Table of Contents

[Cover](#)

[Dedication](#)

[Title Page](#)

[Copyright](#)

[List of contributors](#)

[Preface](#)

[Acknowledgments](#)

[Part 1: Introduction](#)

[Chapter 1: Cardinal manifestations of cancer](#)

[The present](#)

[The future](#)

[Chapter 2: Biological hallmarks of cancer](#)

[Distilling the dauntingly complex manifestations of cancer](#)

[Acquired functional capabilities embody biological hallmarks of cancer](#)

[Aberrations that enable acquisition of the necessary functional capabilities](#)

[The histopathological complexity of cancer, manifested in tumor microenvironments \(TMEs\)](#)

[Therapeutic targeting \(and cotargeting\) of cancer hallmarks](#)

[References](#)

[Part 2: Tumor Biology](#)

[Chapter 3: Molecular biology, genomics, proteomics, and mouse models of human cancer](#)

[Overview: gene structure](#)

[General techniques](#)

[Gene expression: mRNA transcript analysis](#)

[Epigenetic regulation](#)

[Gene expression: protein analysis](#)

[Functional screens for the identification of therapeutic targets in cancer](#)

[Mouse models of human cancer](#)

[References](#)

[Chapter 4: Oncogenes](#)

[Discovery and identification of oncogenes](#)

[Mechanisms of oncogene activation](#)

[New markers from large-scale genomic analysis](#)

[Oncogenes in the initiation and progression of neoplasia](#)

[Oncogenes as target of new drugs](#)

[Summary and conclusions](#)

[References](#)

[Chapter 5: Tumor suppressor genes](#)

[Genetic basis for tumor development](#)

[Somatic cell genetic studies of tumorigenesis](#)

[Retinoblastoma: a paradigm for tumor suppressor gene function](#)

[References](#)

[Chapter 6: Epigenetic contributions to human cancer](#)

[Mechanisms involved in epigenetic regulation of gene expression](#)

[Altered DNA methylation and chromatin in cancer or the “cancer epigenome”](#)

[Clinical implications of altered DNA methylation in cancer](#)

[References](#)

[Chapter 7: Cancer genomics and evolution](#)

[Precis](#)

[Introduction](#)

[The history and methods of cancer genomics](#)

[Cancer genome landscapes](#)

[Cancer evolution](#)

[Cancer genomics and evolution in clinical practice: A case study in melanoma](#)

[Acknowledgments](#)

[Glossary](#)

[References](#)

[Chapter 8: Tumor biology](#)[Chromosomal aberrations in cancer](#)

[Introduction](#)

[Genetic consequences of genomic rearrangements](#)

[Chromosome nomenclature](#)

[Methods that complement karyotype analysis](#)

[Specific clonal disorders](#)

[References](#)

[Chapter 9: MicroRNA expression in cancer](#)

[Background](#)

[Biogenesis and production of microRNAs](#)

[MicroRNA deregulation in cancer](#)

[MicroRNA as biomarkers in cancer](#)

[MicroRNAs as noninvasive biomarkers in cancer](#)

[Selected miRNAs implicated in cancer](#)

[Therapeutic targeting and miRNA](#)

[Human applications for miRNAs](#)

[References](#)

[Chapter 10: Aberrant signaling pathways in cancer](#)

[Growth factor receptors with Tyr kinase activity](#)

[Aberrations affecting growth factor receptors in tumor cells](#)

[Signaling pathways of Tyr kinase receptors](#)

[Other signaling pathways aberrantly deregulated in cancer](#)

[Growth factor signaling and cancer therapy](#)

[Acknowledgments](#)

[References](#)

[Chapter 11: Differentiation therapy](#)

[Molecular mechanisms underlying differentiation blockage in cancer](#)

[Potential cancer cell differentiation-inducing agents](#)

[APL as a successful model of cancer differentiation therapy](#)

[Perspectives](#)

[Acknowledgments](#)

[References](#)

[Chapter 12: Cancer stem cells](#)

[Cancer stem cell hypothesis](#)

[EMT/MET and cancer stem cells](#)

[Signal transduction pathways in cancer stem cells and their therapeutic targeting](#)

[Clinical significance of cancer stem cells and future perspectives](#)

[References](#)

[Chapter 13: Cancer and cell death](#)

[Introduction](#)

[Pathways for cell death](#)

[Cell death resistance mechanisms used by cancers](#)

[Signal transduction pathway alterations in cancers—impact on cell death machinery](#)

[Cytotoxic chemotherapeutic oncology drugs](#)

[Cancer drug discovery by targeting the cell death machinery](#)

[Conclusions](#)

[List of abbreviations](#)

Chapter 2: Biological hallmarks of cancer

Figure 1 The biological hallmarks of cancer. The schematic illustrates what are arguably necessary conditions to manifest malignant disease—the hallmarks of cancer—comprising eight distinct and complementary functional capabilities and two facilitators (in black italics) of their acquisition.^{1,2} These hallmark traits may be acquired at different stages in the multistep development of cancer, via markedly distinctive mechanisms in different forms of human cancer. Two aberrant characteristics of cancerous lesions are demonstrably involved in facilitating the acquisition during tumorigenesis of these functional capabilities: genome instability and the resultant mutation of regulatory genes, and the infiltration of immune inflammatory cells endowed by their biology—for example involvement in wound healing—to contribute to one or another hallmark capability. Different forms of cancer may be more or less dependent on a particular hallmark. Thus, adenomatous tumors typically lack the capability for invasion and metastasis. Leukemias may not require angiogenesis or invasive ability, although progression to lymphoma almost certainly requires both. The necessity of evading tumor immunity may be less important for certain cancers but is increasingly appreciated to be widespread.

Figure 2 The constitution of the hallmark-enabling tumor microenvironment. An assemblage of distinct cell types constitutes the TME of most solid tumors, involving two distinct compartments—the parenchyma of cancer cells and the stroma of supporting cells. Both compartments contain distinct cell and subcell types that collectively enable tumor growth and progression.^{2,3} Notably, the immune inflammatory cells present in tumors can include both tumor-promoting and/or immuno-suppressive as well as tumor-killing subclasses. The lower panels illustrate an important characteristic: the TME is dynamic, varying both in composition and abundance of constituent cell types (and sub-cell types) and in their effects on the histologically distinct stages in multistep tumorigenesis, namely premalignant stages (not shown) and malignant stages, including the cores of primary tumors, invasive margins and frankly invasive lesions, and metastases.

Figure 3 Therapeutic targeting of the hallmarks of cancer. Drugs have been developed that disrupt or interfere with all eight of the hallmark capabilities, and with the two enabling facilitators (genome instability and tumor-promoting inflammation). Some of these hallmark-targeting drugs are approved for clinical use, while others are being tested in late-stage clinical trials; moreover, there is a pipeline full of new hallmark-targeting drugs in development and preclinical evaluation. Recognizing that eventual adaptive resistance during therapeutic treatment is apparent for virtually all of these hallmark-targeting drugs, a hypothesis has emerged: perhaps, by cotargeting multiple independent hallmarks, it will be possible to limit or even prevent the emergence of simultaneous adaptive resistance to independent hallmark-targeting drugs;³⁰ clinical and preclinical trials are beginning to assess the possibilities.

Chapter 3: Molecular biology, genomics, proteomics, and mouse models of human cancer

Figure 1 Gene expression. A gene's DNA is transcribed into messenger ribonucleic acid (mRNA), which, in turn, is translated into protein. The functional components of a gene are schematically diagrammed here. Areas of the gene destined to be represented in mature mRNA are called exons, and intervening areas of DNA between exons are called introns. The portion of the gene that controls transcription, and therefore expression, is the promoter. This control is exerted by specific nucleotide sequences in the promoter region (so-called cis-acting factors) and by proteins (so-called trans-acting factors) that must interact with promoter DNA and/or ribonucleic acid (RNA) polymerase II for transcription to occur. The primary transcript is the RNA molecule made by RNA polymerase II that is complementary to the entire stretch of DNA containing the gene.

Before leaving the nucleus, the primary transcript is modified by splicing together exons (thus removing intronic sequences), adding a cap to the 5' end and adding a poly-A tail to the 3' end. Once in the cytoplasm, mature mRNA undergoes translation to yield a protein.

Figure 2 Structure of base-paired double-stranded DNA. Each strand of DNA consists of a backbone of five-carbon deoxyribose sugars connected to each other through phosphate bonds. Note that as one follows the sequence down the left-hand strand (A to C to G to T), one is also following the carbons of the deoxyribose ring, going from the 5' carbon to the 3' carbon. This is the basis for the 5' to 3' directionality of DNA. The 1 carbon of each deoxyribose is substituted with a purine or pyrimidine base. In double-stranded DNA, bases face each other in the center of the molecule and base pair via hydrogen bonds (dotted lines). Base pairing is specific so that adenine pairs with thymine and guanine pairs with cytosine.

Figure 3 Digestion of DNA with the restriction endonuclease EcoRI and gene cloning. In this example, a small amount of foreign DNA (a few nanograms) is digested with EcoRI. The nucleotide sequence of this stretch of DNA contains the recognition sequence for EcoRI, GAATTC (boxed). EcoRI cuts the DNA in both strands between the indicated nucleotides, resulting in fragments with five single-stranded tails. This foreign DNA can come from any source, the only requirement being that it contains the same restriction endonuclease recognition sites as the vector. Plasmid vector is also digested with EcoRI to create a linear DNA molecule. The “sticky” single-stranded ends of the foreign DNA can align and base pair with the complementary “sticky ends” of the plasmid, after which DNA ligase covalently bonds foreign DNA to plasmid DNA. This recombinant DNA is introduced into *E. coli* by a process called transformation. Because the bacteria themselves are not resistant to ampicillin, growth in ampicillin will select only those bacteria that have taken up the plasmid DNA (which carries an ampicillin resistance gene). The plasmid contains a bacterial origin of replication so that as the bacterial culture grows, plasmids replicate, resulting in several copies in each bacterium. When the culture has grown to sufficient size, plasmid DNA can be isolated biochemically, foreign DNA can be cut from the plasmid using EcoRI, and the resulting yield will often be milligrams of DNA, that is, greater than a 10^6 -fold amplification.

Figure 4 (a) Gateway cloning. Source: Gateway Technology Manual from: <http://www.thermofisher.com/us/en/home/life-science/cloning/gateway-cloning/gateway-technology.html>, page 16. ccdB, negative selection cassette included in donor and destination vectors. (b) Gibson cloning.

Figure 5 Genomic Southern blotting. Genomic DNA is digested with a single-restriction endonuclease, resulting in a complex mixture of DNA fragments of different sizes, that is, molecular weights. Digested DNA is arrayed by size using electrophoresis through a semisolid agarose gel. Because DNA is negatively charged, fragments will migrate toward the anode, but their progress is variably impeded by interactions with the agarose gel. Small fragments interact less and migrate farther; large fragments interact more and migrate less. The arrayed fragments are then transferred to a sheet of nitrocellulose- or nylon-based filter paper by forcing buffer through the gel as shown. The DNA fragments are carried by capillary action and can be made to bind irreversibly to the filter. Now the DNA fragments, still arrayed by size on the filter, can be probed for specific nucleotide sequences using a ^{32}P -radiolabeled nucleic acid probe. The probe will hybridize to complementary sequences in the DNA, and the position of the fragment that contains these sequences can be revealed by exposing the filter to X-ray film.

Figure 6 Polymerase chain reaction. DNA is mixed with short (10–20 base) single-stranded oligonucleotide primers that are complementary to the 5' and 3' ends of the sequence to be amplified. The mixture is heated to denature or “melt” all double-stranded DNA and then cooled to permit the primers to anneal to their complementary sequences on the DNA to be amplified. Note that the 5' primer will anneal to the lower strand and the 3' primer will anneal to the upper strand. A heat-resistant (thermostable) DNA polymerase (Taq polymerase; see text) was present in the original mixture, and it now synthesizes DNA by starting at the primers and using the strands to which the primers are annealed as a template. This results in the formation of two double-stranded DNA copies for every molecule of double-stranded DNA in the original mixture. The reaction is then heated to melt double-stranded DNA and cooled to allow reannealing, and the polymerase makes new double-stranded DNA again. There are now four double-stranded DNA copies for each original DNA molecule. This process can be repeated times (usually 20–50) to result in 2n copies of double-stranded DNA.

Figure 7 Methods to detect loss of heterozygosity in tumor tissue. (a) Restriction fragment length polymorphism (RFLP) and Southern blotting. In this example, an individual is heterozygous for an EcoRI recognition site: the second EcoRI site on chromosome A is absent on its diploid partner, chromosome B. The individual's tumor is assumed to be clonal and to have arisen from a cell that lost the region of chromosome B displayed in the Figure Southern blotting can then be performed using genomic DNA from the individual's normal DNA and tumor DNA in separate lanes of the agarose gel. Probing the DNA with the probe (indicated on the figure) reveals a heterozygous banding pattern in normal DNA (reflecting the presence of both polymorphisms, one on each chromosome pair) and a loss of that pattern in the tumor DNA. This is one of the hallmarks of a tumor suppressor gene. (b) Single nucleotide polymorphism (SNP) array. In this example, an individual is heterozygous for SNPs 2 and 3 and homozygous for SNP 1. Following the polymerase chain reaction (PCR) amplification of genomic fragments containing each SNP individually, these fragments are hybridized to an array composed of oligonucleotides complementary to the ones amplified. The loss of a heterozygous SNP signal on the array indicates loss of the chromosomal region containing this SNP.

Figure 8 DNA polymerase. In this schematic, the enzyme DNA polymerase is creating a new DNA chain (upper strand) using a template (lower strand). Specific nucleotides are added from the 5' to the 3' direction as determined by the next nucleotide in the template.

Figure 9 DNA sequencing using the chain termination method. In this example, DNA ending with the sequence CTTAGGCTAGTAAAAAAA is being analyzed. Four reactions are performed, each using this DNA as a template for a DNA polymerase reaction and each containing one of the four dideoxynucleotides (dideoxyadenosine triphosphate [ddA], dideoxycytidine triphosphate [ddC], dideoxyguanosine triphosphate [ddG], and dideoxythymidine triphosphate [ddT]). In each reaction, chain elongation will terminate when the dideoxynucleotide is incorporated at the position of its complementary nucleotide in the template. This will result in a family of chains of differing lengths that correspond to the position at which polymerization terminated. In this example, these chains can be resolved by electrophoresis through a urea-containing polyacrylamide gel, in which longer chains run near the top of the gel and shorter chains near the bottom. Each new chain is radioactively labeled, and after autoradiography, the pattern of bands can be read from X-ray film. By noting the order in which bands appear, starting at the bottom of the gel, one can read the sequence of the template by substituting the complement of each dideoxynucleotide at every position. Reading from the bottom yields GAATCCGATCATTTTTTTT, and substituting the complementary base at each position yields CTTAGGCTAGTAAAAAAA, the

sequence of the template. The use of fluorescent labels in capillary gel electrophoresis is conceptually similar.

Figure 10 Next generation sequencing using Illumina platform. Source: http://openwetware.org/images/d/de/Illumina_sequencing.pdf. Used under CC BY-SA 3.0 <http://creativecommons.org/licenses/by-sa/3.0/>.

Figure 11 Types of genome alterations that can be detected by second-generation sequencing.

Figure 12 Construction and analysis of serial analysis of gene expression (SAGE) libraries. In step 1, a complementary deoxyribonucleic acid (cDNA) library is constructed from the cells or tissue of interest, and the cDNAs are immobilized on magnetic beads at their three ends. In step 2, the cDNAs are subjected to restriction enzyme digestion with a so-called anchoring enzyme. This anchoring enzyme is a frequent cutter restriction endonuclease (usually NlaIII) that ensures that all of the cDNAs are cut at least once. Subsequently another linker that contains a recognition site for a tagging enzyme is ligated to the cDNA ends. This tagging enzyme is a type two restriction endonuclease (usually MmeI) that cuts at some distance to the three sides of the actual recognition site. These tags are then directly processed for single-molecule DNA sequencing platform. Data are analyzed by using software that reads the sequence obtained, derives the tags, matches them to their cognate cDNA, and gives the gene expression profile in a numeric format.

Figure 13 DNA microarray analysis. In this example, RNA extracted from a tumor is end labeled with a fluorescent marker and then allowed to hybridize to a chip derivatized with complementary DNA (cDNAs) or oligonucleotides, as described in the text. The precise location of RNA hybridization to the chip can be determined using a laser scanner. Because the position of each unique cDNA or oligonucleotide is known, the presence of a cognate RNA for any given unique sequence can be determined.

Figure 14 RNA-seq work flow.

Figure 15 Methods of protein identification and detection. (a) Immune (Western) blotting. A complex mixture of proteins can be separated by size using electrophoresis (SDS-PAGE). The separated proteins are then transferred to a nitrocellulose or nylon filter in an electric field, maintaining their size-specific spatial orientation on the filter. Antibodies directed against one specific protein (in this case, the gray ellipsoid) in the original mixture are added to the filter and bind to the specific protein. Bound antibodies can be radiolabeled or enzymatically labeled themselves, or they can be visualized by incubating the filter with labeled anti-immunoglobulin antibodies. (b) Immunoprecipitation. A complex mixture of radiolabeled proteins (indicated by different geometric shapes) is incubated with antibodies specific for one of those proteins (in this case, the gray ellipsoid). After the antibodies have bound to their protein, small polystyrene or agarose beads containing staphylococcal protein A are added to the mixture. Protein A binds to the antibodies, and when centrifuged, the beads to which the protein A is bound will sediment to the bottom of the centrifuge tube, taking along the antibodies and the specific protein to which they have bound. The unbound proteins remain in the supernatant and can be removed. After boiling to dissociate the protein A/antibody/protein complex, specifically precipitated radiolabeled protein can be visualized by electrophoresis (SDS-PAGE) and autoradiography. (c) Enzyme-linked immunosorbent assay (ELISA). To perform ELISA, one needs to develop two independent antibodies that bind to the protein to be detected (gray ellipsoid in this example) with high specificity and affinity. One of these antibodies is then coupled to a plate, which is then incubated with the protein mix to be analyzed (this can be tissue, blood, or another body fluid). The

specifically bound protein is retained on the plate and is detected with the second antibody generated against it, which is coupled to an enzyme or isotope, allowing quantitation of the bound protein. ELISAs are usually very sensitive and can detect picomolar amounts of proteins.

Figure 16 Mass spectrometry. (a) Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF). For organisms whose genome sequence is known, the identification of “interesting” protein spots from a two-dimensional gel is routinely performed using MALDI-TOF. A complex mixture of proteins is separated by size and charge using two-dimensional electrophoresis. Protein spots are excised from the gel, digested with a protease, mixed with a matrix solution, and allowed to cocrystallize on a target plate. When a laser is fired at the target plate, the matrix absorbs the laser light's energy and vaporizes, carrying some of the sample with it into a vacuum space. At the time the laser is fired, a high voltage is applied to the target plate to accelerate the ionized sample's movement toward the time-of-flight (TOF) mass analyzer. The resulting peptide fingerprint can then be used to search databases to determine the identity of the protein. (b) The liquid chromatography electrospray ionization tandem mass spectrometry (LC-ESIMS-MS) can be used to obtain amino acid sequence information, allowing highly refined database searches. The approach employs capillary high-performance liquid chromatography (HPLC), which allows very slow (submicroliter/min) flow rates that are essential for obtaining high-sensitivity ESI-MS-MS of peptides. Following the liquid chromatography and electrospray ionization, the ions are analyzed by linearly linked tandem mass spectrometers that yield amino acid composition information.

Figure 17 (a) Schematic of the RNA-guided Cas9 nuclease, which is directed to its DNA target by a 20-nt guide sequence (blue). The red triangle represents the approximate nucleotide position where Cas9 would be expected to initiate a DSB. (b) DSBs created by Cas9 can be repaired either via error-prone NHEJ or homologous recombination.

Chapter 4: Oncogenes

Figure 1 Retroviral transduction. An RNA tumor virus infects a human cell carrying an activated *src* gene (red box). After the process of recombination between retroviral genome and host DNA, the oncogene *c-src** is incorporated into the retroviral genome and is renamed *v-src*. When the retrovirus carrying *v-src* infects a human cell, the viral oncogene is rapidly transcribed and is responsible for the rapid tumor formation.

Figure 2 Insertional mutagenesis. (a) The process is independent from genes carried by the retrovirus. Retrovirus, for example, MMTV, infects a human cell. The proviral DNA is integrated into the host genome in infected cells. Rarely, the provirus inserts near a proto-oncogene (e.g., *int-1*) and activates the proto-oncogene. Activated proto-oncogene results in cell transformation and in tumor formation. (b) Sites of integration of MMTV retrovirus near the proto-oncogene *int-1*. All sites determine *int-1* activation.

Figure 3 Transfection assay. DNA from a tumor (e.g., bladder carcinoma) is used to transform a rodent immortalized cell line (NIH3T3). After serial cycles, DNA from transformed cells was extracted and then inserted into p vector that was subsequently used to transform an appropriate *Escherichia coli* strain. Using a specific probe (Alu in the figure), it was possible to isolate and then characterize the involved human oncogene.

Figure 4 Paracrine and autocrine stimulation. (a) A growth factor produced by the cell on the right stimulates another cell carrying the appropriate receptor (left) on cell membrane. This process is named paracrine stimulation. (b) A growth factor is produced by the same cell expressing the

cognate receptor. This process is designated autocrine stimulation.

Figure 5 Representative examples of tyrosine kinase receptor families.

Figure 6 Effect of bcl-2 activity on the control of the cell life. In the presence of BAX only, the cell goes to apoptosis. bcl-2 regulates the cycle of the cell by the interaction with BAX. When bcl-2 is overexpressed, the cell cycle is deregulated and the apoptosis is prevented, eventually leading to tumor formation. This is an important cause for tumor formation. Abbreviations: PCD, program cell death or apoptosis.

Figure 7 Schematic representation of the main mechanisms of oncogene activation (from proto-oncogenes to oncogenes). The normal gene (proto-oncogene) is depicted with its transcribed portion (rectangle). In the case of gene amplification, the latter can be duplicated 100-fold, resulting in an excess of normal protein. A similar situation can occur when following chromosome rearrangements such as translocation, the transcription of the gene is now regulated by novel regulatory sequences belonging to another gene. In the case of point mutation, single amino acid substitutions can alter the biochemical properties of the gene product, causing, in the example, its constitutive enzymatic activation. Chromosome rearrangements, such as translocation and inversion, can then generate fusion transcripts resulting in chimeric oncogenic proteins.

Figure 8 The ras–raf–MAPK signaling pathway.

Figure 9 C-MYC translocations found in Burkitt lymphoma. (a) t(8;14)(q24;q32) translocation involving the locus of immunoglobulin heavy chain gene located at 14q32. (b) t(8;14)(q24;q32) translocation where only two exons of C-MYC are translocated under regulatory elements from the immunoglobulin heavy chain locus located at 14q32. (c) t(8;22)(q24;q11) translocation involving the *I* locus of immunoglobulin light chain gene at 22q11. (d) t(2;8)(p12;q24) translocation involving the *k* locus of immunoglobulin light chain gene located at 2p12.

Figure 10 Gene fusion. The t(9;22)(q34;q11) translocation in CML determines the fusion of the *ABL* gene with the *BCR* gene. Such a gene fusion encodes an oncogenic chimeric protein of 210 KD.

Figure 11 Some possible ways of exposure to a mutagen and a tumor promoter and their effects. Cancer develops exclusively when the exposure to promoter follows the exposure to carcinogen (mutagen, e.g., DMBA) and only when the intensity of the exposure to promoter is higher than a threshold.

Figure 12 Colorectal cancer development. Colorectal cancer results from a series of pathological changes that transform normal colonic epithelium into invasive carcinoma. Specific genetic events, shown by vertical arrows, accompany this multistep process.

Figure 13 Mode of action of imatinib. In (a), the effect of ATP binding on the oncoprotein BCR-ABL is depicted. The fusion protein binds the molecule of ATP in the kinase pocket. Afterward, it can phosphorylate a substrate that can interact with the downstream effector molecules. When imatinib is present (b), the oncoprotein binds imatinib in the kinase pocket (competing with ATP) and then the substrate cannot be phosphorylated.

Chapter 5: Tumor suppressor genes

Figure 1 The inheritance of cancer in a family. The affected members with cancer are indicated by shaded squares (males) or circles (females). This family demonstrates a dominant pattern of inheritance, meaning that each offspring has a 50% chance of inheriting a germline mutation that

predisposes to a high probability of developing cancer.

Figure 2 Chromosomal mechanisms that result in loss of heterozygosity for alleles at the retinoblastoma predisposition (RB1) locus at chromosomal band 13q14. In the inherited form of the disease (top left), the affected son inherits a mutant RB1 allele (rb) from his affected father and a normal RB1 allele (+) from his mother. Thus, he has one wild-type and one mutant RB1 allele in all his cells (i.e., constitutional genotype for RB1 is rb/+). The two copies of chromosome 13 in his normal cells (one from each parent) can be distinguished using polymorphic DNA markers flanking the RB1 locus (the polymorphic alleles are designated by number). A retinoblastoma can arise after inactivation of the remaining wild-type RB1 allele. Among the genetic mechanisms found to inactivate the remaining wild-type RB1 allele during tumor development are chromosome nondisjunction and reduplication of the remaining copy of chromosome 13, mitotic recombination, nondisjunction, and new RB mutations that inactivate the remaining RB1 allele. Shown at the top right is the situation in the noninherited (sporadic) form of the disease. A somatic mutation arises in a developing retinal cell and inactivates one of the RB1 alleles. A retinoblastoma will develop if the remaining RB1 allele is inactivated by one of the mechanisms shown.

Figure 3 Schematic representation of interactions between tumor suppressor gene products and proteins encoded by DNA tumor viruses. Large T antigen from polyomaviruses [such as simian virus 40 (SV40)] bind both the retinoblastoma (pRB) and p53 proteins. For the adenoviruses and the high-risk human papillomaviruses (HPV types 16 and 18), various viral protein products complex with pRB and TP53. A cellular protein known as E6-associated protein (E6-AP) cooperates with the HPV E6 protein to complex and degrade TP53.

Figure 4 The function of the retinoblastoma protein (pRB) is regulated during the cell cycle by phosphorylation. The pRB protein is hypophosphorylated in the G1 phase of the cell cycle, and phosphorylation (Ph) of specific sites appears to increase during progression through the cell cycle. A protein complex that appears to phosphorylate pRB before DNA synthesis (S-phase) includes a cyclin (Cyc) and a cyclin-dependent kinase (Cdk)—for example, cyclin D1 and Cdk4. The CycD1/Cdk4 complex is regulated by the p16 inhibitor protein, which is itself the product of a tumor suppressor gene on chromosome 9p, known as CDKN2 (see text). In its hypophosphorylated state, pRB binds to E2F transcriptional regulatory proteins. When pRB is brought to the promoter regions of genes via its interaction with E2F proteins, pRB represses the expression of the E2F/DP target genes. Phosphorylation of pRB releases it from the E2F/DP protein complex and results in gene activation, including those genes involved in DNA synthesis. The Figure also indicates that pRB phosphorylation increases in G2 with pRB dephosphorylated at or near anaphase.

Figure 5 TP53 functional motifs. Sequences of TP53 involved in transcriptional activation, sequence-specific DNA binding, tetramerization, and binding by the MDM2 protein are indicated. The five distinct regions of TP53 sequence that are highly conserved between p53 proteins of diverse species are indicated. In addition, the locations of several sites in the protein that are phosphorylated (Ph) and that regulate TP53 function are indicated.

Figure 6 Genomic structure, mutations, and transcripts of the CDKN2B (p15) and CDKN2A (p16/p19^{ARF}) locus. The origins of the p15, p16, and p19^{ARF} transcripts are shown schematically, along with a representative depiction of genomic deletions, point mutations (arrows), and promoter methylation (arrowheads) noted in human cancers. The exons of the CDKN2B and CDKN2A loci are shown as rectangles. The transcripts/proteins and presumed functions of the

transcripts/proteins are indicated. The *red rectangles* indicate the open reading frame in transcripts encoding p15; the *yellow rectangles* indicate the open reading frame present in transcripts encoding p19ARF; and the *lavender rectangles* indicate the open reading frame present in transcripts encoding p16. The size of the locus, exons, and transcripts are not shown to scale.

Figure 7 Role of the p19^{ARF} protein in checkpoint control. The p19^{ARF} protein (ARF) responds to proliferative signals normally required for cell proliferation. When these signals exceed a critical threshold, the ARF-dependent checkpoint (*yellow lightning bolts*) is activated, and ARF triggers a TP53-dependent response that induces growth arrest or apoptosis, or both. Signals now known to induce signaling via the ARF-TP53 pathway include Myc, E1A, and E2F-1. In principle, “upstream” oncoproteins, such as products of mutated *ras* alleles, constitutively activated receptors, or cytoplasmic signal transducing oncoproteins, might also trigger ARF activity via the cyclin D-Cdk4-RBE2F or Myc-dependent pathways, both of which are normally necessary for S-phase entry. In inhibiting cyclin D-dependent kinases, p16^{INK4A} can dampen the activity of mitogenic signals. In the figure, E1A is shown to work, at least in part, by opposing RB function. For simplicity, Myc and E2F-1 are shown to activate only TP53 via the effects on ARF, though highly overexpressed levels of these proteins can activate TP53 in ARF-negative cells, albeit with an attenuated efficiency. ARF activation of TP53 likely depends on inactivation of Mdm2-specific function(s). DNA damage signals (e.g., ionizing and ultraviolet radiation, hypoxic stress) activate (*blue lightning bolts*) TP53 through multiple signaling pathways.

Figure 8 Schematic representation of Apc protein domains with respect to mutational analysis results. The relative positions of various Apc domains. A putative domain involved in homo-oligomerization of Apc is located at the amino-terminus. Also noted are a series of repeats of unknown function with similarity to the *Drosophila* armadillo protein, sequences known to mediate binding to p-catenin and its downregulation, a basic domain in the carboxy-terminal third of the protein that appears to facilitate complexing with microtubules (MT), and sequences near the carboxy terminus of Apc that are known to interact with the EB1 and human homolog of the *Drosophila* disc large (hDlg) protein. Germline mutations in the APC gene (predominantly chain terminating) are dispersed throughout the 5' half of the sequence, with two apparent “hot spots” at codons 1061 and 1309. Somatic mutations in the APC gene in colorectal cancer appear to cluster in a region termed the “mutation cluster region,” and mutations at codons 1309 and 1450 are most common.

Figure 9 A model indicating the function of the Apc, axin, and Gsk3p proteins in the regulation of p-catenin (p-cat) in normal cells, and the consequence of Apc or p-cat defects in cancer cells. p-Cat is an abundant cellular protein, and much of it is often bound to the cytoplasmic domain of the E-cadherin (E-cad) cell-cell adhesion protein. (a) In normal cells, the proteins glycogen synthase kinase 3p (Gsk3p), Apc, and axin function to promote degradation of free cytosolic p-cat, probably as a result of phosphorylation of the N-terminal sequences of p-cat by Gsk3p. Gsk3p activity and p-cat degradation are inhibited by activation of the wingless (Wnt) pathway, as a result of the action of the Frizzled receptor and disheveled (Dsh) signaling protein. (b) Mutation of Apc in colorectal and other cancer cells results in accumulation of p-cat, binding to Tcf-4, and transcriptional activation of Tcf-4 target genes, such as *c-myc*, cyclin D1, *MMP-7*, and *PPARS* (see text). (c) Point mutations and small deletions in p-cat in cancer cells inhibit phosphorylation and degradation of p-cat by Gsk3p and Apc, with resultant activation of *c-myc* and other Tcf-4 target genes.

Figure 10 Mismatch repair pathway in human cells. (a,b) During DNA replication, DNA mismatches may arise, such as from strand slippage (shown) or misincorporation of bases (not shown). (c) The mismatch is recognized by MutS homologs, perhaps most often Msh2 and GTBP/Msh6, although another MutS homolog, Msh3, may substitute for GTBP/Msh6 in some cases. (d,e) MutL homologs, such as Mlh1 and Pms2, are recruited to the complex, and the mismatch is repaired through the action of a number of proteins, including an exonuclease, helicase, DNA polymerase, and ligase.

Chapter 6: Epigenetic contributions to human cancer

Figure 1 Nucleosome structure. (a) Model of the double helix wound around the protein structure of the constituent histones as outlined in the text. (b) The schematic representation shows the organization of the H3/H4 tetramer on the DNA, followed by two sets of H2A/H2B dimers forming the histone core with the DNA (*black line*) wrapped around. The amino-terminal histone tails are shown extruding from the nucleosome core of the eight histone proteins.

Figure 2 Depiction of the packaging arrangement of human DNA (straight black line). Panel (a) shows, for normal cells, a more linear arrangement of nucleosomes (yellow circles with DNA wrapped around as outlined in Figure 1) depicting the “open” arrangement of chromatin around most gene promoters containing CpG islands (unmethylated CpG sites shown as white lollipops), which are being actively transcribed or can be induced to transcribe (large light-blue arrow). Exons 1–3 of the model gene are depicted by the numbered light-blue boxes. Regions of DNA within the body of the gene and extending beyond the third exon are depicted as being in the closed, transcriptionally repressed, conformation typical of the majority of the normal human genome. This closed structure is represented by the more packed, three-dimensional organization of the nucleosomes, and the CpG sites in the closed regions are depicted as being methylated (black lollipops). The text in yellow squares depicts the chromatin remodeling protein complexes, histone-modifying enzymes, and enzymes performing DNA methylation (DNA-methylation machinery), which are responsible for DNA packaging as discussed in the text. Panel (b) depicts the altered chromatin patterns present in a typical cancer cell with a switch in positions of the normal closed and open chromatin regions in the genome. Many closed regions now have an open chromatin with loss of DNA methylation, while a large group of gene promoters have assumed a closed chromatin with abnormal, CpG island DNA methylation and repressed transcription (large red X over the transcription start site depicted by the light-blue arrow).

Chapter 7: Cancer genomics and evolution

Figure 1 Cancer results from the stepwise accumulation of diverse, branching mutations. (a) “Vogelgram” model of progressive development of colorectal cancer.³ Inactivation of the tumor suppressor *APC* is commonly observed in colorectal cancer precursor lesions. Subsequent mutational activation of the *RAS* oncogene is associated with transition from early adenoma to early cancer. Progressive accumulation of molecular alterations eventually leads to a malignant tumor that can invade the basement membrane and metastasize to lymph nodes and distant organs. (b) Expanded model depicting disparate cancer-initiating mutations as well as stepwise branching evolution in which cells accumulate secondary mutations followed by clonal expansion leading to both inter- and intratumoral heterogeneity.

Figure 2 Examples of cancer mutation types. (a) The *NRAS* oncogene, located on chromosome 1, is commonly mutationally activated in diverse cancers. A single nucleotide variant (SNV) results in a codon alteration and substitution of lysine (K) for glutamine (Q) at amino acid 61—Q61K

(top figure). Shown below is the chromatogram from Sanger sequencing analysis of a tumor sample harboring the *NRAS* Q61K mutation. (b) CGH log₂ ratio data are plotted for chromosome 17 (left), as well as a focal region of homozygous deletion with a breakpoint within the TP53 tumor suppressor (right). Regions of DNA copy loss are plotted to the left of the axis and regions of gain are plotted to the right. Individual log₂ ratio data (dots) and log₂ ratio moving average (line) are shown. (c) Schematic of the DNA translocation that occurs between the genes *BCR* and *ABL*, leading to the formation of the *BCR-ABL* gene fusion known as the Philadelphia chromosome (left). Shown on the right is interphase and metaphase FISH detection of the t(9;22) *BCR-ABL* gene fusion using fluorescently labeled genomic probes for *BCR* (green) and *ABL* (red). Note that the fusion of *BCR* and *ABL* probes results in a yellow signal indicating colocalization of the red and green probes as a result of the t(9;22).

Figure 3 The history of cancer genomics. (a) Timeline of landmark studies in cancer genetics and genomics from Boveri's formulation of the chromosomally aberrant nature of cancer in 1902 to the advent of 228,000 human genomes sequenced in 2014. (b) Cost of sequencing a 3000 Mb genome (i.e., the size of the human genome) over time.

Figure 4 Number of coding single nucleotide variants (SNVs) per tumor type across a selection of human cancers. DNA sequencing data obtained from published TCGA studies were used to calculate the distribution and median number of coding SNVs mutations in each cancer type. Colored bars indicate the 25% and 75% quartiles. Outlier values (values below $Q1 - 1.5 \times IQR$ or above $Q3 + 1.5 \times IQR$) are not shown and asterisks represent studies with more than 10% outliers.

Figure 5 Precision Medicine clinical trials. (a) Process diagram depicting key steps from patient consent through molecular profiling and treatment plan generation. The entire process from biopsy to treatment plan is designed to be performed in less than 5 weeks. Source: From LoRusso, P et al. Pilot Trial of Selecting Molecularly Guided Therapy for Patients with Non-V600 BRAF-Mutant Metastatic Melanoma: Experience of the SU2C/MRA Melanoma Dream Team. *Molecular Cancer Therapeutics*. 2015 Aug 14(8): 1962–1971. Reprinted with permission. (b) Potential therapeutic implications of significantly mutated genes identified in the primary glioblastoma TCGA data set. (Top) Pathway representation of frequently altered pathways and selected potential therapeutic agents. (Bottom) Table of frequently mutated genes from TCGA mapped to potential FDA-approved therapeutic agents. (Right) Bar chart of level of evidence for the association between an alteration and therapeutic implication.

Figure 6 (a) Linear evolution involves sequential accumulation of mutations over time. As can be seen, linear evolution can result in heterogeneity if a subclone has failed to outcompete its predecessors. (b) Tumor subclones may evolve through a process equivalent to allopatric speciation when subclonal populations are geographically distinct within a tumor. (c) Clonal competition can occur between subclonal populations, where distinct subclones compete for growth advantages (equivalent to an antagonistic relationship). (d) Subclonal populations may cooperate, resulting in a symbiotic relationship.

Figure 7 The genetic basis of cutaneous melanoma. Melanoma, the deadliest of skin cancers, is caused by the transformation of melanocytes (pigment-producing cells) that accumulate genetic alterations, leading to abnormal proliferation and dissemination. Clinically, melanoma lesions can be classified based on location and progression, ranging from benign nevi to metastatic melanoma. Important driver genes in melanomas are shown in the Figure MAPK signaling is often constitutively activated through alterations in membrane receptors or through mutations of RAS or

BRAF.

Figure 8 The genomic landscape of cutaneous melanoma. Total number of mutations, age at melanoma accession, and mutation subtype (BRAF, RAS [N/H/K], NF1, and Triple-WT) are indicated for each sample (a). (Not shown are one hypermutated and one co-occurring NRAS BRAF hot-spot mutant). Color-coded matrix of individual mutations (specific BRAF and NRAS mutations indicated) (b), type of melanoma specimen (primary or metastasis), and mutation spectra for all samples (c) are indicated. For the two samples with both a matched primary and metastatic sample, only the mutation information from the metastasis was included.

Figure 1 MicroRNA biogenesis.

Figure 2 Process of extracellular vesicles release from cells. Apoptotic cells release apoptotic bodies.

Chapter 10: Aberrant signaling pathways in cancer

Figure 1 Families of receptor tyrosine kinases.

Figure 2 Intracellular effectors of receptor tyrosine kinases.

Chapter 11: Differentiation therapy

Figure 1 Differentiation blockade and differentiation therapy in cancer. In addition to self-renewal, normal stem cells are capable of differentiating into specific mature cells, while differentiation blockade may lead to the development of cancer. Cancer stem cells may originate from normal stem cells acquiring genetic and/or epigenetic abnormalities, or from normal progenitor or differentiated cells undergoing de-differentiation and reprogramming also due to genetic and/or epigenetic abnormalities. Differentiation therapy exerts therapeutic efficacy by inducing differentiation of cancer stem cells and undifferentiated cancer cells.

Figure 2 Signaling pathways and transcriptional factors (TFs) regulating the differentiation of hematopoietic stem/progenitor cells (HSPC). Differentiation block may result in leukemia, exemplified by development of acute promyelocytic leukemia (APL), a subtype of acute myeloid leukemia (AML) characterized by accumulation of abnormal promyelocytes in bone marrow/peripheral blood, the presence of t(15;17)/PML-RAR α fusion gene, and severe bleeding syndrome. In fact, almost all the listed signaling molecules and TFs are subject to mutations (gene fusions, point mutations, gene amplifications/deletions) and/or dysregulation of expression in hematological malignancies.

Figure 3 Epigenetic regulation involved in the cell differentiation and tumorigenesis. (a) DNA methylation (cytosine methylation and hydroxymethylation) are regulated by different enzymes DNMTs, TETs, and IDH. (b) Post-translational modifications of histones include phosphorylation, acetylation, methylation, and ubiquitylation or sumoylation, which are regulated by a variety of factors HATs, HDACs, HMTs, HDMs, and so on. Notably, most of these epigenetic modifier genes have been found to be mutated in human cancers including solid tumors and hematological malignancies. (c) Gene expression is controlled in the promoter regions by a combination of chromatin modification and transcriptional factor (TF). In tumor cells, gene expression is silenced by condensing chromatin, methylating DNA, and deacetylating histones, which results the differentiation blockade. Inhibition of HDACs, DNMTs, and IDH may result in active transcription and differentiation of cancer cells. Some HMTs (e.g., MLL and related fusion

[proteins\) may enhance H3K79 methylation by promoting DOT1L to activate transcription of some leukemogenic genes, and inhibitor of DOT1L may suppress the leukemogenic genes to treat leukemia.](#)

[Figure 4 Molecular pathogenesis of APL. PML-RAR \$\alpha\$ plays a key role in leukemogenesis of APL, which exerts dominant negative effects on RAR \$\alpha\$ - and PML-related pathways. Under physiological condition, RAR/RXR heterodimers bind to the specific motifs defined as retinoic acid response elements \(RAREs\) on the promoters of target genes and differentially activates or represses gene transcription while recruiting co-activators \(CoA\) or co-repressors \(CoR\) complex depend on the presence or absence of the ligands, such as ATRA. The fusion protein binding to RXR co-receptor functions as a constitutive transcriptional repressor at RAREs of target genes through recruitment of CoR. In other hand, PML proteins multimerize to form multiprotein subnuclear structures called PML-nuclear bodies \(PML-NBs\) in normal cells. In APL cells, PML-NBs are disrupted owing to the formation of PML/PML-RAR \$\alpha\$ heterocomplex.](#)

[Figure 5 Therapeutic mechanism of APL. ATRA and ATO target respectively the C- and N-terminals of PML-RAR \$\alpha\$, enhancing degradation of PML-RAR \$\alpha\$ oncoprotein. ATRA binds to the ligand-binding domain \(LBD\) of RAR \$\alpha\$ portion in the fusion protein and ATO binds to the RBCC domain of PML moiety, which induces the conformational change and the consequential degradation of the fusion protein. The degradation of PML-RAR \$\alpha\$ generates a restoration of nuclear architecture with reformation of PML-NBs. ATRA binding also leads to displacement of CoR complexes and recruitment of CoA complexes and clear PML-RAR \$\alpha\$ from promoters of target genes, thereby restoring wild-type RAR \$\alpha\$ function. The synergistic effects of ATRA and ATO result in a variety of cellular response including differentiation, apoptosis, and senescence of leukemic cells, and importantly, the eradication of leukemia-initiating cell \(LIC\).](#)

Chapter 12: Cancer stem cells

[Figure 1 Schematic representation of two models of tumorigenesis. \(a\) Depicts “cancer stem cell” model where tumors arise in cells with stem cell properties generating hierarchically organized tumors driven by “cancer stem cells” at the top of hierarchy. These cells then generate differentiated clonal progeny that form the tumor bulk. \(b\) Depicts stochastic or classical model of tumorigenesis where random mutations in any cell generates cancerous clonal populations, which evolve through further mutation.](#)

[Figure 2 Cancer stem cell-targeted drugs and their cellular targets currently being evaluated in early phase clinical trials or FDA approved for other purposes.](#)

Chapter 13: Cancer and cell death

[Figure 1 **Caspase activation pathways.** The major pathways for Caspase activation in mammalian cells are presented. The schematic represents an oversimplification of the events that occur *in vivo*. The extrinsic \(left, upper\) is induced by members of the TNF- family of cytokine receptors such as TNFR1, Fas, and the TRAIL Receptors, DR4 and DR5. These proteins recruit adapter proteins to their cytosolic DDs, including FADD, to assemble “death-inducing signaling complexes” \(DISCs\), which bind DED-containing pro-Caspases, particularly pro-Caspase-8, inducing their activation. Caspase-8 \(and Caspase-10 in humans\) cleaves downstream effector proteases, such as Caspases-3, -6, and -7, as well as pro-apoptotic Bcl-2 family member Bid, which is an agonist of MOMP-inducing Bax and Bak. CTLs and NK cells introduce the protease Granzyme B into target cells \(right, upper\). This protease cleaves and activates multiple members of the Caspase-family, as well as Bid. The intrinsic pathway \(left, lower\) is initiated by release of](#)

Cyt-c from mitochondria, induced by various stimuli, including elevations in the levels of pore-forming pro-apoptotic Bcl-2 family proteins such as Bax and Bak. In the cytosol, Cyt-c binds and activates Apaf-1, allowing it to associated with and activate pro-Caspase-9, forming “apoptosomes.” Active Caspase-9 directly cleaves and activates the effector proteases, Caspase-3 and -7. Exogenous pathogen-associated molecular patterns (PAMPs) and endogenous danger-associated molecular patterns (DAMPs) activate NLR family proteins to cause their oligomerization and assembly of “inflammasomes” that may contain PYD-containing adapter protein ASC in many cases, which binds pro-Caspase-1. Activated Caspase-1 cleaves a variety of cellular proteins, including cytokines as well as plasma membrane proteins that promote osmotic stress and cell death.

Figure 2 **Caspase-independent cell death pathways.** The TNFR1-mediated pathway for necrosis (necroptosis) involves a cascade of events that include recruitment of Rip1, which in turn activates Rip3, which activates MLKL and which causes mitochondrial and probably lysosomal changes that stimulate ROS generation and lead to necrosis. The cytosolic DD of TNFR1 binds the DD-containing adapter protein TRADD, which binds the DD of Rip1. The kinase cascade involves Rip1, followed by Rip3, followed by MLKL. Mitochondria release proteins stored in the intermembrane space, including Cyt-c, Endonuclease G, and AIF. Release can be induced by MOMP (*upper*), which is regulated by Bcl-2 family proteins and which does not involve organelle swelling. Alternatively, release of mitochondrial can occur as a result of by MPTP complex opening, which leads to organelle swelling and loss of the electrochemical gradient ($\Delta\Psi_m$). MPTP opening is induced by Ca^{2+} influx and oxidative stress, among other stimuli. Accumulation of unfolded proteins in the ER results in UPR signaling, including activation of IRE1 α , which splices XBP1 mRNA to generate XBP1 protein (transcription factor) and activation of the kinase PERK, which stimulates phosphorylation events that promote ATF4 mRNA translation and production of transcription factor ATF4. The UPR transcription factors (XBP1, ATF4, and (not shown) ATF6) converge on the promoter of the *CHOP* gene, which encodes a transcription factor that upregulates pro-apoptotic gene *BIM* and downregulates anti-apoptotic gene *BCL-2*. Autophagic vesicles emerge from the ER, form double membrane vesicles, which fuse with lysosomes (*bottom, right*).

Figure 3 **Network of interactions among Bcl-2-family proteins.** The functional and physical interactions among pro-apoptotic and anti-apoptotic Bcl-2-family proteins are depicted as pertains to their regulation of MOMP.

Figure 4 **Signal transduction and cell death regulation.** Some of the transcription factors and kinases that play prominent roles in apoptosis regulation are depicted, including kinases Akt (PKB) and the transcription factors p53, NF- κ B, and CHOP. Illustrative examples of the connections to apoptosis-regulating proteins and genes are shown, without attempting to be comprehensive. The protein kinase Akt (PKB) is activated in response to second messengers produced by PI3K, a lipid kinase that is activated by many growth factor receptors and oncoproteins. PTEN is a lipid phosphatase that prevents accumulation of these second messengers, the expression of which is lost in many tumors through gene deletions, gene mutations, and other mechanisms.⁸⁹ Akt can phosphorylate and either activate (arrows) or inactivate (|) multiple proteins directly or indirectly relevant to apoptosis.¹²¹ Expression of the transcription factor CHOP is stimulated by transcription factors that are elaborated during ER stress, including XBP1, ATF4, and ATF6. See text for additional details.

Figure 1 Normal cells that do not express telomerase activity cannot elongate their telomeres, hence their life span is limited whereas telomerase-expressing cancer cells (~90% of cancer cells, a) can elongate their telomeres by telomerase (with hTERT and hTR subunits, b) resulting in unlimited proliferative lifespan (a hallmark of cancer). This important difference between normal and cancer cells make telomerase an almost universal therapeutic target.

Figure 2 Diagram of hypothetical telomere demonstrating the t-loop structure. This structure is similar in normal and cancer cells but as normal cells generally do not express telomerase, telomeres shorten progressively while cancer cells expressing telomerase can maintain their telomeres (a). There are disadvantages of G-quadruplex stabilizers (b), immunotherapy (c), and gene therapy approaches (d). G-quadruplex stabilizers show their toxic effects by binding and stabilizing T-loop structures and they are also found at the other regions of chromosomes beside telomeres. Thus, these agents are likely to be toxic for both normal and cancer cells (b). One of the most important disadvantages for immunotherapy is that when combination chemotherapy is used with vaccines for cancer patients, some agents can block the effect of immunization as most chemotherapeutic agents are immunosuppressive (c). The main challenge for gene therapy is the delivery of the gene vector to the cancer cells (d) throughout the body. In addition, immunologic responses to therapy can also limit dosing. Gene therapies generally require more invasive approaches to delivery and are generally not orally available for systemic delivery.

Figure 3 Telomerase-targeted therapeutic responses (such as Imetelstat/GRN163L) are dependent on the initial tumor cell telomere length. Cancer cells have variable telomere lengths. Therefore, cells with long telomeres are predicted to take a longer treatment period to be sensitive to telomerase inhibitors compared to cells with shorter telomeres (left side). As a result, any long-term treatment for telomerase may lead to unwanted side effects, high costs, and potentially re-establishing feedback loops establishing a stable new telomere length. In contrast to telomerase-targeted therapies, telomerase-mediated telomere targeting therapies (such as 6-thio-dG or MT-hTERC gene therapy) do not need long treatment periods as they are independent of the initial telomere length, therefore short response time to tumor burden reduction is a key advantage of these approaches (right side). The other most important advantage is that they may be less toxic to normal cells as most do not express telomerase. However, the MT-hTERC approach has the same obvious limitations of all gene therapy approaches of needing to reach almost all cells and delivery concerns. However, new approaches such as 6-thio-dG nucleoside may be orally available with minimal side effect and have the obvious advantage that all small molecules have.

Chapter 15: Cancer metabolism

Figure 1 **Glycolysis.** (a) Catabolism of one glucose molecule via glycolysis yields two molecules of pyruvate, which can then be transported to the mitochondria and used as a source of acetyl-CoA for the TCA cycle. Alternatively, pyruvate can be reduced to lactate and excreted out of the cell. Besides its bioenergetic uses, glycolysis also provides biosynthetic power to cells. Glucose-6-phosphate can be utilized in the PPP to generate NADPH and ribose 5-phosphate for nucleotide biosynthesis; or, its intermediates can be shunted back into glycolysis (shown by gray dashed arrows). In addition, 3-phosphoglycerate can be converted to serine, a carbon donor for the folate (one-carbon) cycle. Folate cycle generates NADPH, as well as provides one-carbon units for the biosynthesis of nucleotide bases and for methylation reactions. GLUT, glucose transporter, HK, hexokinase, PFK1, phosphofructokinase 1, PKM2, pyruvate kinase M2, LDH-A, lactate dehydrogenase A, MCT, monocarboxylate transporter, OxPhos, oxidative phosphorylation. (b) Quiescent cells consume moderate amount of glucose and preferentially catabolize it to pyruvate

to fuel oxidative phosphorylation in mitochondria. In proliferating cells, growth factor signaling or constitutively active oncogenes facilitate the increase in glucose uptake. In contrast to a quiescent cell, the majority of glucose consumed by a growth-stimulated cell goes into biosynthetic pathways to produce nucleotides, amino acids, and lipids—or is expelled as lactate.

Figure 2 Carbon metabolism in mitochondria. Glycolysis-derived pyruvate serves as a donor of acetyl-CoA for the tricarboxylic acid (TCA) cycle. Cataplerotic efflux of citrate into the cytosol (shown by a maroon arrow) allows maintaining the extramitochondrial pool of acetyl-CoA for fatty acid and cholesterol biosynthesis. Glutamine and pyruvate function as anaplerotic substrates to restock the TCA cycle intermediates (shown by solid green arrows). In conditions when acetyl-CoA is limiting, citrate can be produced from the reductive carboxylation of glutamine-derived α -ketoglutarate (shown by dashed green arrows). Pink circles represent a number of carbon atoms in a molecule. GLUT, glucose transporter, PDH, pyruvate dehydrogenase, PC, pyruvate carboxylase, IDH, isocitrate dehydrogenase, SDH, succinate dehydrogenase, FH, fumarate hydratase, ACL, ATP-citrate lyase, GLS1, glutaminase, ASCT2, glutamine transporter.

Chapter 16: Modeling therapy of late or early-stage metastatic disease in mice

Figure 1 Contrasting outcomes of sunitinib versus DC101 (a VEGF receptor-2 targeting antibody, with or without chemotherapy when treating primary tumors vs overt metastases). A spontaneous metastatic variant of MDA-MB-231 called LM2.4¹⁰ was injected into the mammary fat pads of mice to establish primary tumors (a), or the tumors were resected and the mice allowed to develop extensive metastases, at which point therapy was initiated usually ~20 days after tumor resection (b–d). (a) Sunitinib is active against primary tumors once therapy is initiated (arrow), whereas (b) no impact based on survival using the same dose and schedule of sunitinib in postsurgical mice with advanced metastatic disease. Combination of sunitinib with standard paclitaxel does not improve efficacy of paclitaxel, and in fact worsens outcome (c). In contrast, the DC101 VEGFR-2 antibody improves paclitaxel efficacy (d). Similar results to sunitinib were obtained using pazopanib, which are not shown here. Statistical results and experimental details provided in Guerin et al.²⁴

Figure 2 Developing a spontaneous metastatic variant from a breast cancer PDX. (a) Tumor fragments of the triple-negative PDX breast cancer tumor called HCI-002³⁵ were implanted in the mammary fat pads (mfp) of SCID mice. The tumor growth rate remained similar after successive passages. (b) After 2 months, primary tumors were resected and the mice maintained for observation of development of distant overt metastases. (c) After 7 months, one mouse (among 55 examined) developed a lung metastasis that was positive for the human leukocyte antigen (HLA) big enough to be implanted into the mfp of new mice. (d) Fragments of this lung metastasis were implanted in the mfp of new SCID mice. These new tumors grew with an accelerated rate when compared to the parental HCI-002 (tumor volumes of 1000 mm³ were reached after 6 weeks). (e) The tissue architecture of this new variant remained similar to that of the parental tumor. The growth rate of this new variant was also consistently maintained after successive passages. (f) Mouse-derived thymic lymphomas also appeared in the 15.9% of the mice implanted with PDX tumors. These tumors (which were negative for HLA, with no human component) showed high rates of proliferation and were positive for the hematopoietic progenitor cell antigen CD34. The arrow shows a mouse thymoma. Scale bars, 150 μ m. Thus, the results indicate the rarity of development of overt distant metastases using PDXs, the protracted time frame for an overt spontaneous metastasis to develop and the complication of the appearance of the novo mouse thymomas in older SCID mice. Chapter 17: Tumor angiogenesis

Figure 1 Tumors remain avascular in isolated perfused organs.²⁰ Whole organs, supported by perfusion, allow growth of tumors in isolation from a host. The tumor remains very small, less than 1 mm^3 , in an avascular environment compared to growth in mice which can exceed $10,000 \text{ mm}^3$.

Figure 2 (a) A cuff of viable tumor cells surrounding a microvessel in a human melanoma growing in a SCID mouse has an average radius of $85 \mu\text{m}$. The appearance of an ellipsoid is a result of the way the section is cut. (b) A cuff of rat prostate cancer cells surrounding a microvessel has an average radius of $110 \mu\text{m}$.

Figure 3 VEGFR signal transduction. VEGF family members, VEGF, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PlGF bind three VEGFR tyrosine kinases, resulting in dimerization, receptor autophosphorylation, and activation of downstream pathways. Signal transduction via VEGFR2 is shown. Ligand binding to VEGFR2 activates signal-transduction molecules phospholipase C- $[\gamma]$ (PLC- $[\gamma]$), PI3K, Akt, Ras, Src, and MAPK and regulates cell proliferation, migration, survival, and vascular permeability.

Figure 4 Ang/Tie2 signaling pathway. (a) Representation of nascent tumor blood vessel structure in quiescent state. Endothelial cells (ECs; green) are organized to form vessel lumen and tightly interact with perivascular cells (blue), separated by basement membrane. (b) Ang1 ligand binds Tie2 localized on ECs; Tie2 subsequently dimerizes and is phosphorylated. Activated Tie2 activates phosphatidylinositol 3-kinase and Ras/Raf/MEK, promoting EC survival and proliferation/migration. Generally, Ang2 functions as an Ang1 antagonist by inducing increased vascular permeability, sprouting vascularization. Autophosphorylated Tie2 activates Tie1, the extracellular domain of which in turn interferes with Ang1/Tie2 binding, therefore antagonizing Ang1 signaling. Ang1 has anti-inflammatory properties, whereas Ang2 plays a proinflammatory role. Ang1-activated Tie2 inhibits nuclear factor- κB -mediated inflammatory gene expression, whereas Ang2 promotes expression through blockade of Ang1 function. (c) Perivascular cells secrete Ang1, which binds Tie2 expressed on ECs. In this interaction, Ang1 contributes to vessel integrity, reduces vessel permeability, and maintains vasculature quiescence. (d) Ang2 plays a major role in angiogenesis by mediating dissociation of pericytes and destabilizing cellular junctions. In the presence of other proangiogenic factors (e.g., VEGF), ECs proliferate and/or migrate to form new sprouting, disorganized blood vessels. In the absence of proangiogenic factors, Ang2 signaling results in EC apoptosis and regression.

Figure 5 (a) Mice bearing Lewis Lung carcinoma.⁴⁹⁹ Tumors were resected when tumor size reached $1.5\text{--}2 \text{ cm}^2$ and the animals were killed after 5 or 15 days. (b) Upper panel: lungs from animals still bearing the primary tumor. Lower panel: lungs removed at the same time from animals in which the tumor had been resected and the animals killed 15 days later. (c) Left panel: microscopic pulmonary metastasis in an animal in which a primary tumor is in place at the same time as the right panel. There is no evidence of angiogenesis as only a single central microvessel stained with antibody to von Willebrand factor. This dormant metastasis is $200 \mu\text{m}$ in its longest diameter. Right panel: lung metastasis from an animal euthanized 5 days after the primary tumor was removed, showing eight or nine new vessels in an enlarging metastasis. (d) A human prostate carcinoma (LNCaP) growing on the dorsum of an SCID mouse inhibits cornea neovascularization induced by an implanted sustained release pellet of bFGF (80 ng) (right panel). Left panel depicts

bFGF-induced corneal neovascularization at 5 days in the absence of a primary tumor. LNCaP prostate cancer generates angiostatin. (e) A human colon cancer that does not produce an angiogenesis inhibitor, growing in an SCID mouse as a control for (d).

Figure 6 Changes in tumor vasculature during treatment with antiangiogenic agents.²⁷¹ (a) The tumor vascular network is structurally and functionally abnormal. Antiangiogenic therapies might initially improve both the structure and the function of tumor vessels. Continued or aggressive antiangiogenic regimens may eventually result in a vascular supply that is inadequate to support tumor growth. (b) Vascular normalization due to inhibition of VEGFR2. On the left is a two-photon image depicting normal blood vessels in skeletal muscle; subsequent representative images show human colon carcinoma vasculature in mice at day 0, day 3, and day 5 after treatment with a VEGFR2-specific antibody. (c) Diagram illustrating the concomitant changes in basement membrane (blue) and pericyte (red) coverage during vessel normalization. (d) These changes in the vasculature may reflect changes in the balance of pro- and antiangiogenic factors in the microenvironment.

Chapter 18: Cancer bioinformatics

Figure 1 Schematic view of specimen and information flows for sequencing of cancers to identify mutations and/or copy number aberrations as possible biomarkers for clinical application. Amber boxes indicate downstream “biointerpretive” aspects of the pipeline. As indicated by the multiple arrows, many hurdles (scientific, technical, logistical, ethical, and regulatory) must be overcome before possible clinical application. Analogous schematics can be drawn for other data types at the DNA, RNA, protein, and metabolomic levels (including studies based on microarrays, rather than sequencing).

Figure 2 Cost per genome for human whole-genome sequencing. The Figure shows an inflection point in late 2007 as massively-parallel sequencing came into practice. We are awaiting the maturation and cost-effectiveness of “third-generation” technologies, principally based on sequencing of single molecules. Source: genome.gov/sequencingcosts (The National Human Genome Research Institute).

Figure 3 Venn diagram of the somatic point mutations detected by three different mutations callers circa 2013 on 20 TCGA endometrial tumor-normal exome-seq pairs. The differences for point mutations would be smaller now, but an analogous diagram for indels or structural variants would still show considerable lack of concordance. From⁹

Figure 4 Drug versus drug clustered heat map for the activity of platinum-containing compounds against the NCI-60 panel of human cancer cell lines. Drugs are listed on both axes in the same clustered order, hence the heat map is symmetrical around the diagonal. Red indicates high correlation of activity profiles, blue indicates low correlation. The data define 12 families (which are highly correlated with the chemical structures of the compounds). Cluster #4 drugs, which consisted entirely of diaminocyclohexyl derivatives, including oxaliplatin, were selectively active against colorectal cell lines. That information tipped the balance for clinical development of oxaliplatin, now a standard agent for treatment of colorectal cancers (due to T Fojo, T Myers, JN Weinstein).

Figure 5 Simplified generic view of the flow of samples and information in The Cancer Genome Atlas program. Tumor plus normal blood and/or “normal tumor-adjacent tissue” specimens were collected with consent by tissue source sites and handled according to defined protocols for submission to the project. The Biospecimen Core Resource vetted the specimens and

[accompanying clinical data, generated DNA, RNA, and protein samples, quality-controlled the samples, and sent them to the Genome Sequencing and Genome Characterization Centers. Those Centers profiled the samples by sequencing, microarray analysis, or other technologies and sent the data to the Data Coordinating Center. As soon as feasible, non-restricted forms of the data were made public on TCGA's website for use by the research community, including TCGA's Genome Data Analysis Centers. Omitted here for simplicity are many additional components of the information flow such as the Broad Institute's Firehose, which performs and presents large numbers of analyses on the data; Sage Bionetics' Synapse, which provides an environment and tools that facilitate wide collaborative use of the data; Memorial Sloan-Kettering's cBio, which presents the data in a form accessible to nonspecialists; and MD Anderson's compendia of clustered heat maps for pattern recognition in the DNA, RNA, and protein datasets. Also not shown are the expert reviews of clinical data and pathology.](#)

[Figure 6 Data visualizations in TCGA's Urothelial Bladder Cancer Project. Source: The Cancer Genome Atlas Research Network 2014.⁴⁰ Tumor specimens from 131 patients were included in the analyses. Panel A: A compact visualization of mutation profiles across the bladder cancer specimens for genes scored by the MutSig 1.5 algorithm as significantly mutated \(due to J. Kim, A. Cherniack, G. Getz, D. Kwiatkowski\). **Panel B:** An interactive Next-Generation Clustered Heat Map representation of the mRNA expression data. Genes are on the vertical axis; patient specimens are on the horizontal axis \(due to B. Broom, R. Akbani, D. Kane, M. Ryan, C. Wakefield, J. Weinstein\). **Panel C:** Representation of four pathways found to be altered at the DNA level in urothelial bladder cancer. Somatic mutations and copy number alterations \(CNAs\) were found in the p53/Rb pathway, RTK/RAS/PI\(3\)K pathway, histone modification system, and SWI/SNF complex. Red, activating genetic alterations; blue, inactivating genetic alterations. Percentages shown denote activation or inactivation of at least one allele \(due to C. Creighton, D. Kwiatkowski, L Donehower, P Laird\).](#)

Chapter 19: Systems biology and genomics

[Figure 1 A schematic illustration of the influence of extrinsic and intrinsic systems biology upon cellular function with the potential to identify progression and response to therapy in patients. The extrinsic systems biology component consists of the tumor microenvironment including cells of hematopoietic origin, mesenchymal origin, and noncellular components, in addition to distant influences, from the bone marrow and other multiple organs. Together, with a systems biology approach, cellular function can be studied using various endpoints, including cellular proliferation, apoptosis, differentiation, DNA repair, motility, senescence, and metabolism. Our laboratory is striving to combine these endpoints to better understand tumor progression and response to therapy in the laboratory, and how this may correlate to patients in the clinic.](#)

[Figure 2 Schematic illustration of the use of microenvironment microarrays to assess the impact of diverse microenvironments on cancer cell growth. Several thousand microenvironmental proteins printed as ~250 micrometer diameter spots host the growth of cancer cells. Changes in immunofluorescence staining pattern induced by the microenvironmental proteins are recorded using fluorescence image analysis.](#)

Chapter 20: Statistical innovations in cancer research

Figure 1 Prior distributions of response rate r . The left-hand panel in each pair is the prior distribution of response rate r . The right-hand panel is the posterior distribution of r after having observed a response in a single patient. The (predictive) probability of a response for each left-hand panel is 0.500, increasing in the right-hand panels to 0.667, 0.600, 0.571, and 0.556 in cases (a), (b), (c), and (d), respectively. Changes are greater and learning is more rapid when the prior distribution reflects greater uncertainty.

Figure 2 Posterior distributions for response rate r based on an experiment with 20 responses and 20 failures. The eight prior distributions considered are the eight distributions shown in Figure 1. Except for proportionality constants, these are 1 , r , $r(1-r)$, $r^2(1-r)$, $r^2(1-r)^2$, $r^3(1-r)^2$, $r^3(1-r)^3$, and $r^4(1-r)^3$. The corresponding posterior distributions are proportional to $r^{20}(1-r)^{20}$, $r^{21}(1-r)^{20}$, $r^{22}(1-r)^{21}$, $r^{22}(1-r)^{22}$, $r^{23}(1-r)^{22}$, $r^{23}(1-r)^{23}$, and $r^{24}(1-r)^{23}$. These eight posterior distributions are very similar, demonstrating the robustness principle.

Figure 3 Likelihood of r for 22 responses out of 33 observations. The likelihood is $P(22 \text{ of } 33|r)$, which is proportional to $r^{22}(1-r)^{11}$. The likelihoods at $r = 0.5$ and 0.75 are highlighted. These values are used in the calculational example in the text.

Figure 4 Response comparisons. The dot plot on the r -axis shows the observed response proportions given in Table 2. The areas of the dots are approximately proportional to sample sizes n . The pooled-analysis curve shows the distribution of response rate r assuming no study effect. The hierarchical analysis curve shows the Bayesian estimate of the distribution of response rates allowing for heterogeneity across the various studies.

Figure 5 Observed response proportions compared to the adjusted response rate estimates. Values are given in the two rightmost columns in Table 2. The dot plot on the r -axis shows the observed response proportions, just as in Figure 4. The Bayes estimates assume a hierarchical model and show shrinkage toward the overall mean.

Figure 6 Disease-free survival proportions for the three CAF dose groups of CALGB 8541.

Figure 7 Hazards for the three CAF dose groups of CALGB 8541, derived from Figure 6.

Figure 8 A 2×2 factorial design considering drugs A and B and their combination. There are four possible treatment combinations.

Figure 9 A $2 \times 2 \times 3$ factorial design considering drugs A and B, three levels of drug C, and their combinations. There are 12 possible treatment combinations.

Chapter 21: Biomarker-based clinical trial design in the era of genomic medicine

Figure 1 Analysis strategy for randomized phase II design to decide whether phase III trial should be restricted to biomarker-positive population, should include positives and negatives, whether biomarker should not even be measured or whether the conduct of a phase III trial is not supported by phase II results. Data from [3]. HR_+ is hazard ratio in biomarker-positive group. HR_- is hazard ratio for treatment in biomarker-negative group. H_{0+} is null hypothesis that $HR_+ = 1$. H_0 is null hypothesis that overall $HR = 1$.

Figure 2 Schema for phase II and III clinical trials for developing a drug that inhibits a target, which is mutated in only 1–2% of cases. Although the number of patients required for the clinical trials are reasonable, the number screened is very large. It is more efficient to incorporate development of such a drug in an infrastructure of common national and international screening

with regard to multiple targets and then triaging patients to clinical trials for which they are eligible.

Figure 3 (a) The targeted enrichment design is used for evaluating a new treatment in the population of patients who are identified using a predictive biomarker as best candidates for benefit from the new treatment. It is primarily for settings where there is a compelling basis for believing that “marker-negative” patients will not benefit from the new treatment and an analytically validated test is available. (b) The “all comers' design” or “marker stratification design” is used for evaluating the effectiveness of a new treatment versus a control in a population prospectively characterized by a binary predictive marker. A detailed prospective analysis plan should describe the primary comparison of treatment to control, in the marker-positive, marker-negative, and overall populations. With a focused analysis plan that limits the study-wide type I error to the traditional 5% level, claims of treatment effectiveness in marker-positive patients need not be restricted to cases where the treatment is effective overall or there is a significant interaction.

Figure 4 Lung-MAP clinical trial master design. Patients with squamous cell carcinoma of the lung are screened for genomic mutations in their tumors. Depending on the genomic alterations found, patients are enrolled on one of six randomized clinical trials. Each component trial compares the same control treatment to a treatment specially designed for patients with a class of genomic alterations. Each component clinical trial is a randomized phase II/III clinical trial, which may serve as a pivotal trial for approval of the test drug for the selected patient population. Source: National Cancer Institute, <http://www.lung-map.org>.

Chapter 23: Chemical carcinogenesis

Figure 1 Multistep chemical carcinogenesis can be conceptually divided into four stages: tumor initiation, tumor promotion, malignant conversion, and tumor progression. The activation of proto-oncogenes and the inactivation of tumor suppressor genes are mutational events that result from covalent damage to DNA caused by chemical exposures. The accumulation of mutations, and not necessarily the order in which they occur, constitutes multistage carcinogenesis. During these stages, progressive epigenetic changes are also occurring due to chemical exposure.

Figure 2 Epigenetic impact of chemical carcinogens. Chemical carcinogens can affect the activity of the different enzymes involved in epigenomics. Ac: acetyl; Me: methyl; DNMT: DNA methyltransferase; HAT: histone acetyltransferase; HDAC: histone deacetylase; HMT: histone methyltransferase.

Figure 3 The concept of gene–environment interactions is multifaceted: (1) environmental chemicals are altered by the products of metabolic genes; (2) environmental chemicals disrupt the expression (induce or inhibit) of carcinogen metabolizing genes; and (3) environmental exposures cause changes (mutations) in cancer-related genes. The cancer-related genes have been classified as gatekeeper (e.g., APC) and caretaker (e.g., MSH1 and MLH1) genes. The interaction of these genes with external and internal environmental agents can lead to the derangement of regulatory pathways that maintain genetic stability and cellular proliferation.

Figure 4 Mutation accumulation during tumor progression. (1) Random mutations result when DNA damage exceeds the cell's capacity for error-free DNA repair. (2) These random mutations can result in clonal expansion and mutations in mutator genes (M). (3) Repetitive rounds of selection for mutants yield coselection mutants in mutator genes. (4) From this population of mutant cancer cells, there is selection for cells that escape the host's regulatory mechanisms for the

control of cell replication, invasion, and metastasis.

Figure 5 Several reactive oxygen species (ROS) and reactive nitrogen species (RNS) are generated during chronic inflammation. The reactive species can induce DNA damage, including point mutations in cancer-related genes, and modifications in essential cellular proteins that are involved in DNA repair, apoptosis, and cell cycle, either directly or indirectly through the activation of lipid peroxidation and generation of reactive aldehydes, for example, malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE).

Figure 6 Precision medicine. In March 2011, at the request of the Director of the National Institutes of Health, an *ad hoc* committee of the National Research Council met to discuss the feasibility, need, scope, impact, and consequences of defining a “New Taxonomy” of human diseases based on molecular biology. The concept that developed, that of precision medicine, includes four basic premises.⁵² First, the information commons for each disease type has to be populated with a variety of -omic, phenotypic, clinical, and epidemiological data. Second, these data are integrated into a knowledge network that examines the interconnectivity of each layer of data from the information commons. Third, the knowledge network is used to develop new taxonomic classifiers with the goal of improving patient diagnosis, decisions on therapeutic strategies, and health outcomes. Finally, the knowledge is used to guide biomedical and clinical research in mechanistic and observational studies. If realized, the benefits of precision medicine can be leveraged for most, if not all, disease types including cancer.

Figure 7 Connecting exposomics to toxonomics to generate a weighted risk signature for primary prevention and chemoprevention strategies. With the explosion of technology, extensive and massive data set generation over the past decade, we are in a position to use bioinformatics to merge the exposome with the various “omics” collected to generate a weighted and precise risk signature. Quantifying the internal, specific, and general external exposure of an individual or population (exposomics), then linking this to the molecular profile of an individual or population can generate a risk signature for an individual or population. Additional and continued consideration of signs/symptoms, standard lab tests, and family history will bring together a targeted primary and chemo-prevention strategy to reduce the risk of carcinogenesis in an individual or high-risk population of individuals.

Chapter 24: Endocrine and genetic bases of hormone-related cancers

Figure 1 Estradiol and other steroid hormones (e.g., progesterone) drive breast cell proliferation, which facilitates the accumulation of random DNA copying errors in critical genes on the pathway to a malignant phenotype. Germ line mutations in relevant tumor suppressor genes accelerate the transformation to the malignant phenotype.

Figure 2 (a,b) Relative risk of breast cancer by duration and time since last use of hormone therapy according to extent of tumor spread relative to never-users, stratified by study, age at diagnosis, time since menopause, body mass index, parity, and the age of a woman when her first child was born. “Last use within 5 years before diagnosis” includes current users. *Floated standard errors (FTEs) and floated confidence intervals (FCIs) calculated from floated variance for each category.

Figure 3 Age-specific incidence rates for cancers of the endometrium in women using estrogen therapy (ERT) (a) and combination oral contraceptives (COCs) (b) for 5 years. Data are from the UK Birmingham Cancer Registry for the years 1968–1972. These data largely avoid problems arising from the high hysterectomy and oophorectomy rates in the United States, which artificially

distort the age-incidence curves. Dots, actual incidence data; solid lines marked “normal,” mathematic models predicting these rates from the major known risk factors for these cancers.

Chapter 25: Ionizing radiation

Figure 1 Development of radiation injury.

Figure 2 Bystander effect of radiation. The expression of p21^{Waf1} was determined in individual cells in monolayer cultures of human diploid fibroblasts by *in situ* immunofluorescence. In cultures exposed to 0.3 cGy (<1–2% of nuclei traversed by an α particle), enhanced expression occurred in many nonirradiated cells occurring in clusters (*center panel*). The effect was suppressed by incubation with lindane, an inhibitor of gap junction-mediated intercellular communication (*right panel*).

Figure 3 (a,b) Survival curves resulting from lymphoreticular cancers (LR-T), as determined by histopathological analysis of tissues taken from deceased animals that had been irradiated (206 cGy) either with or without amifostine. LR-T includes histiocytic leukemia and lymphoma, lymphocytic–lymphoblastic leukemia and lymphoma, myelogenous leukemia, undifferentiated leukemia and lymphoma, and mixed histiocytic leukemia and lymphoma.

Chapter 26: Ultraviolet radiation carcinogenesis

Figure 1 Diagnosis of first cancer by age and type in XP patients compared with the US general population. (a) Proportion of NMSC patients diagnosed at selected ages. (b) Proportion of melanoma patients diagnosed at selected ages. Individuals with both NMSC and melanoma were used in both panels. Ages shown are at the midpoint of each decade. XP: blue bars; general population: red bars. Colored arrows designate median ages of diagnosis for each population. The age span of Cockayne syndrome patients is also shown (orange): solid bar ends at mean age at death (12.25 years), with dashed line extending to maximum reported ages. XP and general population data redrawn from.²⁷ Cockayne data drawn from.²⁹

Figure 2 Biochemical steps for nucleotide excision repair of CPDs and [6-4]PDs by global genome repair or transcription-coupled repair. Initial recognition of damage by GGR involves the DDB2 and XPC gene products; initial recognition by TCR involves RNA polymerase II arrest and disengagement of the transcription complex from damage by CSA, CSB, and UVSSA. Subsequent steps involve XPA and RPA that bind to photoproducts and download the helicases XPB and XPD for local unwinding. Excision occurs when UV-specific endonucleases (XPF/ERCC1 and XPG) make incisions on the 5' and 3' sides. Excision and subsequent polymerization releases a 29 base oligonucleotide containing the CPD and activates the cryptic XPG endonuclease for the final cut.

Figure 3 Pathways involved in melanoma. Proteins mutated by UV light in XP patients or the general population are designated by a star. Mutations in TERT are UV type but have yet to be reported in XP patients. Note the common *BRAF* melanoma mutation V600E is not induced by UV as it does not occur at a dipyrimidine site, but other mutations are formed by UV light in *BRAF*.¹³⁶ The most common mutated gene in XP patients is *PTEN*, in contrast to the MAPK pathway in the general population.¹³⁶

Chapter 27: Inflammation and cancer

Figure 1 The role of inflammation in tumor initiation, promotion, and progression.

Chapter 28: RNA tumor viruses

Figure 1 (a) Structure of typical retrovirus virion. (b) Structure of typical retroviral genome. All replication-competent retroviruses generate a full-length genomic ribonucleic acid (RNA) that encodes the gag and pol products and a singly spliced RNA that encodes the env product. Some retroviruses also generate smaller multiply spliced messages. Abbreviations: env, envelope; gag, core proteins; pol, polymerase; pro, protease.

Figure 2 Long terminal repeat (LTR) structure. Replication-competent retroviruses contain identical LTRs at the 5' and 3' ends. The U3 portion of the 5' LTR contains all of the enhancer and promoter elements necessary for efficient initiation of transcription of either retroviral or cellular genes. Abbreviations: CA, capsid; FeLV, feline leukemia virus; IN, integrase; MA, matrix protein; MMTV, Maloney mammary tumor virus; MuLV, murine leukemia virus; NC, nuclear capsid; PR, protease; RT, reverse transcriptase.

Figure 3 Alternative methods different retroviruses use to bypass the gag stop codon to generate the pro-pol products from the full-length genomic transcripts.

Figure 4 Life cycle of retrovirus. Following binding of the retrovirus to its specific cell membrane receptor, the viral and cellular membranes fuse, and the core virion is internalized into the cell. Reverse transcriptase-directed double-stranded retroviral genomic deoxyribonucleic acid (DNA) is then generated, followed by integrase-directed integration into host cell DNA. Retroviral transcripts using host transcriptional machinery then proceed, with the eventual formation of new retroviral virions that bud from the cell surface, allowing a new round of infection to occur.

Figure 5 Reverse transcription. From a single-stranded ribonucleic acid genomic precursor (a), reverse transcriptase synthesizes a double-stranded deoxyribonucleic acid (DNA) provirus ready for integration into host cell DNA (b).

Figure 6 Integration. The newly reverse-transcribed double-stranded retroviral deoxyribonucleic acid (DNA) genome and a piece of chromosomal DNA are specifically cleaved by the retroviral integrase protein. This is accompanied by a deletion of two base pairs from the retroviral genome and a duplication of four to six base pairs from the host DNA. Following retroviral genomic insertion into the cleaved host DNA, the DNA is re-ligated.

Figure 7 Four mechanisms of retrovirus-induced oncogenesis. (a) Oncogene capture. A mutated form of a cellular proto-oncogene (v-onc) is transferred (transduced) to a normal cell, thus inducing transformation (*c-oncogene). (b) Insertional activation. There is a significant increase in the rate of proto-oncogene expression secondary to LTR-directed transcriptional enhancement (*c-oncogene). (c) Growth stimulation plus two-step oncogenesis. A mutated env protein from the defective spleen focus-forming virus (SFFV) binds to the erythropoietin (EPO) receptor, causing an erythrocyte hyperplasia. This increases the target population susceptible to the actual transforming event, a retroviral insertional disruption of the Spi-I or TP53 gene. Abbreviations: FrMuLV, Friend murine leukemia virus. (d) Transactivation. The viral transactivating protein (tax in the case of human T-cell leukemia virus type I) causes expansion of the potential target population through transactivation of growth regulatory genes. An unknown second event then induces the actual transformation of a clone of these cells.

Chapter 38: Cancer screening and early detection

Figure 1 The natural history of cancer. In this figure, t_2-t_0 is the duration of the preclinical screen-detectable period, known as the “sojourn time”; t_2-t_1 is the amount of time by which the diagnosis is advanced by screening, known as the “lead time.” Under the assumption of an exponential distribution of sojourn time, the expected lead time of an individual screen-detected case is equal to the mean of the distribution of the sojourn time.

Figure 2 Lead-time bias. In this figure, D_x is the time of diagnosis. Note that the screen-detected cases and the cases diagnosed with symptoms each die at the same time, but the survival time looks greater in the screen-detected case because of lead-time bias.

Figure 3 Length bias. In this figure, the horizontal lines represent the sojourn times of individual tumors detected in a screening program. The two screening examinations detect six out of eight long sojourn time tumors, but only two out of six short sojourn time tumors.

Chapter 39: Nexgen pathology: predicting clinical course and targeting disease causation

Figure 1 Integrated approach to disease management: translating data into knowledge.

Figure 2 (a, b) Cellular profiling. The microscope became the innovative device that allowed Dr. Rudolf Virchow (1821–1902) to describe the cell as the unit of life and main target of disease. Disease classification based on histogenesis was developed. Hematoxylin and eosin (H&E) of bladder cancer histological sections; upper microphotograph illustrating a papillary noninvasive transitional cell carcinoma; lower microphotograph illustrating a transitional cell carcinoma *in situ* of the urinary bladder.

Figure 3 Molecular pathology. Integration of histological, immunochemical, and genetic approaches defines the nature of molecular profiling. Phenotype and genotype are integrated using low- and high-throughput technologies, including histology, protein studies, and nucleic acid analyses. The use of microarray technologies allows the interrogation of multiple analytes on a single assay. H&E: hematoxylin and eosin stain; IHC: immunohistochemistry; WB: western blot; NB: northern blot; SB: southern blot; PCR: polymerase chain reaction; RFLP: restriction fragment length polymorphism; F/U: follow-up.

Figure 4 (a–e) A molecular approach to disease classification: bladder cancer as a model. Bladder tumors present as initial clinical entities as either papillary noninvasive (Ta) tumors that tend to recur but not to progress to invasion, or noninvasive dysplastic carcinoma *in situ* (Tis) lesions that tend to invade and progress to a clinical aggressive disease and, ultimately, metastasis spread. Multiple technologies, including expression profiling, reveal also a two-stage molecular classification, namely superficial and invasive bladder cancer. Superficial papillary bladder tumors are characterized by mutations affecting oncogenes (e.g., H-RAS, FGFR3, and PI3K), and/or chromosome 9 (9q) deletions; while carcinoma *in situ* tumors are characterized by mutations affecting tumor suppressor genes (e.g., p53, RB, and PTEN).

Figure 5 Systems pathology. A novel diagnostic and predictive oncology platform integrating phenotype and genotype using artificial intelligence and algorithms.

Figure 6 (a–d) An integrated system approach for outcome prediction: prostate cancer as a model. Digital conversion of hematoxylin and eosin stain tissue sections (a) into morphometric images that allows quantification of microanatomical features (e.g., number of glands) (b). Protein multiplexing using antibodies to clinical relevant biomarkers (e.g., androgen receptor or AR,

proliferation index by Ki67 analysis) (c) allows quantitation of biological markers and stratification of patients in clinically significant groups, such as prostate cancer patients with low versus high AR levels.

Figure 7 Characteristics of stem cells versus differentiated cells. Essential characteristics of stem cells include an undifferentiated phenotype, asymmetrical cell division, and self-renewal capacity. Differentiated cells divide through symmetrical division, also known as mitosis. The originating cell after completion of asymmetrical cell division or self-renewal persists and continues its physiological functions; while the originating cell in mitosis disappears through nuclear division and cytokinesis producing two identical daughter cells.

Figure 8 Cancer stem cell model of tumorigenesis and tumor progression. It is our working hypothesis that neoplastic transformation initiates in a somatic tissue stem cell capable of sustaining genetic manipulation, based on down-regulated apoptotic programs and an HLA-negative phenotype that favors escaping immune surveillance. This transformed cancer stem cell undergoes self-renewal as well as asymmetrical cell division, producing differentiated clones that rapidly expand, creating heterogeneous populations of differentiated tumor cells.

Figure 9 Cancer stem cell and chemotherapy resistance. Different models have been postulated to address chemoresistance. The transition model proposes that a state transition develops whereby sensitive tumor changes into a resistant clonogenic neoplasm. The selection model follows a Darwinian hypothesis and proposes that heterogeneous subpopulations exist in the primary, untreated tumor and that while sensitive clones die, resistant clones survive and expand. The stemness model proposes that cancer stem cells represent a small subpopulation of the tumor and that such cancer stem cells are nonresponsive to most conventional agents, and while sensitive cells die, the cancer stem cell compartment expands through self-renewal and new resistant clones to the agent are generated through asymmetrical cell division.

Figure 10 A working model for targeting symptomatology and causation. This model postulates that in order to eradicate cancer two different subpopulations need to be targeted: the differentiated tumor clones and the cancer stem cells. This Figure illustrates distinct approaches to combine anticancer stem cell (anti-CSC) therapies with those targeting differentiated cancer clones, including epigenetic agents that could turn an undifferentiated clone into a differentiated clone, as well as novel agents and targeting the microenvironment.

Chapter 40: Molecular diagnostics in cancer

Figure 1 Validation of antibodies for reverse phase protein lysate arrays (RPPAs). Protein lysates from cell lines have been serially diluted on a nitrocellulose-coated slide followed by probing with monospecific antibodies to phosphorylated Akt and signal detection and amplification. Serial dilution curves are used for quantification purposes. Comparisons to western blotting are demonstrated with an r value of 0.878. Quantification and quality control of staining are represented in the upper right panel.

Chapter 42: Interventional radiology for the cancer patient

Figure 1 Transcatheter arterial chemoembolization performed in a 71-year-old man with unresectable hepatocellular carcinoma. (a) Contrast-enhanced CT scan obtained before chemoembolization shows a large, solitary, hypervascular mass in segment IV of the liver (arrow). (b) Anteroposterior digital subtraction angiography (DSA) of the abdomen shows a replaced right hepatic artery arising from the proximal superior mesenteric artery (arrowhead).

This vessel supplies the hypervascular tumor in the left liver (arrows). (c) C-arm cone-beam CT images obtained during the procedure show tip of 3-French catheter in the distal replaced right hepatic artery (arrowhead) confirming origin of vascular supply to the hepatocellular carcinoma (arrows). (d) C-arm cone-beam CT images obtained after chemoembolization demonstrate retention of iodized oil throughout the lesion.

Figure 2 Transhepatic ipsilateral right portal vein embolization (PVE) extended to segment IV using Tris-acryl particles and coils performed in a 52-year-old man with rectal cancer metastatic to the liver. (a) CT scan obtained before PVE shows marginal future liver remnant (FLR) [FLR-to-TELV (total estimated liver volume) ratio = 17%] (arrows). (b) Anteroposterior DSA portogram shows a 6-French vascular sheath in a right portal vein branch (arrowheads) and a 5-French flush catheter within the main portal vein (arrow). (c) Final DSA portogram shows occlusion of the portal vein branches to segments IV through VIII with continued patency of the vein supplying the left lateral liver. (d) CT scan obtained 1 month after right PVE extended to segment IV shows substantial FLR hypertrophy (FLR-to-TELV ratio = 27%) (arrows). The degree of hypertrophy is 10%.

