BEP or 4 cycles of VIP remain the standard of care.

Treatment of patients with “poor-risk” disseminated disease

Patients with disseminated testicular cancer who present with poor prognostic features remain a therapeutic challenge. One approach is the exploration of chemotherapy dose intensification.

Preclinical models, as well as dose-intensity analysis of clinical trials, suggest a steep dose–response relationship for cisplatin. This has been tested in several clinical trials of intensive cisplatin in patients with poor-prognosis germ cell cancer. Ozols and colleagues reported the results of a randomized trial of aggressive, high-dose cisplatin therapy versus PVB in poor-risk testicular cancer patients.¹³⁵ There was a 2 : 1 randomization of 52 poor-risk patients to receive an aggressive arm with cisplatin, 40 mg/m² (double the standard dose) on days 1–5 with vinblastine, bleomycin, and etoposide in standard doses versus classic PVB with cisplatin given at 20 mg/m² on days 1–5. Of the patients receiving the aggressive arm, 88% had a CR, as compared with 67% of the patients receiving PVB. The PVB arm had a high incidence of relapse, with 41% of the patients having disease recurrence, as compared with 17% of the patients receiving high-dose cisplatin, bleomycin, and VP-16 (PVeBV). Overall, 68% of the group were randomized to the aggressive treatment remained disease-free, as compared with only 33% of the patients receiving standard therapy. Unfortunately, there was a substantial increase in toxicity including myelosuppression and hearing loss in the patients receiving the high-dose cisplatin. Whether the apparent superiority of the high-dose regimen was attributable to the high-dose cisplatin, the inclusion of etoposide, or other factors, was not clear.

Rigid testing of the impact of high-dose cisplatin therapy in disseminated germ cell cancer was accomplished in a trial of the SECSG and SWOG in advanced germ cell cancer.¹³⁶ This trial enrolled only patients with advanced disease by the Indiana classification system. Patients were assigned at random to receive standard doses of etoposide and bleomycin and either standard-dose cisplatin (20 mg/m² daily for 5 days) or high-dose cisplatin (40 mg/m² daily for 5 days). One hundred fifty-nine patients with advanced disseminated germ cell cancer were enrolled. Of these, 153 were evaluable for toxicity and response. Among 76 patients assigned to high-dose therapy, 52 (68%) became disease-free with chemotherapy alone or subsequent surgery. Among 77 patients on the standard-dose arm, 56 (73%) became disease-free with chemotherapy alone or surgical resection of residual disease. Overall, 74% of the patients receiving the high-dose cisplatin are alive, and 63% are continuously free of disease, as compared with 74% alive and 61% continuously free of disease on the standard-dose arm. The high-dose arm was associated with significantly more ototoxicity, neurotoxicity, gastrointestinal toxicity, and myelosuppression. In contrast to the NCI study, this large randomized trial found no therapeutic benefit of dose escalation of cisplatin.

In a follow-up to the SECSG trial of cisplatin dose intensity, ECOG conducted a trial testing the substitution of ifosfamide for bleomycin.¹³⁶ Three hundred four patients with advanced-stage disseminated germ cell cancer by the Indiana classification system were entered into this trial, which randomized patients to either four standard courses of BEP or to four courses of VIP with etoposide (75 mg/m² daily for 5 days), ifosfamide (1.2 g/m² daily for 5 days), and cisplatin (20 mg/m² daily for 5 days). Two hundred ninety patients were fully evaluable for toxicity, and 286 were evaluable for response. The rates for complete remission (VIP 37%, BEP 31%), favorable response (VIP 63%, BEP 60%), failure-free at 2 years (VIP 64%, BEP 60%), and 2-year survival (VIP 74%, BEP 71%) were not statistically different between the two treatments. Grade 3 or greater toxicity, primarily hematologic, was significantly greater on the VIP arm ($p < 0.0001$). There were five therapy-related deaths on each arm. This analysis

failed to demonstrate benefit for VIP relative to standard therapy with BEP.

A similar trial evaluating the role of ifosfamide in poor-risk patients with GCT was reported by EORTC and MRC.¹³⁷ Patients were randomized to BEP/EP or intensively scheduled bleomycin, vincristine, and cisplatin followed by VIP-B. There were no differences in time to progression or overall survival. Grade 3 or 4 myelosuppression and weight loss were more pronounced in the bleomycin, Oncovin (vincristine), and prednisone (BOP)/VIP-B arm. The authors concluded that the intensive BOP/VIP-B therapy was more toxic, but without therapeutic advantage.

Another dose-dense regimen including cisplatin, cyclophosphamide, doxorubicin, vinblastine, and bleomycin (CISCA-VB) was compared to BEP in a randomized trial including intermediate- and poor-risk patients. No improved outcome but more toxicity was observed in the dose-dense arm.¹³⁸

A recently published randomized trial by the GETUC group tested the concept of unfavorable tumor marker decline within the first cycle of BEP chemotherapy. Patients with slower than predicted marker decline were randomized to either standard BEP or a dose-dense intensification regimen including bleomycin, paclitaxel, oxaliplatin, cisplatin, ifosfamide, and etoposide.¹³⁹

Three-year progression-free survival was improved in the dose-dense group (59% vs. 48%; $p = 0.05$).

High-dose chemotherapy as primary treatment of poor-risk disease

Investigators in Germany attempted to intensify therapy for poor-risk patients by incorporating growth factors and peripheral blood progenitor cell support to give high-dose, repetitive chemotherapy cycles. Patients with poor-risk disseminated GCTs were given repetitive cycles of cisplatin 25–30 mg/m² on days 1–5, etoposide 100–250 mg/m² on days 1–5, and ifosfamide 2 g/m² on days 1–5 every 22 days for four cycles.¹⁴⁰ At the highest dose levels, support with growth factors and peripheral blood progenitor cells was required. With these supportive care techniques, this high-dose therapy was tolerated with no dose-limiting myelosuppression, mucositis, renal toxicity, or neurotoxicity. However, three of the 32 patients at the highest dose levels died of causes related to therapy. Of the 23 evaluable for response, 20 (87%) attained disease-free status, and three relapsed.

A trial of 115 patients randomized poor-risk patients to conventional therapy with cisplatin, vinblastine, etoposide, and bleomycin versus similar therapy followed by a single cycle of high-dose cisplatin, etoposide, and cyclophosphamide.¹⁴¹ This trial failed to demonstrate an advantage for the high-dose arm.

A large-scale trial has been conducted for poor-risk patients that compared two courses of standard therapy (BEP) followed by two cycles of very high-dose carboplatin, etoposide, and cyclophosphamide versus BEP \times 4.¹⁴² Two hundred nineteen patients were randomly assigned to standard BEP \times 4 ($n = 108$) or BEP \times 2 followed by two high-dose cycles of carboplatin, etoposide, and cyclophosphamide with stem cell rescue with each high-dose cycle. There were 10 deaths on treatment (six on high-dose arm and four on standard BEP). Toxicity was more severe on the high-dose arm. The 1-year durable complete remission rate was 52% on the high-dose arm and 48% on the standard BEP arm ($p = 0.53$), that is, no significant difference between the two arms.

A European trial comparing high-dose VIP to standard therapy in poor-risk GCTs was conducted based on the promising phase 1/2 trial reported by Schmoll and colleagues.¹⁴³ Two hundred twenty-one patients with either Indiana “advanced disease” ($n = 39$) or IGCCCG “poor-prognosis” criteria ($n = 182$)

received one cycle of VIP followed by three to four sequential cycles of high-dose VIP plus stem cell support every 3 weeks, at six consecutive dose levels. After 4-year median follow-up, progression-free survival and disease-specific survival rates in the poor-prognosis subgroup were 69% and 79% at 2 years and 68% and 73% at 5 years, with 76% for gonadal/retroperitoneal versus 67% for mediastinal primaries. Severe toxicity included treatment-related death (4%), treatment-related acute myeloid leukemia (1%), long-term impaired renal function (3%), chronic renal failure (1%), and persistent grade 2–3 neuropathy (5%).

Postchemotherapy surgery

Introduction

Surgical resection of residual masses following chemotherapy for disseminated disease is a vital component of the multimodality treatment of testis cancer. Twenty–fifty percent of patients who undergo induction chemotherapy for metastatic germ cell cancer have significant residual retroperitoneal disease requiring resection for cure. The presence of large residual masses around vital structures and the resultant severe desmoplastic reaction following chemotherapy often make surgery challenging. These operations should ideally be performed by experienced surgeons in high-volume centers.

Indications for postchemotherapy RPLND (PC-RPLND)

Postchemotherapy surgery should be considered only if serum tumor markers have normalized or reached a plateau. Typically postchemotherapy RPLND (PC-RPLND) is indicated if there is radiographic evidence of residual disease postchemotherapy, although the indications are different for seminomas than nonseminomas. Patients who have normalized their markers and have complete resolution of retroperitoneal adenopathy are considered at low risk of relapse and generally do not require surgery.¹⁴⁴ Some authors however advocate PC-RPLND in all cases of nonseminoma due to the increased presence of teratoma and viable GCT even in patients with complete radiographic and serologic response.¹⁴⁵ PC-RPLND should be performed 4–6 weeks following the last round of chemotherapy in order to allow patients to recover. Imaging must include CT scan of the chest, abdomen, and pelvis which should be performed reasonably close to time of surgery to ascertain persistence of residual disease in the retroperitoneum.

Nonseminoma

Although most authors advocate resection of “residual” masses following chemotherapy for NSGCT, there is no consensus on nodal size criteria. It is often difficult to measure the exact size of residual nodal tissue, since nodes are often matted together. The definition of a “normal” CT scan following chemotherapy for testis cancer varies.¹⁴⁶ Investigators have reported that up to one-third of small retroperitoneal postchemotherapy masses measuring ≤ 2 cm in diameter contain residual teratoma or GCT.¹⁴⁷ There are currently no reliable imaging techniques or prediction models to accurately identify patients who have residual teratoma or viable GCT postinduction chemotherapy.¹⁴⁸ The utility of 18-fluorodeoxyglucose positron emission tomography (FDG-PET) scan is limited in the decision-making analysis of postchemotherapy residual masses in NSGCT since it cannot distinguish fibrosis from teratoma. Although a positive PET scan is highly suggestive of residual viable tumor, false-negative rates of up to 40% have been reported.¹⁴⁹ Most experts agree that PC-RPLND is indicated when there are residual radiographically detectable lesions following first-line chemotherapy. Patients with teratoma

present in the orchiectomy specimen are at increased risk of residual teratoma and should be considered for PC-RPLND when there is any residual mass.¹⁴⁷ Patients who have an increased serum AFP, teratoma in the primary tumor, and a postchemotherapy cystic mass in the retroperitoneum may also be candidates for PC-RPLND rather than salvage chemotherapy. Beck *et al.* confirmed that cystic teratomas contain variably elevated levels of HCG and AFP and postulated that a leak into the bloodstream could explain the elevated tumor markers in this situation.¹⁵⁰ Teratomas can rarely invade the vena cava and present with a tumor thrombus, and this should not be mistaken for a deep venous thrombosis.¹⁵¹

Seminoma

Following induction chemotherapy, the presence of distinct residual masses is uncommon. CT scans often reveal a sheetlike distribution of tissue around the IVC and/or aorta that resolves over a prolonged period.¹⁵² Viable cancer is present in approximately 20% patients with residual masses >3 cm and almost no patients with residual masses <3 cm.¹⁵³ Since there is no concern about residual teratoma in pure seminomas, routine PC-RPLND for residual disease postchemotherapy will result in overtreatment in approximately 80% of patients. PC-RPLND in this setting is one of the most challenging surgical scenarios that urologists encounter, and rates of adjunctive surgery and complications tend to be higher.¹⁵⁴ To reduce the morbidity of surgery, a number of investigators have evaluated the role of FDG-PET. In a multicenter study (“SEMPET” trial), 56 PET scans were evaluated in 51 patients with CT-documented residual masses measuring 1–11 cm after adequate chemotherapy for bulky seminoma. All 19 cases with residual lesions >3 cm, and 35 of the 37 cases with residual lesions ≤3 cm were correctly predicted by PET scan. The sensitivity, specificity, and positive predictive values of PET in determining residual viable disease were 80%, 100%, and 100%, respectively.¹⁵⁵ Not all studies have confirmed the reliability of PET, and a number of false positives have been documented.^{156, 157} Nevertheless, PET scans may be the best noninvasive test to predict the presence of viable residual tumor in patients with postchemotherapy residual masses. Resection of postchemotherapy masses in seminoma remains controversial, and management should be individualized. Further management of patients with positive PET scans may include surveillance, biopsy, resection, or radiation.

Extent of surgery

PC-RPLND is a technically demanding operation. The boundaries of surgical resection remain controversial. Although modified nerve-sparing templates may be appropriate for lower-stage disease, several investigators have demonstrated the presence of tumor outside these templates in advanced disease. In 113 patients with initial bulky retroperitoneal tumors, if the residual mass was removed accompanied by a modified RPLND, nine patients (8%) would have tumor left in the retroperitoneum. The outcomes of limited versus full bilateral PC-RPLND in 62 patients based on frozen section analysis of the resected mass were investigated. In patients with necrosis on frozen section (37 patients), a limited dissection was performed, and for those with teratoma or viable cancer, a full bilateral template was utilized. After a median follow-up of 6 years, there was one relapse of teratoma seen in the retroperitoneum in the group who underwent a limited dissection. The concordance between frozen section and final pathology was 89%.¹⁵⁸ In a study of 50 PC-RPLND specimens, all low-volume left-sided primary tumors followed a predictable pattern of spread to a modified left-sided template, whereas right-sided primaries had about a 20% crossover rate. After a mean follow-up of 53 months, there were no infield recurrences.¹⁵⁹ Carver *et al.* reviewed their experience with 532 patients who underwent PC-RPLND for metastatic NSGCT and found that 7–32% patients had evidence of extratemplate retroperitoneal disease. Interestingly 2/24 (8%) patients with residual masses <1 cm had extratemplate

metastases.¹⁶⁰ Therefore, it appears that the most prudent approach would be a full bilateral dissection in the postchemotherapy setting, although a limited template can be considered in low-volume left-sided primaries.

The surgical approach should be adapted to the size and location of the mass. Most masses can be accessed via a midline approach, whereas larger masses and those requiring suprahilar dissections are best approached through a thoracoabdominal incision or a midline incision extended to the costochondral junction. Thoracoabdominal approaches afford the possibility of surgical resection of ipsilateral lung lesions. Adjunctive surgery is required in about 20% of patients undergoing PC-RPLND. The most common adjunctive procedure includes a left nephrectomy and occasionally en bloc vena caval and/or aortic resection with graft placement.¹⁶¹ Although simultaneous PC-RPLND and thoracic resections are feasible, more complex mediastinal masses are probably best approached in a staged manner to reduce complications. Findings of fibrosis in the retroperitoneal specimen should not preclude thoracic resections since up to 20% of patients can have teratoma or viable cancer in the chest.¹⁶²

Complication rates following PC-RPLND performed at high-volume centers are higher than for primary RPLND ranging from 7% to 30% with a mortality rate of about 1%.^{163, 164} The most significant source of morbidity in this postchemotherapy group is pulmonary toxicity related to prior bleomycin. Retrograde ejaculation remains a significant morbidity although patients with smaller masses are candidates for nerve-sparing approaches with about an 80% probability of preservation of ejaculatory function.^{165, 166}

Pathology

The histopathologic findings in postchemotherapy surgical specimens determine the need for further treatment and surveillance protocol. The incidence of persistent cancer is decreasing most likely due to optimized chemotherapy regimens and better selection of patients for surgery. Pathologic findings in patients with advanced NSGCT after induction therapy are approximately: necrosis in 40–50%, teratoma in 35–40%, and viable carcinoma in 10–15% of specimens.¹⁶⁷ Following salvage chemotherapy, the finding of viable carcinoma increases to about 50%.¹⁶⁸ Patients with viable disease resected at postchemotherapy surgery are generally recommended to receive two postoperative cycles of cisplatin-based therapy, with two-thirds remaining disease-free in the long term.¹³⁶ Patients with completely resected very-low-volume disease may be observed. However, patients with unresectable disease, partial resection, or elevated tumor markers should be considered for full salvage chemotherapy.

“Desperation” RPLND

Patients with elevated or rising tumor markers following induction chemotherapy who have progressed after salvage chemotherapy and have resectable retroperitoneal disease may be candidates for “desperation PC-RPLND.” These patients often have chemotherapy-resistant disease and surgery may afford the only chance for cure. PC-RPLND in this setting is technically arduous, often involving removal of adjacent organs and/or great vessels, and is usually associated with significantly lower survival rates. Despite elevated markers, up to 50% of patients will harbor mature teratoma or necrosis/fibrosis in the surgical specimen.¹⁶⁹ In patients with viable germ cell cancers in the resected specimen, up to one-third will have long-term disease-free survival.¹⁷⁰ Incomplete resection portends a poor prognosis.

Chemotherapy of seminoma

Modern chemotherapy series involving patients with bulky stage II or stage III disseminated seminoma report cure rates of more than 90%.⁶² When compared with earlier studies of radiotherapy in this setting

where cure rates ranged from 20% to 60%, cisplatin-based chemotherapy is the treatment of choice. Standard initial therapy remains cisplatin combinations.

Patients with disseminated seminoma and nonpulmonary visceral involvement do less well and are classified as intermediate risk.¹²⁶ Good-risk patients usually receive BEP \times 3 and intermediate-risk patients receive BEP \times 4.

The management of patients with residual radiographic abnormalities after completion of cisplatin-based combination chemotherapy is controversial. Motzer and colleagues report results of 41 patients with bulky stage II, stage III, or stage IV disease treated with cisplatin-based combination chemotherapy.¹⁷¹ Twenty-three patients had significant residual radiographic abnormalities, including 14 patients with masses \geq 3 cm in size. Of these 23 patients, 19 underwent surgical exploration, and five had significant findings other than fibrosis (four viable seminomas and one teratoma). The authors recommend biopsy of residual radiographic abnormalities after chemotherapy for seminoma if the residual disease measures \geq 3 cm.

A different policy has also been adopted. Surgery in this setting is extremely difficult because of a dense desmoplastic reaction. Also, these patients are older, sometimes have had abdominal radiotherapy as well as chemotherapy, and, as in several series, are prone to operative mortalities.¹⁷¹ A review of seminoma from Indiana reports only a 10% incidence of relapse in the setting of residual radiographic disease $>$ 3 cm postchemotherapy.¹⁷² There was no evidence in this series that risk of recurrence was related to the diameter of the residual mass. At Indiana University, close observation is recommended in this setting.

The use of PET scans to predict viable tumor in postchemotherapy residuals of patients with pure seminoma $>$ 3 cm remains controversial.¹⁷³ A widely endorsed conservative policy is to base evaluations and subsequent therapy on size and biopsy findings. Patients who have $<$ 3 cm residual mass after systemic chemotherapy are observed. Patients with 3 cm or greater residual masses are submitted to PET scanning. PET-negative masses are observed without intervention. Patients with large PET-positive masses undergo surgical biopsy or resection, and subsequent approaches are defined by pathological findings.

Radiation therapy for postchemotherapy residual masses had been considered; however, very few of these masses contain seminoma. Furthermore, the curability with radiation is questionable if chemotherapy does not cure the patient. In addition, the risk of long-term complications, including leukemia, is increased when both chemotherapy and radiation are employed. Therefore, radiation for residual masses should not be performed.⁴⁰

Salvage chemotherapy

Twenty–thirty percent of GCT patients will not achieve durable complete remission with first-line therapy.¹⁷⁴ These individuals, as well as those who relapse from complete remission, are candidates for salvage chemotherapy. The decreased efficacy and increased toxicity of second-line chemotherapy requires the expertise of individuals well versed in the intricacies of careful assessment of patients with GCTs and of therapeutic options for this stage of testicular cancer.

Patient selection

There are several clinical situations that may mimic persistent, progressive, or recurrent disease. One involves the appearance of nodular lesions in the chest at the end of chemotherapy or soon after completion.¹ These nodules can represent bleomycin-induced pulmonary injury and are characteristically

located in a subpleural region. This possibility should be considered in a patient who is otherwise responding serologically or radiographically and has new abnormalities in the lungs in separate sites from the original disease.

Another clinical situation frequently mistaken for progressive disease is growing teratoma.¹⁷⁵ Radiographically enlarging metastatic lesions during chemotherapy concurrently with normal or normalizing serologic markers often represent teratoma. Appropriate management is surgical resection of residual radiographic abnormalities rather than salvage chemotherapy.

A conservative policy is to reserve salvage therapy until there is a clear demonstration of rising markers on serial determinations. The vagaries of interpretation of low-level marker elevation makes such a policy necessary to ensure that patients are not treated with intensive salvage chemotherapy on the basis of a false-positive marker elevation.