Figure 3 Percutaneous radiofrequency (RF) ablation performed in a 62-year-old man with biopsy-proven renal cell carcinoma. (a) Contrast-enhanced CT image obtained before RF ablation shows an enhancing mass in the left kidney (arrowhead). (b) CT image obtained with patient in prone position at RF ablation shows single needle electrode in tumor (arrow). (c) Contrast-enhanced CT image obtained after RF ablation shows no residual enhancement in the treated kidney (arrowheads).

Chapter 43: Principles of surgical oncology

Figure 1 Robotic enucleation of insulinoma in the body of the pancreas.

Figure 2 Previously unresectable (involvement of all three hepatic veins) intrahepatic cholangiocarcinoma downstaged using neoadjuvant gemcitabine and cisplatin.

Figure 3 Appropriate and inappropriate biopsy incisions. (a) A patient with a cruciate-shaped biopsy scar overlying the patellar tendon that contained a synovial sarcoma. Note the erythema in this infected incision. This ill-conceived biopsy scar would have required a wide-field soft tissue and osseous composite resection to encompass all of the violated tissue planes. Unfortunately, tumor was *intruded* into the joint space at the time of this biopsy, and this patient ultimately required an above-knee amputation to treat this small, otherwise limb-salvageable sarcoma. (b) An appropriately oriented incisional biopsy scar in the lower extremity. Note the alignment of the scar parallel with the long axis of the extremity and the meticulous placement of small biopsy wound sutures. The entire scar could be excised at surgery (blue ellipse) with minimal concomitant normal tissue sacrifice.

Chapter 44: Principles of radiation oncology

Figure 1 **Effects of radiotherapy at the tissue level are graphically represented.** The solid sigmoid-shaped curves denote idealized probability of tumor control and normal tissue complication risk. The dashed curves denote these same predicted effects following administration of drugs that modulate radiation sensitivity.

Figure 2 An overview is displayed for molecular responses that occur after radiation exposure.

Chapter 55: Pharmacology

Figure 1 Example of E_{\max} model as proposed by Wagner. The maximum effect is 100%, and a concentration of six results in 50% effect. The exponent H , also known as the Hill constant, determines the shape of the curve and is usually between 1 and 2.

Figure 2 Pharmacodynamic plots for drugs with (a) nonsaturable and (b) saturable effects. In the simplest pharmacodynamic model (a), there is a linear relationship between dose and log kill. In (b) there is a maximal effect, resulting in a plateau in the dose-response curve. Abbreviation: SF, survival fraction.

Figure 3 Concentration-time plot for 1-compartment linear pharmacokinetic model. C_0 represents the initial concentration, assuming instantaneous administration and distribution. The half-life is $\log_e(2)/k$. Abbreviation: V , volume of distribution.

Figure 4 Concentration-time plots for representative 2-compartment (a) and 3-compartment (b) linear pharmacokinetic models. The two curves are very similar, with $C_0 \sim 10$ for both models. Note that for each “compartment” there is one term, and the corresponding half-life equals $t_{1/2} \log_e(2)/k^n$, where k^n is the n th term.

Chapter 56: Folate antagonists

Figure 1 Structure of folic acid and structurally related classical antifols, AMT and MTX. (a) Folic acid (pteroylglutamic acid; PGA). (b) Aminopterin (4-amino-PGA). (c) Methotrexate (4-amino- N -10-methyl PGA).

Figure 2 Primary site of action of MTX and MTX(glu) $_n$. MTX enters cells by either the reduced folate carrier (1) or the membrane folate-binding protein (2). MTX is then metabolized by the cytosolic enzyme folylpolyglutamate synthetase (3) to MTX(glu) $_n$, a potent inhibitor of dihydrofolate reductase (DHFR) (4). MTX(glu) $_n$ can be hydrolyzed to MTX by the lysosomal enzyme γ -glutamyl hydrolase (GGH) (5). Abbreviations: CH_2FH_4 , N_5 , N^{10} -methylene tetrahydrofolate; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate/deoxyuridyate; FH_2 , dihydrofolate; FH_4 , tetrahydrofolate; MTX, methotrexate; MTX(glu) $_n$, MTX polyglutamates.

Figure 3 Catabolism of MTX. MTX (a) can be converted in the liver to 7-OH MTX (b). In addition, enteric bacteria will cleave the molecule to dAMPA plus glutamate (c).

Figure 4 Novel folate antagonists of clinical interest.

Chapter 57: Pyrimidine and purine antimetabolites

Figure 1 Uracil/thymine antimetabolites. (a) Natural occurring pyrimidine bases uracil and thymine together with the uracil deoxyribonucleoside (2'-deoxyuridine). (b) Antimetabolites 5-fluorouracil and 5-fluoro-2'-deoxyuridine developed from structural modifications of uracil and 2'-deoxyuridine.

Figure 2 Metabolism and sites of action of 5-fluorouracil. The catabolic (to left of FU) and the anabolic (to right of FU) pathways that 5-FU may enter. Approximately 85% of administered 5-FU is catabolized via the rate-limiting enzymatic step (DPD) to dihydrofluorouracil (FUH_2) and then to fluoroureaidopropionic acid (FUPA) and finally 2-fluoro- β -alanine (FBAL) with only 1–3% being anabolized (the rest being excreted into the urine). 5-FU is anabolized to nucleosides and then nucleotides as shown (these metabolites and the enzymatic steps are described in more detail

in Refs). The three primary sites of action are shown and include (1) inhibition of thymidylate synthase (TS) by the 5-fluoro-2'-deoxyuridylate (FdUMP) in the presence of 5,10 methylene tetrahydrofolate (5,10 CH₂THF); (2) incorporation of 5-fluoro uridylate triphosphate (FUTP) into RNA; and (3) incorporation of 5-fluoro-2'-deoxyuridylate triphosphate (FdUTP) into DNA, which in turn is removed by uracil glycosylase causing DNA fragmentation.

Figure 3 Structure and activation of capecitabine. The prodrug capecitabine is converted into 5-FU by three enzymatic steps carboxylesterase, cytidine deaminase, and uridine (or thymidine) phosphorylase. Intermediate metabolites include 5'-deoxyfluorocytidine (5'dFCR) and 5'-deoxyfluorouridine (5'dFUR).

Figure 4 Cytidine/deoxycytidine antimetabolites. (a) Natural occurring cytosine nucleosides cytidine and deoxycytidine. (b) Antimetabolites cytosine arabinoside, 5-azacytidine, decitabine, and gemcitabine developed from structural modifications of the sugar of the cytosine nucleosides.

Figure 5 Metabolism and sites of action of ara-C. The metabolic pathway used by ara-C. Ara-C is activated to ara-CTP by the sequential action of three kinases: deoxycytidine kinase (*dC kinase*), deoxycytidine monophosphate kinase (*dCMP kinase*), and nucleotide diphosphate kinase (*NDP kinase*). Ara-C is inactivated by both cytidine deaminase (*CdR deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also listed are the sites of action of ara-C.

Figure 6 Metabolism and sites of action of 5-azacytidine. The metabolic pathway used by 5-AC. 5-AC is initially activated by the sequential action of deoxycytidine kinase (*dC kinase*) and deoxycytidine monophosphate kinase (*dCMP kinase*) to 5-ACDP. This can then be converted into 5-ACTP by nucleotide diphosphate kinase (*NDP kinase*) or into 5-AdCDP by the action of ribonucleotide reductase (*Rib Red*). 5-AdCDP can then be converted into 5-AdCTP by *NDP kinase*. 5-AC is inactivated by both cytidine deaminase (*dC deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also listed are the sites of action of 5-AC.

Figure 7 Metabolism and sites of action of gemcitabine (dFdC). The metabolic pathway used by gemcitabine (dFdC). Initially, dFdC must be activated to dFdCTP by the sequential action of three kinases: deoxycytidine kinase (*dC kinase*), deoxycytidine monophosphate kinase (*dCMP kinase*), and nucleotide diphosphate kinase (*NDP kinase*). Similar to ara-C, dFdC is inactivated by both cytidine deaminase (*dC deaminase*) and deoxycytidine monophosphate deaminase (*dCMP deaminase*). Also shown are the sites of action of dFdC.

Figure 8 Hypoxanthine/guanine antimetabolites. (a) Natural occurring purine bases hypoxanthine and guanine. (b) Antimetabolites 6-mercaptopurine and 6-thioguanine developed from structural modifications of hypoxanthine and guanine as well as nelarabine a pro-drug of the dexoyguanosine antimetabolite 9-β-D-arabinofuranosylguanine (ara-G).

Figure 9 Metabolism and sites of action of 6-mercaptopurine (6-MP) and 6-thioguanine (6-TG). 6-MP is converted into 6-thioinosine monophosphate (TIMP) and 6-TG is converted into 6-thioguanine ribonucleotide monophosphate (6-TGMP) by hypoxanthine guanine phosphoribosyltransferase (*HGPRT*) in the presence of PRPP. TIMP is active by inhibiting *de novo* purine biosynthesis at three steps: (1) inhibiting formation of inosine monophosphate (IMP) from glutamine and PRPP, (2) inhibiting conversion of IMP into AMP, and (3) inhibiting conversion of GMP into AMP. Through the sequential activation of nucleotide kinases, 6-TGMP can be eventually converted into the ribonucleotide diphosphate (6-TGDP) and then ribonucleotide triphosphate (6-TGTP). 6-TGTP is active following incorporation into both RNA and DNA, resulting in a disturbance of nucleic acid function.

[Figure 10 Metabolism and sites of action of nelarabine. Nelarabine is a prodrug that following intravenous administration is undergoes O-demethylation in the blood by adenosine deaminase \(*Ade deaminase*\) to Ara-G. Ara-G then transported into cells by nucleoside transporters where it is converted by deoxyguanosine kinases \(*dGua kinase*\) into the monophosphate, ara-GMP, and then through the sequential action of nucleotide kinases, dGMP kinase and NDP kinase, to the active metabolite ara-GTP. Also shown are the sites of action ara-GTP.](#)

[Figure 11 Adenosine antimetabolites. \(a\) The natural occurring purine base adenosine. \(b\) The antimetabolites fludarabine monophosphate, cladribine, and clofarabine developed from structural modifications of adenosine. In addition \(although not discussed in this chapter\), pentostatin, an adenosine analog first isolated from fermentation broths of *Streptomyces antibioticus*, is shown for comparison as it corresponds to the transitional form of adenosine in the adenosine deaminase reaction.](#)

[Figure 12 Metabolism and sites of action of fludarabine \(FAraAMP\). Following intravenous administration, FAraAMP is dephosphorylated in the blood by ubiquitous phosphatases to FAra-A. FAra-A is then transported into cells by nucleoside transporters where it is reconverted by deoxycytidine kinase \(*dCR kinase*\) into the monophosphate, FAra-AMP, and then through the action of nucleotide kinases \(*dAMP kinase and NDP kinase*\) converted into the active metabolite FAra-ATP. Listed are the sites of action for FAra-ATP.](#)

[Figure 13 Metabolism and sites of action of cladribine. Following intravenous administration, cladribine is transported into cells by nucleoside transporters where it is reconverted by deoxycytidine kinase \(*dCR kinase*\) into the monophosphate, 2CFara-AMP, and then through the action of nucleotide kinases \(*dAMP kinase and NDP kinase*\) to the active metabolite 2CFara-ATP. Also listed are the sites of action ara-2CFara-ATP.](#)

Chapter 58: Alkylating agents and platinum antitumor compounds

Chapter 59: DNA topoisomerase targeting drugs

[Figure 1 Topoisomerase molecular mechanisms. \(a–c\) Topoisomerases I \(Top1 for nuclear DNA and Top1mt for mitochondrial DNA\) relax supercoiled DNA \(a\) by reversibly cleaving one DNA strand, forming a covalent bond between the enzyme catalytic tyrosine and the 3'-end of the nicked DNA \(the Top1 cleavage complex: Top1cc; b\). This reaction allows the swiveling of the broken strand around the intact strand. Rapid religation allows the dissociation of Top1 \(c\). \(d–f\) Topoisomerases II act on two DNA duplexes. They act as homodimers, cleaving both strands by forming a covalent bond between their catalytic tyrosine and the 5'-end of the DNA break \(Top2cc; e\). This reaction allows the passage of the intact duplex through the Top2 homodimer \(red dotted arrow; e\). Top2 inhibitors trap the Top2cc and prevent the normal religation \(f\). Topoisomerase cleavage complexes \(b and d\) are the targets of topoisomerase inhibitors.](#)

[Figure 2 Trapping of topoisomerase cleavage complexes by interfacial inhibition. \(a\) Binding of camptothecin and non-camptothecin Top1 inhibitors \(green rectangle\) at the cleavage site generated by the Top1. A single-drug molecule binds reversibly to the Top1cc by stacking against the bases flanking the cleavage site \(intercalation\) and by a network of hydrogen bonds with Top1 \(orange circles and dashed green lines\). \(b\) Same for etoposide with a single-drug molecule \(green\) intercalated in the cleavage site formed by each Top2 monomer. Hydrogen bonds with Top2 are shown as orange circles and dashed green lines.](#)

[Figure 3 Clinical topoisomerase inhibitors. \(a\) Camptothecin derivatives are instable at physiological pH, with formation of a carboxylate derivative within minutes. Irinotecan is a prodrug, which needs to be converted to SN-38 to trap Top1cc. \(b\) Non-camptothecin indenoisoquinoline derivatives in clinical trials. \(c\) Anthracycline derivatives. \(d\) Demethylepipodophyllotoxin derivatives. \(e\) Mitoxantrone. \(f\) Dexrazoxane, which acts as a catalytic inhibitor of Top2.](#)

Chapter 60: Agents targeting microtubules and mitotic processes

[Figure 1 Schematic model of the \$\alpha/\beta\$ -tubulin dimer with the monomers represented by shades of gray and white. The dimers associate linearly to form protofilaments that then in turn associate laterally to form the hollow cylindrical wall of the microtubule. Protofilaments can twist slowly around the microtubule axis, although these shown here are in parallel as in microtubules containing 13 protofilaments. Throughout most of the microtubule, lateral contacts involve \$\alpha\$ - \$\alpha\$ and \$\beta\$ - \$\beta\$ monomer interactions. Monomers of each type thus are in contact along a shallow spiral path around the microtubule.](#)

Chapter 62: Drug resistance and its clinical circumvention

[Figure 1 Alternative cellular responses to cancer therapeutic stress.](#)

Chapter 63: Cytokines, interferons, and hematopoietic growth factors

[Figure 1 In addition to their effects on hematopoiesis and immunocompetence, “hematopoietic” growth factors influence multiple organ systems, including \(but not limited to\) bone remodeling, cardiorespiratory function, hepatic function, and the gastrointestinal tract.](#)

Chapter 64: Monoclonal serotherapy

[Figure 1 Recurrent melanoma, unresponsive to radiotherapy, before immunotherapy with intralesional injections of human monoclonal antibody to GM2 or GD2.](#)

Chapter 65: Vaccines and immunostimulants

[Figure 1 Multiple immunogenic consequences of radiation therapy, chemotherapy, endocrine deprivation, or small-molecule inhibitors that can be harnessed to promote synergy with immunotherapeutic regimens. These immunogenic consequences of anticancer therapy, ranging from immunogenic cell death to immunogenic modulation, can be exploited to achieve optimal synergy with therapeutic cancer vaccines.](#)

[Figure 2 Working model for understanding T-cell-inflamed versus noninflamed tumor microenvironments with implications for vaccine therapy. The potential reasons for lack of spontaneous immune responses against a subset of tumors despite T-cell infiltration include failed immune activation \(a\) by extrinsic inhibition by PD-L1/PD-1 interactions. This local inhibition may be overcome by blockade with anti-PD-L1/PD-1 checkpoint inhibitor monoclonal antibodies, yielding clinical benefit. Other tumor types, termed “noninflamed,” typically do not respond to PD-L1 inhibition due to lack of potential infiltrating responding T cells. This model suggests that these tumors may be converted to an “inflamed” T-cell-infiltrated phenotype by vaccine regimens \(b\). These T cells may then be further activated by PD-L1/PD-1 blockade.](#)

[Figure 3 Tumor growth rates in patients with metastatic prostate cancer, from four trials with chemotherapy and one with PROSTVAC \(PSA-TRICOM\) \(adapted from data in Refs \). \(a\) Tumor growth rate with no therapy. \(b, blue line\) Chemotherapy-induced initial tumor reduction, but tumor growth rate at cessation of therapy due to toxicity or drug resistance was similar to](#)

pretreatment tumor growth rate. (c, red line) PROSTVAC vaccine reduced tumor growth rate following therapy. Thus, patients who received vaccine showed little if any tumor reduction (and virtually no increase in time to progression), but showed an increase in overall survival. (d, green line) Predictions of enhanced overall survival for patients treated with both vaccine and cytotoxic therapy. Combination therapy couples the reduced tumor burden from cytotoxic therapy with the reduced growth rate from immunotherapy, culminating in both objective clinical responses and increased overall survival. This phenomenon could potentially be further enhanced if vaccine were initiated earlier in the disease process or in patients with low tumor burden. Arrows indicate the initiation of treatment; crosses indicate time of death from cancer.

Figure 4 Antigen cascade. Multiple antigens are released from dying tumor cells that can activate an immune response. (a) Cancer therapy induces death of cancer cells. (b) As these tumor cells die, they release a range of tumor protein antigens (including mutated proteins) that are taken up by scavenger cells called antigen-presenting cells. (c) These antigen-presenting cells then travel to regional lymph nodes where they present these multiple antigens to T cells, initiating or potentiating an antitumor immune response. (d) Activated polyclonal tumor-specific T cells can then traffic to areas of tumor to participate in immune-mediated tumor killing, destroying more cancer cells and further potentiating the cascade.

Chapter 67: Cancer immunotherapy

Figure 1 **Potential targets for immunostimulatory therapies.** The majority of T cell coreceptors that are upregulated upon activation of effector cells are also expressed by regulatory T cell populations and both cell types may be important targets for therapeutic interventions.

Chapter 68: Cancer gene therapy

Figure 1 **Transgenic T-cell receptors.** (a) Transgenic α and β T-cell receptors, which need HLA to recognize the targeted antigen, and (b) chimeric antigen receptors, which recognize the antigen in HLA unrestricted manner. For endodomains, first-generation CAR has only CD3 ζ and second- and third-generation CARs also have costimulatory molecules. scFV, single chain variable fragment.

Figure 2 **Tumor evasion mechanism.** The tumor microenvironment consists of tumor cells and several kinds of immunosuppressive cells, such as T_{reg} and MDSCs. Tumor cells themselves express FasL to induce cytotoxic T lymphocytes (CTLs) apoptosis and PD-L1 to inhibit CTL functions. In addition, they secrete immunosuppressive molecules TGF- α , IL-10, IL4, and IL-13.

Chapter 69: Cancer nanotechnology

Figure 1 Schematic illustration of different nanotherapy strategies in cancer treatment. (a) Nontargeted nanoparticles passively extravasate out of the leaky vasculature for tumor accumulation through the EPR effect. The drug molecules may be released from the nanoparticles and diffuse throughout the tissue for bioactivity. (b) For active tumor cell targeting, the nanoparticles are modified with targeting ligands, which recognize receptors present on tumor cell surface. The receptor-mediated endocytosis leads to enhanced accumulation and cell uptake of nanoparticles. (c, d) By incorporating ligands that bind to the receptors on the surface of endothelial cells (c) or stromal/immune cells (d), nanoparticles can actively target tumor microenvironment for cancer therapy. (e) Some nanoparticles can generate heat under an alternating magnetic field or laser irradiation for cancer hyperthermia therapy. (f) Some nanoparticles become therapeutically active by releasing the payloads under either endogenous

stimuli (e.g., pH, enzyme, and redox) or exogenous stimuli (e.g., light, heat, magnetic field, or ultrasound).

Chapter 70: Hematopoietic cell transplantation

Figure 1 Scheme of allogeneic hematopoietic transplantation. The recipient receives a myeloablative preparative regimen designed to eradicate malignant and normal cells. The recipient then receives donor hematopoietic cells that restore hematopoiesis. Abbreviations: D, donor hematopoietic cells; HSCT, hematopoietic stem cell transplant; R, recipient's normal bone marrow cells; RL, recipient's leukemia cells in bone marrow.

Figure 2 Scheme of nonablative allogeneic hematopoietic transplantation. Abbreviations: D, donor hematopoietic cells; DLI, donor lymphocyte infusion; HSCT, hematopoietic stem cell transplant; R, recipient's normal bone marrow cells; RL, recipient's leukemia cells in bone marrow.

Chapter 71: Principles of pediatric oncology

Figure 1 Distribution of pediatric cancer diagnoses by age group. Abbreviations: ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; RMS, rhabdomyosarcoma; STS, soft tissue sarcoma.

Figure 2 Five-year survival rates for all cancers by age group and period of diagnosis from 1975–2002. Source: Smith et al. 2010.⁵ Reprinted with permission. © 2010 American Society of Clinical Oncology. All rights reserved.

Figure 3 Computed tomographic (CT) imaging characteristics of common childhood abdominal tumors. (a) Wilm's tumor: axial contrast-enhanced CT images of the abdomen showing a large well circumscribed heterogeneous left renal mass that does not cross the midline. (b) Neuroblastoma: axial contrast-enhanced CT images of the abdomen demonstrating a large lobulated heterogeneous mass in the right upper quadrant that crosses the midline with characteristic encasement of aorta and displacement of superior mesenteric vein, splenic vein, and pancreas anteriorly. Dense calcifications are present within the mass.

Figure 4 MRI imaging findings of common pediatric brain tumors. (a) Axial T1 image with contrast showing a midline tumor in the cerebellum, and pathology consistent with medulloblastoma. (b) T1-weighted axial MRI image with contrast of typical pilocytic astrocytoma in the cerebellum of a 5-year-old child showing heterogeneously enhancing mural nodule and intratumoral cysts, dilated temporal horns bilaterally suggestive of hydrocephalus. (c) T2-weighted sagittal view showing diffuse enlargement of pons in a patient with diffuse intrinsic pontine glioma.

Chapter 74: Disparities in cancer care

Figure 1 Age-Adjusted Cancer Mortality Rate 1990–2010 by 1990 OMB racial/ethnic category. Note: Age-adjusted mortality rates have declined significantly over the past 20 years for all but Native American/Alaskan Natives. The Native American/Alaskan Native (NA/AN), Hispanic and Asian-Islander (API) death rates are lower rates compared to Whites who have lower rates than Blacks. This graph uses the category Asian-Pacific Islander, which was the category used until 2000. Native Hawaiians are included in the Native American/Alaskan Native Category.

Chapter 75: Neoplasms in acquired immunodeficiency syndrome

Figure 1 Cutaneous Kaposi sarcoma in a white patient with advanced HIV disease. The

violaceous plaques on the chest are of characteristic appearance. These lesions entirely resolved on paclitaxel chemotherapy and antiretroviral medication.

Figure 2 Kaposi sarcoma in an African American male with HIV-1 infection. Skin tone can make the lesions less readily distinguishable from other cutaneous processes and quite distinct from the appearance in lighter skinned individuals.

Figure 3 Lower extremity involvement by Kaposi sarcoma can result in marked edema and limited mobility. This patient had pedal edema that had limited response to chemotherapy despite marked improvement in the circumferential Kaposi sarcoma.

Figure 4 Treatment schema for patients with Kaposi sarcoma. Abbreviations: HAART, highly active antiretroviral therapy; IFN- α , interferon- α ; IL, interleukin; VBL, vinblastine; XRT, radiation therapy.

Chapter 76: Cancer survivorship: new challenge in cancer medicine

Figure 1 Cancer control continuum—elaborated.

Figure 2 Estimated and projected number of cancer survivors in the United States from 1977 to 2022 by years since diagnosis.

Chapter 77: Primary and metastatic neoplasms of the brain in adults

Figure 1 Glioblastoma. This is a postgadolinium T1-weighted MRI of a right posterior frontal glioblastoma. There is irregular contrast enhancement with focal areas of necrosis.

Figure 2 Anaplastic oligodendroglioma. (a) FLAIR image showing extensive tumor infiltrating the right hemisphere. (b) Patchy enhancement is seen throughout the tumor.

Figure 3 Low-grade glioma. (a) FLAIR image demonstrating extensive infiltrative disease predominantly of the left frontal lobe extending across the anterior corpus callosum and involving the deep right frontal white matter. (b) Postcontrast images show no evidence of enhancement of this large lesion.

Figure 4 Low-grade glioma. This is an FDG PET image of a left temporal low-grade glioma showing an area of focal hypermetabolism that corresponded to a focal area of anaplasia.

Figure 5 PCNSL. Pre-gadolinium (a) and postgadolinium (b) images of a right frontal diffusely enhancing PCNSL. Note the edema that surrounds the enhancing mass.

Figure 6 Meningioma. A coronal postgadolinium MRI of a multilobulated meningioma extending below and above the tentorium. There is a second lesion in the left occipito-parietal cortex.

Figure 7 Pathophysiology of the metastatic process. Metastasis is a multistep process. In this illustration: (A) malignant neoplasm arises in an organ distant from the central nervous system and, as it grows, it develops its own vascular supply. (B) Clone(s) of malignant cells with metastatic potential enter blood or lymph channels and eventually reach the venous circulation. (C) The malignant cells enter the right heart with the venous circulation and either exit through the pulmonary artery to the lung (D), or cross a patent foramen ovale (D), to enter the systemic circulation. Most tumors that enter the lung either arrest in the pulmonary capillary bed, grow as pulmonary metastases and subsequently seed the pulmonary venous circulation, or, alternately, (E), transverse the pulmonary vascular bed without arresting (E), to enter the pulmonary venous circulation. Malignant clones in the pulmonary venous circulation then enter the left heart and exit into the systemic circulation (F), along with those cells that may have crossed a patent foramen

ovale (F). Once in the systemic circulation, the likelihood of entering the cerebral circulation is high because, in the resting state, 15–20% of cardiac output supplies the central nervous system. Tumor cells entering the cerebral circulation must then arrest in brain capillaries or venules, cross the vessel wall, and grow within the brain (G, H).

Figure 8 Metastatic small-cell lung cancer before and after radiation therapy. (a) The T1-weighted image before radiation shows two of the multiple contrast enhancing metastases; the larger is surrounded by hypointense brain edema. (b) The T2-weighted image before radiation shows hyperintense edema surrounding the relatively hypointense tumor. (c, d) MRI scans after radiation show an excellent response to radiation therapy.

Chapter 78: Neoplasms of the eye

Figure 1 Artistic rendition of molecular mechanism of retinoblastoma gene action.

Figure 2 Advanced orbital presentation of retinoblastoma.

Figure 3 Leukocoria (white pupillary reflex) caused by retinoblastoma. The tumor can be seen in the vitreous. There are seeds in the anterior chamber, anterior to the iris.

Figure 4 (a) An example of the typical patient undergoing intra-arterial chemotherapy. The globe is full of retinoblastoma with a total retinal detachment visible behind the lens. (b) Fundus photograph before intra-arterial chemotherapy. Note that the large tumor is obscuring the optic nerve head. (c) Fundus photograph after intra-arterial chemotherapy. The tumor has become calcified and there are no vitreous seeds visible. The optic nerve head can now be visualized above the tumor. The retina is flat.

Figure 5 Choroidal nevus located inferior to the macula. Note the yellow drusen indicating benign status.

Figure 6 Malignant melanoma of the choroid.

Figure 7 Adenoid cystic carcinoma of the lacrimal gland in a patient who underwent 2 biopsies of the mass, both of which were equivocal. The patient developed metastases to the parotid gland and later died.

Chapter 79: Neoplasms of the endocrine glands: pituitary neoplasms

Figure 1 A 38-year-old woman with an ACTH-secreting adenoma. (a) Coronal T1-weighted magnetic resonance with contrast demonstrates a hypointense macroadenoma within the sella that extends into the left cavernous sinus and encases part of the carotid artery. (b) Sagittal T1-weighted magnetic resonance with contrast demonstrates a hyperintense macroadenoma within the sella.

Figure 2 (a) Hardy's classification of pituitary adenomas. Grade I and II are enclosed within the sella. Grades III and IV are invasive. Extrasellar classifications A, B, and C are increasing amounts of direct suprasellar adenomas. D is asymmetric extension, and E is lateral extension into the cavernous sinus. Source: Adapted from Hardy J and Somma M.⁶ (b) Knosp classification of cavernous sinus invasion.

Figure 3 A 52-year-old male with diminished libido and a macroprolactinoma. (a) Sagittal T1-weighted magnetic resonance with contrast demonstrates a large sellar/suprasellar adenoma with compression of the optic chiasm. (b) Sagittal T1-weighted with contrast demonstrates a significant reduction in tumor volume after being treated medically with bromocriptine.

Chapter 80: Neoplasms of the thyroid

[Figure 1 Pathologic features of thyroid carcinoma. \(a\) Papillary carcinoma, with characteristic fibrovascular papillary formation, crowded nuclei, and nuclear clearing. \(b\) Follicular variant of papillary carcinoma, with typical cells of papillary carcinoma in follicular formations. \(c\) Tall cell variant of papillary carcinoma, with cells at least twice as tall as they are wide and eosinophilic cytoplasm. \(d\) Follicular carcinoma, demonstrating invasion across a thick capsule into neighboring thyroid. \(e\) Medullary thyroid carcinoma, with nests of spindle-shaped cells. Such nests are often interspersed with clusters of round-to-oval cells. \(f\) Anaplastic carcinoma, showing large, discohesive, pleomorphic tumor cells.](#)

Figure 9 **Computed tomography of a 60-year-old male with large HCC.** (a, b) A 15 cm in diameter HCC involving left lobe, right anterior sector and abutting the right hepatic vein. (c) After treatment with Platinum Interferon, Adriamycin, 5-flourouracil, and transarterial chemoembolization. (d) After extended left hepatectomy including resection of the caudate lobe and the inferior vena cava. The patient is alive without evidence of disease 8 years after surgery.

Figure 10 Gross classification of intrahepatic cholangiocarcinoma.

Figure 11 (a) Typical ring enhancement in enhanced CT scan and (b) gross appearance of intrahepatic cholangiocarcinoma.

Chapter 92: Gallbladder and bile duct cancer

Figure 1 Patterns of lymphatic drainage from the gallbladder. (A) The main pathway of lymphatic drainage and, thus, lymph node metastasis from gallbladder cancer is to the cholecysto-retropancreatic nodes. This pathway drains from the gallbladder to nodes along the cystic duct and common bile duct and then to nodes posterior to the duodenum and pancreatic head. (B) The cholecysto-celiac pathway courses from the gallbladder through the gastrohepatic ligament to celiac nodes. (C) The third lymphatic drainage route is the cholecysto-mesenteric pathway, coursing from the gallbladder posterior to the pancreas to aortocaval lymph nodes.

Figure 2 High-resolution, helical CT scan in a patient with gallbladder carcinoma. Direct tumor invasion into the hepatic parenchyma is evident.

Figure 3 A high-resolution, helical CT scan in another patient with gallbladder cancer. A locally invasive tumor is again noted with areas of calcification (arrow) seen in the thickened gallbladder wall.

Figure 4 Algorithm to guide surgical decision making for patients with gallbladder cancer.

*Regional lymphadenectomy includes complete dissection and removal of the cystic, pericholedochal, pancreaticoduodenal, gastrohepatic, and paraortic lymph nodes.

Figure 5 The distribution of 294 cholangiocarcinomas into intrahepatic, perihilar, and distal subgroups.

Figure 6 High-resolution, helical CT scan during the arterial contrast phase in a patient with an intrahepatic cholangiocarcinoma. The periphery of the tumor (arrow) has irregular margins and enhances with contrast. A relatively hypovascular area of scar and tumor necrosis is evident in the center of the tumor.

Figure 7 High-resolution, helical CT scan in another patient presenting with obstructive jaundice. The tumor mass (a), (large arrow) producing marked intrahepatic biliary duct dilatation is evident. Areas of tumor invasion of the portal vein (b), (small arrows) suggested on the CT scan were confirmed at the time of operation to be tumor invasion of the portal vein.

Figure 8 High-resolution, helical CT scan in a patient presenting with several months of increasing pruritus followed by the development of clinically evident jaundice. The relatively hypodense hilar cholangiocarcinoma (large arrow) is evident. Marked atrophy of the left hepatic lobe is noted with dilated intrahepatic bile ducts (small arrow), but little remaining hepatic parenchyma is evident.

Figure 9 Endoscopic retrograde cholangiopancreatography showing a focal stricture of the proper hepatic bile duct (arrow) with marked dilatation of the intrahepatic bile ducts. This hilar cholangiocarcinoma was completely resected with Roux-en-Y hepaticojejunostomy reconstruction of biliary-enteric continuity.

Figure 10 Bismuth–Corlette classification of hilar cholangiocarcinoma. Types I and II can be resected with excision of the extrahepatic bile duct with or without the hilar plate and caudate lobe. Types IIIA and IIIB can be resected with the addition of an en bloc right or left hepatic lobectomy, respectively. Type IV is, by definition, unresectable.

Chapter 93: Neoplasms of the exocrine pancreas

Figure 1 Schematic presentation of known and suspected risk factors for pancreatic cancer.

Figure 2 Stromal desmoplasia in pancreatic ductal adenocarcinoma. Infiltrating neoplastic glands (white arrows) are surrounded by a florid host response, comprised spindle-shaped cancer-associated fibroblasts and myofibroblasts (red arrowheads) and extracellular matrix, including collagen 1 (black arrow).

Figure 3 Contrast-enhanced computed tomography scan demonstrating a resectable adenocarcinoma of the pancreatic head. The low-density tumor is easily seen in the pancreatic head. Note the absence of tumor extension to the superior mesenteric artery (SMA) (small arrow); there is a normal fat plane between the low-density tumor and the SMA. However, the tumor (area of low density) does extend to the superior mesenteric vein (SMV) just inferior to the tip of the large arrow. This patient may require venous resection and reconstruction at the time of pancreaticoduodenectomy. This subtle finding would not be apparent on a lesser quality scan. The intrapancreatic portion of the common bile duct contains a stent that was endoscopically placed for biliary drainage.

Figure 4 Contrast-enhanced computed tomography scan demonstrating an unresectable adenocarcinoma of the pancreatic head and uncinate process. The low-density tumor is inseparable from the posterior wall of the SMA (small arrow). Direct intraoperative assessment of the extent of retroperitoneal tumor growth in relation to the SMA is not possible until after

gastric and pancreatic transection, at which point the surgeon has committed to resection; accurate preoperative imaging of this vital tumor–vessel relationship is thus critical. The large arrow identifies the SMV.

Figure 5 Endoscopic retrograde cholangiopancreatography demonstrating the smooth tapering common bile duct stricture (arrowhead) seen with biliary obstruction secondary to chronic pancreatitis.

Figure 6 Six surgical steps of pancreaticoduodenectomy.

Figure 7 Illustration of the retroperitoneal margin as defined at the time of tumor resection (a). Medial retraction of the SMV and superior mesenteric-portal vein (SMPV) confluence facilitates dissection of the soft tissues adjacent to the lateral wall of the proximal SMA; this site represents the retroperitoneal margin. Complete permanent-section analysis of the pancreaticoduodenectomy specimen requires that it be oriented for the pathologist to enable accurate assessment of the retroperitoneal margin of excision and other standard pathologic variables. The retroperitoneal margin must be identified and inked with the pathologist (b); it cannot be assessed retrospectively. As shown here, a probe is in both the pancreatic duct and the bile duct, and a Q-tip applicator lies on the indentation of the SMPV confluence. One can then ink (for final pathologic assessment) the soft-tissue margin adjacent to the proximal SMA; this represents the retroperitoneal (or mesenteric) margin of excision.

Figure 8 Venous resection/reconstruction. Illustration of resection of the SMV with splenic vein preservation. The intact splenic vein tethers the portal vein (PV), making a primary anastomosis impossible in most cases. Our preferred method of reconstruction of the SMV is to use an internal jugular vein interposition graft. With the splenic vein intact, exposure is inadequate to separate the specimen from the lateral aspect of the proximal SMA. Therefore, the graft can be placed before specimen removal, thereby allowing medial retraction of the reconstructed SMPV confluence, or after separation of the specimen from the SMA posteriorly. Segmental resection of the SMV with splenic vein preservation adds significant complexity to this operation.

Chapter 94: Neoplasms of the small intestine, vermiform appendix, and peritoneum and carcinoma of the colon and rectum

Figure 1 Extent of resection for colon carcinoma: (a) Cecal or ascending colon cancer; (b) transverse colon cancer; (c) splenic flexure colon cancer; (d) sigmoid colon cancer. Chapter 95: Neoplasms of the anus

Figure 1 Treatment schema for squamous cell cancer of the anal canal.

Chapter 96: Renal cell carcinoma

Figure 1 Normal function of VHL in the normoxic state compared to the aberrant VHL state/hypoxia. Under normal conditions, VHL binds to HIF α and polyubiquitinates it to mark it for destruction in the cellular proteasome. In conditions of hypoxia or when VHL function is lost, HIF α binds HIF β and then translocates into the nucleus to activate HIF responsive elements (HRE). This results in transcriptional activation of genes important in angiogenesis and endothelial stabilization such as VEGF and PDGF.

Chapter 97: Urothelial cancer

[Figure 1 Proposed model for urothelial tumorigenesis and progression. Superficial and invasive tumors have unique molecular profiles and arise from distinct pathways. The locations of molecules indicate events that pose a risk for progression of a particular phenotype. The rare papillary carcinomas that invade are more likely to have genetic alterations at crucial loci. The thickness of arrows represents the relative frequency of occurrence.](#)

[Figure 2 Probability of recurrence-free survival in 164 bladder cancer patients, who underwent radical cystectomy, based on alterations in p53, p21, and/or RB expression. Figure 14 Cowden disease. Multiple trichilemmomas on the upper lip. Similar papules are present on the mucosal surface of the lower lip.

Figure 15 Cowden disease. Translucent keratotic papules on the palmar surface. Source: Courtesy of R.A. Johnson, MD.

Chapter 111: Bone tumors

Figure 1 Survival according to staging by the new American Joint Committee on Cancer staging

system for bone sarcomas.

Figure 2 Enchondroma. Anteroposterior (a) and lateral (b) distal femur radiographs as well as axial (c) and coronal (d) CT scans show the characteristic punctate arcs and rings of hyaline cartilage without prominent endosteal scalloping or cortical destruction to suggest features of chondrosarcoma.

Figure 3 Chondromyxoid fibroma. Anteroposterior shoulder (a) and scapular-Y (b) radiographs, T2-weighted axial (c) and coronal (d) and proton-density axial (e) MRI images show the features of a chondromyxoid fibroma, in this case involving a flat bone, the scapula. Note the cortical thinning and focal cortical destruction that characterizes aggressive behavior and may lead to confusion with chondrosarcoma.

Figure 4 Enostosis (bone island). Anteroposterior (a) and lateral (b) radiographs of the knee show an incidental small radiodense bone lesion. Axial CT (c) shows the characteristic radiating spicules that extend from the periphery of the sclerotic bone island and interdigitate with the surrounding bone trabeculae. As in this case (d), there is usually absence of uptake on bone scan.

Figure 5 Aneurysmal bone cyst. Magnetic resonance images of this radiolucent bone lesion that presented with pain in a 4-year-old show fluid signal characteristics on T1-weighted sagittal images (a), but the septations and fluid–fluid levels characteristic of aneurysmal bone cyst are best seen in this case on the T2-weighted sagittal images (b). Intraoperative fluoroscopic images (c) show that this lesion does not show aggressive features seen with many aneurysmal bone cysts (ballooned-out cortex). This lesion was curetted completely and filled with synthetic graft material (d).

Figure 6 Unicameral bone cyst (simple bone cyst). Plain radiographs of the left humerus of a 9-year-old (a) who has incurred two prior fractures with minimal trauma through this lytic geographic proximal humeral bone lesion abutting the proximal humeral growth plate. At this point, there is evidence of healing within the cyst, which occurs in approximately 1/7th of simple bone cysts after fracture. However, 2 years later (b), the cyst shows signs of recurrence, with increased radiolucency in the mid-diaphysis. Note that the proximal humeral growth plate has grown away from the bone cyst. These lesions are only active during skeletal immaturity.

Figure 7 Langerhans cell histiocytosis (eosinophilic granuloma). This anteroposterior pelvis radiograph (a) of a 4-year-old boy shows a left supra-acetabular lytic bone lesion with moth-eaten borders. Cortical destruction seen on coronal (b) and axial (c) CT scans causes concern for metastatic neuroblastoma or Ewing sarcoma, but biopsy showed sheets of Langerhans cells interspersed with eosinophils. Bone scan (d) showed increased uptake in this lesion, and a skeletal survey was done to exclude other lesions that might not show up on bone scan. In this case, there were only a solitary lesion and no visceral involvement. One year after biopsy and curettage, the lesion is less apparent on radiograph (e), and the patient remains asymptomatic.

Figure 8 Secondary peripheral chondrosarcoma. This 26-year-old woman with underlying multiple osteochondromatosis developed pain and swelling in her right shoulder. Anteroposterior (a) and axillary lateral (b) right shoulder radiographs show numerous osteochondromas arising from the proximal humeral metaphysis but also a large soft-tissue shadow associated with the bone. In addition, particularly on the lateral view, there is cortical irregularity. Magnetic resonance axial T1-weighted (c, e) and T2-weighted (d, f) images show that there is a cartilage cap measuring more than 2 cm thick, indicative of a chondrosarcoma arising from the underlying osteochondroma and extending into the underlying bone as well. (g) Uptake is noted in the right

proximal humerus on bone scan. This patient underwent proximal humeral resection and prosthetic reconstruction.

Figure 9 Conventional osteosarcoma. A 13-year-old girl with right shoulder pain and swelling has shoulder radiographs (a, b) showing a radiodense proximal humeral metaphyseal lesion with permeative borders and Codman triangle periosteal reaction and soft-tissue extension. Coronal T1-weighted (c) and T2-weighted (d) MRI images show the soft-tissue extension and extent of the tumor within the medullary canal. Bone scan (e) shows increased uptake in the proximal humerus. In a young patient, these features are nearly diagnostic of osteosarcoma, and a biopsy confirmed the diagnosis of high-grade osteosarcoma. After neoadjuvant chemotherapy, the patient underwent wide resection and proximal humeral allograft–prosthetic reconstruction (f).

Figure 10 Low-grade central osteosarcoma. This 26-year-old woman was diagnosed with low-grade central osteosarcoma after a prolonged course with pain and swelling over several years. Plain anteroposterior (a) and lateral (b) radiographs show a sclerotic predominately intramedullary lesion of the distal femoral metaphysis. Biopsy showed streaming osteoid separated by a relatively bland fibrous background. Following wide surgical resection, the distal femur was reconstructed with a distal femoral replacement total knee arthroplasty (c).

Figure 11 Secondary chondrosarcoma in osteochondromatosis. A 23-year-old woman with known multiple hereditary exostoses developed pelvic pain. Radiographs were not revealing, but MRI images (a–c) revealed a mass arising from a small osteochondroma on the inner table of the pelvis beginning at the level of the sacroiliac joint and extending to the sciatic notch. Biopsy confirmed low-grade chondrosarcoma. The patient underwent internal hemipelvectomy without reconstruction (d). The pelvis is a common location for development of chondrosarcomas in osteochondromatosis, and regular screening in these patients is advisable.

Chapter 112: Soft tissue sarcomas

Figure 1 Anatomic distribution and site-specific histologic subtypes of 5113 consecutive STSs seen at the University of Texas MD Anderson Cancer Center Sarcoma Center.

Figure 2 Spectrum of grades observed among histologic subtypes of STS.

Figure 3 (a) Weighted T2-fat-saturated magnetic resonance image of a TNM T2b high-grade sarcoma in the posterior thigh compartment of a 55-year-old woman. Note the containment by the superficial fascia overlying the posterior thigh muscles, where there is a “strip” of peritumoral edema. Anteriorly, the lesion can be seen to be separate from the femur, but the edge of the tumor is less clearly defined than its superficial component, presumably because of muscle infiltration. (b) Sagittal MRI of the same patient. The main lesion manifests a well-defined border. However, a clear zone of peritumoral edema is evident tracking proximally toward the head of the femur, seen at the top of the Figure Inferiorly, the edema seems to be even more pronounced as evidenced by the triangular signal enhancement pointing inferiorly. Whether the zone of edema harbors microscopic disease is uncertain, and this uncertainty can complicate accurate treatment planning (see text).

Figure 4 A 57-year-old man with T2 pelvic leiomyosarcoma. (a) Axial T2-weighted fast spin-echo MRI reveals a heterogeneous mass involving the rectum (arrow, air in rectal lumen). (b) Note that the mass abuts right seminal vesicle (arrow).

Figure 5 (a) Coronal fat-saturated gadolinium-enhanced MRI showing a solid liposarcoma, 8.3 cm × 6.6 cm, adjacent to and compressing the upper pole of the left kidney. The mass lies below the

spleen and is separate from the kidney (line of demarcation, arrow), but is part of a larger fatty tumor. The midline vessels are well visualized. (b) CT image of the same lesion. The mass can be seen adjacent to the kidney, as before. An additional mass of fatty attenuation with gray areas of edema, inflammation, or increased cellularity can be seen bounded by a rim anteriorly (arrow). This mass has the appearance of abnormal fat, which must be considered in treatment planning. Note the displacement of the bowel containing contrast. (c) Sagittal MR image of the same case but without gadolinium. The potential advantage of MR imaging in separating the anterior edge of the retroperitoneal sarcoma (long arrow) from the normal fat anteriorly is seen. The more solid component can also be seen (arrowhead) inferior to the spleen. In addition, these images can be exported digitally to a three-dimensional RT treatment planning workstation or CT simulator workstation where the MR images can be fused to the CT planning slices. This can provide more accurate demonstration of tumor in selected cases for contouring the GTV and clinical target volume than may be possible with CT images alone. This is particularly helpful in situations where CT as well as MRI does not show tumor.

Figure 6 Approach for pretreatment evaluation and staging of the patient presenting with a primary extremity soft tissue mass. AJCC, American Joint Committee on Cancer.

Figure 7 (a) The GTV has been contoured on a CT simulator workstation (red outline). This includes the anterior abnormal fat shown earlier (Figure 5b,c). This process is performed with many thin CT slices to permit reconstruction of the image later for three-dimensional treatment planning. The CTV is outlined in yellow to account for potential microscopic spread beyond the GTV. An additional margin will also be added to account for setup variation and organ motion. Note the displacement of the bowel loops by the tumor mass. The straight lines show the path of the beam for a conventional setup with opposed anterior and posterior fields. (b) The contoured GTV and CTV information displayed in a beam's eye view (BEV) using a digitally reconstructed radiograph created by the CT simulator. Shielding (Pb) can be placed once the path of the beam within the target areas defined is seen on the BEV. One can also discern the opaque tumor partially displacing the bowel from target area. (c) A three-dimensional reconstruction with the GTV, CTV, and areas to be shielded (Pb) shown with abdominal wall and anterior structures cut away. Generally, these “cut-away” images are most useful for visualizing the edge of the target volume adjacent to critical anatomy that must be protected and when the spatial relationship cannot be verified precisely with conventional imaging.

Figure 8 A digitally reconstructed radiograph of the head and neck of a young woman with an STS of the right cheek. Because of the proximity to the right eye, preoperative radiotherapy has been chosen because of its ability to permit maximal restriction of the CTV to the local environment of the tumor. The same process was followed using a CT simulator as described in Figure 6. The GTV on the cheek can be seen with the surrounding CTV. Shielding (Pb) is also evident. A hair clip, which the patient was wearing during the CT slice acquisition, is evident in the right parietal area; one can also see her necklace. The smaller inset shows a three-dimensional image of the patient with potential beams applied.

Figure 9 Kaplan–Meier plots for probability of local recurrence, metastasis (local and regional recurrence), progression-free survival, and overall survival in the Canadian Sarcoma Group randomized trial of the NCI of Canada Clinical Trials Group comparing preoperative and postoperative radiotherapy.

Figure 10 Actuarial curves from individual patient data meta-analysis: (a) local recurrence-free interval (RFI), (b) distant recurrence-free interval, (c) overall recurrence-free survival, and (d)

overall survival.

Figure 11 Postmetastasis survival (from time of diagnosis of M1 disease) in a cohort of 230 patients with primary STS of the extremities. The median postmetastasis survival was 11.6 months.

Figure 12 Postmetastasis survival stratified by resection of pulmonary metastatic disease. The median survival among patients undergoing complete resection of pulmonary metastatic disease was 20 months.

Figure 13 Risk and subsequent management of pulmonary metastases in 716 patients with primary or locally recurrent extremity STS.

Figure 14 Schema for approaching the patient with local recurrence of STS. The schema is oriented toward extremity lesions but is equally applicable to other anatomic sites (e.g., head and neck and retroperitoneum). *Abbreviations:* BRT, brachytherapy; EBRT, external beam radiotherapy.

Figure 15 Mutation status of gastrointestinal stromal tumors and location on the KIT or PDGFRA protein.

Chapter 113: The myelodysplastic syndrome

Figure 1 Multiple steps involved in the pathogenesis of MDS affecting a pluripotent hematopoietic stem cell (white circle). Chromosomal abnormalities and ras mutations may occur as early or late events in the pathogenesis of the disease. In younger patients, disease appears to originate in a stem cell committed along a more restricted lineage pathway (●) and is similar to the stem cell origin in some patients with de novo AML. In most patients with MDS, the disease originates from a multipotent stem cell affecting progeny involving multiple hematopoietic lineages (●●). *May result in abnormal gene product; growth dysregulation; loss of growth regulatory factors (e.g., GM-CSF, IL-3, IL-4, IL-5, CSF-1 located on chromosome 5q13–34); loss of growth factor receptors (e.g., cfms, chromosome 5); gene amplification; loss of suppressor genes (e.g., 5q31, 3p, 17p); impaired signal transduction. *Abbreviations:* IL, interleukin; CSF, colony-stimulating factor.

Figure 2 Treatment algorithm for patients with the myelodysplastic syndrome.

Chapter 114: Acute myeloid leukemia in adults: mast cell leukemia and other mast cell neoplasms

Figure 1 Data from ECOG demonstrating that overall survival in AML patients less than age 60 is approximately 40% and varies according to the cytogenetic risk and daunorubicin dose.

Figure 2 M0. Marrow blasts from patients with this undifferentiated type of acute myelogenous leukemia can have variable amounts of agranular cytoplasm. Cells are peroxidase- and Sudan Black-negative and can be confused with FAB M7 or FAB L2. Myeloid commitment of these blasts can be confirmed by immunophenotyping with antibodies against myeloid antigens and/or demonstration of ultrastructural peroxidase-positive granules using transmission electron microscopy.

Figure 3 One of the blasts from a patient with M1 acute myeloid leukemia contains a prominent Auer rod.

Figure 4 M2. Leukemia is characterized by evidence of continued myeloid differentiation with myelocytes and more mature myeloid elements present.

Figure 5 M3. Promyelocytic leukemic cells usually have spherical nuclei with heavily granulated cytoplasm. Extracellular granules are often noted, and blasts with multiple Auer rods (not shown) are common. This leukemia has typical 15;17 translocation and a characteristic clinical picture of disseminated intravascular coagulation.

Figure 6 M4. Myelomonocytic leukemia has blasts with both myeloid and monocytoid appearance.

Figure 7 M5. Monocytic leukemia. Prominent nuclei filled with nucleoli in some cells, light granulation, and large amounts of lightly basophilic cytoplasm give these cells the appearance of promonocytes.

Figure 8 M5. Gingival hypertrophy due to infiltration by leukemic cells in acute monocytic leukemia.

Figure 9 M6. Erythroleukemia is characterized by the presence of bizarre megaloblastic and often multinucleated erythroid precursors. Karyorrhexis is seen in some cells. The somewhat arbitrary distinction between FAB M6 and myelodysplastic syndrome with excess blasts in transformation is made by quantification of the fraction of myeloid blasts.

Figure 10 M7. Megakaryocytic leukemia. Blasts in this category are often morphologically undifferentiated. The presence of multinucleated cells, dysplastic micromegakaryocytes, and cytoplasmic budding can be useful diagnostic clues. The diagnosis is confirmed by immunophenotyping or ultrastructural studies.

Figure 11 Typical granular staining with Sudan Black B of a blast and a neutrophil from a patient with FAB M1 acute myeloid leukemia.

Figure 12 Treatment Groups. In the all-trans retinoic acid (ATRA)–chemotherapy group, the chemotherapy regimen was as follows: idarubicin (IDA) at a dose of 12 mg/m² of body surface area per day on days 2, 4, 6, and 8 of the induction phase; IDA at a dose of 5 mg/m²/day on days 1–4 of the first cycle of consolidation therapy; mitoxantrone (MTZ) at a dose of 10 mg/m²/day on days 1–5 of the second cycle of consolidation therapy; IDA at a dose of 12 mg/m²/day on day 1 of the third cycle of consolidation therapy; and intramuscular or oral methotrexate (MTX) at a dose of 15 mg/m²/week and oral 6-mercaptopurine (6-MP) at a dose of 50 mg/m²/day, alternating with ATRA at a dose of 45 mg/m²/day, for 15 days every 3 months for 2 years. The vertical lines in the induction therapy boxes indicate variability in the duration of remission induction therapy. The arrows indicate the approximate timing and doses of the different chemotherapeutic agents.

Chapter 115: Chronic myeloid leukemia

Figure 1 Survival of patients with newly diagnosed CML in chronic phase referred to MD Anderson Cancer Center (N = 1148; 1965–2010).

Figure 2 Chronic myeloid leukemia. Leukocytosis with myelocytes, metamyelocytes, band cells, and polymorphonuclear leukocytes are characteristics of the peripheral blood in the chronic phase of this disease.

Figure 3 Chronic myeloid leukemia, myeloid blast crisis. The marrow aspiration shows predominance of blast forms, which have a myeloid appearance.

Figure 4 Chronic myeloid leukemia, blast phase. This bone marrow biopsy shows “blasts” with prominent nucleoli comprising about 75% of the marrow cells.

Chapter 128: Skeletal complications

[Figure 1 \(a\) An 81-year-old woman with metastatic breast cancer with a chief complaint of knee pain. Note the destructive lesion in the distal femoral metaphysics above a well-fixed total knee arthroplasty \(b\) A noncontrast CT of the entire femur was obtained, demonstrating an additional destructive lesion in the femoral neck. While the lesion was asymptomatic, it was at high risk of sustaining a displaced pathologic fracture. Significant degenerative changes are also seen in the hip joint. \(c\) and \(d\) The distal femoral lesion was treated with intralesional curettage, internal fixation with a locking plate, and packing with PMMA bone cement. A press-fit long stem total hip arthroplasty was performed to treat the femoral neck lesion and the arthritis. Note the overlap of the two implants that minimize the risk of periprosthetic fracture and protects the entire length of the bone.](#)

[Figure 3 \(a\) A 49-year-old woman with multiple myeloma who sustained a pathologic right proximal humerus fracture. \(b\) The fracture was sufficiently distal to allow the use of a cemented intramedullary nail. Note the cement mantle going up to the proximal diaphysis. Distal interlocking screws were not used as the entire nail is supported by bone cement.](#)

[Figure 2 \(a\) A 67-year-old lady who underwent an intramedullary nailing at an outside institution for a painful lesion in the right femoral neck. No preoperative staging was performed. Femoral canal reamings that were sent to pathology showed metastatic renal cell carcinoma. Note the minimal amount of bone destruction present. A small amount of bone cement was injected along the lag screw at the time of surgery. \(b\) X-rays obtained 6 weeks after surgery show rapid progression of the tumor and destruction of much of the femoral neck and greater trochanter with failure of hardware. \(c\) CT of the pelvis demonstrates a large tumor mass engulfing the proximal femur. \(d\) and \(e\) The patient underwent resection of the tumor, removal of hardware, and a modular proximal femoral replacement. This case underscores the importance of a preoperative staging evaluation of a patient with bone lesions. Had it been performed and the diagnosis of renal cell carcinoma been known at the time of the initial procedure, extensive tumor curettage with an adjuvant and a hemiarthroplasty could have been done, saving the patient from the morbidity of a second more extensive surgical procedure.](#)

[Figure 4 \(a\) A 57-year-old woman with metastatic cancer who sustained a left femoral midshaft diaphyseal fracture. \(b\) and \(c\) The patient underwent resection curettage of the tumor, intramedullary nailing, and packing of PMMA bone cement around the nail into the defect left by the tumor. \(d\) 4 months later, the fracture line over the lateral cortex is no longer visible and bone callus is seen, indicating healing of the fracture. Note the fracture callus forming on the medial side around the cement.](#)

[Figure 5 \(a\) A 69-year-old man with multiple myeloma who sustained bilateral pathologic forearm fractures through one of multiple radiolucent lesions involving much of the length of bilateral radii and ulnae. \(b\) and \(c\) Intramedullary nailing of bilateral radii and ulnae was performed. There was insufficient bone stock to allow fixation of the right distal ulna, so it was resected with minimal functional compromise. Intramedullary nailing was done in a minimally invasive manner and was preferable to fixation with plates and screws that would have required exposure of the entire length of the radius and ulna bilaterally in this already debilitated patient.](#)

Figure 6 (a) A 40-year-old woman with metastatic breast cancer who sustained a subtrochanteric right femur fracture. Note the mixed lytic and blastic changes seen in the femoral head as well as in much of the pelvis. (b) A long-stem cemented hip hemiarthroplasty was performed. A femoral nail would not have been an appropriate choice for this patient as the bone in the femoral head is compromised by metastatic tumor. With an intramedullary nail, risk of lag screw cut-out would have been unacceptably high. The arthroplasty stem serves the same function as a nail in fixing the fracture while the compromised bone in the head of the femur is replaced with the prosthetic head.

Figure 7 (a) A 71-year-old woman with metastatic renal cell carcinoma and a pathologic fracture through a large area of bone destruction in the diaphysis of the humerus. (b) There was not enough bone support for the use of an intramedullary nail or plate and screws, so an intercalary prosthetic replacement was used to reconstruct the defect. Stems cemented into the distal and proximal diaphyseal segments make the construct similar to a fully cemented nail.

Figure 8 (a) A 60-year-old woman who sustained a displaced femoral neck fracture in a fall. Note the subtle cortical irregularity at the lateral border of the acetabulum. (b) Coronal CT shows a large destructive lesion in the supra-acetabular area with destruction of the subchondral plate. Biopsy revealed this to be due to metastatic breast cancer. The femoral neck fracture was not related to the patient's cancer. (c) The patient underwent curettage of the tumor and reconstruction of the defect with a total hip arthroplasty with an acetabular cage. The void left by the tumor was filled with PMMA bone cement.

Figure 9 (a) A 60-year-old woman who sustained a pathologic fracture of her right clavicle through a radiolucent lesion. As a teenager she had a traumatic clavicle fracture that went on to asymptomatic nonunion. (b) Resection of the lateral clavicle, which included the pathologic fracture site, was performed, allowing the patient to return to her baseline status within 2 weeks of surgery.

Figure 10 (a) A 56-year-old woman with metastatic endometrial carcinoma who developed significant lower extremity weakness due to spinal cord compression from a pathologic fracture of the T9 vertebral body. Metastatic deposits in other vertebral bodies are seen. (b) and (c) The patient underwent resection of the T9 vertebral body and fusion with a cage, posterior T8–T10 hemilaminectomy, and instrumentation and fusion from T1 to L1.

Chapter 132: Cardiac complications

Figure 1 Echocardiogram frames of a patient with infective endocarditis involving the mitral valve. (a) Transthoracic 5-chamber image from a patient with suspected infective endocarditis involving the aortic valve. Note significant thickening of the aortic cusps. (b) Transesophageal image from the same patient recorded the same day, more clearly showing the bulky aortic valve vegetation.

Figure 2 Transesophageal echocardiogram demonstrating a large left atrial mass in a patient who presented with angina. Echocardiographic features were consistent with tumor, and pathology was consistent with a pleomorphic myxoid sarcoma.

Figure 3 Electrocardiogram suggesting ischemia in a 26-year-old man with documented (by magnetic resonance imaging) myocardial metastatic disease and no history to suggest other causes of the electrocardiographic abnormality. Note T-wave inversions in the inferior leads (2, 3, and AVF) as well as in the precordial leads (V₄–V₆).

Figure 4 Carcinoid heart disease: (a) two-dimensional four-chamber study showing the thickened

retracted and mal-coapting tricuspid valve leaflets. (b) Image from the same study with color-flow Doppler views showing severe tricuspid regurgitation. Also evident is right atrial and right ventricular chamber enlargement and a small pericardial effusion.

Figure 5 Long-axis echocardiographic view from a patient with cardiac amyloid infiltration. Note thickened septum (S) and posterior wall (P) with stippled appearance (arrows).

Figure 6 Rhythm strip of a patient with episodes of *torsades de pointes*. A previous rhythm strip (not shown) demonstrated prolongation of the QT interval.

Figure 7 An electrocardiogram in a 44-year-old woman during an episode of chest pain while receiving 5-fluorouracil. Acute anterolateral ST elevation was due to coronary vasospasm (a). Electrocardiographic changes normalized shortly after nitroglycerin administration, with resolution of symptoms (b).

Figure 8 Parasternal long-axis echocardiographic view from a 40-year-old patient who received mantle radiation for lymphoma two decades prior. Note the severe thickening and calcification of the aortic and mitral valves. This patient also had severe coronary artery disease, cardiomyopathy, and abnormal pericardial thickening, all likely sequelae of his prior cancer treatment.

Chapter 133: Respiratory complications

Figure 1 Approach to airway obstruction using interventional bronchoscopic therapy.

Figure 2 Left lower lobe collapse secondary to metastatic sarcoma (a and b). Complete obstruction of the LLL basilar segments due to a large obstructing tumor was noted at bronchoscopy (c) which was removed using snare forceps and argon plasma coagulation, revealing a patent distal airway (d).

Figure 3 Complete opacification of the right thorax secondary to obstruction of the right mainstem bronchus by a large, predominantly extraluminal mass (a). A wire stent was placed into the bronchus intermedius (b), resulting in partial reexpansion of the right lung.

Figure 4 Large left-sided pleural effusion causing opacification of the left hemithorax and contralateral shift of the mediastinum (a). Following thoracentesis (b) the mediastinum shifted back the midline.

Figure 5 Large right-sided pleural effusion (a) with ipsilateral shift of the mediastinum following thoracentesis (b), indicating volume loss secondary to atelectasis or mass. A CT scan of the chest (C) demonstrates a large mass compressing the right mainstem bronchus.

Figure 6 Management of malignant pleural effusions (MPE). Patients with chemo- or radiosensitive tumors on initial treatment (lymphoma, breast cancer, small-cell lung cancer, germ cell cancer, ovarian cancer, prostate cancer, and thyroid neoplasms) may be candidates for therapeutic thoracentesis while awaiting systemic treatment results.

Figure 7 Approach to preoperative evaluation for lung resection.

Figure 8 60-year old man presents with a maculopapular rash and progressive dry cough with shortness of breath that developed 12 weeks after starting erlotinib for advanced pancreatic cancer. The extensive, ground glass, and nodular pleural-based infiltrates (a) significantly improved within 2 weeks of discontinuation erlotinib and initiation of systemic steroid therapy (b).

[Figure 9 24-year old woman who developed respiratory distress following abdominal surgery for an unrelated illness 3 months after completing bleomycin-based treatment for Hodgkin's lymphoma. CXR \(a\) and CT scan \(b\) showed bilateral patchy reticulonodular and airspace disease. Work-up was consistent with ARDS associated with bleomycin toxicity, presumably triggered by hyperoxia during surgery.](#)

[Figure 10 CT angiogram showing large central embolus in a patient treated with bevacizumab-based chemotherapy for cholangiocarcinoma \(a\). Associated pulmonary infarct is suggested by the wedge-shaped subpleural density overlying the lateral segment of the right middle lobe \(b\).](#)

[Figure 11 76-year old man who presented with loud snoring, witnessed apneas, and daytime hypersomnolence 9 years following completion of chemoradiation therapy for tonsillar squamous cell carcinoma. BMI at presentation was 22 kg/m². Severe obstructive sleep apnea–hypopnea syndrome with an apnea–hypopnea index of 32 events/hour of sleep and an oxygen saturation nadir of 72% was observed on polysomnography \(5 min view\).](#)

Chapter 134: Gastrointestinal and hepatic complications in cancer patients

[Figure 1 Herpes simplex virus \(HSV\) esophagitis. High-power view of esophageal mucosa shows squamous cells with ground glass nuclear viral inclusions and multinucleated giant cells in a background of neutrophilic exudates.](#)

[Figure 2 Pill-induced esophageal damage. A pill is seen at endoscopy lodged above an esophageal stricture.](#)

[Figure 3 Self-expanding esophageal stent. \(a\) Endoscopic view of a self-expanding stent deployed in the esophagus for treatment of an esophageal stricture. \(b\) Chest radiograph showing stent deployed in the esophagus.](#)

[Figure 4 Pseudomembranous colitis. \(a\) Pseudomembranes adherent to the colonic mucosa seen at colonoscopy. \(b\) Low-power view of colonic mucosa shows a typical volcano \(mushroom\)-like appearance with luminal inflammatory exudates.](#)

[Figure 5 Cytomegalovirus \(CMV\) colitis. \(a\) CMV colitis as seen at endoscopy. \(b\) High-power view of inflamed colonic mucosa demonstrates multiple viral inclusions in stroma cells.](#)

[Figure 6 Graft-versus-host disease involving the colon. The colonic mucosa shows prominent crypt apoptosis and focal crypt dropouts in a background of granulation tissue.](#)

[Figure 7 Sinusoidal obstruction syndrome \(veno-occlusive disease\) of the liver. The small hepatic vein demonstrates fibrous obliteration with fibrin deposits. The perivenular hepatocytes show prominent sinusoidal congestion.](#)

Chapter 135: Oral complications of cancer and their treatment

[Figure 1 Severe oral mucositis with ulceration and pseudomembrane formation of the lateral and ventral surfaces of the tongue and buccal mucosa induced by myeloablative chemotherapy for conditioning before HSCT.](#)

[Figure 2 Severe oral mucositis with ulceration, erythema, and pseudomembrane formation of the left buccal mucosa induced by radiation therapy for treatment of an oral carcinoma.](#)

[Figure 3 Oral mucosal ulcers associated with the administration of an mTOR inhibitor. Note that the lesions are well defined and oval with a central area of necrosis and an erythematous periphery reminiscent of aphthous stomatitis.](#)

[Figure 4 Oral manifestations of graft-versus-host disease characterized by mucosal blistering and lichenoid changes.](#)

Chapter 138: Endocrine complications and paraneoplastic syndromes

[Figure 1 Probability of normal pituitary hormone secretion over time after radiation exposure to the hypothalamic–pituitary areas. Data from four studies were replotted on this single Figure The first set of values \(*closed circle*\) are from Pai et al.,³ where the patient received 55.8–79 Gy to the base of the skull. The second set of values \(*solid square*\) are from Shalet et al.,⁸³ where patients with pituitary tumors were treated with 37.5–42.5 Gy. The third series \(*open triangle*\), from Lam et al.,² shows the effect of radiation treatment for nasopharyngeal carcinoma with 39.8–61.7 Gy. The final series \(*open diamond*\) represents data from Samaan et al.,⁴ in which 11–75 Gy was administered to treat head and neck tumors.](#)

[Figure 2 Approach to evaluation of hyponatremia in a cancer patient.](#)

[Figure 3 Approach to evaluation of hypogonadism in a cancer patient.](#)

[Figure 4 Differential diagnosis of adrenocorticotropin \(ACTH\)-dependent Cushing syndrome. It is difficult to differentiate between a pituitary \(a\) and ectopic \(b\) source of ACTH, the most common causes of ACTH-dependent Cushing syndrome. To differentiate with certainty, placement of catheters in veins draining the pituitary gland \(inferior petrosal sinuses\) combined with stimulation by exogenous corticotropin-releasing hormone permits differentiation with certainty \(discussed in text\). Ectopic corticotropin-releasing hormone \(CRH\) production by a tumor results in increased ACTH production by the pituitary gland \(c\). It is difficult to differentiate between ectopic CRH production and pituitary-dependent Cushing syndrome, necessitating the measurement of CRH in peripheral blood to make the diagnosis with certainty. Malignant tumors occasionally produce both CRH and ACTH, further complicating the diagnostic evaluation \(not shown\).](#)

Chapter 139: Infections in patients with cancer

[Figure 1 Types of febrile episodes in patients with neutropenia.](#)

[Figure 2 Common sites of infection in patients with neutropenia.](#)

[Figure 3 Invasive infection caused by \$\alpha\$ -hemolytic \(viridans\) streptococci. Note the hemorrhagic nature of the lesions in this patient with thrombocytopenia.](#)

[Figure 4 Multiple skin lesions \(ecthyma gangrenosum\) in a patient with *Pseudomonas aeruginosa* bacteremia.](#)

[Figure 5 Characteristic macronodular cutaneous lesions in a patient with acute leukemia and disseminated *Candida krusei* infection.](#)

[Figure 6 Rounded pulmonary lesions with surrounding halo, compatible with invasive pulmonary aspergillosis.](#)

[Figure 7 Pansinusitis caused by *Aspergillus* spp. in an allogeneic bone marrow transplant recipient with persistent fever.](#)

[Figure 8 Gomori methenamine silver \(GMS\) stain from a bronchoalveolar lavage specimen demonstrating multiple organisms in a patient with *Pneumocystis carinii* pneumonia.](#)

[Figure 9 Computerized tomography scan of an allogeneic HCT recipient with CMV pneumonitis,](#)

[showing diffuse bilateral pulmonary infiltrates.](#)

[Figure 10 Typical vesicular rash caused by varicellazoster virus. Note the dermatomal distribution and the hemorrhagic nature of lesions in this patient with thrombocytopenia.](#)

Chapter 140: Oncologic emergencies

[Figure 1 Approach to acutely ill cancer patients.](#)

[Figure 2 Chest imaging of patients with pericardial tamponade and management algorithm. Widening of mediastinum and cardiac silhouette is evident \(b\) when compared with a prior chest radiograph \(a\). Chest CT of a different patient with pericardial tamponade shows the presence of an indwelling drainage catheter \(c\). An algorithm for management of pericardial effusion is shown \(d\).](#)

[Figure 3 Retroperitoneal bleeding. The CT scan of the abdomen and pelvis of a thrombocytopenic leukemia patient showed a large inhomogeneous retroperitoneal collection \(white arrowheads\) consistent with a hematoma in the left psoas muscle displacing bowel loops to the right.](#)

[Figure 4 Massive pleural effusion. The CT scan of the chest of a patient with a massive pleural effusion is shown. L, collapsed lung; E, pleural effusion; A, extensive axillary lymphadenopathy.](#)

[Figure 5 Saddle embolus. This CT scan shows a saddle embolus \(below the three arrowheads\) at the bifurcation into the pulmonary arteries.](#)

[Figure 6 Spinal cord compression. Sagittal MRI images of the spine from three different patients demonstrate an intramedullary lesion \(arrowhead\) in low cervical spine \(a\), compression of the lower portion of the thoracic spinal cord by metastatic disease in the vertebral body \(arrowhead\) \(b\), and compression of the upper portion of the lumbar spinal cord by an epidural tumor \(arrowhead\) \(c\).](#)

[Figure 7 Algorithm for management of status epilepticus adapted for cancer patients. Abbreviations: EEG, electroencephalogram; POC, point-of-care bedside testing; IV, intravenous; IM, intramuscular.](#)

[Figure 8 Pneumoperitoneum. A 53-year-old man with multiple myeloma and amyloidosis involving the gastrointestinal tract, undergoing treatment with thalidomide and dexamethasone, presented with acute abdominal pain and abdominal distention. Abdominal radiographs showed intraperitoneal free air \(arrowheads\). Laparotomy revealed bowel perforation secondary to massive colonic distention.](#)

Chapter 141: A vision for twenty-first century healthcare

[Figure 1 A schematic representation of the many different data types that are present in individual data clouds.](#)

[Figure 2 A schematic diagram of the “network of networks.” Biological networks can operate at the level of genes, of proteins and other molecules, of cells, of organs, and even of social networks of individuals. In disease, some of these networks are altered to become disease perturbed. The difference between normal and disease-perturbed networks provides insights into disease mechanisms, early diagnosis, and improved identification of drug target candidates.](#)

[Figure 3 A schematic diagram of the four hierarchical levels of biological information—DNA to RNA to proteins to interactions, networks, and biological systems.](#)

[Figure 4 Health status change over time. Individuals can move in a trajectory that leads to maintaining or increasing wellness, or can transition to being less well and into disease. Early detection and actionable possibilities can aid in transitioning individuals from a disease trajectory and into a wellness trajectory as well as optimizing wellness for each individual.](#)

[Table 2 Selected clinical trials of targeted agents in metastatic renal cell carcinoma](#)

Chapter 97: Urothelial cancer

[Table 1 Risk factors in metastatic bladder cancer](#)

[Table 2 Results of clinical randomized trials of neoadjuvant chemotherapy for invasive bladder cancer, stages T1–T4](#)

Chapter 98: Neoplasms of the prostate

[Table 1 Growth factors implicated in prostate cancer](#)

[Table 2 TNM clinical and pathologic staging of prostate cancer](#)

[Table 3 Prostate cancer stages](#)

[Table 4 Risk stratification for localized prostate cancer](#)

[Table 5 Comparison of key features of three commercialized genomic tests for prostate cancer.](#)¹⁰⁸

[Table 6 PSA and identification of significant and insignificant tumors](#)

[Table 7 WHO histologic classification of tumors of the prostate](#)

Chapter 99: Tumors of the penis and the urethra

[Table 1 AJCC \(2010\) TNM staging of penile cancer](#)

[Table 2 AJCC \(2010\) TNM staging of urethral cancer](#)

Chapter 100: Testis cancer

[Table 1 Primary tumors of the testis](#)

[Table 2 Markers of testicular germ cell tumors](#)

[Table 3 AJCC staging](#)

[Table 4 International germ cell consensus classification](#)

Chapter 101: Neoplasms of the vulva and vagina

[Table 1 Classifications of vulvar dysplasias](#)

[Table 2 TNM classification and staging of vulvar carcinoma](#)

[Table 3 Prognostic factors of stage, grade, and tumor thickness associated with positive regional nodes](#)

[Table 4 Classification of melanomas of the vulva](#)

[Table 5 FIGO staging classification for vaginal carcinoma](#)

[Table 6 Treatment scheme for vaginal carcinoma](#)

[Table 7 Survival at 5 and 10 years for 547 patients with clear cell adenocarcinoma of the vagina and cervix](#)

Chapter 102: Neoplasms of the cervix

[Table 1 Modification of the WHO histologic classification of epithelial tumors of the uterine cervix](#)

[Table 2 Relapse rates for patients with stage IIB or III cervical cancer](#)

[Table 3 Modified FIGO staging](#)

[Table 4 5-Year survival rates for stage IB-IIA cervical cancer patients after radical hysterectomy and bilateral pelvic lymphadenectomy](#)

[Table 5 Pelvic disease control and survival rates^a](#)

[Table 6 Prospective randomized trials: role of concurrent radiotherapy and cisplatin-containing chemotherapy^a](#)

[Table 7 Single-agent chemotherapy for cervical cancer](#)

Chapter 103: Endometrial cancer

[Table 1 Clinical and molecular features of endometrial carcinoma](#)

[Table 2 Comparison of follow-up of 170 patients with simple and complex hyperplasia and simple and complex atypical hyperplasia](#)

[Table 3 Staging—endometrial carcinoma](#)

[Table 4 Histopathology: degree of differentiation](#)

[Table 5 Single-agent cytotoxic chemotherapy for endometrial cancer](#)

[Table 6 Randomized trials of combination chemotherapy regimens for endometrial cancer](#)

[Table 7 Randomized trials of combination chemotherapy + hormonal therapy for endometrial cancer](#)

Chapter 104: Epithelial ovarian, fallopian tube, and peritoneal cancer

[Table 1 Genetic and epigenetic abnormalities in epithelial ovarian cancer](#)

[Table 2 Putative tumor suppressor genes in epithelial ovarian cancer](#)

[Table 3 Oncogenes associated with epithelial ovarian cancer](#)

[Table 4 Epithelial ovarian tumors](#)

[Table 5 FIGO staging of ovarian, fallopian tube, and peritoneal cancer \(2014\)](#)

[Table 6 Nomenclature for patient status-residual ovarian cancer](#)

[Table 7 Chemotherapy for advanced epithelial ovarian, fallopian tube, and peritoneal cancer: recommended regimens](#)

Chapter 105: Nonepithelial ovarian malignancies

[Table 1 Histologic typing of ovarian germ cell tumors](#)

[Table 2 Combination chemotherapy for GCTs of the ovary](#)

[Table 3 POMB/ACE chemotherapy for GCTs of the ovary](#)

[Table 4 Sex cord–stromal tumors](#)

Chapter 106: Molar pregnancy and gestational trophoblastic neoplasia

[Table 1 Scoring system for gestational trophoblastic tumors based on prognostic factors](#)

[Table 2 Single-agent regimen](#)

[Table 3 EMACO regimen](#)

[Table 4 EMACE regimen](#)

Chapter 107: Gynecologic sarcomas

[Table 1 Classification of uterine sarcomas. College of American Pathologist Classification of Uterine Sarcomas](#)

[Table 2 STAGING—Leiomyosarcoma, endometrial stromal sarcoma, and undifferentiated uterine sarcoma](#)

[Table 3 STAGING—Uterine adenosarcoma](#)

[Table 4 Single-agent activity in uterine sarcomas](#)

Chapter 108: Neoplasms of the breast

[Table 1 Age-specific probabilities of developing invasive breast cancer \(cancers diagnosed in females of all races between 2008 and 2010\)](#)

[Table 2 Rates by race or ethnicity: United States, 2007–2011](#)

[Table 3 Risk factors associated with the development of breast cancer](#)

[Table 4 Relative risk^a of invasive breast carcinoma based on histologic examination of breast tissue without carcinoma](#)

Chapter 109: Malignant melanoma

[Table 1 ABCDEs: clinical features of melanoma](#)

[Table 2 Recommended margins of wide excision for cutaneous melanoma based on primary tumor](#)

[thickness and location](#)

[Table 3 Summary of ASCO-SSO recommendations for sentinel lymph node biopsy in melanoma](#)

[Table 4 Summary of selected final results of the Multicenter Selective Lymphadenectomy Trial 1 \(MSLT-1\)](#)

[Table 5 High-risk features for selecting T1 melanomas for sentinel lymph node biopsy](#)

[Table 6 Summary of follow-up guidelines for patients with completely resected melanoma from various national and international organizations. These guidelines have not been prospectively validated and hence should only be considered as recommendations](#)

[Table 7 Antitumor activity and toxicities of molecularly targeted agents^a](#)

[Table 8 Activity and toxicities of selected CTLA4 and PD-1 blocking antibodies from Phase III trials for advanced melanoma](#)

Chapter 110: Other skin cancers

[Table 1 Common premalignant and malignant neoplasms of the skin](#)

[Table 2 Nonmelanoma skin cancer statistics \(U.S. 2014\)](#)

Chapter 111: Bone tumors

[Table 1 Classification of bone tumors by 4th edition of WHO classification on bone and soft-tissue tumors.³](#)

[Table 2 Classic examples of bone tumors fitting specific patterns of lesional borders, bone response, and lesional matrix on plain radiographs](#)

[Table 3 Musculoskeletal Tumor Society staging system](#)

[Table 4 American Joint Committee on Cancer staging system for bone sarcomas](#)

[Table 5 Mirels scoring system for predicting risk of pathologic fracture in metastatic disease](#)

[Table 6 Mirels definitions, fracture risk, and treatment recommendations based upon point totals](#)

[Table 7 Chondrosarcoma survival, metastatic potential, and local recurrence rates according to grade](#)

[Table 8 Osteosarcoma variants according to grade](#)

[Table 9 Examples of immunohistochemistry markers for evaluation of metastatic disease to bone](#)

[Table 10 Common primary tumors metastatic to bone: Frequency of bone involvement and survival after metastases](#)

Chapter 112: Soft tissue sarcomas

[Table 1 Selected cytogenetic aberrations in nonosseous sarcomas](#)

[Table 2 American Joint Committee on cancer staging system for STSs, 7th edition](#)

[Table 3 Phase 3 trials of adjuvant radiotherapy for localized extremity and trunk sarcoma stratified by grade](#)

[Table 4 Relative indications for preoperative RT, despite concerns related to wound complications](#)

[Table 5 Relative risks and 95% confidence intervals for clinical outcomes with adjuvant chemotherapy \(2008 meta-analysis\)](#)

Chapter 113: The myelodysplastic syndrome

[Table 1 IPSS score](#)

[Table 2 International Prognostic Scoring System—revised \(IPSS-R\) classification of MDS according to prognostic risk subgroups](#)

[Table 3 World Health Organization \(WHO\) classification](#)

[Table 4 Cytogenetics: revised cytogenetic IPSS-R groupings](#)

[Table 5 Gene mutations in MDS](#)

[Table 6 Morphologic and functional cellular abnormalities in myelodysplastic syndromes](#)

[Table 7 Randomized controlled trials in patients with MDS drug versus supportive care ± placebo](#)

Chapter 114: Acute myeloid leukemia in adults: mast cell leukemia and other mast cell neoplasms

[Table 1 Cytogenetics- and genetics-based risk](#)

[Table 2 Recurring karyotypic and molecular abnormalities in AML](#)

[Table 3 Initial diagnostic evaluation](#)

[Table 4 Representative chemotherapy regimens for acute myeloid leukemia](#)

Chapter 115: Chronic myeloid leukemia

[Table 1 Suggested management of most common adverse events associated with imatinib](#)

[Table 2 Response criteria according to the European Leukemia Net.](#)

Chapter 116: Acute lymphoblastic leukemia

[Table 1 Features of adult acute lymphocytic leukemia receiving hyper-CVAD chemotherapy as initial treatment \(N = 204\)](#)

[Table 2 Cytogenetic and molecular abnormalities in ALL](#)

[Table 3 The hyper-CVAD program in ALL](#)

[Table 4 New agents in ALL](#)

Chapter 117: Chronic lymphocytic leukemia

[Table 1 B-cell chronic lymphocytic leukemia as viewed then and now](#)

[Table 2 Malignancies of morphologically mature-appearing B lymphocytes](#)

[Table 3 Phenotypes of lymphoproliferative disorders](#)

[Table 4 Distribution of cases in various series according to Rai staging](#)

[Table 5 Molecular and cytogenetic markers of prognosis in CLL](#)

[Table 6 Front-line regimens for chronic lymphocytic leukemia](#)

[Table 7 Salvage therapy for relapsed chronic lymphocytic leukemia](#)

Chapter 118: Hodgkin lymphoma

[Table 1 The Lugano classification.⁴⁸](#)

[Table 2 Recommended staging](#)

Chapter 119: Non-Hodgkin's lymphoma

[Table 1 Risk factors for the development of lymphoma](#)

[Table 2 World Health Organization Classification of Lymphoid Neoplasms 2008: selected B- and T-cell neoplasms](#)

[Table 3 Revised staging system for primary nodal lymphoma](#)

[Table 4 International Prognostic Index \(IPI\)](#)

[Table 5 Follicular Lymphoma International Prognostic Index \(FLIPI\)](#)

Chapter 120: Mycosis fungoides and Sézary syndrome

[Table 1 Tumor-node-metastasis-blood classification for MF](#)

[Table 2 Clinical staging system for MF/SS](#)

Chapter 121: Plasma cell tumors

[Table 1 Classification of monoclonal gammopathies](#)

[Table 2 Presenting features of multiple myeloma](#)

[Table 3 Myeloma chromosomal alterations](#)

[Table 4 Nonimmunoglobulin sites for illegitimate switch recombination](#)

[Table 5 Durie–Salmon staging system and international staging system](#)

[Table 6 Uniform response criteria from the international myeloma working group](#)

[Table 7 Novel agent induction for newly diagnosed transplant-ineligible patients](#)

[Table 8 Novel agent induction for newly diagnosed transplant-eligible patients](#)

[Table 9 Autologous transplantation versus conventional chemotherapy for newly diagnosed myeloma](#)

[Table 10 Maintenance therapies](#)

[Table 11 Novel therapy for relapsed, refractory multiple myeloma](#)

Chapter 122: Myeloproliferative neoplasms: essential thrombocythemia, primary myelofibrosis, and polycythemia vera

[Table 1 Risk stratification in polycythemia vera and essential thrombocythemia](#)

[Table 2 Proposed risk-adjusted therapy in essential thrombocythemia](#)

[Table 3 Causes of bone marrow fibrosis](#)

[Table 4 Polycythemia vera-related clinical and laboratory features](#)

[Table 5 Classification of erythrocytosis](#)

[Table 6 Suggested treatment algorithm for patients with polycythemia vera](#)

Chapter 123: Neoplasms of unknown primary site

[Table 1 Poorly differentiated neoplasms: IHC staining patterns useful in determining tumor lineage](#)

[Table 2 Carcinoma of unknown primary site: IHC staining patterns useful in identifying the tissue of origin](#)

[Table 3 Sites of origin—Comparison of historical autopsy results and molecular tumor profiling predictions](#)

[Table 4 Recommended initial clinical evaluation](#)

[Table 5 Additional evaluation of specific patient subsets identified by initial evaluation](#)

[Table 6 Summary of favorable treatment subsets](#)

Chapter 124: Anorexia and cachexia

[Table 1 Diagnosis of cancer cachexia](#)

[Table 2 Stages of cancer cachexia](#)

[Table 3 Possible causes of cancer anorexia](#)

[Table 4 Orexigenic \(anabolic\) and anorexigenic \(catabolic\) neuropeptides](#)

[Table 5 Signals involved in cancer-cachexia](#)

Chapter 125: Antiemetic therapy

[Table 1 Emetogenic potential of single antineoplastic agents](#)

[Table 2 Classes and recommended doses of selected antiemetics](#)

[Table 3 Guidelines for prevention of acute and delayed nausea and vomiting in patients depending on emetic risk](#)

Chapter 126: Neurologic complications of cancer

[Table 1 Neurologic complications of cancer](#)

[Table 2 Neurologic complications in cancer patients by site](#)

[Table 3 Primary cancer causing symptomatic spinal cord compression in 583 patients at Memorial Sloan Kettering Cancer Center \(MSKCC\)](#)

[Table 4 Symptoms and signs of spinal cord compression in 213 patients at Memorial Sloan Kettering Cancer Center \(MSKCC\)](#)

[Table 5 Differential diagnosis of epidural spinal cord compression](#)

[Table 6 Frequency of leptomeningeal metastases \(LM\) in various cancers](#)

[Table 7 Metastatic lesions causing cranial neuropathies](#)

[Table 8 Nonmetastatic causes of cranial neuropathy in cancer patients](#)

[Table 9 Neurotoxicity of agents commonly used in cancer patients](#)

[Table 10 Neurologic complications of CNS irradiation](#)

[Table 11 Paraneoplastic neurologic syndromes](#)

Chapter 127: Dermatologic complications of cancer chemotherapy

[Table 1 Immunologically mediated drug hypersensitivity reactions](#)

[Table 2 Major cutaneous reactions associated with chemotherapy](#)

[Table 3 Most common mucocutaneous reactions of the major classes of chemotherapeutic drugs](#)

[Table 4 Cytokine reactions](#)

[Table 5 Chemotherapeutic agents associated with alopecia](#)

[Table 6 Summary of nail abnormalities and associated chemoagents](#)

[Table 7 Chemotherapeutic agents associated with chemical cellulitis](#)

[Table 8 Chemotherapeutic agents associated with hyperpigmentation](#)

[Table 9 Chemotherapeutic agents associated with depigmentation/vitiligo](#)

[Table 10 Chemotherapeutic agents implicated in radiation-associated reactions](#)

[Table 11 Chemotherapeutic agents associated with phototoxicity](#)

[Table 12 Chemotherapeutic agents associated with inflammation of actinic keratoses](#)

[Table 13 Chemotherapeutic agents associated with acral erythema](#)

[Table 14 Miscellaneous reactions and reactions associated with chemotherapy](#)

Chapter 129: Hematologic complications and blood bank support

[Table 1 Causes of anemia, thrombocytopenia, and leukopenia in cancer](#)

[Table 2 Characteristic effects of drugs and treatments on bone marrow](#)

[Table 3 Causes of thrombocytopenia](#)

[Table 4 Risks of transfusion](#)

Chapter 130: Coagulopathic complications of cancer patients

[Table 1 Hemostatic abnormalities in cancer patients](#)

[Table 2 Differential diagnosis of thrombocytopenia in cancer patients](#)

[Table 3 Critical platelet counts and recommendations for transfusion in cancer patients^a](#)

[Table 4 Risk factors for bleeding and thrombotic complications in cancer patients](#)

[Table 5 Wells criteria for pulmonary embolism](#)

[Table 6 Abnormalities in cancer patients with disseminated intravascular coagulation](#)

Chapter 131: Urologic complications

[Table 1 Therapeutic agents associated with nephrotoxicity](#)

[Table 2 Clinical and pathologic features of chemotherapy-associated nephrotoxicity](#)

[Table 3 Types of renal injury caused by cancer chemotherapeutic agents](#)

[Table 4 Drug interactions that can increase serum levels of antineoplastic agents or add renal toxicity](#)

[Table 5 Adjustment of antineoplastic agents based on renal insufficiency](#)

[Table 6 Cockcroft formula](#)

Chapter 132: Cardiac complications

[Table 1 Important cardiovascular complications of cancer](#)

[Table 2 Drugs associated with QT prolongation and known risk of *torsades de pointes*](#)

[Table 3 Anticancer treatments associated with cardiotoxicity](#)

[Table 4 Type I and type II treatment-related cardiac dysfunction](#)

[Table 5 Relative toxicities of anthracycline: a comparison of relative toxicities of different cardiotoxic drugs and dosage schedules](#)

[Table 6 Summary of cardiotoxicity in adjuvant trials involving trastuzumab](#)

Chapter 133: Respiratory complications

[Table 1 Major clinical syndromes and histologic patterns of chemotherapy-induced lung injury](#)

[Table 2 Major clinical syndromes and histologic patterns of lung injury associated with molecularly targeted agents](#)

[Table 3 Noninfectious pulmonary complications following hematopoietic stem cell transplantation](#)

[Table 4 Lung versus pump failure in acute respiratory failure: characteristics and underlying causes](#)

Chapter 134: Gastrointestinal and hepatic complications in cancer patients

[Table 1 Common causes of esophagitis in patients receiving cancer therapy](#)

[Table 2 Differential diagnosis of diarrhea in the cancer and hematopoietic cell transplant patient](#)

[Table 3 Management of ipilimumab-induced enterocolitis](#)

[Table 4 Modified classification of acute and chronic graft-versus-host disease \(GVHD\)](#)

[Table 5 Causes of hepatic abnormalities in cancer patients](#)

[Table 6 Differential diagnosis of hepatic biochemical tests abnormalities associated with cancer therapy](#)

Chapter 135: Oral complications of cancer and their treatment

[Table 1 Staging and management of medication-related osteonecrosis of the jaw](#)

Chapter 136: Gonadal complications

[Table 1 Probability of decreased gonadal function associated with commonly used antineoplastic agents](#)

[Table 2 Gonadal effects of combination chemotherapy](#)

[Table 3 Options for preservation of fertility in patients with cancer](#)

Chapter 137: Sexual dysfunction

[Table 1 Components of multidisciplinary care for common, cancer-related sexual problems in men and women](#)

Chapter 138: Endocrine complications and paraneoplastic syndromes

[Table 1 Dynamic testing of the hypothalamic/pituitary axes](#)

[Table 2 Incidence of hypothyroidism \(including compensated hypothyroidism\) after radiotherapy.^a](#)

Chapter 139: Infections in patients with cancer

[Table 1 Defects in host defense mechanisms and common infections associated with malignant diseases](#)

[Table 2 Common infections in patients with solid tumors](#)

[Table 3 Bacterial infection in 2223 febrile episodes in neutropenic patients](#)

[Table 4 Common infectious agents in patients with cancer](#)

[Table 5 Common empiric antibiotic regimens for febrile neutropenic patients](#)

[Table 6 Antimicrobial agents commonly used in patients with neutropenia](#)

[Table 7 Antimicrobial stewardship strategies](#)

Chapter 140: Oncologic emergencies

[Table 1 Antineoplastic drugs associated with cardiovascular side effects](#)

[Table 2 Commonly used IV antiarrhythmic drugs](#)

[Table 3 Recommendations for acute management of anaphylaxis in adults](#)

[Table 4 Antibody therapies approved by the US Food and Drug Administration](#)

Dedication

From the preparation for the first edition throughout the next eight editions, Emil Frei III, Tom to us and to his legion of friends, was an Editor extraordinaire. His deep knowledge of cancer, his extensive professional and personal contacts, and his vision gave strength to the book and its production. He was a towering figure in world oncology, and through his participation in it and in this treatise promoted its creation as a medical discipline. He was a consummate clinician who trained many of the major oncologists of the United States during his leadership at the National Cancer Institute, MD Anderson Cancer Center and the Dana Farber Cancer Institute of Harvard University. He was a pioneer of translational research. His writings, lectures, and open friendship made him a valued, virtual companion to every working oncologist. His influence will outlive him.