Occult central nervous system (CNS) metastasis should be considered in the setting of systemic sustained remission and elevation of serum tumor markers. CT scans or MRI should be performed, along with evaluations for a testicular sanctuary site. The CNS evaluation should proceed even in the absence of clinical signs or symptoms if the only evidence of progressive disease is a rising marker.

The other important sanctuary site from chemotherapy is the testis. In most settings, the primary in the testis has been removed in the initial diagnostic process. However, in some patients presenting with advanced disease, chemotherapy is initiated without a tissue diagnosis. In such cases, the testis must be removed at the completion of chemotherapy, even if the primary tumor is no longer evident. The possibility of a metachronous contralateral testicular primary should also be entertained.

Prognostic factors in the salvage situation

The importance of clinical prognostic factors in the second-line situation has been increasingly recognized.^{176, 177} Outcomes vary between the different conventional and high-dose regimens reported to date caused by the heterogeneity of the patient population. Patients with gonadal primary tumor sites, cisplatin-sensitive disease, and relapse after CR to first-line therapy are more likely to achieve a favorable treatment outcome with conventional-dose salvage therapy than patients with cisplatin-refractory disease, an incomplete response to first-line therapy, or a mediastinal primary tumor site.¹⁷⁸ Einhorn *et al.*¹⁷⁹ recently reported refractory disease, advanced initial tumor stage, and the timing of high-dose chemotherapy (third or subsequent chemotherapy) as adverse prognostic factors. These risk factors discriminated a good-, intermediate-, and poor-prognosis group with a long-term survival of approximately 80%, 60%, and 40%, respectively. The International Prognostic Factor Study Group developed a prognostic classification for relapsed patients similar to the IGCCCG classification for treatment-naïve patients, which included individual data from almost 2000 relapsed patients collected at high-volume centers around the world.¹⁸⁰ Based on seven significant factors on multivariate analysis including histology (seminoma vs. nonseminoma), primary tumor site (mediastinal vs. retroperitoneal vs. gonadal), response to first-line chemotherapy (CR vs. PR vs. others), progression-free interval following first-line chemotherapy, AFP and HCG level at diagnosis of relapse, and the presence of nonpulmonary visceral metastases, the model is able to differentiate five distinct risk groups ranging from very low to very high. Due to the large, international, and multicenter patient population included, this model is widely applicable and is now considered the new standard prognostic model for relapsed patients.

Standard salvage therapy

Patients relapsing after cisplatin-based first-line chemotherapy have a less favorable prognosis than

patients at initial diagnosis, primarily because of the paucity of active single agents in patients refractory to cisplatin. During the three decades since the introduction of cisplatin, only a few new agents including etoposide (VP-16), ifosfamide, paclitaxel, gemcitabine, and oxaliplatin have demonstrated activity in platinum-refractory patients. The rate of patients responding favorably to conventional salvage chemotherapy is approximately 50% and thus substantially lower than after first-line treatment. Long-term remissions are only achieved in 20–30% of patients.

The salvage chemotherapy regimen that serves as a basis for comparison is the regimen of vinblastine, ifosfamide, and cisplatin (VeIP).¹⁸¹ One hundred thirty-five patients who had not progressed during cisplatin-based therapy received VeIP as initial salvage chemotherapy. Toxicity of the regimen in this pretreated population was significant, with 71% developing granulocytopenic fever. Transfusions of platelets (27%) and red blood cells (49%) were common. Renal insufficiency (serum creatinine >4 mg%) was observed in 7% of patients. Three patients died of causes related to treatment. Despite the formidable toxicity, the therapeutic results were gratifying. Fifty-six patients (45%) achieved a disease-free status with either chemotherapy alone (34 patients, 25%) or by resection of teratoma (15 patients, 12%) or of viable carcinoma (7 patients, 6%). Thirty-two (24%) of these patients are continuously disease-free, and 42 (32%) are currently disease-free (minimum follow-up of 5 years). Among the patients with extragonadal primaries, only six of 31 attained disease-free status, and only one is continuously disease-free. These results have been confirmed by other investigators.¹⁸²

Investigators from Memorial Sloan Kettering Cancer Center evaluated paclitaxel plus ifosfamide plus cisplatin (TIP) as second-line therapy for patients with favorable prognostic features, but relapsed testicular cancers.¹⁸³ Twenty-three of 30 patients (77%) achieved a CR to chemotherapy alone, and an additional patient achieved a durable partial remission with normal markers. Only two patients relapsed and treatment was generally well tolerated. This study underscores the importance of patient selection. TIP has evolved into a widely used standard conventional-dose salvage regimen.^{184, 185}

Recurrent seminoma may be uniquely sensitive to salvage chemotherapy. Miller and colleagues reported the results of VeIP in patients with seminoma recurring after primary cisplatin/etoposide-based treatment.¹⁸⁶ Of these 23 patients, 19 (83%) achieved disease-free status, and 13 (56%) are continuously free of disease.

High-dose chemotherapy as initial salvage therapy

High-dose chemotherapy has been studied as initial salvage chemotherapy. Barnett and colleagues reported the results of 18 patients with recurrent or persistent germ cell cancer after cisplatin-based primary therapy who were given conventional induction chemotherapy with cisplatin, etoposide, vincristine, and bleomycin on a weekly schedule or vinblastine, ifosfamide, and cisplatin combinations.¹⁸⁷ Consolidation with high-dose chemotherapy was given with autologous bone marrow support. Patients received high-dose carboplatin, etoposide, and either cyclophosphamide or ifosfamide. There were two toxic deaths, it was too early to evaluate two patients, and eight of 14 patients remained free of progression.

Siegert and colleagues reported the results of high-dose carboplatin, etoposide, and ifosfamide.¹⁸⁸ Patients received two induction courses of conventional-dose cisplatin, etoposide, and ifosfamide before receiving escalated therapy. Seventy-four patients received treatment with conventional therapy, followed by carboplatin 1500–2000 mg/m², etoposide 1200–2400 mg/m², and ifosfamide 0–10 g/m². Two patients (3%) died of causes related to treatment. Responses included 21 patients (28%) with complete remission

with chemotherapy alone or with adjunctive surgery and 14 (19%) patients with marker-negative partial remission. Twenty-five of these patients (34%) maintained their response from 31 to 261 months.

A randomized trial looking at the concept of a single consolidating high-dose chemotherapy cycle after conventional induction chemotherapy was conducted in patients with favorable prognostic criteria. Most patients included had primary gonadal or retroperitoneal GCTs, and all had previously achieved a complete or partial remission from platinum combination chemotherapy. Patients were randomized to either four cycles of VIP or VeIP or three cycles of VIP followed by one high-dose cycle consisting of carboplatin, etoposide, and cyclophosphamide. The 1-year event-free survival and 3-year survival rates (35% vs. 42% in favor of high-dose chemotherapy) were disappointingly low in particular for the high-dose arm.¹⁸⁹

With the development of peripheral stem cell transplantation, sequential high-dose chemotherapy utilizing two or three high-dose chemotherapy cycles became feasible. Motzer *et al.*¹⁹⁰ reported a 41% long-term disease-free rate in 37 patients with cisplatin-resistant disease and unfavorable prognostic criteria after two cycles of conventional TIP chemotherapy followed by three cycles of high-dose carboplatin and etoposide.

Sequential high-dose chemotherapy consisting of one cycle of VIP followed by three cycles of high-dose carboplatin and etoposide was compared with three cycles of VIP followed by a single high-dose cycle of carboplatin, etoposide, and cyclophosphamide.¹⁹¹ No difference in survival probabilities between single high-dose and sequential high-dose chemotherapy arm was observed. The trial was underpowered to ascertain whether one of the two high-dose regimens should be used as salvage treatment in any particular patient population. However, morbidity and mortality of sequential high-dose chemotherapy with a 2-drug regimen was lower compared to the single 3-drug regimen, and 10% of patients with cisplatin-refractory disease achieved long-term survival.

At Indiana University, 184 patients have been treated with salvage tandem high-dose chemotherapy since 1989. One hundred and seventy patients received two consecutive courses of high-dose carboplatin and etoposide, and 110 of the 184 patients underwent 1–2 cycles of cytoreductive conventional chemotherapy with vinblastine, cisplatin, and ifosfamide prior to high-dose chemotherapy. All patients underwent aggressive resection of residual masses after chemotherapy whenever technically feasible. Overall, the long-term disease-free rate was 63%. Eighteen of 40 patients with progressive metastatic disease and tumors that were refractory to platinum remained disease-free after a median of 49 months, confirming that high-dose chemotherapy is able to overcome cisplatin resistance in a substantial number of patients.

A second large retrospective analysis was performed by the International Prognostic Factor Group and included 1594 patients treated with either SCD-CT or SHD-CT. A significant advantage in favor of SHD-CT was seen across all subgroups.¹⁹²

In summary, high-dose chemotherapy yields excellent results in patients with relapsed germ cell cancer and carries an acceptable morbidity and low mortality in young and fit patients. While high-dose chemotherapy is an established treatment option for patients with unfavorable prognostic criteria, its role in patients with favorable prognostic criteria remains controversial. However, given the low morbidity and mortality, as well as the excellent results, high-dose chemotherapy serves as an alternative to conventional salvage therapy in this setting. Due to the complexity of the disease and therapeutic situation as well as the necessity of close multidisciplinary cooperation between medical oncologists, urologists, and radiation oncologists, all relapsed patients should be referred to a specialized center.

Treatment of multiply recurrent germ cell cancer

High-dose chemotherapy for multiply recurrent germ cell cancer

Investigations into the use of high-dose carboplatin (CBCDA) and etoposide (VP-16) with autologous bone marrow support began in 1986. Initial investigations were on patients who were heavily pretreated and for whom no other curative therapeutic options existed.

The initial phase 1/2 dose escalation study examined the use of two courses of high-dose CBDCA and VP-16 in patients with GCTs refractory to cisplatin (defined as progression after or within 4 weeks of the last cisplatin dose) or recurrent after primary therapy with cisplatin-based therapy and a salvage therapy with an ifosfamide–cisplatin combination.¹⁹³ Overall, seven (21%) of 33 patients died as a consequence of the treatment. Deaths were primarily caused by infection, although one patient died of veno-occlusive disease of the liver. This was a very heavily pretreated patient population; more than half the patients have received three or more prior chemotherapy regimens, and 67% of patients were cisplatin-refractory. Eight patients obtained a complete remission, and six had a partial remission, for an overall response rate of 44% (95% CI, 27–63%). Of the eight patients attaining complete remission, three are long-term disease-free survivors, and a fourth patient died at 22 months, free of germ cell cancer, from a therapy-related acute myeloid leukemia.¹⁹⁴ An overview of the experience at Indiana University with 49 patients with multiply relapsed and refractory germ cell cancer treated with double autologous transplantation demonstrated a 45% long-term disease-free survival after a median of 46-month follow-up.

Other investigations

Other investigators have reported similar results using high-dose chemotherapy in patients with multiply relapsed testicular cancer. Several conclusions can be drawn. First, high-dose chemotherapy can cure 15–20% of patients experiencing multiple cisplatin-refractory/relapses of germ cell cancer and should be the treatment of choice after failure of ≥ 2 conventional regimens. Second, outcomes after SHD-CT in the third- or later-line setting are substantially worse than for SHD-CT in the second-line setting. Third, therapy-related mortality in this heavily treated patient population is now <5%, and there is no standard high-dose salvage regimen, but all are based on etoposide/carboplatin. Lastly, patients with mediastinal nonseminomatous primary tumors fare particularly poorly and represent a group of patients who do not benefit from high-dose chemotherapy.

Salvage (“desperation”) surgery

Some patients in the salvage setting are best approached with salvage surgery rather than chemotherapy. This is especially true for late relapsers or patients with relapsed disease confined to a single anatomic site. Indiana University performed a retrospective review of all patients who felt to have chemotherapy-refractory disease and were submitted to surgery for attempts at curative resection.¹⁹⁵ All patients had serologic or other evidence of progressive cancer. A total of 48 patients were reviewed, the majority of whom underwent isolated retroperitoneal lymphadenectomy (33 patients). Of these, 38 (79%) were rendered free of gross disease by surgery, and 29 (60%) attained a serologic remission. Ten patients (21%) remain continuously free of disease with follow-up ranging from 31 to 89 months. Clinical benefit was obtained only in that group of completely resected patients with a solitary site of disease at the time of surgery. Patients with multiple sites of metastasis, although resectable, were not cured. Albers *et al.* also reported a high long-term disease-free rate after salvage surgery for patients with persistently elevated tumor markers.¹⁹⁶ In carefully selected patients with chemotherapy-incurable disease, salvage

surgery offers a significant prospect of long-term disease-free survival. Such decisions about surgeries should be made at centers with significant experience in GCT management. In general, selection to attempt desperation surgery includes slowly increasing tumor markers after an initial CR to either first-line or second-line chemotherapy, radiographic respectable residual disease in one or two sites, and increasing markers with resectable disease after exhausting all chemotherapy options.¹⁹⁷

New agents

The development of new active compounds offers the best hope of truly changing the prospect for cure in recurrent or resistant GCTs, as well as better therapy for patients presenting with poor-risk features. Several drugs have demonstrated single-agent activity, including oxaliplatin,¹⁹⁸ paclitaxel, and gemcitabine. A phase 2 study from ECOG evaluated the combination of paclitaxel and gemcitabine in 30 patients with refractory GCTs.¹⁹⁹ The overall response rate was 21.4%, including three patients with complete remissions. Two patients remain continuously disease-free for 15+ and 25+ months. Oxaliplatin plus gemcitabine was investigated in three studies with response rates of 16%, 32%, and 46%.^{200–202} All of these studies reported long-term survivors, in particular when chemotherapy was followed by resection of residual lesions. Targeted agents are currently explored within clinical studies.

Special situations

Late relapse

Relapses in patients with disseminated testicular cancer who achieve a complete remission occur the first year following therapy, and the overwhelming majority within 2 years. A late relapse in this disease is generally accepted to be one that appears after a disease-free interval of more than 24 months after initial cisplatin-based chemotherapy. Late relapses following complete remission occur in 2–3% of cases, with recurrences as late as 32 years following complete remission. Those patients who have had recurrences with isolated mature teratoma in general have done well following excision, whereas those with marker-positive carcinoma, disseminated disease, and/or transformation seem to have an unfavorable prognosis. Chemotherapy-naïve patients, for example, relapsing from active surveillance or from primary RPLND, have a very good prognosis with cisplatin-based chemotherapy even if they relapse beyond 3 years.⁷⁵

At Indiana University, 81 patients were analyzed retrospectively who had recurrence of GCT after 2 or more years of being disease-free.²⁰³ Sixty percent had recurrences after >5 years (maximum was 32 years). Serum marker elevation was seen, with 56% of patients having an elevated AFP and 27% of patients an elevated HCG. Fifteen patients (19%) had a recurrence of teratoma, eight are continuously free of disease, and four patients are currently free of disease after further surgery (271–1021 months). Seven patients experienced recurrence with sarcomatous elements (with or without teratoma); four are currently disease-free. Fifty-nine patients had germ cell carcinoma as their initial late recurrence. Only 10 of these patients (17%) are continuously disease-free (101–781 months). Nine other patients are currently disease-free. Aggressive surgery was required in almost all these patients. Overall, 65 patients received cisplatin-based chemotherapy, and 17 (26%) achieved a disease-free status with chemotherapy with or without adjunctive surgery. Twelve of the 17 have relapsed. Only two patients treated with chemotherapy alone are continuously free of disease (neither of these patients had received previous chemotherapy). A second series of 77 additional patients demonstrate similar findings.²⁰⁴

Sharp and colleagues reviewed 75 patients for management of late relapse of GCT. In this modern series, the median time to late relapse was 6.9 years (range, 2.1–37.7 years). Overall, 56 patients (75%) had

recurrence in the retroperitoneum. The 5-year cancer-specific survival was 60% (95% CI, 46–71%). Patients who underwent complete surgical resection at time of late relapse ($n = 45$) had a 5-year cancer-specific survival of 79% versus 36% for patients without complete resection ($n = 30$; $P < 0.0001$). The 5-year cancer-specific survival for chemotherapy-naïve patients was significantly greater than patients with a prior history of chemotherapy as part of their initial management (5-year cancer-specific survival, 93% vs. 49%, respectively). As this was a series of patients referred at the time of late relapse, it is unknown how representative these results are for the late relapsing population as a whole. Nonetheless, these and other data suggest that such patients can obtain long remissions or cures after late relapse. Patients who are chemotherapy naïve often are rendered disease-free with standard approaches including cisplatin-based chemotherapy coupled with postchemotherapy surgery. A consistent feature of such studies is that for patients with regional confined disease who have late presentations with atypical yolk sac findings, elevated AFP and prior chemotherapy are best served by aggressive primary surgery.

Although the appearance of late relapses is relatively rare (1–3% beyond 2 years), these data support current recommendations for continued lifetime follow-up.

Long-term toxicity of chemotherapy

Since the mid-1970s, the majority of testicular cancer patients with disseminated disease have been cured with combination chemotherapy with or without adjunctive surgery or radiation. Late complications of curative therapy have been seen in other malignancies, most notably Hodgkin's disease (e.g., sterility, therapy-related second malignancies). Concerns about similar late effects of cisplatin-based therapy have been raised, and information is now available on a significant number of patients with follow-up of more than 10 years.

Nephrotoxicity

The acute effects of cisplatin on both renal glomerular and tubular functions are well documented, with decreases in both glomerular filtration rate (GFR) and effective renal plasma flow (ERPF) accompanied by magnesium wasting and elevated levels of β_2 -microglobulin, indicative of proximal tubule dysfunction. Most investigators reported that the acute decreases in GFR and ERPF do not deteriorate further during the months to years following completion of chemotherapy; however, long-term subclinical impairment is frequently found.^{205–207}

Vascular toxicity

Raynaud's phenomenon is the most common vascular toxicity seen in patients following chemotherapy for testicular cancer. Although anecdotally reported after therapy with single-agent bleomycin, it is much more common following combination therapy. Vogelzang and colleagues reported a 21% incidence of this phenomenon in patients treated with vinblastine plus bleomycin, as compared with 41% when cisplatin was added to these two drugs.²⁰⁸ Studies employing provocative testing suggest that even asymptomatic individuals may exhibit an exaggerated vasospastic response to cold stimuli.²⁰⁸ Symptoms persist indefinitely, with 49% of patients in one series reporting continued symptoms at a median of 8.5 years from completion of therapy. The vasospasm has, in general, been refractory to therapy, although some success has been reported with the calcium channel blocker nifedipine.²⁰⁹ The replacement of vinblastine by VP-16 in combination therapy with cisplatin and bleomycin has not reduced the incidence of Raynaud's phenomenon.²¹⁰

The relationship of cisplatin-based chemotherapy to large-vessel ischemic events is less clear. There are case reports of myocardial ischemia and infarction, as well as cerebrovascular accidents, following vinblastine administration as a single agent or combined with bleomycin. Several anecdotal reports of major cardiovascular events in young men receiving chemotherapy for testicular cancer suggested a causal association between chemotherapeutic treatments and these events.^{122, 211, 212} Weijl and colleagues identified patients with liver metastases or those receiving high-dose corticosteroids to be at high risk of developing thromboembolic complications.²¹³ Questionnaires to assess cardiovascular toxicity were distributed to all participants in the Testicular Cancer Intergroup Study, and toxicity reviews from the chemotherapy flow sheets were conducted.²¹³ Patients with pathologic stage I testicular cancer were registered and observed after retroperitoneal lymphadenectomy. Patients with pathologic stage II disease were randomized to receive two postoperative courses of adjuvant cisplatin-based chemotherapy or observation. Any patient who experienced a recurrence after observation or adjuvant therapy was given four cycles of cisplatin-based chemotherapy.

A review of toxicity of treatment in those patients receiving adjuvant chemotherapy ($n = 97$) or chemotherapy for recurrent disease ($n = 83$) revealed no cases of acute cardiovascular toxicity. When the median follow-up after study enrollment was 5.1 years, 459 questionnaires were mailed, and 270 were returned. The percentage of returns was equal among the observed, adjuvant, and recurrent groups (59%, 54%, and 64%, respectively). There was a significant increase in the incidence of extremity paresthesias in the two groups receiving chemotherapy. Fatal myocardial infarction was reported in two patients in the observation group, and one nonfatal infarct was reported in the adjuvant treatment group. No patient in any group reported stroke. Three patients in the observation group and one patient in the recurrent group experienced a thromboembolic event.

In contrast, other population-based studies highlight a substantial increase in risk in cardiovascular disease particularly in patients who have received high cumulative doses of cisplatin. Fossa and colleagues identified 38,907 patients, who were 1-year survivors of testicular cancer within 14 population-based cancer registries in North America and Europe.²¹⁴ They calculated standardized mortality ratios (SMRs) for noncancer deaths and evaluated associations between histology, age at testicular cancer diagnosis, calendar year of diagnosis, and initial treatment and the risk of noncancer mortality. A total of 2942 deaths from all noncancer causes were reported after a median follow-up of 10 years, exceeding the expected number of deaths from all noncancer causes in the general population by 6% (SMR = 1.06, 95% CI = 1.02–1.10); the noncancer SMRs did not differ statistically significantly between patients diagnosed before and after 1975 when cisplatin-based chemotherapy came into widespread use. Compared with the general population, testicular cancer survivors had higher mortality from infections (SMR = 1.28, 95% CI = 1.12–1.47) and from digestive diseases (SMR = 1.44, 95% CI = 1.26–1.64). Mortality from all circulatory diseases was statistically significantly elevated in men diagnosed with testicular cancer before age 35 years (1.23, 95% CI = 1.09–1.39) but not in men diagnosed at older ages (SMR = 0.94; 95% CI = 0.89–1.00). Men treated with chemotherapy (with or without radiotherapy) in 1975 or later had higher mortality from all noncancer causes (SMR = 1.34, 95% CI = 1.15–1.55), all circulatory diseases (SMR = 1.58, 95% CI = 1.25–2.01), all infections (SMR = 2.48, 95% CI = 1.70–3.50), and all respiratory diseases (SMR = 2.53, 95% CI = 1.26–4.53). Testicular cancer patients who were younger than 35 years at diagnosis and were treated with radiotherapy alone in 1975 or later had higher mortality from all circulatory diseases (SMR = 1.70, 95% CI = 1.21–2.31) compared with the general population. In longer follow-up, hypertension, glucose intolerance, unfavorable lipid profiles, and vascular events often arose.²¹⁵ The development of metabolic syndrome is well described in association with testicular cancer and cisplatin-based chemotherapy.²¹⁶

Haugnes and colleagues examined this question in a Nordic national follow-up study (1998–2002). Patients >60 years were excluded, leaving 1135 patients eligible who were divided into four treatment groups (surgery ($n = 225$), radiotherapy ($n = 446$)) and two chemotherapy groups (cumulative cisplatin dose 850 mg ($n = 376$) and cisplatin dose >850 mg ($n = 88$)). A control group consisted of 1150 men from the Tromsø Population Study. Metabolic syndrome was defined according to a modified National Cholesterol Education Program definition. Both chemotherapy groups had increased odds for metabolic syndrome compared with the surgery group, highest for the cisplatin >850 group [OR 2.8, 95% CI 1.6–4.7]. Also, the cisplatin >850 group had increased odds (OR 2.1, 95% CI 1.3–3.4) for metabolic syndrome. The association between metabolic syndrome and the cisplatin >850 group was strengthened after adjusting for confounding variables.

Patients with testicular cancer should be followed indefinitely. They need good medical management with weight reduction, smoking cessation, lipid profile monitoring, and appropriate blood pressure management. Patients and their treating physicians should remain cognizant of a persisting unfavorable cardiovascular risk profile in long-term survivors.^{217, 218}

Neurotoxicity

Peripheral neuropathy and ototoxicity observed in treated testicular cancer patients are attributable primarily to cisplatin, with a somewhat lesser contribution in older studies by vinblastine. The peripheral effects became manifest clinically as a distal sensory neuropathy, with paresthesias and dysesthesias, disturbances of position and vibratory sensation, and relative sparing of motor units.²¹⁹ Subjectively, these symptoms may be present for prolonged periods, with 43% of patients in one study reporting persistent symptoms 6–12 years after completion of therapy.²²⁰ Objective studies confirmed the irreversibility of the neuropathy and suggest that the dorsal root ganglion represents the primary target of cisplatin-induced damage.

The ototoxicity associated with cisplatin is primarily high-frequency hearing loss and is related to the cumulative dose of cisplatin.^{221, 222} Other risk factors for ototoxicity include a serum creatinine level higher than 1.5 mg/dL, increased age, and preexisting hearing impairment.

Second malignancies

Second primary cancers are a leading cause of death among men with testicular cancer.²²³ Travis and colleagues reviewed 14 population-based tumor registries in Europe and North America (1943–2001) and identified 40,576 patients who were 1-year survivors of testicular cancer. A total of 2285 second solid tumors were reported in the cohort. The relative risk and excess annual risk decreased with increasing age at testicular cancer diagnosis ($P < 0.001$); the excess annual risk increased with attained age ($P < 0.001$), but the excess relative risk decreased. Among 10-year survivors diagnosed with testicular cancer at age of 35 years, the risk of developing a second solid tumor was increased (RR = 1.9, 95% CI = 1.8–2.1). Risk remained statistically significantly elevated for 35 years (RR = 1.7, 95% CI = 1.5–2.0; $P < 0.001$). Cancers of the lung (RR = 1.5, 95% CI = 1.2–1.7), colon (RR = 2.0, 95% CI = 1.7–2.5), bladder (RR = 2.7, 95% CI = 2.2–3.1), pancreas (RR = 3.6, 95% CI = 2.8–4.6), and stomach (RR = 4.0, 95% CI = 3.2–4.8) accounted for almost 60% of the total excess. Overall patterns were similar for seminoma and nonseminoma patients, with lower risks observed for nonseminoma patients treated after 1975. Statistically significantly increased risks of solid tumors were observed among patients treated with radiotherapy alone (RR = 2.0, 95% CI = 1.9–2.2), chemotherapy alone (RR = 1.8, 95% CI = 1.3–2.5), and both (RR = 2.9, 95% CI = 1.9–4.2). For patients diagnosed with seminomas or nonseminomatous tumors at age of 35 years, cumulative risks of solid tumors 40 years later (i.e., to age of

75 years) were 36% and 31%, respectively, compared with 23% for the general population.

Treatment with high-dose etoposide can result in a unique secondary leukemia. Nichols and colleagues reviewed records of patients with germ cell cancer entering clinical protocols using etoposide at Indiana University.¹⁹⁴ Between 1982 and 1991, 538 patients entered serial clinical trials, with planned etoposide doses from 1500 to 2000 mg/m² in combination with cisplatin plus either ifosfamide or bleomycin. Of these, 348 patients received an etoposide combination as initial chemotherapy, and 190 patients received etoposide as part of salvage treatment. In all, 315 patients are alive, and 337 patients have been followed up beyond 2 years. The median follow-up for patients still alive is 4.9 years. Two patients (0.37%) developed leukemia. One patient developed acute undifferentiated leukemia with a t(4:11)(q21:q23) cytogenetic abnormality 2.3 years after starting etoposide-based chemotherapy, and one patient developed acute myelomonoblastic leukemia with normal chromosome studies 2 years after beginning chemotherapy. During this period, a number of patients were seen outside clinical trials, and we are aware of several hematologic abnormalities in this group, including one patient with acute monoblastic leukemia with a t(11:19) (q13:p13) abnormality. However, this low incidence of secondary leukemia does not alter the risk–benefit ratio of etoposide-based chemotherapy for germ cell cancer.

Fertility

Gonadal dysfunction is common in patients with a history of testicular cancer even when managed by orchidectomy alone. Fertility and sexual functioning have been evaluated in cross-sectional studies of long-term survivors of testicular cancer. In total, 680 patients treated between 1982 and 1992 completed the EORTC Qly-C-30 (qc30) questionnaire, the associated testicular cancer-specific module, and a general health and fertility questionnaire. Patients were subdivided according to treatment: orchidectomy either alone (surveillance [S] *n* = 169), with chemotherapy (C, *n* = 272), radiotherapy (R, *n* = 158), or both chemotherapy and radiotherapy (C/RT *n* = 81). In the surveillance group, 6% of patients had an elevated LH, 41% an elevated FSH, and 11% a low (<10 nmolL⁻¹) testosterone. Hormonal function deteriorated with additional treatment, but the effect in general was small. Low testosterone was more common in the C/RT group (37% *P* = 0.006), FSH abnormalities were more common after chemotherapy (C 49%, C/RT 71% both *P* < 0.005) and LH abnormalities after radiotherapy (11%, *P* < 0.01) and chemotherapy (10%, *P* < 0.001). Baseline hormone data were available for 367 patients. After treatment, compared to baseline, patients receiving chemotherapy had significantly greater elevations of FSH (median rise of 6 (IQR 3–9.25) iu L⁻¹ compared to 3 (IQR 1–5) iu L⁻¹ for S; *P* < 0.001) and a fall (compared to a rise in the surveillance group) in median testosterone levels (–2 [IQR –8.0 to –1.5] vs. 1.0 [IQR –4.0 to 4.0] *P* < 0.001). Patients with low testosterone (but not elevated FSH) had lower quality of life scores related to sexual functioning on the testicular cancer-specific module and lower physical, social, and role functioning on the EORTC Qly-C-30 (qc30) questionnaire. Patients with a low testosterone also had higher body mass index and blood pressure. Treatment was associated with reduction in sexual activity, and patients receiving chemotherapy had more concerns about fathering children. In total, 207 (30%) patients reported attempting conception of whom 159 (77%) were successful and a further 10 patients were successful after infertility treatment with an overall success rate of 82%. There was a lower overall success rate after chemotherapy (C 71%; CRT 67% compared to S 85% (*P* = 0.028)). Elevated FSH levels were associated with reduced fertility (normal FSH 91% vs. elevated 68% *P* < 0.001).

Before the effects of therapy on fertility are examined, it must be recognized that up to 80% of testicular cancer patients will be oligospermic prior to the initiation of any therapy.²²⁴ Although the etiology of this oligospermia is not fully understood, several mechanisms have been proposed, including an autoimmune

process or a primary endocrine dysfunction resulting in impaired spermatogenesis.^{225, 226}

The chemotherapy administered for testicular cancer has acute effects on both spermatogenesis and Leydig cell function; most patients remain azoospermic with elevated serum gonadotropins for the first 12 months following therapy. These toxic effects are reversible in a significant number of patients, however, as approximately 50% will see a return of both spermatogenesis and Leydig cell function during the second year after completion of therapy.^{227, 228} Several factors decrease the likelihood of the return of spermatogenesis, including age over 30 years, treatment duration of more than 6 months, and prior abdominal radiotherapy.^{229, 230} In the Indiana University experience, at least one-third of patients treated with chemotherapy alone have been able to father children without congenital anomalies. Two cycles of adjuvant cisplatin-based chemotherapy given to patients with high-risk stage I GCTs do not adversely affect fertility or sexual activity.²³¹ In an analysis of 170 patients, the probability of spermatogenesis increased after orchiectomy and cisplatin-based chemotherapy to 48% by 2 years and to 80% by 5 years.²³²

Pulmonary toxicity

Bleomycin is solely responsible for the pulmonary toxicity observed in chemotherapy-treated testicular cancer patients. Pulmonary fibrosis develops in approximately 5% of individuals and can be fatal.²³³ Toxicity is related to cumulative dose, with a significant increase above 450 units. The earliest physical finding is an inspiratory lag and should prompt immediate discontinuation of the drug. Subsequent signs and symptoms include bibasilar rales, nonproductive cough, and exertional dyspnea. Laboratory abnormalities include decreases in diffusing capacity and late changes, including hypoxia and hypercapnia. Radiographic abnormalities include subpleural-based nodules, visible on the chest radiograph or chest CT scan.

The risk of developing symptomatic bleomycin-induced lung disease increases with age >70 years, prior or concomitant chest radiotherapy,^{113, 234} decreased renal function,²³⁵ and high concentrations of inspired oxygen. Because the mortality for this condition approaches 50% and therapeutic interventions, such as corticosteroids, are ineffective, early diagnosis of asymptomatic patients and subsequent discontinuation of the drug are particularly important. The incidence of clinically significant bleomycin toxicity is negligible, however, with three cycles of BEP.

Long-term toxicity of radiation therapy

Toxicity of radiation

Acute

Acute radiation toxicity is dependent on what organs are irradiated, the radiation dose, and the volume. MRC TE10 trial randomized patients to PA only or PA with an ipsilateral pelvic field (dogleg [DL]).¹⁰⁴ The acute toxicity of nausea/vomiting was similar but slightly higher in the DL arm. As expected the DL field would not include much more small bowel than the PA area ($p = 0.08$). Nevertheless, both groups experienced nausea requiring medication in 25–30% of patients treated. Since DL treats much more bone marrow, the rates of mild leukopenia were almost twice as high when compared with the PA field alone. Nineteen percent experienced clinically detectable leukopenia for the PA arm versus 42% for the ipsilateral pelvic field arm ($p < 0.0001$). Diarrhea was reported in 7% of the PA arm only, but 14% in the ipsilateral pelvic field arm ($p = 0.013$).

In the MRC TE18 trial comparing 30 Gy with 20 Gy, patients were asked to complete a daily symptom diary in addition to their physician-recorded symptoms.¹⁰³ The patients who received 20 Gy tended to have less significant nausea than the patients who received the higher dose ($p = 0.06$). Leukopenia was also less ($p = 0.02$). Significantly more patients receiving 30 Gy reported moderate or severe lethargy (20% vs. 5%) and an inability to carry out their normal work (46% vs. 28%). But by 12 weeks, the two groups were similar. The lower doses and smaller fields in these trials reduced the acute toxicity without compromising treatment and may lower the chronic and late sequelae of radiation.

Approximately 50% of patients diagnosed with seminoma have some degree of impairment in spermatogenesis with lower than average fertility.²³⁵ Consequently, before adjuvant radiation, appropriate counseling, baseline fertility testing, and semen cryopreservation should be considered in patients considering having children in the future. Exposure of the remaining testis to internal radiation scatter from adjuvant radiotherapy to the PA or PA and ipsilateral pelvic nodes after orchiectomy may further impair fertility. The degree of fertility impairment is dose dependent, and temporary azoospermia may occur at dose levels as low as 40–50 cGy (0.4–0.5 Gy).^{236, 237} Permanent sterility occurs after 2–3.5 Gy. For a patient who is concerned about fertility, the radiation dose can be lowered to below the threshold where permanent spermatogenesis is affected. The difference in testicular dose depending on the treated field is illustrated by the MRC TE10 trial comparing the DL and PA field with the PA field alone. The median time to the first “normal” posttreatment sperm count was 13 months for PA patients and 20 months for DL patients, despite the fact that scrotal shielding was used in 63% of the DL patients and only 3% of the PA patients.¹⁰⁴ Testicular shielding with a clamshell reduces the dose to the testes by approximately 3–10-fold. For patients treated with PA and DL or PA radiation fields with gonadal shielding, the average testicular dose per fraction is 1.48 and 0.65 cGy, respectively.²³⁸ Therefore, for men treated with testicular shielding, the cumulative testicular dose is approximately 0.5–2% of the prescription dose, and the majority of men will recover to their baseline sperm concentrations.^{104, 236, 238} Hormonal changes require much higher doses and are not detectable based on testosterone. Subtle Leydig cell dysfunction, as measured by serum FSH and LH concentrations, may occur, which are also dose and field dependent. Temporary mild elevation of FSH and LH (in the normal range) may occur with resolution to normal by 3 years with PA and DL fields, while minimal increase in FSH but not LH may occur after PA field only.²³⁹

Chronic

The avoidance of chronic toxicity or permanent late effects has raised the profile of surveillance as a preferred treatment option for many young patients with seminoma. Because radiation for seminoma historically incorporated a mediastinal field, cardiac toxicity developed in many patients. At MD Anderson Cancer Center, of 477 men with stage I or II testicular seminoma treated between 1951 and 1999²⁴⁰ with a median follow-up of 13.3 years, the cardiac-specific SMR was 1.61, while the cancer-specific SMR was 1.91. Both toxicities were only evident after 15 years of follow-up. Fifteen years may represent the latency period for chronic toxicity to develop, but it may also demonstrate that radiation treatment doses and fields prior to 1990 are more toxic versus modern practices.

The risk of second malignancies for patients treated with historical methods was quantified in a large international population-based cancer registry study.²²¹ More than 40,000 survivors of testicular cancer were identified, having been diagnosed from as early as 1943 up to 2001. The risk of developing a second solid tumor among 10-year survivors was almost twice that of the general population ($RR = 1.9$). Overall patterns were similar for seminoma and nonseminoma patients, with lower risks observed for nonseminoma patients treated after 1975. Significantly increased risks of solid tumors were observed among patients treated with radiotherapy alone ($RR = 2.0$, 95% CI = 1.9–2.2), chemotherapy alone ($RR =$

1.8, 95% CI = 1.3–2.5), and both (RR = 2.9, 95% CI = 1.9–4.2). For patients given radiotherapy alone, risks were 1.1, 1.5, and 2.0 in the follow-up periods of 1–4, 5–9, and 10 or more years. Relative risks tended to be highest among patients treated with radiation alone in typical infradiaphragmatic sites: stomach (RR = 4.1), pancreas (RR = 3.8), kidney (RR = 2.8), bladder (RR = 2.7), colon (RR = 1.9), and rectum (RR = 1.8). However, there was also increased risk of second malignancy in supradiaphragmatic sites as well, likely related to the supradiaphragmatic radiotherapy fields frequently applied in the past. The cumulative risk of solid tumors at age 75 for men diagnosed at age 35 was 36% for seminoma and 31% for nonseminomatous tumors compared with 23% for the general population. These results are difficult to extrapolate to current practice that uses smaller radiotherapy fields and lower doses.

Sanctuary sites and CNS metastases

It is quite uncommon for testicular cancer patients to present with CNS metastasis,^{52, 53} making CNS prophylaxis inappropriate for any subset of patients with advanced germ cell cancer. In patients with advanced hematogenous metastases or large-volume choriocarcinoma, however, clinical suspicion should be heightened, and careful investigation of even minor CNS symptoms is warranted.

Patients with CNS involvement should be approached with curative intent. All patients require systemic therapy. Resection should be considered for superficial solitary metastasis. Patients with multiple brain metastases or CNS disease accompanying advanced systemic involvement should receive whole-brain radiotherapy (30–50 Gy in 3–6 weeks at <2 Gy per fraction) along with appropriate systemic chemotherapy.^{52, 53, 241, 242} Patients relapsing with a solitary CNS metastasis without involvement of other sites undergo resection followed by CNS radiotherapy and two postoperative courses of “adjuvant” cisplatin-based chemotherapy.

The other important sanctuary site from chemotherapy is the testis. In most settings, the testicular primary was removed in the initial diagnostic process. However, in some patients presenting with advanced disease, chemotherapy is initiated without a tissue diagnosis. In such cases, the testis must be removed at the completion of chemotherapy even if the primary tumor is no longer evident. If there is an intact primary, one must consider this as a possibility as a source of persistent or increasing marker elevation during and after treatment.

The possibility of a metachronous contralateral testis primary must, at times, be entertained. In the setting of complete radiographic remission of systemic disease and a persistent or new elevation of serum tumor markers, the remaining testicle should be carefully examined and testicular ultrasonography be performed to rule out an occult primary. For patients with a metachronous contralateral testis lesion, organ-sparing surgery is now a viable option to preserve fertility.²⁴³

Extragonadal germ cell tumors (EGCTs)

An important subset of GCTs are extragonadal in origin. Overall, approximately 5–10% of all germ cell cancers arise in nongonadal sites, particularly in the mediastinum and retroperitoneum. EGCTs have also been described in the pineal and sacrococcygeal region and rarely in the prostate, vagina, orbita, liver, and gastrointestinal tract.

EGCTs were once thought to represent metastasis from an occult gonadal primary. Autopsy findings in 20 patients with extragonadal mediastinal GCTs found only one case of a testicular primary and one patient with a testicular scar.²⁴⁴ Both these cases were associated with clinically occult lower retroperitoneal involvement. Primary retroperitoneal GCTs are more commonly associated with an occult testicular

primary site, especially when the tumor is not midline in origin. EGCTs more likely represent malignant transformation of germinal elements distributed to these sites without a testicular focus.

In adults, the mediastinum is the most common extragonadal site for the development of GCTs.^{245, 246} The most frequent symptoms at initial presentation include dyspnea (25%), chest pain (23%), and cough (17%), followed by fever (13%), weight loss (11%), vena cava occlusion syndrome, and fatigue/weakness (6%).²⁴⁷ The most common tumor in this site is mature teratoma,²⁴⁸ suggested by the presence of a large circumscribed anterior mediastinal mass with normal serum HCG and AFP. Management of mature teratoma is surgical, and there is no role for chemotherapy or radiotherapy. Although these tumors histologically are benign, removal is often difficult. The tumors are commonly adherent to adjacent structures, such as the pericardium, lung, and great vessels. Nonetheless, excellent outcome is the rule.²⁴⁹ In a series from the Mayo Clinic, 64 of 69 patients were long-term survivors. Four of the remaining patients died as the result of surgical complications.