We editors who treasured his fraternity miss him sorely, and dedicate this ninth edition of Cancer Medicine to this great man.

Holland-Frei Cancer Medicine

Ninth Edition

EDITORS

Robert C. Bast Jr., MD

Vice President for Translational Research, MD Anderson Cancer Center, Houston, Texas

Carlo M. Croce, MD

Distinguished University Professor, The John W. Wolfe Chair in Human Cancer Genetics, Professor and Chair, Department of Molecular Virology, Immunology and Medical Genetics, The Wexner Medical Center, The Ohio State University, Columbus, Ohio

William N. Hait, MD, PhD

Global Head, Research and Development, Janssen Pharmaceutical Companies of Johnson and Johnson, Raritan, New Jersey

Waun Ki Hong, MD, DMSc (Hon)

Professor of Thoracic/Head and Neck Medical Oncology, American Cancer Society Professor, Samsung Distinguished University Chair in Cancer Medicine Emeritus, The University of Texas MD Anderson Cancer Center, Houston, Texas

Donald W. Kufe, MD

Distinguished Physician, Dana-Farber Cancer Institute, Professor of Medicine, Harvard Medical School, Leader, Translational Pharmacology and Early Therapeutic Trials Program, Dana-Farber/Harvard Cancer Center, Boston, Massachusetts

Martine Piccart-Gebhart, MD, PhD

Professor of Oncology, Université Libre de Bruxelles (ULB), Head of the Medicine Department, Jules Bordet Institute, Brussels, Belgium

Raphael E. Pollock, MD, PhD, FACS

Professor and Director, Division of Surgical Oncology, Surgeon in Chief, James Comprehensive Cancer Center, Surgeon in Chief, The Ohio State University Health System, The Ohio State University Wexner Medical Center, Columbus, Ohio

Ralph R. Weichselbaum, MD

Daniel K. Ludwig Distinguished Service Professor of Radiation and Cellular Oncology, Chair,
Department of Radiation and Cellular Oncology, University of Chicago, Hospital Director, Chicago
Tumor Institute, Chicago, Illinois

Hongyang Wang, MD

Professor and Director, National Center for Liver Cancer, China; Eastern Hepatobiliary Surgery Hospital,
Shanghai, China

James F. Holland, MD, ScD (hc)

Distinguished Professor of Neoplastic Diseases, Director Emeritus of Derald H. Rutttenberg Cancer
Center, Icahn School of Medicine at Mount Sinai, New York, New York

ASSOCIATE EDITOR

Fadlo R. Khuri, MD

Executive Associate Dean for Research, Emory University School of Medicine, Atlanta, Georgia;
President, the American University of Beirut, Beirut, Lebanon

Division of Cancer Etiology, Department of Population Sciences
Beckman Research Institute and the City of Hope Comprehensive Cancer Center
Duarte, CA
USA

Donald A. Berry, PhD

Professor
Department of Biostatistics
The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Joseph R. Bertino, MD

Professor

Medicine and Pharmacology

Robert Wood Johnson Medical School

Rutgers, The State University of New Jersey

New Brunswick, NJ

USA

Teena Bhatla, MD

Assistant Professor of Pediatrics

Division of Pediatric Hematology-Oncology

New York University Medical Center

The Stephen D. Hassenfeld Children's Center for Cancer and Blood Disorders

New York, NY

USA

Boris Blechacz, MD, PhD

Assistant Professor

Department of Gastroenterology, Hepat, & Nutr

Division of Internal Medicine

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Mark Bloomston, MD, FACS

Professor

Division of Surgical Oncology

Department of Surgery

The Ohio State University

Wexner Medical Center

Columbus, OH
USA

Otis W. Brawley, MD, MACP
Chief Medical Officer
American Cancer Society, Inc.
Atlanta, GA
USA

Freddie Bray, PhD
Head
Section of Cancer Surveillance
International Agency for Research on Cancer
Lyon
France

Malcolm Brenner, MB, PhD
Professor
Center for Gene Therapy
Baylor College of Medicine
Houston, TX
USA

Robert S. Bresalier, MD
Professor, Gastroenterology, Hepatology & Nutrition
Division of Internal Medicine
The University of Texas MD Anderson Cancer Center
Houston, TX
USA

Kristin Brogaard, PhD
Project Manager
Institute for Systems Biology

Seattle, WA

USA

Lionel Brookes, 3rd, PhD

Postdoctoral student

Department of Dermatology

University of California

San Francisco, CA

USA

Kristoffer W. Brudvik, MD, PhD

Postdoctoral Fellow

Department of Surgical Oncology

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Alan H. Bryce, MD

Assistant Professor of Medicine

Department of Hematology/Oncology

Mayo Clinic Arizona

Scottsdale, AZ

USA

Earle F. Burgess, MD

Attending Physician, Medical Oncology

Levine Cancer Institute, Carolinas HealthCare System

Charlotte, NC

USA

Meredith Buxton, PhD

Assistant Professor

Department of Surgery

UCSF School of Medicine

San Francisco, CA

USA

Aman U. Buzdar, MD, FACP

Professor of Medicine and Internist

Department of Breast Medical Oncology, Division of Cancer Medicine

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Maria E. Cabanillas, MD

Associate Professor

Department of Endocrine Neoplasia and Hormonal Disorders

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Guangwen Cao, MD, PhD

Professor

Department of Epidemiology

Second Military Medical University

Shanghai

China

William L. Carroll, MD

Julie and Edward J. Minskoff Professor of Pediatrics and Pathology

Chief, Division of Pediatric Hematology-Oncology at NYU Langone Medical Center

Stephen D. Hassenfeld Children's Center for Cancer and Blood Disorders

New York, NY

USA

Tina Cascone, MD, PhD

Fellow, Cancer Medicine

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

A. P. Chahinian, MD

Professor

Department of Medicine

Mount Sinai School of Medicine

New York, NY

USA

Richard Champlin, MD

Chair, Professor of Medicine

Department of Stem Cell Transplantation and Cellular Therapy

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Martin C. Chang, MD, PhD, FCAP, FRCPC

Assistant Professor

Lab Med and Pathobiology

Mount Sinai Hospital

Toronto, ON

Canada

Joe Y. Chang, MD, PhD

Director, Stereotactic Radiotherapy Program

Department of Radiation Oncology

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Alejandro Chaoul, PhD

Assistant Professor
Department of Palliative, Rehabilitation & Integrative Medicine
The University of Texas MD Anderson Cancer Center
Houston, TX
USA

Brian F. Chapin, MD

Assistant Professor
Department of Urology, Division of Surgery
The University of Texas MD Anderson Cancer Center
Houston, TX
USA

Sai-Juan Chen, MD, PhD

Professor of Hematology
State Key Laboratory of Medical Genomics
Shanghai Institute of Hematology
Rui-Jin Hospital affiliated to Shanghai Jiao Tong University School of Medicine
Shanghai
China

Zhu Chen, PhD

Vice-Chairman, 12th Standing Committee of the National People's Congress
President, Chinese Medical Association
Beijing
China

Anne Chiang, MD, PhD

Assistant Professor
Department of Medicine, Section of Medical Oncology
Yale School of Medicine, Yale Cancer Center, and Smilow Cancer Hospital
New Haven, CT

USA

Steven J. Chmura, MD, PhD

Associate Professor of Radiation and Cellular Oncology

The University of Chicago Pritzker School of Medicine

Chicago, IL

USA

James E. Cleaver, PhD

Professor Emeritus

Department of Dermatology

University of California

San Francisco, CA

USA

Steven K. Clinton, MD, PhD

Professor

Department of Internal Medicine

College of Medicine

The Ohio State University Comprehensive Cancer Center

Arthur G. James Cancer Hospital and Richard J. Solove Research Institute (OSUCCC – James)

Columbus, OH

USA

Jeffrey I. Cohen, MD

Chief, Laboratory of Infectious Diseases

National Institute of Allergy and Infectious Diseases

National Institutes of Health

Bethesda, MD

USA

Carmel J. Cohen, MD

Professor, Division of GYN Oncology

Department of Obstetrics and Gynecology
Ruttenberg Cancer Center, Icahn School of Medicine at Mount Sinai Medical Center
New York, NY
USA

Harvey J. Cohen, MD
Division Chief of Geriatrics, Director of the Center for the Study of Aging and Human Development
Duke University Medical Center
Durham, NC
USA

Lorenzo Cohen, PhD
Professor and Director
Integrative Medicine Program
Department of Palliative, Rehabilitation and Integrative Medicine
The University of Texas MD Anderson Cancer Center
Houston, TX
USA

Peter D. Cole, MD
Associate Professor
Pediatrics
Albert Einstein College of Medicine
The Children's Hospital at Montefiore
Bronx, NY
USA

Elizabeth Comen, MD
Medical Oncologist
Breast Medicine Service
Memorial Sloan Kettering Cancer Center
New York, NY
USA

Philip P. Connell, MD

Associate Professor
Department of Radiation and Cellular Oncology
University of Chicago Hospital
Chicago, IL
USA

Laurence J. Cooper, MD, PhD

Visiting Scientist
Pediatrics Research
The University of Texas MD Anderson Cancer Center
Houston, TX
USA

Carlos Cordon-Cardo, MD, PhD

Professor and Chair
Department of Pathology
Icahn School of Medicine at Mount Sinai
New York, NY
USA

Christopher L. Corless, MD, PhD

Medical Director of the Cancer Pathology Share Resource
Oregon Health & Science University
Portland, OR
USA

Jorge Cortes, MD

Professor of Medicine
Chair CML and AML Section
Department of Leukemia
The University of Texas MD Anderson Cancer Center

Houston, TX

USA

David Cosgrove, MB, BCh

Assistant Professor, Department of Oncology

Johns Hopkins University

Baltimore, MD

USA

Richard Cote, MD, FRCPath

Professor & Joseph R. Coulter Jr. Chair, Department of Pathology

Professor, Department of Biochemistry and Molecular Biology

Chief of Pathology

Jackson Memorial Hospital

University of Miami Miller School of Medicine

Miami, FL

USA

Kenneth H. Cowan, MD, PhD

Director, Fred and Pamela Buffett Cancer Center

University of Nebraska Medical Center

Omaha, NE

USA

Christopher H. Crane, MD

Professor with Tenure

Department of Radiation Oncology

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Carlo M. Croce, MD

Distinguished University Professor

The John W. Wolfe Chair in Human Cancer Genetics

Professor and Chair

Department of Molecular Virology, Immunology and Medical Genetics

The Wexner Medical Center

The Ohio State University

Columbus, OH

USA

Christopher P. Crum, MD, FRCP

Professor of Pathology, Harvard Medical School

Department of Pathology

Brigham and Women's Hospital

Boston, MA

USA

William Cruz-Munoz, PhD

Postdoctoral Fellow

Biological Sciences Platform

Sunnybrook Research Institute

Toronto, ON

Canada

Steven A. Curley, MD, FACS

Professor of Surgery and Chief

Division of Surgical Oncology

Baylor College of Medicine

Houston, TX

USA

Timothy A. Damron, MD, FACS

Professor of Orthopedic Surgery

Upstate University Hospital

Syracuse, NY

USA

Siamak Daneshmand, MD

Associate Professor of Urology (Clinical Scholar)

Director of Urologic Oncology, USC Institute of Urology

Los Angeles, CA

USA

John W. Davis, MD, FACS

Associate Professor, Department of Urology

Division of Surgery

The University of Texas MD Anderson Cancer Center

Houston, TX

USA

Shaheenah Dawood, MD, MBBch, FACP, FRCP, MPH, CPH

Head of Medical Oncology

Dubai Hospital

Dubai

United Arab Emirates

Lisa M. DeAngelis, MD, FAAN

Neuro-Oncologist

Chair, Department of Neurology

Lillian Rojzman Berkman Chair in Honor of Jerome B. Posner

Memorial Sloan Kettering Cancer Center

New York, NY

USA

Yadwinder S. Deol, PhD

Postdoctoral Research Fellow

University of Michigan Comprehensive Cancer Center

Ann Arbor, MI

USA

Maria T. De Sancho, MD, MSc

Associate Professor of Clinical Medicine

Non-Malignant Hematology Program at Weill Cornell Medicine's Center for Blood Disorders

New York, NY

USA

Summer B. Dewdney, MD

Assistant Professor

Division of Gynecologic Oncology

Rush University Medical Center

Chicago, IL

USA

Radwa G. Diab, MD, MBBCH, PhD

Lecturer of Medical Parasitology

Faculty of Medicine, Alexandria University

Alexandria

Egypt

Robert B. Diasio, MD

Director, Mayo Clinic Cancer Center

William J. and Charles H. Mayo Professor

Departments of Molecular Pharmacology & Experimental Therapeutics and Oncology

Rochester, MN

USA

Preface

Our understanding of cancer at the molecular, cellular, and clinical levels continues to expand. Translation of molecular diagnostics and therapeutics to the clinic has begun to realize the promise of precision medicine with the development and approval of dozens of new targeted drugs, antibodies, and predictive biomarkers. Assimilating this knowledge poses an acute challenge for students, residents, fellows, and established practitioners of oncology. Laboratory-based investigators seeking to translate their discoveries to human application require an accurate overview of clinical oncology, informed by cancer biology. As new therapies and diagnostics may now be applicable across multiple disease sites, it is essential that Pharma and Biotech understand the new advances and the unmet needs across the entire field of oncology.

This 9th Edition of *Cancer Medicine* provides a comprehensive synthesis of clinical oncology and the principles underlying approaches to detection, diagnosis, and cancer management. Biological hallmarks of cancer and the clinical manifestations of neoplastic diseases are described. Oncologists must now be familiar with pathways and processes that explain the origin and pathogenesis of neoplasms. Transformational technologies are discussed in depth to provide oncologists with an understanding of technical procedures such as deep sequencing, methods for measuring epigenetic modification of DNA and histones, transcriptional profiling, ncRNAs, specific functions of RNAs, proteomics, and metabolomics. The heterogeneity within and between cancers and their metastases are described and implications for clinical management are discussed. Quantitative oncology is explained in understandable terms providing an introduction not only to biostatistics and novel trial design, but also to bioinformatics and systems biology.

This work includes concise guidelines for the use of both conventional and novel drugs. As in the past editions, there is an emphasis on multidisciplinary patient care including surgical and radiation oncology, psycho-oncology, and population science. This volume should be of value to oncologists of every discipline. *Cancer Medicine*, 9th Edition, includes electronic web-based access with links to relevant references that will be regularly updated.

The editors have chosen experts who have written authoritatively about the disciplines and diseases covered in their respective chapters. Given the global importance of oncology, editors have now been included from Europe and Asia. As the world of science and medicine chip away the unknowns of the cancer process and its prevention and therapy, we believe the contents of this work will provide a platform for understanding the current state of accomplishment and preparing the reader for a critical evaluation of discoveries still to come.

The Editors
2016

Acknowledgments

The editors gratefully acknowledge the exceptional contributions of Jene' Reinartz whose tireless efforts have been critical to the organization of CM9. We greatly appreciate our assistants Cheryl Ashorn, Michelle Denney, Guishuai Lv, Kate Charlesworth-Miller, Sharon Palko, Kathy Profrock, Ruby Robinson, Catherine Rotsaert, Mary Werowinski, and Elizabeth Wilkins who have helped to make this volume possible. We thank Nancy Hubener for her efforts in completing this edition. We thank Dr. Michael Ewer for his effort and expertise in reviewing multiple chapters.

Working with John Wiley, Inc., has been a particular pleasure. Our initial editor, Thom Moore, was instrumental in establishing the project and in acquiring the rights to CM9. His vision and persistence were essential. Claire Bonnet has been truly outstanding in bringing the book to completion. The Wiley staff has been most helpful.

Our authors have utilized their extraordinary knowledge, experience, and judgment to capture the critical points regarding each topic and disease site. The editors are grateful for their efforts and are proud of each chapter.

Finally, we must acknowledge the contribution of our patients from whom we have learned. It is their courage, equanimity, and strength in coping with illness that inspires us every day. For patients still to come, we hope that *Cancer Medicine*, 9th Edition, will benefit them by helping their doctors.

Part 1

Introduction

Chapter 1

Cardinal manifestations of cancer

James F. Holland, MD, ScD (hc) ■ Waun Ki Hong, MD, DMSc (Hon) ■ Donald W. Kufe, MD ■ Robert C. Bast Jr., MD ■ William N. Hait, MD, PhD ■ Raphael E. Pollock, MD, PhD, FACS ■ Ralph R. Weichselbaum, MD

Overview

Cancer is asymptomatic at its initiation. Symptoms arise when a conduit is impaired, when cancer cells impinge on nerve fibers causing pain or dysfunction, when secretory products of the tumor cause systemic symptoms such as fever, weight loss, or fatigue, when ulceration and bleeding occur, or upon recognition of a mass. Indeed any symptom that lasts two weeks, even intermittently, could be a symptom of cancer, the great imitator. Cancer always belongs in the differential diagnosis.

Cancer is a singular word that embraces a vast diversity of diseases that can occur in any organ system throughout the animal kingdom. The unique characteristic of cancer is the proliferation of cells of a type different from, if ever so slightly, the normal complement of the organism. The proliferation of cancer cells may be rapid or slow, and the accumulation of cells may be massive or miniscule. The essence of the matter, however, is that aberrant cells, distinct from the ordinary evolution of cell types, appear and accumulate. Thus, a cancer differs from hypertrophy and hyperplasia, which involve normal cells.

A cancer cell does not obey the complex rules of architecture and function that govern the usual placement and behavior of cells within a tissue. The wondrous coexistence of cells and tissues of multiple types that make up the eye, the finger, or the kidney, for example, each with appropriate anatomic location with all connections intact to fulfill their appointed tasks, is part of the miracle we call life. The explanation for this marvelous organization is the field of continuing exploration seeking the messages and the exquisite controls that exist in multicellular organisms.

Cancer is distinguished from other abnormal cellular growths that lead to benign tumors in its characteristic independence from the restrictions present in normal tissues. Benign tumors expand and compress, but do not attack or invade adjacent tissues. Accumulated cancer cells make a tissue that ignores the anatomic barriers of adjacent cell membranes and basement membranes. Through chemical and mechanical means, the cancer cell insinuates itself between and into the space of the normal cells, killing them by chemical and physical means, the grand usurper. Even though the placenta in mammals shows this behavior, there is self-limitation in location and in survival of the placental invasion. Although leukocytes normally extravasate and permeate tissues, they do not share the other characteristics of cancer. The cancer cell is partially or absolutely insensitive to such normal constraints and may continue its invasiveness indefinitely.

Upon reaching a circulatory conduit, either lymphatic or capillary vessel, a process that may not be entirely haphazard, cancer cells often penetrate the wall as part of their invasive behavior. They then may be carried by the lymphatic or the venous circulation to remote sites where the possibility of adherence, extravasation, and colonization can occur, establishing metastases. In the absence of an intervening event, and given enough time, with few exceptions, the cancer process, as described, can lead to such anatomic or functional distortions that death ensues.

The cancer process does not start with a fully invasive cancer cell. A disorder in molecular instructions for protein synthesis is the common precursor lesion, nearly always because of qualitatively or quantitatively aberrant ribonucleic acid (RNA) messages transcribed from nuclear deoxyribonucleic acid (DNA). This occurs because of a mutation of the DNA, or because of overexpression of particular genes that encode proteins important as catalysts in pathways for stimulating growth, or because of under expression of genes whose coded proteins control and inhibit growth. Portions of genes may be lost, translocated, or amplified. Indeed, entire chromosomes may be deleted, replicated, or fused in abnormal ways. All such distortions of DNA can give rise to abnormal or unbalanced RNA messages, leading to qualitative or quantitative differences in proteins that result in disordered cellular function. Sometimes the functional abnormality is so extreme as to be lethal to the cell, initiating the suicidal mechanism of apoptosis. In other instances, the functional abnormality results in disease. Some of these diseases display the characteristics of cancer. Mutation, overexpression, and underexpression of genes can result from a wide spectrum of intrinsic and extrinsic causes, with various pathways that lead not to one final common pathway, but by several converging routes to cells with the phenotypic characteristics of cancer. When these cells are limited to an epithelial layer above the basement membrane, they are called *carcinoma-in-situ* or *intraepithelial neoplasia*. Similar changes probably occur, but are more difficult to recognize, in the mesenchymal tissues. Even cancer cells that do not penetrate the basement membrane, and thus lack one of the cardinal features of true cancer, represent a long series of antecedent molecular abnormalities that eventually lead to this optically recognizable cellular change. Furthermore, these evolving cancer cells are the common, if not the exclusive, precursor of invasive cancer.

In their initial stages, as proliferating cells accumulate, cancers are almost always asymptomatic. Cancers cause symptoms as they advance as a consequence of their mass, because they ulcerate on an epithelial surface, or because of change in function of the affected structure or organ. Nearly all the symptoms that can be caused by cancer can also be caused more commonly by noncancerous diseases. The astute clinician must include cancer in the differential diagnosis of virtually every symptom, albeit a benign disease may usually explain it. Doctors never diagnose diseases they do not think of. Cancers occur at any age. A longer life span provides greater opportunity for intrinsic organic events or an encounter with environmental carcinogens, however, and greater opportunity for initial DNA mutations to be fully realized as invasive cancers. Thus, age is the principal risk factor for most, but not all, cancers.

Common symptoms such as sore throat, runny nose, or a chest cold can sometimes be a result of cancers of pharynx, sinuses, or bronchi, respectively. Indeed, patients with these cancer diagnoses usually have been treated, often repeatedly and for extended periods, for the benign disease because cancer was not considered in the differential diagnosis and appropriate observations were not made. Cancer symptoms such as diarrhea, constipation, or mild pain often seem commonplace. Cancer symptoms may be intermittent, with spontaneous temporary improvement, a phenomenon that is usually misinterpreted by patients and often by physicians as evidence against the diagnosis of cancer. In fact, recurrent appearance or chronicity of a symptom which in short duration is characteristic of a common benign disease markedly heightens the possibility of an underlying dysfunction caused by cancer.

Cancers cause their symptoms by a few readily understandable mechanisms.

Occlusion of an essential conduit, partial or complete, can be caused by tumor. A tumor mass grows to such size that it partially or completely occludes an essential conduit. Classic presentations are cancer of the bronchus where partial bronchial occlusion causes cough, diminishes ciliary clearance of secretion, and sometimes leads to bronchopneumonia. Complete bronchial occlusion leads to atelectasis and chronic pneumonia. Compromise of the esophageal lumen by tumor mass or muscular dysfunction resulting from infiltration causes dysphagia, which, in its early presentation, is far too often attributed to benign cause.

Gastric tumors rarely cause complete obstruction, but often impair normal gastric motility. This defect may lead to easy satiety, anorexia, indigestion, and nausea. Decrease in caliber of the transverse and descending colon, sigmoid, or rectum by tumor mass can lead to change in bowel habit, including diminished caliber of stools, constipation, and bouts of cramps and/or diarrhea from peristaltic efforts of the proximal gut. Compromise of the lumen of the common bile duct by carcinoma of the head of the pancreas or of the bile duct itself produces obstructive jaundice, not infrequently after minor antecedent digestive complaints or unexplained pruritus ascribed to accumulated bile salts.

Ureteral obstruction by compression from retroperitoneal masses or bladder tumor leads to hydronephrosis and hydronephrosis, often asymptomatic or revealed by vague discomfort in flank or loin, or by urinary tract infection. Bilateral obstruction leads to uremia with its protean symptomatology. Compromise of the urethra as it courses through the prostate causes diminished urinary stream, inadequate bladder emptying, frequency, urgency, nocturia, and when severe, obstructive uropathy and uremia.

Tumors in the cecum and ascending colon and in the urinary bladder, because their content is not solid and because of greater luminal diameter, uncommonly cause obstruction, but may distort normal function enough to alter bowel or urinary habits.

A mass discovered by palpation or X-ray may be a presenting finding, as in breast carcinoma. Dysfunction from replacement of the substance of a parenchymatous organ by tumor is a subset of mass presentation. The classic example is primary or, more commonly, metastatic brain tumor, which becomes identified by abnormal brain function. Seizure or paralysis, sensory or coordination abnormality, memory defect, and personality change may all be consequences of space occupation. These changes may occur not only because a specific area of the brain is affected but also because of increased intracranial pressure as the calvarium is not distensible. Similar dysfunction of the spinal cord with distal motor and sensory phenomena can reflect space occupation by a mass within or impinging on the cord or cauda equina. Hepatic dysfunction from space occupation by primary or metastatic tumor, often with related intrahepatic bile duct compression, can present as jaundice. Sometimes the liver enlarges to enormous size, causing digestive disorders, pain, and a visible and palpable mass in the upper abdomen. Thyroid cancer usually presents as a mass, and uncommonly this results in hypothyroid laboratory values, but rarely in clinical hypothyroidism.

A sarcoma of the soft tissues usually presents as a palpable mass. Testicular cancer ordinarily presents as a mass: the testicle may only be slightly larger than its fellow, but harder and heavier in the examiner's hand. Ovarian cancer may be detected as an adnexal mass.

A new lump or mass, or a changing one, requires exclusion of cancer based on clinical examination, imaging studies, or a biopsy. Most lipomas, and self-discovery of the xiphoid, are two types of lumps that can usually be dismissed on clinical grounds. A dominant breast mass, or even a questionable one, requires assessment by appropriate imaging—often by cytologic or histologic means. A thyroid nodule, an enlarged lymph node that is hard, a node that remains enlarged without infectious explanation for 2 weeks, a skin mass with the characteristics of melanoma or carcinoma, especially if ulcerated, and a new subcutaneous or abdominal or scrotal mass all require consideration of cancer and appropriate diagnostic study.

Ulceration on the skin or on an epithelial surface can lead to blood loss and occasionally can serve as a portal of infection. Skin ulcerations are commonly ignored for weeks or months and are often interpreted as a common injury of unremembered origin that did not heal. Bronchial ulceration results in hemoptysis, usually blood-tinged sputum, and only rarely massive bleeding. Any of the upper alimentary canal cancers can ulcerate and bleed. Usually the bleeding is slow, intermittent, and silent, leading to iron-deficiency

anemia. Hematemesis or massive melena is uncommon. Carcinomas of the cecum and ascending colon often present with the symptoms of anemia because of ulceration and bleeding.

Carcinoma of the bladder and carcinoma of the kidney commonly manifest hematuria. Sometimes this is fortuitously discovered as a microscopic or chemical abnormality on routine urinalysis. Clots from renal bleeding can lead to ureteral colic. Hematuria less often heralds prostate cancer, but hematospermia implies prostate disease, benign or malignant, because carcinoma of the seminal vesicle is exceedingly rare.

Endometrial carcinoma most often presents as postmenopausal vaginal bleeding, although any vaginal bleeding outside the normal menstrual cycle is worthy of suspicion. Contact bleeding during intercourse is suggestive of cervical ulceration, most commonly a result of cancer.

Pain is commonly thought of as a surrogate for early cancer, although this is mistaken. Most cancers are initially painless. Pain occurs when a tumor invades, presses on, or stretches a nerve, or when proximal smooth muscle contracts in an attempt to bypass an obstructed or dysfunctional distal segment of a conduit. Most pains of short duration that disappear are not caused by cancer. Cancer must enter the differential diagnosis, however, when pain is recurrent or persistent without ready explanation, or atypical, or present when there is no other recognizable cause. New pain, not necessarily severe, must be carefully interpreted. Abdominal pain and skeletal pain distinct from joint symptomatology deserve particular attention and early rather than late studies to establish a cause. Pain in a breast mass does not exclude its being cancer.

Weight loss may first indicate an unsuspected cancer, and when combined with grumbling low-grade discomforts, malaise, and fatigue is a cause for particular scrutiny. A wide variety of other diseases can also cause these common symptoms, but cancer should not be at the bottom of the list. If a diagnosis is not established after initial studies, a second complete history and physical examination after a short interval is imperative.

Effusion caused by cancer in the pleural, pericardial, or peritoneal cavities can lead to dyspnea and discomfort. Increasing abdominal girth, often with malaise, oliguria, constipation, and weight gain, is a cardinal symptom of ascites. In the thorax, bronchogenic carcinoma, mesothelioma, metastatic breast or ovarian cancer, and primary carcinoma of serous membranes are the frequent causes of malignant effusion. Ascites as a presenting symptom is characteristic of ovarian cancer and cancer of the serous membranes. Pancreatic cancer, mesothelioma, metastatic carcinoma on the peritoneum and in the liver and several non-neoplastic diseases also enter the differential diagnosis.

Perforation caused by invasion of the wall of a hollow viscus causes pain, usually sudden. Cancer is not suspected in most cases when this rare event occurs. Pneumothorax from perforation of the pleura by a primary or metastatic pulmonary tumor is an uncommon emergency. Fistulization of gastric cancer into the transverse colon leads to vague abdominal discomfort, which is misinterpreted or neglected, and then sudden onset of diarrhea with prominent gastrocolic reflex. Appendiceal cancer, albeit a rare tumor, frequently presents as acute appendicitis with peritonitis because of rupture. Perforation of the colon is more frequently caused by diverticulitis than by colon cancer. Ruptured ectopic pregnancy due to choriocarcinoma has been reported. Tracheoesophageal fistulization in the course of esophageal or bronchogenic cancers is almost always late in the course.

Fever of unknown origin that persists for more than 1 week must include cancer among its possible causes. Hodgkin disease, other lymphomas, acute leukemia, cancer of the kidney, and cancers of the liver are high on the list of neoplasms that can cause fever. Certain cancers predispose to infections because of ulceration, obstruction, or disordered leukopoiesis.

Endocrine hyperactivity syndromes may occasionally turn out to be caused by cancer. Hyperadrenalism, sometimes first manifest as hirsutism, can indicate adrenal cancer. Cushing syndrome can also result from small cell carcinoma of the lung. Hyperparathyroidism rarely comes from parathyroid cancer but can be mimicked by ovarian cancer and squamous carcinomas. Tumors that secrete thyroid hormone, estrogens, insulin, glucagon, aldosterone, epinephrine, or norepinephrine are often benign tumors of the parent endocrine organ, but cancer must always be considered. Functional neuroendocrine tumors may secrete serotonin and other vasoactive principles that cause the carcinoid syndrome.

Paraneoplastic syndromes may be early symptoms of cancer. Myasthenia gravis, Raynaud syndrome, hypertrophic osteoarthropathy and clubbing, and refractory anemia may herald thymoma, myeloma, lung cancer, and hematologic dyscrasia (and thymoma), respectively. A diligent search must be made for these and other causes.

Absence of cardinal manifestations is usual for cancers detected by screening by Papanicolaou smears, human papillomavirus (HPV) identification, mammography, prostate-specific antigen determinations, colonoscopy, computed tomography, lung scanning, and total skin examination. Asymptomatic cancers discovered by these methods are generally far less advanced than those that cause symptoms. Occasionally, routine chemical or hematologic laboratory data in asymptomatic patients suggest cancer or leukemia. Such incidental discovery reinforces the proposition that early in their pathogenesis most cancers are asymptomatic.

Predisposition to cancer characterizes a broad spectrum of diseases, exposures, and lifestyle behaviors. Patients who have had inflammatory bowel disease, HPV infection of the cervix, hepatitis B or C infection; those with prior radiation exposure, earlier treatment with alkylating agents, anthracyclines, or podophyllotoxin derivatives, or specific environmental exposures such as asbestos; those who have smoked, heavily imbibed alcohol, or sun worshipped, and those with a strong family history of cancer, particularly those neoplasms known in part to be hereditary all are in groups that deserve special consideration for the particular cancers that occur in them at a higher frequency than normal.

Cancerophobia does not predispose to cancer. Depression occurs more frequently with carcinoma of the pancreas than with gastric carcinoma, however, and may be an early symptom of pancreatic neoplasia.

The present

By the time cancer is diagnosed, it is often past the stage of easy curability. Frequently, the earliest symptoms were ignored or rationalized. Technical improvements in imaging, early surgery, and hormonal, chemotherapeutic, and immunologic treatment have decreased mortality from breast cancer; viral discovery, cytology, and early treatment have diminished cervical cancer mortality; and colonoscopy and polypectomy have decreased colon cancer mortality. Other screening programs portend similar promise by diagnosing cancers before they become symptomatic. Cancer has replaced syphilis as the great imitator. Many symptomatic patients with cancer are still curable with today's therapies. Delay cannot possibly help, however, once an early symptom occurs that eventually proves to be caused by cancer. Inclusion of cancer as a possibility in every differential diagnosis can save lives.

The future

The expansion of diagnostic techniques based on genomics and proteomics augurs well for earlier identification of cancers. Not only is it reasonable to believe that clinical diagnosis will be accelerated by laboratory methods, but genomic and proteomic discoveries are likely to alter our understanding of the

cancer process as it occurs in humans. It is hoped that the consequent impact of this knowledge on cancer prevention and on cancer therapy will be revolutionary. The cardinal manifestations of cancer may then become principally of historical interest, while laboratory abnormalities are instrumentally detectable well before clinical presentation. Indeed, departure from a population norm may be less significant than departure from an individual's prior proteomic profile taken as a baseline during health. If such a blue-sky future ever unfolds, public understanding and compliance will still be critical determinants of cancer prevention and early diagnosis.

Chapter 2

Biological hallmarks of cancer

Douglas Hanahan, PhD ■ Robert A. Weinberg, PhD

Overview

An enigma for cancer medicine lies in its complexity and variability, at all levels of consideration. The hallmarks of cancer constitute an organizing principle that provides a conceptual basis for distilling the complexity of this disease in order to better understand it in its diverse presentations. This conceptualization involves eight biological capabilities—the hallmarks of cancer—acquired by cancer cells during the long process of tumor development and malignant progression. Two characteristic traits of cancer cells facilitate the acquisition of these functional capabilities. The eight distinct hallmarks consist of sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, activating invasion and metastasis, deregulating cellular energetics and metabolism, and avoiding immune destruction. The principal facilitators of their acquisition are genome instability with consequent gene mutation and tumor-promoting inflammation. The integration of these hallmark capabilities involves heterotypic interactions among multiple cell types populating the “tumor microenvironment” (TME), which is composed of cancer cells and a tumor-associated stroma, including three prominent classes of recruited support cells—angiogenic vascular cells (AVC), various subtypes of fibroblasts, and infiltrating immune cells (IIC). In addition, the neoplastic cells populating individual tumors are themselves typically heterogeneous, in that cancer cells can assume a variety of distinctive phenotypic states and undergo genetic diversification during tumor progression. Accordingly, the hallmarks of cancer—this set of necessarily acquired capabilities and their facilitators—constitute a useful heuristic tool for elucidating mechanistic bases and commonalities underlying the pathogenesis of diverse forms of human cancer, with potential applications to cancer therapy.

Distilling the dauntingly complex manifestations of cancer

As outlined in the preceding chapter, and comprehensively described elsewhere in this encyclopedic textbook, the manifestations of cancer are disconcertingly complex and diverse. Cancers affecting different organs vary dramatically, in regard to genetics, histopathology, effects on systemic physiology, prognosis, and response to therapeutic intervention, explaining why the discipline of oncology is largely balkanized into organ-specific specialties, and why the chapters of this textbook are largely aligned as individualistic descriptions of organ-specific cancers.

In the face of this disconcerting diversity and complexity of disease manifestations, one might ask whether there are underlying principles—mechanistic commonalities—masked by the genetic and phenotypic complexities that span the multitude of cancer types and forms. In 2000, and again in 2011, we put forward a hypothesis that the vast complexity of human cancers reflects different solutions to the same set of challenges, namely that the lesions we observe in the forms of symptomatic neoplastic disease have all necessarily acquired, by various strategies, a common set of distinct functional capabilities that enable inappropriately chronic cell proliferation, and the focal or disseminated growth of populations of

neoplastic cancer cells. We proposed to call this set of acquired capabilities “hallmarks of cancer.”^{1, 2} We further suggested that two characteristic traits of neoplastic growths—elevated mutability of cancer-cell genomes and inflammation by complex arrays of immune cells—are the key facilitators used by incipient neoplasias to acquire essential hallmark capabilities. Our current conceptualization of the biological hallmarks of cancer incorporates the eight distinct functional capabilities and the two enabling facilitators, these being schematized in [Figure 1](#).

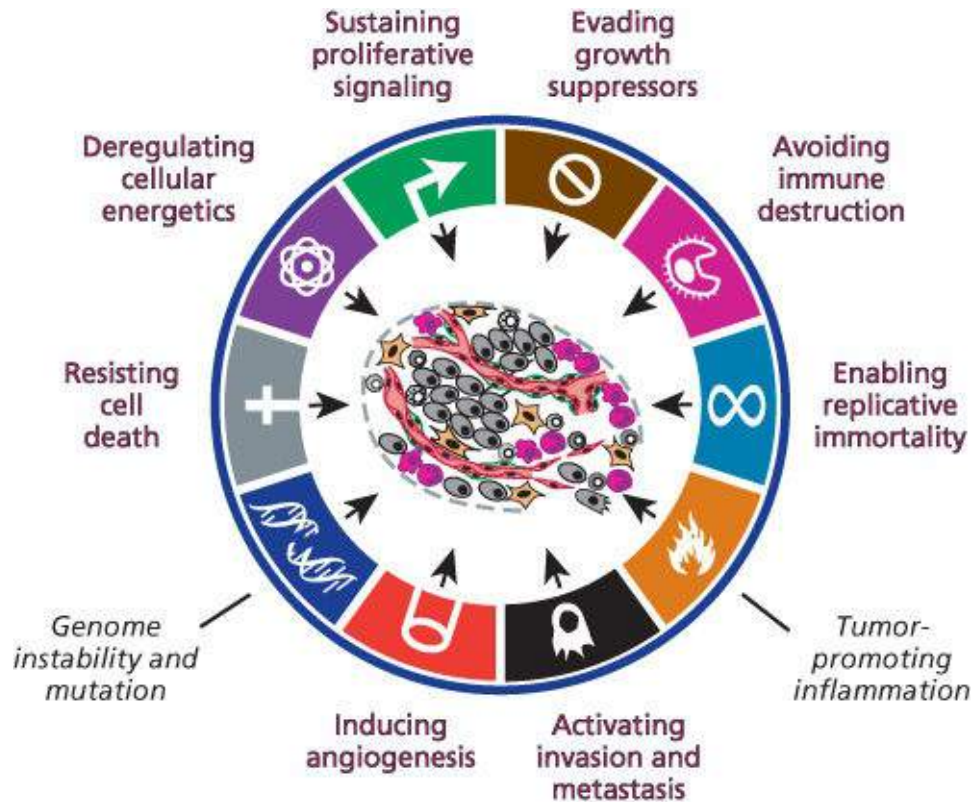

Figure 1 The biological hallmarks of cancer. The schematic illustrates what are arguably necessary conditions to manifest malignant disease—the hallmarks of cancer—comprising eight distinct and complementary functional capabilities and two facilitators (in black italics) of their acquisition.^{1, 2} These hallmark traits may be acquired at different stages in the multistep development of cancer, via markedly distinctive mechanisms in different forms of human cancer. Two aberrant characteristics of cancerous lesions are demonstrably involved in facilitating the acquisition during tumorigenesis of these functional capabilities: genome instability and the resultant mutation of regulatory genes, and the infiltration of immune inflammatory cells endowed by their biology—for example involvement in wound healing—to contribute to one or another hallmark capability. Different forms of cancer may be more or less dependent on a particular hallmark. Thus, adenomatous tumors typically lack the capability for invasion and metastasis. Leukemias may not require angiogenesis or invasive ability, although progression to lymphoma almost certainly requires both. The necessity of evading tumor immunity may be less important for certain cancers but is increasingly appreciated to be widespread.

The following sections describe these 10 key aspects of cancer pathophysiology. Then we introduce the observation that cancer cells recruit a variety of normal cell types that contribute in various ways the acquisition of hallmark functionalities. We conclude with a brief discussion on potential clinical implications of the hallmarks concept. For further detail and background, the reader is referred to our initial publications laying out the concept of the hallmarks of cancer,^{1, 2} as well as to another perspective that expands on the roles of stromal cells in enabling the hallmarks of cancer.³ Notably, only a few recent publications not cited in these three perspective articles are referenced herein. A textbook on the biology of cancer⁴ may provide additional details on many of the mechanisms of cancer pathogenesis described in

outline in this chapter.

Acquired functional capabilities embody biological hallmarks of cancer

In our current conceptualization, there are eight hallmark capabilities that are common to many, if not most forms of human cancer ([Figure 1](#)). Each capability serves a distinct functional role in supporting the development, progression, and persistence of tumors and their constituent cells, as summarized briefly in the following sections.

Hallmark 1: sustaining proliferative signaling

The defining criterion of cancer as a disease is chronic, inappropriate cell proliferation, which results from corruption of cellular regulatory networks that normally orchestrate (transitory) proliferation of cells during embryonic development, physiological growth, and homeostatic maintenance of tissues throughout the body. Both positive (inductive) and negative (repressive) signals govern cell division and proliferation. Thus, this first hallmark capability embodies a complex set of inductive signals that instruct entry into and progression through the cell growth-and-division cycle to produce daughter cells. In the context of cancer, such stimulatory signals are activated and, in contrast to normal situations in which proliferative signaling is transitory, the signals are sustained chronically.

The most well-established and widespread mechanism of sustaining proliferative signaling involves mutational alteration of genes within cancer cells that convert such genes into active drivers of cell proliferation. These activated genes—defined as oncogenes—render otherwise transitory proliferation-promoting signals chronic. Such oncogenes typically encode proteins altered in structure and function or abundance compared to their normal cellular counterparts, which are responsible for receiving proliferative signals from extracellular sources and transmitting the signals through complex regulatory circuits operating within the cell.

Prominent examples of mutated driver oncogenes that sustain proliferative signaling in human cancers include the epidermal growth factor (EGF) receptor and signal transducers in the downstream KRAS–RAF–MEK–MAPK pathway that process and transmit growth-stimulatory signals via a succession of protein phosphorylations to the cell-division machinery operating in the nucleus. Mutations that render one or another of these proteins chronically active are found in many forms of human cancer, including the aforementioned *EGFR* and related receptor tyrosine kinases such as *HER2* and *ALK*; similarly acting mutations result in chronic activation of the downstream signal transducers *KRAS*, *BRAF*, and *MEK*. We note, however, that activation in cancer cells of this central mitogenic pathway does not invariably depend on genetic changes acquired during the course of tumor progression. In certain instances, epigenetic deregulation of autocrine (autostimulatory) and paracrine (cell-to-cell) signaling circuits can also provide cancer cells with chronic growth-promoting signals, doing so in the apparent absence of underlying somatic mutations.

Hallmark 2: evading growth suppressors

The essential counterbalance to proliferative signals in normal cells are braking mechanisms that either overrule the initiation of, or subsequently block, the cell-division process instigated by such signals. The genes encoding these proteins are often termed tumor suppressor genes (TSGs). The most prominent brakes are the direct regulators of progression through the cell growth-and-division cycle, embodied in

the retinoblastoma protein (pRb) and several “cyclin-dependent” kinase-inhibitor proteins. The activity of this molecular-braking system is itself normally regulated by the integration of extracellular pro- and antigrowth signals transduced by receptors on the cell surface, along with monitors of the intracellular physiologic state of the cell, in order to regulate tissue homeostasis and orchestrate transitory physiological proliferation.

An intracellular monitoring system, which is centered upon the p53 protein, serves to ensure that cells only advance through their growth-and-division cycles when the physiologic state of the cell is appropriate. Thus, p53 detects unrepaired damage to a cell's genome as well as stressful physiologic imbalances that could impair accurate genome duplication, chromosomal segregation, and cell division. In response to cellular stress alarms, p53 then proceeds to activate inhibitors of the cell-cycle machinery. In cases of severe genomic damage or stressful physiological abnormalities, p53 and its associates can instead induce programmed cell death (see below), an extreme form of putting on the brakes to cell proliferation.

A number of component genes in both of these generic braking mechanisms—the Rb and p53 pathways—are classified as TSGs by virtue of their frequent loss-of-function via deletion or intragenic mutations; alternatively, other mechanisms may achieve the same end by shutting down expression of these genes through epigenetic mechanisms, notably those involving DNA and histone methylation. Thus the p53 gene is mutated in ~40% of all human cancers, and many of the remaining tumors with wild-type p53 instead carry genetic lesions or epigenetic alterations that compromise p53 signaling in other ways.

Genetic profiling of genomes and transcriptomes indicates that a majority of human tumors contain defects—genetic or epigenetic—in the functions of the Rb and p53 tumor-suppressor pathways. Moreover, a large body of functional studies involving manipulation of these pathways in cultured cancer cells and mouse models of tumor initiation, growth, and malignant progression have clearly established the critical importance of TSGs in these pathways as significant barriers to the development of cancer. As such, evasion of growth suppressors is clearly a hallmark capability, necessary to ensure that continuing cancer cell proliferation and consequent tumor growth is not halted by braking mechanisms that, under normal circumstances, limit the extent of cell proliferation in order to maintain tissue homeostasis.

Hallmark 3: resisting cell death

There exists a second, fundamentally distinct barrier to aberrant cell proliferation, which involves intrinsic cellular mechanisms that can orchestrate the programmed death of cells deemed to be either aberrant or, in the case of normal development and homeostasis, superfluous. The most prominent form of programmed cell death is apoptosis, the genetically programmed fragmentation of a cell destined to die. Included among the situations where normal cells activate their apoptotic program to die are ones where the cell is damaged in various ways, mislocalized, or inappropriately migrating or proliferating. The apoptotic program can be triggered by cell intrinsic and non-cell-autonomous signals that detect different forms of cellular abnormality.

The apoptotic cell-death program involves the directed degradation of the chromosomes and other critical cellular organelles by specialized enzymes (e.g., caspases), the shriveling and fragmentation of the cell, and its engulfment, either by its neighboring cells or by tissue-surveilling phagocytes, notably macrophages. The apoptotic cascade is completed in less than an hour in mammalian tissues, explaining why apoptotic cells are often surprisingly rare when visualized in tissue sections, even in a population of cells experiencing apoptosis-inducing environmental conditions, such as cancer cells in tumors subjected to cytotoxic chemotherapy or to acute hypoxia consequent to vascular insufficiency.

The rapid engulfment of apoptotic cell bodies ensures that their death does not release subcellular components that would otherwise provoke an immune response; this “immune silence” contrasts with a second form of programmed cell death: necroptosis. Long known as necrosis and envisioned as the passive dissolution of a dying cell, necrosis can also be an active, programmed process that is governed by cellular regulators and effectors distinct from those regulating apoptosis. Necroptosis can be activated by various conditions, including oxygen and energy deprivation, viral infection, and inflammation.⁵ Cells dying by necroptosis (or passive necrosis) rupture, releasing their contents and leaving their carcasses as immunogenic debris that can attract (or exacerbate) an immune inflammatory response, which, as discussed below, can have both tumor-promoting and tumor-antagonizing effects.

A third program capable of inducing cell death, termed autophagy, serves as a recycling system for cellular organelles that can help cells respond to conditions of nutrient deprivation, by degrading nonessential cellular organelles and recycling their component parts. Thus, autophagy generates metabolites and nutrients necessary for survival and growth that cells may be unable to acquire from their surroundings. In addition, while generally a survival system, extreme nutrient deprivation or other acute cellular stresses can lead to a hyperactivation of autophagic recycling that drives a cell to a point-of-no return, in which its complement of organelles falls below the minimum level required for viability; as a consequence, the cell dies via “autophagy-associated” cell death, distinct in its characteristics from both apoptosis and necroptosis. Stated differently, depending on the physiologic state of a neoplastic cell, autophagy may either sustain its survival and facilitate further proliferation or eliminate it via autophagy-associated cell death.⁶

These three distinct mechanisms for triggering cell death must be variably circumvented or attenuated by cancer cells if they and their descendants are to continue their proliferative expansion and phenotypic evolution to states of heightened malignancy.

Hallmark 4: enabling replicative immortality

A third intrinsic barrier to chronic proliferation is integral to the linear structure of mammalian chromosomes: the telomeres at the ends of chromosomes record—by progressive reduction of their length during each cell-division cycle—the number of successive cell generations through which a cell lineage has passed. The telomeres are composed of thousands of tandem copies of a specific hexanucleotide DNA sequence located at the ends of every chromosome that are associated with a specialized set of DNA-binding proteins. Operating together, these nucleoprotein complexes protect the ends of chromosomes both from degradation by the DNA-repair machinery, which is designed to detect DNA damage, and from end-to-end fusions with other chromosomes catalyzed by naked DNA ends.

Notably, when the number of telomere repeats erodes below a certain threshold, a tripwire is triggered, causing cell-cycle arrest or apoptosis mediated by the p53 tumor-suppressor protein, operating in its role to sense DNA damage. Circumventing these p53-induced antiproliferative responses (e.g., by mutational inactivation of the p53 gene) allows cancer cells with eroding telomeres to ignore the short-telomere checkpoint and continue proliferating, but only transiently. Sooner or later, the continuing erosion of telomeric DNA leads to loss of the protective nucleoprotein caps protecting the chromosomal DNA ends, which allows end-to-end fusions of chromosomes, breakage–fusion–bridge cycles during mitosis, and resultant karyotypic chaos that leads to cell death instead of cell division.

The cancer cells in many fully developed tumors circumvent the proliferative barrier presented by telomere erosion and the imminent mitotic catastrophe of telomere dysfunction by activating a system for telomere maintenance and extension that is normally used to preserve the replicative capacity of normal

embryonic and tissue stem cells. This system involves expression of the telomere-extending enzyme named telomerase. Less frequently, they engage an alternative interchromosomal recombination-based mechanism for preserving telomere length. Thus, through one strategy or another, cancer cells acquire the capability to maintain their telomeres, avoiding the barrier of intolerably shortened telomeres, thereby enabling the unlimited replicative potential—termed cellular immortality—that is required for continuing expansion of populations of cancer cells.

Hallmark 5: inducing angiogenesis

Like normal organs, tumors require a steady supply of oxygen, glucose, and other nutrients, as well as a means to evacuate metabolic wastes, in order to sustain cell viability and proliferation. The tumor-associated vasculature serves these purposes. The deleterious effect that ischemia has in normal tissue is well established clinically and experimentally: cells die, via one form of programmed cell death or another, causing tissue and organ degradation and dysfunction. Similarly, the growth of developing nests of cancer cells halts when their ability to acquire blood-borne nutrients becomes inadequate, typically when the nearest capillary is more than 200 μ away. Angiogenesis—the formation of new blood vessels—is commonly activated and demonstrably beneficial for many tumor types.

Cells at the diffusion limit from the nearest capillary activate various stress-response systems, of which the most prominent involves the hypoxia-inducible transcription factors (HIF), which regulate hundreds of genes, including ones that directly or indirectly induce angiogenesis and other stress-adaptive capabilities. Much like cells in ischemic tissues, cancer cells lacking sufficient oxygen and glucose will typically die by necrosis/necroptosis, apoptosis, or rampant autophagy. This explains why most vigorously growing tumors are well vascularized with evidence of ongoing angiogenesis.

Of note, the tumor-associated neovasculature is usually aberrant both morphologically and functionally. Tumor blood vessels are tortuous, dilated, and leaky, with erratic flow patterns and “dead zones” in which no blood flow is detectable, in marked contrast to the seamless blood flow operating in the normal vasculature. Moreover, the degree of vascularity varies widely from one tumor type to another, ranging from intensely vascularized renal carcinomas to poorly vascularized pancreatic ductal adenocarcinomas.

Finally, we note that while chronic angiogenesis is a hallmark of most solid tumors, some may devise an alternative means to acquire access to the vasculature: in certain cases, cancers coopt normal tissue vasculature, by employing the hallmark capability for invasion and metastasis. Thus, particular types of cancer cells can proliferate and grow along normal tissue capillaries, creating sleeves whose outer diameters are dictated by the 200- μ diffusion limit. While vascular cooption is evident in certain cases (e.g., glioblastoma) and in some tumors treated with potent angiogenesis inhibitors, most tumors rely to a considerable extent on chronic angiogenesis to support their expansive growth. Still others may adapt to living in quasi-hypoxic environments where most cancer cells would perish.

Hallmark 6: activating invasion and metastasis

The five hallmarks detailed above stand as logical necessities for the chronic proliferative programs of cancer cells. The sixth is less intuitive: high-grade cancer cells become invasive and migratory. Invasive growth programs enable cancer cells to invade into adjacent tissue as well as into blood and lymphatic vessels (intravasation); these vessels serve thereafter as pipelines for dissemination to nearby and distant anatomical sites. The tissue-draining lymphatic vasculature can transport cancer cells to lymph nodes, where metastatic growths—lymph node metastases—can form; such cell colonies may serve, in turn, as staging areas for further dissemination by entering the bloodstream. Cells entering the bloodstream by direct intravasation within a tumor or indirectly via lymph nodes may soon become lodged in the

microvessels of distant organs and extravasate across the vessel walls into the nearby tissue parenchyma. The resulting seeded micrometastases may die or lay dormant in such ectopic tissue locations or, with extremely low efficiency, generate macroscopic metastases—the process of “colonization.”

The regulation of the intertwined capabilities for invasion and metastasis is extraordinarily complex, involving both cell-intrinsic programs and assistance from accessory cells in the tissue microenvironment. Prominent among the cancer cell-intrinsic regulatory mechanisms is the activation in epithelial cancer cells (carcinomas) of a developmental program termed the epithelial–mesenchymal transition (EMT),^{2, 4} which is associated with cell migrations and tissue invasions during normal organogenesis. An interconnected regulatory program induced by the microenvironment in some tumors is the aforementioned hypoxia response system, which triggers the activation of the HIFs, HIF1 α and HIF2 α , consequently altering expression of hundreds of genes,^{7, 8} including components of the EMT program. Both transcriptional regulatory systems control genes that can facilitate invasive migration as well as survival in the blood and lymphatic systems, and in ectopic tissue locations.

Notably, the acquisition of this hallmark capability can occur at various points along the pathways of multistep tumor development and progression that lead incrementally from normal cells of origin to those found in aggressive high-grade malignancies. In some cases, the capability for invasion and metastasis arises late, reflecting mutational or epigenetic evolution of the cancer cell, whereby rare subsets of cells populating such primary tumors are enabled to become invasive/metastatic. In other cases, this capability is acquired early, such that many cancer cells within a tumor may already be capable of invasion and metastasis. Moreover, there are indications that the EMT program may in some cases be transiently active and functionally important for dissemination and seeding, but then switched off in macrometastatic colonies.^{9, 10} It remains unclear whether the acquired traits of invasion and metastasis are beneficial and hence actively selected during the evolution of primary tumors; alternatively, these malignancy-defining capabilities may represent incidental byproducts of activating global regulatory networks (e.g., proliferative signaling, EMT, and HIF) that are initially selected because they facilitate primary tumor formation by contributing to the acquisition of other hallmark functions.

Hallmark 7: deregulating cellular energetics and metabolism

The concept that cancer cells alter their utilization of energy sources—notably glucose—to support their proliferation was introduced almost 90 years ago by Otto Warburg, who observed that certain cultured-cancer cells have enhanced uptake of glucose, which is metabolized via glycolysis, even in the presence of oxygen levels that normally should favor oxidative phosphorylation. The result was counterintuitive, as glycolysis is far less efficient at producing ATP, the primary currency of intracellular energy. However, we now appreciate that the “aerobic glycolysis” described by Warburg produces, in addition to ATP, many of the building blocks for the cellular macromolecules that are required for cell growth and division. Indeed, the metabolism of cancer cells resembles that of actively dividing normal cells rather than being a novel invention of neoplasia. Moreover, it is important to appreciate that there is not a binary switch from oxidative phosphorylation to aerobic glycolysis in cancer cells; rather, cancer cells continue to utilize oxidative phosphorylation in addition to incorporating differing rates of glycolysis, the proportions of which may well prove to be dynamic in time, variable among the cancer cells in different subregions within a tumor and in different tissue microenvironments.

Aerobic glycolysis can be indirectly monitored by positron-emission tomography (PET) using radiolabeled analogs as tracers. PET involving [¹⁸F]-fluorodeoxyglucose is commonly used to visualize glycolytic tumors via their elevated expression of glucose transporters and a resulting increase in the uptake of glucose. Although glucose is the primary fuel source used by most cancer cells, glutamine is

also emerging as another key blood-borne source of energy and a precursor of lipids and amino acids. In most cases, glutamine likely supplements and enhances glucose in supplying energy and biomaterials for growth and proliferation of cancer cells, although in some cases of glucose insufficiency, glutamine uptake and metabolism may be able to compensate.¹¹

A third player in metabolic fueling is lactate. While long considered to be toxic waste that is secreted by cells undergoing aerobic and anaerobic glycolysis, lactate is now appreciated to have diverse tumor-promoting capabilities.¹² In certain cancer cells, particularly those suffering glucose deprivation, extracellular lactate can be imported via specific transporters and used as fuel for generation of ATP and biomaterials. Similarly, some cancer-associated fibroblasts (CAF) can utilize lactate. Hence, metabolic symbioses may be operative in some tumors, involving partnerships between glucose-importing/lactate-exporting cells and lactate-importing cells.¹²

Finally, we note a still unresolved question, about whether this hallmark is significantly independent of the six cited above in terms of its regulatory mechanisms, or conversely is concordantly regulated under the auspices of these other hallmark traits. Thus, oncogenes such as *KRAS* and *cMYC*, as well as the loss of function of TSGs such as *p53*, can serve to reprogram the energy metabolism of cancer cells. For this reason, the reprogramming of cellular energetics and metabolism was initially defined as an “emerging hallmark.”² Irrespective of this qualification, it is clearly a crucial property of the neoplastic cell phenotype.¹³

Hallmark 8: avoiding immune destruction

The eighth hallmark has been on the horizon for decades, originally conceived as the proposition that incipient neoplasias must find ways to circumvent active surveillance by the immune system that would otherwise eliminate aberrantly proliferating premalignant cells. While clearly demonstrable in highly antigenic tumors in mouse models, and implicated in virus-induced human cancers, the generality of immune surveillance of incipient cancer as a barrier to neoplastic progression is unresolved. One factor is immune self-tolerance: the vast majority of antigens expressed by spontaneously arising cancer cells are likely shared with those expressed by their cells-of-origin in normal tissues and thus are ignored, reflecting the tolerance of the immune system for self-antigens. Nonetheless, some cancer cells demonstrably express antigens for which the immune system has failed to develop tolerance, including embryonic antigens, and novel antigens produced by rampant mutation of the genome; such antigens can indeed elicit antitumor immune responses and are an increasing focus for strategies aimed to elicit efficacious tumor immunity.

By contrast, the immune response to the ~20% of virus-induced human tumors is clear: oncogenic viruses express foreign antigens (including oncoproteins responsible for driving cell transformation) to which the immune system is not tolerant, resulting in humoral and cellular immune responses that can kill virus-infected precancer cells and thereby eradicate incipient neoplasias. The fact that virus-transformed cells can nevertheless succeed in evading immune elimination to produce overt cancer testifies to immune-evasive capabilities evolved by such tumor viruses or selected for in virus-transformed cancer cells. Nevertheless, the immune system likely serves as a significant barrier to virus-induced tumors, as indicated by the increased rates of cancer in individuals who are immune-compromised for various reasons, including organ-graft recipients and AIDS patients.

Although the incidence of nonvirus-induced human cancers is not markedly increased in the context of immunodeficiency—suggesting a lack of immune surveillance of incipient neoplasias in the other 80% of human cancers—various lines of evidence suggest that some tumor types must indeed deal with immune

recognition and attack during later stages of tumor progression and, in response, acquire immune-evasive strategies. Here, histopathological analyses of human tumor biopsies have shed light on the potential role of immune attack and immune evasion. For example, among patients with surgically resected colorectal carcinomas, those whose tumors contained dense infiltrates of cytotoxic T lymphocytes (CTLs) have a better prognosis than patients with tumors of similar grade and size that have comparatively few infiltrating CTLs.¹⁴ Such data implicate the actions of the immune system as a significant obstacle to the progressive growth and dissemination of cancer cells, one that is necessarily blunted or circumvented in some aggressive tumor types.¹⁴ Indeed, immune phenotyping of tumors, including their associated stroma, is being evaluated as a new metric in the diagnosis of tumors that may enable, when combined with traditional criteria, more accurate assessments of prognosis and more effective treatment decisions.^{15, 16} Accordingly, it is reasonable to view antitumor immune responses as a significant barrier to be circumvented during the lengthy multistage development of many forms of human cancer.

Nevertheless, the rules of immune engagement remain ambiguous when viewing the spectrum of human cancers. Thus, it is generally unclear when during different organ-specific tumor development pathways the attention of the immune system is attracted, or what the precise characteristics and efficacy of resultant immune responses are, or how the genetic constitutions of patients and the tumors that they harbor affect the development of antitumor immunity. Nevertheless, evading immune destruction seems increasingly to be an important mandate for developing tumors and thus an evident hallmark of cancer.

Taken together, we envision that these eight distinct capabilities define a necessary condition for malignancy ([Figure 1](#)), along with the two associated facilitators of their acquisition described below. Importantly, however, one cannot ignore the complex mechanisms underlying this conceptual simplicity: different tumors acquire these hallmarks by diverse mechanisms, doing so by coopting and subverting a diverse array of mechanisms normally responsible for cell, tissue, and organismic homeostasis.

Aberrations that enable acquisition of the necessary functional capabilities

The lengthy process of tumor development and malignant progression, long appreciated to involve a succession of rate-limiting steps, reflects the need of evolving neoplastic cells to acquire the eight hallmark capabilities discussed earlier. How then are these functional capabilities acquired? Currently, there are two clearly established means by which the hallmarks are acquired: (1) genome instability and the resulting mutation of hallmark-enabling genes in the overt cancer cells and (2) inflammation by cells of the immune system that help provide these capabilities cooperatively.

Genome instability and the consequent mutation of hallmark-enabling genes

Genome instability and the consequent mutation of hallmark-enabling genes is the primary modality of acquiring hallmark capabilities. The cell genome is subject to routine DNA damage, from a variety of chemically reactive products of normal metabolism, from environmental insults, and from its replication during every cell division. The resulting defects, if left unrepaired, become cell-heritable mutations, explaining the need of an elaborate consortium of proteins that continuously monitor DNA integrity and, in response to damage, undertake repair. Irreparable damage provokes the elimination of cells, a task orchestrated by the p53 TSG, which has for this reason been dubbed the “guardian of the genome.”

This highly efficient genome-integrity machine normally keeps the rates of gene mutation and genome

rearrangement at low levels, which is likely incompatible with the efficient acquisition of hallmark functions by genetic evolution and phenotypic selection for these necessary capabilities. This dichotomy provides a compelling explanation for the frequent observation of genome instability in cancer cells. Indeed, many tumor types contain neoplastic cells that carry readily identifiable defects in the complex machinery designed to monitor and repair genomic damage. Most apparent are the frequently documented mutant alleles of p53 that have been found in perhaps 40% of all cancers; without p53 on duty, damaged DNA can persist unrepaired, and mutant cells can survive and pass their damaged genomes on to their progeny. Numerous other specialized DNA repair and genome-maintenance enzymes are also found to be defective in many tumors, and inherited familial defects in DNA repair often lead to elevated risk of cancer development, again by enabling the acquisition of tumor-promoting mutations.

The elevated rates and persistence of proliferation in neoplastic lesions create cell lineages that have undergone far more successive growth-and-division cycles than is typical of cells in normal tissues, further increasing the potential for mutagenic errors occurring during DNA replication. Among these consequences is one that we described earlier: critically shortened and thus dysfunctional, telomeres can trigger chromosomal rearrangements and fusions that can affect gene function in various ways. Mutant cancer cells that survive this karyotypic chaos may have acquired advantageous phenotypes and thus the capability to undergo clonal expansion.

The foundation of cancer in genetic mutation is being further substantiated by the development of high-throughput DNA-sequencing technologies and the consequent ability to systematically analyze large numbers of independently arising cancer-cell genomes. Complemented by other methods for genome scanning, such as comparative genomic hybridization to identify copy number variations and “chromosome painting” to detect translocations, the derangements of the cancer-cell genome are being revealed in unprecedented detail.^{17–20} The results substantiate the fact that almost every form of human cancer involves cancer cells whose genomes have been mutated either through chromosomal rearrangements or more localized intragenic mutations or both. The density of genetic alterations varies over many orders of magnitude, from very low numbers detected in certain pediatric cancers to the blizzards of mutations present in the genomes of UV-induced melanomas and tobacco-induced lung cancers. Thus, the aberrations can range from dozens of point mutations to hundreds of thousands, and from quasi-diploid chromosomal karyotypes to widespread aneuploidy, translocations, and multiple large-scale amplifications and deletions.

The data generated by these increasingly high-throughput genomic technologies is presenting a major challenge to clarify which of the plethora of mutational alterations in the cancer-cell genome actually contribute causally to the acquisition of hallmark capabilities. The numbers of mutations that are being cataloged in many cancer cells greatly exceed those that are likely to be important in reshaping cell phenotype. The recurrence of specific mutations in cohorts of patients with the same cancer type or subtype provides one indication of functional involvement. Many other mutations, however, may reflect alternative solutions utilized in one individual's tumor but not another's, and thus are less frequently recurrent. And yet other mutations—often the great majority in a cancer cell's genome—may simply be ancillary consequences of genomic instability, having been carried along for the ride with other function-enabling mutations that do indeed afford selective advantage and thus clonal expansion during tumor growth and progression. Thus, the concept is emerging that cancer cells contain two classes of mutations: drivers and passengers. One future imperative will be to leverage such genome-profiling data to identify the driver mutations and their mechanistic contributions to the acquisition of hallmark capabilities, not only mutations that are frequent in a particular cancer type, but also others that are infrequent but nonetheless functionally important for an individual patient's tumor growth and progression. A second

imperative will be to clarify the potential of both recurrent and rare driver mutations as therapeutic targets in different tumor types. An added complexity is that advantageous hallmark traits conferred by driver mutations in some tumors may be acquired in other tumors by changes in the epigenome—the spectrum of cell-heritable changes in chromatin that are not reflected by changes in nucleotide sequence.^{21, 22} Indeed, it has been argued that all eight of the hallmark capabilities can be conveyed by epigenetic changes in gene regulation, occurring both in the overt cancer cells and in the supporting cells of the tumor-associated stroma.²³ While the prevalence of epigenetic mechanisms as primary orchestrators of tumorigenesis is currently unresolved, genomic instability may prove to play less prominent roles in some tumors, where mutational alterations in DNA may be consequences of hallmark functions rather than causal of them.

The field of cancer genetics is poised for an extraordinary decade during which tens of thousands of cancer-cell genomes will be comprehensively analyzed for multiple parameters, including alterations in DNA sequence and copy number, changes in gene transcription, splicing, and translation, as well as repatterning of histone and DNA methylation (and other modifications) that mediate regional alterations in chromatin structure, thereby governing gene accessibility for transcription. The challenge and the opportunity will be to distill the identity and contributions of specific alterations—genetic and epigenetic—to hallmark-enabling functions from increasingly massive datasets, and to exploit such knowledge for improved detection, evaluation, and informed treatment of human cancers.

Tumor-promoting immune cell infiltration (inflammation)

Tumor-promoting immune cell infiltration (inflammation) is the second important modality through which developing cancers acquire hallmark capabilities. Strikingly, most tumors are infiltrated by a variety of cell types of the immune system (the so-called infiltrating immune cells, or IIC³). While the inflammation caused by IIC might reasonably be considered a failed attempt to eradicate a tumor, recent evidence now clearly makes a far more insidious point: IIC help convey in paracrine fashion multiple functional capabilities, encompassing seven of the eight hallmarks.³ Thus, IIC can variously supply proliferative and survival signals, proangiogenic factors, and facilitate local invasion and blood-borne metastasis. In addition, some of these IIC (T-regulatory cells and myeloid-derived suppressor cells) can actively suppress the cytotoxic T lymphocytes that have been dispatched by the immune system to eradicate cancer cells.

Tumor-promoting IIC are recruited by a variety of means in different tumor types and at various stages of multistep tumorigenesis. The roster of the recruiting signals—including an ensemble of chemokine and cytokine signaling factors—is still incompletely understood. In some cases, the nature of the neoplastic lesion may trigger tissue abnormality or damage signals that attract IIC, represent the adaptive and innate immune systems. In other cases, oncogenic signaling, by activating transcriptional networks, induces expression of cytokines and chemokines that recruit IIC. In early-stage lesions, the recruited IIC can help incipient cancer cells to proliferate, survive, evade antigrowth controls, or activate angiogenesis. At later stages of progression, IIC at the margins of tumors can facilitate invasiveness. Some experiments reveal that IIC can pair with cancer cells as they migrate through the circulation and become established in distant locations.²⁴ Additionally, certain IIC, such as macrophages, can subject cancer cells to DNA-damaging reactive oxygen species, thereby contributing to the mutational alteration and evolution of the cancer-cell genome.

Most types of solid tumor are associated with tumor-promoting immune infiltrations that range from histologically subtle to the obvious inflammatory responses recognized by pathologists. In addition, the long-appreciated epidemiologic association between chronic inflammation and carcinogenesis supports

the proposition that pre-existing inflammatory conditions can be fertile breeding grounds for the inception and progression of certain forms of cancer. Chronically inflamed tissues share features with wound healing; both involve induction of angiogenesis and stimulation of cell survival, proliferation, and migration/invasion, involving the inflammatory IIC and other cell types (e.g., fibroblasts) that they activate in the affected tissue. These acquired traits represent hallmark capabilities, reinforcing the notion that IIC can inadvertently foster neoplastic initiation and/or progression of incipient cancer cells present in inflammatory tissue microenvironments.

The histopathological complexity of cancer, manifested in tumor microenvironments (TMEs)

Pathologists have long recognized that solid tumors are complex histological structures, incorporating not only cancer cells but also a variety of morphologically distinct cells, recognizable because they are similar to constituents of noncancerous tissues, both normal and affected by conditions such as infections or wound healing. In analogy to the stroma that supports epithelia in many normal tissues, the apparently noncancerous component of tumors has been labeled as the tumor stroma. As in normal tissue stroma, the tumor-associated stroma can be seen to contain blood vessels, assemblages of fibroblastic cells, and in many cases IIC. Historically, a simplistic view of the tumor stroma posited that endothelial cells, through the process of angiogenesis that produced a tumor neovasculature, provided oxygen and nutrients, while cancer-associated fibroblasts (CAFs) were either passengers or provided structural support, and the IIC, discussed earlier, represented ineffectual antitumoral immune responses. As described above, we now appreciate the fact that the diverse stromal cells inside tumors can contribute functionally to the acquisition of seven of the eight hallmarks.³

In analogy to normal tissues, tumors are often conceptually compartmentalized into the parenchyma (formed by the cancer cells) and the stroma (formed by the ostensibly normal supporting cells); the assemblage of these two compartments, incorporating as well extracellular material (including extracellular matrix, ECM, and basement membrane, BM) is increasingly referred to as the “tumor microenvironment” (TME), as illustrated in [Figure 2](#); some also refer to the TME exclusively as the noncancerous stromal compartment, although conceptually the microenvironment incorporates the entirety of the tumor, that is, both its neoplastic and stromal compartments.

Figure 2 The constitution of the hallmark-enabling tumor microenvironment. An assemblage of distinct cell types constitutes the TME of most solid tumors, involving two distinct compartments—the parenchyma of cancer cells and the stroma of supporting cells. Both compartments contain distinct cell and subcell types that collectively enable tumor growth and progression.^{2, 3} Notably, the immune inflammatory cells present in tumors can include both tumor-promoting and/or immuno-suppressive as well as tumor-killing subclasses. The lower panels illustrate an important characteristic: the TME is dynamic, varying both in composition and abundance of constituent cell types (and sub-cell types) and in their effects on the histologically distinct stages in multistep tumorigenesis, namely premalignant stages (not shown) and malignant stages, including the cores of primary tumors, invasive margins and frankly invasive lesions, and metastases.

The three classes of stromal cell—angiogenic vascular cells (AVC), consisting of endothelial cells and supporting pericytes; CAF; and IIC—constitute the bulk of the stromal component of the TME.³ These simple classifications, however, mask important diversity in cellular phenotypes. Thus, there are a number of CAF subtypes, of which the two most prevalent are derived either from myofibroblasts, mesenchymal stem cells, and tissue stellate cells that all characteristically express alpha-smooth muscle actin, or from connective tissue-derived fibroblasts that do not. Both subtypes of CAF arise via epigenetic reprogramming of their respective normal cells of origin by paracrine signals emanating from the TME; these inductive signals reflect similar signaling circuits used to engage fibroblasts in wound healing or

inflammatory responses. A growing number of IIC subtypes are being recognized, each with distinctive functions and characteristics; some may be lineage derived (e.g., expressed by definition in immune-cell progenitors recruited from the bone marrow) and others the result of “local education” by particular inductive signals in the TME. The list of tumor-promoting IIC includes forms (subtypes) of macrophages, neutrophils, partially differentiated myeloid progenitors, and in some cases specialized subtypes of B and T lymphocyte. The endothelial cells and pericytes of the tumor vasculature are comparatively less diverse, although both epitope and gene-expression profiling have revealed tissue and tumor type-specific features of both endothelial cells and pericytes, likely with subtle functional implications in regard to tumor biology. A second distinct class of endothelial cells forms the lymphatic vascular network, which becomes enlarged via lymphangiogenesis proximal to many tumors and is implicated in lymphatic metastasis.

This recent and more nuanced view of stromal cells elevates their importance in understanding disease pathogenesis by virtue of their hallmark-enabling functional contributions.^{2, 3} CAFs, as an example not discussed earlier, can in different neoplastic contexts secrete proteases, proliferative signaling ligands, and/or other bioactive molecules that contribute to different tumor phenotypes. CAFs have been variously documented to liberate epithelial cells from the growth-suppressive effects imposed by normal tissue architecture, to induce tumor-promoting inflammation, to facilitate both local invasion and metastatic seeding, and to provide cancer cells with metabolic fuel. CAFs can also induce angiogenesis and, remarkably, act in an immune-suppressive manner to blunt the attacks of tumoricidal CTLs.

Looking to the future, an important goal will be to continue mapping the multidimensional landscape of stromal cell types and subtypes operative within different forms of cancer, and at different stages of progression.

Another dimension of the TME involves genetic and functional heterogeneity within populations of cancer cells. Indeed, the cancer cells within individual neoplastic lesions have long been recognized to be morphologically and genetically heterogeneous. Genome-profiling technologies (karyotyping, comparative genomic hybridization, allelic loss analysis, exome (gene) sequencing, and more recently whole-genome sequencing, now at the single-cell level) have documented the mutational evolution of the genome as nascent cancer cells in incipient neoplasias progress to spawn the genetically diverse subpopulations that coexist within high-grade tumors.

A second dimension of intratumoral heterogeneity is evident at the epigenetic level. Thus, in many carcinomas, cancer cells at the margins of invasive tumors are phenotypically distinct, having undergone an EMT that renders them more fibroblastic, with attendant capability for invasion. Others retain various degrees of differentiation characteristic of the cell type from which they originated, for example, squamous epithelia. In addition, the regional variation in histological characteristics seen in various tumor types is now realized to reflect (at least in some cases) genetically distinct clones of cancer cells, the result of mutational alteration of unstable genomes and clonal outgrowth, presumably reflecting different genetic solutions within the same neoplasia to the challenge of acquiring hallmark-enabling capabilities that enable malignant progression.

In addition, most tumors are now appreciated to contain distinct subpopulations—comparatively rare—of cancer cells exhibiting phenotypic similarity, at least superficially, to normal tissue stem cells. These cancer stem-like cells (CSC) typically proliferate comparatively slowly, express cell-surface markers diagnostic of tissue stem cells, and have enhanced capability to form new cancers upon ectopic transplantation of small numbers of cells into appropriate animal hosts, as compared to their more abundant counterparts, who proliferate more rapidly but are inefficient at or incapable of seeding

transplant tumors.^{9, 25} (This latter assay operationally defines such cells as tumor-initiating cells, TIC.) One hypothesis was that the cell of origin of a cancer was a normal tissue stem or progenitor cell, which underwent neoplastic transformation into a CSC that in turn spawned cancer cells much like normal tissue stem cells spawn differentiated cell types, and indeed there are indications of such cases. For example, the CSCs in squamous cell carcinomas of the skin produce partially differentiated cancer cells with features of squamous cells much as normal skin stem cells produce the squamous epithelium. A number of hematopoietic malignancies evidently also arise from transformation of normal stem/progenitor cells into CSCs. In certain other cases, however, it appears that a dynamic interconversion operates between CSCs and their non-CSC counterparts, whereby CSCs can be converted into non-CSCs and vice versa, such that cancer cells can be converted into CSCs, and vice versa; in some such cases, the EMT appears to switch on the CSC phenotype in cancer cells, while its converse (the mesenchymal-to-epithelial transition, MET) reduces the abundance of CSCs in tumors.^{9, 25} There are indications that the comparatively less proliferative CSC may be more resistant to some genotoxic anticancer drugs, providing an avenue for drug resistance and clinical relapse. As such, therapeutic targeting of CSCs may be crucial to achieving enduring cancer therapies.

Therapeutic targeting (and cotargeting) of cancer hallmarks

An important question for cancer medicine is whether there are clinical applications of the hallmarks conceptualization? One possible benefit of this concept may come from helping cancer researchers appreciate common principles and thereby rationalize the diverse molecular and cellular mechanisms by which particular forms of human cancer develop and progress to malignancy. A wealth of data is being generated by multiplatform analysis—whole genome sequencing, and genome-wide profiling of RNA transcripts, proteins and phospho-proteins, and DNA and histone methylations—of cancer cells and neoplastic lesions in different tumor types (see, e.g., Ref. 26 and chapters throughout this textbook). Moreover, there will be other extrapolations of these increasingly powerful analytic technologies, including the profiling of lesional stages in tumorigenesis and tumor progression, in particular metastases; additionally, these technologies will likely provide insights into the adaptations that occur in tumors and metastases during the response and relapse phases to mechanism-targeted therapies. The challenge will be to integrate all of this information in order to understand the key determinants of particular carcinogenesis pathways; to identify new therapeutic targets; to identify modes of adaptive resistance to therapy; and then to use the data for diagnosis, prognosis, and treatment decisions. It is possible, although as yet unproven, that the hallmarks of cancer will prove useful in this integration and distillation: perhaps by filtering such cancer “omics” data—of the genome, the transcriptome, the proteome and phosphoproteome, and the methylome—through the growing knowledge base of regulatory pathways, it will be possible to identify the genetic and epigenetic signatures that underlie the acquisition of various hallmarks, potentially informing more precise management of disease.

We also envision that the hallmarks concept will prove useful in the design of future clinical treatment protocols. Notably, there are either approved drugs or drugs in late-stage clinical trials that target each of the eight hallmark capabilities and both of the enabling facilitators of those hallmarks ([Figure 3](#)); moreover, for most of the 10, there are multiple distinctive drugs targeting the same mechanistic effectors of these hallmarks. Although this is a provocative development in cancer therapeutics, these mechanism-based therapies targeting individual hallmarks have not in general been transformative for the treatment of late stage, aggressive forms of human cancer. An exception to this rule may be in the exciting ascendance of therapeutic immunomodulation to activate and sustain antitumoral immunity, involving most notably inhibitors of immune checkpoint receptors expressed on T lymphocytes (CTLA4 and PD1). Signaling

from these checkpoint receptors can disable cytotoxic T cells, evidently rendering antitumoral immune responses ineffectual, thereby contributing to the hallmark capability for evading immune destruction. Notably, exciting clinical responses are being observed in melanoma and other selected tumors^{27, 28} treated with therapeutic antibodies that inhibit checkpoint activation, particularly when both checkpoints are cotargeted with therapeutic antibody cocktails.²⁹ Nevertheless, not all patients respond to such immunotherapies, and the duration of response remains to be ascertained, as does the prevalence of adaptive resistance to such immunotherapies.

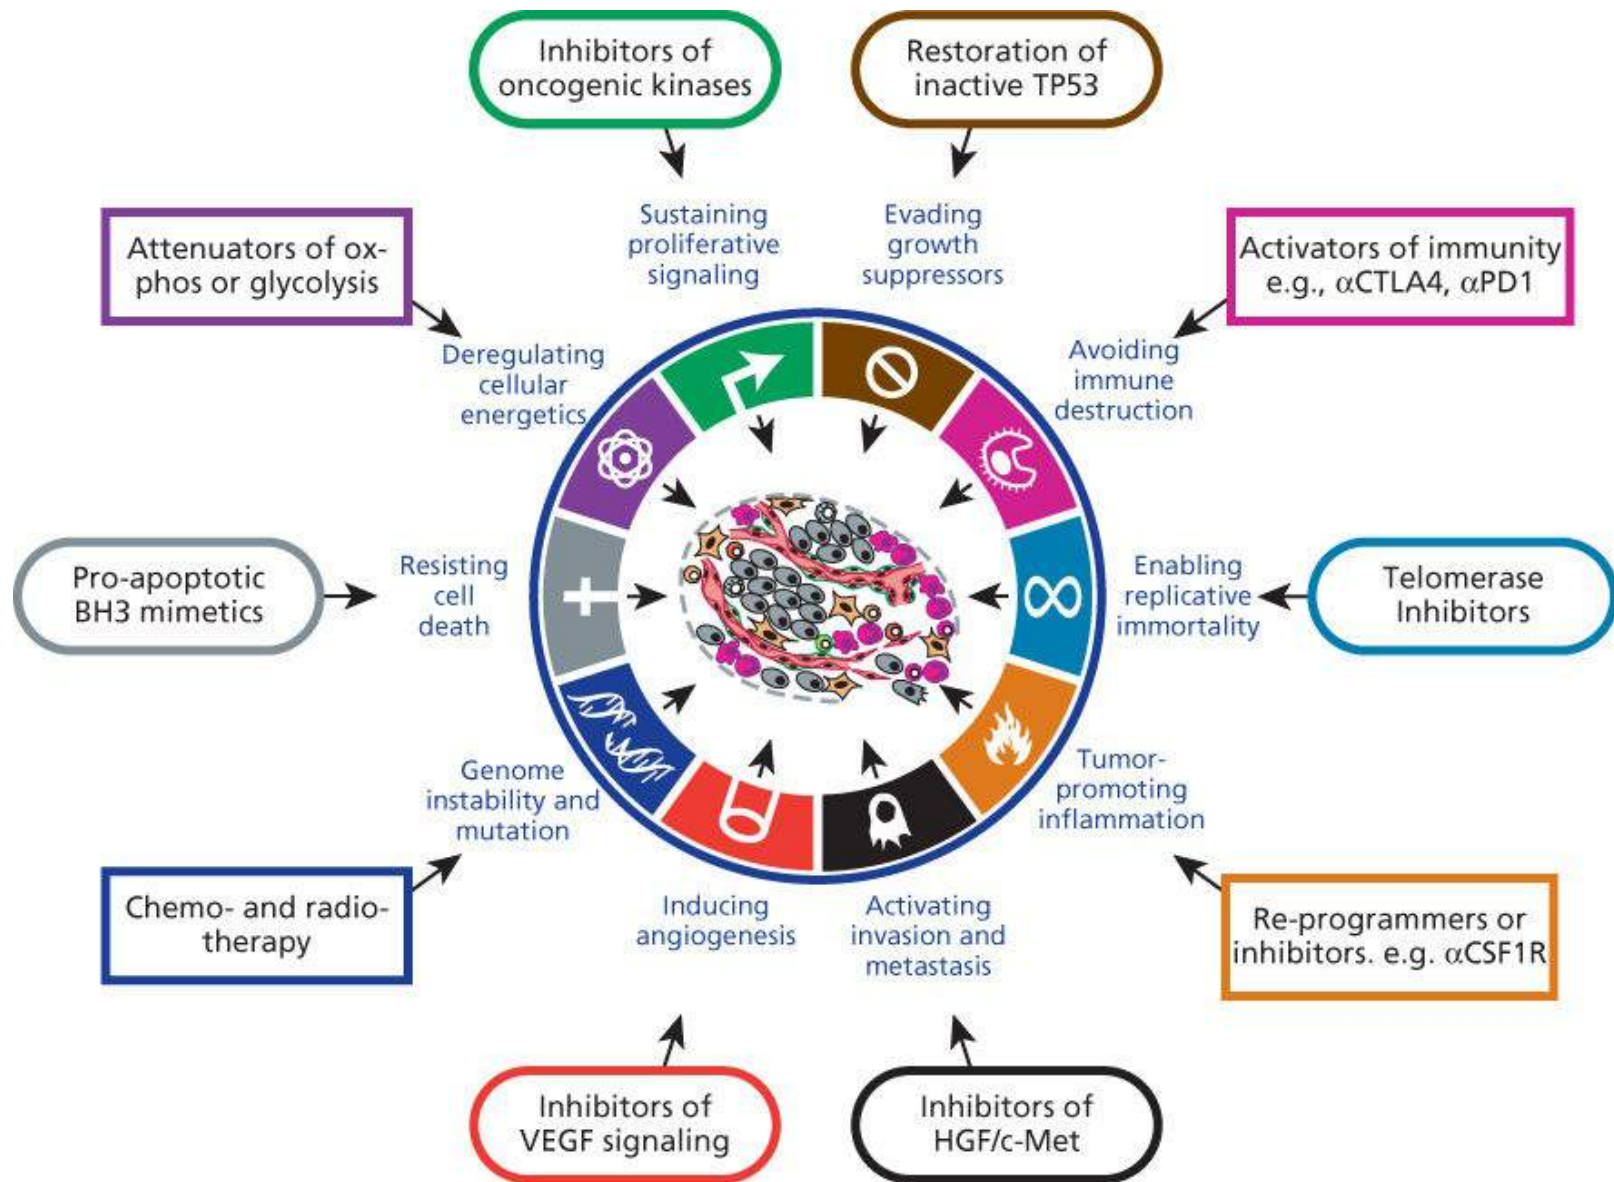

Figure 3 Therapeutic targeting of the hallmarks of cancer. Drugs have been developed that disrupt or interfere with all eight of the hallmark capabilities, and with the two enabling facilitators (genome instability and tumor-promoting inflammation). Some of these hallmark-targeting drugs are approved for clinical use, while others are being tested in late-stage clinical trials; moreover, there is a pipeline full of new hallmark-targeting drugs in development and preclinical evaluation. Recognizing that eventual adaptive resistance during therapeutic treatment is apparent for virtually all of these hallmark-targeting drugs, a hypothesis has emerged: perhaps, by cotargeting multiple independent hallmarks, it will be possible to limit or even prevent the emergence of simultaneous adaptive resistance to independent hallmark-targeting drugs;³⁰ clinical and preclinical trials are beginning to assess the possibilities.