The principles of management of extragonadal NSGCTs parallel those of testicular germ cell cancer. The diagnosis should be considered in any young person with a poorly differentiated cancer arising in midline structures. Serum tumor markers should be obtained, and, if the clinical condition is stable, a biopsy also should be obtained. In most settings, surgical debulking should not be considered part of primary management. Cisplatin-based chemotherapy should be given as with testicular germ cell cancer. However, cure rates for NSGCTs of mediastinal origin are significantly inferior compared with those of testicular origin. An international analysis of 635 patients with EGCTs demonstrated an almost 90% chance of cure with pure seminoma irrespective of the primary site, but only 45% survival at 5 years for patients with mediastinal nonseminomatous tumors.²⁴⁷ High-dose chemotherapy with autologous stem cell support is not recommended outside of clinical trials.

Patients with residual radiographic abnormalities after completing chemotherapy for nonseminomatous EGCTs should be considered for surgical extirpation of residual disease whenever feasible even if elevated tumor markers have normalized. Vuky and colleagues report the surgical results of 32 patients with nonseminoma GCTs arising from the mediastinum who underwent adjunctive surgery following chemotherapy.²⁵⁰ Viable tumor was discovered in 66% of patients and teratoma in 22%.

Several important biologic associations with mediastinal NSGCTs include a high frequency (up to 20%) of Klinefelter's syndrome.^{12, 251}

Approximately 10% of patients with mediastinal NSGCTs develop associated malignant hematologic dyscrasias. Between 1976 and 1989, of the 40 patients with mediastinal NSGCTs at Indiana University, six developed a hematologic malignancy.³² In addition, 11 other patients were referred to Indiana University, or a case material was forwarded for evaluation of this association. Of this group of patients, six developed acute megakaryoblastic leukemia, five had acute nonlymphocytic leukemia (not M7), two developed a virulent myelodysplastic syndrome, two were found to have extramedullary megakaryocytic myelosis, and two presented with massively elevated platelet counts and cytogenetic abnormalities or excess blasts in the marrow. The median time to the development of the hematologic abnormalities was 6 months, with five of the patients having simultaneous presentations of the two disorders. Thirty-three similar patients have been reported in the literature. The median interval between the two diagnoses in this review was 5 months, with 13 cases presenting simultaneously. A retrospective review of 287 patients with nonseminomatous mediastinal GCTs revealed 17 patients with hematologic disorders with a median time of onset occurring 6 months after the diagnosis of GCT and a median survival of only 5 months after the diagnosis of the hematologic disorder.²⁵²

Careful clinical and cytogenetic analyses of these cases suggest that these tumors do not arise as a

consequence of therapy for GCTs, but represent a unique and biologically important association between these disorders. Similar cases are not found among those patients with testicular or retroperitoneal germ cell cancer treated with identical chemotherapy. Most compelling, however, is the finding of the most common karyotypic abnormality of germ cell cancer, isochromosome 12p, in a mediastinal GCT and in the leukemic blasts of one of these patients.³¹ This implies that the mediastinal GCT and the hematologic malignancy arose from a common progenitor cell.

Patients with EGCTs, particularly those with retroperitoneal or nonseminomatous tumors, are at an increased risk of metachronous testicular cancer.²⁵³ The cumulative risk 10 years after a diagnosis of EGCT was approximately 14% for patients with retroperitoneal or nonseminomatous EGCTs.

Associations of mediastinal NSGCTs with other nonhematologic non-GCTs are unproven. Ulbright and colleagues found 269 cases of teratoma-containing material, including 209 testicular, 28 retroperitoneal, and 32 mediastinal primary sites.²⁵⁴ Among this group of patients, 11 demonstrated malignant nongerm cell elements, including embryonal rhabdomyosarcoma, adenosquamous carcinoma, leiomyosarcoma, Wilms' tumor, and glioblastoma multiforme. They were identified prior to the initiation of therapy in 10 of the 11 cases. In patients with multiple samples available, histologic progression was often identified, moving from atypical features to overt nongerm cell elements. The authors suggested that these malignant nongerm cell elements are derived from the teratomatous elements within the tumor. Three of the 11 cases were patients with mediastinal primaries (27%), whereas mediastinal primaries made up only 12% of cases reviewed. In contrast, no association between nonhematologic non-GCTs and EGCTs was found in the largest series of EGCTs to date.²⁵⁵

Unrecognized germ cell tumor syndrome

On occasion, a patient will present with a clinical picture compatible with an EGCT, but without corroborating serologic or histopathologic evidence of a GCT. Greco and colleagues suggest that such patients should undergo a thorough histopathologic evaluation and, in some cases, receive empiric cisplatin-based chemotherapy.¹⁶⁸ The clinical features of the “unrecognized GCT syndrome” include patients younger than 50 years of age; tumor primarily involving the midline (mediastinum or retroperitoneum), lungs (in the form of multiple pulmonary nodules), or lymph nodes; an elevated β HCG or AFP; or clinical evidence of rapid tumor growth. Seventy-one prospectively identified patients fitting this description were classified as having poorly differentiated carcinoma or poorly differentiated adenocarcinoma and one or more of the above clinical features. Results of serologic investigation revealed normal AFP and HCG in 51 of these patients. Thirteen had elevation of one marker, and five had elevation of both markers. Light microscopy revealed poorly differentiated carcinoma in 48 patients (68%), poorly differentiated adenocarcinoma in 18 patients (25%), and poorly differentiated large cell carcinoma in five patients (7%). Electron microscopy resulted in a change in the histologic diagnosis in 17 (52%) of the 33 patients with poorly differentiated carcinoma undergoing this procedure, with neuroendocrine tumors being the most frequent new diagnosis. Sixty-eight of the patients were treated, with 62 patients receiving cisplatin-based treatment. Fifteen patients (23%) had CR, and 18 patients (29%) had PR. Patients obtaining a response were generally young, were male, and had midline involvement of the retroperitoneum, mediastinum, or cervical lymph nodes. All 15 had the light microscopic diagnosis of poorly differentiated carcinoma. A series of 41 patients with poorly differentiated carcinoma of unknown primary were evaluated at Memorial Sloan Kettering Cancer Center.¹⁰⁷ Thirty percent were found to have tumors containing i(12p), increased copies of 12p, or a deletion of the long arm of chromosome 12. Seventy-five percent of patients demonstrating chromosomal

abnormalities responded to cisplatin-based chemotherapy versus 18% in patients for whom no diagnosis could be made.

These results suggest that poorly differentiated carcinomas of unknown primary are responsive to chemotherapy and may even be curable. A subset of these patients probably represents histologically and serologically atypical germ cell cancers. Patients with metastatic poorly differentiated carcinoma should be investigated to identify a primary site. Serum HCG and AFP should be measured. Patients with a dominant pulmonary or mediastinal mass should have fiber-optic bronchoscopy. Thorough investigations with light microscopy, immunoperoxidase staining, and cytogenetics should be carried out to further characterize the tumor. Patients should receive a trial of cisplatin-based chemotherapy.

Chapter 101

Neoplasms of the vulva and vagina

Summer B. Dewdney, MD ■ Jacob Rotmensch, MD

Overview

Vulvar and vaginal carcinomas are uncommon diseases that generally affect post-menopausal women, although 19% of vulvar carcinomas occur in women >50 years old. Risk factors for vulvar cancer include human papilloma virus and chronic inflammation. Vulvar intraepithelial neoplasia can often be managed with wide local excision, but several other modalities have been utilized. Most vulvar malignancies are squamous cell carcinomas that are managed by surgical excision and radiotherapy. Sentinel lymph node biopsy has been used to spare the morbidity observed after regional lymph node dissection. For more advanced lesions, chemo-radiotherapy with agents such as 5-FU, cisplatin, and mitomycin C is utilized. Other vulvar malignancies include Bartholin gland carcinomas, basal cell carcinomas, verrucous carcinomas, and melanomas. Carcinomas of the vagina are most frequently squamous cell, but clear cell adenocarcinomas have been seen in younger women. In the past, clear cell carcinomas were associated with prenatal exposure to diethylstilbestrol. Vaginal melanomas can occur, as well as endodermal sinus tumors, rhabdomyosarcomas, and fibroepithelial vagina polyps.

Cancer of the vulva

Incidence and epidemiology

Vulvar cancer accounts for about 4% of cancers in the female reproductive organs and 0.6% of all cancers in women. It is the fourth most frequent gynecologic cancer.¹ The American Cancer Society estimated that in 2014, about 4850 cancers of the vulva were diagnosed in the United States and about 1030 women die of this cancer.²

Risk factors include cigarette smoking, human papillomavirus (HPV), vulvar or cervical intraepithelial neoplasia, chronic immunosuppression, chronic vulvar inflammatory diseases (e.g., lichen sclerosis and lichen planus), and northern European ancestry.³ Most vulvar carcinomas occur in older women, with more than 50% of the patients being 60–79 years of age. Kumar et al. found that younger patients with vulvar cancer are increasing with frequency, and through evaluation of the SEER database found that 19.3% of patients diagnosed with vulvar cancer are <50 years old. In addition, there is a striking survival difference between the younger and older women with squamous cell vulvar cancer ([Figure 1](#)).⁴

Figure 1 Comparison of survival of younger patients (<50 years; blue line) with that of older patients (≥50 years; green line) with squamous cell cancer of the vulva, 1988–2005. Log-rank $p = 0.001$. Source: Kumar 2009.⁴ Reproduced with permission of Elsevier.

This increased frequency in younger patients may be attributed to an increase in HPV, specifically HPV-related vulvar intraepithelial neoplasia that progresses to cancer.

Vulvar cancer is thought to develop through two types of pathways, the first related to HPV infections and the second related to a chronic inflammatory process.⁵ Several epidemiologic studies suggest a sexually transmitted origin for carcinoma of the vulva. Condyloma acuminatum associated with HPV has been noted in many patients with premalignant and malignant vulvar disease. It has been estimated that in the United States, over 1 million women each year develop perineal warts and that as many as 10% are infected with HPV.⁶ Currently, HPV types 6 and 11 are most frequently found in benign vulvar warts, and HPV types 16, 18, 31, 33, and 45 are more frequently associated with intraepithelial neoplasia or invasive carcinoma.^{6–8} HPV can be found in approximately 50% of vulvar carcinomas; the tumors are often multifocal and associated with vulvar dysplasias. HPV-negative tumors are often found in older women.^{9, 10} These can be associated with chronic inflammatory disease as seen with vulvar dystrophies.

Although epidemiologic evidence strongly suggests a viral cause, other associations have been implied as well. Factors such as granulomatous diseases of the vulva, diabetes, hypertension, and obesity also have been associated with vulvar carcinoma, but perhaps this is because of the usually advanced age of patients. A case–control study by Mabuchi et al.¹¹ found that domestic servants, or those working in laundry or cleaning plants, have an increased risk of vulvar carcinoma, thus suggesting an environmental component.

The association of carcinoma *in situ* (CIS) with invasive carcinoma of the vulva indicates a continuum from preinvasive to invasive carcinoma. Jones et al.¹² evaluated 405 cases of vulvar intraepithelial neoplasia (VIN) 2–3, they found that 3.8% of patients that are treated will progress to cancer, and 10 patients who did not undergo treatment progressed in 3.9 years (mean). Progression, however, may differ between younger and older patients. Some authors suggest that the multifocal CIS of women in their thirties or forties is less likely to progress compared to older women.^{13–15}

Vulvar intraepithelial neoplasias

In 2004, The International Society for the Study of Vulvar Disease developed the current classification system for VIN ([Table 1](#)). Previous classification included VIN 1, 2, and 3 according to the degree of abnormality. Currently, only high-grade disease is defined as VIN and hence would take that nomenclature. It has been shown that VIN 1 is not a cancer precursor and therefore is not described as VIN. In 2004, they developed two categories to describe VIN: VIN, usual type (includes former VIN 2 and 3 of warty or basaloid and mixed types), and VIN, differentiated type (associated with lichen sclerosis).¹⁶ In addition, the College of American Pathologists and the ASCCP confirmed a two-tier system with the recent Lower Anogenital Squamous Terminology (LAST) terminology project.¹⁷ American College of Obstetrics and Gynecology (ACOG) and the American Society for Colposcopic and Cervical Pathology (ASCCP) issued a committee opinion on treatment of VIN cases given that there has been such an increase over the past 30 years, confirming agreement with International Society for the Study of Vulvovaginal Disease (ISVDD) nomenclature of VIN differentiated type and usual type, and discussing treatment recommendations. Of note, many pathologists and practitioners still use the old classifications.

Table 1 Classifications of vulvar dysplasias

Old classifications
<i>Intraepithelial dysplasia</i>
Mild dysplasia (VIN I)
Moderate dysplasia (VIN II)
Severe dysplasia (VIN III)
Current classifications (ISSVD 2004)
VIN-differentiated (associated with vulvar dermatologic conditions)
VIN-usual type (including warty, basaloid, and mixed VIN, associated with HPV)

Abbreviations: VIN, vulvar intraepithelial neoplasia; HPV, human papillomavirus.

VIN can present with a variety of symptoms. The most common is irritation or itching; however, 20% of patients are asymptomatic.¹⁸ Grossly, the lesions can be flat, raised (maculopapular), or verrucous. In color, they may be brown (hyperpigmented), red (erythroplastic), white, or discolored. White lesions can appear to have a whitish, thickened keratin layer (leukoplakia) or a diffuse, white, brittle, paperlike appearance (lichen sclerosus) ([Figure 2](#)). Areas of squamous hyperplasia (hyperplastic dystrophy) and dysplasia can also have a white appearance. Unlike lichen sclerosus, however, the tissue often is thickened, and the process tends to be focal or multifocal rather than diffuse.¹⁵ It is important to biopsy lichen sclerosis as there may be an underlying vulvar carcinoma.^{19, 20}

Figure 2 White, brittle paperlike appearance or lichen sclerosus of the vulva.

Microscopically, atypical changes in the vulvar epithelium consistent with preinvasive lesions usually are marked by loss of maturation of the squamous epithelium. There are increased mitotic activity and an increase in the nuclear cytoplasmic ratio.

There is suggestion that there are two distinct causes of vulvar dysplasia leading to vulvar cancer. The first type is seen in younger patients and is related to HPV infection and smoking. This type presents itself as a “wart” dysplasia. The more common type is in elderly patients and is unrelated to smoking or HPV. This group is more related to lichen sclerosus adjacent to the tumor. Approximately 20% of vulvar cancer has been reported to have vulvar dysplasia.

The best method of establishing a diagnosis is a high index of suspicion and early biopsy. Several methods also can be used to help assess these lesions. Cytology, colposcopy, acetic acid, and toluidine blue O can be used cautiously before biopsy. In general, however, cytologic evaluation of the vulva has not been helpful as a screening examination because the vulvar skin often is thickened and keratinized. Colposcopic examination of the vulva is difficult because unlike cervical lesions, the changes are difficult to recognize. Therefore, colposcopic examination is not used for routine vulvar examination; rather, it is primarily employed for patients who are being evaluated or followed for vulvar atypia or intraepithelial malignancies. The toluidine blue O test is nonspecific and stains nuclei in the superficial part of the epithelium. Colposcopy is performed after applying a 1% aqueous solution of toluidine blue O to the vulva for 1 min and decolorizing the tissue with 1% acetic acid. Areas that retain the stain are biopsied. A positive test, however, does not always indicate a premalignant condition because 20% of benign areas on the vulva stain positively.¹⁹

To obtain the entire thickness of the skin for a definitive diagnosis, a biopsy of the vulva usually is done with a Keyes dermal punch. Occasionally, a larger biopsy is needed, in which case a larger field can be

locally anesthetized with lidocaine and a small scalpel or cervical biopsy punch used to obtain a specimen.²¹

Once the correct diagnosis has been established by biopsy, appropriate therapy can be undertaken. For lichen sclerosis, local measures, for example, wearing cotton underclothes and avoiding strong soaps and detergents, often are used to diminish irritation. Topical fluorinated corticosteroids applied twice daily for 1–2 weeks are helpful in controlling pruritus, but prolonged use of these steroid preparations can lead to vulvar atrophy or contracture. If long-term therapy is needed, a nonfluorinated compound such as 1% hydrocortisone is used. Some patients with lichen sclerosus have severe contracture in the area of the posterior fourchette. Treating these areas surgically with plastic repair of the fourchette has been suggested.^{22, 23}

VIN can be treated by a variety of methods, and many authors have reported successful control of the disease by wide local excision.^{10, 22} Adequate margins must be obtained with wide excision; however, this often may be difficult because of the multifocal nature of the disease. Wallbillich et al.²⁴ found that positive margins increased recurrence from 11% to 32%, and recurrence was associated with smoking and a large lesion size.

Other modalities also have been reported in the treatment of VIN. Carbon dioxide laser vaporization and photodynamic therapy²⁵ of the vulva to a depth of 3 mm have been used, and current evidence indicates that laser therapy is as effective as surgical excision for the control of this disease. Before lasering the vulva, however, it is necessary to ascertain by histologic confirmation that invasive disease does not exist. Leuchter et al.²⁶ treated 142 patients with CIS of the vulva. Of those treated by laser, 17% had a recurrence, a result that is similar to that in lesions treated by local excision.

Imiquimod has been used also for conservative medical treatment. A systematic review that included two randomized control trials found a complete response rate of 51%.²⁷ 5-Fluorouracil (5-FU) cream has been used successfully to treat CIS of the vulva, and application of this has been reported to be successful in 75% of cases. With continuous application, however, this treatment causes edema and pain. Most recently, a multicenter, randomized, phase 2 trial between cidofovir and imiquimod for treatment of VIN3 showed a response rate of approximately 46% for both groups treated.²⁸

Paget disease

Paget disease is a rare intraepithelial disorder of the vulvar skin that is seen in postmenopausal women.^{29–31} Unlike VIN, the intraepithelial neoplastic cells are glandular rather than squamous. The lesion primarily occurs in Caucasians of an average age of 65 years. Grossly, it appears as a reddish, eczematoid lesion. Microscopically, this type of lesion is characterized by large pale cells that often occur in nests and infiltrate the epithelium. Once the diagnosis is made, it is important to rule out the presence of an underlying cancer. Invasive vulvar Paget disease occurs in approximately 10% of Paget disease.²⁰ If the anal area is involved, one needs to consider an anal carcinoma. A review by Lee et al.³⁰ reported a total of 75 cases of Paget disease of the vulva: 16 (22%) of the patients had underlying invasive carcinoma of the adnexal structures and 7 (9%) had adnexal CIS.

Paget disease of the vulva often spreads in an occult manner, with margins extending beyond the normal appearance of the lesion.³¹ If there is no evidence of an underlying malignant neoplasm, a wide local excision or total vulvectomy usually is performed.³² If a wide local excision is performed, a slightly deeper excision is needed to remove the epidermis down to the level of the underlying fat to ensure removal of adnexal skin structures. Because this lesion extends subepithelially, a frozen section in the

operating room may assist in ensuring complete removal.

Bergen et al. evaluated 14 patients with Paget disease of the vulva that was treated by vulvectomy, skinning vulvectomy with a graft, or hemivulvectomy.³² With a median follow-up of 50 months, all patients were free of disease; however, three patients had locally recurrent disease. Other modalities (topical 5-FU cream, laser) have not been used for treatment of this disease. Because both local and distant recurrence is a major risk, close follow-up is required.

Invasive vulvar carcinomas

The International Federation of Gynecology and Obstetrics (FIGO) adopted a new surgical staging system in 2009 ([Table 2](#)). This surgical staging has been modified once prior, in 1995, after it became a surgically staged cancer in 1989. The most recent staging system addresses lack of predictive value seen in the previous stages with regard to the size of the lesion, and number and size of lymph node metastasis.³² Specifically, in the new system, there was an addition of three pathologic groupings within stage III (A, B, and C): this identifies the number of positive node, the size of each node, and extracapsular spread. In addition, many centers use the tumor, node, and metastasis (TNM) classification.

Table 2 TNM classification and staging of vulvar carcinoma

TNM classification	
T	Primary tumor
Tis	Preinvasive carcinoma (CIS)
T1	Tumor confined to the vulva and/or perineum; 2 cm or less in diameter
T2	Tumor confined to the vulva and/or perineum; more than 2 cm in diameter
T3	Tumor of any size with adjacent spread to the urethra, vagina, or anus
T4	Tumor of any size infiltrating the bladder mucosa, the rectal mucosa, or both, including the upper part of the urethral mucosa, or fixed to the anus
N	Regional lymph nodes
N0	No nodes palpable
N1	Unilateral regional lymph node metastases
N2	Bilateral regional lymph node metastases
M	Distant metastases
M0	No clinical metastases
M1	Distant metastases (including

	pelvic lymph node metastases)	
FIGO staging (2009)		
IA	T1aN0M0	Tumor confined to the vulva and/or perineum: 2 cm or less in greatest dimension, ≤1 mm stromal invasion, no nodal metastasis
IB	T1aN0M0	Tumor confined to the vulva and/or perineum: 2 cm or greater in greatest dimension, >1 mm stromal invasion, no nodal metastasis
II	T2	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
IIIA	T1 or T2, N1a or N1b, M0	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, and anus) and positive inguinofemoral lymph node, (1) 1–2 lymph node metastasis (<5 mm) or (2) 1 lymph node metastasis ≥5 mm
IIIB	T1 or T2, N2a or N2b, M0	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, and anus) and positive inguinofemoral lymph node, (1) 3 or more lymph node metastasis (<5 mm) or (2) 2 or more lymph node metastasis ≥5 mm
IIIC	T1 or T2, N2c, M0	Positive node with extracapsular spread
IVA		Tumor invades any of the following: upper urethra, bladder mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis
IVB		Any distant metastasis including pelvic lymph nodes

Source: Adapted from Barakat 2013.

Vulvar cancer can spread by direct extension, lymphatic embolization, or hematogenous dissemination. Metastasis to the femoral nodes without inguinal node involvement has been reported but is uncommon. The direct lymphatic pathways from the clitoris to the pelvic nodes have been described but are not of clinical significance. The overall incidence of lymph node metastasis is approximately 30%. Pelvic node metastasis is uncommon with an overall frequency of 9%. Approximately 20% of patients with positive groin nodes have positive pelvic nodes.^{33, 34}

Squamous cell carcinoma

Squamous cell carcinomas comprise approximately 90% of primary vulvar malignancies. Grossly, these carcinomas usually appear as ulcerated or polyploid masses on the vulva. Biopsy reveals the characteristic histologic appearance: the tumor appears in nests and cords of squamous cells infiltrating the stroma, often with islands of keratin. On physical examination, there is usually an ulcerated lesion or wart-like lesion. Recently, there has been an increased incidence of warty carcinoma accounting for 20% of all cases.

Different clinical results have been reported with this definition. Spread to regional lymph nodes has varied from 0% to 10% in tumors with less than a 5 mm depth of invasion.^{35–40} For example, Hoffman et

al.³⁸ reported no nodal metastases in 43 patients whose tumor invaded <2 mm. Lesions that were at risk of spreading to inguinal nodes included tumors with confluent tongues rather than those with individual tongues merely extending into the stroma. Depth of invasion of the stroma to ≤ 1 mm is associated with a risk of lymph nodes metastasis of <1%, hence no need for patient with <1 mm stromal invasion to undergo an inguinal lymph node dissection. Tumors with a depth of invasion of 1.1–3.0 mm are associated with lymph node metastasis of 6–12%, and this rate increases to 15–20% with a depth of invasion of 3.1–5 mm.⁴¹

The risk of nodal involvement may be decreased when CIS is present in the lesion. Rowley et al.³⁹ noted that only 1 of 35 cases with adjacent CIS had nodal metastases. By contrast, 5 of 27 had positive lymph nodes when superficial stage I lesions penetrating 2.1–5.0 mm did not have adjacent CIS.

Sentinel inguinal lymph node biopsy

Sentinel lymph node biopsy (SLNB) is being used in vulvar cancer. In patients with a clinically negative groin examination, an SLNB is an alternative to inguinofemoral lymphadenectomy. SLNB results in less morbidity without compromising detection for lymph node metastases. The Gynecologic Oncology Group (GOG 173) compares SLNB to inguinofemoral lymphadenectomy in 452 women with squamous cell vulvar cancer, for tumors with a depth >1 mm, and size between 2 and 6 cm.⁴² The sensitivity of the SLNB is 92%, and the negative predictive value is 96% in this study. Another multicenter observational study GROINigen International Study on Sentinel nodes in Vulvar cancer (GROINSS-V) analyzed 623 groins from 403 patients, confirming a decrease in short- and long-term morbidities.

Patients undergoing an SLNB report less treatment-related morbidity compared to inguinofemoral lymphadenectomy without compromising the overall quality of life.⁴³ The results of the observational study GROINSS-V II, evaluating and performing a full inguinofemoral lymph node dissection in the setting of a positive SLNB and observation only of a negative SLNB, are still pending.

The above-mentioned studies are all based on surgeons with “vast experience” performing SLNBs. It is still recommended that in the setting of lack of expertise with SLNB, an inguinofemoral lymphadenectomy is done, which is common in the setting of vulvar cancer, which is overall a rare cancer.

Treatment

Clinical stage IA

Tumors showing a depth of the stroma 1 mm or less have minimal risk for lymphatic dissemination. They do not require an inguinofemoral lymph node dissection because the risk of lymph node metastases in this setting is very low risk. These lesions are usually treated with a wide radical excision. These patients have a high cure rate; however, surveillance is needed to rule out recurrence.

Clinical stage I/II

The recommendation for a clinical stage I or II vulvar cancer is a wide radical excision with unilateral or bilateral SLNB versus an inguinal femoral lymphadenectomy (depending on size, location, and institution) for both staging and therapeutic purposes. Margins need to include at least a 2 cm margin lateral of normal tissue, with the deep margin to the deep perineal fascia. The laterality of the lesion determines the need for bilateral versus unilateral inguinofemoral lymph node dissection (or SLNB). A subanalysis of

GOG 173 shows that a bilateral lymph node dissection is required except when the tumor is located more than 2 cm or greater from the midline. For both stages I and II, surgical resection usually leads to excellent long-term survival and local control.

The pattern of spread for this carcinoma relates to the intricate lymphatic drainage of the vulva ([Figure 3](#)). Tumors located in the middle of either labium initially drain to the ipsilateral inguinal femoral nodes, whereas midline perineal tumors can spread to either the left or right side. Using technetium-99 m colloid, Iversen and Aas showed that when radioactivity was injected to one side of the vulva, 98% of it localized in the ipsilateral nodes and <2% in the contralateral nodes.³⁴ Tumors along the midline in the clitoral or urethral areas may spread to either groin. From the inguinal-femoral nodes, lymphatic spread continues to the deep pelvic iliac and obturator nodes. Although there has been concern in the past that tumors in the clitoral–urethral area could spread directly to the deep pelvic nodes, current evidence indicates that this is rare.

Figure 3 Lymphatic drainage of the vulva.

Stages I, II, and III invasive carcinoma

The prognosis of a patient with vulvar carcinoma relates to the stage of disease ([Figure 4](#)). The presence of carcinoma in the regional lymph nodes correlates with the size and thickness of the primary lesion, the degree of tumor differentiation, and the involvement of vascular spaces by the tumor as seen in [Table 3](#), which comes from a classic study by Sedlis et al.⁴⁴ In 272 women with invasive vulvar carcinoma reported by the GOG, regional nodes were involved in 8.9% of stage I, 25.3% of stage II, and 31.1% of stage III lesions.^{45, 46} With larger lesions, 4 mm or greater in thickness, 31% of nodes were positive.

Hacker et al.⁴⁷ reported an actuarial 5-year survival rate of 96% in those with negative nodes survival decreased to 94% with one positive node, 80% with two positive nodes, and 12% with three or more nodes involved by tumor.

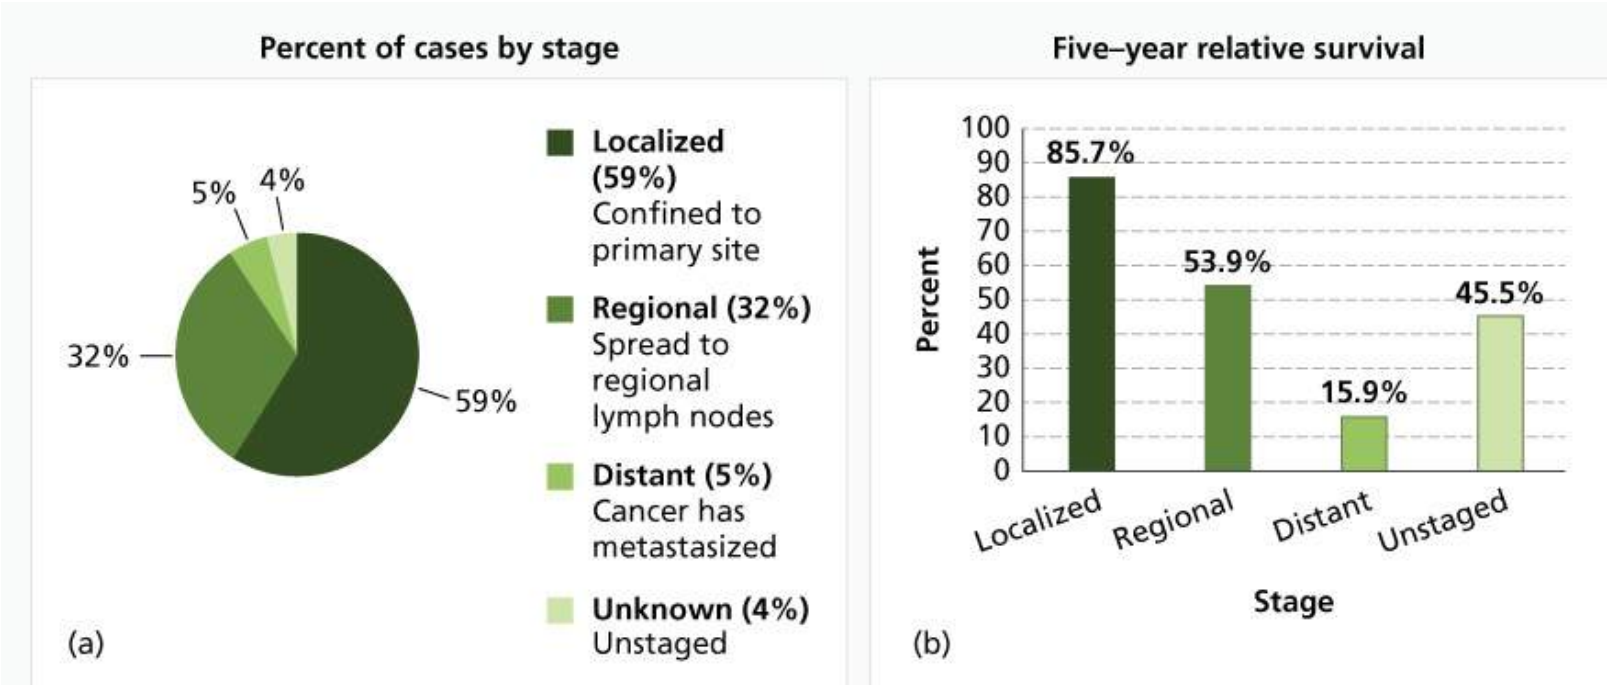

Figure 4 (a) Percent of cases and (b) 5-year relative survival by stage at diagnosis: vulvar cancer. Source: National Cancer Institute, Surveillance, Epidemiology, and End Results Program (SEER) 2011. Stat Fact Sheets: Vulvar Cancer (reproduced from <http://seer.cancer.gov/statfacts/html/vulva.html>, accessed 12 Feb 2015).

Table 3 Prognostic factors of stage, grade, and tumor thickness associated with positive regional nodes

Stage	Positive nodes (%)	Grade	Positive nodes (%)	Tumor thickness (mm)	Positive nodes (%)
I	8.9	1	0	<1	3.1
II	25.3	2	8.0	2	8.9
III	31.1	3	24.6	3	18.6
IV	62.5	4	47.7	>4	31.0

Source: Sedlis 1987.⁴⁴ Reproduced with permission of AJOG.

Not only is the number of nodes important but there also appears to be a correlation with the size of the metastases. Hoffman et al.⁴⁸ noted that 14 of 15 patients with inguinal lymph node metastases measuring <36 mm survived free of disease for 5 years compared with 12 of 29 patients whose tumor metastases measured >100 mm. No additional treatment may be advised if only one lymph node in the groin is microscopically positive; however, this is controversial. Patients with stage 1 lesions did not have positive nodes, yet in patients with stage 4 lesions, 47.7% of nodes were positive. Vascular space involvement is prognostic with 72% vascular invasion showing regional node metastasis compared to 34% of those without vascular invasion. Nodal involvement also correlates with the location of the primary lesion.⁴⁹ Lesions on the labia are associated with 7.4% positive nodes, whereas clitoral lesions have a higher incidence of positive nodes (27.4%).⁵⁰ Boyce et al.⁵¹ reported that six tumors under 1 cm in diameter had no metastases to regional nodes but that the fraction of tumors with positive nodes rose to 55% for 29 cases with lesions over 4 cm.

Therapy for stages I and II and early stage III vulvar carcinoma is accomplished with radical vulvectomy and either bilateral inguinal femoral node dissection⁵² or SLNB. In the past, en bloc of radical vulvectomy and bilateral dissection of the groin and pelvic nodes were standard treatments (specimen seen in [Figure 5](#)). Over the past 30 years, there has been modification of this surgical approach through triple incisions, decreasing the morbidity of the surgery. Since often, the disease occurs in younger women with small tumors and concern of morbidity associated with en bloc resection. The deep pelvic nodes are rarely removed unless the inguinal nodes are involved. Most oncologists now remove only the inguinal and femoral nodes at the time of operation and treat the deep pelvic nodes with external radiation if superficial nodes are involved with tumor.

Figure 5 Gross vulvectomy specimen showing a vulvar carcinoma.

A wide variety of management options of the primary lesion have been proposed. Management of patients with small lesions should be individualized. Since the early 1980s, radical local excision has been advocated in patients with small tumors. The literature indicates that the incidence of local invasive recurrence is similar with local excision and more radical approaches. Radical local excision is most appropriate for unilateral, isolated lesions. This approach has been used for risk factors such as large tumor sites, positive capillary-lymphatic space invasion, or surgical margins that are <8 mm.

Different surgical approaches to invasive vulvar carcinoma have been evaluated. Classically, an en bloc dissection has been performed. Radical vulvectomy and groin dissection have been carried out through a single suprapubic incision that extends between the left and right anterior iliac spines ([Figure 5](#)). This operation removed the entire vulva, including the clitoris, subcutaneous tissue, and inguinal femoral nodes. If the lesion involved the distal urethra, this has often been removed without the loss of urinary continence. In this procedure, the major complication has been wound breakdown and infection (occurring in 50% of the patients). Modifications have been introduced to decrease the incidence of wound breakdown. These modifications include performing the inguinal femoral node dissection through separate inguinal incisions and then completing the radical vulvectomy, which is the standard currently. Tumor recurrences rarely occur in the skin bridge when separate groin incisions are used.^{46, 53}

Modifying the approach for these early-stage lesions appears to be effective and is associated with less morbidity than the standard radical vulvectomy. If the nodes are free from tumor in stages I and II

carcinomas of the vulva, no further therapy is required. If the nodes (especially the femoral nodes) are involved, pelvic irradiation is required. From a randomized study, Homesley et al.⁴⁵ reported an improved survival rate in 118 patients with positive lymph nodes who received 4500–5000 cGy of radiation ([Figure 6](#)).

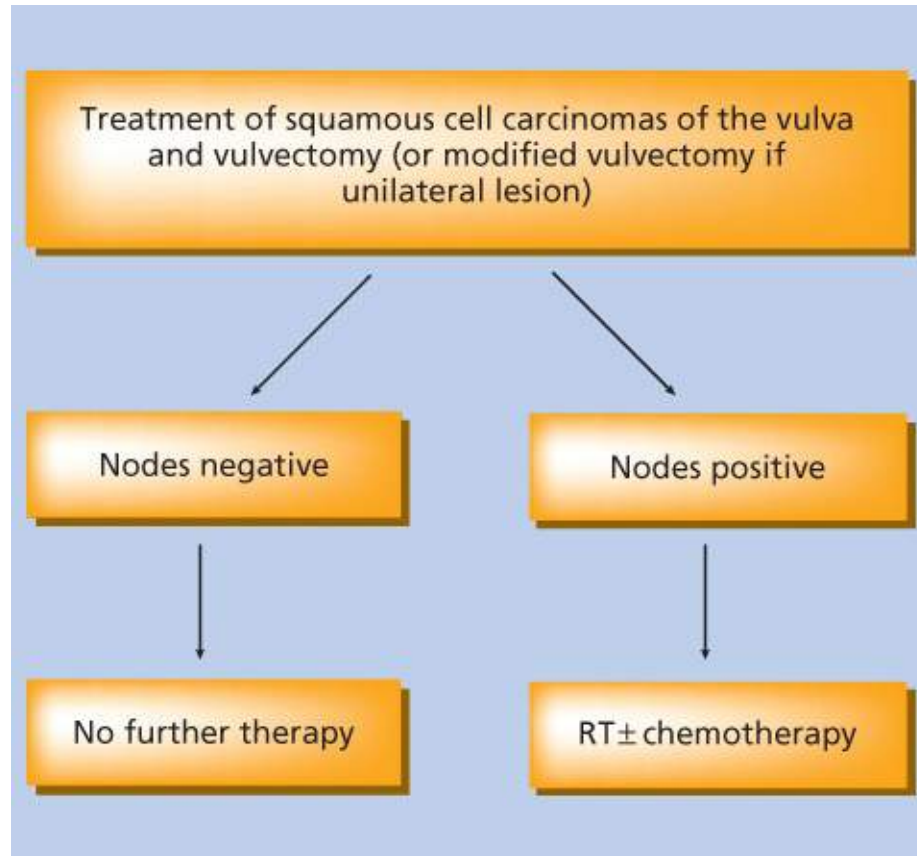

Figure 6 Treatment of squamous cell carcinomas of the vulva. RT, radiation therapy.

Advanced vulvar tumor

Large tumors of the vulva encroaching on the anorectal area and the urethra require more extensive treatment than a radical vulvectomy. Depending on location and ability for resection, approaches can include a radical surgery versus neoadjuvant chemoradiation followed by resection. A radical surgery may leave larger defect that could require skin grafts such as gracilis myocutaneous grafts. If the nodes are negative, a 5-year survival rate of 50% has been reported.^{49, 54}

A combination of preoperative radiation and surgery is usually the standard depending on location and need for extensive radical surgery. External radiation using newer techniques such as intensity-modulated radiotherapy (IMRT) often is given to reduce the size of the tumor before surgical removal by radical vulvectomy, with or without regional lymph node dissection. Approximately 4000–4500 cGy is delivered to the pelvis and inguinal nodes, the operation being performed 5 weeks after the completion of radiation. This approach may obviate a urinary or fecal diversion. Boronow et al.^{55, 56} reported a 5-year survival rate of 80% in 26 patients with primary carcinoma of the vagina and vulva who were treated with this technique. Rotmensch et al.⁵⁷ recently reported 16 patients with advanced vulvar lesions who were treated with preoperative radiation to the vulva and achieved an overall 5-year survival rate of 45%. Recurrences were more likely if the resection margins were within 1 cm of the tumor. Complications have included stenosis of the introitus and urethra as well as rectovaginal fistula.

The approach has been to not only administer preoperative radiation for advanced lesions but also add chemotherapy. Commonly, agents such as 5-FU, cisplatin, and mitomycin C have been used, producing up

to 46% reduction in tumor with chemoradiation; in previous studies, the most common toxicities were acute cutaneous and wound complications.⁵⁸ The GOG performed a phase II trial (GOG 101), which enrolled locally advanced T3 or T4 tumors not amenable to surgical resection via radial vulvectomy, and treated them with radiation plus weekly cisplatin followed by surgical resection of residual tumor. They found a 64% complete response rate.⁵⁹ Because the vulvar skin is prone to radiation dermatitis, fibrosis, and ulceration, radiation as the sole therapy has been less than desirable. However, if the patient is inoperable because of medical conditions, radiation can be used as the primary treatment of a vulvar carcinoma.⁶⁰

Recurrent vulvar cancer

Recurrences may be local or distant. More than 80% of recurrences occur in the first 2 years after therapy. The risk of recurrence of vulva carcinoma increases as the stage of disease increases. In an analysis of 502 patients, the majority of recurrences were local; 53.4% were located in the perineal region.⁶¹ Other areas included the inguinal regional, 19% and then distant recurrences in pelvis and beyond, 6% and 8%, respectively.