For other hallmark-targeting therapies, it is typical, after a period of response, to see adaptive resistance mechanisms kick in, enabling the surviving cancer cells (and cancer stem cells) to circumvent the

mechanistic blockade imposed by the treatment and resume progressive growth. Various solutions can be proposed to overcome the failures of currently employed, targeted therapies. We suggest that a fruitful therapeutic strategy might involve applying the concept of functionally distinct hallmarks traits, more specifically by targeting multiple hallmarks concomitantly. This multi-targeting may reduce the likelihood of acquired resistance to treatment, thereby yielding significant improvements in initial responses and in long-term survival.³⁰ Certainly, an important issue will be effectively managing the toxicities of such combinations. Thus, in addition to simple cocktails, it may be necessary to use hallmark-targeting drugs sequentially, episodically, or in layers, fine-tuned to maximize efficacy while managing toxicity and limiting adaptive resistance. It is further envisioned that refined preclinical mouse models—both genetically engineered *de novo* and patient-derived xenograft (PDX) transplants—will have utility in testing alternative therapeutic trials designs aimed to reduce the matrix of possibilities to clinically feasible numbers, taking the best-performing trial arms from preclinical trials into clinical trials and personalized treatments.^{31–33}

In conclusion, the hallmarks of cancer may provide the student of modern oncology with a foundation and a framework for absorbing the subsequent topical chapters of this textbook, and more generally for investigating and interpreting pathogenic mechanisms and applying such knowledge toward the development of more effective diagnosis and treatment of human cancers.

Part 2

Tumor Biology

Chapter 3

Molecular biology, genomics, proteomics, and mouse models of human cancer

Srinivas R. Viswanathan, MD, PhD ■ David A. Tuveson, MD, PhD ■ Matthew Meyerson, MD, PhD

Overview

Cancer is a genetic disease. It is typified by abnormalities in genes that control cellular proliferation and lead to the unrestrained growth that characterizes a malignant cell. Thus, to gain the initiative in cancer detection and treatment, oncologists must begin to understand the molecular roots of the disease: genes, their messenger ribonucleic acids (mRNAs), and the proteins they produce. In short, oncologists should be conversant with the tools of molecular biology.

This chapter is a basic survey of molecular biology and is directed toward the clinician or trainee who wants a fundamental understanding of this discipline. It is “methods oriented” and will serve as a frame of reference for other chapters in this book. It describes the principles that underlie the procedures used most commonly by molecular biologists and provides examples of clinically relevant situations that draw on particular techniques. Molecular biology already plays an important role in clinical cancer medicine, both in terms of diagnosis (e.g., in the analysis of tumors for prognostic or pathogenetic information) and in treatment (e.g., in the production of pharmacologic and biologic agents, such as recombinant growth factors and monoclonal antibodies).

We begin with an overview of genes, gene expression, and gene cloning. Our discussion of techniques follow the flow of genetic information as we explain the procedures used to analyze gene expression at the levels of DNA, RNA, and protein. Good general overviews of these topics can be found in several books.^{1–3}

Overview: gene structure

Genes and gene expression

The gene is the fundamental unit of inheritance and the ultimate determinant of all phenotypes. The DNA of a normal human cell contains an estimated 20,000–25,000 protein-coding genes, but only a fraction of these are expressed in any particular cell at any given time. For example, genes specific for erythroid cells, such as the hemoglobin genes, are not expressed in brain cells. The identity of each gene expressed in a particular cell at a given time and its level of expression are defined as the “transcriptome.”

According to the central dogma of molecular biology, a gene exerts its effects by having its DNA transcribed into an mRNA, which, in turn, is translated into a protein, the final effector of the gene's action. Thus, molecular biologists often investigate gene expression or activation, by which is meant the process of transcribing DNA into RNA or translating RNA into protein. The process of transcription involves creating an RNA copy (a “transcript”) of the gene using the DNA of the gene as a template. The mRNA transcript is then translated into a protein by the ribosome, which decodes the sequence

information contained within the transcript to build a corresponding protein composed of amino acids.

Functional components of the gene

Every gene consists of several functional components, each involved in a different facet of the process of gene expression ([Figure 1](#)). Broadly speaking, however, there are two main functional units: the promoter region and the coding region.

Figure 1 Gene expression. A gene's DNA is transcribed into messenger ribonucleic acid (mRNA), which, in turn, is translated into protein. The functional components of a gene are schematically diagrammed here. Areas of the gene destined to be represented in mature mRNA are called exons, and intervening areas of DNA between exons are called introns. The portion of the gene that controls transcription, and therefore expression, is the promoter. This control is exerted by specific nucleotide sequences in the promoter region (so-called cis-acting factors) and by proteins (so-called trans-acting factors) that must interact with promoter DNA and/or ribonucleic acid (RNA) polymerase II for transcription to occur. The primary transcript is the RNA molecule made by RNA polymerase II that is complementary to the entire stretch of DNA containing the gene. Before leaving the nucleus, the primary transcript is modified by splicing together exons (thus removing intronic sequences), adding a cap to the 5' end and adding a poly-A tail to the 3' end. Once in the cytoplasm, mature mRNA undergoes translation to yield a protein.

The promoter region controls when and in what tissue a gene is expressed. For example, the promoter of the hemoglobin gene is responsible for its expression in erythroid cells and not in brain cells. How is this tissue-specific expression achieved? In the DNA of the gene's promoter region, there are specific

structural and sequence elements (see section titled “Structural Considerations”) that permit the gene to be expressed only in an appropriate cell. These are the elements in the hemoglobin gene that instruct an erythroid cell to transcribe hemoglobin mRNA from that gene. These structures are referred to as “cis-acting elements” because they reside on the same molecule of DNA as the gene. In some cases, other tissue-type-specific cis-acting elements, called enhancers, reside on the same DNA molecule but at a great distance from the coding region of the gene.^{4, 5} In the appropriate cell, the cis-acting elements bind protein factors that are physically responsible for transcribing the gene. These proteins are called trans-acting factors because they reside in the cell's nucleus, separate from the DNA molecule bearing the gene. For example, brain cells would not have the right trans-acting factors that bind to the hemoglobin promoter and activate gene expression; therefore, brain cells would not express hemoglobin. They would, however, have trans-acting factors that bind to neuron-specific gene promoters.

The structure of a gene's protein is specified by the gene's coding region. The coding region contains the information that directs an erythroid cell to assemble amino acids in the proper order to make the hemoglobin protein. How is this order of amino acids specified? As described in detail later, DNA is a linear polymer consisting of four distinguishable subunits called nucleotides. In the coding region of a gene, the linear sequence of nucleotides encodes the amino acid sequence of the protein. This genetic code is in triplet form so that every group of three nucleotides encodes a single amino acid. The 64 triplets that can be formed by four nucleotides exceed the 20 distinct amino acids used to make proteins. This makes the code degenerate and allows some amino acids to be encoded by several different triplets.⁶ As discussed in the section titled “Nucleotide Sequencing”, the nucleotide sequence of any gene can be determined using a variety of methods (see below). By translating the code, one can therefore derive a predicted amino acid sequence for the protein encoded by a gene.

Structural considerations

Fine structure

The basic repeating units of the DNA polymer are nucleotides ([Figure 2](#)). Nucleotides consist of an invariant portion, a five-carbon deoxyribose sugar with a phosphate group, and a variable portion, the base. Of the four bases that appear in the nucleotides of DNA, two are purines, adenine (A) and guanine (G), and two are pyrimidines, cytosine (C) and thymine (T). Nucleotides are connected to each other in the DNA polymer through their phosphate groups, leaving the bases free to interact with each other through hydrogen bonding. This base pairing is specific, so that A interacts with T and C interacts with G. DNA is ordinarily double stranded; that is, two linear polymers of DNA are aligned so that the bases of the two strands face each other. Base pairing makes this alignment specific, so that one DNA strand is a perfectly complementary to the other. This complementarity means that each DNA strand carries the information needed to make an exact replica of itself.

Figure 2 Structure of base-paired double-stranded DNA. Each strand of DNA consists of a backbone of five-carbon deoxyribose sugars connected to each other through phosphate bonds. Note that as one follows the sequence down the left-hand strand (A to C to G to T), one is also following the carbons of the deoxyribose ring, going from the 5' carbon to the 3' carbon. This is the basis for the 5' to 3' directionality of DNA. The 1 carbon of each deoxyribose is substituted with a purine or pyrimidine base. In double-stranded DNA, bases face each other in the center of the molecule and base pair via hydrogen bonds (dotted lines). Base pairing is specific so that adenine pairs with thymine and guanine pairs with cytosine.

In every strand of a DNA polymer, the phosphate substitutions alternate between the 5 and 3 carbons of the deoxyribose molecules. Thus, there is directionality to DNA: the genetic code reads in the 5–3 direction. In double-stranded DNA, the strand that carries the translatable code in the 5–3 direction is called the sense strand, whereas its complementary partner is termed the antisense strand.⁷

Gross structure

In eukaryotes, the coding regions of most genes are not continuous. Rather, they consist of areas that are transcribed into mature mRNA (exons) interrupted by stretches of DNA that do not appear in mature mRNA (introns) ([Figure 1](#)). The exact functions of introns are not known with certainty. Some may contain regulatory sequences, and certainly an important purpose is implied by their conservation across evolution. There is reason to believe that the overall physical structure of introns might be more important than their specific nucleotide sequences, because the nucleotide sequences of introns diverge more

rapidly in evolution than do the sequences of exons. Overall, the DNA that ultimately encodes for protein comprises only a tiny minority of total DNA. Between genes, there are vast stretches of untranscribed DNA that are assumed to play an important structural role. There are also many regions that give rise to transcribed “noncoding” RNA species—these regulatory RNAs are transcribed and functionally active without being translated into proteins.^{8–10}

In the nucleus, DNA is not present as naked nucleic acid. Rather, it is found in close association with a number of accessory proteins, such as the histones, and in this form is called chromatin.¹¹ A multitude of accessory DNA proteins allow for the correct packaging of DNA. For example, DNA's double helix is ordinarily twisted on itself to form a supercoiled structure.¹² This structure must partially unwind during DNA replication and transcription.¹³ Accessory proteins such as topoisomerases, histone acetylases, and histone deacetylases, are involved in regulating this process.

Summary

Genes specify the sequence and structure of proteins that are responsible for their phenotype. Although the nucleus of every human cell contains 20,000–25,000 genes, only a tiny fraction of them are expressed in any given cell at any given time. The promoter (with or without an enhancer) is the part of the gene that determines when and where it will be expressed. The coding region is the part of the gene that dictates the amino acid sequence of the protein encoded by the gene. In addition to the proportion of the DNA that contains genes encoding for proteins, the genome contains vast stretches of regulatory sequences and noncoding RNA sequences. DNA is a linear polymer of nucleotides. Ordinarily, the nucleotide bases of one strand of DNA pair with those of the complementary strand (A with T, C with G) to make double-stranded DNA. In the cell's nucleus, DNA is associated with accessory proteins and packaged into the higher order form known as chromatin

General techniques

Restriction endonucleases and recombinant DNA

In eukaryotic chromosomes, individual molecules of DNA are several million base pairs long. Because these molecules are far too large to analyze directly, scientists are usually interested in cutting DNA into fragments of more manageable size. Fortunately, for molecular biologists, bacteria have evolved a highly diverse set of enzymes, the restriction endonucleases, which cleave DNA internally within the polymer¹⁴

In nature, these enzymes have evolved to protect bacteria from invasion by foreign species, such as bacteriophages. To discriminate between “domestic” and “foreign” DNA, these enzymes recognize specific nucleotide sequences. DNA without such specific sequences is left undisturbed by the enzymes. However, when a restriction endonuclease spots a recognition site, it binds to the site and cleaves both strands of the DNA to which it has bound. Individual restriction endonucleases recognize specific sequences, usually in the order of four to six bases in length, and these sequences are often palindromes (i.e., the 5–3 sequence in the upper strand is identical to the 5–3 sequence in the lower strand) ([Figure 3](#)).¹⁵

Figure 3 Digestion of DNA with the restriction endonuclease EcoRI and gene cloning. In this example, a small amount of foreign DNA (a few nanograms) is digested with EcoRI. The nucleotide sequence of this stretch of DNA contains the recognition sequence for EcoRI, GAATTC (boxed). EcoRI cuts the DNA in both strands between the indicated nucleotides, resulting in fragments with five single-stranded tails. This foreign DNA can come from any source, the only requirement being that it contains the same restriction endonuclease recognition sites as the vector. Plasmid vector is also digested with EcoRI to create a linear DNA molecule. The “sticky” single-stranded ends of the foreign DNA can align and base pair with the complementary “sticky ends” of the plasmid, after which DNA ligase covalently bonds foreign DNA to plasmid DNA. This recombinant DNA is introduced into *E. coli* by a process called transformation. Because the bacteria themselves are not resistant to ampicillin, growth in ampicillin will select only those bacteria that have taken up the plasmid DNA (which carries an ampicillin resistance gene). The plasmid contains a bacterial origin of replication so that as the bacterial culture grows, plasmids replicate, resulting in several copies in each bacterium. When the culture has grown to sufficient size, plasmid DNA can be isolated biochemically, foreign DNA can be cut from the plasmid using EcoRI, and the resulting yield will often be milligrams of DNA, that is, greater than a 10^6 -fold amplification.

Although restriction endonucleases cut DNA into smaller fragments, there is a lower limit to the size of useful fragments. One would not want to cut DNA into such small pieces that the informational content of each piece is negligible. Statistically, the longer a restriction endonuclease's recognition sequence, the less frequently this sequence will occur in a stretch of DNA. Therefore, the enzymes most commonly used to cut DNA into usefully large fragments are those that recognize a 6-nt recognition site (so-called six-base cutters). For example, an endonuclease isolated from *Escherichia coli*, called EcoRI, recognizes the sequence GAATTC, and wherever this occurs in double-stranded DNA, it will cleave between the G and A ([Figure 3](#)). (Note that the antisense strand, which reads CTTAAG in the 3'–5' direction, will also read GAATTC in the 5'–3' direction. This is what is meant by a palindromic sequence.)

Gene cloning

Mechanics

The most powerful technique available for gene analysis, and the one technique that is the cornerstone for all others, is gene cloning ([Figure 3](#)). In the gene cloning process, a discrete piece of DNA is faithfully replicated in the laboratory. Cloning provides quantities of specific DNA sufficient for biochemical analysis or for any other manipulation, including joining to a foreign piece of DNA. In the early 1970s, Cohen et al.¹⁶ drew on two fundamental properties of bacteria and their viruses (phages) that made this innovation possible: plasmids and DNA ligases.

Plasmids are circular molecules of DNA that replicate in the cytoplasm of bacterial cells, separate from the bacteria's own DNA. In nature, plasmids often carry genetic information useful to the host bacterium, such as genes that confer resistance to antibiotics. For the purposes of gene cloning, plasmids are important because they contain all of the information necessary for directing bacterial enzymes to replicate the plasmid DNA, in some cases, to many thousands of copies per bacterium.

DNA ligases are enzymes produced by bacteria (and some phages when they infect bacteria) that can link or ligate together separate pieces of DNA. The nucleotide sequence in a piece of DNA does not influence the activity of a DNA ligase so that a DNA ligase can join any two pieces of DNA together, even ones that are not ordinarily connected to each other in nature. Indeed, the power of cloning comes in the ability to “mix and match” segments of DNA in a fashion tailored to the desired use.

Cloning with restriction endonucleases

In the traditional form of gene cloning, one uses a restriction endonuclease to cut open the circular plasmid DNA in a region of the plasmid not necessary for replication ([Figure 3](#)). Suppose, for example, that the enzyme EcoRI cuts open the plasmid in such a nonessential area. EcoRI recognizes the sequence GAATTC and cuts both DNA strands between the G and the A nucleotides. Protruding from the cut ends will be single-stranded DNA “tails” with the sequence AATT. (Note that the tail's sequence in the sense strand is the same as the sequence in the antisense strand when the nucleotides are read in the 5′–3′ direction.) Any other piece of DNA that has been cut with EcoRI will also have single-stranded AATT tails, and the AATT tails on this foreign piece of DNA can base pair with the complementary TTAA tails (reading 3′–5′) on the cut plasmid. When this happens, the foreign DNA piece physically closes the gap in the plasmid, forming a closed circular plasmid again (which is necessary for plasmid propagation).

Although the nucleotides at the ends of the plasmid and foreign DNA now abut each other, they are not covalently connected. This is an unstable situation that the DNA ligase rectifies. The DNA ligase covalently joins the plasmid and foreign DNA to create a recombinant plasmid, which still has all of the information needed to be replicated in a bacterium but which also contains a foreign DNA insert. Obviously, the EcoRI-cut ends of the plasmid can also base pair with themselves again to reform the native plasmid, but molecular biologists have developed a number of tricks to suppress this phenomenon. It should be pointed out that single-stranded tails are not always necessary for making recombinant DNA. Under certain conditions, the DNA ligase can join together two fragments of blunt-ended DNA without these tails.

When a recombinant plasmid is reintroduced into a host bacterium (by a process called transformation), the plasmid will replicate normally. Now, however, its foreign DNA insert is replicated along with the plasmid into which it was inserted. The transformed bacteria can then be grown to large numbers in liquid culture. With each bacterial cell division, the progeny bacteria contain plasmid molecules that continue to replicate. When the bacterial culture contains the desired quantity of this plasmid (this may be milligrams of plasmid DNA in a 1 L culture), it can be reisolated as pure DNA. The cloned foreign piece of DNA can then be cut out (with EcoRI, in our example) for further analysis or manipulation. One can also use bacterial viruses (or phages) in the same manner by infecting host bacteria with recombinant phage-bearing foreign DNA sequences. In all of these experiments, the plasmid or phage that houses the foreign DNA is called a vector because it is the vehicle that directs the foreign DNA into the host bacterium.

These extraordinarily powerful tools, which are now part of the standard armamentarium of all molecular biology laboratories, have been responsible for the development of nearly all of the analytic techniques described later. Several excellent manuals that describe these techniques in detail have been published.^{17, 18}

Gateway cloning

Gateway cloning is a proprietary commercial system that has gained widespread popularity for the ease with which it allows researchers to transfer DNA fragments between plasmids. In Gateway cloning, a DNA fragment of interest is first appended with specific Gateway sequences on the 5′ and 3′ ends (termed “attB1” and “attB2”, respectively). A proprietary recombinase named BP Clonase that recognizes these Gateway sequences is then used to recombine the fragment into a so-called Gateway Donor vector, to generate a clone in which sequences termed “attL1” and “attL2” flank the fragment of interest. Once in the Gateway Donor vector, the fragment (now termed an “entry clone”) can be transferred to any one of thousands of available Gateway Destination vectors using another recombinase mix termed “LR Clonase”.¹⁹ This recombinase-based technology therefore allows gene fragments to be easily shuttled

between plasmids without the need for restriction digestion and purification steps ([Figure 4a](#)).

BP Reaction: Facilitates recombination of an *attB* substrate (*attB*-PCR product or a linearized *attB* expression clone) with an *attP* substrate (donor vector) to create an *attL*-containing entry clone (see diagram below). This reaction is catalyzed by BP Clonase™ enzyme mix.

LR Reaction: Facilitates recombination of an *attL* substrate (entry clone) with an *attR* substrate (destination vector) to create an *attB*-containing expression clone (see diagram below). This reaction is catalyzed by LR Clonase™ enzyme mix.

Gibson cloning

A recent development in cloning has been termed the Gibson Assembly method. This allows for the facile assembly of multiple overlapping DNA fragments. In this method, two or more fragments to be assembled

are mixed together with a combination of three DNA enzymes—an exonuclease, a polymerase, and a ligase. The exonuclease removes the 5' ends of the fragments to be joined, thereby exposing a 3' single-stranded DNA overhang. Overlapping fragments then anneal via their 3' overhangs, and the gaps and nicks are filled in by the DNA polymerase and DNA ligase, respectively. These fragments can be joined together in a one-step isothermal reaction. This powerful synthetic biology method can be routinely used to enzymatically assemble multiple DNA fragments of up to several hundred kilobases.²⁰ For example, it was recently applied to synthesize the complete mouse mitochondrial genome, a size of 16.3 kilobases, using 600 overlapping fragments ([Figure 4b](#)).²¹

Gene probes and hybridization

We shall see in the following sections that what lies at the heart of gene analysis is the ability to identify a specific gene (or mRNA) in a complex mixture of all of the DNA (or RNA) in a cell or tissue. This can be done only when one already has a cloned fragment of DNA from the gene of interest. Such fragments are usually obtained from gene libraries constructed from genomic DNA or complementary deoxyribonucleic acid (cDNA) or generated using polymerase chain reaction (PCR, to be described below). These DNA fragments can be almost any size, from a fraction of the size of the gene (a few hundred or even fewer nucleotides) to the size of an entire gene (several thousand nucleotides). These cloned gene fragments are called probes because they are used to probe native DNA or RNA for the gene of interest.

To be useful, a gene probe must contain a sufficient number of nucleotides so that it will recognize the sequences of its corresponding gene. Recognition occurs by a process called nucleic acid hybridization, in which two pieces of DNA can align themselves (or “anneal”) by base pairing. Hybridization occurs by the specific pairing of A to T bases and of G to C bases ([Figure 2](#)). Perfectly matched sequences pair more tightly than sequences containing mismatches, and long-matched sequences pair more tightly than shorter matched sequences. Hybridization is the concept that underlies many molecular biology methods, such as Southern blotting, Northern blotting, microarray analysis, PCR, and others (see below).

Summary

Total genomic DNA can be cut into smaller pieces using restriction endonucleases that recognize specific nucleotide sequences. Individual genes can be captured from total genomic DNA and replicated in bulk for detailed analysis. This process is called cloning and employs bacterial plasmids and viruses (phage) as carriers for the cloned genes. Enzymes called DNA ligases join foreign DNA to plasmid or phage vectors, which can then replicate within bacterial cells to create gene libraries. Using nucleic acid hybridization, cloned genes can be used as probes to detect the presence of their native counterparts in complex mixtures of DNA or RNA.

Gene analysis: DNA

Southern blotting

One of the most useful techniques for analyzing a gene at the level of genomic DNA is Southern blotting, named for its inventor, E. M. Southern.²² In general, it allows one to determine whether specific nucleotide sequences in a cloned probe are present in a sample of genomic DNA. The presence of these sequences usually means that the gene itself is present in the genomic DNA. [Figure 5](#) diagrams the technique. Purified genomic DNA is digested with a specific restriction endonuclease, which, as described earlier, will produce an array of differently sized DNA fragments. Electrophoresis through an agarose gel then separates these fragments according to size. (Because the phosphate groups in DNA make

the molecules negatively charged, they will migrate toward the anode in an electric field. The semiporous agarose will allow molecules of DNA to pass with varying degrees of ease, at a rate inversely proportional to their size. At any time after electrophoresis begins, smaller molecules will be closer to the anode than larger molecules.)

Figure 5 Genomic Southern blotting. Genomic DNA is digested with a single-restriction endonuclease, resulting in a complex mixture of DNA fragments of different sizes, that is, molecular weights. Digested DNA is arrayed by size using electrophoresis through a semisolid agarose gel. Because DNA is negatively charged, fragments will migrate toward the anode, but their progress is variably impeded by interactions with the agarose gel. Small fragments interact less and migrate farther; large fragments interact more and migrate less. The arrayed fragments are then transferred to a sheet of nitrocellulose- or nylon-based filter paper by forcing buffer through the gel as shown. The DNA fragments are carried by capillary action and can be made to bind irreversibly to the filter. Now the DNA fragments, still arrayed by size on the filter, can be probed for specific nucleotide sequences using a ^{32}P -radiolabeled nucleic acid probe. The probe will hybridize to complementary sequences in the DNA, and the position of the fragment that contains these sequences can be revealed by exposing the filter to X-ray film.

The final goal of Southern blotting is to identify specific fragments of cut DNA using nucleic acid hybridization. Because the agarose gel used in electrophoresis is thick and the DNA fragments can move within it, DNA in the gel is not in a suitable form for further analysis. The DNA fragments must therefore be transferred to a solid support to which they are irreversibly bound to carry out nucleic acid hybridization studies. Thus, after electrophoresis, a paper-thin membrane microfilter (made of nitrocellulose or nylon) is placed over the flat portion of the gel. Liquid is then forced through the agarose gel in a direction perpendicular to the direction in which the DNA moved during electrophoresis. As the liquid perfuses the gel, it carries DNA fragments with it, depositing them on the membrane filter, to which the DNA sticks. After transfer, the DNA fragments are arrayed by size on the solid support.

At this point, a fragment of cloned DNA (the probe) is radiolabeled by using any of a variety of techniques. The membrane containing the transferred DNA is then soaked in a solution containing the radiolabeled probe. If there are any sequences in the genomic DNA that are complementary to those in the probe, the probe will hybridize to those sequences on the filter. The unbound probe can be washed away, and the remaining specifically hybridized probe can be visualized by exposing the filter to X-ray film.

What results from these studies is a pattern of one or more bands on an X-ray film. Each band corresponds to a restriction endonuclease-generated DNA fragment containing nucleotide sequences complementary to those in the radioactive probe. For any particular gene probe, the size (i.e., length) of the band it identifies will be the same from individual to individual (see below for a discussion of restriction fragment length polymorphisms [RFLPs], an important exception). Therefore, if a gene has undergone a structural rearrangement, the pattern may change.

As an example, suppose that the c-abl probe ordinarily recognizes a 2000-base EcoRI fragment in normal genomic DNA. If the translocation break point in a chronic myelogenous leukemia (CML) patient occurs within that fragment, part of the c-abl gene and one of its EcoRI sites will move to chromosome 22 from chromosome 9. Southern blot analysis of the patient's DNA may now detect either (1) a larger fragment than normal if the recipient chromosome has an EcoRI site farther away than the old EcoRI site or (2) a smaller fragment if it has an EcoRI site closer than the old one. Southern blotting is thus a sensitive technique for detecting large structural rearrangements in the genome, such as those that are occasionally associated with malignancy.

Because the amount of the radiolabeled probe that hybridizes to a Southern blot is proportional to the number of copies of the specific gene present in the target DNA, this technique can also be used quantitatively. For example, in an analysis of primary breast cancer tissue, Southern blotting was used to determine that 30% of these samples contained multiple copies of HER-2/neu oncogene DNA—that is to say, the gene was amplified.²³

Polymerase chain reaction (PCR)

To detect gene sequences by Southern blotting, at least 1–2 mg of genomic DNA are required. This translates into several milligrams of tissue that must be used fresh or freshly frozen. PCR is a powerful technique that can be used to amplify specific fragments of DNA, thus lowering the theoretic limit of detectable DNA sequences in a sample to a single molecule of DNA. With some advance knowledge of the nucleotide sequences in the DNA to be detected, microscopically small amounts of tissue, even a single cell, contain enough DNA to be amplified, and the amplified DNA can be easily used for downstream analysis. Even fixed tissue in paraffin blocks or on slides can yield sufficient DNA for analysis using PCR.²⁴ The concepts underlying PCR are diagrammed in [Figure 6](#). Two short single-stranded DNA fragments, called primers, are designed with sequences complementary to those that flank the stretch of DNA to be amplified. Primers and target DNA are mixed, the mixture is heated to dissociate the paired double strands of target DNA, and the temperature is then lowered to permit hybridization, or annealing, of the primers to their complementary sequences on the target DNA. A DNA polymerase enzyme is added to the mixture, which will add nucleotides to the 3' end of the primers using the target DNA as a sequence template. This step generates one copy of each strand of one target DNA molecule. The mixture is heated again to dissociate the strands and then cooled to allow more primers to anneal to the target sequences on both the original and new pieces of DNA. DNA polymerase is added again and now generates four copies of the target sequences. These steps are repeated, resulting in a geometrically increasing amount of target DNA, that is, a chain reaction. With the discovery and cloning of the DNA polymerase from the thermophilic bacterium *Thermus aquaticus* (the “Taq polymerase”), which retains

activity after being heated to 95°C, heating and cooling steps could be carried out on the same mixture without adding a new enzyme for each cycle.^{25, 26} This allowed the PCR procedure to be automated. There are now automated thermal cyclers in every molecular biology laboratory and in many clinical laboratories; these thermocyclers can take PCR mixtures through 20 to 50 cycles, producing large amounts of synthetic DNA from a tiny quantity of starting sample, to be used for subsequent analysis.

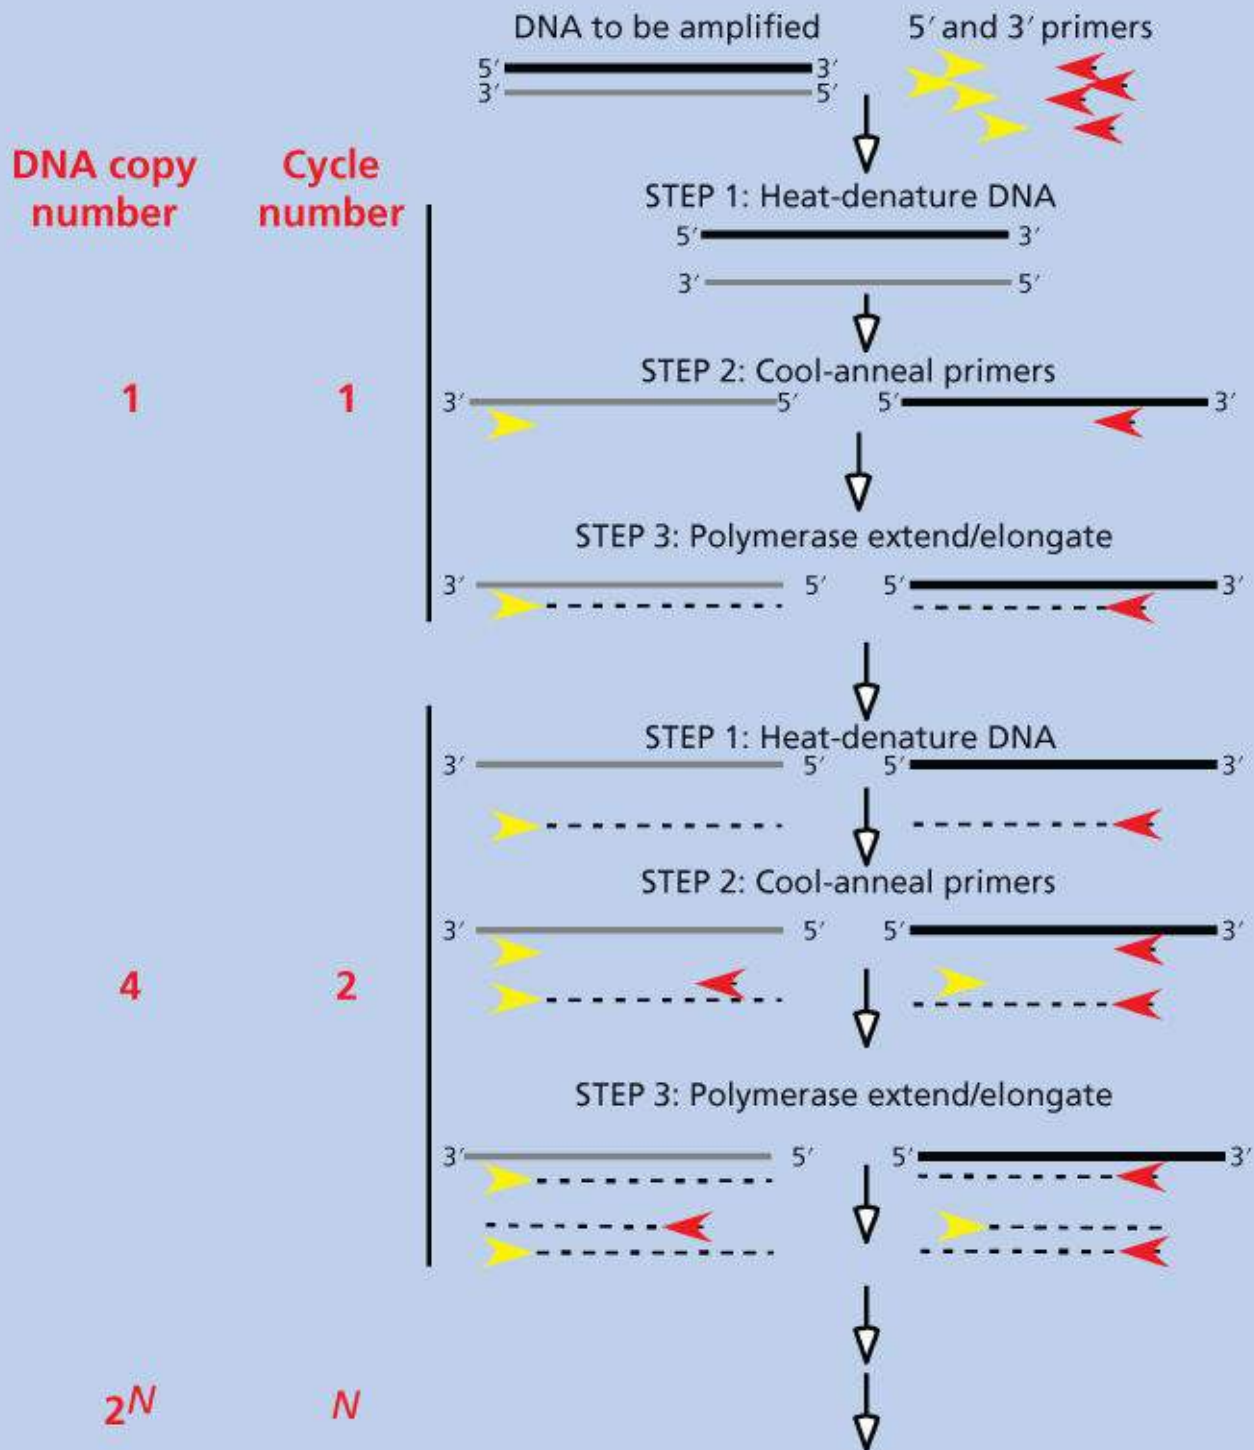

Figure 6 Polymerase chain reaction. DNA is mixed with short (10–20 base) single-stranded oligonucleotide primers that are complementary to the 5' and 3' ends of the sequence to be amplified. The mixture is heated to denature or “melt” all double-stranded DNA and then cooled to permit the primers to anneal to their complementary sequences on the DNA to be amplified. Note that the 5' primer will anneal to the lower strand and the 3' primer will anneal to the upper strand. A heat-resistant (thermostable) DNA polymerase (Taq polymerase; see text) was present in the original mixture, and it now synthesizes DNA by starting at the primers and using the strands to which the primers are annealed as a template. This results in the formation of two double-stranded DNA copies for every molecule of double-stranded DNA in the original mixture. The reaction is then heated to melt double-stranded DNA and cooled to allow reannealing, and the polymerase makes new double-stranded DNA again. There are now four double-stranded DNA copies for each original DNA molecule. This process can be repeated times (usually 20–50) to result in 2^n copies of double-stranded DNA.

DNA polymorphisms

A genetic polymorphism (which literally means “many forms”) is defined as the occurrence of two or more relatively common normal alleles for a single locus. The difference between a polymorphism and a mutation is that a polymorphism occurs more commonly and is associated with a normal variant phenotype. The usual distinction is that a gene is polymorphic when its least frequent manifestation appears in at least 1% of the population. Examples include blood types and major histocompatibility complex molecules.

Polymorphisms need not necessarily be associated with an obvious phenotype. For example, changes in nucleotide sequence within introns or in regions between genes would not necessarily result in altered proteins and could therefore be “silent.” However, if these changes are polymorphic and frequent enough, then there is a high probability that an individual might be heterozygous for the polymorphism. In other words, it would be possible for the two chromosomes of a diploid pair to each carry a different version of the polymorphism. Then, if the chromosomal position of the polymorphic change were known, it could be used as a marker for mapping other genes. There are several varieties of DNA polymorphisms, and they provide the basis for gene mapping techniques that have identified the genomic locations of several important cancer genes.

RFLPs appear as differences among individuals in the pattern of bands on a Southern blot probed with a single cloned DNA. There are two mechanisms whereby DNA polymorphisms are detectable by Southern blotting. First, a single nucleotide change might either create or destroy the recognition site for a restriction endonuclease. This would cause an alteration in the Southern blot pattern of that gene when the DNA is digested with a particular restriction endonuclease. For example, if a stretch of DNA with the sequence...AGGATTTCGA...in one individual contained a single nucleotide change in a second individual so that the sequence was...AGGAATTTCGA..., the recognition site for EcoRI (GAATTC) would be created in the second individual. Digesting the second individual's DNA with EcoRI would generate two new restriction fragments and remove one old one when compared with the first individual's DNA ([Figure 3](#)).

The second mechanism of RFLP involves one of the more mysterious features of genomic DNA in eukaryotes, namely, that it is replete with repeated sequences of unknown function. The sequences often stretch themselves along the DNA polymer, one set of sequences after the other, in so-called tandem repeats. In humans, the best known repetitive sequence is called Alu (because it contains recognition sites for the restriction endonuclease AluI); its nucleotide sequence is so specific to humans that it can be used to identify human DNA in a mixture of DNAs from many species. In many cases, the number of tandem Alu repeats varies among individuals.²⁷ Therefore, if one does a Southern blot with a DNA probe that recognizes a restriction fragment containing tandem repeats, the size of that fragment may vary from one individual to the next. This type of RFLP is also called variable number of tandem repeats (VNTRs).

Both of these types of RFLPs are stably inherited in a Mendelian fashion, which permits them to be used in gene mapping. RFLPs occur at specific positions (loci) in genomic DNA. If all of the affected individuals in a family with a particular genetic disease inherit the same RFLP, there is presumptive evidence that the gene for the disease is close (or “linked”) to the RFLP locus. Linking a disease locus to an RFLP maps the location of the gene for that disease and is the first step toward cloning the gene responsible for the disease. These are the tools of reverse genetics, which have also led to the identification of many of the genes associated with malignant transformation. A prime example is the BRCA1 gene on chromosome 17, whose mutations are responsible for a relatively significant fraction of heritable breast cancer.²⁸

RFLPs have also been used to demonstrate gene loss in cancer ([Figure 7a](#)). This approach relies on an individual being heterozygous for an RFLP, that is, having one polymorphism on one chromosome and another polymorphism on the other. If an individual with cancer is heterozygous for a particular RFLP (termed an informative individual), his or her tumor can be analyzed by Southern blotting, using the probe that recognizes the polymorphism, and compared with normal tissue analyzed the same way. If one of the RFLPs present in the heterozygous individual's normal DNA is missing from the tumor cell DNA, the tumor is said to have undergone a reduction to homozygosity, or a loss of heterozygosity (LOH). This implies a loss of genetic material from the tumor, specifically the DNA that includes the missing RFLP. This is the hallmark of tumor suppressor genes, such as Retinoblastoma (Rb) or TP53.^{29, 30}

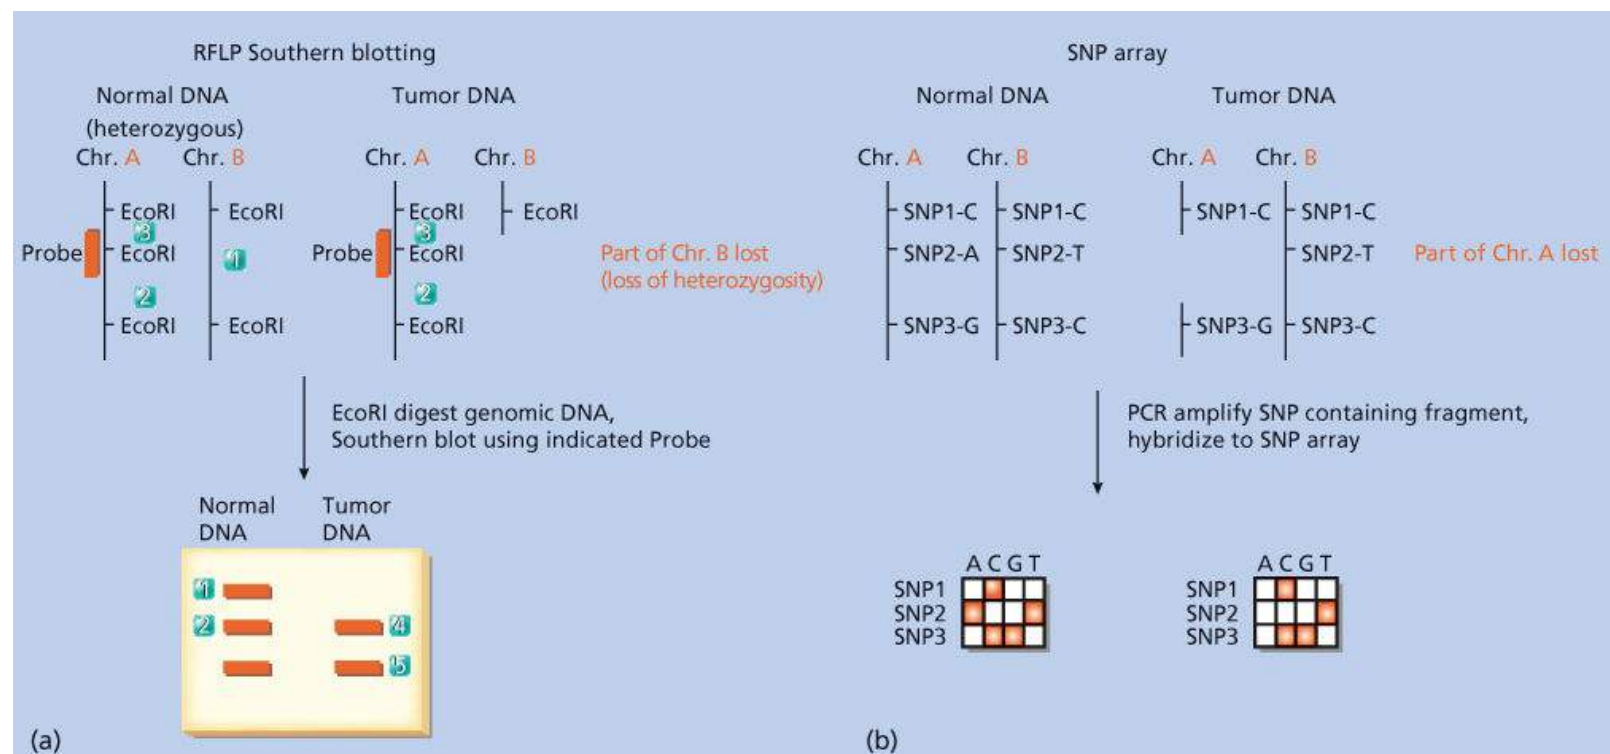

Figure 7 Methods to detect loss of heterozygosity in tumor tissue. (a) Restriction fragment length polymorphism (RFLP) and Southern blotting. In this example, an individual is heterozygous for an EcoRI recognition site: the second EcoRI site on chromosome A is absent on its diploid partner, chromosome B. The individual's tumor is assumed to be clonal and to have arisen from a cell that lost the region of chromosome B displayed in the figure. Southern blotting can then be performed using genomic DNA from the individual's normal DNA and tumor DNA in separate lanes of the agarose gel. Probing the DNA with the probe (indicated on the figure) reveals a heterozygous banding pattern in normal DNA (reflecting the presence of both polymorphisms, one on each chromosome pair) and a loss of that pattern in the tumor DNA. This is one of the hallmarks of a tumor suppressor gene. (b) Single nucleotide polymorphism (SNP) array. In this example, an individual is heterozygous for SNPs 2 and 3 and homozygous for SNP 1. Following the polymerase chain reaction (PCR) amplification of genomic fragments containing each SNP individually, these fragments are hybridized to an array composed of oligonucleotides complementary to the ones amplified. The loss of a heterozygous SNP signal on the array indicates loss of the chromosomal region containing this SNP.

Another type of interesting type of polymorphism is known as a microsatellite. For unknown reasons, about 50,000 copies of the repetitive sequence dC-dA (tandemly repeated 10–60 times) are dispersed throughout the human genome.³¹ Because the longer tandem repeats (VNTRs, as mentioned earlier) have been called minisatellite DNA, the shorter dC-dA repeats are called microsatellite DNA. (The term satellite refers to the fact that the buoyant density of repetitive DNA is different from the majority of

genomic DNA. This leads to the appearance of small satellite bands distinct from the main DNA band when genomic DNA is purified by density gradient centrifugation.) The number of repeats at a particular locus varies in a polymorphic way among individuals, and because these sequences are stably inherited, they can serve as polymorphic markers. The difference in the number of repeat units between two polymorphic microsatellites can be as small as a few nucleotides. These differences cannot be detected by Southern blotting, which has a resolution of 100 nt. However, these differences can easily be resolved using PCR. Primers that flank the repeat region are used in a PCR in the presence of radiolabeled deoxynucleotides, and the products are separated on a DNA-sequencing-style polyacrylamide gel. Mini- and microsatellite polymorphic markers are much more useful in gene mapping than RFLPs because, unlike RFLPs, which usually have only two alleles, the variable number of repeats creates multiple alleles for each locus, significantly raising the likelihood that an individual will be heterozygous for the marker.

Although the number of repeats in a microsatellite marker is usually stable, in some cancers, most notably colorectal cancer, the number of microsatellite repeats in the tumors differs from that in normal colorectal tissue from the same patient. Because the variability in repeat number occurs at all positions throughout the genome of the tumor, this suggests that the tumors experience overall genetic instability.^{32, 33} The basis of this instability is believed to be a mutation in the human homologs of DNA “proofreading” genes that, when mutated in yeast, lead to the appearance of unstable numbers of dC/dA repeats. One of these human genes, MSH2, which maps to chromosome 2, is responsible for hereditary nonpolyposis colorectal cancer.^{34, 35}

Of course, a polymorphism need not create a restriction site, tandem repeat, or other obvious marker. Indeed, most common polymorphisms within the genome are so-called single nucleotide polymorphisms (SNPs).³⁶ SNPs are single base variations within a coding or noncoding DNA sequence; they occur approximately once every 1350 base pairs in the average individual.^{37–39} Like the RFLPs and microsatellite polymorphisms discussed, analysis of SNPs can also be used to localize cancer-causing genes and to determine LOH in human cancers.

The major approach for LOH detection by SNP analysis is through the use of microarrays, or through sequencing (see below). In the microarray approach, genomic DNA is PCR amplified and hybridized to a microarray containing probes corresponding to large numbers of human SNPs. This permits the detection of chromosomal regions of LOH (i.e., regions containing tumor suppressors) as well as the detection of regions of amplification (i.e., regions containing oncogenes) ([Figure 7b](#)). SNP arrays provide a high-throughput and automatable method for large-scale copy number analysis.^{40, 41} Next-generation nucleotide sequencing methods (discussed in detail below) also allow for the inference of copy number alterations, which are characterized by changes in sequencing depth for a given locus in the cancer sample compared with the normal control.⁴² Both of these technologies can be employed on cells from paraffin-embedded tissue specimens, thereby allowing genomic studies on standard pathologic specimens.⁴³

Nucleotide sequencing

Sanger sequencing

The nucleotide sequence within a gene's coding region encodes the amino acid sequence of its corresponding protein. Thus, the nucleotide sequence of a gene can be used to predict the structure and function of its protein product. Historically, the major method used for sequencing DNA has been the “enzymatic chain termination” method devised by Sanger and colleagues.⁴⁴ The chain termination method

relies on properties of enzymes called *DNA polymerases* ([Figure 8](#)). These are enzymes that create new DNA polymers starting from individual nucleotides. However, for a DNA polymerase to work, it needs a template of single-stranded DNA on which to create the new polymer. DNA polymerase adds a new nucleotide to the 3' end of a growing DNA chain, but the base of the new nucleotide must be able to base pair (i.e., be complementary) to the base on the template over which the polymerase is positioned. After the addition of that nucleotide, the polymerase moves to the next nucleotide on the template and adds a new nucleotide to the 3' end of the growing chain. Again, the new nucleotide must be complementary to the next base in the template. When the process is completed, the DNA polymerase will have made a new DNA chain whose nucleotide sequence is completely complementary to the template DNA.

Figure 8 DNA polymerase. In this schematic, the enzyme DNA polymerase is creating a new DNA chain (upper strand) using a template (lower strand). Specific nucleotides are added from the 5' to the 3' direction as determined by the next nucleotide in the template.

Nucleotide sequencing is based on the observation that when DNA polymerase adds a synthetic abnormal nucleotide to a growing chain, the polymerization stops. The synthetic “terminating” nucleotides used most commonly are dideoxynucleotides that have no alcohol substitutions on the 3' carbon of their deoxyribose groups and thus cannot be joined by a phosphate bridge to the next nucleotide ([Figure 2](#)). For example, in the presence of dideoxyadenosine triphosphate (ATP), chain termination will occur wherever an A appears in the new DNA sequence (a T in the template) ([Figure 9](#)). These reactions are performed *in vitro* in a test tube, where millions of new DNA molecules are being made at once. If normal deoxy-ATP is mixed with dideoxy-ATP in the proper proportion, only a few of these molecules will terminate at each T in the template. This will generate a series of new DNA polymers, each one stretching from the beginning of the chain to the position of an A (i.e., a T in the template). If the newly formed DNA is fluorescently labeled, the products can be separated electrophoretically in a polyacrylamide gel or capillary gel (see below). Each step of the ladder is a fragment of DNA that stretches from the start of the new polymer to the position of an A. Four separate reactions are performed using each of the four

dideoxynucleotides, each coded with a distinct fluorescent color. The four reactions are run together in a capillary gel, and the order of nucleotides is read by the order of the different colors.

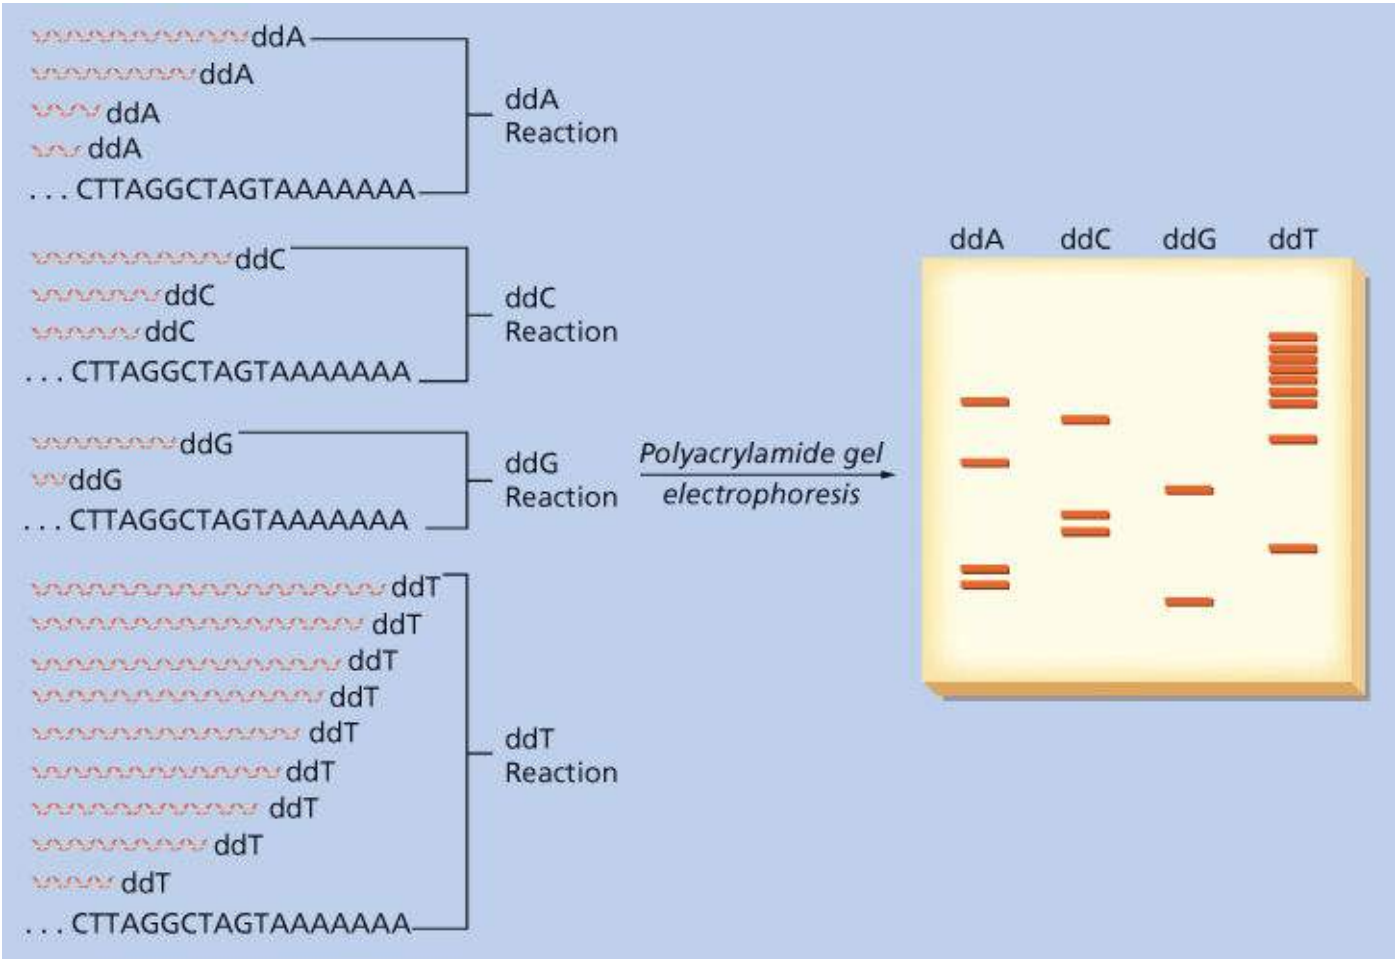

Figure 9 DNA sequencing using the chain termination method. In this example, DNA ending with the sequence CTTAGGCTAGTAAAAAAA is being analyzed. Four reactions are performed, each using this DNA as a template for a DNA polymerase reaction and each containing one of the four dideoxynucleotides (dideoxyadenosine triphosphate [ddA], dideoxycytidine triphosphate [ddC], dideoxyguanosine triphosphate [ddG], and dideoxythymidine triphosphate [ddT]). In each reaction, chain elongation will terminate when the dideoxynucleotide is incorporated at the position of its complementary nucleotide in the template. This will result in a family of chains of differing lengths that correspond to the position at which polymerization terminated. In this example, these chains can be resolved by electrophoresis through a urea-containing polyacrylamide gel, in which longer chains run near the top of the gel and shorter chains near the bottom. Each new chain is radioactively labeled, and after autoradiography, the pattern of bands can be read from X-ray film. By noting the order in which bands appear, starting at the bottom of the gel, one can read the sequence of the template by substituting the complement of each dideoxynucleotide at every position. Reading from the bottom yields GAATCCGATCATTTTTTTT, and substituting the complementary base at each position yields CTTAGGCTAGTAAAAAAA, the sequence of the template. The use of fluorescent labels in capillary gel electrophoresis is conceptually similar.

Sanger sequencing has served as the backbone for a generation of biological discovery, and was instrumental to the Human Genome Project, which launched in 1990 and was completed in 2003. Following the successful assembly of the human genome sequence, genome researchers shifted their efforts from *de novo* to comparative sequencing. These studies have aimed to sequence the genome in both its normal and diseased states, with the aim of understanding the genomic changes associated with disease.

Perhaps the most active area of comparative sequencing has been in cancer genomics. Early sequencing studies targeted to particular genes or gene families identified key differences between the cancer and normal genomes; in many cases, these discoveries provided the rationale for targeted therapeutics. For example, the discovery of mutations in the c-kit protein tyrosine kinase gene by DNA sequencing of gastrointestinal stromal tumors (GISTs)⁴⁵ led to the successful treatment of GIST with the c-kit inhibitor STI-571 or Gleevec.⁴⁶ In lung adenocarcinoma, activating mutations in the epidermal growth factor receptor (*EGFR*) tyrosine kinase gene are common, especially in East Asian populations.^{47–49} These activating mutations have been shown to predict response to the kinase inhibitors gefitinib and erlotinib.^{47–49} Activating mutations in the *BRAF* serine-threonine kinase gene have been found in over half of all melanomas⁵⁰ and subsequently in other cancer types, including colorectal, lung, and thyroid carcinomas. The *BRAF* inhibitor Vemurafenib leads to improved overall survival in patients with metastatic melanoma harboring an activating *BRAF* V600E mutation.⁵¹ Mutations in the phosphatidylinositol 3-kinase catalytic subunit gene *PIK3CA* mutations have been discovered in colorectal carcinoma, glioblastoma,⁵² and breast carcinomas. And in myeloproliferative diseases such as polycythemia vera, the *JAK2* V617F activating mutation is a pathognomonic finding.^{53–55}

Next-generation sequencing

More recent cancer genomics studies have employed “next-generation” sequencing technologies, which far surpass traditional Sanger sequencing in throughput, scale, and resolution. Next-generation sequencing methods allow for millions of short-fragment sequencing reactions to proceed in parallel.^{56–59} One of the biggest advantages of next-generation sequencing with respect to cancer genomics is the ability to effectively detect the numerous mutations present in a heterogeneous cancer sample,⁶⁰ without the need for purification of a clonal DNA template. Indeed, next-generation sequencing assays have become the technology of choice for cancer mutation detection in the research arena and are beginning to be incorporated in clinical diagnostic testing as well.

Next-generation sequencing was employed to sequence the first cancer genome, acute myeloid leukemia, in 2008.⁶¹ Since then, the coding regions (exomes) or whole genomes of a number of other tumor types have been sequenced. Many of these efforts have been coordinated through the Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC) initiatives.⁶⁴

Most commercially available sequencing platforms fall under the category of “cyclic array sequencing.” This term refers to iterative cycles of enzymatic-based sequencing and imaging-based sequence detection, done in parallel on a large array of DNA molecules.⁵⁸ A number of cyclic array sequencing methods currently exist, including those by Illumina (Solexa), Pacific Bio, 454/Roche, SOLiD, and Ion Torrent.

In all of the above approaches, the DNA sample to be sequenced is initially sheared into a library of small DNA fragments. Common adapter sequences are then ligated to each of the fragments, and these adapters are used as the initiating points for PCR-based amplification. This ultimately results in spatially clustered clonal amplicons of each fragment. The amplicons are then sequenced by synthesis, with imaging done at the end of each cycle across the entire array. In this manner, a large number of DNA fragments can be sequenced in parallel in a high-throughput fashion.⁵⁸

Each of the cyclic array sequencing approaches differs in the method used to generate spatially-clustered PCR amplicons of DNA fragments and in the biochemistry underlying the sequencing process. There are also variations in read length, throughput, cost, and accuracy between the different methods. Currently, the Illumina sequencing platform is the most widely used for a majority of applications.⁶² Illumina sequencing

generates clonal amplicons through a method known as “bridge PCR.” In this method, forward and reverse primers complementary to the adapter sequences are immobilized to a glass slide. PCR-based amplification results in a spatial cluster of approximately 1000 copies of each DNA fragment. Cyclic sequencing then occurs. In each cycle of sequencing, a DNA polymerase incorporates fluorescently labeled dNTPs with a reversible 3' termination moiety. Similar to the Sanger sequencing concept, the 3' termination moiety allows only a single base to be added to each fragment. All fragments (or “features”) are then imaged in four colors, with each color corresponding to one of the dNTP species. The reversible 3' termination moiety is then cleaved, and then next cycle of sequencing begins anew. At the end of this process, one is able to obtain the DNA sequence for each of the many fragments, all sequenced in parallel ([Figure 10](#)).⁵⁸

Randomly fragment genomic DNA and ligate adapters to both ends of the fragments

Bind single-stranded fragments randomly to the inside surface of the flow cell channels

Add unlabeled nucleotides and enzyme to initiate solid-phase bridge amplification

The enzyme incorporates nucleotides to build double-stranded bridges on the solid-phase substrate

Denaturation leaves single-stranded templates anchored to the substrate

Several million dense clusters of double-stranded DNA are generated in each channel of the flow cell

The first sequencing cycle begins by adding four labeled reversible terminators, primers, and DNA polymerase

After laser excitation, the emitted fluorescence from each cluster is captured and the first base is identified

The sequencing cycles are repeated to determine the sequence of bases in a fragment, one base at a time

Target enrichment and clinical panel testing

While the methodology described above can be used to sequence an entire genome, this is not always technically or computationally feasible, cost-effective, or necessary. “Target enrichment” refers to the process whereby a nucleotide library is enriched for particular genomic regions of interest prior to sequencing. Target enrichment can be performed through a variety of methods, including PCR, molecular inversion, and hybrid capture; hybrid capture has emerged as the most popular method in most situations. An excellent review is available on this topic.⁶³

In hybrid-capture target enrichment, oligonucleotide probes for genomic regions of interest are hybridized to a fragmented DNA library, and nonbinding fragments are washed away. The hybridization reaction may occur either on a surface (i.e., a slide) or in solution. In cancer genomics, hybrid capture technology is commonly used to reduce a full genome library to only those fragments that correspond to “exomes,” or the protein-coding genomic regions. So-called whole-exome sequencing reduces the total amount of DNA to be sequenced from 3 Gb to 30 Mb. This reduces computational demands, cost, and sequencing time while still elucidating the majority of somatic mutations likely to occur in human cancers.^{63, 64}

As next-generation sequencing has decreased in cost and increased in reliability, it is being increasingly incorporated into clinical testing. Several institution-specific and commercially marketed targeted gene panel tests are currently available. These panels use target enrichment and next-generation sequencing technologies to sequence a selected set of cancer-driving genes with the aim of providing genomic data likely to influence prognostication or choice of therapy.

Bioinformatics approaches

Perhaps equally important as the sequencing technologies described above are the bioinformatics approaches for analyzing the data generated by those technologies. Once DNA sequences are obtained from a tumor sample and a matched germline control, the first step is to quality control the raw reads by removing low-quality sequences (usually at read ends) and removing the sequences corresponding to the adapters. The tumor and normal sample reads are then aligned to the reference genome using one of several available sequence alignment algorithms, and differences from the reference sequence are identified. In general, bioinformatics tools are then used to assess for three major types of alterations: single nucleotide substitutions or small insertion-deletions, copy number alterations, and structural rearrangements ([Figure 11](#)).^{42, 64}

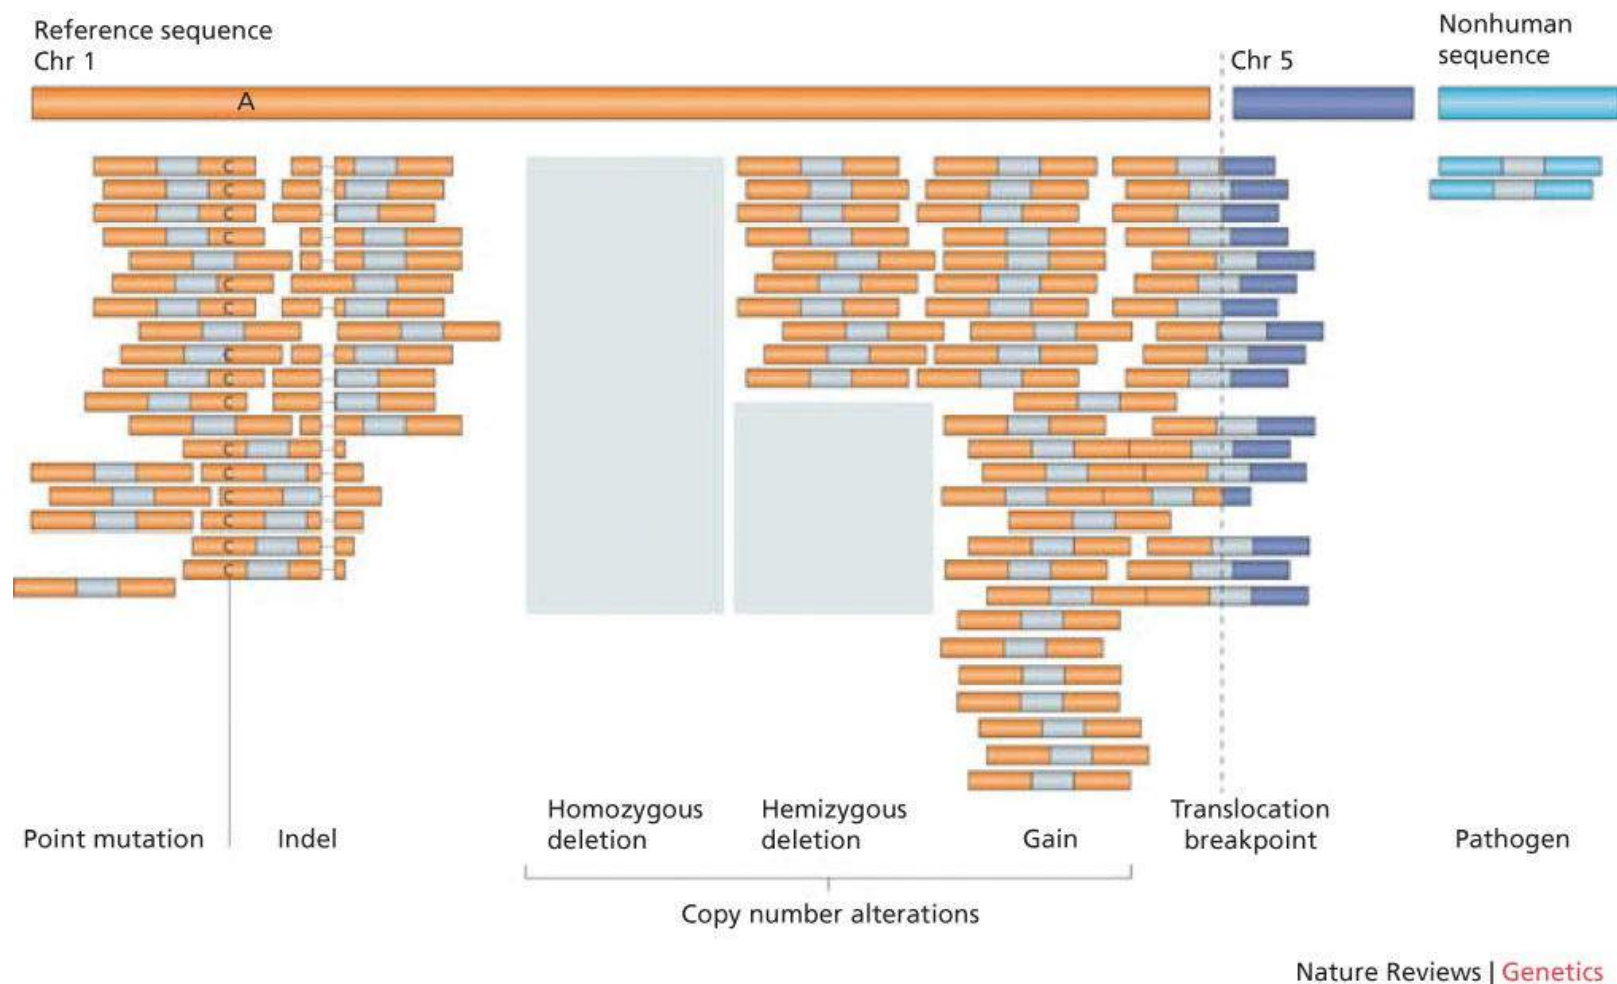

Figure 11 Types of genome alterations that can be detected by second-generation sequencing.

Single-nucleotide substitutions and small insertion-deletions

A single-nucleotide substitution or small insertion-deletion (“indel”) is detected as a change in the tumor sequence that varies in frequency from the germline control and from the reference genome. For example, germline mutations are generally found in a frequency of either 50% (if heterozygous) or 100% (if homozygous), but single-base substitutions within a tumor sample may be found at a range of frequencies, depending on the mutant allele fraction within the tumor tissue, the purity of the tumor sample, and the ploidy of the tumor. Ultimately, mutation calling is a statistical task and is based in the statistical significance of the number of mutation counts in the cancer sequence compared with the matched normal.^{42, 64} A number of somatic mutation calling tools exist, including MuTect,⁶⁵ VarScan2,⁶⁶ JointSNVMix,⁶⁷ and MutSigCV.⁶⁸ These and other mutation callers differ in their precise methodologies, but the general goal of all of them is to apply statistical methods to detect somatic mutations with low allele fractions with a high degree of specificity. The major causes of missed mutation calls include tumor admixture with normal tissue, intratumoral heterogeneity, and differences in ploidy. A fundamental advantage of next-generation sequencing over Sanger sequencing is that it is digital, rather than analog. This means that the same stretch of DNA can be read multiple times, allowing for “oversampling” or sufficient depth of coverage necessary to confidently call somatic alterations at a statistically significant level.^{42, 64}

Copy-number variations

Next-generation sequencing affords the ability to interrogate copy-number changes at single-nucleotide

levels, a significant increase in resolution over array-based technologies. In simplistic terms, copy number can be inferred from next-generation sequencing data by comparing the number of reads at a locus in the tumor sample to that in the normal control. Several bioinformatics tools for inferring copy number from next-generation sequencing data exist. These tools take into account the fact that copy-number reads within a given window must be normalized for sequence coverage in that region. This is critical, since coverage can vary across the genome based on GC content, ambiguously mapped reads, and other factors.^{64, 69}

Structural rearrangements

Typically, sequence reads are obtained from both sides of a sequence. So-called paired-end sequencing allows one to determine whether the two ends of a sequenced fragment map to the reference genome at an expected distance from each other. When reads are “split,” the two ends of the read map to distinct parts of the genome. Interrogation of split reads can be used to identify intra- and interchromosomal rearrangements, inversions, duplications, and other structural changes.^{42, 70, 71}

Summary

Genomic DNA is too large to be analyzed easily in the laboratory, but it can be cut into manageable fragments using restriction endonucleases isolated from bacteria. Electrophoresis through an agarose gel can separate these fragments by size. Fragments that carry nucleotide sequences corresponding to a gene of interest can then be detected by Southern blotting. Specific nucleotide changes (mutations) that give rise to stable genetic differences can be determined by DNA sequencing, which can be performed via either the traditional “Sanger” method or through next-generation methods. PCR technology permits the detection of specific genes in extremely small amounts of tissue. There are various types of polymorphic sites throughout genomic DNA; some create or destroy restriction endonuclease sites leading to RFLPs; others contain a variable number of tandemly repeated sequences and are called microsatellites; a third group, SNPs, represents single base variations. Nucleotide polymorphisms can be interrogated by microarray technology or next-generation sequencing methods to allow for gene mapping and cancer diagnostics. Next-generation sequencing can be used for high-throughput and high-resolution sequencing of cancer samples, thus allowing for the detection of low-frequency mutations, copy-number alterations, and structural rearrangements in heterogeneous tumor tissue.

Gene expression: mRNA transcript analysis

Structural considerations

The first step in gene expression is transcription of the genetic information from DNA into RNA. The individual building blocks of RNA, ribonucleotides, have the same structure as the deoxyribonucleotides in DNA, except that: (1) the 2' carbon of the ribose sugar is substituted with an -OH group instead of H and (2) there are no thymine bases in RNA, only uracil (demethylated thymine), which also pairs with adenine by hydrogen bonding. Just like the DNA polymerases described earlier, the enzyme RNA polymerase II uses the nucleotide sequence of the gene's DNA as a template to form a polymer of ribonucleotides with a sequence complementary to the DNA template.

For transcription to be “correct,” RNA polymerase II must (1) use the antisense strand of DNA as a template, (2) begin transcription at the start of the gene, and (3) end transcription at the end of the gene. The signals that ensure faithful transcription are provided to the RNA polymerase II by DNA in the form

of specific nucleotide sequences in the promoter of the gene. After reading and interpreting these signals, the RNA polymerase generates a primary RNA transcript that extends from the initiation site to the termination site in a perfect complementary match to the DNA sequence used as a template. However, not all transcribed RNA is destined to arrive in the cytoplasm as mRNA. Rather, sequences complementary to introns are excised from the primary transcript, and the ends of exon sequences are joined together in a process termed splicing.⁷² In addition to splicing, the primary transcript is further modified by the addition of a methylated guanosine triphosphate “cap” at the 5' end⁷³ and by the addition of a stretch of anywhere from 20 to 40 adenosine bases at the 3' end (poly-A tail).⁷⁴ These modifications appear to promote the translatability^{75, 76} and relative stability of mRNAs and help direct the subcellular localization of mRNAs destined for translation.

Northern blotting

The fundamental question in the analysis of gene expression at the RNA level is whether RNA sequences derived from a gene of interest are present in a cell type of interest under conditions of interest. Detecting specific RNA sequences can be accomplished by Northern blotting, the whimsically named RNA analog of Southern blotting. RNA can be isolated from cells in its intact form, free from significant amounts of DNA.⁷⁷ mRNA is much smaller than genomic DNA, so it can be analyzed by agarose gel electrophoresis without the enzymatic digestion steps that are necessary for the analysis of high-molecular-weight DNA.

RNA is single stranded and has a tendency to fold back on itself. This allows complementary bases on the same stretch of RNA to base pair with each other and to form what is termed secondary structure. Because secondary structure can lead to aberrant electrophoretic behavior, RNA is electrophoretically separated by size in the presence of a denaturing agent, such as formaldehyde or glyoxal/dimethyl sulfoxide. After electrophoresis through a denaturing agarose gel, the RNA is transferred to a nitrocellulose or nylon-based membrane in the same manner as DNA for Southern blotting ([Figure 5](#)). Hybridization schemes and blot washing are essentially the same for Northern blotting as for Southern blotting. In this manner, specific RNA sequences corresponding to those in cloned DNA probes can easily be identified.

There is a lower limit to the sensitivity of Northern blotting so that only moderately abundant mRNAs can be detected using this technique. One way to increase the sensitivity of Northern blotting is to enrich the RNA preparation for mRNA. Ordinarily, mRNA makes up <10% of the total RNA content of a cell or tissue; the remainder is made up primarily of ribosomal RNA and transfer RNA. An RNA preparation can be enriched for mRNA species by removing all RNA molecules that lack the 3' poly(A) tail.⁷⁸ This can be done by exposing the RNA preparation to a tract of poly(U) or poly(T) bound to an immobilized support, such as a plastic bead. The poly(A) portion of mRNA will bind to the poly(U) or poly(T) material, and non-poly(A)-containing RNA can be washed away. After washing, the poly(A)-containing mRNA can be recovered from the solid support and used in Northern blot analysis. This procedure improves the sensitivity of Northern blotting by nearly two orders of magnitude.

A dramatic use of Northern blotting in cancer research has been the demonstration of oncogene expression in some human tumors. RNA was isolated from human tumor samples and analyzed by Northern blotting using cloned DNA probes derived from various oncogenes. The earliest observations included expression of c-abl and c-myc in human tumor cell lines and leukemic blasts.^{79, 80} Since these early discoveries, a large number of proto-oncogenes have been shown to be transcribed in primary human tumor tissue.

Complementary deoxyribonucleic acid

The flow of genetic information usually runs from DNA to RNA to protein, according to the so-called central dogma of molecular biology. There are, however, exceptions to this rule, the most prominent of which involves the life cycle of retroviruses. These viruses encode their genetic information in RNA rather than in DNA. When they invade a susceptible host cell, they direct the synthesis of a DNA intermediate that is a complementary copy of their genomic RNA. The enzyme that accomplishes this task, reverse transcriptase, is a DNA polymerase (see above) that uses RNA, rather than DNA, as a template to form a cDNA copy of the RNA.^{81, 82} This enzyme can be used *in vitro* to make cDNA copies of any available RNA.

One important application of cDNA synthesis has been the construction of cDNA libraries, which are basically gene libraries consisting only of the genes that are expressed in a cell or tissue of interest.^{83, 84} Most of the time, one is not really concerned with all of the DNA in the genome, as a large proportion of the cell's DNA is composed of intronic sequences, promoters, and vast regions of “noncoding” DNA that lies between genes. Therefore, one way to construct a library comprising only tissue-specific expressed genes is to clone all of the mRNA in a specific cell or tissue of interest. Practically speaking, this is done by using all of the mRNA in a cell as a template for making double-stranded cDNA, which can then be inserted into a cloning vector.

To make a cDNA library, one isolates all of the mRNA from a cell or tissue. Then, using this mRNA as a template, reverse transcriptase is used to make cDNA copies of each mRNA molecule in the mixture. The cDNA is ligated into a plasmid or phage vector as described earlier ([Figure 3](#)), and the recombinant vectors are introduced into bacteria. After growth on agar plates, each bacterial colony or phage plaque of a cDNA library houses a unique recombinant vector containing the cDNA copy of a single mRNA transcript. Desired clones can be detected by nucleic acid hybridization to the plaques or colonies using a radiolabeled gene probe.^{85, 86} Alternatively, if the vector containing the cDNA molecules can direct transcription of mRNA by host bacterial cells, mRNA will be synthesized, and that mRNA will be translated. In this case, each bacterial colony or plaque will produce a different protein, and each protein will have been encoded by an mRNA from the original cell or tissue being investigated. If an antibody directed against a protein of interest is available, the cDNA clone corresponding to the mRNA that encodes that protein can be identified by binding the antibody to the colonies or plaques of the cDNA library. This technique, called expression cloning, often employs the bacteriophage λ gt11 as the cloning vector.⁸⁷

cDNA libraries can be used to clone cDNA for a known gene to discover the sequence of the mRNA it encodes. One application of this is the generation of expressed sequence tag databases by sequencing clones of various cDNA libraries. Alternatively, cDNA libraries can also be used to identify previously unknown genes. In a process called differential screening, cDNAs that owe their existence to a particular differentiation or activation state in the cell of origin can be discovered. For example, this technique has been used to identify genes whose expression is turned on by hormones or by growth factors.⁸⁸

Sequence-based gene expression profiling

The most comprehensive way to display a unique pattern of gene expression that determines the identity of a cell or tissue would be to construct a cDNA library from it and sequence every clone. This was originally thought to be an impossible task and, historically, a technique called serial analysis of gene expression (SAGE) was developed to approximate this goal. In SAGE, the investigator sequences a small and unique fragment (10–17 nucleotides in length) of each expressed gene (called a SAGE tag) and quantifies the number of times it appears (called the SAGE tag number). The SAGE tag numbers, therefore, directly reflect the abundance of the corresponding transcript.

The sensitivity and the quantitative accuracy of SAGE are theoretically unlimited. The generation of a SAGE library does not require any prior knowledge of what genes are expressed in the cell of interest. Therefore, SAGE is able to detect and quantify the expression of previously uncharacterized genes.

The generation of a SAGE library used to be a technically challenging multistep procedure that has been described in detail elsewhere.⁸⁹ However, it has become much more feasible with (and, in many cases, has been replaced by) the emergence of single-molecule sequencing platforms.⁵⁶ [Figure 12](#) outlines the essence of the method.

Figure 12 Construction and analysis of serial analysis of gene expression (SAGE) libraries. In step 1, a complementary deoxyribonucleic acid (cDNA) library is constructed from the cells or tissue of interest, and the cDNAs are immobilized on magnetic beads at their three ends. In step 2, the cDNAs are subjected to restriction enzyme digestion with a so-called anchoring enzyme. This anchoring enzyme is a frequent cutter restriction endonuclease (usually *NlaIII*) that ensures that all of the cDNAs are cut at least once. Subsequently another linker that contains a recognition site for a tagging enzyme is ligated to the cDNA ends. This tagging enzyme is a type two restriction endonuclease (usually *MmeI*) that cuts at some distance to the three sides of the actual recognition site. These tags are then directly processed for single-molecule DNA sequencing platform. Data are analyzed by using software that reads the sequence obtained, derives the tags, matches them to their cognate cDNA, and gives the gene expression profile in a numeric format.

SAGE has been used for the comparison of gene expression profiles of different cell types from normal and tumor tissue⁹⁰ and is one of the techniques that was used by the National Cancer Institute–funded Cancer Gene Anatomy Project (CGAP),⁹¹ an international database aimed at cataloging the genes expressed in various normal and cancerous tissue types. SAGE libraries generated as part of the CGAP

project are deposited on the National Center for Biotechnology Education/CGAP SAGE map Web site (<http://cgap.nci.nih.gov/SAGE>).^{91, 92}

DNA microarray analysis

Another approach to comparative gene expression profiling employs the use of DNA microarrays, often referred to as DNA chips. Two basic types of DNA microarrays are currently available: oligonucleotide arrays^{93, 94} and cDNA arrays.^{95, 96} Both approaches involve the immobilization of DNA sequences in a gridded array on the surface of a solid support, such as a glass microscope slide or a silicon wafer. In the case of oligonucleotide arrays, 25-nt-long fragments of known DNA sequence are synthesized *in situ* on the surface of the chip using a series of light-directed coupling reactions similar to photolithography. Using this method, as many as 400,000 distinct sequences representing over 18,000 genes can be synthesized on a single 1.3×1.3 cm microarray. In the case of cDNA microarrays, cDNA fragments are deposited onto the surface of a glass slide using a robotic spotting device. For both microarray approaches, the next step involves the purification of RNA from the source of interest (e.g., from a tumor), enzymatic fluorescent labeling of the RNA, and hybridization of the fluorescently labeled material to the microarray. Hybridization events are then captured by scanning the surface of the microarray with a laser-scanning device and measuring the fluorescence intensity at each position in the microarray. The fluorescence intensity of each spot on the array is proportional to the level of expression of the gene represented by that spot. This process is illustrated in [Figure 13](#).

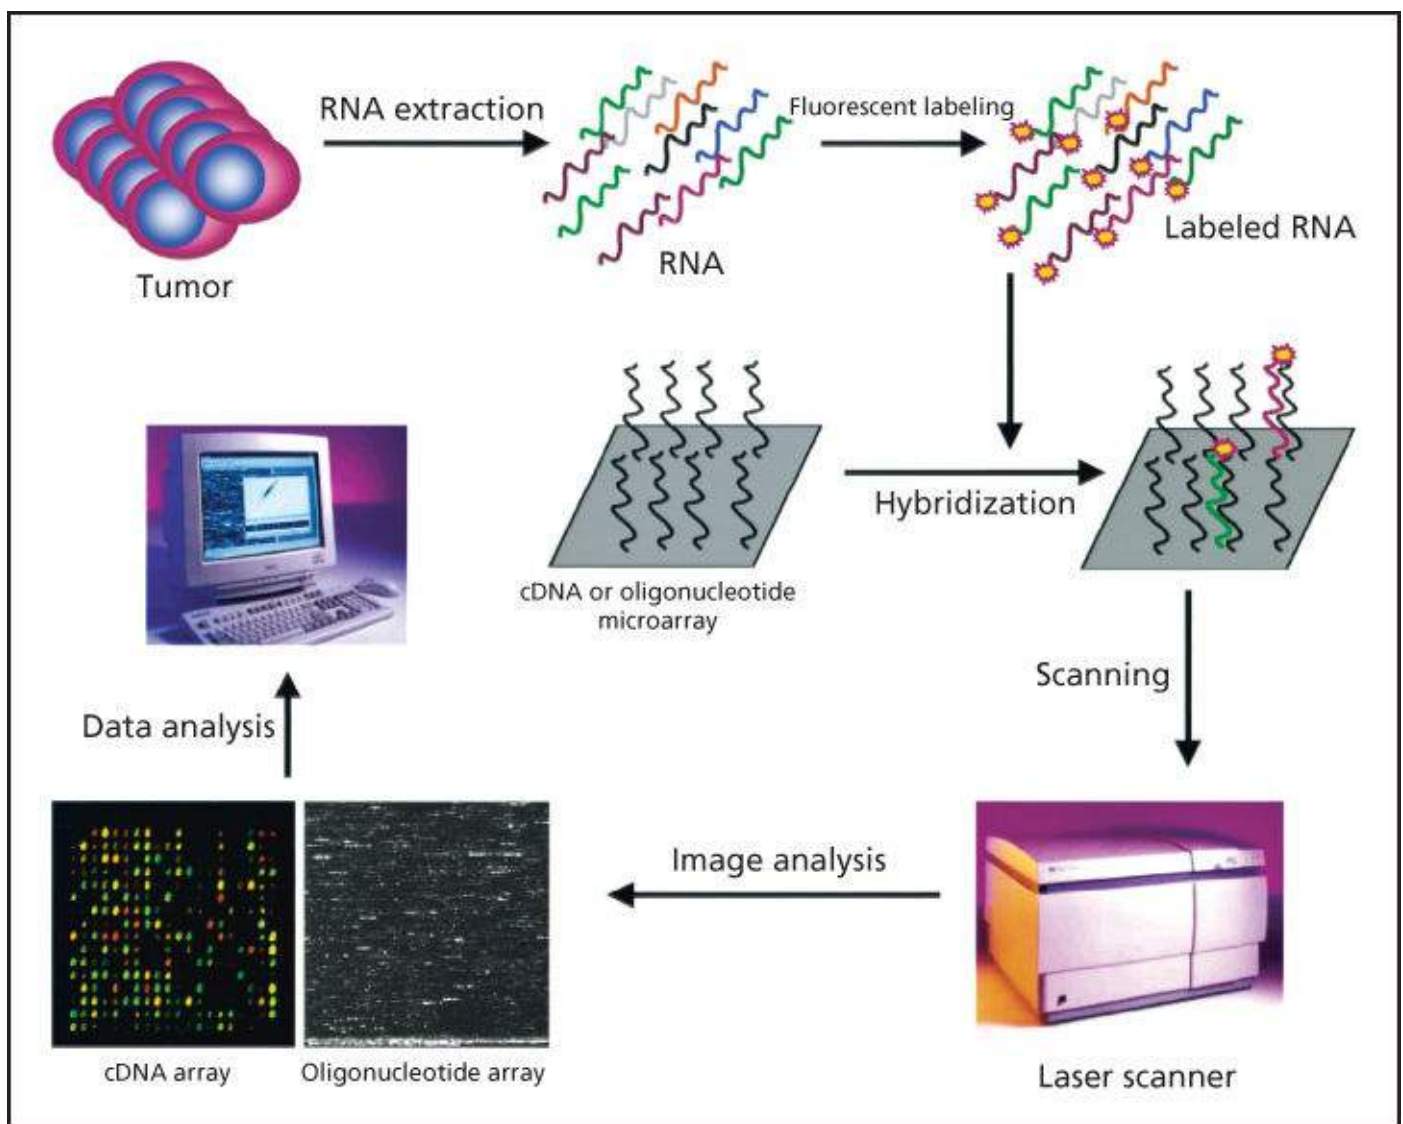

Figure 13 DNA microarray analysis. In this example, RNA extracted from a tumor is end labeled with a fluorescent marker and then allowed to hybridize to a chip derivatized with complementary DNA (cDNAs) or oligonucleotides, as described in the text. The precise location of RNA hybridization to the chip can be determined using a laser scanner. Because the position of each unique cDNA or oligonucleotide is known, the presence of a cognate RNA for any given unique sequence can be determined.