Different modalities have been used to treat local recurrences. Both radiation therapy and resection of local vulvar recurrence provide effective control and a 5-year survival rate of approximately 60% if local.⁶¹ Local vulvar recurrences can be further excised. However, if recurrence is located in the inguinal region, survival drops dramatically, with a 5-year survival of 27%. The combination of chemotherapy and radiation therapy has been used to treat recurrent disease and some large primary vulvar carcinomas. Disseminated disease requires chemotherapy, but, unfortunately, no chemotherapy has been successful in this situation. There are no prospective trials in this patient population and much of the data that exists is extrapolated from metastatic cervical cancer. Therefore, most metastatic recurrences are treated with a platinum-based regimen, usually carboplatin and paclitaxel, second to better tolerance to cisplatin plus paclitaxel seen in a cervical cancer trial. Palliative care is recommended for patients who cannot tolerate chemotherapy. Overall prognosis is poor for this population ([Figure 7](#)).

Figure 7 (a) Survival rate after vulvar carcinoma recurrence by type of therapy. The number of cases is shown in parentheses. There was a statistical difference between surgery and other forms of treatment (p , 0.000001). (b) Survival rate of patients with disease recurrence according to the site of the recurrence (the number of patients is shown in parentheses). Source: Maggino 2000.⁶¹ Reproduced by permission of John Wiley and Sons.

Bartholin gland carcinoma

Primary carcinoma of Bartholin gland accounts for 5% of all vulvar cancers, and over 200 cases have been reported⁶²; approximately 50% of those tumors are nonepidermoid in nature. Bartholin gland carcinomas can be squamous if they originate near the orifice of the duct or papillary if they arise from the transitional epithelium of the duct, or they can be adenocarcinomas if they arise from the gland itself. An enlargement of Bartholin gland in a postmenopausal female should raise the suspicion of malignancy. These tumors are treated similarly to primary squamous cell carcinomas of the vulva by radical vulvectomy and bilateral inguinal femoral lymphadenectomy. The overall 5-year survival rate of approximately 70% is below that reported for all carcinomas of the vulva and probably relates to a delay in diagnosis. A Bartholinian gland carcinoma of the vulva is classified if the tumor is in the correct anatomic position, deeply located in the labium majora, the underlying skin is intact, and there is some normal gland present.

The adenoid cystic variety of Bartholin gland carcinoma invades locally and rarely metastasizes. It is slow growing with a tendency to recur locally and invade the periocular tissue. It usually requires only wide local excision for adequate therapy. Rosenberg et al.⁶³ reported five cases of adenocystic carcinoma of Bartholin's gland, with four patients alive and free of disease 28–57 months after treatment.

Basal cell carcinoma

Basal cell carcinoma is rarely encountered in the female genital tract. Such lesions are usually locally invasive, nonmetastatic tumors that are commonly found on the labium majus. Metastasis to the regional lymph nodes is uncommon. Therapy consists of wide local excision of the lesion. If the surgical margins are free of tumor, the disease is cured.

Verrucous carcinoma

Verrucous carcinoma of the vulva is a variant of epidermoid carcinoma. Clinically, it appears as large, condylomatous lesions. They are locally aggressive, nonmetastatic, fungating tumors that gradually increase in size, pushing into rather than invading the underlying structures. Histologically, they consist of mature squamous cells with extensive keratinization. To establish the diagnosis, adequate biopsy is important because biopsy of a large verrucous carcinoma often can lead to an incorrect diagnosis of condyloma acuminatum.

These tumors tend to grow slowly and invade locally, rarely spreading to regional lymph nodes. In 24 cases of verrucous carcinoma, Japaze et al.⁶⁴ found no lymph node metastases. Depending on the size and location of the tumor, a wide local excision or simple vulvectomy is effective therapy; radical vulvectomy with inguinal node dissection or radiation therapy is not indicated as treatment for this entity. Radiation therapy is ineffective and can even worsen the prognosis, causing malignant changes within the tumor. The 17 cases treated surgically by Japaze et al. had an excellent 5-year survival rate of 94%. Close long-term follow-up is needed because disease can recur locally, especially if the tumor is large. If concurrent squamous cell carcinoma is found within the verrucous carcinoma, local excision is an inadequate therapy.⁶⁵

Melanoma

Melanoma is the most frequent nonsquamous cell malignancy of the vulva and comprises approximately 5% of primary carcinomas of the vulva. Approximately 400 cases of melanoma of the vulva have been reported, with an overall 5-year survival rate of approximately 33%, irrespective of the therapeutic modality used. Patients with malignant melanoma of the vulva vary widely in age, ranging from 10 to 96 years, with an average age of approximately 60 years. These lesions most often affect the labia minora or the clitoris.⁶⁶

For vulvar melanomas, the FIGO classification usually has been used. This classification is not, however, as good a prognostic indicator as is the depth of invasion. A system for vulvar melanoma analogous to that used by Clark for cutaneous melanoma has been adopted ([Table 4](#)). New prognostic factors have been described to predict survival. These include the primary tumor thickness, ulceration, number of metastatic lymph nodes, micrometastatic disease in the sentinel lymph node, and the site of distant metastasis. Levels I–V have been identified based on the Clark classification. The level of invasion correlates with survival, which varies from 100% for level II to 83% for level IV and 28% for level V.⁶⁷

Table 4 Classification of melanomas of the vulva

<i>Clark level</i>	
I	Intraepithelial
II	Extension to papillary dermis
III	Filling the dermal papillae
IV	Invasive of collagen in reticular dermis
V	Extension into subcutaneous fat
<i>Breslow depth of invasion</i>	
I	<0.75 mm from skin surface
II	0.76–1.4 mm from skin surface
III	>1.5 mm from skin surface

Two varieties of melanoma have been described: nodular and superficial spreading melanoma.⁶⁸ The superficial spreading melanoma is more common and has a better prognosis, with a 5-year survival rate of 71%. Nodular melanoma has a worse prognosis, and this directly relates to its potential for vertical growth. The 5-year survival rate for nodular melanoma, which is more invasive, is only 38%.

The thickness of the tumor also may be useful in evaluating this lesion. Breslow⁶⁹ reported a classification using depth of invasion as measured from the skin surface. In his classification, Breslow reported the overall prognosis as excellent and the spread to regional nodes as unlikely for melanomas with a thickness of <0.76 mm, measured from the surface to the deepest point of penetration.

Wide local excision has been recommended for Clark level I and II disease when no palpable regional nodes are present.⁷⁰ In a report of 36 melanoma cases, Rose et al.⁷¹ noted that wide excision was as effective as radical vulvectomy. Prognosis was better for younger patients, presumably because most had superficial spreading rather than nodular melanomas.

A reasonable approach is to excise a melanoma with a 2 cm margin and without node dissection for cases that are <2 mm thick. However, others would recommend a radical local excision with 1–2 cm margins from the primary lesions and an ipsilateral inguinofemoral lymphadenectomy. This is based on a multi-institutional nonrandomized trial of elective lymph node dissection versus observation for intermediate thickness cutaneous melanoma. This study showed elective lymph node dissection had a significantly better 5-year survival rate than observation for melanomas of 1–4 mm.

An excision with a 2–3 cm margin combined with node dissection could be performed for more advanced melanomas. An alternative approach for lesions that have extended to Clark levels III, IV, and V is radical vulvectomy with groin and pelvic lymphadenectomy;⁷² although the therapeutic benefit of a lymph node dissection in this population is controversial.

It has been reported that melanoma of the vulva can metastasize to pelvic nodes, bypassing the inguinal femoral nodes, but current evidence indicates that pelvic node involvement does not occur without prior inguinal node involvement. A further therapeutic consideration is that patients with melanoma whose pelvic nodes are involved with tumor usually do not survive their disease.

Long-term results generally are not available for large series of melanomas. Most series of malignant melanoma report an overall survival rate of approximately 50%.⁷³ For lesions that correspond to Clark level I or II (lesions 0.76 mm thick) and are treated by wide local excision, the 5-year survival rate is in

the vicinity of 100%. Prognosis becomes poorer with melanomas more than 3 mm thick. If the regional nodes are negative, the survival rate is approximately 60%; if the regional nodes are involved with tumor, survival is only 30%.

The role of chemotherapy for distant metastasis has not been well established. Regressions, but not cures, have been reported with various multiagent cytotoxic programs, including chemotherapy and/or immunotherapy. These patients should be encouraged to enroll in clinical trials if available.

Sarcoma

Sarcomas of the vulva are rare. Leiomyosarcomas appear to be the most frequently encountered sarcomas in this group of patients⁷⁴ and surgical removal by wide local excision is the recommended initial treatment of choice. The 5-year survival rate is reported to be approximately 100%. Locally recurrent lesions are similarly treated. Chemotherapeutic considerations are the same as for those sarcomas in other sites of the female genital tract.⁷⁵

Cancer of the vagina

Primary vaginal cancers are rare, constituting about 3% of all gynecologic malignancies.^{2, 76–78} It is estimated that 3170 cases of vaginal cancer had been diagnosed in the United States in 2014 and 880 of those women died of this cancer.

Carcinoma of the vagina is defined as a primary carcinoma arising in the vagina and not involving the external os of the cervix superiorly or the vulva inferiorly. The majority of vaginal tumors are secondary to metastasis from other sites. Approximately 30% of primary vaginal cancers have *in situ* or invasive cervical cancers previously treated.

The most common symptom of vaginal carcinoma is abnormal painless bleeding or discharge. With advanced tumors, pain or urinary frequency occasionally occurs, especially in cases of anterior wall tumors. Constipation or tenesmus has been seen with tumors involving the posterior vaginal wall. These tumors usually are diagnosed by direct biopsy of the tumor mass, and abnormal cytologic findings often will lead to diagnosis of a vaginal cancer.

The staging criteria for vaginal carcinomas according to the FIGO are given in [Table 5](#).

Table 5 FIGO staging classification for vaginal carcinoma

Stage	
0	CIS
I	Carcinoma limited to vaginal wall
II	Carcinoma involves subvaginal tissue without extension to pelvic sidewall
III	Carcinoma extends to pelvic sidewall
IV	Carcinoma extends beyond true pelvis or involves mucosa of bladder or rectum IVA Spread to adjacent organs and/or direct extension beyondthe true pelvis IVB Spread to distant organs

Abbreviations: CIS, carcinoma *in situ*; FIGO, International Federation of Gynecology and Obstetrics.

Premalignant vaginal disease

Premalignant disease of the vagina is generally detected on cytologic screening. Once an abnormal cytology is obtained, a biopsy directed by colposcopic examination is required to verify the severity of the changes. Because vaginal intraepithelial neoplasia is often multifocal, it is necessary to inspect the entire vaginal canal.⁷⁹

Most lesions occur at the vaginal apex. Audet-Lapointe et al.⁸⁰ noted that 61 of 66 cases of vaginal intraepithelial neoplasia occurred in the upper third of the vagina. These lesions usually can be excised locally. Other modalities often are preferred, however, because of the multifocal nature of this disease or the necessity of excising large areas, requiring skin grafting.⁸¹

Nonsurgical approaches for treating these lesions include laser ablation and 5-FU cream for widespread multifocal disease. Carbon dioxide laser frequently has been used and, if carried to a depth of 2–4 mm, allows for vaporization of abnormal tissue. Preliminary results reported by Petrilli et al.⁸² with this modality have shown a success rate of approximately 90%. Radiation currently is not recommended for the treatment of noninvasive disease because of the proximity of the bladder and rectum and the availability of newer modalities.

Another approach to treating vaginal intraepithelial neoplasia is the use of 5% 5-FU cream for approximately 7 days, repeated every 3–4 weeks if the vaginal intraepithelial neoplasia persists. Hyperkeratotic lesions appear to be less sensitive to treatment because of their thickness and parakeratosis. Krebs⁸³ reported on the use of 5% 5-FU daily for 10 days and noted that 17 of 20 patients with vaginal condylomas responded to this therapy. Petrilli et al.⁸² and Ballon et al.⁸⁴ reported success rates of 80–90% for vaginal intraepithelial neoplasia after multiple cycles of therapy. Another approach is the use of imiquimod as described for treatment of vulvar dysplasias (as seen above in vulvar sections), there have been retrospective studies describing response, however the use considered off label.

Invasive carcinomas of the vagina

Squamous cell carcinomas of the vagina may appear grossly as either ulcerated or fungating tumors or they may be exophytic and protrude through the vaginal canal. They are the most common vaginal malignancy and account for 90% of primary vaginal cancers. The disease occurs primarily in women over 50 years of age. Most squamous cell carcinomas occur in the upper third of the vagina. In examining the patient, it is important to visualize the entire vagina because lesions on the posterior wall can be concealed by the speculum.⁸⁵ Microscopically, these tumors have the classic findings of invasive squamous cell carcinoma. They have pleomorphic squamous cells with occasional keratin pearls.

The location of the tumor determines the areas of lymphatic spread ([Figure 8](#)).⁸⁶ The lymphatics of the middle and upper vagina communicate superiorly with the lymphatics of the cervix and drain into the pelvic nodes of the obturator, internal, and external iliac chains. The lymphatics of the distal third of the vagina drain to the inguinal and pelvic nodes, with a pattern of drainage similar to that of the vulva. The posterior wall lymphatics drain to the rectal lymphatic system. Positive inguinal nodes are present in 31.6% of disease in the lower vagina. The treatment for vaginal cancer is individualized.

Figure 8 Lymphatic drainage of the vagina.

Depending on the location, both radiation including high dose rate brachytherapy and surgery have been

used effectively in treating these lesions ([Table 6](#)). Treatment is often individualized, depending on the size, stage, and location of the tumor.^{84, 87}

Table 6 Treatment scheme for vaginal carcinoma

Stage	External therapy (cGy)	Implant (interstitial) cGy
I		
Σ, small tumors (<2 cm)	—	6000–7000
Σ, all others	Whole pelvis (4000)	3000–4000 cGy
II	Whole pelvis (4000–5000)	3000–4000 cGy
III	Whole pelvis (5000)	2000
IV	Whole pelvis (5000; an additional 1000–2000 through reduced field if implant not possible)	2000 (if possible)

Source: Adapted from Nori et al.⁹⁰ Reproduced with permission from Elsevier.

1 cGy = 1 rad.

If the tumor is <2 cm thick, some investigators advocate using only local radiation.^{88, 89} If the carcinoma is <0.5 cm thick, intracavitary irradiation with a vaginal cylinder to deliver 8000 cGy to the mucosa will give over 90% tumor control.⁹⁰ Spirtos et al.⁹¹ studied 23 stage I patients and noted only two local recurrences, and both of these had tumor doses of <7500 cGy. For larger lesions, external radiation is used, with a concomitant reduction in the local vaginal component of primary tumor treatment.⁹² Implants, however, often cannot be used in patients with larger stage III or IV carcinomas. If such is the case, only external beam radiation is used, and a central boost is given after an initial whole-pelvis dose of 5000 cGy radiation.⁹³

Small tumors located in the upper third of the vagina often can be excised.^{94, 95} In patients with these, a radical hysterectomy, partial vaginectomy, or pelvic lymphadenectomy usually is effective. Surgery has been preferred in younger patients.

If distant metastasis occurs, effective cis-platinum-based chemotherapy for recurrent squamous cell carcinoma of the vagina has not been developed.⁹⁶ For squamous cell carcinoma, a variety of regimens using multiagent chemotherapy similar to those for cervical carcinoma have been employed.

The overall survival rate for patients with primary carcinoma of the vagina is related to the stage of the disease.

Clear cell adenocarcinoma of the vagina

Clear cell adenocarcinomas have been seen more frequently in young women since 1970 because of the association with intrauterine exposure to diethylstilbestrol.^{97, 98} Three predominant histologic patterns are found with clear cell carcinoma; they have been described as tubulocystic, solid, and papillary patterns.^{99, 100} Most clear cell carcinomas of the vagina are polypoid or nodular, with a reddish color.

Clear cell carcinomas can spread locally and by the lymphatic and hematogenous routes. Metastases to regional pelvic nodes have been found in approximately one-sixth of stage I cases. Spread to regional

pelvic nodes becomes more frequent in higher-stage tumors.

Clear cell adenocarcinomas are staged as other carcinomas of the vagina are by the FIGO. Some 80% have been diagnosed as stage I or II.

Several prognostic factors have been identified. Older patients (i.e., >19 years of age) have a more favorable prognosis than younger patients.¹⁰¹ This difference has been associated with the presence of a more favorable tubulocystic pattern of clear cell adenocarcinoma, which is the most frequent histologic pattern found in older patients. In addition, smaller tumor diameter and superficial depth of invasion correlate with improved patient survival. Survival also depends on the stage of the disease. In 547 patients treated for clear cell adenocarcinoma of the vagina, the 5-year survival rate for those in stages I, II, III, and IV has been 93%, 83%, 37%, and 0%, respectively ([Table 7](#)).¹⁰¹

Table 7 Survival at 5 and 10 years for 547 patients with clear cell adenocarcinoma of the vagina and cervix

	Survival (%)	
Stage	5 years	10 years
I	93	87
IIA	80	66
IIB	58	49
II (vagina)	83	67
III	37	12
IV	0	0

Because of the young age of these patients, surgery often is the primary therapy. For stage I and early stage II disease ([Figure 9](#)), radical hysterectomy, partial or complete vaginectomy, pelvic lymphadenectomy, and replacement of the vagina with a split-thickness skin graft have been the approaches most frequently used.¹⁰²

Figure 9 Clear cell adenocarcinoma of the anterior wall, with vaginal adenosis on the posterior wall at the edge of the tumor.

In patients with small stage I tumors of the vagina, efforts have been made to preserve fertility. The tumor has been excised with retroperitoneal lymph node dissection, followed by local radiation. Senekjian et al.¹⁰² reported that the survival rate of patients with small vaginal tumors treated with such an approach compares favorably with that of patients treated with conventional therapy. In their series, eight pregnancies were reported in five patients who were treated locally.

Larger tumors have been treated with whole-pelvis radiation in addition to intracavitary implant. For tumors >2 cm, whole-pelvis radiation of 4000–5000 cGy has been given, with an additional implant of 3000–4000 cGy.¹⁰³ In a few instances, exenterative surgery has been performed for larger tumors; however, this procedure usually has been applied to central recurrences following primary radiation therapy.¹⁰⁴

If there is a recurrence, therapy consists of additional radical surgery, often requiring exenteration or extensive radiation localized to the pelvis. Systemic chemotherapy has been used in cases of metastatic

disease. Cisplatin (75–100 mg/m²) with a continuous infusion of 5-FU (1 g/m² for 3–5 days every 3–4 weeks) is currently recommended. However, no single agent or combination of chemotherapeutic agents has emerged as the most effective.¹⁰⁵ Prolonged follow-up is necessary because recurrences, especially in the lungs and supraclavicular areas, have been reported as long as 19 years after primary therapy.

Vaginal melanomas

Malignant melanomas of the vagina are rare; they constitute <1% of all melanomas occurring in females. The age distribution of the neoplasm has ranged from 26 to 98 years,⁵³ with a median age of 70 years. Most patients are postmenopausal and present with vaginal bleeding, discharge, or a mass. Tumors may vary from 0.5 to 7.5 cm in diameter, with approximately 30% being 2 cm or less in diameter. Most of these tumors develop in the distal third of the vagina, commonly on the anterior wall. Primary vaginal melanomas presumably arise from vaginal melanocytes that are present in approximately 3% of normal females. Histologically, this neoplasm is similar to other melanomas found elsewhere and tends to be deeply invasive in the vagina.

The prognosis is worse than that of vulvar melanomas. Chung et al.¹⁰⁶ reported a 5-year survival rate of only 21% in a series of 19 patients. Reid et al.¹⁰⁷ reported a 5-year survival rate of 17.4% in 15 cases, but the prognosis was improved for those tumors that were small and <3 cm in diameter. More recently, Borazjani et al.¹⁰⁸ reported improved survival for cases in which there were fewer than six mitoses/10 high-power fields. The best prognostic factor is the size of the lesion.

Optimal treatment has not been established. Treatment usually consists of radical surgery or wide excision of the vagina and dissection of the regional lymph nodes, depending on the location of the lesion. Recently, a more conservative approach has been used for wide local excision followed by pelvic radiation. Because of the poor prognosis, adjunctive radiation and chemotherapy have been used as local recurrences, and distant metastases with this disease are common. If possible, these patients should enroll in a clinical trial.

Rare vaginal tumors in young females

Endodermal sinus tumor is a rare germ cell malignancy that is usually found in the ovary.¹⁰⁹ This tumor secretes alphafetoprotein, which often is a useful tumor marker for monitoring patients with this neoplasm. It is usually found in infants and children under the age of 3.^{110, 111} Patients generally present with complaints of bleeding or spotting from the vagina. On physical examination, there is a friable red to pinkish-white polypoid tumor. This tumor is aggressive, and most patients have died. Therapy has involved surgery, radiation, and chemotherapy. Young and Scully¹¹² reported six patients who were disease free from 2 to 9 years after local therapy with operation, irradiation, or both, followed by systemic chemotherapy with vincristine, actinomycin D, and cyclophosphamide (VAC).¹¹² Copeland et al.¹¹³ reported similar results using the combination of chemotherapy and excision,¹¹³ and Collins et al.¹¹⁴ recently noted the regression of tumor with chemotherapy alone.¹¹⁵ In this report, a 5-month-old patient had regression of the tumor after VAC therapy.

Another rare tumor found in the vaginas of young females is sarcoma botryoides, or embryonal rhabdomyosarcoma.¹¹⁶ This tumor is usually found in children <8 years of age. As with endodermal sinus tumor, the most common symptom has been vaginal bleeding. In 58 cases reviewed by Hilgers,⁵⁰ the average age at onset of symptoms was 38.3 months. This tumor resembles clusters of grapes and forms multiple polypoid masses that are believed to begin in the subepithelial layers of the vagina and to rapidly

expand, filling the vagina. Histologically, these tumors are identified by the presence of rhabdomyoblasts that may contain cross-striations. Because of infiltration of the tumor under the vaginal epithelium, there is often a distinct subepithelial zone, called the cambium layer. The 5-year survival rate of these tumors in the past has ranged from 10% to 35%, and exenterative procedures have often been used.¹¹⁷ Hilgers reviewed the literature on pelvic exenterations in 21 cases of embryonal rhabdomyosarcoma and found that this form of therapy was ineffective in curing these patients.¹¹⁸ Effective control with less radical surgery has been achieved using multimodal treatment consisting of multiagent chemotherapy, VAC, combined with operation or radiation.

Hayes et al.¹¹⁹ recently reported 21 patients with vaginal rhabdomyosarcoma who received chemotherapy.¹¹⁹ In their series, seven relapsed, with five of these seven having had residual disease following incomplete resection. In 17 of 21 patients who received chemotherapy before surgery, a subsequent delayed excision could be performed. Data regarding the long-term survival of a large number of patients are not available, but such a combined approach appears to result in effective therapy with less mutilating surgery.

A rare, benign, fibroepithelial vaginal polyp that resembles sarcoma botryoides can be found in the vaginas of infants or pregnant women.^{68, 120, 121} Although large atypical cells are present microscopically, epithelial infiltration, a cambium layer, and strap cells are absent. Grossly, these polyps do not resemble the grape-like appearance of sarcoma botryoides. These hormonally stimulated hyperplastic lesions are called pseudosarcoma botryoides, and treatment by local excision is effective.

Overview

Cervical cancer is the third most common cancer among women worldwide and the fourth leading cause of cancer deaths in females, with an estimated 529,800 new cases and 275,100 deaths in the year 2008. The incidence is declining in the United States with 12,900 new cases and 4100 deaths in 2015. Squamous cell carcinoma is the most common histology with the human papilloma virus (HPV) being the most common etiology. Cervical cancer can be easily prevented with pap smears, HPV testing, and hopefully the HPV vaccine. Early stage cervix cancer can be treated with surgery including now fertility sparing surgery and there are high cure rates. Local advanced cervical cancer is treated with combination of chemotherapy and radiation therapy with high survival rates but there is room for improvements with advancing stage. Systemic chemotherapy can be used for treatment of both recurrent and metastatic disease, but careful attention should be paid to balancing benefit and toxicity. The key to success will be the transportation of success seen in the developing countries to success in areas of the world where advanced-stage invasive cervical cancer is most common.

Epidemiology

Incidence and mortality

Cervical cancer is the third most common cancer among women worldwide and the fourth leading cause of cancer deaths in females, with an estimated 529,800 new cases and 275,100 deaths in the year 2008.¹ The incidence of cervical cancer in developing countries remains nearly twice that in developed countries, with the highest rates observed in Africa, South-Central Asia, and South America (29 per 100,000 per year) and the lowest in Western Asia, Australia/New Zealand, and North America (7.5 per 100,000 per year).² In the United States, it is estimated that there will be 12,900 new cases of cervical cancer in 2015, with 4100 related deaths.³ Cervical cancer is frequently seen in the Hispanic population (10.5% of all cases of cervical cancer) followed by the African-American population (10.2%), American Indians (9.5%), whites (7.1%), and Pacific Islanders/Asian (6.4%).³

In the past 40 years, primarily because of the introduction of screening with the Pap smear, the incidence and mortality rates for cervical cancer have declined in most developed countries.⁴ In the United States; incidence rates have declined nearly by 70% during this period. Rates of invasive cancer per 100,000 females have declined from 10.2 in 1998 to 8.5 in 2002.⁵ In developing countries, however, cervical cancer continues to be a significant health problem owing to suboptimal screening programs and a lack of therapy for precancerous conditions.

There are no reliable data on the prevalence and incidence of precancerous cervical lesions. In the United States, the National Cancer Institute (NCI) estimates that each year approximately 300,000 women are found to have premalignant cervical lesions, whereas the American Cancer Society reported that in 2001, an estimated 65,000 women were found to have carcinoma *in situ* (CIS) of the cervix. From the SEER

data, the overall incidence of squamous cell CIS among whites is 41.4 per 100,000 woman-years from 1991 to 1995.⁶

Risk factors for cervical neoplasia

Human papillomavirus and other sexually transmitted agents

Epidemiologic evidence has long suggested a sexually transmitted etiology for cervical neoplasia. Supporting this hypothesis, several measures of sexual behavior (including multiple sexual partners, early age at first sexual intercourse, and sexual habits of male partners) have consistently been associated with an increased risk of cervical neoplasia.⁷ In the mid-1970s, the hypothesis of a causal relationship between human papillomavirus (HPV) and cervical neoplasia was first proposed.⁸ Since then, a large body of experimental, clinical, and epidemiologic research has accumulated supporting an etiologic role for some types of HPV.⁹

Of the more than 78 types of HPV that have been described, in excess of 35 types are associated with anogenital disease, and 30 or more are associated with cancer.¹⁰ Similarly, HPV DNA has been detected by polymerase chain reaction (PCR) in up to 94% of women with preinvasive lesions [cervical intraepithelial neoplasia (CIN)] and in up to 46% of women with cytologically normal tissue.^{9, 11}

HPV types classified as intermediate and high risk have been identified in about 77% of high-grade squamous intraepithelial lesions (HGSILs) (CIN 2 and 3) and in 84% of invasive lesions.¹² In the series studied by Bosch and colleagues, HPV types 16, 18, 31, and 45 were detected in approximately 80% of the cases.¹³ HPV 16 is by far the most prevalent HPV type in women with cervical neoplasia, present in up to 50% of HGSILs and invasive lesions, and it is the most common HPV type identified in cytologically normal women.^{12, 14, 15}

The association between cervical neoplasia and HPV is independent of study population, study design, and HPV detection method.¹³ Higher risk has been associated with specific HPV types (16, 18, 31, 33, 35, and 45), increasing viral load, and concurrent infection with multiple HPV types.^{16, 17} An increased risk of high-grade CIN ranging from 16- to 122-fold has been reported among women whose test results were positive for HPV of any type.¹⁷ The percentage of cases of CIN attributed to HPV has been estimated to range from 60% to 92%.¹¹ In addition, adjustment for HPV status appears to account for most of the associations between cervical neoplasia and number of sexual partners and other characteristics of sexual behavior.^{11, 16, 17}

Although a strong and consistent association between HPV and cervical neoplasia has been clearly established, the discrepancy between HPV prevalence and the incidence of cervical neoplasia suggests that other cofactors are necessary for the development and progression of the disease.

Numerous studies have addressed the association between HIV and cervical neoplasia.⁷ The Centers for Disease Control and Prevention added invasive cervical cancer to the list of conditions related to AIDS in 1993.¹⁵ HIV-positive women have been reported to have higher rates of cervical abnormalities, larger lesions, higher grade histology, and higher recurrence rates than HIV-negative women. In addition, HIV-positive women have been reported to have higher HPV prevalence and HPV persistence rates than HIV-negative women. A meta-analysis by Mandelblatt and colleagues concluded that HIV is a cofactor in the association between HPV and cervical neoplasia, and this association seems to vary with the level of immune function.¹⁸

Other molecular markers

Other specific genetic abnormalities may also play an important role in carcinogenesis and the aggressiveness of cervical tumors, although, to date, the role of most of these genetic abnormalities in cervical cancer does not appear as important as the role of HPV. Most studies report a 32–34% incidence of *c-myc* activation in cervical cancers, predominantly through amplification.^{19, 20} Amplification has been related to tumor size and nodal status as well as a risk factor for relapse.²¹ Mutations have been reported in the *K-ras* and *H-ras* genes in cervical cancer at a rate of only 10–15%.²² One report found that increased *ras* p21 expression correlated with risk of lymph node metastasis.²³

Epidermal growth factor receptor (EGFR) is expressed not only in a large proportion of cervical carcinomas but also in normal and premalignant epithelia. The prognostic role of EGFR in cervical carcinoma remains controversial, although two studies found EGFR prognostic for overall survival (OS) and disease-specific survival (DSS) in patients with invasive cervical cancer.^{24, 25}

The apoptosis inhibitor Bcl2 prevents apoptosis. Two studies have shown that Bcl2 is overexpressed in 61–63% of all cervical cancer and correlates inversely with OS,^{26, 27} whereas other studies have found no correlation with survival.²⁸

Angiogenesis is critical for the progression of most cancers. One angiogenic factor, VEGF, has recently been associated with cervical cancer,^{29, 30} but the precise role that angiogenic factors play in the development and progression of cervical cancer requires further elucidation.

Sexual behavior

Although previous studies report a strong and consistent association between cervical neoplasia and some characteristics of sexual behavior of women and their male sexual partners, a weaker association has been found in more recent studies in which HPV infection has been taken into account.^{16, 31} This, characteristics of sexual behavior may be only a proxy measurement for infection with HPV and other infectious agents that may be causally related to cervical neoplasia.

The association between early age at first sexual intercourse and increased risk has been less consistent. After controlling for HPV and other risk factors, a statistically significant association between age at first sexual intercourse and cervical neoplasia has remained in some studies, but in others, no association has been observed.^{16, 17, 32} The association between cervical neoplasia and early age at sexual intercourse may indicate a period of higher susceptibility of the cervical tissue, a higher likelihood of exposure, or a longer period of exposure to carcinogenic factors. Establishing age at first sexual intercourse as an independent effect is, however, difficult because of its high correlation with number of sexual partners.

An association between factors related to male sexual partners and an increased risk of cervical neoplasia has also been suggested.³³ Among men, the prevalence of HPV has been associated with the number of sexual partners and sexual contact with prostitutes.³⁴ In addition, higher HPV prevalence has been reported among males in geographic areas with higher rates of cervical cancer incidence than among males in geographic areas with lower rates, which supports a possible contribution of male partners to cervical carcinogenesis in their female sex partners.³⁴ Male circumcision has been associated with a reduced risk of penile HPV infection and, in the case of men with a history of multiple sexual partners, a reduced risk of cervical cancer in their current female partners.³⁵

Reproductive factors

No consistent relationships have been established between cervical neoplasia and menstrual or reproductive characteristics, including age at menarche or menopause, parity, number of spontaneous or induced abortions, age at first pregnancy, first live birth, or last birth, and number of vaginal deliveries or Cesarean sections. There is an association among increased risk of cervical neoplasia and higher parity, early age at first birth, higher number of live births, and vaginal deliveries.^{16, 17, 35, 36} Repeated trauma to the cervix during childbirth could be an etiologic factor.³⁵

Smoking habits

Several epidemiologic studies have provided evidence supporting an approximately twofold increased risk among smokers and a dose–response relationship with duration and intensity of smoking.^{37, 38} Some support an independent effect of smoking, whereas others do not.^{16, 17, 39} High levels of nicotine, cotinine and tobacco-specific *N*-nitrosamines have been detected in the cervical mucus of active and passive smokers. DNA damage has been found in cervical tissue and exfoliated cells of women smokers. The local cell-mediated immune response is impaired in smokers. Furthermore, reduction of cervical lesion size has been documented among women participating in smoking cessation intervention.⁴⁰ Although the mechanism of smoking-induced carcinogenesis in cervical tissue is not fully understood, current biologic, epidemiologic, and clinical studies suggest that cigarette smoking may be a risk factor for cervical neoplasia.

Risk factors for cervical adenocarcinoma

Adenocarcinoma of the cervix accounts for more than 20% of all cervical cancers. However, in most developing countries, the incidence is increasing, particularly among younger women. Between the early 1970s and mid-1980s, the incidence of adenocarcinoma more than doubled among women under 35 years of age.⁴¹ Adenocarcinoma is associated with a higher likelihood of HPV-16 and HPV-18, which is present in more than 80% of cases. HPV 18 accounts for approximately 50% of adenocarcinoma of the cervix but only 15% of squamous cell carcinoma.⁴² Adenocarcinoma has been linked to several other risk factors more commonly associated with endometrial cancer, including obesity⁴³ and nulliparity.⁶

Summary

Cervical neoplasia continues to be a major health problem worldwide. Higher incidence and mortality rates are observed in developing countries. Among more developed countries, a significant decline in incidence and mortality has been observed in the past 50 years, which has been attributed to the introduction of screening programs. Current epidemiologic data support a strong role for HPV infection in the etiology of cervical neoplasia. This association satisfies all criteria for causality in epidemiologic research: strength, consistency, and specificity of the association; dose–response and temporal relationship; and biologic plausibility.¹¹ HPV infection appears to explain many of the established risk factors for cervical neoplasia, including sexual behavior and cigarette smoking. Nonetheless, the high prevalence of HPV infection in young healthy women compared with the low incidence of cervical neoplasia and the low progression rate of untreated CIN lesions support the existence of other cofactors in cervical carcinogenesis.⁴⁴ Future epidemiologic studies will need to further assess the role of these cofactors and their interaction with HPV. In addition, the role of viral factors such as HPV persistence and HPV variants in the progression of cervical neoplasia as well as of the determinant factors of HPV persistence will require further evaluation.⁴⁵ Similarly, the impact of recent trends in environmental factors such as smoking, exogenous hormones, and dietary factors deserves further attention.⁷

Histologic classification of epithelial tumors

The histologic classification of epithelial tumors of the uterine cervix by the World Health Organization (WHO) separates them into three main groups: squamous cell carcinomas, adenocarcinomas, and other epithelial tumors ([Table 1](#)).^{46, 47}

Table 1 Modification of the WHO histologic classification of epithelial tumors of the uterine cervix

Squamous cell carcinoma
Microinvasive squamous cell carcinoma
Invasive squamous cell carcinoma
Verrucous carcinoma
Warty (condylomatous) carcinoma
Papillary squamous cell (transitional) carcinoma
Lymphoepithelioma-like carcinoma
Adenocarcinoma
Mucinous adenocarcinoma
Endocervical type
Intestinal type
Signet-ring type
Endometrioid adenocarcinoma
Endometrioid adenocarcinoma with squamous metaplasia
Clear cell adenocarcinoma
Minimal-deviation adenocarcinoma
Endocervical type (adenoma malignum)
Endometrioid type
Serous adenocarcinoma
Mesonephric carcinoma
Well-differentiated villoglandular adenocarcinoma
Other epithelial tumors
Adenosquamous carcinoma
Glassy cell carcinoma
Mucoepidermoid carcinoma
Adenoid cystic carcinoma
Adenoid basal carcinoma
Carcinoid-like tumor
Small cell carcinoma
Undifferentiated carcinoma

Squamous cell carcinoma

The majority of cervical carcinomas are squamous cell carcinomas, which are classified as either large cell nonkeratinizing or large cell keratinizing. Nonkeratinizing carcinoma is characterized by squamous cells with somewhat hyperchromatic nuclei and a moderate amount of cytoplasm growing in discrete nests separated by stroma ([Figure 1](#)). In the center of some of the nests, the squamous cells appear to differentiate and degenerate. Keratinizing carcinoma is characterized by cells with very hyperchromatic nuclei and densely eosinophilic cytoplasm growing in irregular invasive nests. Many of these nests have central “pearls” that contain abundant keratin. The average age of patients with squamous cell carcinoma is 51.4 years. Selected variants of squamous cell carcinoma are described in the following paragraphs.

[Figure 1](#) Squamous cell carcinoma, nonkeratinizing.

Verrucous carcinoma

Verrucous carcinomas are exophytic with frond like papillae and macroscopically resemble condylomas. They rarely metastasize, but local invasion can be extensive. Death usually occurs because of ureteral obstruction, infection, or hemorrhage.

This tumor rarely goes to the nodes, therefore, for early-stage disease, the treatment of choice is a type II modified radical hysterectomy without lymphadenectomy.

Papillary squamous cell carcinoma

Papillary squamous cell carcinomas of the uterine cervix with transitional or squamous differentiation often resemble transitional cell carcinomas of the urinary tract ([Figure 2](#)). Urinary tract transitional cell carcinomas have a cytokeratin profile strongly positive for cytokeratin 20, whereas primary genital tract transitional cell carcinomas stain positive for cytokeratin 7.⁴⁸ Invasive papillary transitional cell carcinomas of the uterine cervix are potentially aggressive carcinomas. It is important to distinguish these carcinomas from benign squamous papillomas and condyloma acuminata.⁴⁹ Biopsy material must include the underlying stroma to permit identification of invasion.

[Figure 2](#) Papillary squamous cell (transitional) carcinoma.

Lymphoepithelioma-like carcinoma

Lymphoepithelioma-like carcinomas are histologically similar to lymphoepitheliomas arising in the nasopharynx and salivary glands ([Figure 3](#)). These carcinomas are usually well circumscribed and composed of undifferentiated cells. The cancer cells are surrounded by inflammatory infiltrates composed of lymphocytes, plasma cells, and eosinophils.⁵⁰ Hasumi and colleagues reported 39 cases from the Cancer Institute Hospital in Tokyo. Their patients, 72% of whom were younger than 50 years of age, were treated with radical hysterectomy and pelvic lymphadenectomy. Two patients had positive lymph nodes. At the time of the report, 38 of the 39 patients were alive. The single death occurred 5 months after surgery and was due to serum hepatitis.

Figure 3 Lymphoepithelioma-like carcinoma.

Adenocarcinoma

Adenocarcinomas represent 20–25% of cervical carcinomas today, whereas from 1950 to 1960, they represented only 5%.⁵¹ This change in prevalence is a worldwide phenomenon.⁵² The mean age at diagnosis for patients with invasive adenocarcinoma is between 47 and 53 years. Selected variants of adenocarcinoma are described in the following paragraphs.

Mucinous adenocarcinoma is the most common type of cervical adenocarcinoma.⁵³ In the WHO classification, the first type of mucinous adenocarcinoma is composed of cells that resemble the columnar cells of the normal endocervical mucosa and is referred to as the endocervical type ([Figure 4](#)). The second type is termed the intestinal type because it is composed of cells similar to those present in adenocarcinomas of the large intestine. A third type is composed of signet-ring cells and designated the signet-ring type. Frequently, mucinous adenocarcinomas are a mixture of these cell types.

Figure 4 Mucinous adenocarcinoma, endocervical type.

Endometrioid adenocarcinoma is the second most common type of primary endocervical tumor, accounting for 30% of all primary endocervical tumors. Endometrioid adenocarcinomas resemble typical endometrioid adenocarcinoma arising from the endometrial cavity ([Figure 5](#)). Identification of the site of origin (i.e., whether the primary tumor is in the endocervix or endometrium) may be difficult, but proper identification is important as the site or origin significantly influences therapy.

Figure 5 Endometrioid adenocarcinoma.

Adenoma malignum is difficult to distinguish cytologically from normal endocervical glands ([Figure 6](#)) and is referred to as minimal-deviation adenocarcinoma. A distinguishing feature of adenoma malignum is a bizarre and irregular glandular branching pattern. These irregular glands invade deeply into the stroma, and diagnosis requires a large tissue specimen from a cone biopsy or hysterectomy specimen. Adenoma malignum is extremely rare and is sometimes associated with Peutz–Jegher syndrome.⁵⁴ The survival rate is poor if the well-differentiated pattern leads to under treatment.

Figure 6 Mucinous adenocarcinoma, endocervical type (adenoma malignum).

Other epithelial tumors

Adenosquamous carcinoma is defined as a cancer that contains an admixture of histologically malignant squamous and glandular cells.⁵⁵ Adenosquamous carcinomas account for 5–25% of the cervical carcinomas in some series.^{56, 57} These carcinomas are similar in their clinical presentation, epidemiology, and pattern of spread to squamous cell carcinomas and adenocarcinomas. The poorly differentiated form of adenosquamous carcinoma can be made up of large uniform polygonal cells with a finely granular cytoplasm of the ground-glass type, hence the term “glassy cells” ([Figure 7](#)). Similar to other

undifferentiated tumors, glassy cell carcinomas spread early and are aggressive.⁵⁷ The mucoepidermoid carcinoma, also placed in this category, contain large cell nonkeratinizing or focally keratinizing squamous carcinoma, which stains positive for mucin but lacks recognizable glands. The mucinous component includes goblet or signet-ring-type cells localized in a nest of squamous cells. These carcinomas represent 20% of the carcinomas in some series if mucin is measured.