Microarray analysis has proved to be a powerful method for the analysis of gene expression patterns in human cancer and for cancer classification. Gene expression profiles have been used for class prediction, for determining which samples belong to which tumor class, and for class discovery of new tumor types. The first proof of principle for gene expression analysis in cancer was the demonstration that acute myeloid leukemias and acute lymphoid leukemias could be accurately distinguished on the basis of their gene expression profile⁹⁷ Since then, new cancer classes have been discovered in leukemias,⁹⁸ lymphomas,^{99, 100} brain cancer,¹⁰¹ breast cancer,^{102, 103} prostate cancer,^{104, 105} lung cancer,^{106, 107} and others.

The challenge in interpreting microarray data is in recognizing meaningful gene expression patterns and in distinguishing those patterns from noise. Such noise (random gene expression levels) can be generated by (1) variability among microarrays, (2) variability in RNA labeling and hybridization methods, and, perhaps most importantly (3) biologic variability among samples. It is likely that all of the above sources of variability are significant. Many of the problems associated with array-based technologies are eliminated with the use of sequence-based methods described below in the section titled “Transcriptomic

Sequencing”. Thus, as sequencing technologies have improved and become more affordable and widely available, microarray technology has become less used.

Reverse-transcriptase polymerase chain reaction (RT-PCR)

Another important use of cDNA technology has allowed PCR to be applied to RNA. Because the Taq polymerase is a DNA polymerase (see above), it cannot use RNA as a template. Therefore, simply adding primers and Taq polymerase to an RNA preparation will not result in amplification. However, if an RNA of interest is made into cDNA, then PCR can proceed as usual.

The first step in this analysis is generating a cDNA copy of the mRNA of interest using reverse transcriptase. This can be done using a primer consisting of Ts (complementary to the poly(A) tail) or of another sequence complementary to some portion of the 3' region of the mRNA. Once the single-stranded cDNA is produced, it can be amplified in a standard PCR reaction using Taq polymerase as described earlier ([Figure 6](#)). In one of the first applications of this technique, Philadelphia-chromosome-positive leukemias were diagnosed by identifying chimeric bcr-abl mRNA species in clinical material using PCR. Since then, so-called reverse transcriptase polymerase chain reaction (RT-PCR) has come into widespread clinical and laboratory use.¹⁰⁸

One inherent problem in using standard PCR to monitor mRNA expression is quantitation of the amplified PCR products. In Northern blotting analysis, the intensity of the hybridization signal is directly proportional to the amount of target RNA in the sample. Thus, one can compare the number of RNA molecules in one sample with another. With PCR, however, a slight change in the efficiency of polymerization in an early cycle in one sample will lead to a geometrically increasing discrepancy between the amount of amplified product in that sample compared with another sample, and the amounts of PCR product when the reaction reaches saturation can also differ significantly. Fortunately, a number of techniques have been described for normalizing the products of PCRs to allow quantitative comparisons.

Most notably, quantitative real-time PCR¹⁰⁹ is a method for continuous monitoring of amplification. This method makes quantitative comparisons of amplifications during the unbiased linear range in which each cycle gives a constant increase in amplification. In one common method of quantitative real-time PCR, a fluorogenic probe that contains a fluorescent tag on one end and a quencher on the other end is designed within the amplified region. Amplification leads to digestion of the probe, thus liberating a free fluorescent molecule; the increase in fluorescence with each cycle is measured, and it is proportional to the amplification.

Transcriptomic sequencing

A major advance in analysis of the transcriptome has been the development of RNA-sequencing technology. RNA-sequencing (RNA-Seq) allows for precise characterization of the transcripts present in a cell at single-nucleotide resolution. While microarray analysis, SAGE, quantitative RT-PCR, and Northern blotting can all be used to quantify known transcript abundance, RNA-Seq also allows for *novel* transcript discovery. This affords the ability to discover new classes of RNA species, to analyze alternative-splicing patterns, and to interrogate RNA-editing and other RNA-processing events.

To perform RNA-Seq, total RNA is first isolated from a sample of interest. Most commonly, polyadenylated RNA is then selected from the total RNA population, although other types of enrichment for different RNA species (i.e. small RNAs, as shown in [Figure 14](#)) can also be performed. Once the RNA subtype of interest has been selected from the total RNA population, this RNA is then fragmented and reverse transcribed into cDNA using a reverse transcriptase. Once cDNA is produced, it can be

amplified and sequenced using the next-generation platforms described above. Typically, 50–200 million short reads are produced from an RNA-Seq run, with most read lengths in the 50–250 bp range ([Figure 14](#)).¹¹⁰

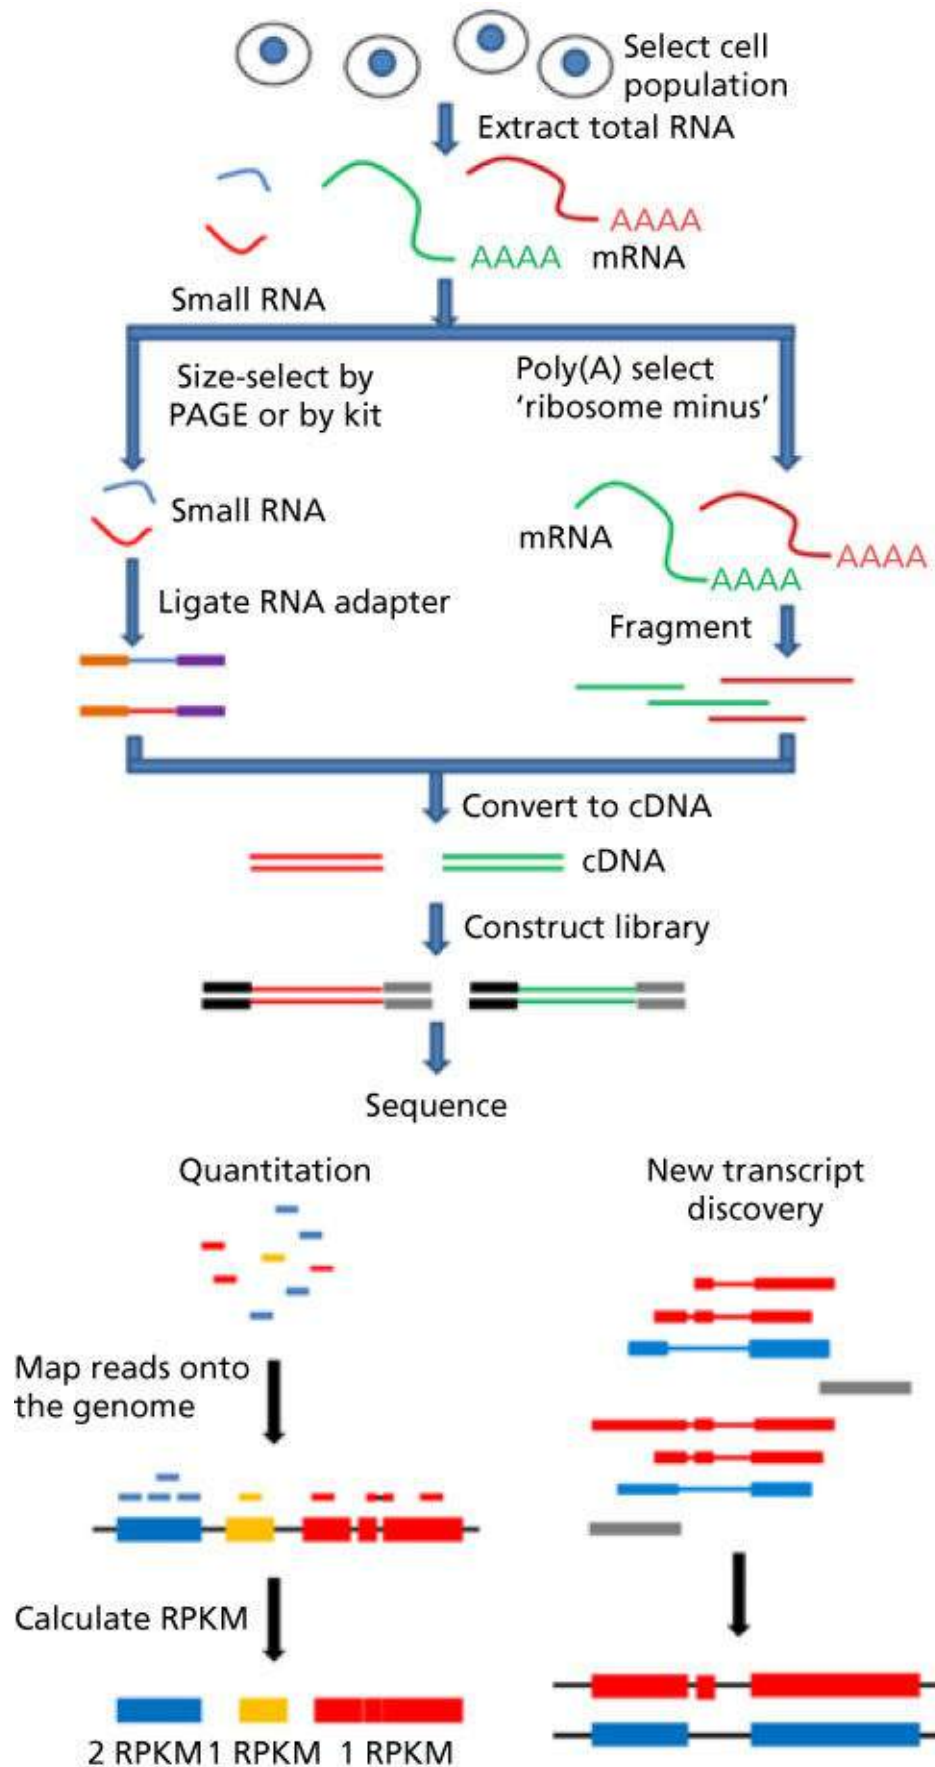

Figure 14 RNA-seq work flow.

Source: Zeng 2012.¹¹⁰ Reproduced with permission of Nature Publishing Group. RPKM, reads per kilobase per million mapped reads.

After these short RNA sequences have been obtained, they must be “assembled” to reconstruct the transcripts that comprise the transcriptome. This is usually done by aligning the reads to a reference genome. The use of paired-end reads—or fragments that are sequenced from both ends—allows for higher quality sequencing data, and is more likely to produce faithful alignments to the reference genome. Read alignments are then assembled into transcript models using computational methods, and expression levels of individual transcripts are then quantified. A common unit used to quantify transcript expression level is “RPKM,” or reads per kilobase per million mapped reads.^{111–113}

RNA-Seq offers the ability to quantify transcript abundance, as well as the opportunity to identify unannotated transcripts, splice variants, gene fusions, nonhuman transcripts, and somatic mutations, among other events. This is a significant advantage over microarray analysis, which is limited by a defined set of predesigned probes.¹¹⁰ Therefore, RNA-Seq has begun to supplant microarray technology as a method for studying transcriptomes.

Clinical application of gene expression profiling

A number of gene-expression-profiling-based diagnostic tests have been approved by the Federal Drug Administration (FDA), and these are increasingly being incorporated into the clinical management of patients diagnosed with early-stage breast cancer.^{114, 115} Examples include the Oncotype DX,¹¹⁶ Mammaprint,¹¹⁷ PAM50,¹¹⁸ and the H : I ratio Breast Cancer Index.¹¹⁹ Each of these tests uses the expression level of a set of genes (ranging in number from two genes in the Breast Cancer Index to 70 genes in the Mammaprint assay) to provide prognostic information about a patient's breast cancer recurrence risk. These and other expression-based tests vary in their clinical utility, indications, and diagnostic validity. Of these tests, the Oncotype DX, or 21-gene recurrence score, is the most widely used and has been incorporated into management guidelines from the American Society of Clinical Oncology (ASCO).

The Oncotype DX score was developed on the basis of testing of the expression of a candidate gene set (250 cancer-related genes) by quantitative real-time PCR in fixed tissue from a large number of patients collected from three different datasets. The score was then validated in an independent dataset derived from samples banked on the NSABP B-14 trial, a large prospective randomized trial designed to test the benefit of adjuvant tamoxifen in hormone-receptor-positive, node-negative breast cancer.¹¹⁶ It was found that a gene signature composed of 21 genes predicted 10-year breast cancer recurrence. The expression levels of these 21 genes measured by quantitative RT-PCR are fed into an algorithm and used to produce a number between 0 and 100, which is termed the recurrence score. The recurrence score is categorized into low (score <18), intermediate (score >18 but <30), and high (score ≥30). Several follow-up studies in various cohorts have confirmed that the Oncotype DX recurrence score is among the best-validated prognostic assays available. It is currently used to guide prognosis in women with node-negative, estrogen receptor (ER)-positive breast cancer, and to inform the decision about whether these women are likely to glean benefit from adjuvant chemotherapy. In practice, those women with a low recurrence score have a favorable prognosis and are unlikely to derive a significant absolute benefit from adjuvant chemotherapy.

As more and more genomic and transcriptomic data is generated and curated, there has been increasing effort placed on developing molecular prognostic tests for a variety of tumor types. It is important to carefully consider the clinical utility, exact indications, and precisely defined patient population for application of these tests. At present, the molecular prognostic profiles available can supplement, but not replace, clinical prognostic factors.

Summary

The genetic information in DNA is copied, or transcribed, into mRNA by the enzyme RNA polymerase II. Before being transported to the cytoplasm, primary transcripts in the nucleus are modified by splicing out introns, adding a 5' cap and adding a 3' poly(A) tail. A retroviral enzyme called reverse transcriptase can be used to make cDNA copies of mRNA transcripts. These cDNAs can be cloned into cDNA libraries, which are useful for isolating and analyzing expressed genes. The expression level of cytoplasmic mRNA can be interrogated using a variety of techniques, including Northern blotting, RT-PCR, microarray analysis, and transcriptomic sequencing (RNA-Seq). Rapid developments in microarray and RNA-Seq technologies have made clear that the successful elucidation of genetic networks through expression profiling requires the expertise of a new generation of scientists, namely, computational biologists. Gene expression profiles of tumors may be used to guide treatment planning of individual cancer patients in a personalized fashion.

Epigenetic regulation

In recent decades, the search for genes implicated in tumorigenesis focused on genes that are genetically altered in tumors. However, recent progress in understanding the role of epigenetic regulation of tumor suppressor genes and oncogenes suggests that epigenetic modifications are also likely to play a role in tumorigenesis. Epigenetic modifications affect the expression of genes without causing any alterations in DNA sequence. Epigenetic regulatory programs depend on DNA methylation, chromatin (histone) modification, and noncoding RNAs. Each of these mechanisms has been shown to play a role in regulating cellular differentiation and tumorigenesis. For example, DNA methylation has been demonstrated to play an important role in silencing gene expression, imprinting, and X-chromosome inactivation.^{120–122} Inherited defects in DNA methylation and imprinting result in developmental defects and increase the risk of tumorigenesis. Recent data also implicate DNA methylation and chromatin changes as initiating events in neoplasia preceding the occurrence of genetic alterations.^{123–125} This was experimentally proved in mice by introducing into the germline a hypomorphic allele of the DNA methyltransferase gene DNMT1, which led to 90% decrease in DNA methylation and subsequently to cancer development.¹²⁶

The increased interest in analyzing epigenetic modifications led to the development of novel technologies that allow the analysis of these changes in a comprehensive manner and at a genome-wide scale. Methylation-sensitive arbitrarily primed polymerase chain reaction (MS-AP-PCR),¹²⁷ methylated CpG island amplification followed by restriction difference analysis (MCARDA),¹²⁸ CpG island arrays coupled with differential methylation hybridization (DMH),¹²⁹ restriction length genome scanning (RLGS) using methylation-sensitive enzymes,¹³⁰ methyl-CpG-binding domain affinity chromatography,¹³¹ and gene expression profiling following demethylation/deacetylation treatment,¹³² all have been successfully used for the identification of novel methylated loci in different cancer types.¹³³ Methylation-specific digital karyotyping (MSDK) is a sequence-based technology that enables comprehensive and unbiased genome-wide DNA methylation analysis.¹³⁴ Using a combination of a methylation-sensitive mapping enzyme (e.g., EagI) and a fragmenting enzyme (e.g., NlaIII), short sequence tags can be obtained and uniquely mapped to genome location. The number of MSDK tags obtained from a sample reflects the methylation status of the mapping enzyme sites.

DNA methylation and chromatin modification are interrelated processes and noncoding RNAs may link the two processes together.^{133, 135} In the past several years, the number and type of known histone modifications increased dramatically, and a large set of enzymes that play a role in mediating these

processes has been identified. The four core histones (H2A, H2B, H3, and H4) have been found to subject to various posttranslational modifications, including acetylation, methylation, phosphorylation, ubiquitination, sumoylation, ADP ribosylation, deimination, and proline isomerization. Most of these modifications regulate transcription by influencing the recruitment of other proteins, and a few of them are also involved in DNA repair and chromatin condensation. Using antibodies specifically recognizing methylated histone H3-lys9 and the recently developed ChIP-on-chip,¹³⁶ GMAT (genome-wide mapping technique),¹³⁷ and ChIP-Seq¹³⁸ technologies, it is now possible to analyze heterochromatin changes at a genome-wide scale.

Several recent studies suggest that cancers display a profound genome-wide epigenetic dysregulation.¹³⁹ Interestingly, several large-scale cancer genome sequencing projects have also revealed somatic mutations in epigenetic modifier proteins. Examples include mutation of the DNA methyltransferase DNMT3A in acute myeloid leukemia,^{140, 141} mutation of enzymes involved in DNA demethylation (e.g., TET2, IDH1, IDH2) in myeloid leukemias and gliomas,^{142–144} mutation of the histone methyltransferase SETD2 in renal cell carcinoma,¹⁴⁵ mutation of the histone demethylase KDM6A in bladder cancer,¹⁴⁶ and many others. This highlights the fact that tumorigenesis is likely promoted through cooperation between aberrant epigenetic modifications and genetic mutations, with the genetic mutations at times occurring in the epigenetic modifiers themselves.

Summary

The role of epigenetic programs in tumor initiation and progression is becoming increasingly clear. It is likely that epigenetic alterations may precede genetic events and promote the acquisition of genetic changes. Rapidly evolving technology now allows for analysis of epigenetic marks on a genome-wide scale. Cancer genome sequencing initiatives have identified recurrent mutations in a number of epigenetic modifier proteins. Because epigenetic programs are reversible and targetable with inhibitors of DNA and histone modifier enzymes, the efficacy of epigenetic therapy is currently being tested in several different cancer types.

Gene expression: protein analysis

Structural considerations

Proteins are polymeric molecules consisting of amino acids linked by peptide bonds. The sequence of amino acids in a protein is dictated by the sequence of nucleic acids in the mRNA that encodes the protein. Because amino acids are joined to each other in a linear polymer, there is directionality to proteins, just as there is to DNA and RNA. The 5' end of the mRNA corresponds to the amino end of its cognate protein and the 3' end corresponds to the carboxy end ([Figure 1](#)).

For many proteins, the linear polymer of amino acids must undergo a number of alterations to be functional. These alterations are referred to as posttranslational modifications. For example, proteins destined to be secreted from a cell initially exist as propeptides with a 20- to 30-amino acid sequence at their amino ends. This highly hydrophobic tail, called a leader sequence, remains embedded in the membranes of the endoplasmic reticulum and secretory granule until the protein is to be secreted, at which point, the leader sequence is cleaved. There are many examples of propeptides that undergo cleavage of specific amino acids before they become mature, functional proteins.

Other posttranslational modifications include the addition of various nonpeptide substituents to the side

chains of amino acids. These include simple and complex carbohydrate chains, sulfate groups, and phosphate groups. Phosphorylation of intracellular proteins, usually on serine, threonine, or tyrosine residues, plays an important regulatory role in protein function. For example, many of the cell surface receptors for growth factors, such as the platelet-derived growth factor (PDGF) receptor¹⁴⁷ and the receptor for macrophage colony-stimulating factor (M-CSF)^{148, 149} are themselves protein tyrosine kinases. When this type of receptor binds its ligand, the receptor undergoes a conformational change that activates its kinase activity. The activated receptor then adds phosphate groups to some of its own tyrosine residues and to tyrosines in other proteins. These phosphorylations are part of the signal transduction process, whereby a message is sent from the cell surface receptor to the nucleus. The importance of tyrosine phosphorylation in cell growth may be reflected in the fact that tyrosine kinases form the largest functional subset of oncogenes. Tyrosine kinase inhibitors, such as imatinib mesylate or Gleevec, which blocks the action of the c-abl and c-kit tyrosine kinases, have been proved as effective anticancer chemotherapeutic treatments.^{46, 150}

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis

As with nucleic acids, the most common analytic technique applied to proteins is separation by size using electrophoresis. However, unlike nucleic acids, not all proteins are anionic, and they do not have a uniform charge-to-mass ratio. In the presence of an electric field, a mixture of unmodified and uncharacterized proteins would migrate in an unpredictable way, providing little or no information about their structures. This problem has been overcome by performing protein electrophoresis in the presence of the anionic detergent sodium dodecyl sulfate (SDS). SDS binds to proteins in a uniform way, at approximately one molecule of SDS for every two amino acids. Thus, all proteins become polyanions in the presence of SDS, and the number of negative charges (supplied by the sulfate group in SDS) is directly proportional to the size, or molecular weight, of the protein.

Because proteins are generally smaller than the most commonly analyzed nucleic acids, electrophoresis is performed through a solid support made of polyacrylamide, which resolves low-molecular-weight molecules better than agarose. In the presence of an electric field, proteins in SDS will migrate toward the anode at a rate inversely proportional to the log of their molecular weights.¹⁵¹ Proteins can be analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in the presence or absence of β -mercaptoethanol (β -ME), which reduces sulfhydryl groups on the side chains of cysteines that can bind two separate protein chains together. Electrophoresis in the presence of β -ME permits the analysis of protein subunits, whereas electrophoresis in the absence of β -ME can reveal multimeric protein associations. SDS-PAGE is routinely employed to test the purity of a protein preparation. It is also an integral component of the techniques of immune precipitation and Western blotting, discussed below.

Immunoblotting

One of the most valuable immunologic identification techniques is immunoblotting ([Figure 15a](#)).¹⁵² A mixture of proteins can be electrophoretically separated by SDS-PAGE, and the separated proteins can be transferred to a nitrocellulose or nylon-based filter by electrophoresis in a direction perpendicular to that of the first electrophoresis. The proteins will remain bound to the membrane support. By analogy to Southern blotting for DNA and Northern blotting for RNA, this technique for protein transfer has been called Western blotting. The protein blot can be soaked in a solution that contains a specific antibody that binds to the protein of interest. The presence of the bound antibody on the blot can then be detected if the antibody is labeled. The label can be an enzyme that reveals its presence by catalyzing a color or light-

emitting reaction, or it can be a radionuclide, such as ^{125}I , that can be detected by autoradiography. Alternatively, an unlabeled antibody can be detected by washing the blot in a solution that contains a labeled anti-immunoglobulin antibody. This technique has been used to demonstrate overexpression of the HER2/protein in some breast cancers in which Southern blotting revealed no gene amplification.²³ Because the protein is the effector of gene function and the determinant of phenotype, overexpression of the protein can be highly significant and a Western blot is often considered to be the “gold standard” technique for detecting overexpression.

Figure 15 Methods of protein identification and detection. (a) Immune (Western) blotting. A complex mixture of proteins can be separated by size using electrophoresis (SDS-PAGE). The separated proteins are then transferred to a nitrocellulose or nylon filter in an electric field, maintaining their size-specific spatial orientation on the filter. Antibodies directed against one specific protein (in this case, the gray ellipsoid) in the original mixture are added to the filter and bind to the specific protein. Bound antibodies can be radiolabeled or enzymatically labeled themselves, or they can be visualized by incubating the filter with labeled anti-immunoglobulin antibodies. (b) Immunoprecipitation. A complex mixture of radiolabeled proteins (indicated by different geometric shapes) is incubated with antibodies specific for one of those proteins (in this case, the gray ellipsoid). After the antibodies have bound to their protein, small polystyrene or agarose beads containing staphylococcal protein A are added to the mixture. Protein A binds to the antibodies, and when centrifuged, the beads to which the protein A is bound will sediment to the bottom of the centrifuge tube, taking along the antibodies and the specific protein to which they have bound. The unbound proteins remain in the supernatant and can be removed. After boiling to dissociate the protein A/antibody/protein complex, specifically precipitated radiolabeled protein can be visualized by electrophoresis (SDS-PAGE) and autoradiography. (c) Enzyme-linked immunosorbent assay (ELISA). To perform ELISA, one needs to develop two independent antibodies that bind to the protein to be detected (gray ellipsoid in this example) with high specificity and affinity. One of these antibodies is then coupled to a plate, which is then incubated with the protein mix to be analyzed (this can be tissue, blood, or another body fluid). The specifically bound protein is retained on the plate and is detected with the second antibody generated against it, which is coupled to an enzyme or isotope, allowing quantitation of the bound protein. ELISAs are usually very sensitive and can detect picomolar amounts of proteins.

Immune precipitation

A primary goal of molecular biology is to use gene probes to detect the presence of a particular gene in a complex mixture of DNAs or RNAs. In a similar way, a specific antibody can be used as a probe to detect the presence of a particular protein in a complex mixture of proteins. An antibody directed against a protein of interest can be added to a mixture of proteins under conditions that allow the antibody to bind to its target protein ([Figure 15b](#)). One can then collect all of the immunoglobulins in that mixture by adding a protein that binds to immunoglobulins, such as anti-immunoglobulin antibodies or staphylococcal protein A. These proteins are often bound to a solid support, such as polystyrene beads, which can be removed from the solution by gentle centrifugation. As the beads collect at the bottom of the centrifuge tube, their attached immunoglobulin and target proteins collect there as well. When boiled in SDS and β -ME, the protein complexes dissociate, and they can be electrophoretically separated by SDS-PAGE. This process is called immune precipitation. To document the specificity of the antibody, a second immune precipitation is usually performed with a control antibody that does not bind the protein of interest. The two precipitations can be run side by side on SDS-PAGE, and the protein of interest can be identified by its presence in the experimental lane and its absence from the control lane. The proteins can be identified by staining reactions or, if the protein preparation is radiolabeled, by autoradiography.

An important application of this technique was the demonstration that the protein product of the retinoblastoma susceptibility gene (Rb) binds to proteins encoded by DNA tumor viruses. Antibodies directed against adenovirus proteins were used in an immune precipitation of proteins from cells transformed or infected by adenovirus. In addition to the adenovirus proteins, the precipitated proteins contained another protein that was proved to be the protein encoded by the retinoblastoma susceptibility gene.¹⁵³ Similar experiments using antibodies directed against the large T antigen of SV40 revealed an interaction between the T antigen protein and the RB protein.¹⁵⁴ In both cases, these interactions appear to be central to the mechanisms whereby these viruses oncogenically transform susceptible host cells.

Enzyme-linked immunosorbent assay

Measurement of serum protein levels can be a valuable tool in cancer screening, cancer diagnosis, and monitoring the results of therapy. One of the most important applications of this approach is the measurement of prostate-specific antigen (PSA) levels for the detection and follow-up of prostate cancer.^{155, 156} The method used to measure PSA and other serum protein levels is ELISA.¹⁵⁷ This method is diagrammed in [Figure 15c](#). The principle is essentially the same as immune precipitation, except that instead of binding the antibody to protein A beads, the specific antibody is immobilized onto the surface of a transparent plastic plate. The specific test protein then binds to the antibody (i.e., the immunosorbent part of the assay), and other proteins are washed away. A second antibody, which recognizes a distinct epitope or antigenic region of the same antigenic protein, is then added. This antibody is covalently coupled to an enzyme (hence the enzyme-linked part). Specific binding of the second antibody leads to an enzyme concentration proportional to the amount of protein. The addition of a substrate for a fluorescent, chemiluminescent, or colorimetric reaction then gives a signal proportional to the amount of enzyme and hence the amount of antigenic protein. Small molecule concentrations (i.e., drug levels) can be measured in the same way if there are two independent antibodies, both of which can bind to the molecule at the same time.

Protein sequencing

The ultimate in protein identification is direct determination of amino acid sequence. Automated sequenators that have considerably simplified this technically demanding analysis are now available. In addition, recent advances in protein chemistry have permitted sequencing to be performed on mere picomoles of protein. In fact, Western blotting can be used to purify small amounts of protein, and the fragment of the blot containing the stained protein of interest can be used directly in an automated sequenator.¹⁵⁸

Direct protein sequencing was responsible for ushering in the modern era of molecular oncology. The protein encoded by the oncogene v-sis, the transforming gene of the simian sarcoma virus, was found to be nearly identical to the empirically determined amino acid sequence of the B chain of human PDGF.^{159, 160} This was the first demonstration of a connection between oncogenes and the components involved in normal cellular proliferation.

Mass spectrometry

Dramatic advances in mass spectrometric methods in recent years have made mass spectrometry a preferred method for protein analysis and offer promise for use in diagnostic analysis as well. Mass spectrometry is a technique to convert molecules into ions and then to measure their mass. The distinct mass of a given protein is a method to identify that protein in a mixture. Furthermore, proteins can be identified unambiguously by tandem mass spectrometry, in which the proteins are first fragmented into peptides and separated, and then the peptides are fragmented further for sequencing.^{161, 162} Mass spectrometry is summarized briefly in [Figure 16](#). A recent application of mass spectroscopy has been a technique known as SILAC,¹⁶³ or stable isotope labeling by amino acids in cell culture. In SILAC, cells are cultured in the presence of medium containing either a normal or a heavy (nonradioactive) amino acid. As the cells grow, the amino acids are incorporated into proteins synthesized by the cell. The samples are then combined and subjected to mass spectroscopy. Chemically identical proteins containing either heavy or light amino acid can be distinguished on the basis of their mass. This allows for a quantitative assay of protein abundance between the two samples. SILAC has emerged as a powerful means to perform

quantitative proteomics in cancer biology. Excellent reviews of mass spectroscopy¹⁶⁴ and SILAC are available.¹⁶⁵

Figure 16 Mass spectrometry. (a) Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF). For organisms whose genome sequence is known, the identification of “interesting” protein spots from a two-dimensional gel is routinely performed using MALDI-TOF. A complex mixture of proteins is separated by size and charge using two-dimensional electrophoresis. Protein spots are excised from the gel, digested with a protease, mixed with a matrix solution, and allowed to cocrystallize on a target plate. When a laser is fired at the target plate, the matrix absorbs the laser light's energy and vaporizes, carrying some of the sample with it into a vacuum space. At the time the laser is fired, a high voltage is applied to the target plate to accelerate the ionized sample's movement toward the time-of-flight (TOF) mass analyzer. The resulting peptide fingerprint can then be used to search databases to determine the identity of the protein. (b) The liquid chromatography electrospray ionization tandem mass spectrometry (LC-ESIMS-MS) can be used to obtain amino acid sequence information, allowing highly refined database searches. The approach employs capillary high-performance liquid chromatography (HPLC), which allows very slow (submicroliter/min) flow rates that are essential for obtaining high-sensitivity ESI-MS-MS of peptides. Following the liquid chromatography and electrospray ionization, the ions are analyzed by linearly linked tandem mass spectrometers that yield amino acid composition information.

Engineered protein expression

The final goal of many experiments in molecular biology is the use of biologic systems to synthesize the protein encoded by the gene being studied. This process, called engineered protein expression, can be an experimental end in itself. When the expressed protein synthesized by recombinant DNA methods can be shown to have all of the properties of the natural protein, this is considered to be proof that the proper gene has been cloned. Alternatively, expression can be an end in itself when one wants to produce large amounts of a particular protein that might be difficult to obtain from natural sources.

In vitro translation

One very simple expression method is *in vitro* translation, in which translation occurs entirely in a test tube. All of the components necessary for translating mRNA can be obtained from cells that are highly efficient in protein synthesis, such as reticulocytes (usually from rabbits) or wheat germ. Under the appropriate conditions, and in the presence of all 20 amino acids, a synthetic or purified RNA added to such a system will be efficiently translated into protein. If a radioactive amino acid, such as [³⁵S]methionine, is included in the mix, the reaction products can be analyzed by SDS-PAGE and autoradiography. Demonstrating an appropriately sized protein or one that is recognized by a specific antibody constitutes good evidence that the mRNA in hand is the one the investigator desires.

Large-scale production of recombinant proteins

In vitro translation can be applied only at a small-scale analytic level. To produce large amounts of protein, one must turn to *in vivo* expression systems. One of the simplest involves cloning the cDNA for the desired protein into a bacterial plasmid or phage that contains a transcriptional promoter active in bacteria. When introduced into the appropriate bacterial host, large amounts of mRNA will be transcribed, which, in turn, will be translated into protein. The recombinant protein can then be purified away from all of the bacterial proteins. This is the way in which some clinically available interferons^{166–168} have been produced.

As noted earlier, many eukaryotic proteins require posttranslational modifications for maximal activity. Bacteria do not have the machinery required to accomplish complex modifications, such as the addition of

specific carbohydrate groups. Moreover, the interior milieu of a bacterial cell is a reducing environment so that disulfide bonds essential to the structure and function of many eukaryotic proteins cannot form. When these modifications are required, mammalian cells can be used for expression. The basic concept is the same as in bacterial systems: a cDNA is cloned into a vector with a eukaryotic transcriptional promoter, and the resulting recombinant DNA is introduced into mammalian cells.¹⁶⁹ However, there are still significant disadvantages in the use of mammalian cells for large-scale recombinant protein production. Mammalian cells are expensive to grow *in vitro* because they require a medium rich in nutrients and growth factors. Yeast cells, insect cells, and even plant cells are being exploited as an attractive compromise between mammalian cell culture and bacterial culture for protein expression. These eukaryotic cells can execute most of the posttranslational modifications required by mammalian proteins, including disulfide bonding. At the same time, these cells are easier and more economical to grow *in vitro*. A number of expression vectors analogous to those described here for bacteria and animal cells have been developed for these alternative eukaryotic hosts. Interested readers are referred to other sources for in-depth descriptions.^{170, 171}

Methods for analyzing protein–protein interactions

An important and challenging task in post-genomic biology is to understand the function of proteins encoded by the genome and to determine their involvement in signaling pathways and cellular networks. One approach to understanding protein function is to investigate its interaction with other proteins of known function. By performing such analysis at a genome-wide level, one can create protein–protein physical interaction networks.¹⁷² These networks can be combined with gene expression or other genomic data to generate regulatory and signaling networks at the cellular level. Several methods allow the characterization of protein–protein interactions at a genome-wide scale. These include comprehensive protein pull-down assays, protein chips, and two-hybrid screens. Comprehensive protein pull-down assays use the combination of immunoprecipitation and mass spectrometric methods discussed earlier, whereas protein chips are the application of the microarray technology originally used for DNA or RNA profiling (see above) for protein interaction analysis.

The classic two-hybrid screen is performed in yeast and is based on the Gal4 system. Gal4 is a yeast transcriptional factor with well-defined and functionally distinct DNA binding (DB) and trans-activator (TA) domains and a DNA target sequence. In the two-hybrid screen, the two proteins to be analyzed are fused to the DB and TA domains of Gal4, respectively. The resulting fusion proteins are referred to as “bait” and “prey.” If the two proteins interact, then the DB and TA domains are brought into close proximity and create a functional transcriptional activator, the activity of which can be monitored using various reporter genes. The two-hybrid screen can be performed at three different levels: (1) testing the interaction of two known proteins, (2) testing the interaction of a known protein with all proteins, and (3) testing the interaction among all proteins. Unlike other approaches used for analyzing protein–protein interactions, the yeast two-hybrid screen does not require the expression and purification of any recombinant proteins. Thus, it is fairly straightforward to perform at a genome-wide scale and is applicable for nearly all protein interaction studies. A few such genome-wide studies were recently performed, and the resulting “interactome” maps greatly facilitate the functional annotation of the genome.^{173–175}

Summary

The genetic information in DNA is transcribed into RNA, and the information in RNA is ultimately translated into protein. Like DNA and RNA, proteins are also directional. The amino and carboxy termini

of proteins are specified by the 5' and 3' ends, respectively, of their cognate mRNAs. After translation, proteins may require further modification to be fully functional.

Proteins can be fractionated by size using electrophoresis through polyacrylamide gels in the presence of the anionic detergent SDS (SDS-PAGE). SDS-PAGE is an integral component of the analytic techniques of immune precipitation and Western blotting. Automated analyzers that can directly determine the amino acid sequence of a protein using vanishingly small amounts of material are now available. Mass spectroscopy using methods such as SILAC allows for large-scale quantitative proteomics.

The mRNA that encodes a protein can be translated *in vitro* using cellular extracts of rabbit reticulocytes or wheat germ. For expressing larger quantities of protein, bacterial cells are a simple and economical option, but they cannot perform many of the posttranslational modifications required by mammalian proteins. Vectors that permit mammalian cells to express foreign proteins with great efficiency and fidelity have been designed. Eukaryotic expression systems using yeast cells, insect cells, or plant cells also provide excellent alternatives.

Global analysis of protein interactions is used for the generation of interactome maps that reveal regulatory and functional networks, greatly facilitating our understanding of cellular function at the systemic level.

Functional screens for the identification of therapeutic targets in cancer

One consequence of the sequencing of the human genome is that we now have a comprehensive catalog of all of the genes that can be expressed. Cancer genome sequencing efforts have also given us a catalog of the genes most commonly mutated in cancer. The challenge going forward is to integrate this data with functional studies, and to systematically compile a list of genes whose mutation or aberrant expression drives cancer initiation or maintenance. Recent technical advances provide the means to search systematically for genes involved in cancer development. Broadly, these efforts can be divided into loss-of-function approaches (i.e., assessment of cellular phenotype after inhibition of gene expression) or gain-of-function approaches (i.e., assessment of cellular phenotype after enforcement of gene expression).

Loss-of-function approaches

RNA interference

RNA interference (RNAi) refers to an ancient biological pathway by which small (18–21 nt), double-stranded RNA (dsRNA) molecules can catalytically induce degradation of complementary mRNA molecules in a sequence-specific manner. There are two flavors of dsRNA capable of inducing RNAi. In plants and some other lower eukaryotes, so-called short interfering RNAs (siRNAs) may be endogenously processed from longer dsRNA substrates; in the laboratory, siRNAs can be synthesized and delivered into cultured cells.^{176, 177} MicroRNAs (miRNAs) represent a second flavor of small dsRNAs; miRNAs are components of the eukaryotic genome, and many are deeply conserved across evolution (including in humans).^{178, 179} miRNAs are transcribed from the genome, much like mRNAs, and are processed into a mature form that is about 22 nt in length. In their final processed forms, siRNAs and miRNAs function similarly, as sequence-specific negative regulators of gene expression.

Soon after the discovery of miRNAs and the report of sequence-specific endogenous silencing by dsRNAs, it became clear that siRNAs could be designed to inhibit the expression of any gene of

interest.¹⁸⁰ Indeed, over the past 15 years, RNAi technology has become a staple of loss-of-function analyses in research laboratories. RNAi has been widely adopted for applications ranging from inhibiting the function of single genes in cell culture to developing gene therapy techniques *in vivo* to specifically target disease-associated alleles.

In mammalian cells, RNAi-mediated gene suppression can be induced by the transfection of chemically synthesized siRNAs, or by the use of plasmids expressing short hairpin RNAs (shRNAs), which get processed to siRNAs endogenously by the Drosha and Dicer ribonucleases.^{181, 182} The shRNAs can be either expressed from a plasmid containing an RNA polymerase III promoter, or can be expressed from within a miRNA-like context as part of a longer transcript, under the control of an RNA polymerase II promoter.¹⁸³ In either case, the siRNA becomes incorporated into the RNA-induced silencing complex (RISC) and directs sequence-specific degradation or translational suppression of the target mRNA, resulting in decreased protein expression.¹⁸⁴ Although siRNAs are easily synthesized and highly effective in inducing gene knockdown, such oligonucleotide reagents are relatively expensive and can only be used for transient loss-of-function experiments. Vector-based systems offer the possibility of adding selectable markers, such as drug resistance, stable expression of the RNAi construct, as well as being a renewable resource through propagation in bacteria. More recently, inducible RNAi vectors have also been developed, allowing fine temporal and spatial regulation of RNAi-induced gene knockdown.¹⁸⁵

Both siRNA and shRNA libraries have been used successfully in transfection-based arrayed screens looking at phenotypes that develop shortly after gene suppression, such as apoptosis, cell signaling events, or cell cycle distribution.^{186–188} For many other cancer-related phenotypic assays, such as anchorage-independent colony formation, bypass of senescence, or tumor xenografts, long-term gene suppression is essential, requiring stable integration and expression of the RNAi vector. An additional significant advantage of the retroviral-based libraries is the ability to work with cells that are refractory to transfection. This is particularly true for the lentiviral-based systems, which can even be used to infect post-mitotic and other difficult-to-transduce cells, including primary cells or differentiated cells.^{189, 190}

CRISPR/CAS9

A major discovery in the past 5 years has been the observation that aspects of the microbial adaptive immune system can be exploited to engineer changes into the genomes of mammalian cells. It had been observed for many years that microbial genomes contain clusters of repeat elements with intervening spacer sequences.^{191, 192} These clusters were termed CRISPR, or clustered *regularly interspaced short palindromic repeats*. Adjacent to these repeat elements, were CRISPR-associated (Cas) genes. It had also been observed that many of the spacer sequences that intervene CRISPR repeats are of phage origin, suggesting that the CRISPR-Cas system represents a form of bacterial adaptive immunity against phage infection. Indeed, mechanistic studies have now shown that the CRISPR array is transcribed as a noncoding RNA transcript known as a crRNA, which is then processed and associated with a Cas protein complex. In the most widely studied type of CRISPR/Cas system, known as the Type II CRISPR, the crRNA associates with another trans-activating RNA (known as a tracrRNA) as well as the Cas9 DNA nuclease. The crRNA and tracrRNA form an RNA hybrid that recognizes DNA containing a protospacer-adjacent motif (PAM) sequence, and mediates cleavage near the recognition site. The CRISPR/Cas system has now been established as the basis for an adaptive immune system in many archaea and bacteria that protects against foreign genetic elements (i.e., bacteriophages or plasmids). Readers are directed to an excellent reviews for further detail on this rapidly evolving field.^{193, 194}

A watershed moment in this field was the realization that the Type II CRISPR/Cas9 system could be

modified and transferred to other cell types for use as an exceptionally powerful genome editing tool. The tracrRNA:crRNA hybrid can be engineered as a single RNA chimera,¹⁹⁵ or sgRNA, and the spacer (or guide) sequence can be modified to target a desired sequence of DNA for cleavage. This allows for an RNA-programmable molecular machine that can be directed to cleave near almost any desired site in the genome. Indeed, it has been shown that CRISPR/Cas9 cleavage can be engineered in mammalian cells in a highly generalizable fashion.^{196, 197} The double-strand breaks induced by Cas9 are most often repaired by the error-prone process of nonhomologous end joining (NHEJ), which frequently introduces small indels (which may induce frameshifts) at the site of cleavage. Thus, CRISPR/Cas9 technology offers a powerful means of inducing loss of function of a gene of interest. In addition, when Cas9 is used in conjunction with a homology-directed repair template, the cuts induced by Cas9 can be repaired via homologous recombination, allowing for precise genome-editing.

Recent studies have reported genome-scale lentiviral libraries of sgRNAs, analogous to the genome-wide RNAi libraries discussed above.¹⁹⁸ These CRISPR libraries allow one to target each gene in the genome and assess the effect on a phenotype of interest. As compared with shRNAs, CRISPR-mediated inhibition of gene expression is often more robust, and possibly accompanied by fewer “off-target” effects. Thus, it is likely that genome-scale screening with CRISPR/Cas9 libraries will become a cornerstone of functional genomics that builds upon and refines previous advances made by shRNA screening efforts ([Figure 17](#)).

Figure 17 (a) Schematic of the RNA-guided Cas9 nuclease, which is directed to its DNA target by a 20-nt guide sequence (blue). The red triangle represents the approximate nucleotide position where Cas9 would be expected to initiate a DSB. (b) DSBs created by Cas9 can be repaired either via error-prone NHEJ or homologous recombination.

Gain-of-function approaches

Most gain-of-function screens involve introduction of a cDNA library into cells either transiently or stably, ideally resulting in the hyperactivation of pathways positively regulated by the gene corresponding to the introduced cDNA. Several large collections of cloned cDNAs have been used successfully to this end.^{200, 201} Several of these are compatible with recombination-mediated transfer systems, allowing shuttling of the open reading frames (ORFs) of interest into different vectors, facilitating adaptation of the

system to individual needs.

Gain-of-function approaches have been used for a variety of purposes, including to identify modulators of signal transduction pathways as assessed by transcriptional reporters,²⁰² to identify genes whose expression can bypass senescence,²⁰¹ and to identify genetic programs conferring drug resistance phenotypes.²⁰³ Depending on the goal of the screen, the cDNA can either be transiently expressed by transfection (an approach that works well with transcriptional reporter-driven systems focused on short-term events) or stably integrated by using a viral cDNA expression vector (an approach that is often needed for many screens relevant to oncogenic transformation that require long-term expression and selection.)

Another type of gain-of-function approach utilizes miRNA expression libraries to screen using phenotypic assays. As discussed above, miRNAs are endogenous small RNAs that function by downregulating expression of their target genes, either through induction of transcript degradation or translational inhibition. miRNAs implicated in cancer include let-7, a negative regulator of RAS, c-Myc and other oncogenes²⁰⁴; the miR-17-92 cluster, which is upregulated in lymphomas and can promote lymphomagenesis²⁰⁵; and miR-15 and miR-16, negative regulators of BCL2, that are downregulated in chronic lymphocytic leukemia.²⁰⁶ These examples suggest that full extent of the contribution of miRNAs to tumorigenesis is not yet known. Thus, further functional studies are necessary. For example, work using a retroviral expression library of miRNAs identified miR-372 and miR-373 in a Ras-induced senescence bypass screen, suggesting possible oncogenic function for these miRNAs.²⁰⁷ Future applications of this approach will likely yield many more cancer-relevant miRNAs and the identification of their respective targets are also likely to provide further insight into the oncogenic process.

Summary

Increasingly, unbiased genome-wide functional screens have been used for the identification and validation of novel therapeutic targets in cancer. Most of these screens are performed in cell culture models, with the hits then validated by analysis of primary human tumor samples. RNA interference and CRISPR/Cas9 screens represent the main loss-of-function approaches while ORF screens represent the predominant gain-of-function approach. Several of these screens have resulted in the discovery of genes with key roles in tumorigenesis. Improvements in culture models and the application of these technologies in animal models increase the likelihood that the findings are validated in human cancer patients.

Mouse models of human cancer

Despite advances in our understanding of the biology of cancer at the molecular level, the application of this knowledge to the clinical management of cancer patients has been lagging. One of the factors limiting the translation of discoveries made in the laboratory to the clinic has been the availability of *in vivo* animal models of cancer that faithfully reproduce the human disease. Animals, particularly rodents, have been used in cancer research for decades to explore fundamental biological properties of tumors and to evaluate anti-neoplastic therapies.²⁰⁸ Initially, such rodent models were largely limited to spontaneous or carcinogen-induced neoplasms, or, more commonly, the ectopic or orthotopic transplantation of murine or human tumor cells into syngeneic or immunodeficient mice. Although none of these approaches accurately represents the complexity of human cancer, preclinical studies with these models are nonetheless traditionally required during the regulatory approval of investigational antineoplastic agents.

Improved animal cancer models became available with the advent of genetically engineered mouse

models (GEMMs) of cancer following advances in molecular biology and embryology in the early 1980s. GEMMs enabled the direct investigation of potential tumorigenic genes *in vivo*, and, today, models that accurately represent nearly every major human cancer exist.²⁰⁹ The first generation of GEMMs was transgenic tumor-prone mice produced through the ectopic introduction of activated oncogenes. Indeed, such “oncomice” confirmed the tumorigenic properties of c-Myc, Ras, and several viral oncoproteins; mice transgenic for these oncogenes developed lymphoma, breast cancer, and pancreatic cancer.²¹⁰ Although many early oncomouse models were informative, most human cancers could not be accurately modeled using this approach, likely due to the nonphysiological properties inherent in ectopic expression cassettes and tissue mosaicism. An alternative early approach to model human cancer was through the disruption or “knockout” (KO) of endogenous putative tumor suppressor alleles that were identified in cancer-prone kindreds. Indeed, KO mice confirmed Knudsen's hypothesis of tumor suppressor gene function, although the tumor spectrum in such KO mice oftentimes was quite distinct from the cognate human condition. A detailed description of the basic methodologies required for the generation of transgenic and KO mice can be found in an excellent manual on the manipulation of the mouse embryo.²¹¹ These early mouse models were very powerful in validating the cancer-relevant role of particular genes or their combination in tumorigenesis and allowed the identification of cooperating genetic alterations by insertional mutagenesis. However, a major drawback of these early mouse models is that genetically engineered mutations are present in every cell of the mouse. This is problematic for multiple reasons. First, it can lead to embryonic lethality or abnormalities if the affected oncogene or tumor suppressor gene is required for normal development. Second, with the exception of hereditary cancer predisposition syndromes, the *modus operandi* of these mutational events does not reproduce the human disease because the majority of human tumors evolve owing to acquired somatic genetic changes. Third, it does not allow the interrogation of the role of cancer-relevant genes in a particular organ type or stage of tumorigenesis. Recognizing these deficiencies, investigators have been developing ever more sophisticated mouse models that more faithfully reflect the human disease.

Current state-of-the-art mouse models employ new genetic tools to address the shortcomings of classic oncomice and KO mice.²¹² Indeed, the advent of inducible and conditional mutant alleles enables the sophisticated spatial and temporal control of cancer gene expression. A common type of inducible cancer allele is transcriptionally regulated by variants of the *E. coli* Tetracycline operon, usually with the chemical analog doxycycline. It has two different variations, TET-OFF and TET-ON, depending on whether the expression of the targeted gene (regulated by a TET-responsive TA) is expressed in the presence (TET-ON) or absence (TET-OFF) of doxycycline.²¹³ Doxycycline-sensitive alleles can include putative oncogenes, and such alleles were used to demonstrate a causal role for oncogenes in the development and maintenance of many tumor types in mouse models.^{209, 214} In addition, doxycycline-dependent alleles can reversibly suppress gene expression through the expression of dominant-negative tumor suppressor genes and short hairpin interfering RNA constructs.²¹⁵ To control the cell lineage in which the doxycycline-dependent genetic element is expressed, cell-type-specific promoters are used to encode the tetracycline TA.²¹³ Another inducible gene expression system utilizes chimeric proteins containing the gene of interest fused to the ligand binding portion of the estrogen receptor (ER). Such fusion proteins are held in a latent state in the cytoplasm in complex with heat shock proteins and are released following the addition of estrogenic analogs such as Tamoxifen. ER fusions with Myc and P53 have been used to generate a variety of clever mouse models of various cancer types.^{216, 217} Conditional mutant alleles are employed to directly modulate gene expression through either deleting putative tumor suppressor genes or expressing a single allele of an activated oncogene from its endogenous promoter. Conditional mutant alleles are controlled by the Bacteriophage P1 Cre/loxP system, whereby the Cre recombinase will direct the looping and excision of DNA elements that are flanked by 34 bp LoxP sites.

Conditional tumor suppressor alleles thus consist of genes that contain exons surrounded by intronic LoxP sites, and these alleles are expressed at diploid levels until Cre recombinase is introduced and mediates the deletion of the gene with loss of mRNA and protein. Conditional oncogenes are latent alleles that are not expressed until Cre recombinase causes the removal of transcriptional silencing or “Stop” elements; and in this scenario, the gene dosage changes from haploid to diploid with half of the gene dosage consisting of the oncogenic alleles. There are additional recombinases now available for mouse modeling, and there are a variety of related strategies to control conditional gene expression. Inducible cancer alleles can be used alone, or in tandem with conditional mutant alleles such that added ligands can control the expression of Cre recombinase, enabling exquisite spatial and temporal control of cancer gene expression.^{218, 219} Using these state-of-the-art strategies, GEMMs that faithfully model the development of preinvasive and invasive carcinomas of the lung, pancreas, prostate, ovary, and breast have now been developed.²⁰⁹ Such models oftentimes demonstrate additional pathophysiological sequelae, including cachexia and metastasis, and somatic biochemical and genomic alterations that are common in the cognate human malignancy. A major advance using these GEMMs is the identification of new pathways in human cancers by cross-species comparisons.²²⁰ Investigations are now under way to determine the role of GEMMs of cancer in diagnostic and therapeutic development. Unanswered questions about GEMMs include the absence of evidence demonstrating a superior predictive therapeutic utility of GEMMs to xenografted tumor models, and whether species-specific differences in drug metabolism, the tumor microenvironment, and cell intrinsic pathways will preclude the translation of information in GEMMs to the clinical setting. Nonetheless, several publications suggest that these models will be informative in the preclinical assessment of antineoplastic agents.

Recently, developments in CRISPR/Cas9-based genome editing (see above) have also been extended to animal models. For example, a recent report used hydrodynamic injection to directly deliver CRISPR plasmids and sgRNAs to the mouse liver in order to target the tumor suppressor genes Pten and p53. The result was a loss of Pten and p53 function comparable to that achieved by genetic KO, with the mice developing liver tumors.²²¹ In another study, CRISPR/Cas9-mediated genome editing of tumor suppressor genes was overlaid on a Kras-driven lung cancer model to functionally characterize a panel of potential tumor suppressor genes.²²² In the coming years, it is likely that CRISPR/Cas9 technology will become more widely used as a complement to traditional genetic manipulation methods in an effort to create mouse models of cancer that faithfully recapitulate the human disease.

Summary

Rodent models are required components in anticancer drug development. Several GEMMs faithfully recapitulate the human disease and are useful for studying disease biology and for preclinical testing of potential therapeutics. CRISPR/Cas9 technology can complement traditional genetic manipulation methods, and will likely help further refine the degree to which current GEMMs recapitulate the human disease.

Chapter 4

Oncogenes

Marco A. Pierotti, PhD ■ Milo Frattini, MD, PhD ■ Francesca Molinari, PhD ■ Gabriella Sozzi, PhD ■ Carlo M. Croce, MD

Overview

The initiation and progression of human neoplastic diseases is a multistep process involving the accumulation of genetic changes in somatic cells. These genetic changes typically consist of the activation of cooperating oncogenes and the inactivation of tumor suppressor genes, which both appear necessary for a complete neoplastic phenotype. Oncogenes are altered versions of normal cellular genes called proto-oncogenes, usually involved in the regulation of cell growth and activated by mutation, chromosomal rearrangement, or gene amplification. In this chapter, at first we will describe the methods that have been applied by the researchers for the discovery and the identification of oncogenes. Then we will present the genetic mechanisms of proto-oncogenes activation (point mutations, gene amplifications, chromosomal rearrangements) with several examples, and we will describe the role played by oncogenes in the initiation and progression of various cancers.

The identification of oncogene abnormalities has provided tools for the molecular diagnosis and monitoring of cancer. Most important, oncogenes represent potential targets for new types of cancer therapies, which are continuously discovered and tested in clinical trials. The goal of these new drugs is to kill cancer cells selectively while sparing normal cells. These new therapies display an evident benefit for the treatment of several neoplastic diseases that were, before targeted therapies development, very hard to be treated and cured. However, they are not able to kill 100% of neoplastic cells, essentially due to the occurrence of mechanisms of secondary resistance. In the last part of the chapter, we will review all the genes for which a targeted therapy has been developed.

Since the early proposal of Boveri more than a century ago, multiple experimental evidence have confirmed that, at the molecular level, cancer is due to lesions in the cellular DNA. First, it has been observed that a cancer cell transmits to its daughter cells the phenotypic features characterizing the “cancerous” state. Second, most of the recognized mutagenic compounds are also carcinogenic. Finally, the karyotyping of several types of human tumors, particularly those belonging to the hematopoietic system, led to the identification of recurrent chromosomal aberrations, reflecting pathologic rearrangements of the cellular genome. Taken together, these observations suggest that the molecular pathogenesis of human cancer is due to structural and/or functional alterations of specific genes whose normal function is to control cellular growth and differentiation or, in different terms, cell birth and cell death.^{1, 2}

The identification and characterization of the genetic elements playing a role in the scenario of human cancer pathogenesis have been made possible by the development of DNA recombinant techniques during the past decades, enhanced by the possibility to sequence even the whole genome. One milestone was the identification of the cellular origin of the “viral oncogenes” followed by the possibility to transfer the tumorigenic properties to the RNA tumor viruses also known as retroviruses.^{3, 4} Lastly, it was discovered

that most cellular transforming genes do not have a viral counterpart. Besides the source of their original identification, viral or cellular genome, these transforming genetic elements have been designated as proto-oncogene in their normal physiologic version and oncogene when altered in cancer.⁵ A second relevant experimental approach has regarded the identification and characterization of clonal and recurrent cytogenetic abnormalities (including translocations and inversions) in cancer cells, especially those derived from the hematopoietic system. Additional oncogenes have been identified through the analysis of anomalously stained chromosomal regions (homogeneously staining regions (HSRs), representing gene amplification.⁶ Furthermore, the detection of chromosome deletions has been instrumental in the process of identification and cloning of a second class of cancer-associated genes, the tumor suppressors (which act in the normal cell as negative controllers of cell growth and are inactive in tumor cells).^{5, 6} Lastly, using automated sequencing instruments, it has been demonstrated that also point mutations are a frequent mechanism of oncogene activation.⁷ In the last subgroup, we can also number those obtained by the analysis of the protein kinases (kinome)⁸ or phosphatases (phosphatome)⁹ of the human genome or of several isoforms of a relevant protein involved in cancer development (such as PI3K).¹⁰

In this chapter, the methods by which oncogenes were discovered will be first briefly described. The various functions of cellular proto-oncogenes will then be presented, and the genetic mechanisms of proto-oncogene activation will be summarized. Then, the role of specific oncogenes in the initiation and progression of human tumors will be discussed. Lastly, the discovery that oncogenes may represent relevant target for new drugs will be described.

Discovery and identification of oncogenes

The first oncogenes were discovered through the study of *retroviruses*, RNA tumor viruses whose genomes are reverse transcribed into DNA in infected animal cells.¹¹ During the course of infection, retroviral DNA is inserted into the chromosomes of host cells. The integrated retroviral DNA, called the provirus, replicates along with the cellular DNA of the host, leading to the production of viral progeny that bud through the host cell membrane to infect other cells.¹¹ Acutely transforming retroviruses can rapidly cause tumors within days after injection. Chronic or weakly oncogenic retroviruses can cause tissue-specific tumors in susceptible strains of experimental animals after a latency period of many months.

Retroviral oncogenes are altered versions of host cellular proto-oncogenes that have been incorporated into the retroviral genome by recombination with host DNA, a process known as retroviral *transduction*.⁵ This surprising discovery was made through study of the Rous sarcoma virus (RSV) ([Figure 1](#)), revealing that the transforming gene of RSV was not required for viral replication.¹² Molecular hybridization studies then showed that the RSV transforming gene (designated *v-src*) was homologous to a host cellular gene (*c-src*) that was widely conserved in eukaryotic species.¹³ Studies of many other acutely transforming retroviruses from fowl, rodent, feline, and nonhuman primate species have led to the discovery of dozens of different retroviral oncogenes ([Table 1](#)). In every case, these retroviral oncogenes are responsible for the rapid tumor formation and efficient *in vitro* transformation activity, characteristic of acutely transforming retroviruses.

Figure 1 Retroviral transduction. An RNA tumor virus infects a human cell carrying an activated *src* gene (red box). After the process of recombination between retroviral genome and host DNA, the oncogene *c-src** is incorporated into the retroviral genome and is renamed *v-src*. When the retrovirus carrying *v-src* infects a human cell, the viral oncogene is rapidly transcribed and is responsible for the rapid tumor formation.

Table 1 Oncogenes

Oncogene	Chromosome	Identification	Method neoplasm mechanism of activation	Protein function	
Growth factors					
V-SIS	22q12.3–13.1	Sequence homology	Glioma/fibrosarcoma	Constitutive production	B-chain
INT2	11q13	Proviral insertion	Mammary carcinoma	Constitutive production	Member family
KS3	11q13.3	DNA transfection	Kaposi sarcoma	Constitutive production	Member family
HST	11q13.3	DNA transfection	Stomach carcinoma	Constitutive production	Member family

<i>Growth factor receptors</i>					
Tyrosine kinases: integral membrane proteins					
<i>EGFR</i>	7p1.1–1.3	DNA amplification/DNA sequencing	Squamous cell carcinoma	Gene amplification/protein/point mutation	EGF receptor
<i>v-FMS</i>	5q33–34 (FMS)	Viral homolog	Sarcoma	Constitutive activation	CSF1 receptor
<i>v-KIT</i>	4q11–21 (KIT)	Viral homolog/DNA sequencing	Sarcoma/GIST	Constitutive activation/point mutation	Stem cell factor receptor
<i>v-ROS</i>	6q22(ROS)	Viral homolog	Sarcoma	Constitutive activation	Chimeric receptor
<i>MET</i>	7p31	DNA transfection	MNNG-treated human osteocarcinoma cell line	DNA rearrangement/ligand-independent constitutive activation (fusion proteins)	HGF/SF receptor
<i>TRK</i>	1q32–41	DNA transfection	Colon/thyroid carcinomas	DNA rearrangement/ligand-independent constitutive activation (fusion proteins)	NGF receptor
<i>NEU</i>	17q11.2–12	Point mutation/DNA amplification	Neuroblastoma/breast carcinoma/NSCLC	Gene amplification/point mutation	Unknown
<i>RET</i>	10q11.2	DNA transfection	Carcinomas of thyroid Men 2A/Men 2B	DNA rearrangement/point mutation (ligand-independent constitutive activation/fusion proteins)	GDNF/TrkA receptor
Receptors lacking protein kinase activity					
<i>MAS</i>	6q24–27	DNA transfection	Epidermoid carcinoma	Rearrangement of 5' noncoding region	Angiotensin II receptor
<i>Signal transducers</i>					
Cytoplasmic tyrosine kinases					
<i>SRC</i>	20p12–13	Viral homolog	Colon carcinoma	Constitutive activation	Protein kinase
<i>v-YES</i>	18q21–23 (YES)	Viral homolog	Sarcoma	Constitutive activation	Protein kinase
<i>v-FGR</i>	1p36.1–36.2 (FGR)	Viral homolog	Sarcoma	Constitutive activation	Protein kinase
<i>v-FES</i>	15q25–26 (FES)	Viral homolog	Sarcoma	Constitutive activation	Protein kinase

<i>ABL</i>	9q34.1	Chromosome translocation	CML	DNA rearrangement (constitutive activation/fusion proteins)	Protein kinase
Membrane-associated G proteins					
<i>HRAS</i>	11p15.5	Viral homolog/DNA transfection	Colon, lung, pancreas carcinomas	Point mutation	GTPase
<i>KRAS</i>	12p11.1–12.1	Viral homolog/DNA transfection	AML, thyroid carcinoma, melanoma/colon/lung	Point mutation	GTPase
<i>NRAS</i>	1p11–13	DNA transfection	Carcinoma, melanoma	Point mutation	GTPase
<i>BRAF</i>	6	DNA sequencing	Melanoma, thyroid, colon, ovary	Point mutation	Ser/Thr
<i>GSP</i>	20	DNA sequencing	Adenomas of thyroid	Point mutation	Gs alpha
<i>GIP</i>	3	DNA sequencing	Ovary, adrenal carcinoma	Point mutation	Gi alpha
GTPase exchange factor (GEF)					
<i>DBL</i>	Xq27	DNA transfection	Diffuse B-cell lymphoma	DNA rearrangement	GEF for Cdc42H
<i>VAV</i>	19p13.2	DNA transfection	Hematopoietic cells	DNA rearrangement	GEF for
Serine/threonine kinases: cytoplasmic					
<i>v-MOS</i>	8q11 (MOS)	Viral homolog	Sarcoma	Constitutive activation	Protein (ser/thr)
<i>v-RAF</i>	3p25 (RAF-1)	Viral homolog	Sarcoma	Constitutive activation	Protein (ser/thr)
PIM-1	6p21 (PIM-)	Insertional mutagenesis	T-cell lymphoma	Constitutive activation	Protein (ser/thr)
Cytoplasmic regulators					
<i>v-CRK</i>	17p13 (CRK)	Viral homolog	—	Constitutive tyrosine phosphorylation of cellular substrates (e.g., paxillin)	SH-2/SI
<i>Transcription factors</i>					
<i>v-MYC</i>	8q24.1 (MYC)	Viral homolog	Carcinoma myelocytomatosis	Deregulated activity	Transcri
<i>N-MYC</i>	2p24	DNA amplification	Neuroblastoma: lung	Deregulated activity	Transcri
<i>L-MYC</i>	1p32	DNA amplification	Carcinoma of lung	Deregulated activity	Transcri
<i>v-MYB</i>	6q22–24	Viral homolog	Myeloblastosis	Deregulated activity	Transcri
<i>v-FOS</i>	14q21–22	Viral homolog	Osteosarcoma	Deregulated activity	Transcri

					API
<i>v-JUN</i>	p31–32	Viral homolog	Sarcoma	Deregulated activity	Transcri API
<i>v-SKI</i>	1q22–24	Viral homolog	Carcinoma	Deregulated activity	Transcri
<i>v-REL</i>	2p12–14	Viral homolog	Lymphatic leukemia	Deregulated activity	Mutant I
<i>v-ETS-1</i>	11p23–q24	Viral homolog	Erythroblastosis	Deregulated activity	Transcri
<i>v-ETS-2</i>	21q24.3	Viral homolog	Erythroblastosis	Deregulated activity	Transcri
<i>v-ERB A1</i>	17p11–21	Viral homolog	Erythroblastosis	Deregulated activity	T3 Tran factor
<i>v-ERB A2</i>	3p22–24.1	Viral homolog	Erythroblastosis	Deregulated activity	T3 Tran factor
Others					
<i>BCL2</i>	18q21.3	Chromosomal translocation	B-cell lymphomas	Constitutive activity	Antiapo
<i>MDM2</i>	12q14	DNA amplification	Sarcomas	Gene amplification/increased protein	Comple

Abbreviations: AML, acute myeloid leukemia; CML, chronic myelogenous leukemia; GTPase, guanosine triphosphatase; PDGF, platelet-derived growth factor.

In contrast, weakly oncogenic retroviruses do not carry viral oncogenes. These retroviruses, which include mouse mammary tumor virus (MMTV) and various animal leukemia viruses, induce tumors by a process called *insertional mutagenesis* ([Figure 2](#)).⁶ This process results from the integration of the provirus DNA into the host genome in infected cells and acquires relevance when (rarely) the provirus is inserted near a proto-oncogene, whose expression is then abnormally driven by the transcriptional regulatory elements contained within the long terminal repeats of the provirus.⁶ Therefore, proviral integration represents a mutagenic event that activates a proto-oncogene. The long latent period of tumor formation of weakly oncogenic retroviruses is therefore due to the rarity of the provirus insertional event that leads to tumor development from a single transformed cell. Insertional mutagenesis by weakly oncogenic retroviruses, first demonstrated in bursal lymphomas of chickens, frequently involves the same oncogenes (such as *myc*, *myb*, and *erb B*) that are carried by acutely transforming retroviruses.^{6, 14} In many cases, however, insertional mutagenesis has been used as a tool to identify new oncogenes, including *int-1*, *int-2*, *pim-1*, and *lck*.⁶

Figure 2 Insertional mutagenesis. (a) The process is independent from genes carried by the retrovirus. Retrovirus, for example, MMTV, infects a human cell. The proviral DNA is integrated into the host genome in infected cells. Rarely, the provirus inserts near a proto-oncogene (e.g., *int-1*) and activates the proto-oncogene. Activated proto-oncogene results in cell transformation and in tumor formation. (b) Sites of integration of MMTV retrovirus near the proto-oncogene *int-1*. All sites determine *int-1* activation.

The demonstration of activated proto-oncogenes in human tumors was first shown by the DNA-mediated transformation technique.^{15, 16} This method, also called *gene-transfer* or *transfection* assay, verifies the ability of donor DNA from a tumor to transform a recipient strain of rodent cells called NIH 3T3, an immortalized mouse cell line (Figure 3).¹⁷ This sensitive assay, which can detect the presence of single-copy oncogenes in a tumor sample, also enables the isolation of the transforming oncogene by molecular cloning techniques.¹⁸ Overall, approximately 20% of individual human tumors have been shown to induce transformation of NIH 3T3 cells in gene-transfer assays. The value of transfection assay was reinforced by Weinberg's laboratory, which showed that the ectopic expression of the telomerase catalytic subunit (hTERT), in combination with the simian virus 40 large T product and a mutated oncogenic H-ras protein, resulted in the direct tumorigenic conversion of normal human epithelial and fibroblast cells.¹⁹ Many of the oncogenes identified by gene-transfer studies are identical or closely related to oncogenes transduced by retroviruses.²⁰ A number of new oncogenes (such as *neu*, *met*, and *trk*) have also been identified by the gene-transfer technique.²¹ In many cases, however, oncogenes identified by gene transfer were shown to be activated by rearrangement during the experimental procedure and are not activated in the human tumors that served as the source of the donor DNA, as in the case of *ret* that was subsequently found genuinely rearranged and activated in papillary thyroid carcinomas.²²

Figure 3 Transfection assay. DNA from a tumor (e.g., bladder carcinoma) is used to transform a rodent immortalized cell line (NIH3T3). After serial cycles, DNA from transformed cells was extracted and then inserted into p vector that was subsequently used to transform an appropriate *Escherichia coli* strain. Using a specific probe (Alu in the figure), it was possible to isolate and then characterize the involved human oncogene.

Chromosomal translocations have served as guideposts for the discovery of new oncogenes, especially in many hematological and solid tumors.^{23, 24} These abnormalities include chromosomal rearrangements as well as the gain or loss of whole chromosomes or chromosome segments. The first consistent karyotypic abnormality identified in a human neoplasm was a characteristic small chromosome in the cells of patients with chronic myelogenous leukemia (CML).²³ Later identified as a derivative of chromosome 22, this abnormality was designated the Philadelphia chromosome, after its city of discovery. The application of chromosome banding techniques in the early 1970s enabled the precise cytogenetic characterization of many chromosomal translocations in human leukemia, lymphoma, and solid tumors.²⁵ The subsequent development of molecular cloning techniques then enabled the identification of proto-oncogenes at or near chromosomal breakpoints in various neoplasms. Some of these proto-oncogenes, such as *myc* and *abl*, had been previously identified as retroviral oncogenes. In general, however, the cloning of chromosomal breakpoints has served as a rich source of discovery of new oncogenes involved in human cancer. More recently, the use of high-throughput sequencing technologies and bioinformatics from the Human Genome Project led to the discovery of new genes involved in cancer development, such as *BRAF* and *PIK3CA*.^{7, 10}

Oncogenes, proto-oncogenes, and their functions

Proto-oncogenes encode proteins that are involved in the control of cell growth. Alteration of the structure and/or expression of proto-oncogenes can activate them to become oncogenes capable of inducing in susceptible cells the neoplastic phenotype. Oncogenes can be classified into five groups based on the functional and biochemical properties of protein products of their normal counterparts (proto-oncogenes). These groups are (1) growth factors, (2) growth factor receptors, (3) signal transducers, (4) transcription factors, and (5) others, including programmed cell death regulators. [Table 1](#) lists examples of oncogenes according to their functional categories.

Growth factors

Growth factors are secreted polypeptides that function as extracellular signals to stimulate the proliferation of target cells that possess a specific receptor in order to respond to a specific type of growth factor.² A well-characterized example is platelet-derived growth factor (PDGF), an approximately 30-kDa protein consisting of two polypeptide chains.²⁶ PDGF, released from platelets during the process of blood coagulation, stimulates the proliferation of fibroblasts, a cell growth process that plays an important role in wound healing. Other well-characterized examples of growth factors include nerve growth factor (NGF), epidermal growth factor, and fibroblast growth factor.

The link between growth factors and retroviral oncogenes was revealed by study of the *sis* oncogene of simian sarcoma virus, a retrovirus first isolated from a monkey fibrosarcoma. Sequence analysis showed that *sis* encodes the beta chain of PDGF.²⁶ This discovery established the principle that inappropriately expressed growth factors may constitutively activate their receptor, resulting in self-sustained aberrant cell proliferation and therefore functioning as oncogenes. The mechanism behind is called *autocrine stimulation* ([Figure 4](#)).²⁶ This model, derived from experimental animal systems, has been demonstrated

in a human tumor, dermatofibrosarcoma protuberans (DP), an infiltrative skin tumor that was demonstrated to present specific cytogenetic features: reciprocal translocation and supernumerary ring chromosomes, involving chromosomes 17 and 22.²⁶ Molecular cloning of the breakpoints revealed a fusion between the *collagen type Ia1* (*COL1A1*) gene and PDGF-B gene. The fusion gene resulted in a deletion of PDGF-B exon 1 and a constitutive release of this growth factor. Subsequent experiments of gene transfer of DP's genomic DNA into NIH 3T3 cells directly demonstrated the occurrence of an autocrine mechanism by the human rearranged PDGF-B gene involving the activation of the endogenous PDGF receptor.²⁶ Another example of a growth factor that can function as an oncogene is *int-2*, a member of the fibroblast growth factor family. *Int-2* is sometimes activated in mouse mammary carcinomas by MMTV insertional mutagenesis.²⁷

Figure 4 Paracrine and autocrine stimulation. (a) A growth factor produced by the cell on the right stimulates another cell carrying the appropriate receptor (left) on cell membrane. This process is named paracrine stimulation. (b) A growth factor is produced by the same cell expressing the cognate receptor. This process is designated autocrine stimulation.

Growth factor receptors

Some viral oncogenes are altered versions of normal growth factor receptors that possess intrinsic tyrosine kinase (TK) activity.²⁸ Receptor tyrosine kinases (RTKs), as these growth factor receptors are collectively known, have a characteristic protein structure consisting of three principal domains: (1) the extracellular ligand-binding domain, (2) the transmembrane domain, and (3) the intracellular TK catalytic

domain ([Figure 5](#)). RTKs are molecular machines that transmit information in a unidirectional manner across the cell membrane. The binding of a growth factor to the extracellular ligand-binding domain of the receptor results in the activation of the intracellular TK catalytic domain, usually after dimerization, leading to the activation of downstream proteins that physically interact with RTK, mainly represented by the mitogen-activated protein kinases (MAPKs) pathway, by the PI3K/AKT axis and by STAT proteins. These pathways are activated differently, depending on the specific RTK, overall resulting in abnormal cell duplication and in escaping from programmed cell death (apoptosis).²⁸

Figure 5 Representative examples of tyrosine kinase receptor families.

The list of RTK includes *ERB B1*, *ERB B2*, *FMS*, *KIT*, *MET*, *RET*, *ROS*, *ALK*, and *TRK*, which can be converted into oncogenes through different mechanisms, often depending on tumor type.²⁸ *ERB B1* (the epidermal growth factor receptor—EGFR) can be oncogenically activated by deletion of the ligand-binding domain, by point mutations in the TK domain in a subgroup of patients affected by non-small-cell lung cancer (NSCLC) (more commonly in Japan than in other western countries, suggesting that ethnic differences may have a significant impact on *ERB B1* activation),²⁹ or at germ-line level in patients showing multiple lung adenocarcinomas,³⁰ by overexpression of ligands or by gene amplification in colorectal cancer (CRC) patients.^{31, 32}

Another example is represented by *ERB B2*, whose growth factor is still unknown, which is altered by gene amplification in breast and gastric cancers and by point mutations in gastric, colorectal, and breast cancers. Interestingly, immunohistochemical staining for *ERB B2* revealed no differences between tumors with or without *ERB B2* mutations, indicating that overexpression probably does not accompany the mutation.³³

Last example is *KIT*, whose activation in tumor cells can be due to three different mechanisms: (1) autocrine and/or paracrine stimulation of the receptor by its ligand, stem cell factor (SCF); (2) cross-

activation by other kinases and/or loss of regulatory phosphatase activity; and (3) acquisition of activating mutations of several different exons of the *KIT* gene.³⁴ *KIT* mutations (typically in exon 17) are most commonly found in mastocytosis/mast cell leukemia, acute myelogenous leukemia (AML), seminoma/dysgerminoma, and sinusoidal natural killer/T-cell lymphoma. In gastrointestinal stromal tumors (GISTs), more heterogeneous mutations are described: mutations most commonly occur in exon 11 (encoding the juxtamembrane region) (in about 65% of all GISTs), whereas about 10% of GISTs have *kit* exon 9 mutations and 2% exon 13 or exon 17 mutations. In GIST showing any alterations in the *KIT* gene, point mutations may occur in *PDGFRA*, a gene belonging to the same family as *KIT*. Approximately 5% of GIST have a constitutively activating mutations in *PDGFRA*, mostly (80%) found in exon 18 and the rest either in exon 12 (10–15%) or 14 (1–5%).³⁴ *KIT* and *PDGFRA* mutations are mutually exclusive. Gastric GISTs with exon 11 deletions are more aggressive than those with substitutions. The less common *KIT* exon 9 codons 502–503 duplication occurs predominantly in small intestinal GISTs. *PDGFRA* mutations are associated with gastric GISTs, epithelioid morphology and a less malignant course of disease.³⁴ Germ-line mutations in *KIT* gene have been found in patients manifesting multiple GIST arising at earlier age, urticaria pigmentosa, melanocytic nevi, melanomas, achalasia, or neuronal hyperplasia of the mesenteric plexus.

Signal transducers

Mitogenic signals are transmitted from RTK on the cell surface to the cell nucleus through a series of complex interlocking pathways collectively referred to as the signal transduction cascade.²⁸ This relay of information is accomplished in part by the stepwise phosphorylation of interacting proteins in the cytosol. Signal transduction also involves guanine nucleotide-binding proteins and second messengers such as the adenylate cyclase system. The first retroviral oncogene discovered, *SRC*, was subsequently shown to be involved in signal transduction.^{13, 28}

Many proto-oncogenes are members of signal transduction pathways.³⁵ These consist of two main groups: nonreceptor protein kinases and guanosine triphosphate (GTP)-binding proteins. The nonreceptor protein kinases are subclassified into TKs (e.g., *ABL*, *LCK*, and *SRC*) and serine/threonine kinases (e.g., *RAF-1*, *MOS*, and *PIM-1*). GTP-binding proteins with intrinsic guanosine triphosphatase (GTPase) activity are subdivided into monomeric and heterotrimeric groups. Monomeric GTP-binding proteins are members of the important *RAS* family of proto-oncogenes that includes *HRAS*, *KRAS*, and *NRAS*.³⁶ Heterotrimeric GTP-binding proteins (G proteins) implicated as proto-oncogenes currently include *GSP* and *GIP*. Signal transducers are often converted to oncogenes by mutations that lead to their unregulated activity, which in turn leads to uncontrolled cellular proliferation.³⁶

Transcription factors

Transcription factors are nuclear proteins that regulate the expression of target genes or gene families.³⁷ Transcriptional regulation is mediated by protein binding to specific DNA sequences or DNA structural motifs (such as zinc fingers), usually located upstream of the target gene. The mechanism of action of transcription factors also involves binding to other proteins, sometimes in heterodimeric complexes with specific partners. Transcription factors are the final link in the signal transduction pathway that converts extracellular signals into modulated changes in gene expression.

Many proto-oncogenes are transcription factors that were discovered through their retroviral homologs.³⁷ Examples include *ERB A*, *ETS*, *FOS*, *JUN*, *MYB*, and *C-MYC*. Together, *fos* and *jun* form the AP-1 transcription factor, which positively regulates a number of target genes whose expression leads to cell

division.³⁸ *ERB A* is the receptor for the T3 thyroid hormone, triiodothyronine.³⁹ Proto-oncogenes that function as transcription factors are often activated by chromosomal translocations in hematologic and solid neoplasms. In certain types of sarcomas, chromosomal translocations cause the formation of fusion proteins involving the association of *EWS* gene with various partners and resulting in an aberrant tumor-associated transcriptional activity. Interestingly, a role of the adenovirus *E1A* gene in promoting the formation of fusion transcript *fli1/ews* in normal human fibroblasts was recently reported.⁴⁰ An important example of a proto-oncogene with a transcriptional activity in human hematologic tumors is the *C-MYC* gene, which helps to control the expression of genes leading to cell proliferation.⁴¹ As will be discussed later in this chapter, the *C-MYC* gene (which is encoded for a nuclear DNA-binding protein belonging to the helix-loop-helix/leucine zipper superfamily, involved in transcriptional regulation) is frequently activated by chromosomal translocations in human leukemia and lymphoma.

Programed cell death regulation

Normal tissues exhibit a regulated balance between cell proliferation and cell death. Programmed cell death is an important component in the processes of normal embryogenesis and organ development. A distinctive type of programmed cell death, called apoptosis, has been described for mature tissues.⁴² Studies of cancer cells have shown that both uncontrolled cell proliferation and failure to undergo programmed cell death can contribute to neoplasia and insensitivity to anticancer treatments.

The first proto-oncogene shown to regulate programmed cell death is *BCL-2*, discovered in human lymphomas. Experimental studies show that *BCL-2* activation inhibits (in a dominant mode) programmed cell death in lymphoid cell populations. The *BCL-2* gene encodes a protein localized to the inner mitochondrial membrane, endoplasmic reticulum, and nuclear membrane. The mechanism of action of the *bcl-2* protein has not been fully elucidated, but studies indicate that it functions in part as an antioxidant that inhibits lipid peroxidation of cell membranes,⁴³ and in part through protein–protein interaction with homolog proteins. Site-directed mutagenesis of BH1 and BH2 domains showed that these two regions are important for binding of *bcl-2* to *bax*, a member of the *bcl-2*-family that promotes cell death and whose interaction with *bcl-2* is necessary to regulate the apoptotic pathway ([Figure 6](#)). Although translocation is the main mechanism of *BCL-2* gene activation, *BCL-2* point mutations (in high-grade B-cell lymphomas) and amplification (in about 30% of high-grade diffuse large cell lymphomas (DLCL) lacking *bcl-2* translocation) have been reported.⁴⁴ Clinical relevance of *BCL-2* expression has been shown in solid tumors, such as breast, prostate, thyroid, and lung.^{45, 46}

Figure 6 Effect of bcl-2 activity on the control of the cell life. In the presence of BAX only, the cell goes to apoptosis. bcl-2 regulates the cycle of the cell by the interaction with BAX. When bcl-2 is overexpressed, the cell cycle is deregulated and the apoptosis is prevented, eventually leading to tumor formation. This is an important cause for tumor formation. *Abbreviations:* PCD, program cell death or apoptosis.

The second oncogene involved in apoptosis is caspase-9, which is activated by the following intrinsic pathway. Release of cytochrome c into the cytosol results in activation of the caspase adaptor Apaf-1 and procaspase-9, which form a holoenzyme complex named apoptosome.⁴⁷ Caspase-9, in turn, activates downstream caspases, especially caspase-3 and also caspase-6, 7, and 8, leading to DNA fragmentation and apoptosis. It has been demonstrated that Akt may regulate apoptosome function by phosphorylation of caspase-9 at the Ser-196 level.⁴⁸ This phosphorylation event has relevant functional consequences, leading to the suppression of apoptosis caspase-9-mediated. The Akt suppression is specific for caspase-9 and probably is due to the inactivation of the intrinsic catalytic activity. More recently, it has been demonstrated that bax is also involved, leading to caspase-9 stimulation (through Apaf-1) in response to mitochondrial membrane damage.⁴⁹

Mechanisms of oncogene activation

The activation of oncogenes involves genetic changes to cellular proto-oncogenes. The consequence of these genetic alterations is to confer a growth advantage to the cell. Four genetic mechanisms activate oncogenes in human neoplasms: (1) mutation, (2) gene amplification, (3) chromosome rearrangements, and (4) overexpression. The first three mechanisms result in either an alteration of proto-oncogene structure or an increase in proto-oncogene expression ([Figure 7](#)). Because neoplasia is a multistep process, more than one of these mechanisms may occur, leading to a combination of proto-oncogene activation and tumor-suppressor gene loss or inactivation.

Figure 7 Schematic representation of the main mechanisms of oncogene activation (from proto-oncogenes to oncogenes). The normal gene (proto-oncogene) is depicted with its transcribed portion (rectangle). In the case of gene amplification, the latter can be duplicated 100-fold, resulting in an excess of normal protein. A similar situation can occur when following chromosome rearrangements such as translocation, the transcription of the gene is now regulated by novel regulatory sequences belonging to another gene. In the case of point mutation, single amino acid substitutions can alter the biochemical properties of the gene product, causing, in the example, its constitutive enzymatic activation. Chromosome rearrangements, such as translocation and inversion, can then generate fusion transcripts resulting in chimericoncogenic proteins.

Mutation

Mutations activate proto-oncogenes through structural alterations in their encoded proteins. These alterations, which usually involve critical protein regulatory regions or directly the catalytic domain, often lead to the uncontrolled, continuous activity of the mutated protein. Various types of mutations, such as base substitutions, deletions, and insertions, are capable of activating proto-oncogenes.⁵⁰ Retroviral oncogenes, for example, often have deletions that contribute to their activation. Examples include deletions in the amino-terminal ligand-binding domains of the *ERB B*, *KIT*, *ROS*, *MET*, and *TRK* oncogenes. In human tumors, however, most characterized oncogene mutations are base substitutions (point mutations) that change a single amino acid within the protein.

Point mutations are frequently detected in the ras family of protooncogenes (*KRAS*, *HRAS*, and *NRAS*). The human *ras* genes encode for membrane-bound 21 kd proteins (189 amino acids) involved in signal transduction, with a guanine nucleotide-binding activity as well as an intrinsic GTPase activity. When activated, ras proteins transduce the signal by linking TKs to downstream serine/threonine kinases, such as raf, and MAP kinases (Figure 8).⁵¹ Stabilization of ras proteins in their active state causes a continuous flow of signal transduction, which results in malignant transformation. This status can be achieved after point mutation, mainly at codon 12 (in *KRAS* gene), 13 and 61 (mainly in *NRAS* gene) level. Rare mutations can be detected in codons 59, 117, and 146.⁵² Mutations of *ras* in human tumors have been

linked to carcinogen exposure: for example, the occurrence of *KRAS* mutations in NSCLC seems to be due to smoking exposure, in particular to benzo(a)pyrene.⁵³ It has been estimated that as many as 15–20% of unselected human tumors may contain a *RAS* mutation. Mutations in *KRAS* predominate in tumors derived from endodermal tumors, including carcinomas of pancreas (90%), colorectal (40%) and lung.^{36, 51} This finding is due to the fact that *KRAS*, but not *HRAS* or *NRAS*, promotes the expansion of an endodermal stem/progenitor cell and blocks its differentiation.⁵⁴ *NRAS* mutations are preferentially found in hematologic malignancies, with up to a 25% incidence in AMLs and myelodysplastic syndromes, or in melanoma and in a subgroup of CRC.⁵⁵ The majority of thyroid carcinomas have been found to have *RAS* mutations distributed among *KRAS*, *HRAS*, and *NRAS*, without preference for a single *RAS* family member, but showing an association with the follicular type of differentiated thyroid carcinomas. Moreover, again in CRC, the identification of *KRAS* mutations in stool samples may be used in early diagnosis,⁵⁶ and in plasma samples for monitoring patients' follow-up.⁵⁷

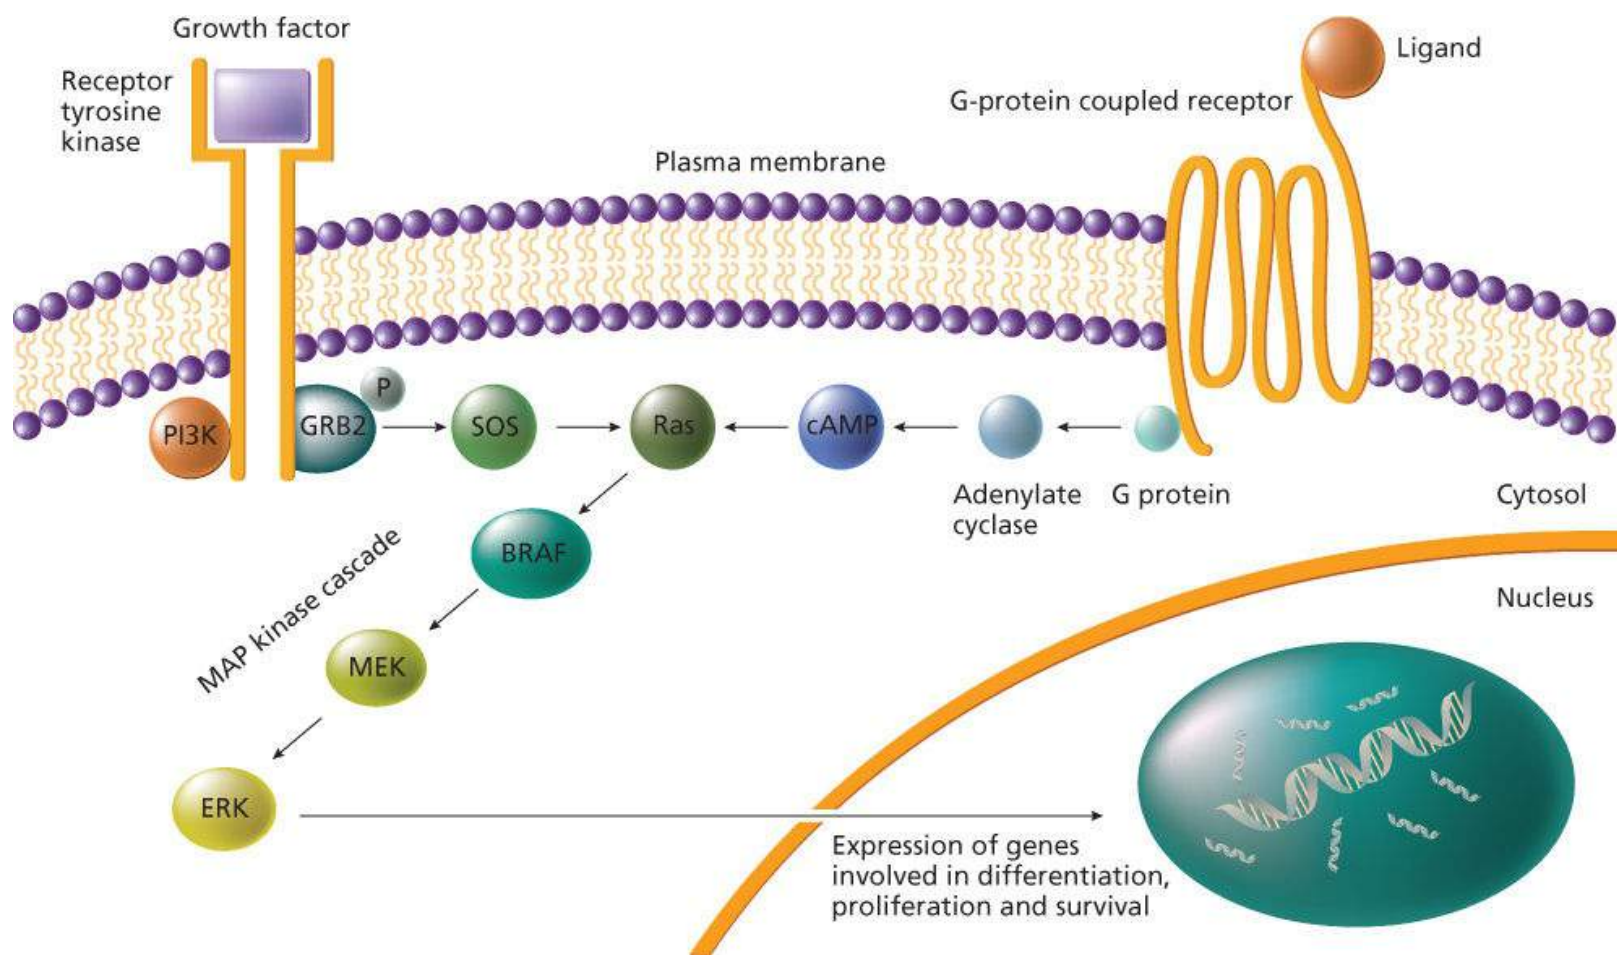

Figure 8 The ras-raf-MAPK signaling pathway.

In addition to cancer, *RAS* mutations are involved in other diseases. Specifically, *NRAS* mutations cause a human autoimmune lymphoproliferative syndrome,⁵⁸ while *HRAS* and *KRAS* germ-line mutations underlie disorders of the Noonan syndrome spectrum.⁵¹ The last data, coupled with the evidence that cancers rarely occur in these individuals, is leading to a re-evaluation of the effective role played by *RAS* genes in carcinogenesis.

Another example of activating point mutations is represented by those occurring in *BRAF* gene, the first result of the human genome project in the screening of cancer genes using high-throughput genomic technologies.⁷ The *BRAF* gene product is recruited to the plasma membrane upon binding to ras-GTP and represents a key point in the signal transduction through the MAP kinase pathway (Figure 8). The most common oncogenic mutation of *BRAF*, occurring in more than 90% of cases, is the valine to glutamic acid

change at codon 600, which mimics the phosphorylation of threonine 599 and serine 602, required for BRAF activation.⁷ In tissue specimens, *BRAF* mutations occur in melanomas (75%), thyroid (45%), colorectal (12%), and ovarian cancer (14%)⁵⁹ and in acute lymphoblastic leukemia (ALL).⁶⁰ Furthermore, it has been shown that *BRAF* mutations occur in CRC only when tumors do not carry mutations in the *KRAS* gene, and in papillary thyroid carcinoma when *RET* or *TRK* rearrangements are absent. These mutual exclusions have led to the assumption that *BRAF* and *K-ras* alterations, or *BRAF*, *RET*, and *TRK* alterations, could have the same functional effect in colorectal or in thyroid carcinogenesis, respectively.^{59, 61} As regards CRC, *BRAF* mutations are frequently present in sporadic cases with methylated *hMLH1* promoter but not in HNPCC-related cancers, thus representing a possible strategy for exclusion criteria for HNPCC.⁶² Moreover, *BRAF* mutations are frequently found in hyperplastic polyps and serrated adenomas,⁶³ suggesting that they represent an early and critical event in these types of lesions. *BRAF* mutations may have an influence on patients' prognosis depending on the tumor type where they occur: in ovarian cancer, *BRAF* mutations are associated with type I tumors that are slow growing and generally confined to the ovary at diagnosis⁶⁴ and with the aggressive papillary thyroid and colorectal carcinomas.⁵⁹ *BRAF* mutations, especially the V600E change that is very easy to investigate, are now acquiring a role in early diagnosis or disease monitoring in patients' follow-up: indeed, they are investigated to improve the diagnosis in fine-needle aspiration biopsy with cytological findings suspicious for papillary thyroid carcinomas.⁶⁵ On the contrary, in melanoma, *BRAF* mutations could be only used to monitor in serum the follow-up of patients receiving biochemotherapy⁶⁶ and not for early diagnosis because they even precede the neoplastic transformation, as all types of nevi besides Spitz and Blue nevi show *BRAF* alterations at a high frequency.⁶⁷

Another significant example of activating point mutations is represented by those affecting the *RET* proto-oncogene in multiple endocrine neoplasia (MEN) type 2 (2A and 2B) syndrome and familial medullary thyroid carcinomas (FMTC). MEN 2A is associated most frequently with mutations of codon 634 (85%), particularly C634R. This germ-line point mutation affecting one of the cysteine residues located in the juxtamembrane domain of the ret receptor has been found to confer an oncogenic potential through the abnormal formation of intermolecular disulfide bonding, resulting in a ligand-independent activation of the TK activity of the receptor. Most MEN2B patients carry the M918T mutation in the kinase domain, which confers an aggressive phenotype to MEN2B subtype. Sporadic mutations of V804, M918, and E768 occur in about 50% of sporadic medullary thyroid carcinomas, whereas FMTC mutations are evenly distributed among the various cysteins in the extracellular cysteine-rich domain and occasionally in the TK domain. M918T mutation lead to a ligand-independent activation of the kinase without causing a constitutive dimerization of the receptor and alters also the substrate specificity of the kinase. More recently, two mutations (V804 and E805) in tandem were found in a MEN2B subtype, affecting the hinging motion of the kinase lobes.⁶⁸

Gene amplification

Gene amplification refers to the expansion in copy number of a gene within the genome of a cell. Gene amplification was first discovered as a mechanism by which some tumor cell lines can acquire resistance to growth-inhibiting drugs. The process of gene amplification occurs through redundant replication of genomic DNA, often giving rise to karyotypic abnormalities called double-minute chromosomes (DMs) and HSRs.⁶⁹ DMs are characteristic minichromosome structures without centromeres. HSRs are segments of chromosomes that lack the normal alternating pattern of light and dark staining bands. Both DMs and HSRs represent large regions of amplified genomic DNA, containing up to several hundred copies of a gene. Amplification leads to the increased expression of genes, conferring a selective advantage for cell

growth.

The frequent observation of DMs and HSRs in human tumors suggested that the amplification of specific protooncogenes may be a common occurrence in cancer.⁶⁹ Studies then demonstrated that three proto-oncogene families—*MYC*, *ERBB*, and *RAS*—are amplified in a significant number of human tumors ([Table 2](#)). About 20–30% of breast and ovarian cancers show *C-MYC* amplification.⁶⁹ *N-MYC* was discovered as a new member of the *MYC* proto-oncogene family through its amplification in neuroblastomas.⁷⁰ Amplification of *N-MYC* correlates strongly with advanced tumor stage in neuroblastoma ([Table 3](#)), suggesting a role for this gene in tumor progression.⁷⁰ *L-MYC* was discovered through its amplification in small-cell lung carcinoma and bladder neoplasia.⁷¹ Furthermore, *C-MYC* activation may be mediated by APC and/or b-catenin alterations in several tumors, leading to an increase of *C-MYC* transcription through an accumulation of b-catenin into the cytoplasm and the nucleus.⁷² A nuclear accumulation of c-myc may identify high-risk subsets of patients with synovial sarcoma of the extremities.⁷³ Amplification and overexpression of *C-MYC*, in combination with *ERBB* *B2* alterations, have been reported to be associated with tumor progression from noninvasive to invasive and with poor prognosis⁷⁴ in patients with breast carcinoma. In melanoma⁷⁵ and in medulloblastoma,⁷⁶ c-myc expression seems to be a useful prognostic marker able to identify high-risk patients. Amplification of *ERBB* *B* is found in up to 50% of glioblastomas (often accompanied by the loss of the exons 2–7, leading to the so-called *ERBB* *B1* variant III, which is constitutively activated),⁷⁷ in 10–20% of head and neck squamous carcinomas, and in about 50% of CRC.⁷⁸ Gene amplification and overexpression of *ERBB* *B2* have been reported in approximately 25% of breast, ovarian, endometrial, gastric, and salivary gland carcinomas.³³ It was detected also in 16% of non-small-cell lung carcinoma and in a subset of malignant pancreatic endocrine tumor (gastrinoma). Overexpression of the *ERBB* *B2*, performed at immunohistochemical level, was detected in thick melanoma, pancreatic carcinoma, and prostatic tumors.³³

Table 2 Oncogene amplification in human cancers

Tumor type	Gene amplified	%
Neuroblastoma	<i>MYCN</i>	20–25
Small-cell lung cancer	<i>MYC</i>	15–20
Glioblastoma	<i>ERB B1 (EGFR)</i>	33–50
Breast cancer	<i>MYC</i>	20
	<i>ERB B2 (EGFR2)</i>	~20
	<i>FGFR1</i>	12
	<i>FGFR2</i>	12
	<i>CCND1</i> (cyclin d1)	15–20
Esophageal cancer	<i>MYC</i>	38
	<i>CCND1</i> (cyclin d1)	25
Gastric cancer	<i>KRAS</i>	10
	<i>CCNE</i> (cyclin e)	15
Hepatocellular cancer	<i>CCND1</i> (cyclin d1)	13
Sarcoma	<i>MDM2</i>	10–30
	<i>CDK4</i>	11
Cervical cancer	<i>MYC</i>	25–50
Ovarian cancer	<i>MYC</i>	20–30
	<i>ERB B2 (EGFR2)</i>	15–30
	<i>AKT2</i>	12
Head and neck cancer	<i>MYC</i>	7–10
	<i>ERB B1 (EGFR)</i>	10
	<i>CCND1</i> (cyclin d1)	~50
Colorectal cancer	<i>MYB</i>	15–20
	<i>HRAS</i>	29
	<i>KRAS</i>	22

Table 3 Correlation of N-myc copy number with stage and survival in neuroblastoma

Tumor type	Number of cases	%
Benign ganglioneuromas	0/64	(0)
Low stages	31/772	(4)
Stage 4-S	15/190	(8)
Advanced stages	612/1.974	(31)
Total	658/3000	(22)

In breast cancer, *ERB B2* amplification correlates with advanced stage and poor prognosis. Members of the *RAS* gene family, including *KRAS* and *NRAS*, are sporadically amplified in various carcinomas.³³

Chromosomal rearrangements

Recurring chromosomal rearrangements are often detected in hematological malignancies and some solid tumors.⁷⁹ These rearrangements consist mainly of chromosomal translocations and, less frequently, chromosomal inversions. Chromosomal rearrangements can lead to hematological malignancy by two different mechanisms: (1) the transcriptional activation of proto-oncogenes or (2) the creation of fusion genes. Transcriptional activation results from chromosomal rearrangements that move a proto-oncogene close to an immunoglobulin or T-cell receptor (TCR) gene ([Figure 7](#)). Therefore, the proto-oncogene is constitutively activated in blood cells, leading to cancer development.

Fusion genes can be created by chromosomal rearrangements when the chromosomal breakpoints fall within the loci of two different genes, leading to a composite structure consisting of the head of one gene and the tail of another gene. Fusion genes encode chimeric proteins with transforming activity. In general, both genes involved in the fusion contribute to the transforming potential of the chimeric oncoprotein. Mistakes in the physiologic rearrangement of immunoglobulin or TCR genes are thought to give rise to many of the recurring chromosomal rearrangements found in hematologic malignancy.⁸⁰ Examples of molecularly characterized chromosomal rearrangements in hematologic and solid malignancies are given in [Table 4](#). In some cases, the same proto-oncogene is involved in several different translocations (i.e., *C-MYC*, *EWS*, and *RET*).

Table 4 Molecularly characterized chromosome rearrangements in tumors

Affected gene	Rearrangements	Disease	Protein type
<i>Hematopoietic tumor</i>			
<i>Gene fusion</i>			
<i>C-ABL</i> (9q34) <i>BCR</i> (22q11)	t(9;22)(q34;q11)	Chronic myelogenous leukemia and acute leukemia	Tyrosine kinase activated by BCR
<i>ALK</i> (2p23) <i>NPM</i> (5q35)	t(2;5)(p23;q35)	Anaplastic large cell lymphomas	Tyrosine kinase activated by NPM
<i>PDGFR-B</i> (5q33) <i>TEL</i> (12p13)	t(5;12)(q33;p13)	Chronic myelomonocytic leukemia	Tyrosine kinase activated by tel
<i>PBX1</i> (1q23) <i>E2A</i> (19p13.3)	t(1;19) (q23;p13.3)	Acute pre-B-cell leukemia	Homeodomain (HLH)
<i>PML</i> (15q21) <i>RAR</i> (17q21)	t(15;17) (q21;q11–22)	Acute myeloid leukemia	Zn finger
<i>CAN</i> (6p23) <i>DEK</i> (9q34)	t(6;9)(p23;q34)	Acute myeloid leukemia	No homology
<i>REL</i> <i>NRG</i>	ins(2;12) (p13;p11.2–14)	Non-Hodgkin's lymphoma No homology	NF-κB family
<i>Oncogenes juxtaposed with IG loci</i>			
<i>C-MYC</i>	t(8;14)(q24;q32) t(2;8)(p12;q24) t(8;22)(q24;q11)	Burkitt's lymphoma. BL-ALL	HLH domain

<i>TRK—T3</i>	t(1q31:3)	Papillary thyroid carcinomas	Tyrosine kinase activated by TFG
<i>Hematopoietic and solid tumors</i>			
<i>Oncogenes juxtaposed with other loci</i>			
<i>PTH</i> deregulates <i>PRAD1</i>	inv(11)(p15;q13)	Parathyroid adenoma	PRADI-GI cyclin
<i>BTG1</i> deregulates <i>MYC</i>	t(8:12)(q24;q22)	B-cell chronic lymphocytic	MYC-HLH domain

Abbreviations: IG, immunoglobulin; TCR, T-cell receptor; HLH, helix–loop–helix structural domain; zn, zinc; HMG, high mobility group; H4; ELE1; TPR and 1TFG, partially uncharacterized genes with a dimerizing coiled-coil domain; RIa, regulatory subunit of PKA enzyme; TPM3, isoform of nonmuscle tropomyosin.

Gene activation

The t(8;14)(q24;q32) translocation, found in about 85% of cases of Burkitt's lymphoma, is a well-characterized example of the transcriptional activation of a proto-oncogene. This chromosomal rearrangement places the *C-MYC* gene, located at chromosome band 8q24, under the control of regulatory elements from the immunoglobulin heavy-chain locus located at 14q32. The *C-MYC* gene is also activated in some cases of Burkitt's lymphoma by translocations involving immunoglobulin light-chain genes. These are t(2;8)(p12;q24), involving the *k* locus located at 2p12, and t(8;22)(q24;q11), involving the λ locus at 22q11 ([Figure 9](#)). The position of the chromosomal breakpoints relative to the *C-MYC* gene may vary considerably in individual cases of Burkitt's lymphoma, but with the same effect. An alternative mechanism of *C-MYC* alteration is represented by gene mutations, which can occur in the gene transactivation domain and in the coding region after translocation into the *Ig* gene⁸¹ or in the noncoding gene exon 1 and at the exon 1/intron 1 boundary with or without *C-MYC* gene translocation.⁸² In T-cell ALL (T-ALL), the *C-MYC* gene is activated by the t(8;14)(q24;q11) translocation, when it is placed under the control of regulatory elements within the TCR.⁸³ In this tumor, several other proto-oncogenes encoding nuclear proteins are activated by various chromosomal translocations involving α or β loci of the TCR.

These include *HOX11*, *TAL1*, *TAL2*, and *RBTN1/TGT1*.⁸⁴ The proteins encoded by these genes are thought to function as transcription factors through DNA-binding and protein–protein interactions, whose inappropriate expression leads to uncontrolled cellular proliferation.

Figure 9 *C-MYC* translocations found in Burkitt lymphoma. (a) t(8;14)(q24;q32) translocation involving the locus of immunoglobulin heavy chain gene located at 14q32. (b) t(8;14)(q24;q32) translocation where only two exons of *C-MYC* are translocated under regulatory elements from the immunoglobulin heavy chain locus located at 14q32. (c) t(8;22)(q24;q11) translocation involving the *I* locus of immunoglobulin light chain gene at 22q11. (d) t(2;8)(p12;q24) translocation involving the *k* locus of immunoglobulin light chain gene located at 2p12.

A number of other proto-oncogenes are also activated by chromosomal translocations in leukemia and lymphoma.

Gene fusion

The first example of gene fusion was discovered through the cloning of the breakpoint of the Philadelphia chromosome in CML.²⁵ The t(9;22)(q34;q11) translocation in CML fuses the *C-ABL* gene, normally located at 9q34, with the *BCR* gene at 22q11 (Figure 10). The *BCR/ABL* fusion, created on the der(22) chromosome, encodes a chimeric protein of 210 kD with increased TK activity and abnormal cellular

localization.²⁵ The precise mechanism by which the *BCR/ABL* fusion protein contributes to the expansion of the neoplastic myeloid clone is not yet known. The t(9;22) translocation is also found in up to 20% of cases of ALL. In these cases, the breakpoint in the *BCR* gene differs somewhat from that found in CML, resulting in a 185-kD bcr/abl fusion protein.⁸⁵ It is unclear at this time why the slightly smaller bcr/abl fusion protein leads to such a large difference in neoplastic phenotype. Inhibition of bcr/abl TK activity has been introduced as a chemotherapeutic approach in patients with CML. Administration of imatinib resulted in an antileukemic effect in CML patients in whom treatment with standard chemotherapy had failed.⁸⁶ However, cases of imatinib-resistance have also been recently documented.⁸⁷ Cause of such a failure is due to either *BCR/ABL* gene amplification or single amino acid substitutions affecting residues that are in direct contact with ATP or are within the ATP pocket of the kinase domain of abl, resulting in structural changes that could influence inhibition sensitivity. Strategies for overcoming resistance have been suggested, exploiting dependence of bcr/abl protein on the molecular chaperone heat shock protein 90.⁸⁷

Figure 10 Gene fusion. The t(9;22)(q34;q11) translocation in CML determines the fusion of the *ABL* gene with the *BCR* gene. Such a gene fusion encodes an oncogenic chimeric protein of 210 KD.

Additional genes encoding TKs involved in gene fusion events in hematologic malignancy are represented by the t(2;5)(p23;q35) translocation in anaplastic large cell lymphomas fusing the *NPM* gene (5q35) with the *ALK* gene (2p23)⁸⁸ and the t(5;12)(q33;p13) translocation fusing the *tel* gene (12p13) with the TK domain of the *platelet-derived growth factor receptor b* gene (*PDGFR-B* at 5q33) in chronic myelomonocytic leukemia (CMML) (Table 4).⁸⁹

Gene fusions sometimes lead to the formation of chimeric transcription factors.⁹⁰ The t(1;19)(q23;p13) translocation, found in childhood pre-B-cell ALL, fuses the *E2A* transcription factor gene (19p13) with the *PBX1* homeodomain gene (1q23).⁹¹ The E2A/PBX1 fusion protein consists of the amino-terminal transactivation domain of the E2A protein and the DNA-binding homeodomain of the PBX1 protein. Another gene fusion leading to a chimeric transcription factor is represented by the t(15;17)(q22;q21) translocation in acute promyelocytic leukemia, fusing the *PML* gene (15q22) with the *RARA* gene at 17q21.⁹² Leukemia patients with the *PML/RARA* gene fusion respond well to retinoid treatment. In these cases, treatment with all-trans retinoic acid induces differentiation of promyelocytic leukemia cells.

The *ALL1* gene, located at chromosome band 11q23, is involved in approximately 5–10% of acute

leukemia cases overall in children and adults.⁹³ *ALL1* is unique because it participates in fusions with a large number of different partner genes on the various chromosomes. Over 20 different reciprocal translocations involving the *ALL1* gene at 11q23 have been reported, the most common of which are those involving chromosomes 4, 6, 9, and 19. In approximately 5% of cases of acute leukemia in adults, the *ALL1* gene is fused with a portion of itself. This special type of gene fusion is called self-fusion.⁹⁴ Self-fusion of the *ALL1* gene, which is thought to occur through a somatic recombination mechanism, is found in high incidence in acute leukemias with trisomy 11 as a sole cytogenetic abnormality. The *ALL1* gene encodes a large protein with DNA-binding motifs, a transactivation domain, and a region with homology to the *Drosophila trithorax* protein (a regulator of homeotic gene expression). The various partners in *ALL1* fusions encode a diverse group of proteins, some of which appear to be nuclear proteins with DNA-binding motifs.⁹⁴ The *ALL1* fusion protein consists of the amino terminus of *ALL1* and the carboxyl terminus of one of a variety of fusion partners. It appears that the critical feature in all *ALL1* fusions, including self-fusion, is the uncoupling of the *ALL1* amino-terminal domains from the remainder of the *ALL1* protein.

Solid tumors, especially sarcomas, sometimes have consistent chromosomal translocations that correlate with specific histological types of tumors.⁹⁵ In general, translocations in solid tumors result in gene fusions that encode chimeric oncoproteins. Studies thus far indicate that in sarcomas, the majority of genes fused by translocations encode transcription factors.⁹⁶ [Table 4](#) summarizes translocations in solid tumors, with the most relevant represented by the t(12;16)(q13;p11) translocation fusing the *FUS (TLS)* gene at 16p11 with the *CHOP* gene at 12q13 in myxoid liposarcomas,⁹⁷ and the t(11;22)(q24;q12) translocation, fusing the *EWS* gene at 22q12 with the *FLI1* gene at 11q24 in Ewing's sarcoma.⁹⁸

In DP, both a reciprocal translocation t(17;22)(q22;q13) and supernumerary ring chromosomes derived from the t(17;22) have been described.⁹⁹

Although early successful studies in this field have been performed with lymphomas and leukemia, as we have discussed before, the first chromosomal abnormality in solid tumors to be characterized at the molecular level as a fusion protein was an inversion of chromosome 10 found in papillary thyroid carcinomas.¹⁰⁰ In this tumor, two main recurrent structural changes have been described, including inv(10)(q112.2; q21.2), as the more frequent alteration, and a t(10;17)(q11.2; q23). These two abnormalities represent the cytogenetic mechanisms that activate the proto-oncogene *RET* on chromosome 10, forming the oncogenes *RET/PTC1* and *RET/PTC2*, respectively. Moreover, other chromosomal rearrangements leading to *ret* activation were recently described, especially in children of the Chernobyl-contaminated areas.^{101, 102} Virtually, all breakpoints in the *RET* gene occur within intron 11, leading intact the TK domain of the receptor and enabling the *RET/PTC* oncoprotein to bind to SHC via Y1062 and activate the downstream cascade.¹⁰³ Somatic chromosomal rearrangements involving the *RET* gene represent the most frequent genetic alteration in *PTC*, although wide variations in frequency ranging from 5% to 70% have been observed in different geographic areas.¹⁰⁴ Recent results suggest that a broad variability in the reported prevalence of *RET/PTC* rearrangements is at least in part a result of the use of different detection methods and tumor genetic heterogeneity.¹⁰⁵ Alterations of chromosome 1 in the same tumor type have then been associated to the activation of NTRK1 (chromosome 1), an NGF receptor, which, like *RET*, forms chimeric fusion oncogenic proteins in *PTC*.¹⁰⁶ A comparative analysis of the oncogenes originated from the activation of these two TK receptors has allowed the identification and characterization of common cytogenetic and molecular mechanisms of their activation. In all cases, chromosomal rearrangements fuse the TK portion of the two receptors to the 5'-end of different genes that, because of their general effect, have been designated as “activating genes.” In the majority of cases, the

latter belong to the same chromosome where the related receptor is located, 10 for *RET* and 1 for *NTRK1*.

Furthermore, although functionally different, the various activating genes share the following three properties:

1. They are ubiquitously expressed.
2. They display domains demonstrated or predicted to be able to form dimers or multimers.
3. They translocate the signal from the membrane to the cytoplasm.

These characteristics can explain the mechanism(s) of oncogenic activation of *RET* and *NTRK1* proto-oncogenes. In fact, following the fusion of their TK domain to the activating gene (1) *RET* and *NTRK1*, whose tissue-specific expression is restricted to subsets of neural cells, become expressed in the epithelial thyroid cells; (2) their dimerization triggers a constitutive, ligand-independent trans-autophosphorylation of the cytoplasmic domains and, as a consequence, the latter can recruit SH2- and SH3-containing cytoplasmic effector proteins, such as Shc and Grb2 or phospholipase C gamma (PLC), thus inducing a constitutive mitogenic pathway; and (3) the relocation in the cytoplasm of *RET* and *NTRK1* enzymatic activity could allow their interaction with unusual substrates, perhaps modifying their functional properties. *RET* rearrangements are mutually exclusive with *NTRK1* rearrangements and *BRAF* mutations and show similar but distinct gene expression patterns in PTC.⁵⁹ Overall, papillary carcinomas with *RET/PTC* rearrangements typically present at younger age and have a high rate of lymph-node metastases, clinical papillary histology, and possibly more favorable prognosis.¹⁰³

Protein overexpression and constitutive phosphorylation

Protein overexpression refers to a general deregulation driven by a mechanism not understood or not investigated. An example is Akt, three serine-threonine kinases that represent major effectors mediating survival signal. Generally, Akt proteins possess six sites of phosphorylation: Ser124 and Thr450 are basally phosphorylated, Tyr315 and Tyr316 depend on Src, Thr308 represents the major site of regulation and is phosphorylated by 3-phosphoinositides-dependent protein kinase 1, Ser473 is only required for maximal Akt activity but the mechanism by which it is phosphorylated remains controversial. Akt is phosphorylated and therefore activated after cell stimulation from different growth factors and a series of interleukins, while its action is inhibited by PTEN. Once activated, Akt dissociates from the plasma membrane and translocates to both the cytoplasm and the nucleus. Akt inhibits directly, through phosphorylation of Bad and caspase-9, and indirectly, by inducing *de novo* gene expression of IKK protein kinase and transcription factors. Akt determines cell survival also by virtue of its involvement in cell-cycle progression.¹⁰⁷ Analyses of tissue specimens pointed out that the protein encoded by *AKT3* is overexpressed in poorly differentiated breast and prostate cancers and may contribute to the progression of sporadic melanoma.¹⁰⁸ Akt1 is especially involved in the pathogenesis of sporadic thyroid cancer, whereas Akt2 seems to be the isoform that plays a pivotal role in ovarian, pancreatic, thyroid, and CRC. Mutations in *AKT* genes are rare.¹⁰⁹

New markers from large-scale genomic analysis

Kinases

A recent analysis organized the protein kinase complement of the human genome (the so-called kinome) into a dendrogram containing nine broad groups of genes.¹¹⁰ Using high-throughput sequencing

technologies and bioinformatics from the human genome project, one major branch of the histogram, containing three of the nine major groups, was selected for mutational analysis. The selected groups included the 90 tyrosine kinase genes (TK group), the 43 tyrosine kinase-like genes (TKL group), and the 5 receptor guanylate cyclase genes (RGC group). The analysis took into consideration all exons encoding their predicted kinase domains in 35 CRC cell lines and in 147 colorectal specimens.⁸ Thirty-five different types of somatic mutations were identified in seven genes (*NTRK3*, *FES*, *KDR*, *EPHA3*, *NTRK2* belonging to the TK group, *MLK4* to *TKL*, and *GUCY2F* to *RGC*), representing an attractive target for chemotherapeutic intervention.⁸

Phosphatases

The protein tyrosine phosphatases (PTPs), gene superfamily (the so-called phosphatome) is composed of three main families: (1) the classic PTPs, including the receptor protein tyrosine phosphatases (RPTPs) and the nonreceptor protein tyrosine phosphatases (NRPTPs); (2) the dual specificity phosphatases (DSPs), which can dephosphorylate serine and threonine in addition to tyrosine residues; and (3) the low molecular weight phosphatases (LMPs).¹¹¹ Using high-throughput technologies, a mutational analysis of all the coding exons of 53 classic PTPs (21 RPTPs and 32 NRPTPs), 32 DSPs, and 1 LMP was performed in 175 CRCs.⁹ Six genes containing somatic mutations were identified, including three members of the RPTP subfamily (*PTPRF*, *PTPRG*, and *PTPRT*), and three members of the NRPTP subfamily (*PTPN3*, *PTPN13*, and *PTPN14*). Overall, 77 mutations were identified, in aggregate, affecting 26% of colorectal tumors analyzed. The great majority of the mutations would result in proteins devoid of phosphatase catalytic activity.⁹ The identification of protein phosphatases mutated could lead to reactivation of their activity through new targeted pharmacologic treatments or, better, inactivate the corresponding kinases that phosphorylate substrates normally regulated by the mutant phosphatases.

PI3K isoforms

Phosphatidylinositol 3-kinases (PI3K) belong to the lipid kinase family that regulate signal transduction.¹¹² Hidden-Markov models identified eight *PI3K* and *PI3K*-like genes, including two uncharacterized genes, in the human genome. By the analysis of the predicted kinase domains, it has been found that *PIK3CA* was the only gene with somatic mutations.¹⁰ Hyperactivating *PIK3CA* mutations were also identified in several cancers from the colon, the lung, the ovaries, the liver, the brain, the stomach, and the breast.^{113–115} The analysis of *PIK3CA* mutations in patients affected by hereditary CRCs revealed alteration in 21% of FAP invasive carcinomas, 21% of HNPCC invasive carcinomas, and 15% of sporadic invasive carcinomas, thus demonstrating that *PIK3CA* mutations are involved in both types of familial colorectal carcinogenesis (FAP and HNPCC) without an evident segregation (at odds with *BRAF*) and with a similar extent that seen in sporadic patients.¹¹⁶ In addition to point mutations, *PIK3CA* may be altered through gene amplification, especially in ovarian cancer.¹¹⁷

Oncogenes in the initiation and progression of neoplasia

Human neoplasia is a complex multistep process involving sequential alterations in proto-oncogenes (activation) and in tumor-suppressor genes (inactivation). Statistical analysis of the age incidence of human solid tumors indicates that five or six independent mutational events may contribute to tumor formation. In human leukemias, only three or four mutational events may be necessary, presumably involving different genes.

The study of chemical carcinogenesis in animals provides a foundation for our understanding of the multistep nature of cancer.¹¹⁸ In the mouse model of skin carcinogenesis, tumor formation involves three phases, termed *initiation*, *promotion*, and *progression*. Initiation of skin tumors can be induced by chemical mutagens such as 7,12-dimethyl-benzanthracene (DMBA) ([Figure 11](#)). After application of DMBA, the mouse skin appears normal. If the skin is then continuously treated with a promoter, such as the phorbol ester TPA, precancerous papillomas will form. Chemical promoters such as TPA stimulate growth but are not mutagenic substances. Over a period of months of continuous application of the promoting agent, some of the papillomas will progress to skin carcinomas. Treatment with DMBA or TPA alone does not cause skin cancer. Mouse papillomas initiated with DMBA usually have *HRAS* oncogenes with a specific mutation in codon 61 of the *HRAS* gene. The mouse skin tumor model indicates that initiation of papillomas is the result of mutation of the *HRAS* gene in individual skin cells by the chemical mutagen DMBA. For papillomas to appear on the skin, however, growth of mutated cells must be continuously stimulated by a promoting agent. Additional unidentified genetic changes must then occur for papillomas to progress to carcinoma.

Figure 11 Some possible ways of exposure to a mutagen and a tumor promoter and their effects. Cancer develops exclusively when the exposure to promoter follows the exposure to carcinogen (mutagen, e.g., DMBA) and only when the intensity of the exposure to promoter is higher than a threshold.

Although a single oncogene is sufficient to cause tumor formation, transformation by a single oncogene is not usually seen in experimental models of cancer. On the contrary, different oncogenes frequently cooperate in producing the neoplastic phenotype.¹¹⁹ Cooperation between oncogenes can also be demonstrated by *in vitro* transformation studies using nonimmortalized cell lines. For example, studies have shown cooperation between the nuclear myc protein and the cytoplasmic-membrane-associated ras protein in the transformation of rat embryo fibroblasts.¹²⁰

Collaboration between two different categories of oncogenes (e.g., nuclear and cytoplasmic) can often be demonstrated but is not strictly required for transformation.¹²¹ These transgenic mice strains, in fact, generally show an increased incidence of neoplasia and the tumors that result frequently are clonal, implying that other events are necessary.¹²²

Cytogenetic studies of the clonal evolution of human hematologic malignancies have provided much insight into the multiple steps involved in the initiation and progression of human tumors.¹²³ The evolution

of CML from chronic phase to acute leukemia is characterized by an accumulation of genetic changes seen in the karyotypes of the evolving malignant clones. The early chronic phase of CML is defined by the presence of a single Philadelphia chromosome. The formation of the *BCR/ABL* gene fusion as a consequence of the t(9;22) translocation is thought to be the initiating event in CML.²⁵ The biologic progression of CML to a more malignant phenotype corresponds with the appearance of additional cytogenetic abnormalities such as a second Philadelphia chromosome, isochromosome 17, or trisomy 8.¹²⁴ Although the karyotypic changes in evolving CML are somewhat variable from patient to patient, the accumulation of genetic changes always correlates with progression from differentiated cells of low malignancy to undifferentiated cells of high malignancy.

The initiation and progression of human neoplasia involve the activation of oncogenes and the inactivation or loss of tumor-suppressor genes. The mechanisms of oncogene activation and the time course of events, however, vary among different types of tumors. In hematologic malignancies, soft-tissue sarcomas, and the papillary type of thyroid carcinomas, initiation of the malignant process predominantly involves chromosomal rearrangements that activate various oncogenes.⁹⁰ Many of the chromosomal rearrangements in leukemia and lymphoma are thought to result from errors in the physiologic process of immunoglobulin or TCR gene rearrangement during normal B-cell and T-cell development. Late events in the progression of hematologic malignancies involve oncogene mutation, mainly of the *RAS* family, inactivation of tumor-suppressor genes such as *TP53*, and sometimes additional chromosomal translocations.¹²⁵

In lung cancers, the initiation of neoplasia has been shown to involve oncogene and tumor-suppressor gene mutations. These mutations are generally thought to result from chemical carcinogenesis, especially in the case of tobacco-related lung cancers, where a novel tumor-suppressor gene (designated *FHIT*) has been found to be inactivated in the majority of cancers, particularly in those from smokers.¹²⁶ Later, *KRAS* (especially in the adenocarcinoma subtype) and *TP53* alterations drive the malignant transformation of lung cancer.¹²⁷

As far as CRC is concerned, intensive screening for genetic alteration led to the identification of two major types of CRC that are distinct by their carcinogenic process. One is characterized by normal karyotype, normal DNA index, and genetic instability at microsatellite loci (MSI) and was called RER-positive tumor for replicative error-positive phenotype and now is called MSI-positive cancer.¹²⁸ The second one is represented by alterations of *APC*, *KRAS*, and *TP53* genes and genetic losses at MSI.¹²⁹ The second type led to the association between the stepwise progression from normal to dysplastic epithelium to carcinoma and the accumulation of multiple clonally selected genetic alterations. This model, first proposed by Vogelstein in 1990,¹³⁰ suggests that *APC* (or, better, the *APC*-*b-catenin* pathway) represents the initial mutational event that determines hyperplastic proliferation and then early adenoma formation. The stage of late adenoma is achieved with *K-ras* protein stabilization. Loss of tumor-suppressor genes at chromosome 18q (such as *DCC*) and mutations in the *TP53* gene lead to carcinoma *in situ* formation ([Figure 12](#)).^{128–130}

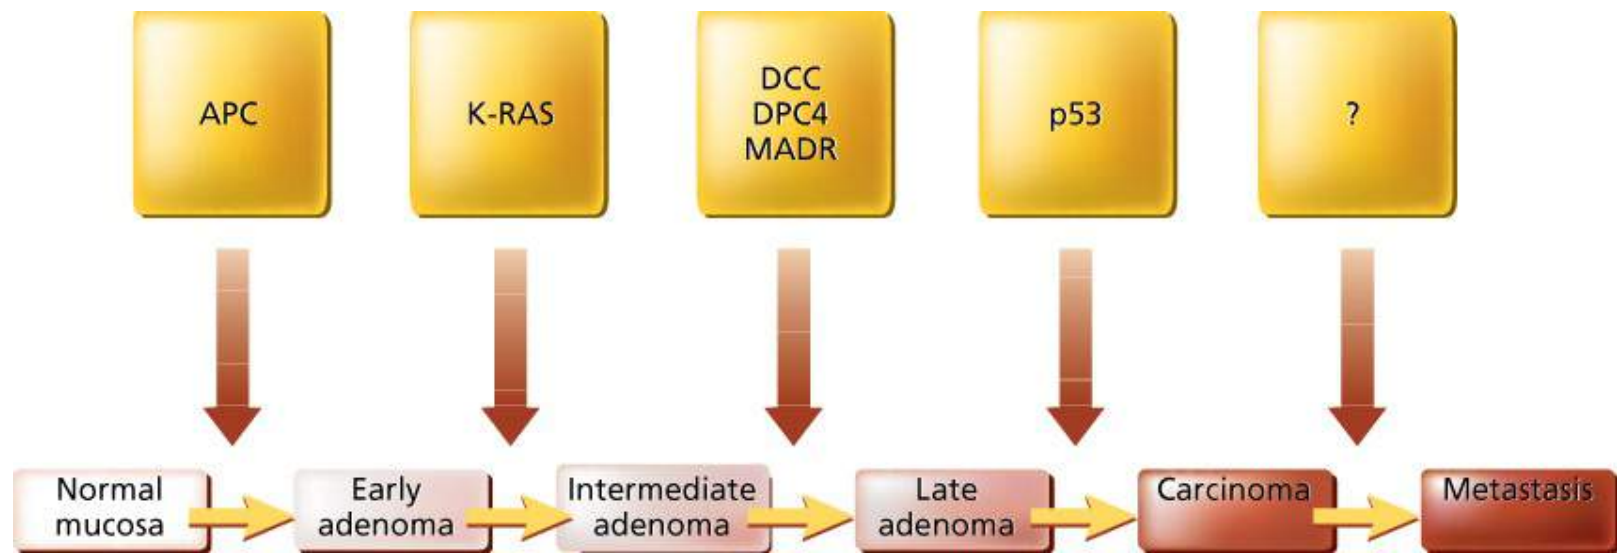

Figure 12 Colorectal cancer development. Colorectal cancer results from a series of pathological changes that transform normal colonic epithelium into invasive carcinoma. Specific genetic events, shown by vertical arrows, accompany this multistep process.

In melanoma, *BRAF* mutations occur in the vast majority of cases and represent a very early event, as they were also detected in preneoplastic lesions such as Spitz and Blue nevi.^{7, 67}

Although there is variability in the pathways of human tumor initiation and progression, studies of various types of malignancy have clearly confirmed the multistep nature of human cancer.

Oncogenes as target of new drugs

Several oncogenes act in key points of cell life. Most of them, in fact, codify for growth factor receptors or are involved in the signal transduction. Therefore, they represent a natural target for the development of new drugs that are able to block selectively the cells carrying a deregulation in the drug target. The new insights in targeted therapies are summarized here.

ERB B2

ERB B2 gene amplification occurs in a consistent fraction of breast cancers. A monoclonal antibody (MoAb) against erb B2 receptor, trastuzumab, was the first anti-erb B2 drug that entered clinical practice, with evident benefit for patients harboring *ERB B2* gene amplification/overexpression. Trastuzumab is indicated for patients affected by a metastatic breast cancer and, more recently, also for the adjuvant and neo-adjuvant setting. Currently, additional targeted therapies, both MoAbs (pertuzumab and a second-generation trastuzumab named T-DM1, with trastuzumab conjugated with emtansine) and small-molecule tyrosine kinase inhibitors (TKIs) (lapatinib) have been developed and are routinely used for the treatment of metastatic patients and in the neo-adjuvant setting. Unfortunately, not all patients showing *ERB B2* gene amplification may benefit from trastuzumab administration. This is probably due to the deregulation of *ERB B2* downstream members. Indeed, at preclinical level, it has been demonstrated that activating point mutations in the *PIK3CA* gene as well as the loss of expression of PTEN protein lead to trastuzumab resistance.³³

More recently, it has been demonstrated that *ERB B2* can be deregulated in other solid tumors, with a putative relevant clinical role. *ERB B2* gene amplification or protein overexpression occur in up to 34% of patients affected by an advanced gastric or gastroesophageal junction cancers, and trastuzumab is approved for erb B2 positive patients (as evaluated by fluorescent *in situ* hybridization or

immunohistochemistry).³³ In CRC, *ERB B2* gene amplification is a rare phenomenon (observed in <5% of cases), linked to resistance to EGFR-targeted therapies.¹³¹ However, the efficacy of trastuzumab in CRC, proposed in *in vivo* models (xenografts), deserves additional confirmatory studies. In lung adenocarcinoma, a recent retrospective study showed that patients with *ERB B2* gene mutations (occurring in about 1% of cases) may benefit from the administration of trastuzumab. Furthermore, the occurrence of *ERB B2* gene mutations or amplification seems to be represented by a mechanism of secondary resistance to anti-EGFR therapies.³³

ERB B1

ERB B1 codify for a receptor TK playing an important role in cancer cell proliferation, angiogenesis, and metastasis. Therefore, targeting erb B1 is a valuable molecular approach in cancer therapy. Two classes of erb B1 antagonists have been successfully tested in phase III trials and are now in clinical use: MoAbs and TKIs. MoAbs, represented by cetuximab and panitumumab, are able to bind to the extracellular domain of the receptor when it is in the inactive configuration, compete for receptor binding by occluding the ligand-binding region, and thereby block ligand-induced TK of the receptor. TKIs, represented by gefitinib and erlotinib, compete reversibly with ATP to bind to the intracellular catalytic domain of the receptor and, therefore, inhibit receptor autophosphorylation and downstream signaling.⁷⁷

In NSCLC, only 10–20% of patients have a partial response to gefitinib/erlotinib. Several retrospective and prospective studies confirmed that patients carrying an *EGFR* mutation were particularly sensitive to gefitinib/erlotinib, with a response rate up to 80% of mutated patients. Many types of mutations in the *ERB B1* have been reported, but so far, only four drug-sensitive mutations have been ascertained, including exon 19 deletions, and exon 18 (G719A/C), exon 21 L858R and exon 21 L861Q substitutions. In addition, *ERB B1* gene copy number gain (chromosome 7 high polysomy or gene amplification) is emerging as another relevant method for patients' selection.¹³² Patients characteristics associated with increased responsiveness to gefitinib/erlotinib are never smoking history, Asian ethnicity, female gender, and adenocarcinoma histology. Acquisition of drug resistance in patients initially responsive to gefitinib/erlotinib has been linked to a specific secondary somatic mutation (*T790M*) occurring in exon 20 of the *ERB B1* gene. In addition, *MET* and *ERB B2* gene amplification represents alternative mechanisms of TKIs resistance (Takezawa et al., 2012). Novel inhibitors are currently under evaluation to specifically act against the T790M mutation: these drugs are named “irreversible inhibitors.”^{134, 135}

In CRC, the class of erb B1 inhibitors showing clinical efficacy is represented by MoAbs. Cetuximab or panitumumab monotherapy is associated with response rates of 9–12%, that increase to 20–30% when the drugs are used in combination with irinotecan in patients who did not benefit from a previous therapy with irinotecan. Recent data indicate that erb B1 protein expression as evaluated by immunohistochemistry as well as *ERB B1* gene status by fluorescent *in situ* hybridization cannot be used to predict the efficacy of EGFR-targeted therapies (in contrast with earlier studies), essentially due to the fact that these two methodologies are not reproducible. On the contrary, *KRAS* and *NRAS* gene mutations are negative predictors of EGFR-targeted therapies efficacy and are mandatory to be tested before MoAbs administration.¹³⁶ In addition, the detection of gene or protein alterations of other *ERB B1* downstream members, such as *BRAF* and *PIK3CA* point mutations, and the loss of expression of PTEN protein, has been proposed to be additional mechanisms of the resistance to cetuximab/panitumumab, but the data reported so far are controversial and therefore their test is not required before drug administration.¹³⁷

Cetuximab and panitumumab are effective also in 10–13% of patients affected by head and neck

squamous cell carcinoma, and EGFR-targeted therapy is the first and only molecularly targeted therapy to demonstrate a survival benefit for patients with recurrent or metastatic disease.¹³⁸

KIT* and *PDGFRA

It has been clearly demonstrated that imatinib, an inhibitor of TK activity in bcr-abl-positive leukemia, was effective in treating GIST ([Figure 13](#)). In this pathology, *KIT* and *PDGFRA* mutational status predicts for the likelihood of achieving response to such a targeted drug. Patients with a *KIT* exon 11 mutation have a partial response rate up to 85–90%, while those with a *KIT* exon 9 mutation have a partial response rate of around 50%. Recent data points out that for patients with *KIT* exon 9 mutation the better treatment is represented by a double dose of imatinib. Patients who have GIST with *KIT* exon 11 mutation also have longer median time to treatment failure as compared to those with GIST harboring other types of mutations. Patients who have no detectable mutation of *KIT* or *PDGFRA* respond less frequently to imatinib than those with exon 11 mutants, but still up to 39% do respond. The rare patients who have GIST with *KIT* exon 13 or 17 mutation or *PDGFRA* mutation may also respond to imatinib. The rare patients who have GIST with a mutation known to be resistant to imatinib, such as D842V *PDGFRA* exon 18 mutation, may be the only exception to this rule. Interestingly, the D842V *PDGFRA* exon 18 mutation is functionally equivalent to the D816V *KIT* exon 17 mutation, never found in GIST, but which confers resistance to imatinib treatment in leukemia.¹³⁹ A majority of patients with a GIST metastatic disease ultimately cease to respond to imatinib. The reasons for failure usually include secondary mutations at the ATP/imatinib binding pocket (exon 13 or exon 14) or in the activation loop (exon 17) of the kit protein kinase that prohibit imatinib binding. Patients who progress despite imatinib dose escalation are candidates for a trial with other TK inhibitors. Sunitinib (SU11248) is an inhibitor of kit, pdgfra, fms-like TK-3 and vascular EGFR-2, and has been approved by the Food and Drug Administration for the treatment of GIST patients whose disease has progressed on imatinib or are unable to tolerate treatment with imatinib.

Figure 13 Mode of action of imatinib. In (a), the effect of ATP binding on the oncoprotein BCR-ABL is depicted. The fusion protein binds the molecule of ATP in the kinase pocket. Afterward, it can phosphorylate a substrate that can interact with the downstream effector molecules. When imatinib is present (b), the oncoprotein binds imatinib in the kinase pocket (competing with ATP) and then the substrate cannot be phosphorylated.

More recently, the clinical role of *KIT* mutations has expanded to melanoma. It has been shown that *KIT* mutations occur in specific subtypes of melanoma patients, in the majority of uveal, in up to in 39% of mucosal, 36% of acral, and 28% of melanomas arising from chronically sun-damaged skin, but not in any (0%) cutaneous melanomas without chronic sun damage.¹⁴⁰ The typical alteration is represented by the L576P point mutation. Results from case reports and from human uveal melanoma cell lines demonstrated that imatinib inhibits cell proliferation and invasion rates.¹⁴¹ These results justify the need for clinical trials (which are now under evaluation) to investigate in vivo the response of uveal melanoma to imatinib.

RET

Recently, various kinds of therapeutic approaches, including TKIs, gene therapy with dominant negative *RET* mutants, MoAbs, and nuclease-resistant aptamers that recognize and inhibit RET, have been developed. The use of these strategies in preclinical models has provided evidence that RET is indeed a potential target for selective cancer therapy. In clinical cases, in addition to papillary thyroid cancers where they play a relevant role, *RET* rearrangements have been found in a small subgroup of lung cancers (1–2%). Two specific gene fusions (*CCDC6-RET* and *KIF5B-RET*) have been described. *RET* rearrangements appear limited to adenocarcinoma histology and are not seen concurrently with *ERBB1* or *KRAS* mutations, or *ALK* rearrangements. There are currently at least six marketed TKIs against RET (vandetanib, sorafenib, sunitinib, cabozantinib, regorafenib, and ponatinib), but the efficacy of these

agents in RET rearranged lung cancers has not been completely established.^{81, 142}

RAS

A number of different approaches aimed at abrogating *KRAS* activity have been explored in clinical trials. Usually, the inhibitors directly addressed to K-RAS are too toxic for human cells. Currently, the most promising agents are represented by aminobiphosphonates that have entered clinical practice in the treatment of bone metastases from several neoplasms, including breast and prostate adenocarcinomas.

KRAS mutations play also a role in the prediction of efficacy of treatment targeted to upstream activated RTK, such as EGFR. Indeed, *KRAS* mutations represent an independent predictive factor in cetuximab- or panitumumab-treated advanced CRC patients.¹³⁷ Until 2013, only the characterization of *KRAS* codons 12 and 13, located in exon 2, was mandatory before the administration of EGFR-targeted therapies. However, starting from the evidence that also different *KRAS* mutations (at codons 59, 61, 117, and 146, located in exons 3 and 4, which can be cumulatively found in up to 5% of cases) can be detected in CRC and that also these regions are important for K-ras activity, the analysis of large cohorts demonstrated that also *KRAS* exons 3-4 mutations are negative predictors of efficacy of MoAbs against EGFR.^{136, 143, 144} Furthermore, *NRAS* mutations may occur in CRC patients (in up to 5% of cases, in the same codons altered in *KRAS* gene), and recently, it has been demonstrated that also patients carrying mutations in this gene are resistant to anti-EGFR therapies.^{55, 136, 145} Overall, therefore, the combined analysis of *KRAS* and *NRAS* gene mutations is now mandatory before the administration of EGFR-targeted therapies in CRC patients with a metastatic disease. As far as the clinical role of *KRAS* mutations in the prediction of efficacy of TKIs against EGFR in lung adenocarcinoma patients is concerned, at odds with preliminary data, essentially obtained in preclinical models and in few selected cohorts, the current hypothesis is that *KRAS* mutations cannot predict the efficacy of these drugs.

BRAF

BRAF now provides a critical new target for drugs treating malignant melanoma, including antisense oligonucleotides and small molecules. These inhibitors block the expression of *BRAF* protein, block the *BRAF*/ras interaction, block its kinase activity, or the kinase activity of the *BRAF* target protein MAP kinase. Besides these approaches, vemurafenib is a selective *BRAF* TKI inhibitor approved for the treatment of melanoma patients. The Food and Drug Administration approved this drug for the administration to patients carrying the V600E specific mutation, whereas the European Medicine Agency approved it for all the patients carrying any mutation at codon 600 (therefore including V600K, V600D, and V600G, overall accounting for more than 10% of melanoma cases). The effect of vemurafenib on *BRAF* mutant patients is extremely fast in terms of tumor regression, but after 10–12 months, secondary alterations (represented by abnormally spliced *BRAF* proteins or other *BRAF* somatic mutations) lead to a rapid reappearance of metastatic lesions.¹⁴⁶

A recent role has been proposed also in NSCLC. *BRAF* mutations occur not only in a small proportion of cases (up to 2%), mainly at codon 600, but also in other hot-spot codons (466, 469, and 594); therefore, lung cancer represents the tumor with the widest spectrum of *BRAF* mutations. A number of *BRAF* inhibitors, including sorafenib, vemurafenib, and dabrafenib, are under clinical development in V600E *BRAF* mutant lung cancer patients, with vemurafenib showing the most promising results, at least on the basis of few case reports. For lung cancers harboring non-V600E *BRAF* mutations, MEK inhibitors are being explored.^{81, 147}

AKT

Deregulation of AKT expression seems to be involved into AKT drug response and radioresistance in several tumors,¹⁴⁸ especially in metaplastic cancer, where it confers resistance to hormone therapy,¹⁴⁹ and in ovarian cancer, where it confers resistance to cisplatin by modulating the direct action of p53 on the caspase-dependent mitochondrial death pathway.¹⁵⁰ Moreover, recent efforts have been made in the development of small-molecule inhibitors that directly bind to AKT, such as triciribine and pyridine derivatives. However, several drawbacks have been found because of toxicity issues owing to the involvement of AKT in insulin signaling.¹⁰⁸

PIK3CA

Owing to the relevance in carcinogenesis, PIK3CA represents a natural target with specific drugs. Most of these have been developed, but many of these showed high toxicity for human cells. Some PIK3CA inhibitors entered clinical trials and the evaluation is awaited. *PIK3CA* mutations are linked, at least at preclinical level, to resistance against trastuzumab in metastatic breast cancers,¹⁵¹ whereas it has been proposed that only specific mutations (i.e., those occurring at exon 20) represent a mechanism of primary resistance to cetuximab or panitumumab in metastatic CRC patients, but this data deserves additional confirmation.¹³⁷ Furthermore, the clinical efficacy of selective inhibitors in *PIK3CA* mutant ovarian cancers is under investigation in on-going clinical trials. However, the major clinical application of *PIK3CA* mutations in clinical diagnosis is in CRC patients before the administration of aspirin in an adjuvant setting. Aspirin, in fact, is a drug efficiently preventing colorectal adenomas and carcinomas, and the effect is thought to be driven by the inhibition of cyclooxygenase enzymes. This anticancer effect has reported to be restricted to patients with cyclooxygenases overexpression. Two large prospective studies demonstrated that a stronger effect is observed in patients additionally carrying a *PIK3CA* mutation, probably because it seems that *PIK3CA* gene product further induces cyclooxygenases expression. A more recent study based on retrospective analysis has confirmed the predictive value of *PIK3CA* mutations for patients treated with aspirin in an adjuvant setting. Interestingly, this effect could not be observed in patients taken the specific cyclooxygenase inhibitor rofecoxib.^{152, 153}

BCL-2

Many groups have been working to develop anticancer drugs that block the function of antiapoptotic BCL-2 members, thus favoring cell death. Methods include the downregulation of BCL-2 expression through antisense oligonucleotides, or the use of peptides or small organic molecules to the BCL-2 binding pocket, preventing its sequestration of proapoptotic proteins. One of the most promising aspects of these small-molecule inhibitors in treating cancer is that their targets and mechanisms of action are different from those of cytotoxic drugs and radiation. This makes it feasible to combine small-molecule inhibitors with other treatments, creating a synergistic therapy, without likely development of cross-resistance or increased toxicity.¹⁵⁴

MET

MET is an RTK activated by hepatocyte growth factor. MET protein overexpression has been observed in a number of neoplastic diseases, usually associated with poor prognosis. *MET* gene amplification is responsible of protein overexpression in only a subgroup of MET-positive cancers. In NSCLC, *MET* gene amplification occurs in 2–4% of both squamous and nonsquamous cancers. Interestingly, *MET* amplification represents one of the major mechanisms of secondary resistance to TKI against EGFR.

Several MET inhibitors have been developed, both TKI (such as crizotinib and tivantinib) and MoAbs (such as onartuzumab), but the efficacy of these compounds has to be still proven in lung as well as in other cancers.^{81, 155}

FGFR

FGFR family includes four members, with FGFR1 showing the most promising clinical role in cancers. In particular, in NSCLC, *FGFR1* gene amplification occurs in approximately 20% of cases with a squamous histology but in <2% of adenocarcinoma. These amplifications appear to confer an FGFR1-addiction to tumoral cells. FGFR1 inhibitors (such as AZD4547, JNJ-42756493, BGJ398, and ponatinib) are under evaluation.^{81, 156}

DDR2

Discoidin death receptor 2 (DDR2) is an RTK mutated in approximately 4% of squamous NSCLCs and in about 1% of lung adenocarcinoma. The multitarget kinase inhibitor dasatinib, the sole DDR2 promising inhibitor, has demonstrated good efficacy in both preclinical models and few patients.^{81, 157}

ALK

Rearrangements of ALK primarily occur as fusion to *EML4* gene. These fusion proteins can be found in approximately 3–7% of lung adenocarcinoma. Among EML4-ALK fusion proteins, several *EML4* breakpoints have been described. In rare cases, other fusion partners have been observed, including *TFG* and *KIF5B* genes.⁸¹ The first ALK-selective inhibitor was represented by the multitargeted inhibitor crizotinib. The first clinical trial including ALK-positive patients showed very attractive results: 61% of overall survival, 71% of disease control rate, and increased progression-free survival, leading a rapid approval of crizotinib by the Food and Drug Administration for the treatment of lung adenocarcinomas characterized by *ALK* translocation, as evaluated by fluorescent *in situ* hybridization.¹⁵⁸ Unfortunately, the duration of clinical benefit of crizotinib is limited, owing to the occurrence of variable systemic resistance mechanisms: occurrence of secondary mutations in ALK active site, erb B family pathway activation, *ALK* copy number gain, *KIT* gene amplification, and *KRAS* mutations. Currently, a major effort is on the development of second-generation ALK inhibitors, capable of blocking lung adenocarcinoma that developed crizotinib resistance.⁸¹ ALK rearrangements are also considered one (but not the most frequent) of the mechanisms of acquired resistance to TKI against EGFR in *ERB B1*-mutant lung adenocarcinoma.⁸¹

ROS1

Rearrangements of *ROS1* oncogene appear to occur in approximately 1–2% of lung adenocarcinoma. *ROS1* has a high degree of homology with *ALK* (49% within the TK domain and 77% with the ATP-binding site) and patients with *ROS1* rearrangements display superimposable clinicopathological features with whom carrying *ALK* translocations.⁸¹ The multitargeted inhibitor crizotinib have demonstrated efficacy in *ROS1* rearranged patients, with preliminary response rate of 57% and disease control rate of 79%. Consequently, *ROS1* rearrangements have entered clinical diagnosis for lung adenocarcinoma patients.¹⁵⁹

Summary and conclusions

The initiation and progression of human neoplasia is a multistep process involving the accumulation of genetic changes in somatic cells. These genetic changes then consist of the activation of cooperating oncogenes and the inactivation of tumor-suppressor genes, both of which appear necessary for a complete neoplastic phenotype. Oncogenes are altered versions of normal cellular genes called proto-oncogenes. Proto-oncogenes are a diverse group of genes involved in the regulation of cell growth. The functions of proto-oncogenes include growth factors, growth factor receptors, signal transducers, transcription factors, and regulators of programmed cell death. Proto-oncogenes may be activated by mutation, chromosomal rearrangement, or gene amplification. Chromosomal rearrangements that include translocations and inversions can activate proto-oncogenes by deregulation of their transcription (e.g., transcriptional activation) or by gene fusion. Tumor-suppressor genes, which also participate in the regulation of normal cell growth, are usually inactivated by point mutations or truncation of their protein sequence coupled with the loss of the normal allele.

The discovery of oncogenes represented a breakthrough for our understanding of the molecular and genetic basis of cancer. Oncogenes have also provided important knowledge concerning the regulation of normal cell proliferation, differentiation, and programmed cell death. The identification of oncogene abnormalities has provided tools for the molecular diagnosis and monitoring of cancer. Most important, oncogenes represent potential targets for new types of cancer therapies. The goal of these new drugs will be to kill cancer cells selectively while sparing normal cells. One promising approach entails using specific oncogene targets to trigger programmed cell death. The first example of the accomplishment of such a goal is represented by the inhibition of the tumor-specific TK bcr/abl in CML, by imatinib. The same compound has been proven active also in a different tumor type, GIST where it inhibits the TK receptor *c-KIT* and in chordomas, where it switches off the PDGFR. Another example is represented by gefitinib and cetuximab, which inhibit the intracellular TK and the extracellular domain, respectively, of ERB B1. Thereafter, a plethora of new targeted drugs has entered clinical trials, with evident benefit for the treatment of several neoplastic disease that were, before targeted therapies development, very hard to be treated and cured. The use of high-throughput technologies for the identification of new oncogenes and the rapidly expanding knowledge of the molecular mechanisms of cancer hold great promise for the development of better combined methods of cancer therapy in the near future.

Chapter 5

Tumor suppressor genes

David Cosgrove, MB, BCh ■ Ben Ho Park, MD, PhD ■ Bert Vogelstein, MD

Overview

Cancer is a genetic disease. Mutations and other alterations in growth promoting genes (oncogenes) and tumor suppressor genes can accumulate during the lifetime of a normal cell resulting in cancer. Unlike oncogenes, tumor suppressor genes generally require biallelic inactivation in order to demonstrate a cancerous phenotype. Importantly, the discovery of heritable tumor suppressor gene mutations that lead to familial forms of cancer has revealed great insight into tumor suppressor function. This has clinical screening implications for individuals with a family history of cancer and has led to newer therapies to target cancer cells with loss of specific tumor suppressors.

A genetic basis for the development of cancer has been hypothesized for over a century, supported by familial, epidemiologic, and cytogenetic studies. However, only in the past 40 years has definitive evidence emerged that cancer is a genetic disease. It is now known that cancers arise through a multistage process in which inherited and somatic mutations of cellular genes lead to repeated waves of clonal selection in which cells with the most robust and aggressive growth properties prevail. Two classes of genes, oncogenes and tumor suppressor genes, are primary targets for the mutations as these genes control the ratio of cell birth and cell death. In all normal tissues of the adult, this ratio is exactly 1.0; mutations increase the ratio. A third class of genes, called genomic stability genes, do not alter the ratio when mutated, but it can indirectly contribute to tumorigenesis through an acceleration of mutations in oncogenes and tumor suppressor genes.

The vast majority of the mutations that contribute to the development and behavior of cancer cells are somatic (i.e., arising during tumor development) and are present only in the neoplastic cells of the individual. A small fraction of mutations in cancer cells are constitutional, present in all somatic cells and can be passed on to progeny, increasing cancer risk in subsequent generations.

The identification and function of oncogenes are reviewed in other chapters of this book. We provide a brief summary of their general properties as a comparison to tumor suppressor genes. In general, oncogenes have critical roles in a variety of growth regulatory pathways, and their protein products are distributed throughout many subcellular compartments. The mutant alleles present in cancers have sustained gain-of-function alterations resulting from point mutations, chromosomal rearrangements, gene amplifications, or other changes to the oncogene sequence. In the overwhelming majority of cancers, mutations in oncogenes arise somatically in the tumor cells, although germline mutations have been described, notably in *RET* (rearranged during transfection) and *MET* (metastasis), leading to familial medullary thyroid cancer and hereditary papillary renal cell carcinoma, respectively.

Although oncogenic alleles harbor activating mutations, tumor suppressor genes are defined by their inactivation in human cancer, and, as with oncogenes, the cellular functions of tumor suppressor genes appear to be diverse.

Defects in genomic stability genes have also been implicated in a broad spectrum of human cancers. Like

tumor suppressor genes, the genomic stability genes are inactivated in human cancers. However, unlike the mutations in tumor suppressor genes, mutations in genomic stability genes are more often inherited in mutant form. For example, inherited mutations in the breast cancer 1 (*BRCA1*) early-onset or breast cancer 2 (*BRCA2*) early-onset genes play a key role in hereditary breast and ovarian cancers, but these genes are rarely mutated somatically in nonfamilial forms of breast cancers.

Enormous progress has been made in the identification of inherited and somatic mutations in oncogenes, tumor suppressor genes, and genomic stability genes in human cancers. The function of these genes has been elucidated, in part, through the analysis of a variety of model systems employing mice, flies, worms, and other organisms, and through the investigation of human cancer cell lines and sequencing of human cancer cells. The principal aims of this chapter are to review the somatic cell genetic and epidemiologic studies that established the existence of tumor suppressor genes; to describe the identification and cloning of representative tumor suppressor genes; to highlight selected studies of the function of tumor suppressor genes in the regulation of cell birth and cell death; and to illustrate an example of a genomic stability gene that plays a causal role in common human cancers.

Genetic basis for tumor development

The inherited basis of human cancer has been appreciated for almost 150 years. In 1866, Broca described a family in which many members developed breast or liver cancer, and he proposed that an inherited abnormality within the affected tissue allowed for tumor development.¹ Following the rediscovery of Mendel's work, studies of the rates of spontaneous mammary tumor formation in various inbred strains of mice led Haaland to argue that tumorigenesis could behave in a formal sense as a Mendelian genetic trait.² Similarly, Warthin's analysis of the pedigrees of cancer patients at the University of Michigan Hospital between 1895 and 1913 identified four multigenerational families with susceptibilities to specific cancer types that appeared to be transmitted as autosomal dominant Mendelian traits ([Figure 1](#)).³ Although these and other studies suggested the existence of an inherited genetic basis for some cancers, other explanations for familial clustering were certainly possible (e.g., shared exposure to a carcinogenic agent in the environment or diet). Furthermore, it was highlighted that most cancers in humans appeared to arise as sporadic, isolated cases.

Figure 1 The inheritance of cancer in a family. The affected members with cancer are indicated by shaded squares (males) or circles (females). This family demonstrates a dominant pattern of inheritance, meaning that each offspring has a 50% chance of inheriting a germline mutation that predisposes to a high probability of developing cancer.

A role for somatic mutations in the development of cancer was first proposed by Boveri,⁴ who noted that, in sea urchin eggs fertilized by two sperms, abnormal mitotic divisions leading to the loss of chromosomes occurred in daughter cells, and atypical tissue masses could be seen in the resulting gastrula. He believed that these abnormal tissues appeared physically similar to the poorly differentiated tissue masses seen in tumors and hypothesized that cancer arose from a cellular aberration producing abnormal mitotic figures. Boveri's hypothesis apparently did not gain favor at the time, initially because of the lack of direct experimental support from studies of the karyotypes of animal and human tumors. Such karyotypes were impossible to obtain with the available technology. Once the karyotypic studies were performed decades later, and appeared to support his hypothesis, Boveri was still doubted because of uncertainty about whether the changes in chromosome number in tumors were a cause or an effect of the neoplastic process.

A landmark observation in the search to identify a genetic basis for cancer was reported by Rous in 1911, when he showed that sarcomas could be reproducibly induced in chickens by cell-free filtrates of a sarcoma that had previously arisen in another chicken.⁵ Although this observation provided strong evidence that neoplasms could be virally induced, the observation also provided support for the view that cancer could be attributed to discrete genetic elements. Sixty years after Rous's initial report, the oncogenic region of the Rous sarcoma virus was identified. Further characterization and cloning of the transforming sequences demonstrated that the oncogenicity of the virus depended on *vsrc*, a transduced and mutated copy of the *csrc* cellular oncogene. Subsequently, all oncogenes of acutely transforming ribonucleic acid (RNA) tumor viruses have been found to be transduced cellular genes. (In fact, they were defined as oncogenes.) The viral oncogenes cause transformation because they are mutated versions of cellular oncogenes or are expressed at abnormally high levels. In human cancers, somatic mutations generate oncogenic alleles from oncogenes.

Oncogenes play a role in most forms of human cancer, but are particularly prominent in “liquid” tumors, such as leukemias and lymphomas, as well as in sarcomas. Such cancers often have characteristic chromosomal translocations that alter oncogenes at the breakpoints, fusing them with unrelated genes and

endowing the fusion product with new properties that increase cell birth or decrease cell death.

Somatic cell genetic studies of tumorigenesis

The studies of Ephrussi et al.⁶ and Harris⁷ provided compelling evidence that the ability of cells to form a tumor behaves as a recessive trait at the cellular level. They observed that the growth of murine tumor cells in syngeneic animals could be suppressed when the malignant cells were fused to nonmalignant cells, although reversion to tumorigenicity often occurred when the hybrids were propagated for extended periods in culture. The reappearance of malignancy was found to be associated with specific chromosome losses. The interpretation of those authors, that malignancy can be suppressed in somatic cell hybrids, was subsequently supported by additional studies on mouse, rat, and hamster intraspecies somatic cell hybrids, as well as by interspecies hybrids between rodent tumor cells and normal human cells.^{8,9} The karyotypic instability of the rodent human hybrids, however, complicated the analysis of the human chromosomes involved in the suppression process. Stanbridge and his colleagues overcame this problem by studying hybrids made by fusing human tumor cell lines to normal, diploid human fibroblasts.^{10,11} Their analysis confirmed that hybrids retaining both sets of parental chromosomes were suppressed, with tumorigenic variants arising only rarely after chromosome losses in the hybrids. Moreover, it was demonstrated that the loss of specific chromosomes, and not simply chromosome loss in general, correlated with the reversion to tumorigenicity. Tumorigenicity could be suppressed even if activated oncogenes, such as mutant *ras* genes, were expressed in the hybrids.^{11,12}

The observation that the loss of specific chromosomes was associated with the reversion to malignancy suggested that a single chromosome (and perhaps even a single gene) might be sufficient to suppress tumorigenicity. To directly test that hypothesis, the technique of microcell-mediated chromosome transfer was used to transfer single chromosomes from normal cells to tumor cells. It was found that the transfer of a single chromosome 11 into the HeLa cervical carcinoma cell line suppressed the tumorigenic phenotype of the cells.¹³ Similarly, transfer of chromosome 11 into a Wilms tumor cell line was found to suppress tumorigenicity, whereas the transfer of several other chromosomes had no effect.¹⁴ Many studies have demonstrated that transfer of even very small chromosome fragments will specifically suppress the tumorigenic properties of certain cancer cell lines.

Although tumorigenic growth in immunocompromised animals can often be suppressed in hybrids resulting from fusion between malignant and normal cells or by transfer of unique chromosome fragments, other traits characteristic of the parental tumor cells, such as immortality and anchorage-independent growth *in vitro*, may be retained. This observation is consistent with the notion that most malignant tumors arise as a result of multiple genetic alterations. Suppression of tumorigenicity following cell fusion or microcell chromosome transfer might thus represent correction of only one of many alterations.

In summary, somatic cell genetic approaches provided early and persuasive evidence for the existence of critical growth-regulating genes in normal cells that can suppress phenotypic traits of immortal or even fully cancerous cells.

Retinoblastoma: a paradigm for tumor suppressor gene function

Essentially concurrent with the initial cell fusion experiments of Harris and colleagues, Knudson's analysis of the age-specific incidence of retinoblastoma led him to propose that two “hits” or mutagenic

events were necessary for retinoblastoma development.¹⁵ Retinoblastoma occurs sporadically in most cases, but, in some families, it displays an autosomal dominant inheritance. In an individual with the inherited form of the disease, Knudson proposed that the first hit is present in the germline, and thus in all cells of the body. However, the presence of a mutation at the susceptibility locus was argued to be insufficient for tumor formation, and a second somatic mutation was hypothesized to be necessary for promoting tumor formation. Given the high likelihood of a somatic mutation occurring in at least one retinal cell during development, the dominant inheritance pattern of retinoblastoma in some families could be explained. In the nonhereditary form of retinoblastoma, both mutations were proposed to arise somatically within the same cell. Although each of the two hits could theoretically have been in different genes, subsequent studies (see later) led to the conclusion that both hits were at the same genetic locus, ultimately inactivating both alleles of the retinoblastoma 1 (*RB1*) susceptibility gene. Knudson's hypothesis served not only to illustrate mechanisms through which inherited and somatic genetic changes might collaborate in tumorigenesis but also to link the notion of recessive genetic determinants for human cancer to somatic cell genetic findings on the recessive nature of tumorigenesis.

The first clue to the location of a putative gene responsible for inherited retinoblastoma was obtained from karyotypic analyses of patients with retinoblastoma. Constitutional deletions of chromosome 13 were observed in some cases.¹⁶ Subsequent cytogenetic studies of patients with retinoblastoma identified detectable germline deletions of chromosome 13 in only about 5% of all patients. However, in cases where deletions were observed, the common region of deletion was centered around chromosome band 13q14.¹⁷ When compared with karyotypically normal family members, patients with deletions of 13q14 were found to have reduced levels of esterase D, an enzyme of unknown physiologic function.¹⁸ This finding implied that the esterase D gene might be contained within chromosome band 13q14. Indeed, analysis of the segregation patterns of esterase D isozymes and retinoblastoma development in families with inherited retinoblastoma established that the esterase D and *RB1* loci were genetically linked.¹⁹

Subsequently, a child with inherited retinoblastoma was found to have esterase D levels approximately one-half of normal, although no deletion of chromosome 13 was seen in karyotype studies of his blood cells and skin fibroblasts.²⁰ Interestingly, tumor cells from this patient had a complete absence of esterase D activity, despite harboring one apparently intact copy of chromosome 13. Based on these findings, it was proposed that the copy of chromosome 13 retained in the tumor cells had a submicroscopic deletion of both the esterase D and *RB1* loci. Moreover, it was concluded that the initial *RB1* mutation in the child was recessive at the cellular level (i.e., cells with inactivation of one *RB1* allele had a normal phenotype). However, the effect of the predisposing mutation could be unmasked in the tumor cells by a second event, such as the loss of the chromosome 13 carrying the wild-type *RB1* allele. This proposal was entirely consistent with Knudson's two-hit hypothesis.^{15, 21}

To establish the generality of these observations, Cavenee and colleagues undertook studies of retinoblastomas, both inherited and sporadic, by using deoxyribonucleic acid (DNA) probes from chromosome 13. Probes detecting DNA polymorphisms were used, so that the two parental copies of chromosome 13 in the cells of the patient's normal and tumor tissues could be distinguished from one another. By using such markers to compare paired normal and tumor samples from each patient, the Cavenee group was able to demonstrate that loss of heterozygosity (LOH—i.e., the loss of one parental set of markers) for chromosome 13 alleles had occurred during tumorigenesis in more than 60% of the cases studied.²² LOH for chromosome 13, and specifically for the region of chromosome 13 containing the *RB1* gene, occurred via a number of different mechanisms ([Figure 2](#)). In addition, through study of inherited cases, it was shown that the copy of chromosome 13 retained in the tumor cells was derived from the affected parent and that the chromosome carrying the wild-type *RB1* allele had been lost.^{22, 23}

These data established that the unmasking of a predisposing mutation at the *RB1* gene, whether the initial mutation had been inherited or had arisen somatically in a single developing retinoblast, occurred by the same chromosomal mechanisms.

Figure 2 Chromosomal mechanisms that result in loss of heterozygosity for alleles at the retinoblastoma predisposition (*RB1*) locus at chromosomal band 13q14. In the inherited form of the disease (*top left*), the affected son inherits a mutant *RB1* allele (*rb*) from his affected father and a normal *RB1* allele (+) from his mother. Thus, he has one wild-type and one mutant *RB1* allele in all his cells (i.e., constitutional genotype for *RB1* is *rb*/+). The two copies of chromosome 13 in his normal cells (one from each parent) can be distinguished using polymorphic DNA markers flanking the *RB1* locus (the polymorphic alleles are designated by number). A retinoblastoma can arise after inactivation of the remaining wild-type *RB1* allele. Among the genetic mechanisms found to inactivate the remaining wild-type *RB1* allele during tumor development are chromosome nondisjunction and reduplication of the remaining copy of chromosome 13, mitotic recombination, nondisjunction, and new *RB* mutations that inactivate the remaining *RB1* allele. Shown at the *top right* is the situation in the noninherited (sporadic) form of the disease. A somatic mutation arises in a developing retinal cell and inactivates one of the *RB1* alleles. A retinoblastoma will develop if the remaining *RB1* allele is inactivated by one of the mechanisms shown.

Patients with the inherited form of retinoblastoma were known to be at an increased risk for the

development of a few other cancer types, particularly osteosarcomas. LOH for the chromosome 13q region containing the *RB1* locus was seen in osteosarcomas arising in patients with the inherited form of retinoblastoma, suggesting that inactivation of both *RB1* alleles was critical to the development of osteosarcomas in those with inherited retinoblastoma.^{24, 25} Chromosome 13q LOH was also frequently observed in sporadic osteosarcomas. These molecular studies of retinoblastomas and osteosarcomas provided strong support for Knudson's two-hit hypothesis and suggested that a variety of tumors might arise through the inactivation of various tumor suppressor loci.^{11, 21, 23} In addition, the studies demonstrated that the inherited and sporadic forms of a specific tumor type both appeared to arise as a result of genetic alterations in the same gene.

Cloning and analysis of the *RB1* gene

The molecular cloning of the *RB1* gene was facilitated by the identification in the chromosome 13q14 region of an anonymous DNA marker that detected DNA rearrangements in retinoblastomas.²⁶ Analysis of the DNA sequences flanking this DNA marker revealed a gene with the properties expected of *RB1*.^{27–29} The *RB1* gene has a complex organization, with 27 exons spanning more than 200 kb of DNA, and an RNA transcript of about 4.7 kb. The *RB1* gene appears to be expressed ubiquitously rather than to be restricted to retinoblasts and osteoblasts.

Cloning of *RB1* allowed study of mutations that inactivate the gene. Although gross deletions of *RB1* sequences are observed in a small subset of retinoblastoma and osteosarcoma cases, most tumors appear to express full-length *RB1* transcripts and lack detectable gene rearrangements when analyzed by Southern blotting.^{30–33} Hence, the detection of inherited and somatic mutations in the *RB1* gene in most cases requires detailed characterization of its sequence. Extensive analysis of mutant *RB1* alleles has provided definitive molecular evidence supporting Knudson's two-hit model. As predicted, patients with inherited retinoblastoma have been found to have one mutated and one normal allele in their constitutional (blood) cells. In retinoblastomas of such individuals, the remaining *RB1* allele has been found to be inactivated by somatic mutation, usually by loss of the normal allele through a gross chromosomal event ([Figure 2](#)), but in some cases by point mutation. Multiple tumors arising in an individual patient with inherited retinoblastoma were all found to contain the same germline mutation, but different somatic mutations affected the remaining *RB1* allele. The vast majority of patients with a single retinoblastoma and no family history of the disease have two somatic mutations in their tumors and two normal alleles in their constitutional cells.

The observation that *RB1* is ubiquitously expressed is rather puzzling, given the restricted spectrum of tumors that develop in patients with germline *RB1* mutations. Patients with germline mutations of *RB1* are at elevated risk only for the development of a rather limited number of tumor types, including retinoblastoma in childhood, osteosarcoma, soft-tissue sarcoma, and melanoma later in life. *RB1* germline mutations fail to predispose to most common cancers, despite the fact that somatic *RB1* mutations have been observed in a wide variety of cancer types, including breast, small cell lung, bladder, pancreas, and prostate cancers.³⁴ It is possible that retinoblastoma protein functions differently in retinal epithelial cells than in other cell types, so that the *RB1* gene acts as a “gatekeeper” in retinal cells but not in other cell types.

Function of retinoblastoma protein P105-RB

The protein product of the *RB1* gene is a nuclear phosphoprotein known as p105-Rb or, more commonly, pRB. Its molecular weight is about 105,000 Da. Studies by Whyte and colleagues provided critical insights into pRB function, connecting human tumorigenesis with experimental tumors caused by DNA

tumor viruses. They demonstrated that pRB formed a complex with the E1A oncoprotein encoded by the murine DNA tumor virus adenovirus type 5.³⁵ Prior studies of E1A had established that it had many effects on cell growth, including cell immortalization and cooperation with other oncogenes (e.g., mutated ras oncogene alleles) in neoplastic transformation. It was thus hypothesized that functional inactivation of pRB through its interaction with E1A might contribute to some of E1A's transforming functions. Additional support for that proposal was provided by data establishing that mutations inactivating the ability of E1A to bind to pRB also inactivated E1A's transforming function.^{36, 37} The significance of physical interaction between pRB and a DNA tumor virus oncoprotein was further supported by the subsequent demonstration that other DNA tumor virus oncoproteins also formed complexes with pRB, including SV40 T antigen and the E7 proteins of human papillomavirus (HPV) types 16 and 18 ([Figure 3](#)).^{38, 39} Many of the mutations that inactivated the transforming activities of these oncoproteins also inactivated their ability to interact with pRB. Furthermore, E7 proteins from “high-risk” HPVs (i.e., those linked to cancer development), such as HPV 16 and 18, formed complexes more tightly with pRB than did E7 proteins of “low-risk” viruses (e.g., HPV types 6 and 11). These studies of pRB provided compelling evidence that DNA tumor viruses might transform cells at least in part by inactivating tumor suppressor gene products. In addition, given the critical dependence of DNA tumor viruses on harnessing the cell's machinery for replication of the viral genome, the studies also provided support for the hypothesis that pRB might control normal cell growth by interacting with cellular proteins that regulate the cell's decision to enter into the DNA synthesis (S) phase of the cell cycle.

Figure 3 Schematic representation of interactions between tumor suppressor gene products and proteins encoded by DNA tumor viruses. Large T antigen from polyomaviruses [such as simian virus 40 (SV40)] bind both the retinoblastoma (pRB) and p53 proteins. For the adenoviruses and the high-risk human papillomaviruses (HPV types 16 and 18), various viral protein products complex with pRB and TP53. A cellular protein known as E6-associated protein (E6-AP) cooperates with the HPV E6 protein to complex and degrade TP53.

The functional activity of pRB is regulated by phosphorylation during normal progression through the cell cycle. Accordingly, pRB appears to be predominantly unphosphorylated or hypophosphorylated in the G1 phase of the cell cycle and maximally phosphorylated in G2 ([Figure 4](#)). The critical phosphorylation events regulating the function of pRB are likely to be mediated at the boundary between the G1 and S

phases of the cell cycle by cyclin and cyclin-dependent kinase (Cdk) protein complexes.^{34, 40} When it is not phosphorylated, pRB forms complexes with proteins in the E2F family and inhibits transcription by recruiting proteins involved in transcriptional repression.⁴⁰ When phosphorylated, pRB can no longer efficiently form complexes with E2Fs ([Figure 4](#)). The E2F proteins, when dimerized with their differentiation-regulated transcription factor partner (DP) proteins, are then capable of activating the expression of a number of genes that are likely to regulate or promote entry into S-phase, including DNA polymerase α , thymidylate synthase, ribonucleotide reductase, cyclin E, and dihydrofolate reductase.⁴⁰ The E2F family members that directly affect cellular proliferation were shown in conditional mouse knockout models.⁴¹ Several other cellular proteins that bind to pRB have been identified, but their functions and the significance of their interactions with pRB remain less-well characterized than the interactions of pRB with E2Fs. Future studies will undoubtedly shed further light on the means by which loss of pRB function and that of pRB homologs p107 and p130⁴² contribute to cancer development.

Figure 4 The function of the retinoblastoma protein (pRB) is regulated during the cell cycle by phosphorylation. The pRB protein is hypophosphorylated in the G1 phase of the cell cycle, and phosphorylation (Ph) of specific sites appears to increase during progression through the cell cycle. A protein complex that appears to phosphorylate pRB before DNA synthesis (S-phase) includes a cyclin (Cyc) and a cyclin-dependent kinase (Cdk)—for example, cyclin D1 and Cdk4. The CycD1/Cdk4 complex is regulated by the p16 inhibitor protein, which is itself the product of a tumor suppressor gene on chromosome 9p, known as *CDKN2* (see text). In its hypophosphorylated state, pRB binds to E2F transcriptional regulatory proteins. When pRB is brought to the promoter regions of genes via its interaction with E2F proteins, pRB represses the expression of the E2F/DP target genes. Phosphorylation of pRB releases it from the E2F/DP protein complex and results in gene activation, including those genes involved in DNA synthesis. The figure also indicates that pRB phosphorylation increases in G2 with pRB dephosphorylated at or near anaphase.