Figure 7 Glassy cell carcinoma.

Small cell neuroendocrine carcinoma contains small anaplastic cells with scant cytoplasm ([Figure 8](#)). These highly aggressive cancers diffusely infiltrate the cervical stroma.⁵⁸ Staining reveals neuroendocrine markers in most cases. Women with small cell carcinoma are likely to be 10 years younger than those with squamous cell carcinoma. Small-cell carcinomas are frequently associated with widespread metastasis to multiple sites, including bone, liver, skin, and brain. These tumors should not be confused with small squamous cell carcinomas, which are associated with a better prognosis. Efforts to treat these cancers with approaches typically used for small cell carcinomas of the lung have had mixed results.

Figure 8 Small cell carcinoma.

Non-small cell neuroendocrine carcinoma

Nonsmall cell neuroendocrine carcinomas of the cervix have been reported, but they are not listed in the current WHO classification of cervical tumors.⁵⁹ The tumors contain intermediate to large cells, high-grade nuclei, and eosinophilic cytoplasmic granules of the type seen in neuroendocrine cells. A trabecular pattern is frequently evident, with or without glandular differentiation ([Figure 9](#)). Tumors are usually immunoreactive for chromogranin. Reported survival rates for patients with these aggressive carcinomas are similar to those for patients with small cell carcinoma.

Figure 9 Non-small-cell neuroendocrine carcinoma.

Diagnosis and treatment of precancerous lesions

The most recent guidelines for screening for cervical cancer are listed in [Figure 10](#).⁶⁰ CIN is an increasingly common finding among sexually active young women. Since the introduction of the Bethesda system, the proportion of Pap smears identified as having low-grade cytologic abnormalities, minimal or ambiguous cytologic changes classified as atypical squamous cells of undetermined significance (ASCUS), or low-grade squamous intraepithelial lesions (LGSIL)s has increased.⁴⁴ Approximately 50 million Pap smears are done yearly in the United States, and 5–10% of these smears are reported as having low-grade cytologic abnormalities. Although near consensus exists regarding the evaluation and management of HGSILs and carcinoma detected on Pap smears, controversy continues regarding appropriate management of ASCUS and low-grade abnormalities.⁶¹ Issues include the risk of progression of the disease, the anxiety caused to the patient, the risk of overtreating patients with minor disease, and, more recently, the financial implications of prompt intervention and treatment.⁶²

Figure 10 Screening guidelines for the early detection of cervical cancer.

As more studies of women with mildly atypical Pap smears were published, data showed that 5–20% of women presenting with a single mildly atypical Pap smear were at risk of HGSILs or other more severe lesions.⁶³ In addition, it has recently been estimated that more than one-third of the HGSIL cases in a routine screening population are preceded by a cytologic diagnosis of ASCUS.⁶⁴ This has led some clinicians to suggest that it is safer and more expeditious to perform colposcopy in women with a finding of ASCUS.⁶⁵ However, given the relatively high frequency of low-grade cytologic abnormalities in the absence of significant disease and the high financial and emotional cost of colposcopy, some have argued that these women should be evaluated by repeat cytology rather than colposcopy. The American College of Obstetricians and Gynecologists and a NCI consensus panel have acknowledged that managing a single mildly atypical Pap smear by repeating the test is an acceptable practice.^{61, 66}

The main goal in managing ASCUS and low-grade cytologic abnormalities is to identify those women at higher risk of HGSILs, primarily women more than 25 years old who cannot be relied on to return for long-term follow-up, who are suspected of having or known to have a history of abnormal cytologic findings or treatment of cervical neoplasia, who may be promiscuous, and who have no history of adequate screening.⁶⁷ Currently, two strategies are recommended for managing these lesions: the physician may repeat the Pap smear and perform a colposcopic evaluation, or, for patients with an ASCUS cytologic diagnosis or LGSILs without clinical evidence of cervical disease and without risk factors, the physician may repeat the Pap smear without performing colposcopy ([Figure 11](#)).^{61, 67} The American Society for Colposcopy and Cervical Pathology (ASCCP) also emphasizes HPV testing when triaging with ASCUS or LGSIL PAPs (Papanicolaous).

Figure 11 Management of women with biopsy-confirmed cervical intraepithelial neoplasia-grade 1 (CIN 1).

Source: Massad et al. 2013.⁶⁷ Reproduced with permission of the American Society for Colposcopy and Cervical Pathology.

Management of low-grade cytologic abnormalities

Low-grade cytologic abnormalities are usually treated first with antibiotics and repeating the smear several months later. If the smear result regressed to normal, the patient is scheduled for an annual Pap smear screening, whereas patients whose smears remained abnormal are referred for colposcopic evaluation, and Pap test every 4–6 months for 2 years. After three consecutive negative smears in the 2-year follow-up period, patients can be monitored using a routine cervical cancer screening protocol.^{68, 69} For patients with clinical suspicion of cancer or persistent abnormal Pap smears during the 2-year follow-up, colposcopic evaluation is recommended. Recommended management form ASCCP for women with ASCUS or LGSIL Paps is based on age. For women aged 21–24 years with ASCUS or LGSIL, the recommendation is to repeat cytology at 12 months. For older women with LGSIL Pap and no HPV testing or positive HPV testing, recommendation is to proceed with colposcopy ([Figure 12](#)).⁶⁷

Figure 12 Management of women with biopsy-confirmed cervical intraepithelial neoplasia grades 2 and 3 (CIN 2.3).

Source: Massad et al. 2013.⁶⁷ Reproduced with permission of the American Society for Colposcopy and Cervical Pathology.

In view of the costs, both emotional and economic, associated with evaluating women with low-grade cytologic abnormalities, considerable interest has arisen in developing novel cost-effective triage strategies for these patients. HPV DNA testing, automated cytology screening, and cervicography are being evaluated as adjunct methods in the assessment and triage of patients with low-grade cytologic abnormalities. Most research has focused on the assessment of HPV testing.

Several researchers have assessed the value of HPV DNA testing as a specific and economical alternative for triage of low-grade cytologic abnormalities and as an adjunct to cervical cytology in primary screening.^{70–73} With second-generation HPV DNA detection methods, including PCR-based methods and the hybrid capture HPV DNA assay, both of which have a higher sensitivity and detect a broader range of HPV types with high oncogenic risk than earlier methods, results have been more consistent, supporting the role of HPV typing in the triage of patients with low-grade cytologic abnormalities and as an adjunct to cytology in primary screening.^{70–73}

New data on HPV primary screening from the ATHENA trial were presented to the FDA in the spring of 2014 supporting the evidence that HPV testing alone is an excellent alternative screening strategy.⁷⁴ More experience and data analysis pertaining to this new strategy will permit a more formal ACS evaluation in the future.

The preferences of clinician and patient and cost considerations should dictate the choice of treatment of CIN, but proper management of LGSILs is expected to remain a fiercely debated question. Although management guidelines have increasingly included nontreatment of LGSILs as an option for patients who may be reliable for long-term follow-up, concerns over legal responsibility for progressive lesions continue to drive intensive follow-up protocols, particularly in the United States, that may not be cost-efficient.⁷⁵ Guidelines recently published may be helpful to follow.

Management of high-grade cytologic abnormalities

Optimal management of HGSILs includes colposcopic evaluation and biopsy or in women older than 24 years of age to proceed to a loop electrical excision procedure (LEEP) without performing colposcopic evaluation. The consensus is that HGSILs should be treated once diagnosed.⁷⁶ For biopsy-proven HGSILs with negative findings on endocervical curettage (ECC), a satisfactory colposcopy examination, and congruent Pap smear and biopsy results, ablation of the transformation zone has been the standard of care for several decades. Three outpatient therapies are used in the United States for treating these lesions: cryotherapy, laser ablation, and LEEP. For patients with unsatisfactory colposcopic examination findings, a Pap smear result more severe than the biopsy findings, the presence of an adenomatous component, suspicion of invasive cancer, or positive findings on ECC, a cone biopsy is indicated. Cone biopsies (talked about later in the chapter) remove tissue to a depth of 20–30 mm and up to 30 mm in diameter, including the transformation zone.

The three outpatient therapies of cryotherapy, laser vaporization, and LEEP have been the focus of controversy. Safety, efficacy, and cost issues have dominated the debate. Cryotherapy, introduced in 1972, was the first outpatient treatment of CIN and remains a dependable treatment because of its reliability,

low complication rate, ease of use, and low cost.⁷⁷ Another advantage of cryotherapy is that leaving a large dead viral HPV load within disrupted cells may improve the immune response to the causative agent of CIN. Major disadvantages include lack of ability to tailor treatment to the size of the lesion, lack of a tissue specimen, and the risk of treatment of undetected invasive lesions. Eligible for cryotherapy are patients with satisfactory findings on colposcopic examination, negative findings on ECC, and small lesions (2.5–3.0 cm in diameter) that allow the entire lesion and transformation zone to be covered by the cryotherapy probe.

Laser vaporization was introduced in 1977. It has the advantage of being easily tailored to lesion size, but the cost of the equipment and the lack of a tissue specimen are major disadvantages.⁷⁷ In addition, laser vaporization requires more training and skills than the other two procedures and is associated with more serious safety issues (eye injuries and inadvertent burns). Candidates for this procedure are patients with large CIN lesions, young women with suspicious or invasive lesions or adenocarcinoma *in situ* in whom preservation of fertility is desired, and patients unwilling to undergo LEEP under local anesthesia.

LEEP was introduced in 1989, and it is currently the technique of choice for the treatment of HGSILs. LEEP is reliable and easy to use. It can be tailored to lesion size and provides a tissue specimen.⁷⁷ The advantage of this last characteristic is underscored by the finding of unsuspected adenocarcinoma *in situ* and microinvasive squamous cell carcinoma in 2–4% of LEEP specimens.^{67, 77} LEEP, however, has the potential to result in unintentional removal of excessive cervical stroma and removal of disease-free tissue (more frequent when LGSILs are treated). Other disadvantages include its high cost and the increased risk of bleeding and infection. Bleeding after LEEP has been reported in 2–7% of cases.⁷⁷ The high rates of overtreatment observed with LEEP have been related to misdiagnosis of abnormality and multiple punch biopsies of small lesions before treatment.⁶⁷ The use of LEEP in see-and-treat protocols has been shown to improve patient compliance with treatment when patient selection is adequate. This strategy has been suggested as having the greatest potential benefit for populations with poor treatment compliance.⁶⁷

No statistically significant differences in success rates (based on recurrence and persistence) between cryotherapy and laser vaporization have been reported, but variability in these rates from study to study is striking.^{77, 78}

Prevention

Chemopreventative management

One of the more exciting research areas in therapy for CIN is the use of chemopreventative agents. These therapies involve ingestion of an agent that reverses precancerous changes, returning the tissue to normal. Laboratory data have shown that retinoids can induce apoptosis in dysplastic cervical cells, suggesting that these compounds may be active in cell-cycle control.⁷⁹ Women with HGSIL and colposcopically evident lesions are the target population for chemoprevention studies because they have a higher risk of persistent disease or progression to cancer. α -Difluoromethylornithine and retinoids (vitamin A derivatives) are two drugs currently receiving attention in the United States and China.^{80, 81}

Vaccine development

Papillomaviruses are epitheliotropic agents that induce benign papillomas of the skin and mucous membranes. In contrast to hepatitis B virus (HBV), there are more than 100 HPV genotypes (types). A subset of HPV types that are almost always transmitted sexually is the main cause of human cervical

cancer. Infection with these HPV types is a strong risk factor for cervical cancer, and HPV DNA from one or more of these types is found in virtually all cervical tumors.^{82, 83} The virus encodes oncoproteins that appear to be required for both the induction and the maintenance of the cancer.

Because papillomaviruses contain oncogenes, and a prophylactic vaccine would be directed toward healthy young individuals, efforts to develop a prophylactic vaccine have emphasized a subunit approach, analogous to that used for HBV vaccine. Indeed, constitutive high-level expression of the L1 major structural viral protein, even in nonmammalian cells, leads to its efficient self-assembly into virus like particles (VLPs) that resemble authentic viral capsids structurally and antigenically. Preparative amounts of VLPs can be synthesized in insect cells or yeast. Such VLPs are suitable immunogens that, as is true of authentic virions, possess the immunodominant conformational epitopes capable of raising high titers of neutralizing antibodies.

Two vaccines have been developed: Gardasil, a quadrivalent vaccine targeting HPV 6, 11, 16, and 18,⁸⁴ and Cervarix, a bivalent vaccine that targets HPV 16 and 18.⁸⁵ These vaccines are now licensed in more than 55 countries worldwide and are expected to be an enormous asset to cervical cancer prevention efforts. The FUTURE (Female United to Unilaterally Reduce Endo/Ectocervical Disease) II study group performed a randomized, double-blind, placebo-controlled trial in order to evaluate a quadrivalent vaccine (Gardasil) against HPV types 6, 11, 16, and 18 for the prevention of high-grade cervical lesions associated with HPV 16 and 18. After 3-year follow-up from the first dose of the vaccine, the efficacy of the vaccine in preventing the primary endpoint was 98% in the per-protocol susceptible population and 44% in an intention-to-treat population of all women who had undergone randomization. The study concluded that the quadrivalent vaccine was highly effective in preventing HPV 16- and 18-related high-risk cervical lesions, and that widespread immunization of girls may result in a substantial decrease in cervical cancer resulting from infection with HPV 16 and 18.⁸⁴

The interim analysis of the randomized double-blind-controlled trial of the Papilloma Trial against Cancer In young Adults (PATRICIA) looking at the efficacy of prophylactic administration of bivalent vaccine against infection with HPV 16 and 18 was published in June 2007.⁸⁵ This vaccine has also shown evidence of cross-protection against HPV 45 and 31. The vaccine had an efficacy of 90.4%, and there were no significant safety profile differences between the study groups.⁸⁵

HPV vaccines are presently recommended for all 11–12-year-old girls, though vaccination can be started as early as 9 years, and women between the age of 13 and 26 should also be vaccinated if they are not yet sexually active. Recent data from the United States suggest that HPV vaccination and biennial cervical screening from the age of 24 years will reduce the annual total PAP test volume by 43% and result in the reduction in the workload at sexually transmitted disease clinics.⁸⁶ The Markov model of incorporation of the HPV vaccination into a UK national cervical screening program predicts a 76% reduction in cervical cancer deaths and 66% reduction in high-grade lesions.⁸⁶ However, there are problems in world widespread distribution of the vaccinations including price of the vaccine, accessibility of the vaccines in countries due to lack of immunization infrastructure, and opposition by conservative groups to the vaccination of young girls against what is perceived to be an sexually transmitted disease.⁸⁷

Diagnosis and treatment of invasive lesions patterns of spread

During the transition from *in situ* to invasive carcinoma, tumor cells penetrate the epithelial basement membrane and enter the underlying cervical stroma. Once the cervical stroma is invaded, the lymphatics and blood vessels are accessible, and dissemination beyond the cervix is possible.

The cervical, vaginal, and uterine lymphatic channels coalesce to form major drainage pathways. The major lymphatic trunks are the utero-ovarian (infundibulopelvic), parametrial, and presacral, which drain into the paracervical, obturator, hypogastric, external iliac, common iliac, inferior gluteal, presacral, and lower aortic lymph nodes. A series studying the incidence and distribution pattern of retroperitoneal lymph node metastases in 208 patients with stages 1B, IIA, and IIB cervical carcinomas who underwent radical hysterectomy and systemic pelvic node dissection reported that 53 patients (25%) had node metastasis.⁸⁸ The obturator lymph nodes were the most frequently involved, with a rate of 19% (39 of 208), and the authors proposed them as sentinel nodes for cervical cancers. In fact, finding negative obturator nodes may be an indication that the pelvic lymph node dissection can be limited.

Cervical cancers of similar size may have very different metastatic potentials, depending on their intrinsic aggressiveness and histologic cell type. Cervical carcinomas also invade directly. As the cancer grows, disease may extend to the lateral pelvic walls, into the bladder or rectum, or into the vagina.

The incidence of lymph node metastasis at diagnosis for each of the squamous cell carcinoma stages designated by the International Federation of Gynecology and Obstetrics (FIGO) has been well defined by surgical series.^{89–91} Pelvic node involvement occurs in 10–25% of stage I carcinomas, 25–30% of stage II carcinomas, and 30–45% of stage III and IV carcinomas. Stage I carcinomas are more likely to metastasize to nodes once they reach 3 cm.^{92, 93} Because most patients with large bulky adenocarcinomas are treated with radiation therapy, the incidence of positive nodes by tumor size is not as well defined for adenocarcinoma as it is for squamous cell carcinoma. The incidence of positive nodes for poorly differentiated squamous cell carcinoma and for poorly differentiated adenocarcinoma is higher than that for the better-differentiated carcinomas.

Carcinoma of the cervix spreads in an orderly manner. Nodes adjacent to the cervix are usually the first to be involved, and “skip” metastases are uncommon. Patients with positive para-aortic nodes usually have positive pelvic nodes. The incidence of positive para-aortic nodes in 978 patients with stage IB and IIA carcinoma whose aortic nodes were sampled before radical hysterectomy was 4.7% and 8.4%, respectively. The incidence of positive nodes in patients with adenocarcinomas is probably equal to that in patients with squamous cell-carcinomas when cancer size, histologic differentiation, and extent of tumor or FIGO stage are similar. Many large series report poorer survival rates for patients with adenocarcinomas than for patients with squamous cell carcinomas, especially those who have bulky lesions.^{94, 95} Small cell carcinoma and some of the carcinomas classified as other epithelial tumors are particularly aggressive. Carcinomas of the cervix, regardless of histology and size of the primary tumor, may contain highly malignant clones of cells that can prove unpredictable and spread extensively.

Clinical symptoms

The clinical symptoms of carcinoma of the cervix are vaginal bleeding, discharge, and pain. The growth pattern of the carcinoma plays a role in the development of symptoms. Exophytic carcinomas bleed earlier in a sexually active patient (because of contact) than lesions that expand the cervix. Lesions that expand the endocervix in a barrel-shaped configuration may leave the squamous epithelium of the exocervix intact until the lesions exceed 5 or 6 cm in transverse diameter; therefore, carcinomas with this growth pattern may be silent and grow large before the patient bleeds. Cytologic findings may be negative unless the endocervix is sampled with a brush device. Ulcerative lesions that destroy the exocervix bleed early, and necrosis and infection induced by the cancer's outgrowing its blood supply result in a foul-smelling vaginal discharge.

Severe pelvic pain experienced during the pelvic examination may indicate salpingitis. Tubal infections

require management before radiation therapy. Patients with an adnexal mass need surgical treatment before radiation therapy is started.

Paracervical extension of a carcinoma may remain silent until fixation to the pelvic wall occurs. Fixation with or without nodal involvement may obstruct a ureter. Ureteral encroachment is usually a silent process. Patients may present with bilateral ureteral obstruction with impending renal failure and report no history of urinary system complaints. Direct invasion of branches of the sciatic nerve roots causes back pain, and encroachment on the pelvic wall veins and lymphatics causes edema of a lower extremity. The triad of back pain, leg edema, and a nonfunctioning kidney is evidence of an advanced carcinoma with extensive pelvic wall involvement.

The anatomic position of the bladder, so closely adjacent to the cervix, favors contiguous spread from the cervix to the bladder. Urinary frequency and urgency are early manifestations of such spread; patients with advanced disease may present with hematuria or incontinence, suggesting direct extension of tumor to the bladder. Cystoscopy and biopsy should confirm the cause of hematuria or incontinence.

In contrast, posterior extension to the rectum and disruption of the rectal mucosa is an unusual pattern of disease spread in untreated patients. The deep cul-de-sac provides anatomic separation of the rectum and cervix. In patients who present with rectal mucosal involvement, there is usually extensive involvement of the posterior vaginal wall with direct extension to the rectum. For staging and treatment planning, cystoscopy and sigmoidoscopy are essential.

Metastatic carcinoma in para-aortic nodes may extend through the node capsule and directly invade the vertebrae and adjacent nerve roots. Back pain owing to involvement of the lumbar vertebrae and psoas muscles may be a manifestation of massive nodal disease; however, hematogenous spread to the lumbar vertebrae and involvement of the psoas muscle without significant nodal disease may occur.

Diagnosis