TP53 gene

Studies in the late 1970s revealed that a cellular phosphoprotein with a relative molecular mass of about 53,000 Da formed a tight complex with SV40 T antigen; hence, the name of the p53 protein.^{43–45} Further

work established that TP53 also formed a complex with other viral oncogene products, including the adenovirus E1B protein, and that TP53 was present at low levels in normal cells and high levels in many tumors and tumor cell lines.^{43, 46–48} These initial findings suggested that increased levels of TP53 might contribute to cancer. Consistent with that notion, gene transfer studies provided data demonstrating that *TP53* functioned as an oncogene in *in vitro* experiments.^{47, 49–51} However, subsequent studies in human tumors showed that *TP53* was in reality a tumor suppressor gene.⁵²

The rationale for the human cancer studies was the observation that chromosome 17p LOH was common in a number of tumor types, including colorectal, bladder, breast, and lung cancer.^{53, 54} Detailed mapping showed that region 17p, which was lost in colorectal cancers, included the *TP53* gene.⁵² Analysis of the sequence of the *TP53* alleles retained in those cancers with 17p LOH demonstrated that the remaining *TP53* allele was mutated,⁵² in perfect accord with Knudson's hypothesis for the alterations expected in tumor suppressor genes. These observations were soon extended to other cancer types, and they explained many previous observations concerning TP53 that had been confusing when *TP53* was believed to be an oncogene.^{55–59} Additional evidence that *TP53* functions as a tumor suppressor gene in human cancer is provided by gene transfer studies, but such overexpression studies cannot be easily interpreted, as many genes with no role in neoplasia can inhibit the growth of transfected cells.^{60–63} Based on genome-wide sequencing of multiple tumor types, it is now clear that *TP53* is believed to be the most frequently mutated gene in human cancers in general.⁶⁴

Germline mutations in the *TP53* gene have been seen in those affected by Li–Fraumeni syndrome (LFS) and in a small subset of pediatric patients with sarcomas or osteosarcomas that do not meet the more strict criteria for diagnosis of LFS.^{65–67} Those with LFS are at risk for developing a number of tumors, including soft-tissue sarcoma, osteosarcoma, brain tumors, breast cancer, and leukemia. Between one-half and two-thirds of patients with LFS have germline mutations in the central core domain of the *TP53* coding sequences that resemble the somatic mutations frequently seen in sporadic cancers.⁶⁸ Some LFS patients and families with phenotypic features of LFS have germline mutations in a gene termed *hCHK2* that phosphorylates *TP53* and controls the cell's response to DNA-damaging events.⁶⁹

In addition to somatic and inherited mutations in the gene, *TP53* function can be inactivated by other mechanisms. As noted earlier, most cervical cancers contain high-risk or cancer-associated HPV genomes (i.e., HPV type 16 or 18). The *E6* gene product of high-risk, but not low-risk, HPV types binds to a cellular protein known as E6-AP (for E6-associated protein) and stimulates TP53 degradation.^{70–74} A cellular TP53-binding protein known as mouse double minute 2 (MDM2) is overexpressed in a subset of soft-tissue sarcomas as a result of gene amplification involving chromosome 12q sequences.⁷⁵ More recent studies have identified another TP53-binding protein, MDM4, which is overexpressed in a variety of cancers as a result of gene amplification of chromosome 1q sequences.⁷⁶ DNA transfection studies have shown that both the *MDM2* and *MDM4* genes can function as oncogenes when overexpressed. The oncogenic function is presumably mediated through their binding to and inactivation of TP53. Both proteins mask TP53's transcriptional activation domain and promote TP53's ubiquitination and subsequent degradation by the proteasome.^{77–79} Consistent with the notion that MDM2 is a critical inhibitor of TP53 function, sarcomas with *MDM2* amplification and overexpression rarely harbor somatic mutations in *TP53*.⁸⁰ Disruption of the *MDM2* and *MDM4* genes in the germline of mice is lethal, probably because such disruption allows unregulated activity of *TP53*. Accordingly, disruption of the murine *TP53* gene rescues MDM2-deficient and MDM4-deficient mice from embryonic lethality.^{81, 82} Other mechanisms of regulating TP53 function have also been described, including mutation of a nuclear-cytoplasmic shuttle protein called nucleophosmin in almost 100% of adult acute myelogenous leukemias that demonstrate

cytoplasmic localization of this protein, with the notable exception of acute promyelocytic leukemia.⁸³

TP53 function

The p53 protein has been shown to function as a transcriptional regulatory protein^{84, 85} though other, nontranscriptional functions for p53 have been described (ref. to recent review). In its wild-type state, the p53 protein is capable of binding to specific DNA sequences with its central core domain (Figure 5). The amino terminal sequences of p53 function as a transcriptional activation domain, and the carboxyl terminal sequences appear to be required for TP53 to form dimers and tetramers with itself. TP53 activates transcription of a number of genes with roles in the control of the cell cycle, including *WAF1/CIP1/p21* (which encodes a regulator of Cdk activity),⁸⁶ *MDM2* (as noted earlier, encoding a protein that is a known negative regulator of *TP53*), and 14-3-3 (a regulator of G2/M progression),⁸⁷ and various genes that likely function in apoptosis, including *PUMA* and *NOXA*. Experimental disruption of these genes by targeted homologous recombination can re-create some of the phenotypes associated with *TP53* inactivation.^{88, 89}

Figure 5 TP53 functional motifs. Sequences of TP53 involved in transcriptional activation, sequence-specific DNA binding, tetramerization, and binding by the MDM2 protein are indicated. The five distinct regions of TP53 sequence that are highly conserved between p53 proteins of diverse species are indicated. In addition, the locations of several sites in the protein that are phosphorylated (Ph) and that regulate TP53 function are indicated.

The vast majority of the somatic mutations in TP53 are missense mutations leading to amino acid substitutions in the central portion of the protein (exons 5–9).⁹⁰ Consistent with the structure of the p53

protein, these missense mutations have marked effects on the p53 protein's ability to bind to its cognate DNA recognition sequence through either of two mechanisms.⁹¹ Some mutations (e.g., mutations at codons 248 or 273) alter *TP53* sequences that are directly responsible for sequence-specific DNA binding. Other mutations (e.g., codon 175) appear to affect the folding of *TP53* and thus indirectly affect its ability to bind to DNA. Evidence that these missense mutations can confer “gain of function” rather than a dominant negative effect was demonstrated via “knock in” mouse models, whereby precise missense mutations were introduced into the endogenous *TP53* gene.^{92–96}

Under some circumstances, TP53 acts at the G1/S checkpoint to regulate the cell's decision to synthesize DNA, although TP53 also appears to have a critical function at G2/M.^{97, 98} In other settings, TP53 appears to exert control over the cell's decision to undergo apoptosis or programmed cell death.⁸⁵ Of particular interest with regard to cancer treatment are data suggesting that some tumor cells lacking TP53 function are less sensitive to irradiation and chemotherapeutic agents such as cisplatin.^{92, 99, 100} However, studies of other tumor cells suggest that *TP53* status shows a very different relationship to chemotherapeutic response, with cells that lack functional TP53 being markedly sensitive to DNA-damaging agents but resistant to 5-fluorouracil.¹⁰¹ Thus far, studies of primary human cancers have emphasized that a rather complex relationship is likely to exist between *TP53* mutational status and the responsiveness of cancer cells to chemotherapy or radiation therapy, or both. In particular, it is difficult to distinguish the effects of *TP53* mutation on the natural progression of disease from its effects on responses to treatment and other cellular stresses.^{102, 103} Hopefully, further research on *TP53* will clarify our understanding of its normal functions, the basis for its frequent inactivation in many different cancers, and the consequences of its inactivation on tumor growth and response to therapy.

Cyclin-dependent kinase inhibitor 2A locus

Studies of the cyclin-dependent kinase inhibitor 2A (*CDKN2A*) locus on chromosome 9p illustrate well how observations from initially disparate lines of investigation often converge to implicate a particular locus as a critical factor in cancer development. The LOH of chromosome 9p was frequently found in many different tumor types, including melanoma, glioma, nonsmall cell lung, bladder, head and neck cancers, and leukemia.^{104–107} Of considerable interest were observations establishing that a subset of such tumors had homozygous (complete) deletions affecting the 9p21 region,^{108–110} strongly supporting the existence of a tumor suppressor gene in the region. In addition to the frequent somatic alterations of chromosome 9p sequences in cancers, linkage studies of some families with inherited melanoma indicated a melanoma predisposition gene mapped to essentially the same region of 9p.¹¹¹ These observations stimulated great interest in the chromosome 9p region presumed to contain the tumor suppressor gene or genes. One of the genes identified in the region as a result of positional cloning efforts was initially termed multiple tumor suppressor 1 (*MTS1*).¹¹² Sequence analysis of *MTS1* showed that it was identical to a previously described gene that encoded the Cdk inhibitor protein known as p16.¹¹³ Because the p16 protein functioned by inhibiting Cdk4 and Cdk6, it was termed an inhibitor of cyclin-dependent kinase 4 (*INK4*) protein. Another highly related gene, mapping immediately next to the *p16/MTS1* gene on chromosome 9p, was found to encode a second *INK4* protein, known as p15 ([Figure 6](#)). The gene encoding the p16 protein is most often termed *INK4A*, and the gene for p15 is *INK4B*.^{114, 115} The approved symbols are *CDKN2A* and *CDKN2B*, respectively.

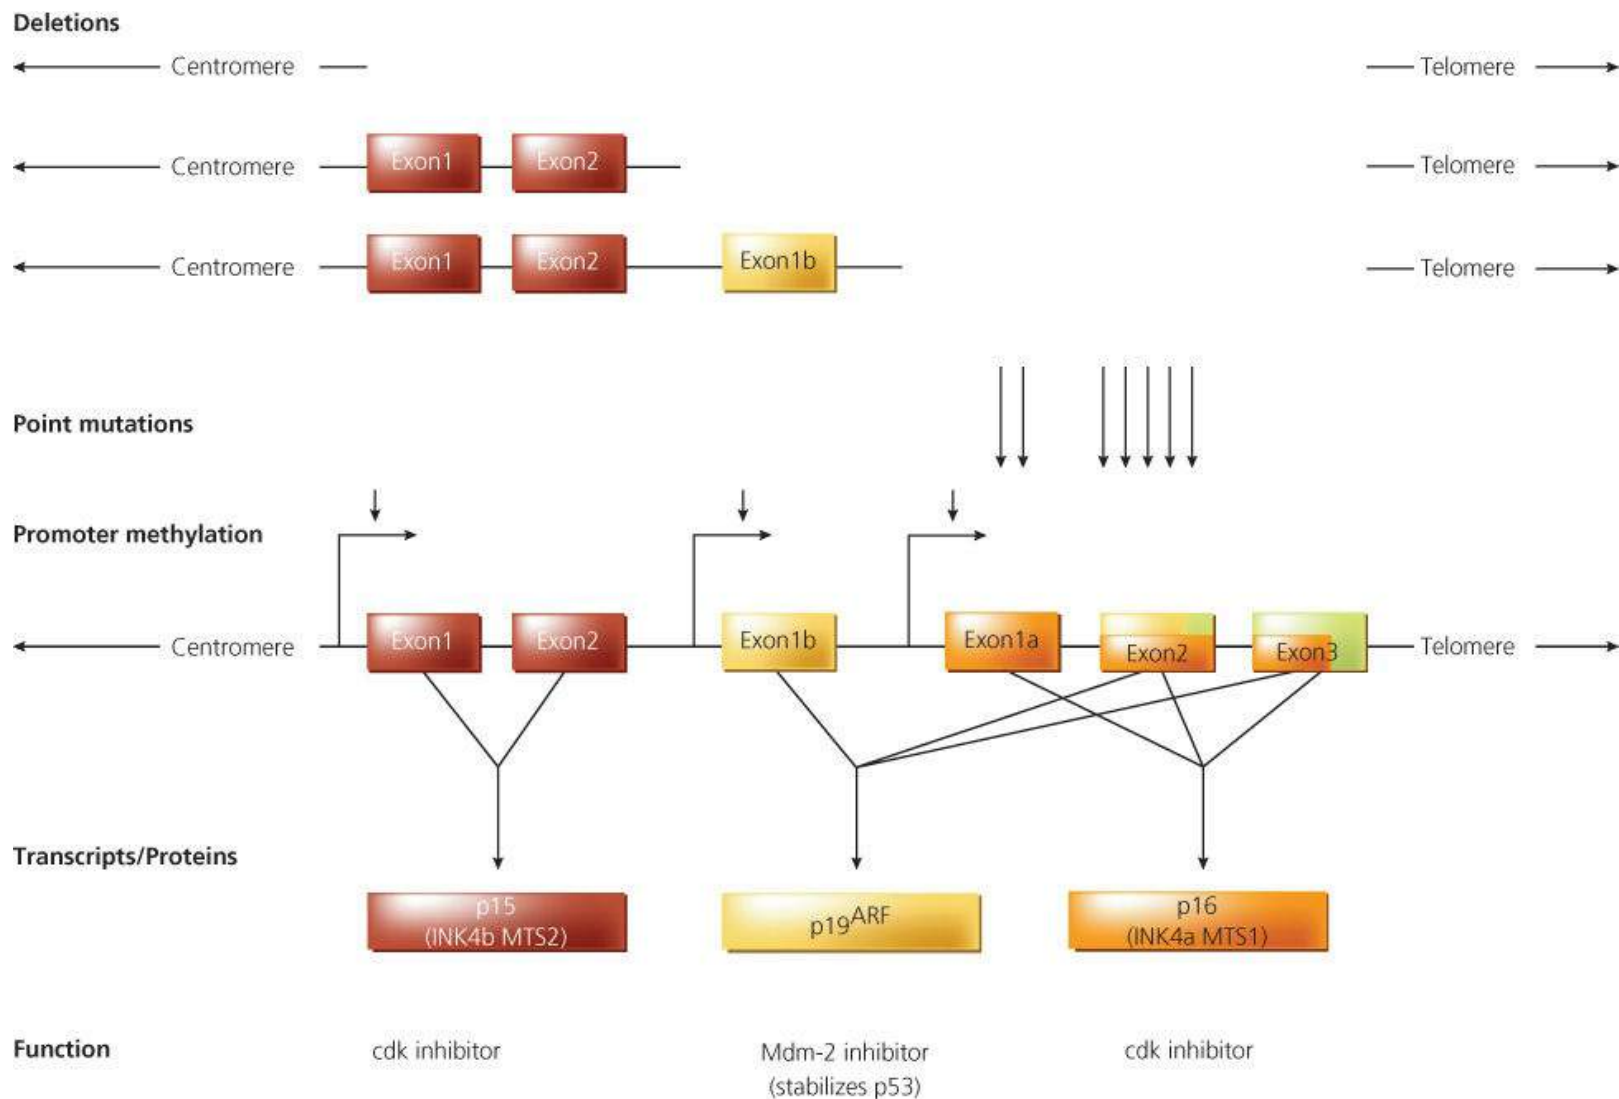

Figure 6 Genomic structure, mutations, and transcripts of the *CDKN2B* (p15) and *CDKN2A* (p16/p19^{ARF}) locus. The origins of the p15, p16, and p19^{ARF} transcripts are shown schematically, along with a representative depiction of genomic deletions, point mutations (*arrows*), and promoter methylation (*arrowheads*) noted in human cancers. The exons of the *CDKN2B* and *CDKN2A* loci are shown as *rectangles*. The transcripts/proteins and presumed functions of the transcripts/proteins are indicated. The *red rectangles* indicate the open reading frame in transcripts encoding p15; the *yellow rectangles* indicate the open reading frame present in transcripts encoding p19^{ARF}; and the *lavender rectangles* indicate the open reading frame present in transcripts encoding p16. The size of the locus, exons, and transcripts are not shown to scale.

Subsequent studies show that heterozygous mutations in *CDKN2A* are present in some families with inherited predispositions to melanoma or pancreatic cancer.^{116–119} Somatic mutations in *CDKN2A* are present in many different cancer types, including but not limited to melanoma, glioma, pancreatic and bladder cancers, and leukemia. In some tumors, deletions affecting the *CDKN2A* gene also involve the *CDKN2B* gene. In rare tumors, deletions inactivate *CDKN2B* but not *CDKN2A*.¹²⁰ The prevalence and specific nature of *CDKN2A* mutations vary markedly from one tumor type to another. In contrast to other tumor suppressor genes, such as *RB1* and *TP53*, homozygous deletion is a fairly common mechanism of *CDKN2A* inactivation in cancer.¹²¹

Detailed studies of the *CDKN2A* locus led to the identification of a novel alternative transcript containing nucleotide sequences identical to those in transcripts for the p16^{INK4A} protein, but with unique 5' sequences ([Figure 6](#)).^{114, 115, 122} The alternative *CDKN2A* locus transcript encodes a protein known as

p14 alternative reading frame (p14^{ARF}). Of note, human p14^{ARF} is the same product as the originally identified mouse protein p19^{ARF}, which was designated as p19 due to its apparent weight.

The p14^{ARF} protein contains sequences from a distinct first exon (exon 1 β). Exon 1 β is located upstream of exon 1 α , the first exon present in transcripts for p16 ([Figure 6](#)). Exon 1 β is spliced to exon 2, which, along with exon 3, is present in the transcripts for both the p14^{ARF} and p16^{INK4A} proteins. However, the p14^{ARF} protein shares no sequence similarity with the p16^{INK4A} protein because p14^{ARF} synthesis initiates at a unique methionine codon in exon 1 β and continues through exon 2, using an alternative open reading frame with no similarity to the p16^{INK4A} open reading frame. Careful studies of somatic and inherited mutations at the *CDKN2A* locus indicate that localized mutations inactivating the p16^{INK4A} protein are common in human cancer, with more than 60 germline mutations identified, but that localized mutations inactivating p14^{ARF} are uncommon.^{114, 115} However, the frequent occurrence of homozygous deletions at the *CDKN2A* locus implies that mutational inactivation of both proteins—and of p15^{INK4B}—may be strongly selected for during tumor development ([Figure 6](#)). Other findings suggest that p16^{INK4A} and p14^{ARF} expression may be lost in some tumor types as a result of methylation of DNA regulatory sequences at the *CDKN2A* locus ([Figure 6](#)).^{123–125} Recent studies have demonstrated the importance of DNA methyltransferases in initiating and maintaining epigenetic silencing of the p16 tumor suppressor.^{126, 127} Furthermore, studies of mice with germline inactivation of p14^{ARF} and p16^{INK4A} indicate that these proteins function as tumor suppressor genes *in vivo*.^{128–130}

The mechanism through which the p16^{INK4A} protein controls tumorigenic growth is apparently through its inhibition of Cdk4 activity. As indicated earlier, phosphorylation of pRB impedes its ability to transcriptionally regulate E2F-target genes ([Figure 4](#)). The cyclin D1/Cdk4 complex has a critical role in regulating pRB phosphorylation and function.¹²⁴ Hence, the p16^{INK4A} protein, by virtue of its regulation of Cdk4 activity, is, in turn, a critical factor in regulating pRB phosphorylation. Presumably, inactivation of p16^{INK4A} results in inappropriate phosphorylation of pRB and a subsequent inability of hyperphosphorylated pRB to bind E2Fs and appropriately regulate gene expression at the G1–S transition. p14^{ARF} functions as a tumor suppressor by direct binding to the MDM2 protein, inhibiting the MDM2-induced degradation of TP53, thus maintaining appropriate function of TP53 in cells,¹¹⁵ much like p16^{INK4A} maintains normal pRB function.

Contrary to this interpretation, however, is the fact that alterations of p14^{ARF} and TP53 often coexist in cancer cells, suggesting that they do not alter the same pathway, whereas Rb and p16^{INK4A} alterations are mutually exclusive, supportive of the fact that they affect the same pathway.¹³¹ Nevertheless, these findings emphasize the concept that oncogenes and tumor suppressor genes do not function in isolation. Rather, they function in intricately linked cascades or networks that have important consequences for both tumorigenesis and therapy ([Figure 7](#)).^{85, 132}

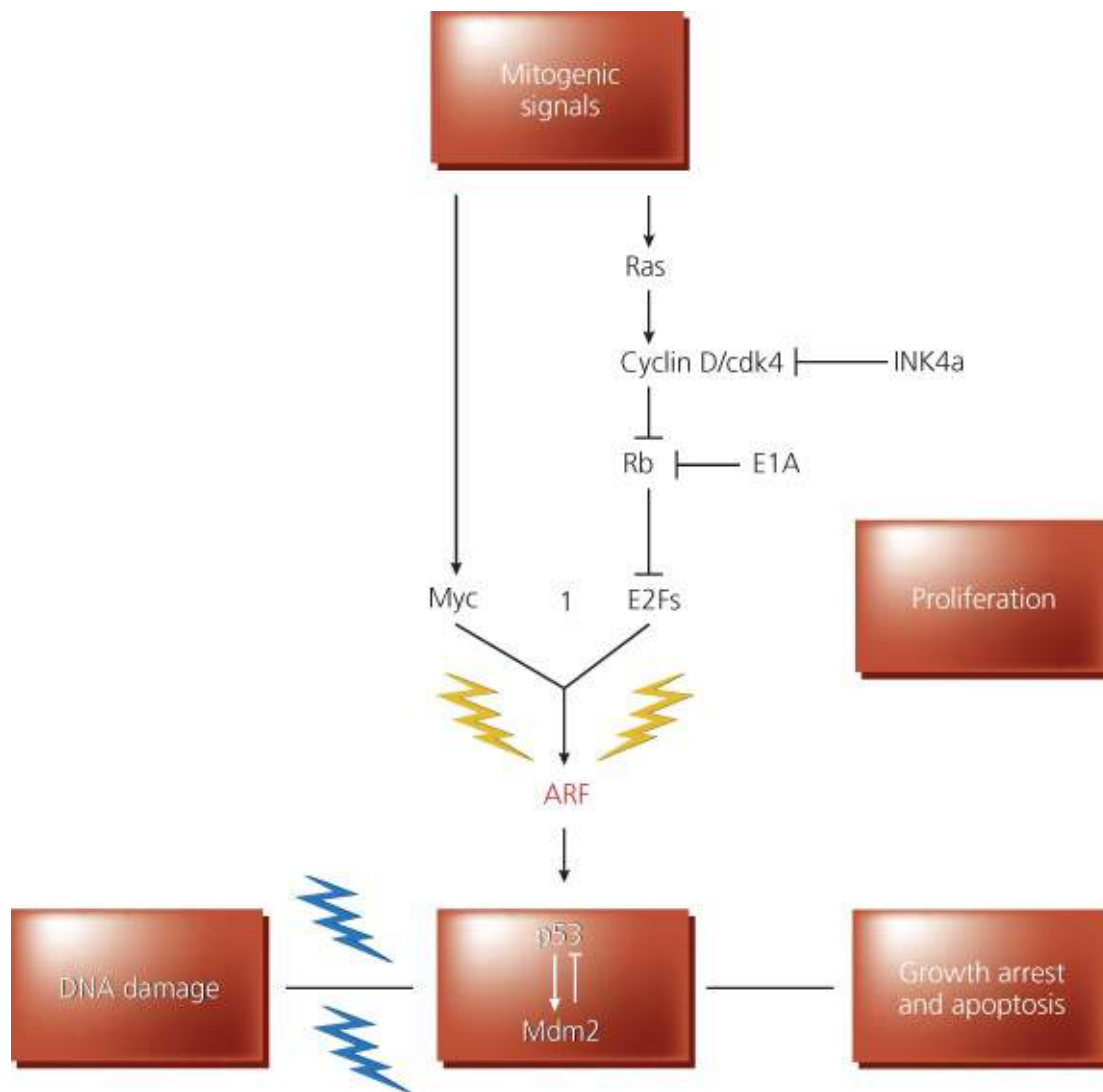

Figure 7 Role of the p19^{ARF} protein in checkpoint control. The p19^{ARF} protein (ARF) responds to proliferative signals normally required for cell proliferation. When these signals exceed a critical threshold, the ARF-dependent checkpoint (*yellow lightning bolts*) is activated, and ARF triggers a TP53-dependent response that induces growth arrest or apoptosis, or both. Signals now known to induce signaling via the ARF-TP53 pathway include Myc, E1A, and E2F-1. In principle, “upstream” oncoproteins, such as products of mutated *ras* alleles, constitutively activated receptors, or cytoplasmic signal transducing oncoproteins, might also trigger ARF activity via the cyclin D-Cdk4-RBE2F or Myc-dependent pathways, both of which are normally necessary for S-phase entry. In inhibiting cyclin D-dependent kinases, p16^{INK4A} can dampen the activity of mitogenic signals. In the figure, E1A is shown to work, at least in part, by opposing RB function. For simplicity, Myc and E2F-1 are shown to activate only TP53 via the effects on ARF, though highly overexpressed levels of these proteins can activate TP53 in ARF-negative cells, albeit with an attenuated efficiency. ARF activation of TP53 likely depends on inactivation of Mdm2-specific function(s). DNA damage signals (e.g., ionizing and ultraviolet radiation, hypoxic stress) activate (*blue lightning bolts*) TP53 through multiple signaling pathways.

Adenomatous polyposis coli gene

Identification and germline mutations

Colon cancers arising in a minority of hereditary syndromes do so from a state of polyposis. One of the polyposis syndromes is known as familial adenomatous polyposis (FAP) or adenomatous polyposis coli (APC). FAP is an autosomal dominant disorder affecting about 1 in 8000 individuals in the United States.

The syndrome is characterized by the development of hundreds of adenomatous polyps in the colon and rectum of affected individuals by early adulthood. The lifetime risk of colorectal cancer in those with the classic form of FAP is extremely high, approaching 100% by age 60 years.

An interstitial deletion of chromosome 5q in a patient with features of FAP, but without any family history of the syndrome, greatly aided localization of the *APC* gene.¹³³ Subsequent DNA linkage studies confirmed that, in multiple kindreds with FAP, or the related condition known as Gardner syndrome, the polyposis phenotype segregated with DNA markers near 5q21.^{134, 135} In 1991, positional cloning efforts identified the *APC* gene as the specific gene responsible for FAP.^{136–139} The *APC* gene is large, with more than 15 exons, and alternative splicing affects the 5' untranslated portion of transcripts. The predominant *APC* transcript encodes a 2843-amino acid protein expressed in many adult tissues.

In the great majority of individuals with FAP, heterozygous germline mutations can be identified in the *APC* gene.^{140–142} All of the germline *APC* mutations in those with FAP appear to inactivate APC protein function. The overwhelming majority of these germline mutations are localized nonsense or frameshift mutations in the 5' half of the coding region of *APC* ([Figure 8](#)). Consistent with Knudson's two-hit hypothesis, inactivation of the remaining wild-type APC allele by somatic mutation in those carrying a germline *APC* mutation is observed in the cancers that arise.^{143, 144} Correlations between the location of a particular germline *APC* mutation and clinical features have been found,¹⁴⁵ although clear insights into the molecular basis for the predisposition to extracolonic tumors (e.g., jaw osteomas and desmoid tumors) in FAP patients with variant phenotypes are lacking. However, some light has been shed on the variability in polyp number seen in families with polyposis.^{143, 146} Mutations in the 5' region of the *APC* gene appear to be correlated with an attenuated phenotype attributable to reentry of the ribosome on the APC transcript downstream of the premature stop codon, resulting in an APC protein that retains some of its normal activity.¹⁴⁶ Mutations in 3' third of the *APC* gene are also associated with a milder polyposis phenotype than mutations in the central third of the gene, perhaps because the mutated APC proteins similarly retain some tumor suppressor activity. Unexpectedly, extracolonic features such as desmoid tumors appear to be more common in patients with 3' mutations.¹⁴³ Finally, a missense mutation in the middle of the *APC* gene has been found to predispose to colorectal cancers in Ashkenazi Jewish families.¹⁴⁷ This mutation does not alter the function of the gene product, but creates a “hot spot” that appears to be highly mutable, resulting in somatic deletions or insertions of surrounding nucleotides that produce truncations.

Figure 8 Schematic representation of Apc protein domains with respect to mutational analysis results. The relative positions of various Apc domains. A putative domain involved in homo-oligomerization of Apc is located at the amino-terminus. Also noted are a series of repeats of unknown function with similarity to the *Drosophila* armadillo protein, sequences known to mediate binding to p-catenin and its downregulation, a basic domain in the carboxy-terminal third of the protein that appears to facilitate complexing with microtubules (MT), and sequences near the carboxy terminus of Apc that are known to interact with the EB1 and human homolog of the *Drosophila* disc large (hDlg) protein. Germline mutations in the *APC* gene (predominantly chain terminating) are dispersed throughout the 5' half of the sequence, with two apparent "hot spots" at codons 1061 and 1309. Somatic mutations in the *APC* gene in colorectal cancer appear to cluster in a region termed the "mutation cluster region," and mutations at codons 1309 and 1450 are most common.

Somatic mutations in sporadic colon tumors

Although germline *APC* mutations are an uncommon cause of colorectal cancer in the general population and are present in only about 0.5% of all colon cancers, somatic *APC* mutations are present in the vast majority of sporadic colorectal adenomas and carcinomas.¹⁴⁸ The initial observation suggesting that *APC* inactivation might be common in colon tumors was the observation that the chromosome 5q region containing the *APC* gene was affected by LOH in many sporadic colorectal adenomas and carcinomas.^{54, 149} Since the identification of the *APC* gene, detailed analyses of the somatic mutations inactivating the *APC* gene in colorectal tumors have been carried out. The somatic *APC* mutations in sporadic tumors are similar in nature and location to the germline *APC* mutations found in those with FAP (Figure 8). Present findings suggest that up to 90% of colorectal tumors, regardless of their size or particular histopathologic

features, harbor somatic mutations that inactivate APC.^{143–150}

Function

The *APC* gene encodes a large protein of roughly 300 kDa that is hypothesized to regulate cell adhesion, cell migration, or apoptosis in the colonic crypt. The localization of the APC protein in the basolateral membrane of colonic epithelial cells, with an apparent increase in APC expression in cells near the top of the crypt, implies that APC may regulate shedding or apoptosis of cells as they reach the crypt apex.¹⁵¹ Perhaps consistent with this view, restoration of APC protein expression in colorectal cancer cells lacking endogenous APC expression has been reported to promote apoptosis.^{152, 153}

The APC protein binds to a number of proteins, including β -catenin, Y-catenin (also known as plakoglobin), glycogen synthase kinase 3β (GSK3 β), end-binding protein 1 (EB1), human Drosophila large discs (hDLG), microtubules, and the related proteins axin and conductin.¹⁵⁴ With the exception of β -catenin, GSK3 β , and the conductin and axin proteins, the significance and role of APC's interactions with its various binding partners are not well understood. Several lines of evidence imply that APC has a critical function in regulating β -catenin.^{154, 155} β -Catenin is an abundant cellular protein, first identified because of its role in linking the cytoplasmic domain of the E-cadherin cell–cell adhesion molecule to the cortical actin cytoskeleton, via β -catenin's binding to α -catenin. The truncated (mutant) APC proteins present in many colorectal cancers lack some or all of the repeat motifs crucial for binding to β -catenin. APC not only binds to β -catenin, but, in collaboration with the GSK3 β enzyme and other proteins, such as axin and conductin, it appears to regulate the abundance of β -catenin in the cytosol via phosphorylation. In colorectal cancers in which *APC* is mutated and unable to bind or effectively coordinate the regulation of β -catenin, β -catenin accumulates in the cell, complexes with the transcription factor T-cell factor-4 (Tcf-4), and translocates to the nucleus ([Figure 9](#)). Once there, β -catenin functions as a transcriptional coactivator, activating expression of Tcf-4-regulated genes, typically bypassing regulatory proteins, such as Wnt. Consistent with the notion that β -catenin is a critical target of *APC* regulation, somatic mutations in β -catenin have been found in the small fraction of colorectal cancers lacking *APC* mutations.^{156–158} These mutations consistently alter GSK3 β phosphorylation consensus sites near the amino terminus of the β -catenin protein, and the mutations presumably render the defective β -catenin proteins oncogenic as a result of their resistance to degradation by APC and GSK3 β . Although somatic mutations in *APC* appear to be rare in cancers arising outside the colon and rectum, oncogenic mutations in β -catenin's *N*-terminus have been observed in many different cancer types.^{159, 160}

Figure 9 A model indicating the function of the Apc, axin, and Gsk3p proteins in the regulation of p-catenin (p-cat) in normal cells, and the consequence of Apc or p-cat defects in cancer cells. p-Cat is an abundant cellular protein, and much of it is often bound to the cytoplasmic domain of the E-cadherin (E-cad) cell–cell adhesion protein. (a) In normal cells, the proteins glycogen synthase kinase 3p (Gsk3p), Apc, and axin function to promote degradation of free cytosolic p-cat, probably as a result of phosphorylation of the N-terminal sequences of p-cat by Gsk3p. Gsk3p activity and p-cat degradation are inhibited by activation of the wingless (Wnt) pathway, as a result of the action of the Frizzled receptor and disheveled (Dsh) signaling protein. (b) Mutation of Apc in colorectal and other cancer cells results in accumulation of p-cat, binding to Tcf-4, and transcriptional activation of Tcf-4 target genes, such as *c-myc*, cyclin D1, *MMP-7*, and *PPARδ* (see text). (c) Point mutations and small deletions in p-cat in cancer cells inhibit phosphorylation and degradation of p-cat by Gsk3p and Apc, with resultant activation of *c-myc* and other Tcf-4 target genes.

Wilms tumor gene

Wilms tumors are the most common renal neoplasm in children, accounting for approximately 6% of all pediatric cancers.¹⁶¹ Wilms tumors are similar to retinoblastomas in a number of ways: both can occur bilaterally or unilaterally, with single or multiple foci, and in a sporadic or inherited fashion. The two mutation model originally proposed for retinoblastoma was also proposed to explain Wilms tumor.¹⁶² However, hereditary cases are not as common among Wilms tumor patients as they are in retinoblastoma patients. Almost all patients inheriting a mutation at the *RB1* locus develop a retinoblastoma, but only approximately 50% of individuals carrying a germline mutation predisposing to Wilms tumor develop the disease (i.e., lower penetrance).¹⁶¹

Perhaps the first finding to offer insight into an inherited genetic basis for Wilms tumor was a report describing six patients with Wilms tumor and sporadic aniridia (i.e., congenital absence of the iris).¹⁶³ It was proposed that the simultaneous occurrence of these two very rare conditions might result from chromosomal aberrations affecting two or more loci, a situation now often called a contiguous gene syndrome—mutation of one locus presumably leading to aniridia and mutation of another leading to Wilms tumor. This hypothesis was subsequently supported by the discovery of interstitial deletions of chromosome 11p13 in peripheral blood samples from children with the WAGR syndrome (Wilms tumor

with aniridia, genitourinary abnormalities, and mental retardation) of Wilms tumor.¹⁶⁴ Cytogenetic studies of tumor tissues in a few cases of sporadic-type Wilms tumors revealed deletions or translocations of chromosome band 11p13.^{165, 166} Subsequent studies of paired samples of Wilms tumor and normal cells from patients, using probes that detect restriction fragment length polymorphisms (RFLPs) on chromosome 11p, revealed that LOH of 11p occurred frequently in Wilms tumors of both the inherited and sporadic types.^{167–170}

The Wilms tumor 1 (*WT1*) gene was identified in 1990 by virtue of mutations inactivating the gene in patients with the WAGR syndrome and by analysis of somatic mutations in the gene in tumors from a minority of patients with unilateral Wilms tumor and no associated congenital malformation.¹⁷¹ *WT1* is encoded by 10 exons and its transcripts are subject to alternative splicing.^{172, 173} In contrast to the rather ubiquitous expression of the *RB1*, *TP53*, and *APC* genes, expression of the *WT1* gene appears to be restricted to embryonic kidney and a small subset of other tissues.^{174, 175} *WT1* messenger ribonucleic acids (mRNAs) encode proteins with molecular masses of 45,000–49,000 Da and 4 zinc-finger motifs. Based on their predicted amino acid sequences, the *WT1* proteins were suspected from the outset to function in transcriptional regulation.¹⁷⁴ Several studies provide evidence to support that notion, although some *WT1* isoforms may have a role in RNA processing, rather than in transcription regulation.^{173, 174} *WT1* proteins suppress the transcriptional activity of promoter elements from a number of growth-inducing genes, including the genes for early growth response (*EGR1*), insulin-like growth factor-2 (*IGF-2*), and platelet-derived growth factor A (*PDGFA*) chain, suggesting that *WT1* may function in gene repression.¹⁷⁶ Other studies suggest that *WT1* can activate or repress gene expression, depending on the cell type and promoter context.¹⁷⁷ Consistent with the notion that *WT1* may have a physiologic function in transcriptional activation, recent work indicates that *WT1* activates expression of amphiregulin, a member of the epidermal growth factor family.¹⁷⁸ Loss of amphiregulin expression may contribute to loss of appropriate differentiation during Wilms tumor development. Adding to the complex nature of *WT1*'s role as a transcriptional regulator, recent studies suggest that certain *WT1* splice variants have dramatically different effects in their ability to regulate gene expression,^{179, 180} including acting as an oncogene in a variety of adult cancers.

WT1 inactivation clearly contributes to Wilms tumor development in those with the WAGR syndrome. Moreover, approximately 10% of apparently sporadic Wilms tumors harbor detectable somatic mutations in the *WT1* gene.¹⁸¹ Nevertheless, much evidence indicates that Wilms tumors arise through mutations in genes other than *WT1*. First, the chromosome 11p allelic losses seen in Wilms tumor frequently involve band 11p15, but not band 11p13, where the *WT1* gene resides.^{181–183} Second, the 11p15 region harbors a gene responsible for Beckwith–Wiedemann syndrome (BWS), a congenital disorder in which affected individuals manifest hyperplasia of the kidneys, endocrine pancreas, and other internal organs; macroglossia; and hemihypertrophy.^{184, 185}

Those affected by BWS are also at increased risk of developing embryonic tumors, such as hepatoblastoma and Wilms tumor. Finally, linkage studies of three families with dominant inheritance of Wilms tumor exclude linkage of the susceptibility locus in those families to any part of chromosome 11p.^{186, 187} These data and others suggest that germline mutations in any one of at least three different genes (i.e., *WT1*, the BWS gene, and at least one gene not on chromosome 11p reference to haber's paper on X-chromosome gene) predispose to Wilms tumor. Whether a combination of inherited and somatic mutations in more than one of those genes is ultimately required for the transformation of a developing kidney cell into a Wilms tumor, or whether alternative genetic pathways for the development of Wilms tumors exist, remains to be established. The genetic heterogeneity observed among Wilms tumors

provides an important contrast to the apparently less complex genetic pathway of retinoblastoma.

Neurofibromatosis 1 and 2 genes

Neurofibromatosis 1 gene

Von Recklinghausen's disease, also called neurofibromatosis 1 (NF1), is a dominantly inherited syndrome with variable disease manifestations. The consistent feature is that tissues derived from the neural crest are commonly affected. In addition to the nearly uniform development of neurofibromas, NF1 patients are at elevated risk for developing pheochromocytomas, schwannomas, neurofibrosarcomas, and primary brain tumors.^{188–190} The *NF1* gene was initially localized to the pericentromeric region of chromosome 17q by linkage analyses.^{191, 192} Subsequently, karyotype studies of two NF1 patients identified germline chromosomal rearrangements involving band 17q11.^{193, 194} In further work, both patients were found to have genetic alterations of a localized region of band 17q11. Intensive positional cloning efforts in this chromosome region led to the identification of the *NF1* gene in 1991.^{195–197} The *NF1* gene is large, spanning roughly 350 kb of DNA, and it encodes a protein product with a molecular mass of about 300 kDa.^{188, 190, 198} Although germline mutations in the *NF1* gene are believed to underlie the development of the associated disease features in all or nearly all NF1 patients, specific germline *NF1* mutations have been identified in approximately one-half to two-thirds of NF1 patients.^{188, 190, 198, 199} Difficulties in identifying germline mutations in the *NF1* gene in the remaining NF1 patients may be a result of the inherent inefficiencies and insensitivity associated with mutation detection strategies in such a large gene, and over 1500 distinct mutations have thus far been described.

In addition to germline *NF1* mutations in those patients with NF1, the *NF1* gene is affected by somatic mutations in a fraction of colon cancers, melanomas, neuroblastomas, and bone marrow cells from patients with the myelodysplastic syndrome.^{188, 198, 200–202} Consistent with its presumed tumor suppressor role, the mutations inactivate *NF1*. Studies of leukemias arising in pediatric neurofibromatosis patients provide the clearest evidence that both copies of the *NF1* gene are inactivated during tumorigenesis,²⁰³ as predicted by the Knudson model. Like the *RB1*, *TP53*, and *APC* genes, the *NF1* gene is expressed ubiquitously. Thus, as for other inherited cancer syndromes, the basis for the tissue specificity of the malignant tumors observed in neurofibromatosis patients is puzzling. The NF1 protein product, termed neurofibromin, is a member of the guanosine triphosphate (GTPase)-activating protein family.^{188, 204–206} Perhaps the best studied GAP is Ras-GAP, which markedly enhances the GTPase activity of the wild-type K-Ras, H-Ras, and N-Ras proteins. Although the means through which *NF1* defects alter cell growth is not fully described, it is currently postulated that inactivation of neurofibromin function leads to alterations in signaling pathways regulated by small Ras-like GTPase proteins.²⁰⁷

Neurofibromatosis 2 gene

Neurofibromatosis 2 (NF2—also known as central neurofibromatosis) is an autosomal dominant disorder that is distinct from NF1 in both genetic and clinical features.^{188, 208, 209}

A hallmark of NF2 is the occurrence of bilateral schwannomas that affect the vestibular branch of the eighth cranial nerve (acoustic neuromas). NF2 patients are also at elevated risk for meningiomas, spinal schwannomas, and ependymomas. The neurofibromatosis 2 (*NF2*) gene was mapped to chromosome 22q by a combination of linkage analyses and LOH studies^{210–212} and was cloned in 1993 using positional cloning approaches.^{213, 214} Germline mutations inactivating the *NF2* gene were observed in those patients with NF2, and somatic *NF2* mutations were also observed in a subset of sporadic schwannomas and

meningiomas. Somatic *NF2* mutations in most other tumor types appear to be infrequent. However, preliminary studies indicate that the *NF2* gene may be frequently affected by somatic mutations in malignant mesotheliomas^{215, 216} despite this tumor type not being seen at increased frequency in patients with *NF2*.²⁰⁹ The *NF2* gene encodes a protein, Merlin, with a high sequence homology to a cytoskeletal protein family [ERM (Ezrin/Radixin/Moesin)], which acts as linker proteins between integral membrane proteins and scaffolding proteins of the filamentous submembrane lattice.²¹⁴ Consequently, *NF2* gene alterations might contribute to tumor development, at least in part, by effects on cell shape, cell–cell interactions, or cell movement (or a combination).

von Hippel–Lindau gene

von Hippel–Lindau (VHL) syndrome is a rare dominant disorder predisposing affected individuals to the development of hemangioblastomas of the central nervous system and retina, renal carcinomas of clear cell type, and pheochromocytomas.^{217–219} The *VHL* gene was mapped to chromosome 3p by linkage analysis. As with many other inherited cancer genes, LOH studies established that the *VHL* gene behaves as a typical tumor suppressor gene, with both alleles inactivated during tumorigenesis.^{218, 220} Positional cloning efforts identified the *VHL* gene in 1993.²²¹ Germline mutations inactivating one *VHL* allele are seen in the majority of individuals in families displaying features of the VHL syndrome.^{217–219} As with some other inherited cancer syndromes, preliminary genotype–phenotype relationships have been observed. Specifically, a certain class of *VHL* germline mutations is associated with the development of renal cancer only, a second class is linked to predisposition to both renal cancer and pheochromocytoma, and yet a third mutation class is associated only with pheochromocytoma.²¹⁸ Somatic mutations in the *VHL* gene are also seen in more than 80% of sporadic renal cell carcinomas of the clear cell type, but not in renal cell carcinomas of other histopathologic types (e.g., papillary type).^{218, 219} Approximately, 20% of sporadic clear cell renal cancers do not carry a detectable mutation in the *VHL* gene. However, in many of these cases, the *VHL* gene may be inactivated by epigenetic silencing,²²² a mechanism noted earlier in this chapter in connection with inactivation of the *CDKN2A* locus. In tumor types other than clear cell renal cancer, inactivation of the *VHL* gene appears to be uncommon.²¹⁸

The *VHL* gene encodes a 213-amino acid protein whose major function appears to be in the regulation of angiogenesis through protein degradation. The protein encoded by *VHL* is part of a ubiquitin ligase complex that degrades hypoxia-inducing factor 1a (HIF-1a) in the presence of oxygen. In the absence of oxygen in normal cells, or when *VHL* is mutated in tumor cells, the HIF-1a transcription factor is stabilized, leading to the expression of cytokines such as vascular endothelial growth factor and the stimulation of angiogenesis. Further biochemical and cell biology studies on *VHL* and renal cell carcinomas are likely to offer definitive insights into angiogenesis, one of the most important stromal processes associated with neoplasia.^{223, 224}

Genomic stability genes

Several recessive cancer predisposition syndromes resulting from inactivation of genes that function in DNA damage recognition and repair have been described, including ataxia telangiectasia (AT), Bloom syndrome, xeroderma pigmentosum, and Fanconi anemia. In each case, the specific cancer type and the DNA-damaging agents that increase cancer risk are distinct. Although AT heterozygotes may subtly increase the risk of breast cancer,²²⁵ in other recessive cancer syndromes, only homozygotes appear to clearly increase cancer risk. This observation contrasts sharply with the picture in the dominant cancer predisposition syndromes discussed earlier (e.g., inherited retinoblastoma, FAP, *NF1*, and *NF2*), where

heterozygotes have a clearly elevated cancer risk. Homozygous mutations in tumor suppressor genes rarely if ever exist, probably because the condition is lethal during embryogenesis. It is important to remember that the tumor suppressor genes do not only function as guardians against cancer; their main function is the control of normal cell balance, and their inactivation is expected to be incompatible with normal embryonic development.

Because recessive cancer syndromes are quite rare, this discussion of the role of genomic stability genes in cancer will focus on syndromes that are inherited in an autosomal dominant fashion. These syndromes include the most common types of familial cancers, predisposing to tumors of the colon, breast, and other organs.

DNA mismatch repair gene defects and hereditary nonpolyposis colorectal cancer

Familial clustering of colon cancer has long been recognized, with approximately 5% of all colon cancers attributable to inheritance of a gene defect with a strong effect on cancer risk and another 10–15% with a moderate effect on risk. Germline *APC* mutations are responsible for 0.5–1% of colorectal cancer cases in the Western world, and hereditary nonpolyposis colorectal cancer (HNPCC) is responsible for 2–4%.^{226–228}

Diagnostic criteria for identifying those individuals and families most likely to be affected by HNPCC have been determined,^{226–229} despite the absence of overt clinical findings before cancer diagnosis, and the potential for chance clustering of colon cancer within a family. Representative diagnostic criteria include (1) exclusion of familial polyposis; (2) colorectal cancer in at least three relatives, one of them being a first-degree relative of the others; (3) two or more successive generations affected; and (4) at least one of the affected individuals being younger than 50 years of age at the time of diagnosis. Although not all individuals affected by HNPCC meet these criteria, familial aggregations of colorectal cancer that are likely to have a genetic basis distinct from that underlying the majority of HNPCC cases can be excluded.^{226, 228}

Several genes responsible for HNPCC have been identified, including two on chromosome 2p [*mutS* homologs 2 and 6 (*MSH2*, *MSH6*)], another on chromosome 3p [*mutS* homolog 1 (*MLH1*)], and another on chromosome 7p [postmeiotic segregation 2 (*PMS2*)]. Together, germline mutations in these four genes account for virtually all classic HNPCC cases.^{226, 228–231} The protein products of the *MSH2* and *MLH1* genes appear to have critical roles in the recognition and repair of DNA mismatches ([Figure 10](#)). In cells with one normal and one mutant allele of a DNA mismatch repair (MMR) gene, DNA repair is minimally impaired, if at all. However, inactivation of the remaining allele can occur as a result of somatic mutation in a normal epithelial cell. This “second hit” abrogates MMR function, and hundreds to thousands of mutations may thereby occur during each subsequent cell-division cycle. Because these mutations preferentially arise in mononucleotide, dinucleotide, and trinucleotide repeat tracts (i.e., microsatellite sequence tracts), the phenotype is often called the microsatellite instability (MSI) phenotype.²²⁶

Figure 10 Mismatch repair pathway in human cells. (a,b) During DNA replication, DNA mismatches may arise, such as from strand slippage (shown) or misincorporation of bases (not shown). (c) The mismatch is recognized by MutS homologs, perhaps most often Msh2 and GTBP/Msh6, although another MutS homolog, Msh3, may substitute for GTBP/Msh6 in some cases. (d,e) MutL homologs, such as Mlh1 and Pms2, are recruited to the complex, and the mismatch is repaired through the action of a number of proteins, including an exonuclease, helicase, DNA polymerase, and ligase.

Germline mutations in the known MMR genes have been detected in only 2–4% of colorectal cancer patients, although approximately 15–20% of all colon cancers display the MSI phenotype.^{226, 229–234}

Clearly, only a small fraction of the sporadic colorectal cancers with the MSI phenotype develop as the result of a germline mutation in a known MMR gene. Somatic mutations in MMR genes have been found in some sporadic colorectal cancers with the MSI phenotype.²³⁵ In most sporadic cases, however, inactivation of the *MLH1* gene occurs as a result of epigenetic inactivation.^{236, 237}

Many of the mutations arising in cells with MMR deficiency are likely to be detrimental to cell growth. A small fraction of the total mutations that arise presumably activate oncogenes or inactivate tumor suppressor genes. Some genes are preferentially mutated in MMR-deficient cancers, presumably because the mutations confer a selective growth advantage. For instance, genes that contain repetitive DNA sequences, such as microsatellite tracts, might be expected to be targets of mutation in these cancers, and data support this prediction.

BRCA1 and BRCA2 genes

As in the case of colorectal cancers, family history has long been hypothesized to be a major risk factor in breast cancer. The greatest risk is seen in those who have a history of breast cancer in multiple first-degree relatives. However, only in the late 1980s was evidence obtained that predisposition to breast cancer in some families could be attributed to a highly penetrant autosomal dominant allele. In 1990, Hall and colleagues reported the localization of one such breast cancer predisposition gene, *BRCA1*, on chromosome 17q21.²³⁸ Others found that germline *BRCA1* mutations substantially increase the risk not only of breast cancer but also of ovarian cancer.^{239, 240} Intensive research efforts were focused on the region of chromosome 17q harboring *BRCA1*, and the gene was ultimately identified by positional cloning approaches in 1994.^{241, 242}

Studies of germline *BRCA1* mutations in breast cancer patients have yielded important results. In studies of families with four or more cases of breast or ovarian cancer (or both) diagnosed before age 60 years, germline *BRCA1* mutations were identified in nearly 50% of families studied.^{243–245} In fact, germline *BRCA1* mutations may account for cancer predisposition in roughly 75% of families who manifest both breast and ovarian cancer.^{243, 244} Many distinct germline *BRCA1* mutations have been identified, although most of the mutations result in the synthesis of a truncated BRCA1 protein.^{243, 244} Although most germline *BRCA1* mutations have been identified in only one or a few families, some mutations have been found recurrently. The 11 most common mutations account for about 45% of the total BRCA1 mutations observed.^{244, 245} In fact, the two most common mutations in *BRCA1* (185delAG and 5382insC) account for approximately 10% of the total. Of note, the 185delAG frameshift mutation at codon 185 of *BRCA1*, involving a deletion of two bases (adenine and guanine), has been identified in more than 20 Jewish families with familial breast or ovarian cancer. Moreover, population surveys of Ashkenazi Jews, chosen without regard to a family history of cancer, indicate that approximately 1% carry the 185delAG mutation.^{244–246} Based on studies of families with germline *BRCA1* mutations, the lifetime risks of breast cancer and ovarian cancer in those carrying an inactivating mutation are estimated to be 85% and 50%, respectively.^{243, 244, 247} Whether specific germline *BRCA1* mutations confer a greater risk of breast and ovarian cancer than do other mutations remains uncertain.

As with most tumor suppressor genes and their associated familial cancer syndromes, germline mutations of *BRCA1* lead to the presence of a mutant allele in every cell of the body. Cancers then arise through inactivation of the second wild-type allele by the mechanisms outlined in [Figure 2](#). In the case of *BRCA1* (and *BRCA2*), LOH of the remaining wild-type allele is usually responsible for the second “hit” leading to inactivation of the *BRCA1* gene. In addition, LOH of the *BRCA1* locus was found in approximately 50% of unselected breast cancers and 65–80% of unselected ovarian cancers.^{244, 248} Because most breast and

ovarian cancers are not associated with a hereditary predisposition (i.e., they are sporadic), these studies of unselected cancers led investigators to hypothesize that *BRCA1* would play an important role in the development of sporadic breast and ovarian cancers. However, despite these LOH data, sporadic breast and ovarian cancers rarely harbor mutations in the *BRCA1* gene, demonstrating that at least one wild-type allele is still present in most of these sporadic cancers.^{244, 248} Somewhat surprisingly, this finding would suggest that *BRCA1* does not have a role in the genesis of the more common, nonfamilial forms of breast and ovarian cancers. However, it is still possible that downstream effectors of the *BRCA1* protein are altered in sporadic breast and ovarian cancers, suggesting that the pathway, rather than the gene, is an important contributor to the carcinogenic process of these cancers.²⁴⁹

Although germline mutations in the *BRCA1* gene underlie cancer predisposition in roughly 40–50% of families with multiple breast cancer cases, another highly penetrant autosomal dominant susceptibility gene termed *BRCA2* plays a critical role in a significant fraction of the families with multiple breast cancer cases lacking *BRCA1* mutations. The *BRCA2* gene was mapped to chromosome 13q12-13 in 1994²⁵⁰ and identified by positional cloning strategies in 1995.²⁵¹ Although germline mutations in *BRCA1* and *BRCA2* appear to confer essentially similar lifetime risks of female breast cancer (i.e., ~80%), the risk of ovarian cancer is reduced to approximately 10% in those with *BRCA2* mutations compared with approximately 40–50% in those with *BRCA1* mutations. The risk of male breast cancer is markedly elevated in *BRCA2* mutation carriers, with a lifetime risk of approximately 7%, as opposed to a 1% lifetime risk of in *BRCA1* mutation carriers.²⁵² There also appears to be an elevated risk of pancreatic and several other cancers in both male and female *BRCA2* mutation carriers.²⁴⁴ As is the case for *BRCA1*, LOH of the *BRCA2* locus at 13q12, but not at the *RB1* locus at 13q14, has been observed in some sporadic breast, pancreatic, head and neck, and other cancers, suggesting that *BRCA2* may be a target for somatic mutations in cancer. However, as with *BRCA1*, detections of somatic *BRCA2* mutations in sporadic cancers have been few,²⁴⁴ once again suggesting that perhaps the pathway, rather than the gene, is the target of genetic alteration in sporadic forms of these cancers.

The *BRCA1* and *BRCA2* genes each encode a large nuclear protein. The amino acid sequences of the two proteins have only short regions of similarity with one another or other well-characterized proteins. Although their lack of obvious functional motifs stymied initial attempts to define the cellular functions of *BRCA1* and *BRCA2*, several lines of evidence indicate that both proteins interact directly or indirectly with homologs of yeast Rad51, a protein that functions in the repair of double-stranded DNA breaks.^{253–260} Moreover, the *BRCA1*, *BRCA2*, and Rad51 proteins all appear to be present in a stable multiprotein complex in the cell's nucleus. Consequently, it has been suggested that *BRCA1* and *BRCA2* may function in the response to or repair of DNA damage, particularly double-strand DNA breaks.²⁶¹ Other findings imply that *BRCA1* and perhaps *BRCA2* may have a role in regulating transcription.²⁶² Although the DNA repair and transcription regulation functions may be distinct, it is entirely possible that the two functions are linked in a process sometimes called transcription-coupled DNA repair.²⁵⁵ There is precedent for this idea, in that some nucleotide excision repair genes causing xeroderma pigmentosum can also function in transcription,²⁶³ and repair of certain types of DNA damage is known to be coupled to transcription.²⁶⁴

Candidate tumor suppressor genes

The tumor suppressor genes discussed earlier and others summarized in [Table 1](#) are distinguished by the fact that germline-inactivating mutations in the genes are associated with inherited cancer predisposition. The link between germline mutation and elevated cancer risk provides incontrovertible evidence of the gene's role in tumorigenesis. Other findings, such as the demonstration in sporadic cancers of LOH of one

tumor suppressor gene allele accompanied by somatic mutation of the remaining allele, offer evidence for a more widespread role for many of the inherited cancer genes. Although the tumor suppressor genes in [Table 1](#) are definitively linked to inherited cancer syndromes, it is possible that germline mutations in other bona fide tumor suppressor genes may be associated with a more modest cancer risk, as has already been demonstrated for the I1307K mutation in *APC*. A complete listing of all documented tumor suppressor genes is beyond the scope of this chapter and is ever-evolving as new data come to light from detailed sequencing studies of human cancers. Based on the prevalence of inactivating mutations identified in such studies, it is estimated that there are approximately 100 tumor suppressor genes that play a role in human cancers of various types.⁶⁴ The majority of these genes are only inactivated somatically and do not give rise to inherited cancer predisposition syndromes.

Table 1 Select tumor suppressor and stability genes associated with inherited cancer predisposition syndromes

Gene ^a	Syndrome	Hereditary pattern	Pathway ^b	Major hereditary tumor types ^c
<i>APC</i>	FAP	Dominant	APC	Colon, thyroid, stomach, intestine
<i>AXIN2</i>	Attenuated polyposis	Dominant	APC	Colon
<i>CDH1</i> (E-cadherin)	Familial gastric carcinoma	Dominant	APC	Stomach
<i>GPC3</i>	Simpson–Golabi–Behmel syndrome	X-linked	APC	Embryonal
<i>CYLD</i>	Familial cylindromatosis	Dominant	APOP	Pilomatricomas
<i>EXT1, EXT2</i>	Hereditary multiple exostoses	Dominant	GLI	Bone
<i>PTCH</i>	Gorlin	Dominant	GLI	Skin, medulloblastoma
<i>SUFU</i>	Medulloblastoma predisposition	Dominant	GLI	Skin, medulloblastoma
<i>FH</i>	Hereditary leiomyomatosis	Dominant	HIF1	Leiomyomas
<i>SDHB, SDHC, SDHD</i>	Familial paraganglioma	Dominant	HIF1	Paragangliomas, pheochromocytomas
<i>VHL</i>	von Hippel–Lindau	Dominant	HIF1	Kidney
<i>TP53</i> (<i>p53</i>)	Li–Fraumeni	Dominant	TP53	Breast, sarcoma, adrenal, brain, and so on
<i>WT1</i>	Familial Wilms tumor	Dominant	TP53	Wilms
<i>STK11</i> (<i>LKB1</i>)	Peutz–Jeghers	Dominant	PI3K	Intestinal, ovarian, pancreatic
<i>PTEN</i>	Cowden	Dominant	PI3K	Hamartoma, glioma,

				uterus
<i>TSC1, TSC2</i>	Tuberous sclerosis	Dominant	PI3K	Hamartoma, kidney
<i>CDKN2A (p16INK4A, p14ARF)</i>	Familial malignant melanoma	Dominant	RB	Melanoma, pancreas
<i>CDK4</i>	Familial malignant melanoma	Dominant	RB	Melanoma
<i>RB1</i>	Hereditary retinoblastoma	Dominant	RB	Eye
<i>NF1</i>	Neurofibromatosis	Dominant	RTK	Neurofibroma
<i>BMPR1A</i>	Juvenile polyposis	Dominant	SMAD	Gastrointestinal
<i>MEN1</i>	Multiple endocrine neoplasia type I	Dominant	SMAD	Parathyroid, pituitary, islet cell, carcinoid
<i>SMAD4 (DPC4)</i>	Juvenile polyposis	Dominant	SMAD	Gastrointestinal
<i>BHD</i>	Birt–Hogg–Dube	Dominant	?	Renal, hair follicle
<i>HRPT2</i>	Hyperparathyroidism jaw-tumor	Dominant	?	Parathyroid, jaw fibroma
<i>NF2</i>	Neurofibromatosis	Dominant	?	Meningioma, acoustic neuromas
<i>MUTYH</i>	Attenuated polyposis	Recessive	BER	Colon
<i>ATM</i>	Ataxia telangiectasia	Recessive	CIN	Leukemias, lymphomas, brain
<i>BLM</i>	Bloom	Recessive	CIN	Leukemias, lymphomas, skin
<i>BRCA1, BRCA2</i>	Hereditary breast cancer	Dominant	CIN	Breast, ovary
<i>FANCA, FANCC, FANCD2, FANCE, FANCF, FANCG</i>	Fanconi anemia A, C, D2, E, F, and G	Recessive	CIN	Leukemias
<i>NBS1</i>	Nijmegen breakage	Recessive	CIN	Lymphomas, brain
<i>RECQL4</i>	Rothmund–Thomson	Recessive	CIN	Bone and skin
<i>WRN</i>	Werner	Recessive	CIN	Bone and brain
<i>MSH2, MLH1, MSH6, PMS2</i>	HNPCC	Dominant	MMR	Colon, uterus
<i>XPA, XPC; ERCC2, ERCC3, ERCC4, ERCC5; DDB2</i>	Xeroderma pigmentosum	Recessive	NER	Skin

^a Representative genes of all major pathways and hereditary cancer predisposition types are listed. Approved gene symbols are provided for each entry; alternative names are in parentheses.

^b In many cases, the gene has been implicated in several pathways. The single pathway that is listed for each gene represents a “best guess” (when one can be made) and should not be regarded as conclusive.

^c In most cases, the nonfamilial tumor spectrum caused by somatic mutations of the gene includes those occurring in familial cases but also additional tumor types. For example, mutations of *TP53* and *CDKN2A* are found in many more tumor types than those to which Li–Fraumeni and familial malignant melanoma patients, respectively, are predisposed.

Abbreviations: APC, adenomatous polyposis coli; APOP, apoptotic pathway; BER, base excision repair; CIN, chromosomal instability; FAP, familial adenomatous polyposis; GLI, glioma-associated oncogene; HIF1, hypoxia-inducing factor 1; MMR, mismatch repair; NER, nucleotide excision repair; PI3K, phosphatidylinositol 3-kinase; RB, retinoblastoma; RTK, receptor tyrosine kinase pathway; SMAD, SMA- and MAD-related protein 4; wt, wild type.

Studies of RNA have revealed a large number of genes whose transcription is reduced in cancers. Some of these genes were initially termed tumor suppressors solely on the basis of this reduced expression. A small subset of these genes may, indeed, have critical roles in growth regulation, but expression data provide insufficient evidence to invoke causality. The altered expression of genes in cancers more often reflects the effect rather than the cause of the neoplastic process (i.e., the altered growth and differentiation properties of cancer cells and their abnormal microenvironment compared with normal cells in the tissue or organ from which the cancer arose). Moreover, many genes that play no role in cancer can dramatically alter cell growth when expressed exogenously at high, unphysiologic levels, rendering functional analyses of such candidates problematic. In the end, the functional evidence should be carefully weighed before a conclusion can be drawn that a gene has a causal role in tumorigenesis and that it should appropriately be designated a tumor suppressor gene. The only definitive way to identify a tumor suppressor gene at present is to document a highly statistically significant number of inactivating mutations in it in specific cancer types.⁶⁴

Summary

There is now overwhelming evidence that mutations in tumor suppressor genes are major molecular determinants for most common human cancers. Thus far, dozens of confirmed tumor suppressor genes have been identified by molecular cloning techniques. In some cases, these genes are inactivated in the germline, and their inactivation predisposes to cancer. Far more frequently, these same tumor suppressor genes are inactivated by somatic mutations during tumor development.

Although much has been learned about tumor suppressor genes, a great deal of work remains. Advancements in our understanding of tumorigenesis will continue with the detailed characterization of their normal cellular functions and the mechanisms through which mutations of these genes subvert these normal functions. It is essential to point out that tumor suppressor genes, unlike oncogenes, are in general not directly targetable by drugs: all drugs inactivate their target proteins and tumor suppressor genes are already inactivated in cancers. Therefore, the best hope for exploiting tumor suppressor gene mutations in cancers is through targeting downstream pathways that are consequently upregulated. Understanding the pathways through which these genes act is therefore of paramount importance.

Chapter 6

Epigenetic contributions to human cancer

James G. Herman, MD ■ Stephen B. Baylin, MD

Overview

Over the past 20 years, an exciting advance in our understanding of the mechanisms underlying cancer development has been our growing appreciation that these diseases are not driven solely by genetic changes, but also by epigenetic changes.^{1–4} Strictly speaking, the term epigenetic refers to heritable changes in gene expression, in dividing somatic cells, which are mediated by alterations other than changes in the primary base sequence of DNA.^{5–7} This definition encompasses two critical translational characteristics concerning epigenetic alterations in cancer and their clinical importance. First, the coding and noncoding genes affected by epigenetic changes in cancer remain wild type for DNA sequence rather than harboring irreversible mutations. Second, and closely related, the changes are, then, potentially reversible if normal gene expression can be restored such that the wild-type gene function can emerge.^{1, 2, 4, 7–10}

This recognition of epigenetic changes, which are fundamental to cancer initiation and progression, is occurring in the midst of a dynamic explosion of knowledge as to how the human genome is normally controlled, via chromatin packaging of DNA, to regulate gene expression in different tissues and during development.^{5–7, 11} For example, epigenetic processes play a fundamental role during normal embryonic development and adult-cell renewal. As such, these processes control the emergence of different cellular phenotypes, all with the exact underlying DNA sequence, which occur during development and differentiation. While this knowledge of gene regulation continues to grow rapidly, our understanding of the complete spectrum of epigenetic changes that are key to cancer development is expanding rapidly but could even still, relatively, be in its early stages. However, there is much that has already been learned, and this knowledge in the understanding of basic cancer biology and carcinogenesis already has palpable translational implications, which are discussed in this chapter.

Mechanisms involved in epigenetic regulation of gene expression

Formation of chromatin

While all of the fundamental information for gene expression lies in the primary base sequence of DNA, which can be viewed as a “hard drive” for storage of this essential coding, the patterns of gene expression in cells are determined by how this DNA is modified following synthesis and replication and how it is packaged into the nucleus by the proteins, or chromatin, by which it is arranged.^{5–7, 11} The latter processes of packaging might, then, be viewed as the “software,” which provides the readout of the hard-drive information contained in the DNA sequence. The primary role of the DNA modification and chromatin packaging is required to balance the genome such that the majority of DNA is encompassed in a

silent or low-transcription state to guard against unwanted expression of repeat sequences, potential transposable elements, and viral insertions accrued over evolution.^{5, 6, 12} The first element of DNA packaging is its interactions with proteins forming chromatin. The fundamental scaffolding proteins for chromatin are the histone proteins, and their assembly with DNA, in turn, forms the key element, or nucleosomes ([Figure 1](#)), which are essential for arranging DNA in the nucleus.^{13, 14}

Figure 1 Nucleosome structure. (a) Model of the double helix wound around the protein structure of the constituent histones as outlined in the text. (b) The schematic representation shows the organization of the H3/H4 tetramer on the DNA, followed by two sets of H2A/H2B dimers forming the histone core with the DNA (*black line*) wrapped around. The amino-terminal histone tails are shown extruding from the nucleosome core of the eight histone proteins.

Nucleosomes consist of ~146 bp of DNA wrapped twice around an octamer of the core histone proteins, H2A, H2B, H3, and H4.^{13, 14} For functional mediation of gene expression profiles from DNA, nucleosomes must not only be properly distributed linearly along DNA, but must also be arranged into higher-order, multinucleosome structures^{13, 14} ([Figure 2](#)). These dynamics are mediated by chromatin-remodeling proteins, and the more widely and irregularly spaced the nucleosomes are in their linear placement along DNA, and the less compacted the higher-order structures, the more “open” the chromatin is and the more available the DNA is for active-gene transcription ([Figure 2](#)). This is often the case in areas in and around active-gene promoters. Conversely, the more regular and evenly the nucleosomes are spaced, and the more compacted their higher-order structures ([Figure 2](#)), the more “closed” is the chromatin and the more repressive for gene transcription. This latter configuration dominates most of the human genome, as noted earlier, to prevent unwanted gene expression and to facilitate chromosome structure.

Figure 2 Depiction of the packaging arrangement of human DNA (straight black line). Panel (a) shows, for normal cells, a more linear arrangement of nucleosomes (yellow circles with DNA wrapped around as outlined in [Figure 1](#)) depicting the “open” arrangement of chromatin around most gene promoters containing CpG islands (unmethylated CpG sites shown as white lollipops), which are being actively transcribed or can be induced to transcribe (large light-blue arrow). Exons 1–3 of the model gene are depicted by the numbered light-blue boxes. Regions of DNA within the body of the gene and extending beyond the third exon are depicted as being in the closed, transcriptionally repressed, conformation typical of the majority of the normal human genome. This closed structure is represented by the more packed, three-dimensional organization of the nucleosomes, and the CpG sites in the closed regions are depicted as being methylated (black lollipops). The text in yellow squares depicts the chromatin remodeling protein complexes, histone-modifying enzymes, and enzymes performing DNA methylation (DNA-methylation machinery), which are responsible for DNA packaging as discussed in the text. Panel (b) depicts the altered chromatin patterns present in a typical cancer cell with a switch in positions of the normal closed and open chromatin regions in the genome. Many closed regions now have an open chromatin with loss of DNA methylation, while a large group of gene promoters have assumed a closed chromatin with abnormal, CpG island DNA methylation and repressed transcription (large red X over the transcription start site depicted by the light-blue arrow).

Integrally involved with this dynamic chromatin structure is a dependency of nucleosome function on states of chromatin, which are determined by differing ratios of active and repressive histone “modifications.”^{6, 7, 11, 14, 15}

These consist of additions or modifications to key amino acids, primarily located in the tails of the histones that stick out from the nucleosome assembly, in the form of lysine acetylation, lysine and arginine methylation, serine and threonine phosphorylation, glutamic acid ADP-ribosylation, and lysine

ubiquitination and sumoylation.^{6, 7, 11, 14, 15}

The balance of these marks form what was initially termed a “histone code,” now realized to be more complex than envisioned, that participates, along with nucleosome positioning, in packaging the genome such that both constitutive and cell type-dependent chromatin patterns of open and/or closed configurations are maintained from cell division to cell division and ensuring that these patterns remain stable in nondividing cells.^{6, 7, 11} It is in this way that cells maintain a “memory” for patterns of gene expression and chromosome structure that facilitate normal patterns of development and the maintenance of mature-cell renewal and differentiation states.^{14, 15}

The best characterized of the histone modifications, mentioned earlier, are lysine methylation and acetylation, which are most closely associated with either high or low states of gene transcription. These marks in turn are established by families of enzymes consisting of histone methyltransferases (HMTs) that catalyze the methylation, histone demethylases that remove these methyl additions, and histone acetylases or (HATs) and histone deacetylases (HDACs), which place and remove the acetyl groups, respectively.^{7, 11, 15–17} For these dynamic events, examples of key methylation marks associated with gene states are methylation of lysine 4 of histone 3 (H3K4me3), which is associated with open chromatin typical of active transcription, and methylation of lysine 9 or lysine 27 (H3K9me3, H3K27me3), which is characteristic of repressed-gene expression.^{6, 15} Adding to the information contained in this histone code is the fact that lysine methylation may be present in either monomeric, dimeric, or trimeric, states.^{6, 7, 11, 15} There is also a regulated balance for histone acetylation in which enzymatic activities of the HATs and HDACs determine the states of histone–lysine acetylation that are typical of open, transcriptionally active chromatin, and deacetylation, more associated with closed chromatin and repressed transcription.^{7, 11, 15} Key examples of such active marks at gene promoters are H3K9acetyl and H4K16acetyl.^{7, 11, 15}

DNA methylation

While not present in all multicellular organisms, humans, other mammals, and other higher organisms add an additional layer of epigenetic regulation. Working in close concert with chromatin states to package the human genome is a key modification consisting of methylation added directly to postreplicated DNA.^{7, 10, 17, 18} This step consists of attachment of a methyl moiety to the C5 position of the base, cytosine, only when it is located preceding a guanine or in a “CpG” dinucleotides context. The methyl group is transferred from S-adenosyl methionine to DNA through catalysis by a family of DNA methyltransferase (DNMT) enzymes.^{17–19}

The role of this DNA methylation¹⁹ is closely tied to the distribution of the CpG dinucleotide in human and other genomes. This is a nonrandom and uneven distribution in which there has been a global and progressive depletion of CpGs over evolution because the deamination of methylated CpGs results in changing the cytosines (Cs) to thymidines (Ts).^{7, 17, 18} Failure to repair these thymidines then results in transition of the Cs to Ts. However, there remains interspersed conservation of nondepleted, CpG-rich stretches (~0.4 to several thousand kb) or the so-called “CpG islands,” which are particularly important to the DNA-methylation patterns.^{17, 18} These islands, especially when found in the 5′ end of about 50–60% of human genes,^{17, 18} remain non-DNA methylated, while the majority of the CpG′ sites in the remainder of DNA are methylated^{4, 7, 17, 18} ([Figure 2](#)).

This pattern of DNA methylation, depicted in [Figure 2](#), works in tight concert with the nucleosome positioning and histone modifications previously discussed to determine the epigenetic regulation of the genome. Thus, methylated DNA associates with, and helps maintain in a tight heritable state, the relatively

transcriptionally inert status of the majority of the genome, which is most apparent in the closed chromatin or “heterochromatic regions” concentrated in pericentromeric parts of chromosomes. In contrast, the non-DNA-methylated CpG islands associated with gene-start sites appear to reflect and facilitate a transcriptional ready and/or active transcription state.^{4, 7, 17} This tight interaction between histone modifications and DNA methylation is reflected in the fact that transcriptional repression is associated with DNA methylation, which serves to help maintain the repression of many closed chromatin states. Thus, deacetylated histone lysines, such as for H3K9, and repressive methylation marks, such as H3K9me3, associate with methylated DNA.^{17–19} In turn, such marks, and particularly H3K9me, appear important for targeting of DNA methylation.^{17–19}

It is important to note that an important exception to the above role of DNA methylation in repression of gene transcription has been recently noted. Thus, one common site of 5mC is in the body of active and not repressed genes. This methylation appears to work with the mark of H3K36 me3 to allow transcriptional elongation and enhanced gene expression.^{7, 10, 20, 21}

There have been recent and most important advances in our understanding of how DNA-methylation patterns are established and maintained for inserting and maintaining DNA methylation in the epigenome. It has long been recognized that three biologically active enzymes, DNA methyltransferases (DNMTs), are responsible for establishing and maintaining sites of DNA methylation.¹⁹ In this regard, DNMT 1 is predominantly a maintenance DNMT, which is responsible for preserving patterns of established DNA methylation during DNA replication. DNMT3A and DNMT3B are predominantly de novo DNMTs, which can establish new sites of DNA methylation. However, much data suggests a more complex scenario in which there can be cooperativity between the three DNMTs and interacting proteins such that they can, in some instances, replace one another in function when stress situations require this.²² For example, DNMT3A and DNMT3B may function to repair errors made by DNMT1 during DNA synthesis.¹⁴

While the above scenarios for establishing DNA-methylation patterns have been appreciated, it was long thought that removal of this modification is a passive event accomplished only by failure to replace methylation sites during DNA replication. However, an exciting new era has emerged in which we appreciate that, as for histone modifications, there are distinct active steps for erasing DNA methylation. A family of enzymes, termed TET (ten-eleven translocations) family proteins, can, through oxidative steps, convert 5-methyl cytosine (5MT) to 5-hydroxymethyl cytosine (5hMT), which, through subsequent DNA repair steps, convert 5MT back to cytosine.^{19, 23, 24} These conversions are important during normal development and adult-cell functions, and later we outline their importance for cancer.^{25–27}

Altered DNA methylation and chromatin in cancer or the “cancer epigenome”

Loss of DNA methylation

Virtually all cancer types harbor what appears to be a marked shift away from the normal epigenetic patterns, described in the previous sections, for normal cells^{4, 7, 8} (Figure 2). This has been best studied to date for DNA methylation, where there are at least two major changes that are now well appreciated. First, there are global losses of this modification from the widespread regions of the genome, which harbor DNA methylation in normal cells^{1, 2, 7, 8, 10} (Figure 2). Indeed, this was the first chromatin abnormality well cataloged for cancer²⁸ although much remains to be learned about the ramifications of this change. As these are generally areas of closed chromatin where the DNA methylation helps to

maintain transcriptionally repressed DNA, such losses could associate with abnormal transcription.¹⁻⁴ Indeed, a number of genes with oncogenic potential, and which normally have low expression in normal cells, have now been reported to be upregulated in association with cancer-specific decreases in promoter DNA methylation.¹ Moreover, pericentromeric regions are a target for DNA-methylation losses in multiple cancer types and this may play a role in the genesis of chromosomal instability in neoplasia.^{1-4, 29} Most recently, losses of DNA methylation from gene body regions have also been observed in tumors. This can have an opposite effect on gene expression to those above as methylation in these regions, as discussed earlier, actually facilitates gene expression through enhancing transcriptional elongation.^{7, 20, 21}

Gene promoter DNA hypermethylation

The best-studied chromatin change associated with epigenetic abnormalities in cancer, and the one with the most-recognized ramifications, to date, entails localized increases in DNA methylation in gene promoter CpG islands, which are protected from this change, as discussed earlier, in normal cells ([Figure 2](#)).^{1-4, 7, 8} This change is associated with tight transcriptional repression of genes and can, thus, serve in a process that provides an alternative to gene mutations for loss of function of a number of well-characterized tumor-suppressor genes.^{1-4, 7, 8} In addition to these classic-suppressor genes, data derived from random screens of cancer-cell DNA for DNA-hypermethylated genes, such as in the Cancer Genome Atlas Project (TCGA), indicate that hundreds of such genes appear to exist, for multiple cancer types analyzed, in a given patient's tumor.^{1-4, 7, 8, 30-33} While all of these gene changes may not be pivotal for driving the initiation or progression of the particular cancers that harbor them, many, including the classic-suppressor genes, do encode for genes for which loss of function would be important for tumor development.^{3, 4, 7, 8} Many genes, which are seldom or never mutated in cancers, may still have important roles in tumorigenesis, as they undergo promoter DNA hypermethylation and silencing during tumor progression.^{4, 7, 8} In this regard, virtually every critical pathway known to play a role in tumorigenesis is now known to be involved with genes bearing cancer-specific DNA hypermethylation in one or more tumor types^{3, 4, 7, 8} ([Table 1](#)). Finally, many of the genes involved exhibit the DNA-methylation change in preinvasive lesions, which have the potential for malignant progression, as demonstrated by “benign” colon polyps.^{1, 2, 4, 7, 8, 34} In these preinvasive colon lesions, multiple hypermethylated genes are already present and encode for key genes that, when inactivated, would deregulate key pathways, such as the Wnt pathway, which are well known to drive the initiation and progression of all colon cancers.^{1, 2, 4, 7, 8, 34} These findings have led to the hypothesis that epigenetic changes may be in many cases important for tumor initiation and for the appearance of abnormally expanding cells, which arise in cancer-risk states, such as chronic inflammation.^{4, 7, 34-36} In addition to the above findings, it is now increasingly appreciated that differential DNA increases may affect key genomic regions other than just gene proximal promoter regions.^{3, 4, 7, 14, 19, 37, 38} Regions just distal to promoter CpG islands called “shores” can be differentially methylated between normal and cancer tissues.^{37, 38}

Table 1 Examples of pathways altered by gene-promoter hypermethylation and gene silencing in cancer

Pathway	Genes 3–5
Wnt pathway	APC, SFRP family, SOX17
Altered cell-cycle control	Rb, p16, p15, p14, p73
Repair of DNA damage	MLH1, O6-MGMT, GST-Pi, BRCA1
Apoptosis	DAP kinase, caspase 8, TMS-1
Tumor-cell invasion, angiogenesis	THBS1, E-cadherin, VHL, APC, LKB1, TIMP3,
Tumor architecture	Growth-factor response ER, RAR-beta, SOCS-1*

The above shore regions are also differentially methylated between normal tissues, so the meaning for cancer per se, and especially as reflective of associated gene expression changes, is less clear than for proximal promoter, CpG island regions. Similarly, there is a building body of data for increased methylation in gene-enhancer regions, or DNA-regulatory sequences, which through binding of key proteins and histone modifications are master regulators of gene expression. These sequences can lie at variable, and often large, distances away from gene proximal promoters.^{39–41} De novo DNA-methylation changes at enhancers may also contribute key gene expression abnormalities in cancer and especially for increasing cancer-risk states.^{42, 43} While the theme of differential enhancer DNA methylation in cancer is under more and more investigation, the role of these changes, and their balance with gene promoter CpG island hypermethylation, is still being clarified.

Long-range changes in DNA methylation and chromatin in cancer

A recent exciting advance in studying both normal and cancer epigenomes, stemming from in-depth analyses of CpG methylation and chromatin throughout the genome, is that there are nonrandom regional configurations that can be altered between cancer and normal cells. These occupy megabase regions in many chromosomes (100 kb to 10 Mb).^{3, 4, 7, 8, 44–46} These are largely CpG poor regions, and the constituent CpGs are heavily methylated but to degrees that vary significantly throughout different normal tissues leading to the term partially methylated domains.^{3, 4, 7, 8, 44–46} Cancers characteristically have losses of normal DNA methylation throughout these areas, creating the so-called megabase islands or canyons of hypomethylated domains as particularly defined to date in colon and other cancers.^{3, 4, 7, 8, 44–46} Within these blocks of sequence, cancers can establish long-range appearance of repressive histone modifications, such as for H3K9 methylation as well.^{3, 4, 7, 8, 44–46} In some regions, there may be long-range areas of nonrepressive or more open chromatin.^{45, 47–50} Intriguingly, much smaller-embedded genes within these large domains, which harbor promoter CpG islands, can have the de novo gains in DNA methylation discussed in detail earlier.^{3, 4, 7, 8, 45} Thus, in essence, hypomethylated canyons in cancer often exhibit many of the cancer-associated losses and more focal CpG island gains of DNA methylation in cancer.^{3, 4, 45} Moreover, these large domains may harbor a much higher than expected percentage of genes with a history of embryonic and adult stem cell chromatin regulation that are particularly vulnerable to abnormal, promoter CpG island DNA hypermethylation.^{3, 4, 7, 8, 35, 45, 51, 52}

The increasing connections between genetic and epigenetic alterations in cancer

One of the most intriguing themes to emerge over the past several years is the recognition that, in virtually all tumor types, one of the most frequent type of mutations is in genes encoding for proteins that establish

and maintain the epigenome.^{3, 4, 7, 53, 54} While the exact implications of these remain to be defined, there are now several key links between these genetic alterations and either tumorigenesis, DNA-methylation abnormalities, or chromatin changes. One important example concerns the relationships between mutations in IDH 1 and 2 genes, and also in the TET genes, and DNA hypermethylation. As now recognized in low-grade gliomas in younger patients and in hematologic cancers,^{55–57} these mutations associate with altered DNA and histone-demethylation pathways. These can include changes in histone-methylation levels and a pattern of increased frequency of promoter region CpG island DNA hypermethylation, which resembles what was initially characterized, in a subset of colon cancers, as the CpG island methylator phenotype or CIMP.^{56–59} Much is coming to be understood about why the IDH mutations, especially, produce chromatin and DNA-methylation changes. The mutated genes lead to the massive accumulation of 2-hydroxy-glutarate formed from, and leading to depletion of, ketoglutarate.^{60–62} The latter is a key cofactor for multiple enzymes that help regulate and maintain key chromatin marks and the previously mentioned TET proteins that can protect against abnormal DNA methylation.^{63, 64} These changes are thought to incite, over time, a molecular progression from increases in repressive-histone marks and subsequently the above DNA hypermethylation.^{60–62} Recent mouse studies indicate that IDH mutations are drivers for early tumor-progression events⁶⁵ by blocking normal differentiation of normal stem/progenitor cells and thus facilitating abnormal self-renewal and diminished lineage commitment and differentiation.^{57, 60, 66} Importantly, drugs directly targeting the IDH mutations have been developed and are now undergoing trials in AML and brain tumors.

Another fascinating set of mutations has been delineated in a pediatric subtype of brain tumor in a key repressive, histone mark itself. Thus, mutations in H3K27, present in only one allele of the multiple copies of histone H3, block the activity of the enzyme, EZH2, which catalyzes H3K27 methylation. Accordingly, the tumors have a marked loss of H3K27me3,^{3, 67, 68} and this is postulated to induce abnormal activation of genes to drive initiation and/or progression of the tumors.

Clinical implications of altered DNA methylation in cancer

Although the full impact of understanding chromatin alterations in cancer is still to emerge, important progress is being made in at least two broad categories of translational application. First is the use of DNA-hypermethylated gene promoter sequences as tumor biomarkers, and second is the use of epigenetic therapies, which may be efficacious because they target reversal of abnormal gene silencing.^{1, 2, 9, 69–71}

Cancer DNA methylation biomarkers

There are some simple advantages that the detection of DNA-methylation changes in cancer allows over other molecular approaches. First, the overall frequencies of methylation changes appear to be greater in many instances than mutational changes.^{3, 7, 30, 69} This appears to be true for all major solid and liquid cancer types examined thus far, although the specific genes altered are different among tumor types. A second advantage of the detection of DNA-methylation changes associated with gene silencing is that this change is confined to the promoter region for many genes, making this alteration easily targeted for assays that can potentially serve as molecular markers for cancer. The large numbers of these genes allow for construction of gene panels for which DNA-hypermethylation markers essentially cover cancer genomes providing for high chance of marker detection in any given patient.⁷² The fact that the abnormality arises for many genes in early, preinvasive stages of cancer and for others later in progression allows for potential uses of such markers in cancer-risk assessment, early diagnosis, molecular restaging of tumors, and prediction of tumor behavior. Thus, the high frequency, early occurrence of such changes, and the

ability to assay methylation of each gene with a single assay, facilitate the use of such approaches for the early detection of cancer. Examples of each of the marker possibilities mentioned earlier include those listed in [Table 2](#). Thus, for cancer-risk assessment, detection of DNA-hypermethylated gene sequences in sputum DNA now holds considerable promise for predicting which individuals at high risk for developing lung cancer will actually manifest this disease within a defined period after initiation of marker monitoring.^{2, 73} Detection of colon cancer has been explored by detection of altered DNA methylation in either the blood or stool and these are emerging as especially useful when added to mutation detection.^{74–79} Detection of such genes in urine can potentially stratify the risk for, or provide for early diagnosis of, bladder cancer⁸⁰ and in prostate biopsies for improvement in the diagnosis of prostate cancer.^{81, 82} Several of the tests, for stool, and prostate biopsies are now available to clinicians via CLIA-approved tests.

Table 2 Examples of using gene-promoter DNA-hypermethylated sequences as cancer biomarkers: nearing clinical use

<p><i>Early diagnosis and/or detection of high-risk states:</i></p> <p>Detection of CpG-island DNA hypermethylation of gene panels in sputum from individuals at high risk for lung cancer^{5, 22}</p> <p>Detection of GSTP1 DNA hypermethylation in prostate biopsies and urine specimens for prostate cancer^{27, 28}</p>
<p><i>Prognosis:</i></p> <p>Detection of DNA hypermethylation in gene panels in tumor, and lymph node DNA, to restage stage 1 non-small-cell lung carcinoma and predict early recurrences³¹</p> <p>Detection of DNA hypermethylation to predict sensitivity of glioblastomas to Temazolamide^{32–34}</p> <p>Hypermethylation of specific genes Whole DNA-methylome profiles Histone-modification maps</p>
<p><i>Prediction:</i></p> <p>CpG-island hypermethylation as a marker of response to chemotherapy, hormone therapy, and targeted therapy, for example, MGMT in patients with glioma and temozolomide treatment</p>

A second area in which the changes of DNA methylation may be used in the management of cancer follows the observation that these genes are part of key pathways in the development of cancer. This allows the use of DNA methylation in these genes to potentially be used as prognostic or predictive biomarkers ([Table 2](#)). In general, the presence of DNA methylation for most genes has been associated with adverse outcome, thus providing a prognostic biomarker. This is consistent with the role that silencing of key tumor-suppressor genes can play in altering key signaling pathways. Thus, tumors with alterations of single genes, or multiple genes, are more aggressive or molecularly advanced, and thus lead to worse outcomes.^{83, 84} Recently, detection of a small panel of DNA-hypermethylated genes simultaneously in tumor and mediastinal lymph node DNA provides an extremely promising approach to restaging of stage 1 lung cancer patients to stage 3, thus predicting which of these individuals has a high risk of rapid recurrence.⁸⁵

Another useful tool for the management of patients by medical oncologists is the possibility that DNA methylation in specific genes may affect the cancer-cell sensitivity to different therapies. For example, silencing of a DNA repair gene may increase likelihood of tumor response to DNA-damaging agents that would be repaired by this protein. The most clear example of this has been demonstrated for patients with the virulent brain tumor, glioblastoma, where detection of tumor DNA hypermethylation for the DNA

damage-repair gene, *O6MGMT*, predicts for higher likelihood of response and post-treatment period of freedom from disease recurrence, for patients treated with the DNA-alkylating agent, Temazolamide.^{86–88} Other studies have suggested that sensitivity to cisplatin may be mediated by silencing of *FANCF* in ovarian cancer^{89, 90} and sensitivity of colon cancer to topoisomerase inhibitors may be mediated by silencing of the Werner syndrome gene (*WRN*).⁹¹ Recently, the promoter methylation of *SMAD1* has been reported to predict resistance to doxorubicin, for patients with diffuse large B-cell lymphoma (DLCL).⁹² Low doses of DNMT inhibitors reverse the repression of this gene, and this was found to relieve the chemoresistance.⁹² These preclinical findings are being tested in a phase I clinical trial with early findings suggesting that the DNMT inhibitor used can prime for better chemotherapy responses.⁹² Before clinical use, all of these studies need to be confirmed in additional populations and ideally in prospectively evaluated patients. However, such developments might greatly aid in optimizing the therapeutic choices offered to patients, who only have one opportunity for first-line therapy. An ever-increasing number of larger and larger clinical trials seek to validate the marker approaches and push their incorporation into standard oncology practice. Finally, other DNA-methylation changes, such as losses of normal DNA methylation in tumor DNA, and changes in chromatin marks for active or repressed-gene function, will almost certainly appear as promising molecular cancer markers.

“Epigenetic” cancer therapy

This type of therapy refers to cancer treatments based on the concept of reverting abnormal gene expression patterns toward normal as a means of cancer treatment. To date, two classes of drugs, which may achieve this goal, those which can experimentally induce DNA demethylation (5-aza-cytidine, azacytidine and 5-aza-2'-deoxycytidine, or decitabine) and those which inhibit histone deacetylases (SAHA), have been approved by the FDA for treatment of the preleukemic state, myelodysplasia (MDS), and cutaneous T-cell lymphoma, respectively. Both azacytidine⁹³ and decitabine^{7, 94–96} have shown clinical benefit, and most recently, in a randomized phase III trial, azacytidine has shown a survival benefit.⁹⁷ Although, in both instances, these drugs achieve impressive response rates, and durable responses, in previously refractory diseases, it must be cautioned that their exact mode of efficacy remains to be proven—that is, they may not work clinically, solely, or partially—through the epigenetic effects, they mediate experimentally.^{70, 95, 98, 99} Thus, use of these drugs in other hematologic malignancies is the focus of many ongoing trials, and potentially promising results are being seen especially for the DNA-demethylating agents in acute myelogenous leukemias (AML) and chronic myelogenous leukemias (CML).^{94, 100} In addition, there is experimental evidence for synergy of DNA demethylating, and histone deacetylase inhibition, for re-expression of DNA hypermethylated cancer genes.¹⁰¹ Thus, multiple trials are exploring the clinical potential of using combination therapies with these agents. Most of these trials are joined with studies trying to examine whether DNA demethylation and re-expression of abnormally silenced genes corresponds with, or predicts, therapeutic response. Probably, over the next few years, all of these clinical studies will establish the true position of these drugs and their mechanism of clinical efficacy, in the clinical arena.

The use of epigenetic therapy in solid tumors, while less well explored, has been introduced in the past^{102, 103} and is now becoming a major focus with some promising and important results.^{70, 71} The universal presence of the therapeutic targets, as discussed in multiple sections of this chapter, makes the potential for such approaches as compelling in these cancers as in the hematologic malignancies. Recent preclinical studies have investigated how low doses of DNMT inhibitors can affect solid tumor cells and suggest that nanomolar doses of both Vidaza and Dacogen can yield antitumor responses, which may reflect the ability of these drugs to “reprogram” cancer cells with little off-target effects.¹⁰⁴ Using such

low-dose approaches, plus the availability of new DNA-demethylating agents, such as SGI-110, which acts as a prodrug for DAC,^{105, 106} clinical trials are increasing. These include combining these drugs with other epigenetic therapy agents such as histone deacetylase inhibitors (HDACis). For example, such a combination, in recent trials in 65 patients with advanced, pretreated, non-small-cell lung cancer resulted in robust, durable responses in a small subset of patients.¹⁰⁷ In addition, results in these same trials suggest that the epigenetic therapy could prime a larger group of patients for better responses to subsequent therapies,¹⁰⁷ including standard chemotherapies and exciting new forms of immunotherapy.^{108, 109} With respect to the immunotherapy, preclinical work suggests that the DNA-methylation inhibitors can, in lung cancer cells and other solid tumor types, induce complex immune cell attraction pathways involving hundreds of genes.¹¹⁰ The potential for the above sensitization of NSCLC patients to chemotherapy and immunotherapy is now undergoing testing in larger in larger trials. In addition to these studies in NSCLC, others are finding that DNA-methylation inhibitors can prime patients with advanced serous ovarian cancer to subsequent chemotherapy.¹¹¹

It is certain that, over the next few years, many trials will appear for epigenetic-therapy approaches in solid tumors and, as in the leukemias, these will include studies to elucidate the precise mechanisms underlying clinical efficacy. All of these investigations, plus those in the hematologic malignancies, will not only guide the use of currently existing agents, but foster the development of newer and possibly more potent and specific drugs, as well. As we learn more about what precisely mediates abnormal DNA methylation and the components of chromatin that collaborate to initiate and maintain such changes, new molecular targets will almost surely emerge. Combination therapies exploiting these targets will likely follow. In this regard, small molecule inhibitors for several key steps in chromatin assembly have been developed and several of these are already in clinical trials.^{4, 70, 71, 112–116}

Summary

Work over the past decade, especially for DNA-methylation changes, has amply established that, from initiation through progression to advanced stages, cancer is a disease of epigenetic as well as genetic alterations. These studies, closely entwined with an explosion of basic knowledge about how chromatin constituents package the human genome to regulate gene-expression patterns, are providing a rich substrate for new cancer biomarker and therapy strategies. There is enormous potential for these strategies to enter usage in the cancer clinical arena over the next decade.

Chapter 7

Cancer genomics and evolution

William P. D. Hendricks, PhD ■ Aleksandar Sekulic, MD, PhD ■ Alan H. Bryce, MD ■ Muhammed Murtaza, MBBS, PhD ■ Pilar Ramos, PhD ■ Jeffrey M. Trent, PhD

Overview

Over 100 years ago, the Nobel Prize in Physiology or Medicine was given to Paul Ehrlich for postulating that “magic bullets” could specifically target and kill cells such as cancer cells based on their unique molecular features. The completed Human Genome Project and the cancer genomics revolution have now mapped the specific genetic changes underlying unique features of many common malignancies. However, although cancer has long been recognized to be heterogeneous in its clinical presentation, course, and pathology, we now recognize that it is far more molecularly heterogeneous than anticipated and that such variability will require an individualized approach to patient care. Rather than a single magic bullet, we will need an arsenal and this arsenal will require precise delivery. While inter- and intratumoral genomic heterogeneity present significant challenges to cancer management and drug discovery, a number of developments foster hope for accelerated progress in the war on cancer. First, our catalog of genomic targets underlying diverse cancers is rapidly growing. Second, we are beginning to understand how diverse mutations converge on a small number of druggable pathways. Third, we continue to develop drugs and biologic agents (e.g., immune checkpoint inhibitors) that target an increasingly wide array of genomic subtypes of cancer. Finally, advances in next-generation sequencing technologies now enable far earlier detection of disease recurrence than ever before. This chapter will focus on these developments and how their integration is aiding in the precise delivery of “magic bullets.”

Precis

Cancer is a genetic disease in which the stepwise accumulation of oncogene and tumor suppressor gene (TSG) mutations in clonally expanding cell populations drives malignant transformation. Throughout the twentieth century, overwhelming evidence steadily accumulated in support of this model while a growing understanding of the mutations underlying cancer subtypes helped to guide innovation in clinical cancer management. The genomics revolution begun in the twenty-first century has now transformed our understanding of cancer by generating exhaustive catalogs of cancer-driving mutations and identifying the great genomic diversity existing between and within individual tumors. These data are enabling targeted drug development, genomics-guided clinical management, and new approaches to early disease detection. Yet, gaps nonetheless remain in our knowledge of the causative mutations underlying some cancers, in our understanding of the biology of the mutations we have identified, in developing drugs capable of targeting many of these diverse mutations, and in fending off the inevitable emergence of drug resistance. In this chapter, we review the history and methods of cancer genetics and genomics, summarize current knowledge of the spectrum of mutations in cancers, discuss emerging concepts in cancer evolution and genomic heterogeneity, and present a case study on the clinical impact of melanoma genomics.

Introduction

As detailed in the previous chapters, cancer is a genetic disease resulting from the stepwise accumulation of mutations that confer upon cells a selective growth advantage.¹ Such mutations alter the birth and death rate as well as the genomic stability of cells as they undergo waves of clonal expansion. With the accumulation of mutations in cancer genes, cell populations acquire increasingly malignant phenotypes in successive generations. These hallmark cancer phenotypes include sustained proliferation, evasion of growth suppression, evasion of the immune system, promotion of inflammation, activation of invasion and metastasis, induction of genomic instability, immortal replication, induction of angiogenesis, deregulation of cellular energetics, and resistance to cell death.² Cancer genes in which mutation confers a growth advantage are classified as oncogenes or TSGs. Oncogenes, when activated through mutation in recurrent hotspots, drive constitutive activation of cell signaling pathways accelerating the cell birth rate. TSGs, when mutationally inactivated, are no longer able to promote cell death and thereby decrease the cell death rate. This model has been well characterized in colorectal cancer in which mutations in the *APC* tumor suppressor have been shown in most cases to drive adenoma formation. Additional mutations in cancer genes comprising proliferative, cell cycle, and apoptosis pathways then result in the formation of malignant tumors capable of invasion and metastasis.^{3,4} Multiple other cancers have also been shown to follow this model, although we now know that there are many disparate evolutionary paths to malignancy even within the same cancer type ([Figure 1](#)).

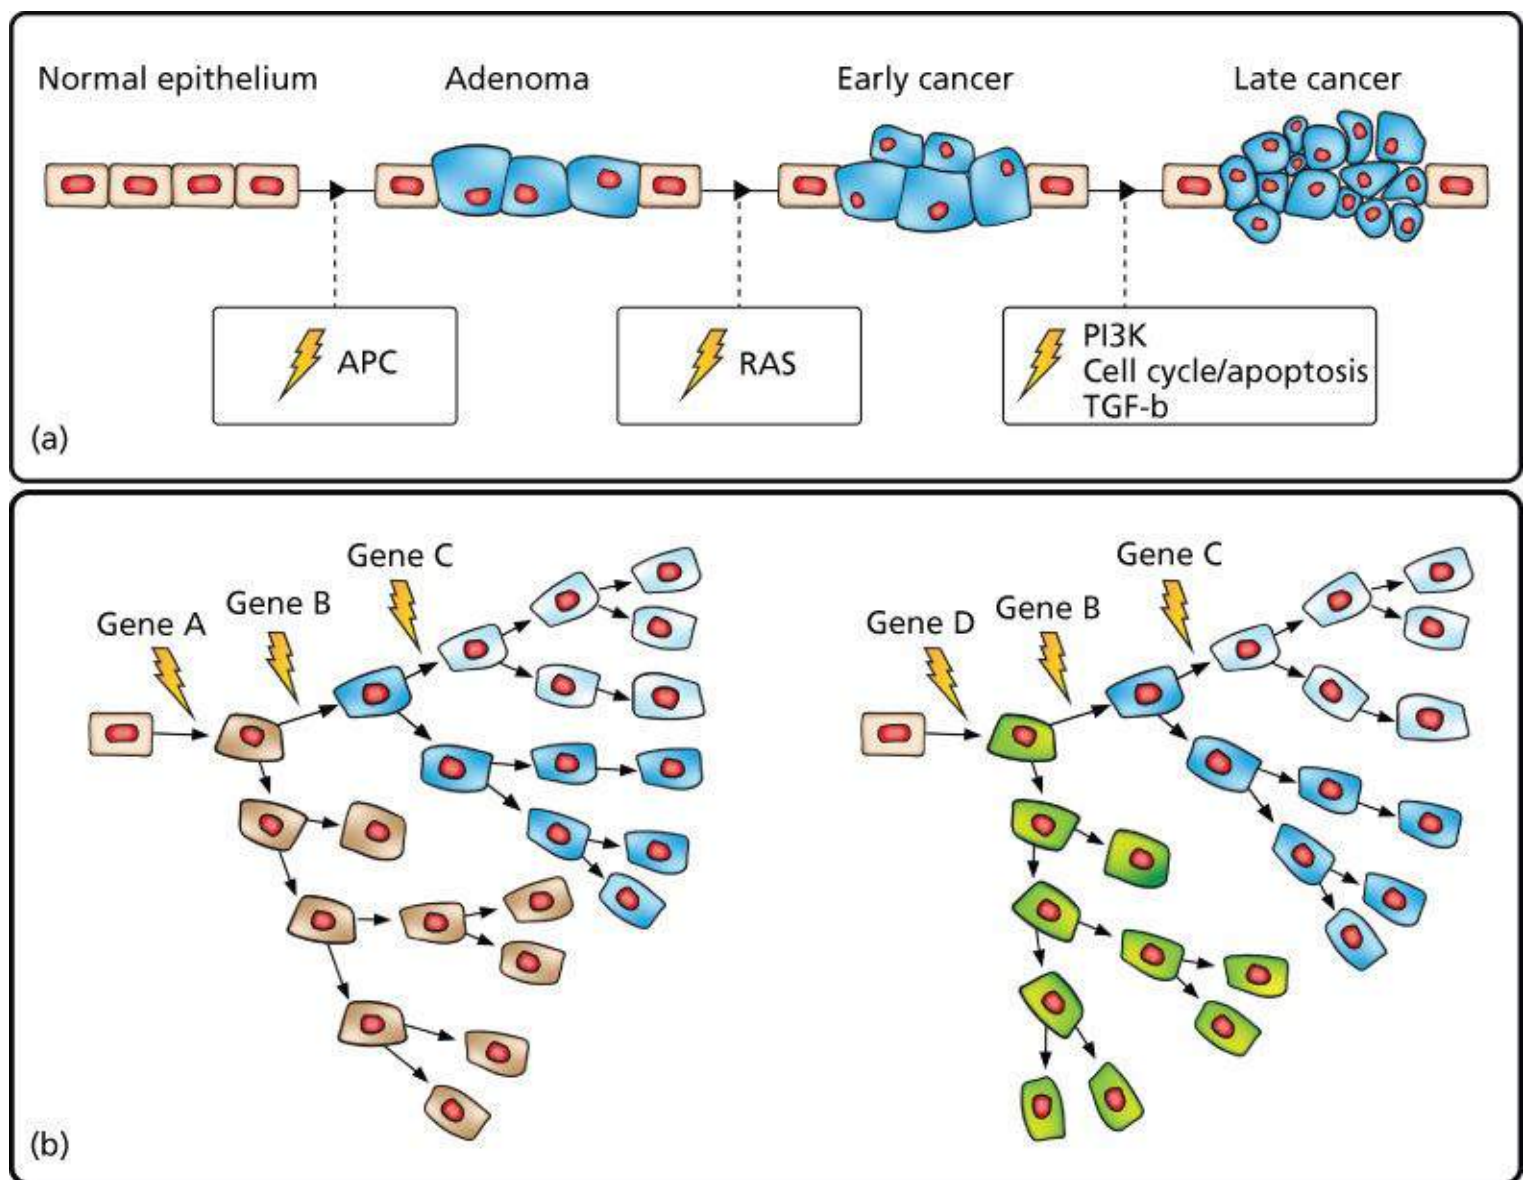

Figure 1 Cancer results from the stepwise accumulation of diverse, branching mutations. (a) “Vogelgram” model of progressive development of colorectal cancer.³ Inactivation of the tumor suppressor *APC* is commonly observed in colorectal cancer precursor lesions. Subsequent mutational activation of the *RAS* oncogene is associated with transition from early adenoma to early cancer. Progressive accumulation of molecular alterations eventually leads to a malignant tumor that can invade the basement membrane and metastasize to lymph nodes and distant organs. (b) Expanded model depicting disparate cancer-initiating mutations as well as stepwise branching evolution in which cells accumulate secondary mutations followed by clonal expansion leading to both inter- and intratumoral heterogeneity.

While some mutations in cancer genes occur in the germ line and are heritable, the majority (90%) arise sporadically in somatic tissues over an individual's lifetime (i.e., they are tumor specific) owing to replication error, genotoxic stress, and/or environmental damage.⁵ These mutations may result from subtle sequence alterations (single-base substitutions and insertions or deletions of one or a few bases), changes in chromosome copy number (amplification, deletion, chromosome loss, or duplication), or changes in chromosome structure (inter- and intrachromosomal translocation, inversion, or other types of rearrangement). For the remainder of this chapter, we will refer to these alterations as somatic single nucleotide variants (SNVs), copy number variants (CNVs), or structural variants (SVs). Classic examples of SNVs, CNVs, and SVs are shown in [Figure 2](#) and include an activating missense SNV in *NRAS* (one of the most commonly mutated oncogenes), an inactivating homozygous deletion CNV in one of the most commonly inactivated tumor suppressors *TP53*, and an activating translocation SV involving *BCR* and

ABL. Epigenomic modifications of cancer genes can also significantly alter gene function. These modifications of DNA, while not altering the DNA sequence itself, can include DNA methylation changes, chromatin modifications, or noncoding RNA-dependent gene regulation that may be heritable and play a role in tumorigenesis. This increasingly important area of study will be discussed in other chapters. We will focus here on DNA sequence-altering mutations.⁶⁻⁹ In this chapter, we use specific examples to highlight the state of cancer genomics knowledge by describing current methods in genomic analysis, compiling results from landmark cancer genomic studies, and assessing the role of cancer evolution in determining its clinical management. We then conclude with a detailed case study of melanoma genomics, evolution, and genomics-guided medicine.

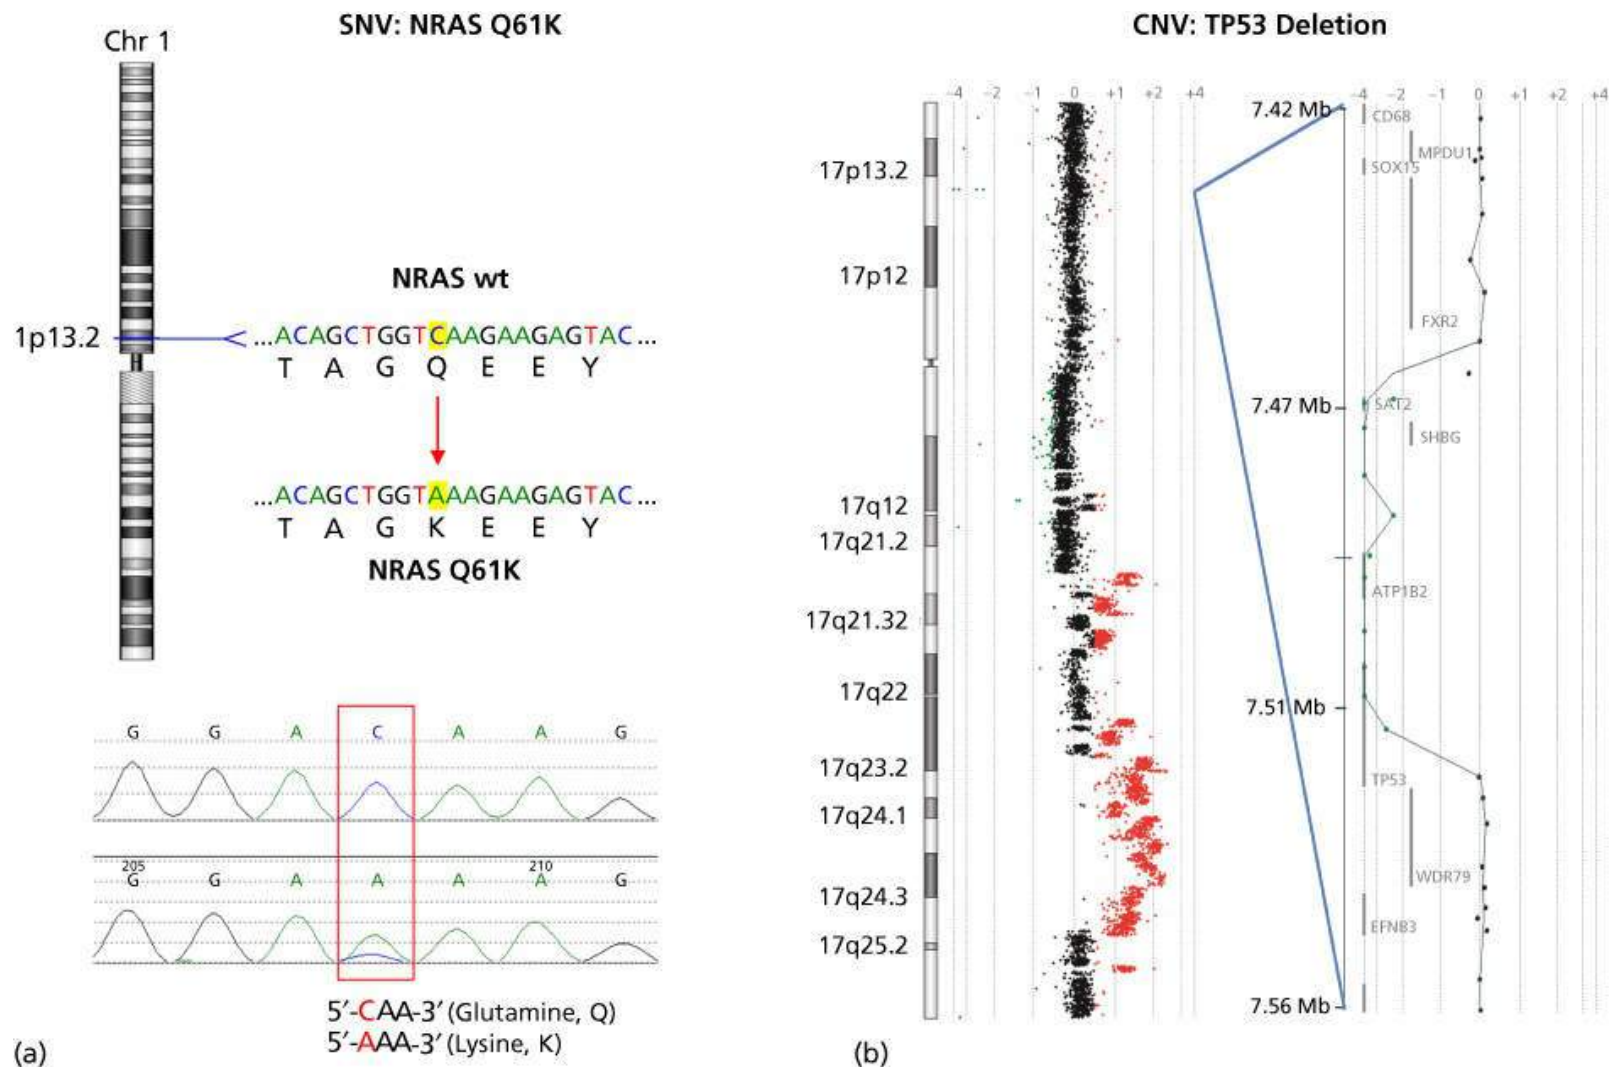

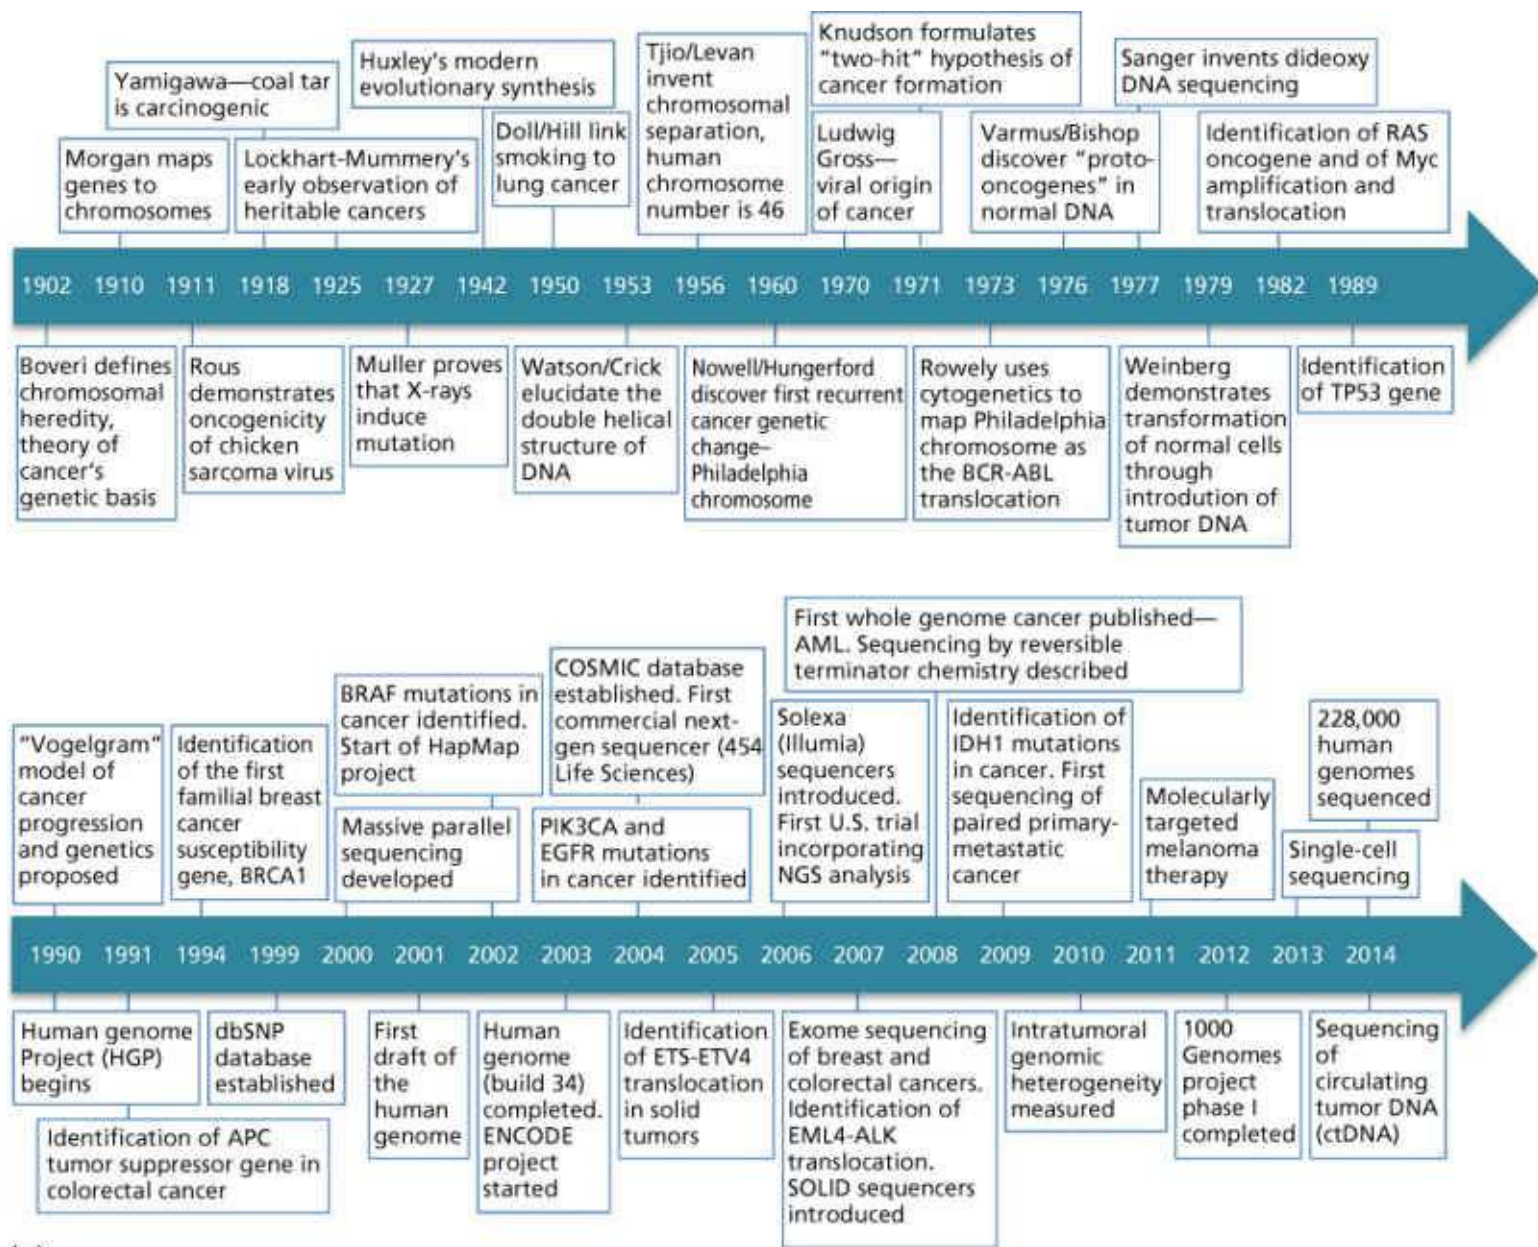

Figure 2 Examples of cancer mutation types. (a) The *NRAS* oncogene, located on chromosome 1, is commonly mutationally activated in diverse cancers. A single nucleotide variant (SNV) results in a codon alteration and substitution of lysine (K) for glutamine (Q) at amino acid 61—Q61K (top figure). Shown below is the chromatogram from Sanger sequencing analysis of a tumor sample harboring the *NRAS* Q61K mutation. (b) CGH log₂ ratio data are plotted for chromosome 17 (left), as well as a focal region of homozygous deletion with a breakpoint within the *TP53* tumor suppressor (right). Regions of DNA copy loss are plotted to the left of the axis and regions of gain are plotted to the right. Individual log₂ ratio data (dots) and log₂ ratio moving average (line) are shown. (c) Schematic of the DNA translocation that occurs between the genes *BCR* and *ABL*, leading to the formation of the *BCR-ABL* gene fusion known as the Philadelphia chromosome (left). Shown on the right is interphase and metaphase FISH detection of the t(9;22) *BCR-ABL* gene fusion using fluorescently labeled genomic probes for *BCR* (green) and *ABL* (red). Note that the fusion of *BCR* and *ABL* probes results in a yellow signal indicating colocalization of the red and green probes as a result of the t(9;22).

The history and methods of cancer genomics

The early history of cancer genetics

The elucidation of cancer's genetic etiology and breadth of its diversity has paralleled seminal advances in genetics and genetic technology ([Figure 3a](#)). Many landmark studies in the late nineteenth and early twentieth century laid the groundwork for cancer genomics—development of the theory of evolution by natural selection,¹⁰ discovery of heritable biological units,¹¹ identification of chromosomes,¹² chromosomal heredity^{13, 14} and chromosomal genes,¹⁵ and modern evolutionary synthesis linking biology, genetics, and evolutionary theory.¹⁶ The subsequent discovery of DNA's structure then provided a framework for understanding the genetic code and the mechanism for molecular transmission of genetic information.¹⁷ Meanwhile, reports of heritable breast and colorectal cancers had arisen¹⁸ and cancer was increasingly understood to be able to be caused by chemical agents such as coal tar¹⁹ and cigarette smoke,²⁰ physical agents such as radiation,²¹ and biological agents such as viruses.²² Discovery that these carcinogenic agents were also mutagenic drove speculation that cancer was a disease of mutation. Ultimately, although cancer had been suggested by some to be a chromosomal disease or a disease of mutation, the concept of cancer as a genetic disease did not gain traction until later in the twentieth century when cytogenetic and sequencing technology alongside experimental transformation of normal cell lines with oncogenes enabled assessment of cancer gene mutations at the molecular level and establishment of their causal role in tumorigenesis. Some of these landmark studies are shown in [Figure 3a](#).

Molecular cytogenetics: Identification of recurrent chromosomal alterations in cancer

Mid-twentieth century developments in the field of cytogenetics such as chromosome staining in fixed leukocytes from peripheral blood finally enabled empirical observation of the chromosomal complement of a cell.^{23, 24} Using this approach, Nowell was the first to discover a specific recurrent genetic change associated with a cancer type—the “Philadelphia chromosome” fragment occurring in nearly all evaluated cases of chronic myelogenous leukemia (CML).²⁵ Over a decade later, Rowley then used chromosome banding to map the components of this fragment, determining the Philadelphia chromosome to be a balanced reciprocal translocation between chromosomes 9 and 22.^{26, 27} These discoveries drove a search for recurrent structural aberrations both within and across cancer types. They led to identification of characteristic translocations in sarcomas, leukemias, and lymphomas. However, most carcinomas were found to possess few recurrent alterations, instead displaying great variety in the number and type of chromosome aberrations.²⁸

After Nowell and Rowley's discoveries, rapid innovation in chromosomal banding and spectral karyotyping (SKY) allowed progressively detailed views of chromosome aberrations in cancer cells using techniques based on fluorescence *in situ* hybridization (FISH), which relies on fluorescent DNA probes that hybridize to specific chromosomal regions.^{29–38} Approaches for genome-wide cytogenetic analysis have also been developed including SKY,²⁹ multiplex-fluorescence *in situ* hybridization (M-FISH),³⁹ chromosome microdissection,³⁸ and comparative genomic hybridization (CGH).⁴⁰ CGH is a particularly powerful fluorescent molecular cytogenetic technique for screening genome-wide chromosomal copy number changes in tumor genomes.

Novel approaches to printing nucleic acids on slides (microarrays) soon revolutionized molecular cytogenetics by reducing cost and increasing throughput. Array comparative genomic hybridization (aCGH) originally involved spotting large probes (large-insert clones or artificial chromosomes)^{41, 42} onto slides in intervals (1–3 Mb resolution) across chromosomal regions. Now, high-resolution genome-wide platforms consisting of small, customizable oligonucleotide probes^{43, 44} have demonstrated increased throughput and sensitivity in characterizing cancers such as breast,^{45–47} melanoma,^{48–50} B-cell lymphoma,^{51, 52} and many others. Similarly, oligonucleotide arrays designed to genotype thousands of single nucleotide polymorphisms (SNPs) are useful for characterizing tumor genome complexity with rapid genotyping of over millions of SNPs now possible (Affymetrix, Illumina). Similar to CGH arrays, SNP arrays quantitate locus-specific hybridization signal and can be used to estimate copy number or loss of heterozygosity (LOH).^{53–55} Notable cancer studies incorporating SNP arrays include genotyping of the NCI-60 cell line panel⁵⁶ as well as lung cancer,⁵⁷ AML,^{55, 58} neuroblastoma,⁵⁹ melanoma,^{56, 60, 61} basal cell carcinoma,⁵⁴ breast cancer,⁶² colorectal cancer,^{62–64} glioblastoma,^{65, 66} and pancreatic cancer.⁶⁷

Both SVs and CNVs can be characterized using the tools of molecular cytogenetics and cytogenomics. Translocations are some of the most common SVs observed in cancer and, as in the case of the Philadelphia Chromosome in CML, are signature aberrations for many liquid cancers and sarcomas. They

involve the movement of a chromosomal segment from one position to another, either within the same chromosome (intrachromosomal) or a different chromosome (interchromosomal). Other types of SV include chromosomal deletions, duplications, inversions, insertions, rings, and isochromosomes. These SVs may result from errors in double-stranded break (DSB) repair or other means of intra- or interchromosomal recombination.⁶⁸ Translocations and other SVs can either activate oncogenes (such as when the *ABL* tyrosine kinase is constitutively activated by fusion with the *BCR* gene) or inactivate TSGs (such as when translocations involving the *TP53* tumor suppressor interrupt the gene and lead to loss of function). CNVs involving a gain or loss of an entire chromosome are some of the simplest and most common chromosomal aberrations. They result from defective chromosomal segregation. The functional consequence of CNVs can be difficult to establish because the aberrations may extend over tens of thousands of megabases and may affect hundreds to thousands of genes. It has been easier to establish the cancer relevance of more limited regions of chromosomal gain and loss, created by amplification or deletion, as these smaller aberrations have been shown to alter the dosage of known oncogenes or TSGs. Classic examples of oncogene amplification in solid tumors discovered through molecular cytogenetics include *ERBB2* in breast cancers and *MYC* in a variety of tumor types, while loss of specific regions of the genome is often associated with loss of TSGs such as *TP53*, *RB1*, *PTEN*, and *CDKN2A*. Such deletions of TSGs are critical for promotion of tumorigenesis both in cases of heritable cancers in which germline mutation of a single TSG allele must be coupled with loss of the wild-type allele as well as in sporadic cancers in which both alleles must be inactivated.

Molecular genetics: Identification of recurrent sequence alterations in cancer

While some molecular cytogenetic techniques are capable of detecting chromosomal breakpoints at base pair resolution, advances in molecular genetics were required to allow detection of subtle sequence changes in DNA itself. These advances were enabled by developments in molecular cloning and invention of the polymerase chain reaction (PCR) capable of generating the millions of DNA copies necessary for detection of these mutations.⁶⁹ Coupled with the Sanger sequencing method based on dideoxynucleotide chain termination and agarose gel electrophoresis,⁷⁰ progressive advances in this methodology, including fluorescently labeled nucleotides, capillary electrophoresis, paired-end sequencing, shotgun sequencing, and improved laboratory automation have allowed scaling to sequence entire genomes. This technology enabled the Human Genome Project (HGP), launched in 1990 as a \$3 billion dollar publicly funded international collaboration. The rough draft of the human genome, covering 94% of the genome, was published in 2001^{71, 72} with the complete draft finished ahead of schedule in 2003.⁷³ In addition to establishing genome-wide ground truth for the locations, organization, and sequences of all human genes, the technical and informatic lessons learned in the course of this project made possible the first ambitious cancer mutation screens on the level of entire gene families^{74–77} and the majority of the protein-coding genome.^{62, 65–67} Nonetheless, genome sequencing projects using Sanger-based sequencing continued to be expensive and logistically challenging and thereby limited the application of this approach toward large-scale characterization of cancer genomes until the advent of massively parallel sequencing.

Gene expression microarrays: Cancer signatures and pathways

Microarrays such as those employed in aCGH studies were originally developed for high-throughput gene expression studies. Complementary DNA (cDNA formed from reverse transcription of RNA) and later oligonucleotide microarrays were implemented in high-throughput quantitation of mRNA transcripts. Advances in this technology paralleled improvements in automated Sanger sequencing in the 1990s and

the turn of the millennium. They provided some of the first insights into gene signatures and pathways correlating to specific cancer subtypes. A parallel method, serial analysis of gene expression (SAGE) was developed to enable high-throughput digital quantitation of transcripts.⁷⁸ While originally designed to assay the expression of individual genes, gene expression profiling methods were later adapted to profile and map global transcription on the exon and genome levels,⁷⁹ as well as to profile the expression of mature human micro-RNAs (miRNAs).⁸⁰ Gene expression patterns have been widely used to subclassify cancers into homogeneous entities not easily discernible using traditional histopathologic or cytogenetic techniques, for instance, in diffuse large B-cell lymphoma (DLBCL),^{81, 82} lung cancer,⁸³ melanoma,⁸⁴ and breast cancer.^{85, 86} In some instances, subgroups have been shown to represent distinct disease states responding differently to standard therapies. Gene expression profiles have also been widely mined to specifically identify sets of genes predictive of disease progression, response to therapy, or metastasis,^{87–89} as well as the presence of specific recurrent cytogenetic abnormalities,^{90–92} or gene mutations.^{93–96} Although advances in massively parallel sequencing have largely supplanted microarrays in sensitivity and robustness, if not cost and clinical readiness, gene expression profiling continues to play a significant role in cancer biology and medicine. In fact, commercially available clinical tests based on microarray signatures (OncoType DX and MammaPrint) are available for breast cancer profiling.

Massively parallel sequencing: Charting cancer genome landscapes

Explosive growth in our understanding of cancer genomics has been built on the backbone of the advances that emerged from the completion of the human genome at the turn of the twenty-first century. However, although these advances had driven the cost of one genome down from an estimated \$1 billion to the \$1 million mark at the time of the HGP's completion, this extraordinary cost nonetheless held back large-scale genomic studies.⁹⁷ Thus, the National Human Genome Research Institute initiated a \$70 million sequencing technology program intended to drive the price down to the \$1000 mark. The cost of a human genome sequence now lies slightly below \$2000 and is steadily approaching \$1000 ([Figure 3b](#)).

The quest for the \$1000 genome required fundamental rethinking of the approach to DNA sequencing. Sanger sequencing, even in its most expert execution, faced insurmountable bottlenecks including (1) the need for molecular cloning steps and/or individual PCR reactions to generate sequencing templates and (2) every sequencing reaction can only accommodate a relatively small genomic region. Therefore, cloning/amplifying and sequencing many regions, even when run in parallel in multiwell plates, requires large amounts of materials, equipment, and analysis time. The paradigm shift in sequencing cost and throughput was brought about by the invention of approaches that allowed generation of sequencing templates without cloning or individual PCR reactions, immobilization of entire sequencing libraries in a single reaction chamber, and massively parallel sequencing of millions of templates in that chamber. The ability of this approach to collect data on clonal populations derived from single DNA molecules additionally provides great power for detection of rare variants from heterogeneous tumor samples. These rapid, accurate, and inexpensive approaches are also referred to as next-generation sequencing (NGS).

Key inventions in the 1990s and early 2000s such as sequencing-by-synthesis, pyrosequencing, colony sequencing, and emulsion PCR enabled development of the first NGS platforms.^{98–101} The first such platform was developed by Lynx Therapeutics (later acquired by Solexa) in 2000, although it did not achieve widespread adoption.¹⁰² 454 Life Sciences offered the first commercially available system—the 454 FLX Pyrosequencer—in 2004,¹⁰³ followed by the Solexa (now Illumina) Genome Analyzer in 2006, and the Supported Oligonucleotide Ligation and Detection (SOLiD) System from Applied Biosystems in 2007 that also incorporated polony sequencing.^{104, 105} The Solexa system was used in 2008 to sequence

James Watson's genome within a single laboratory in only 2 months.¹⁰⁶ These platforms at last made the possibility of sequencing and assembling multiple cancer genomes a reality as evidenced by the characterization of genome-wide SVs in two lung cancer genomes.¹⁰⁷ This study utilized a paired-end approach, demonstrating strikingly complex genomic rearrangements including those resulting in previously unreported fusion transcripts. Importantly, this study also demonstrated that DNA copy number can be estimated by the relative local abundance of genomic fragments sequenced, providing sensitivity comparable to aCGH platforms while at the same time providing DNA sequence information. Massively parallel sequencing methods have now dramatically decreased the cost of sequencing while greatly increasing throughput. Presently, sequencing of 500 billion bases (e.g., sequencing the equivalent of 156 human genomes or 156X average genome coverage) within a single 6-day commercial instrument run is standard, with throughput still steadily increasing.

Many massively parallel sequencing platforms exist today and are reviewed in more detail elsewhere.¹⁰⁸ [Table 1](#) provides an overview of some of the most common platforms in use today. They have been adapted to a variety of purposes ranging from diverse DNA sequence, copy number, and structural analyses to transcriptomics and epigenomics. DNA sequencing applications include *de novo* sequencing, such as the first such application in determining the previously unknown genomic sequence of *Acinetobacter baumannii*.¹⁰⁹ In addition, resequencing of human genomes is performed in order to characterize normal variation or variation in specific disease states such as cancer. Resequencing is undertaken by mapping NGS sequencing reads to the reference genome and identifying differences between the sample and reference.⁶⁵ Of course, it is not always necessary or informative to assess whole genomes, and thus, a number of target-enrichment strategies have been conceived that enable more cost-effective and focused analyses. The first of these—direct genomic selection—was based on hybridizing defined genomic regions to biotinylated BACs and capturing these sequences on streptavidin beads before sequencing.¹¹⁰ New enrichment methods such as hybridization-based capture (using oligonucleotides either in solution or on microarrays), highly multiplexed PCR, and microdroplet PCR are common.^{111–114} A relatively small fraction of the human genome has been functionally characterized, and therefore, it is often most expedient to assess the 1% of the genome containing coding regions (all exons—the exome). Thus, a number of commercially available human exome and other targeted capture kits (such as panels of common cancer genes) are available. This ability to target specific genes to enable rapid, accurate, affordable sequencing is aiding not only in biological discovery but also in clinical laboratory testing by enabling practical complex testing.

Table 1 Massively parallel sequencing platforms

Company	System platform ^a	Latest release	Template preparation	Sequencing chemistry	Maximum read length	Bases per run (Gb)	Accuracy	Run time	Applications
Illumina	Illumina HiSeq 4000	2015	Emulsion PCR	Reversible terminator	150	1500	>99%	<1–3.5 days	WGS, E-S, RNA-S, T-S, C-S, M-S
	Illumina HiSeq 3000	2015	Emulsion PCR	Reversible terminator	150	750	>99%	<1–3.5 days	WGS, E-S, RNA-S, T-S, C-S, M-S
	Illumina HiSeq 2500	2014	Solid-phase	Reversible terminator	125	500	> 99%	6 days	WGS, E-S, RNA-S, T-S, C-S, MG, DN-S
	Illumina HiSeq X (Ten/Five)	2014	Solid-phase	Reversible terminator	150	1800	>99%	<3 days	WGS
	Illumina MiSeq	2014	Solid-phase	Reversible terminator	300	15	>99%	4 h	E-S, RNA-S, T-S, C-S, DN-S
	Illumina NextSeq 500	2014	Solid-phase	Reversible terminator	150	120	>99%	30 h	WGS, E-S, RNA-S, T-S, C-S, M-S
Life Technologies	IonTorrent Personal Genome Machine	2014	Emulsion PCR	Proton detection	400	2	>99%	2 h	Microbial WGS, E-S, RNA-S, T-S, C-S, M-S
	IonTorrent Proton	2014	Emulsion PCR	Proton detection	200	10	>99%	2–4 h	Microbial WGS, E-S, RNA-S, T-S, C-S, M-S
	SOLiD	2014	Emulsion PCR	Sequencing by ligation	75	120	99.99%	8 days	WGS, DN-S, E-S, RNA-S, T-S, C-S, M-S
Pacific Biosciences	PacBio RS II	2014	Single molecule	Real-time sequencing	15,000	3	85%	20 min	DN-S, T-S
Roche	454 GS Junior	2014	Emulsion PCR	Pyro-sequencing	400	0.07	>99%	10 h	Microbial DN-S, E-S
	454 GS FLX	2014	Emulsion PCR	Pyro-sequencing	700	0.7	100%	24 h	Microbial DN-S, E-S

^a Additional versions are available for some models.

Cancer genome landscapes

Landmark cancer genomic studies

Despite commonalities observed within and between individual types of cancer in historic genetic studies, the high-throughput genomic studies of the past decade have provided a much more complex view of cancer. The first large-scale cancer mutation screens implemented high-throughput Sanger sequencing of individual genes such as *BRAF* in large cohorts^{115, 116} or focused on gene families such as protein kinases in diverse cancer types.^{74–77, 117, 118} Notably, such screens have led to the identification of activating *BRAF* mutations in a large percentage of human melanomas¹¹⁵ and nevi,¹¹⁹ as well as *ERBB2* mutations in human breast cancer.¹¹⁸ The first cancer gene panels (110 exons from 12 target genes) were completed in 140 acute myeloid leukemia (AML) samples in 2003.¹²⁰ This study identified six previously described and, strikingly, seven previously unknown coding mutations in AML genomes. Soon after, results of Sanger-based exome sequencing of 13,023 genes in 11 breast and 11 colorectal cancers were published in 2006.¹²¹ This study revealed a surprising total of 189 frequently mutated genes with an average of 90 mutant genes per tumor, although only a subset was thought to be causally related to tumorigenesis or progression (an average of 11 per tumor). In a follow-up analysis of an additional 7000 genes in the same tumors, it was confirmed that a handful of commonly mutated genes (the “mountains” in the genomic landscape) existed among a large number of less frequently mutated “hills”. In 2008, four Sanger-based exome projects additionally characterized over 20,000 genes in glioblastoma multiforme^{62, 65, 66} and pancreatic cancer.⁶⁷ Amidst an average of 63 and 47 mutations per pancreatic tumor or glioblastoma, these studies identified novel genes bearing low-frequency mutations such as *IDH1* and *PIK3R1* mutations in glioblastoma. Strikingly, they uncovered few unknown genes recurrently mutated at high rates. In these and future studies, it was found that the high-frequency mountains had already largely been identified using the low-throughput genetic technologies of the past decades. The growing challenge has since been interpretation and characterization of the many hills. However, these studies all show that multiple genes within core signaling pathways, rather than single genes, tend to be mutated in these cancers, suggesting an avenue for treating tumors based on aberrant pathways instead of individual aberrant genes.

Following these landmark studies, the number, breadth, and size of cancer genome projects rapidly accelerated in keeping with the advent of massively parallel sequencing. The first cancer whole genome sequences generated by massively parallel sequencing were those of two lung cancers published in 2008¹⁰⁷ followed shortly by those of individual AML cases published in 2008 and 2009.^{122, 123} These studies focused on assessment of genome-wide SVs and missense mutations, respectively. The first analysis of paired primary and metastatic tumors enabling genome-wide assessment of evolution was conducted in breast cancer in 2009, identifying both shared and exclusive mutations in each sample.¹²⁴ The first studies to systematically assess genome-wide mutations of all classes, published in 2010, were conducted in the melanoma cell line COLO-829¹²⁵ and a small cell lung cancer cell line.¹²⁶ These studies uncovered an extraordinary mutation burden (over 33,000 mutations in melanoma and 23,000 in lung) and mutational signatures supporting ultraviolet (UV) radiation etiology and tobacco smoke etiology in melanoma and lung, respectively. Discovery has since continued at a rapid pace and, as discussed later,

large genomic analyses having been completed in all common cancers, many rare cancers, primary/recurrent/metastatic matched cohorts, and even cancers undergoing treatment.

Large-scale cancer genomic studies have also been powered by national and international consortia. The US National Cancer Institute (NCI) and National Human Genome Research Institute (NHGRI) launched a large collaborative project in 2005, the Cancer Genome Atlas (TCGA; see <http://cancergenome.nih.gov/>). Using multiple state-of-the-art genomic technologies to comprehensively identify all genomic alterations associated with multiple cancer types, the TCGA effort began with large pilot studies of glioblastoma multiforme⁶⁵ ovarian cancer,¹²⁷ and squamous cell lung cancer.¹²⁸ TCGA studies have since included colorectal,¹²⁹ breast,¹³⁰ endometrial,¹³¹ AML,¹³² clear cell renal cell,¹³³ expanded glioblastoma,¹³⁴ urothelial bladder,¹³⁵ lung adenocarcinoma,¹³⁶ gastric,¹³⁷ chromophobe renal cell,¹³⁸ papillary thyroid,¹³⁹ head and neck squamous cell,¹⁴⁰ low-grade glioma,¹⁴¹ cutaneous melanoma,¹⁴² and a suite of 18 pan-cancer studies.¹⁴³ Across 34 cancer types, data have been collected from more than 11,000 cases. Similarly ambitious studies have been undertaken by members of the International Cancer Genome Consortium (ICGC; see <http://icgc.org>)¹⁴⁴ launched in 2010 to comprehensively catalog all genomic aberrations associated with at least 50 different cancers. This consortium currently encompasses 55 projects covering 33 cancer types with over 13,000 donors and has produced publications on bisulfite sequencing techniques,^{145, 146} DLBCL,¹⁴⁷ Burkitt lymphoma,¹⁴⁸ X chromosome hypermutation,¹⁴⁹ signatures of mutational processes,¹⁵⁰ and primary CNS lymphoma.¹⁵¹ The ultimate success of these comprehensive, large-scale projects will continue to rapidly advance our understanding of cancer genetics and genomics and will potentially revolutionize our approach to the diagnosis and treatment of cancer.

Cancer genomic data repositories and analysis tools

Data generated by the TCGA, ICGC, and other curated genomic repositories are publicly available. Systematic analysis of these data remains challenging, but improved web-based tools for both novices and experienced bioinformaticians are greatly democratizing cancer genomics research ([Table 2](#)). One of the oldest and most comprehensive resources for mining such data is the Catalogue of Somatic Mutations in Cancer (COSMIC; see <http://www.sanger.ac.uk/genetics/CGP/cosmic>) maintained by the Wellcome Trust Sanger Institute Cancer Genome Project.¹⁵² COSMIC is manually curated from publications and therefore entails a broad reach across targeted studies and genome projects (currently more than 20,000). The current build (August 2014) describes over 2 million mutations in more than 1 million samples encompassing 12,000 cancer genomes. In addition to SNVs, it details over 6 million noncoding mutations, 10,000 fusions, 61,000 SVs, 700,000 CNVs, and 60 million expression variants. These data are easily queried using key words or by gene or cancer type. COSMIC also includes more advanced tools that are in some cases linked to other databases. These include a detailed census of all human genes that have been causally linked to tumorigenesis (Cancer Gene Census; see <http://www.sanger.ac.uk/genetics/CGP/Census>)^{5, 153} as well as tools to assess mutation signatures and drug sensitivity. Another highly versatile data portal is the cBioPortal for Cancer Genomics maintained by Memorial Sloan-Kettering Cancer Institute.¹⁵⁴ This portal primarily contains highly processed Cancer Cell Line Encyclopedia (CCLE) and TCGA data sets but also provides a powerful, intuitive web interface enabling queries by gene or cancer type as well as more advanced analysis through an application programming interface and also integration with R and MATLAB. A similar portal is available for ICGC data (see <http://dcc.icgc.org>).

ICGC	Visualization tool; genomic, transcriptomic, and epigenomic characterization of 50 tumor types	http://dcc.icgc.org
MethylCancer	Methylation database; interprets the correlation of methylation, gene expression, and cancer biology	http://methycancer.psych.ac.cn
SomamiR	Archive of experimentally validated somatic mutations in noncoding RNA	http://compbio.uthsc.edu/SomamiR
UCSC Cancer Genome Browser	Multipurpose data viewer incorporating multiple data types including clinical information	https://genome-cancer.soe.ucsc.edu

While the above-mentioned portals enable advanced analysis with only modest bioinformatics training,

additional repositories exist for advanced users to access various levels of raw data. The Cancer Genomics Hub (CGHub), hosted by the University of California Santa Cruz (UCSC), is a secure central repository for data generated through the NCI including TCGA, CCLE, and Therapeutically Applicable Research to Generate Effective Treatments (TARGET).¹⁵⁵ The European Genome-phenome Archive (see <http://ega.crg.eu>) similarly collects and distributes sequencing and genotyping data, primarily cancer data emerging from the ICGC. Data repositories and analysis tools are also available for other data types. Cytogenetic aberrations and fusions observed in over 65,000 human tumors have been compiled and are maintained online (The Mitelman Database of Chromosome Aberrations in Cancer at the US National Cancer Institute [NCI] Cancer Genome Anatomy Project [CGAP] Web site: <http://cgap.nci.nih.gov>).²⁸ Data from numerous gene expression microarray studies are warehoused by multiple entities, including the US National Center for Biotechnology Information (NCBI Gene Expression Omnibus; see <http://www.ncbi.nlm.nih.gov/geo/>) and the European Bioinformatics Institute (EBI Array Express; see <http://www.ebi.ac.uk/microarray-as/ae/>). Additional data repositories and web resources are outlined in Table 2.

The vast and varied landscapes of human cancers

Although few new mutational “mountains” have been discovered in the past 10 years, systematic study of cancer genomes has revealed many new “hills” as well as mutational processes and dysregulated pathways. The total mutation burden itself can reflect cancer etiology and have bearing on clinical course. This burden is much more variable than originally anticipated. In some pediatric cancers such as rhabdoid tumors¹⁵⁶ and small cell carcinoma of the ovary,¹⁵⁷ cases with only a single coding SNV have been discovered, while leukemias such as AML bear a median of nine coding SNVs (Figure 4). Conversely, cancers with mutagenic etiology such as bladder, lung, and melanoma bear high mutation rates with medians of 148, 217, and 254 coding SNVs, respectively, while tumors with mismatch repair defects can contain thousands of coding SNVs. Distinct mutational signatures can also reflect these external and internal mutagenic factors such as enrichment for C > T transition in dipyrimidines as seen in cancers from UV-damaged sites.¹⁵⁰ Overall, coding SNVs are generally more common in cancers than coding CNVs and SVs, although broad variability in CNV and SV profiles also exists across cancer types. Thirty-seven percent of cancers experience whole-genome doublings with a quarter of most solid tumor genomes containing large-scale chromosomal variations and 10% containing focal CNVs. Over 140 genomic regions have been found to contain recurrent CNVs, only 38 of which contain known cancer genes.^{158–160} Most solid tumors also contain dozens of SVs although many of these occur in regions that do not contain genes and are likely passengers. Whole genome sequencing has also recently uncovered “chromothripsis” events, occurring in 2–3% of cancers when errors in chromosome segregation during mitosis lead to shattering of a single or a few chromosomes and massive rearrangement in a single cell generation.^{161–163}

Figure 4 Number of coding single nucleotide variants (SNVs) per tumor type across a selection of human cancers. DNA sequencing data obtained from published TCGA studies were used to calculate the distribution and median number of coding SNVs mutations in each cancer type. Colored bars indicate the 25% and 75% quartiles. Outlier values (values below $Q1 - 1.5 \times IQR$ or above $Q3 + 1.5 \times IQR$) are not shown and asterisks represent studies with more than 10% outliers.

In addition to mutagenic etiology, variability in mutation burden is the likely result of mutation timing, patient age, and the number of divisions that have occurred in precursor cells with mutations accumulating in dividing cells over time, although a “punctuated evolution” model has also been proposed.^{164–166} Ultimately, only a few such mutations can “drive” cancer (driver mutations) insofar as they confer a selective growth advantage on the cells that carry them. Other mutations are “passengers” with no phenotypic effect on cell growth.¹⁶⁷ Several methods have been developed to classify mutations as drivers or passengers based on the pattern and frequency with which they arise across cancers,^{4, 168, 169} but experimental validation is required to confirm the role of these mutations in cancer.

It has been estimated that more than 138 cancer driver genes exist⁴ with 571 genes causally implicated in cancer catalogued in the Cancer Gene Census (see <http://cancer.sanger.ac.uk/census>).⁵ The top 10 most commonly mutated cancer genes are given in Table 3, while cancer genes associated with the most lethal cancers in the United States are given in Table 4. While this vast array of mutations may seem

overwhelmingly complex, particularly from the therapeutic perspective, there is nonetheless some hope. For example, dramatic clinical responses are seen with agents targeting mutant proteins in highly complex cancers such as mutant BRAF and ALK in melanoma and lung cancer.^{194, 195} Further, multiple cancer genes often converge on an individual pathway and may be functionally equivalent. Thus, specific pathways may collectively be subject to genomic aberrations at a frequency far higher than any of their individual gene components. Indeed, most driver genes converge on the hallmark pathways and can ultimately be reduced to those impacting cell differentiation, cell proliferation, cell death, and genomic maintenance.² Thus, the integration of multiple types of genomic data will clearly be necessary to unravel the complexity of somatic cancer genetics.

Table 3 Ten most commonly mutated oncogenes and tumor suppressor genes (TSG) in the COSMIC database

Gene	Classification ^a	SNVs in COSMIC	Homozygous deletions (TSGs) or amplifications (oncogenes) in COSMIC ^b	Fusions in COSMIC
TP53	TSG	28,253	17	1
NPM1	TSG	5224	1	319
CDKN2A	TSG	4836	1046	0
APC	TSG	4351	10	0
PTEN	TSG	3296	275	0
VHL	TSG	2443	2	0
TET2	TSG	2085	3	0
NOTCH1	TSG	2009	12	0
NF2	TSG	1076	12	0
CEBPA	TSG	706	3	0
JAK2	Oncogene	42,963	109	35
BRAF	Oncogene	41,637	105	625
KRAS	Oncogene	32,021	231	1
EGFR	Oncogene	24,189	646	0
FLT3	Oncogene	15,789	102	0
IDH1	Oncogene	8508	11	0
PIK3CA	Oncogene	7983	425	0
KIT	Oncogene	7413	106	0
CTNNB1	Oncogene	5372	12	22
NRAS	Oncogene	4278	31	0

^a Oncogene and TSG status were determined by the 20/20 rule⁴ using sample data in the COSMIC database (see <http://www.sanger.ac.uk/genetics/CGP/cosmic/>).

^b Amplifications shown for samples in which average genome ploidy ≤ 2.7 and total gene copy number ≥ 5 or average genome ploidy > 2.7 and total gene copy number ≥ 9. Homozygous deletions shown for samples in which the average genome ploidy ≤ 2.7 and total gene copy number = 0 or average genome ploidy > 2.7 and total copy number < (average genome ploidy – 2.7).

Table 4 Commonly mutated cancer genes in the deadliest cancers

Cancer ^a	Familial cancer genes	Common somatically mutated genes	References
Breast	BRCA1, BRCA2, PTEN, TP53	PIK3CA, TP53, MAP3K1, GATA3, MLL3, CDH1, PTEN, ERBB2, MAP2K4, CDKN2A, PTEN, RB1	62, 121, 130, 170–172
Colorectal	APC, MSH2, MLH1, MSH6, PMS2, MUTYH, LKB1, SMAD4, BMPR1A, PTEN, KLLN	APC, TP53, KRAS, PIK3CA, FBXW7, SMAD4, TCF7L2, NRAS, ARID1A, SOX9, FAM123B, ERBB2, IGF2, NAV2, TCF7L1	62, 121, 129, 173, 174

Ovarian	STK11, BRCA1, BRCA2	FBXW7, AKT2, ERBB2, TGFBR1, TGFBR2, BRAF, KRAS, PIK3CA, PTEN, ARID1A, BRCA1, MMP-1, BRCA1, BRCA2, MLPA, MAPH	127, 189–192

^a The seven cancers estimated to cause the greatest number of deaths in the United States in 2015.¹⁹³

While it seems possible that the majority of cancer genes have now been discovered, new genes are occasionally implicated in cancer, although at low frequency across many cancer types or at high frequency in a rare and previously uncharacterized cancer. However, most cancers require 5–8 driver mutations based on epidemiological studies¹⁹⁶ and only 3–6 drivers have been found in most cancers with notable exceptions (such as pediatric cases) in which three or fewer drivers have been discovered.⁴ Remaining knowledge gaps are likely due to both technical limitations of sequencing technology and study design as well as limitations in our growing understanding of mutations occurring in noncoding regions of DNA or through epigenomic mechanisms. Clearly, the catalogue of cancer-driving mutations is still incomplete and although the maps of cancer genome landscapes have been broadly charted, much work remains to characterize these vast landscapes in detail in order to guide clinical cancer management.

Clinical implications of cancer genome landscapes

Exhaustive information now available from cancer genomics projects has greatly improved our comprehension of the development, progression, and clinical behavior of human neoplasms. These data and the technology used to generate them are also impacting cancer screening, diagnostics, and treatment. As sequencing costs continue to decline, exome- and genome-wide population screening becomes increasingly viable and it is likely that each patient's personal genome sequence will comprise a key

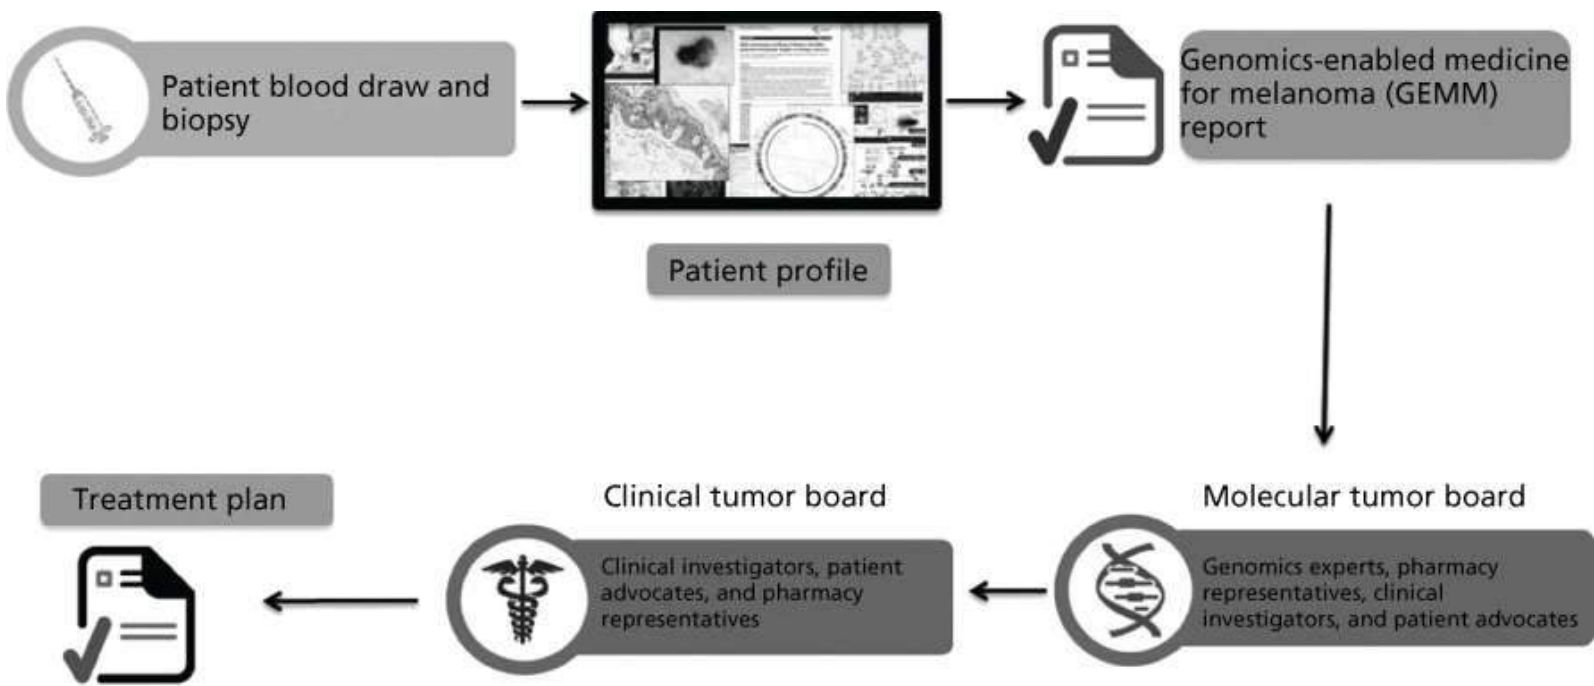

component of their medical record. Such screening may reveal *de novo* mutations that would otherwise go undiagnosed until disease presentation and the power of this approach will grow exponentially as we continue to connect genetic variants to disease phenotypes. The NIH has acknowledged the importance of this new healthcare approach through the establishment of the Precision Medicine Initiative.¹⁹⁷ Targeted Sanger sequencing of small gene panels is already commonly used in familial cancer screening. In cases such as germline *BRCA1/2* or *MLH1/MSH2* mutations, which dramatically increase lifetime risk for breast/ovarian or colorectal cancer, genomic testing can guide clinical decisions about surveillance and prophylactic surgery. Now, NGS-based sequencing of hundreds of genes can be completed at a similar cost and thereby enable detection of lower penetrance rare variants not detectable with smaller panels. For example, in a study of 141 *BRCA1/2*-negative patients with a family or personal history of breast cancer, a panel of 40 additional genes identified 16 patients with pathogenic variants in nine genes other than *BRCA1/2* such as *TP53* and *PTEN*.¹⁹⁸ These findings have shaped new guidelines from the National Comprehensive Cancer Network recommending targeted panels for patients' breast or ovarian cancer family history who are negative for common hereditary mutations.¹⁹⁹ Targeted NGS panels have also shown greater sensitivity and specificity than traditional diagnostic tools in genetic testing of familial cancer genes such as *BRCA1/2*, *TP53*, and *APC* in additional studies.^{170, 200–202} NGS panels may also facilitate differential diagnosis and patient stratification given that the diagnostic yield of NGS panels, exomes, or even whole genomes has been shown in multiple studies to outperform small Sanger-based panels.^{203, 204}

Cancer genetics discoveries have driven targeted drug development since the first report of a recurrent chromosomal abnormality—the BCR-ABL translocation in CML. The selective tyrosine kinase inhibitor imatinib, designed to target the BCR-ABL chimeric fusion gene and its constitutively active tyrosine kinase protein product in CML, was the first successful targeted therapy.^{205–207} The paradigm of targeting cancer-specific mutations to vastly improve the therapeutic index of chemotherapy has now been repeated with dramatic success. Examples include expansion of imatinib to *PDGFR*- and *KIT*-mutated gastrointestinal stromal tumors (GIST) and hypereosinophilic syndromes^{208–210}; dasatinib and nilotinib in primary and imatinib-resistant CML^{211–213}; trastuzumab, a neutralizing antibody targeted to the Her2/ErbB2 tyrosine kinase receptor whose encoding gene *ERBB2* is amplified and overexpressed in 25–30% of breast carcinomas^{214, 215}; sunitinib in renal cell carcinoma, GIST, and pancreatic neuroendocrine tumors^{216–218}; gefitinib and erlotinib with striking efficacy in the 5–10% of lung adenocarcinoma patients with European ancestry and 25–30% of Japanese patients who harbor activating mutations in *EGFR*^{219, 220}; crizotinib in *ALK*-rearranged lung cancer^{221, 222}; vismodegib in basal-cell carcinoma bearing hedgehog pathway mutations²²³; and vemurafenib in *BRAF*-mutant melanoma.²²⁴ Cancer gene mutations have also been associated with innate or acquired resistance to these targeted therapies. For example, amplification of the *BCR-ABL* gene is common in CML patients resistant to imatinib.^{205, 225} Preclinical studies and clinical trials are ongoing for numerous novel therapeutic agents directed against genomic targets in cancer in addition to agents capable of circumventing or treating drug-resistant disease.

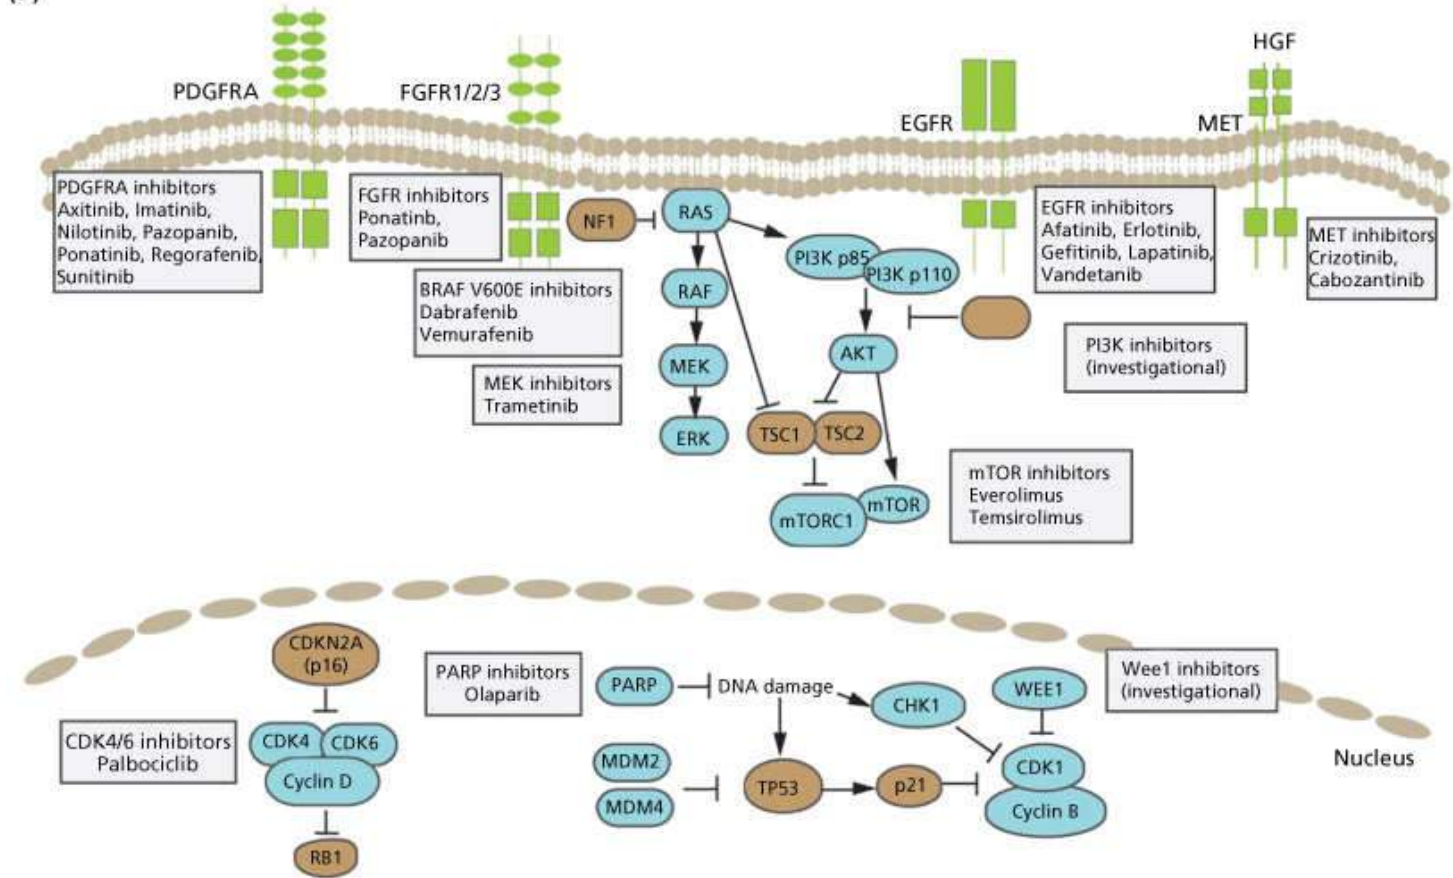

The fundamental goal of oncology practice is recommendation of the most effective treatment supported by scientific evidence for an individual patient. Genomic data would be expected to provide just such data. However, although the HGP was completed in 2003, genomic medicine's entrance into the care stream has been painstakingly slow. In 2010, results from one of the first pilot studies using personalized molecular profiling to guide treatment selection in refractory metastatic cancer were published. Despite considerable challenges including the absence of a precedent for the novel trial design, overall patient attrition, and a diverse pharmacopeia, it was found that in 27% of 68 patients, treatment selection guided by molecular profiling (gene expression microarray analysis) resulted in a longer progression-free

survival than that during the most recent regimen on which the patient had progressed.²²⁶ The next major step in bringing genomic tools to the patient was a novel study combining whole genome sequencing and comprehensive RNA sequencing to individualize treatment of metastatic triple-negative breast cancer (TNBC) patients.²²⁷ TNBC is characterized by the absence of expression of estrogen receptor (ER), progesterone receptor (PR), and HER-2. This study identified somatic mutations in the RAS/RAF/MEK and PI3K/AKT/mTOR signaling pathways that have led to clinical trials combining agents targeting MEK and mTOR genes with encouraging results.

New trial designs, such as those above and including adaptive, basket, and umbrella trials, are aimed at extending individualized therapy to all cancer patients. Multiple large academic observational and interventional trials have now appeared in publication^{228–233} or are ongoing (see <http://clinicaltrials.gov>). These include adaptive trials such as I-SPY 2 (Investigation of Serial Studies to Predict your therapeutic response with imaging and molecular analysis) in which treatment arms are modified in the course of the study based on patient response.²³⁴ Basket trials such as the NCI MATCH trial assign patients with various advanced cancers to treatment baskets based on mutational profiles, then treat with agents matched to their tumor's mutations.²³¹ Umbrella trials are also ongoing in which multiple drugs are studied in a single disease. For example, the ongoing Stand Up To Cancer and the Melanoma Research Alliance Dream Team Clinical trial is assessing molecularly guided therapy in a single-histology patient population that lacks a universal therapeutic target—non-V600 *BRAF* metastatic melanoma. In a nontreatment pilot study (now a randomized treatment study), a combination of whole genome and whole transcriptome sequencing was used to identify molecular aberrations matched to an appropriate clinical treatment from a pharmacopeia comprised standard of care, FDA-approved and investigational agents.²³⁰ The challenge of returning actionable information during a clinically relevant time period is considerable. This includes patient consent, tumor biopsy, quality DNA/RNA extraction, DNA- and RNA sequencing, data integration, report generation, and tumor board review to formulate a treatment plan ([Figure 5](#)). Streamlining this process will be critical to expansion of these tools beyond major academic research centers.

Large-scale genomic characterization of tumors in the context of clinical trials has allowed identification of predictive biomarkers—recurrent genomic alterations that identify patients most likely to benefit from a particular drug. These provide tremendous clinical value by allowing patient stratification to the most relevant treatment option and have been rapidly commercialized. A broadening array of sequencing tests that may aid in diagnosis and treatment decisions is available to oncologists and their patients. Over 100 academic centers and 50 commercial laboratories have made such tests available. Examples of such commercial tests are provided in [Table 5](#). Although cost is still prohibitive for widespread use, expanded panel-, exome-, or whole genome-based sequencing will continue to transform screening and diagnostics in coming years. However, routine clinical use will not only require further cost reduction but also more comprehensive data supporting genomics-correlated clinical outcomes to illustrate the benefit of such testing and off-label drug use. Accordingly, commercial sequencing laboratories will need to acquire FDA and Medicare approval. These data will ensure that insurance companies will cover these tests. Promising signs already include the addition of procedural terminology codes and a preliminary list of 21 sequencing tests included in the fee schedule of the Centers for Medicare and Medicaid Services. Finally, germline genomic analysis (whether part of hereditary cancer testing or conducted in tumor-matched normal tissue) entails the high likelihood of incidental secondary findings of putatively pathogenic genomic variants with unclear disease association and therefore presents a challenge. Widespread controversy exists over the balance between patient autonomy and the perception that patients knowledge of this information would result in physical or mental harm.²³⁵

Table 5 Commercial cancer genome tests

Provider	Product	Description ^a
Ambry Genetics	Exome Next	Full exome + mitochondrial genome, SNVs, CNVs
Ambry Genetics	<i>BRCA1</i> and <i>BRCA2</i> gene sequencing	SNVs, CNVs, <i>BRCA1/2</i> SVs
Arup Laboratories	Gastrointestinal hereditary cancer panel	15 genes + intron/exon junctions, SNVs, CNVs
Ashion Analytics	GEM Cancer Panel	562 genes, tumor/germline, SNVs, CNVs
	GEM GW	Whole exome, tumor/germline, SNVs, CNVs, SVs
	RNA sequencing	RNA, tumor/germline. Gene expression, fusions, alternative

		splicing, SNVs
Cancer Genetics Incorporated (CGI)	FOCUS:CLL	Seven actionable CLL targets
	FOCUS:Myeloid	54 genes, prognostic and therapeutic assessment
Caris	MI Profile	47 genes, SNVs
Foundation Medicine	Foundation One	236 genes, 47 introns from 19 genes associated with SV. SNVs, CNVs, SVs
	Foundation One Heme	405 genes, 31 introns associated with SV, and RNA-seq of 265 genes. SNVs, CNVs, SVs, fusions, and gene expression in hematologic tumors
GeneDx	XomeDx	Full exome, SNVs
	XomeDx Plus	Full exome + mitochondrial genome, SNVs
	XomeDx Slice	Targeted exome, SNVs
	Comprehensive cancer panel	29 genes, SNVs, CNVs
GPS@WUSTL	Comprehensive Cancer Gene Set Analysis	Sequencing of 42 genes. Mutation analysis
Agendia	Mammaprint	Microarray gene expression analysis of 70 genes. Predicts chemotherapy benefit and risk of recurrence of breast cancer
Myriad Genetics	BRACAnalysis	Sanger, <i>BRCA1/2</i> , breast and ovarian cancer risk
	COLARIS	Sanger, six genes, hereditary colorectal cancer
	COLARIS AP	Sanger, <i>APC</i> and <i>MYH</i> genes, adenomatous polyposis colon cancer risk
	MELARIS	Sanger, <i>CDKN2A</i> , hereditary melanoma
	PANEXIA	Sanger, <i>PALB2</i> + <i>BRCA2</i> genes, pancreatic cancer risk
	Myriad myRisk Hereditary Cancer	Sanger, 25 genes, breast, ovarian, gastric, colorectal, pancreatic, melanoma, prostate, and endometrial cancer risk
NeoGenomics Laboratories	NeoTYPE Cancer Exome Profile	4813 genes, identify SNVs
	NeoTYPE Profiles	Custom gene panels, SNVs
OncotypeDX	OncotypeDX Breast Cancer Assay	RT-PCR, 21 genes, gene expression, chemotherapy benefit, and likelihood of recurrence for invasive breast cancer
	OncotypeDX Colon Cancer Assay	RT-PCR, 18 genes, gene expression, recurrence risk in stage II and stage III colon cancer
	OncotypeDX Prostate Cancer	RT-PCR <17 genes, gene expression, treatment selection for prostate cancer

	Assay	
Paradigm	PCDx	Number of genes not specified, DNA and RNA analysis, SNVs, CNVs, SVs, gene expression, fusions, alternative splicing
Personal Genome Diagnostics (PGDX)	Whole Genome Analysis	Whole genome, tumor or ctDNA and germline, SNVs, CNVs, SVs
	CancerXome	Full exome, SNVs, CNVs, SVs
	Cancer Select (R88, R203)	88 or 203 genes, SNVs, CNVs, SVs
	ImmunoSelect-R	Exome, ineoantigen prediction to asses utility of immunotherapy
	PlasmaSelect-R	58 genes in ctDNA, SNVs
Quest Diagnostics	OncoVantage	34 genes, SNVs

^a These descriptions are derived from company web sites and may not be complete. They also do not constitute endorsement of any particular product.

Unlike relative differences in mRNA or protein expression between tumor and normal tissue, somatic mutations in cancer genes are exclusive and specific markers of cancer cells. This fact has been recently leveraged to use cell-free tumor-specific DNA in plasma (ctDNA) as an accurate circulating biomarker of tumor burden. The value of ctDNA for monitoring tumor burden, treatment response, and recurrence was first recognized in colorectal cancer.²³⁶ This study identified somatic mutations in patient tumors in recurrently mutated colorectal cancer genes (*TP53*, *PIK3CA*, *APC*, and *KRAS*) and retrospectively analyzed plasma samples using highly sensitive assays specifically design for each patient. The results showed ctDNA levels reflect changes in tumor burden during treatment when compared with imaging and carcinoembryonic antigen. The challenges in implementation of ctDNA as a routine biomarker for tumor monitoring include the need to identify somatic alterations in each patient, design of patient-specific molecular assays, and low abundance of mutations in circulation, particularly in early stages of disease. Another recent study used NGS of tumors and digital PCR and found ctDNA levels during treatment reflected disease progression in metastatic breast cancer.²³⁷ In these results, ctDNA was found to be more responsive and applicable to the largest fraction of patients when compared with enumeration of circulating tumor cells or CA-125, a glycoprotein biomarker of breast cancer. Similar results supporting the role of serial analysis of ctDNA for monitoring tumor burden have been published for lung cancer,^{238, 239} melanoma,²⁴⁰ and osteosarcoma.²⁴¹

Advances in molecular methods including the use of high-depth noise-corrected targeted NGS assays are enabling the study of patients with localized, potentially resectable cancers.^{242, 243} Recent work in localized breast cancer shows ctDNA can predict postoperative recurrence of cancer a median of 8 months before tumors become detectable on imaging.²⁴⁴ This study and additional papers describing ctDNA in localized cancers demonstrate novel opportunities for optimizing treatment of cancer with curative intent by individualizing therapeutic strategies.²⁴⁵

Prospective trials are needed to establish benefit of guiding clinical cancer management using ctDNA as a biomarker. Nevertheless, observational studies reported so far show superior performance of ctDNA to monitor tumor burden compared to a number of circulating tumor cell or glycoprotein biomarkers.²⁴⁶ With some variations between cancer types, ctDNA has wide applicability across patients as shown in a recent comprehensive survey of 640 patients.²⁴⁶ The same study found ctDNA was detectable in 55% of patients

with potentially curable disease. These results suggest that improved molecular assays may enable detection of ctDNA in presymptomatic individuals with cancer, potentially leading to a screening test with higher specificity than traditional methods.^{247–250}

Cancer evolution

The ability to sequence cancer genomes has shed light on the process of molecular evolution and its importance for understanding cancer biology and treatment. Although not new, historical consideration of this concept has largely been confined to a process of linear clonal evolution driving the development of an increasingly malignant cancer phenotype.¹ However, it is increasingly clear that cancer evolution generates tremendous heterogeneity by continuously generating clonal diversity. As a result, multiple related, but distinct clonal lineages may coexist within a single patient.²⁵¹ These lineages differ in their ability to progress and metastasize²⁵² as well as to respond to or resist therapy.²⁵³ The implications of this complex, branched evolution model will be critically important for understanding cancer biology and developing better treatment approaches.

The cornerstone of cancer evolution lies in the accumulation of genomic mutations, ultimately impacting cellular phenotype. Although the majority of acquired cancer mutations are likely to be passengers, a small proportion will impact critical cellular pathways and processes, thereby acting as disease drivers. However, the exact molecular mechanisms leading to increased mutagenesis in cancer are incompletely understood. Recent analysis, carried out on thousands of cancer genomes, identified at least 20 distinct mutational signatures pointing to diverse processes driving mutagenesis in various cancers, with most cancers showing evidence of more than one such process at play.¹⁵⁰ Although the factors leading to several identified mutational signatures such as UV, smoking, or exposure to chemotherapy agents are well known, many are not associated with a known causative processes. Elucidating such novel mechanisms of mutagenesis will be important for facilitating development of better prevention and treatment strategies.

The accumulation of mutations clearly provides the raw material (population diversity) for cancer evolution. However, this accumulation often contributes to the process of clonal evolution within temporal and spatial constraints. The order in which mutations are acquired can dramatically impact cell fate. For example, a loss of *BRCA1* or *BRCA2* leads to cell cycle arrest in the context of normal *TP53* but not in the setting of *TP53* loss.²⁵⁴ Consistent with this observation, a loss of the second copy of *BRCA1* in breast cancer typically occurs after the loss of *TP53*. The order of mutational events may also depend on the cell type and state of differentiation. This is seen with *KRAS* or *NRAS* mutations, which occur early in colon cancer development, whereas similar *NRAS* mutations are seen mainly at a late stage in myelodysplastic syndrome.^{255, 256} Spatial constraints of clonal diversification, on the other hand, have been noted in clear cell renal cell carcinoma and non-small-cell lung cancer,^{257, 258} where divergent clones develop in specific geographic locations of the tumor. In fact, such spatial separation could lead to “parallel evolution” characterized by distinct mutations arising independently in individual clones, but targeting the same gene or the same pathway, as observed in a variety of cancers.²⁵⁹ An important practical implication of such parallel evolution is that an effective targeted therapy would have to be capable of simultaneously inhibiting independent and molecularly distinct clones within a single patient.

Although clonal diversification is crucial, recent data indicates that simple outgrowth of the most aggressive clones does not fully account for the extent of clonal evolution in cancer. Indeed, similar to the principles of evolutionary biology in general, where no species evolves in isolation, cancers seem to

evolve within an ecosystem of interactions not only with the host but also with other coexisting tumor clones. For example, in an experimental model of glioblastoma, a minor clone harboring an *EGFR* mutation appears to support the major *EGFR*-wt clone through paracrine mechanisms.²⁶⁰ Similarly, within heterogeneous tumors in zebrafish melanoma xenograft models, a phenomenon of “cooperative invasion” is seen. Here, the presence of an invasive clone enables invasion by another, otherwise poorly invasive clone.²⁶¹ Such clonal cooperation does not only apply to tumor survival and progression but also extends into the realm of therapeutic resistance. In a model of colon cancer, for instance, the presence of an *EGFR* inhibitor-resistant, *KRAS*-mutated minor clone appears to support the survival of a drug-sensitive, *KRAS*-wt clone through paracrine mechanisms involving transforming growth factor α and amphiregulin.²⁵³

On the basis of the above-mentioned temporal and spatial constraints as well as clonal interactions, several models of clonal evolution have been proposed.²⁵⁹ These range from (1) a simple model of linear evolution, where successive accumulation of mutations leads to increasingly aggressive clones that outcompete their predecessors, to (2) models of allopatric speciation, where subpopulations evolve in geographically distinct areas of the tumor, to the models incorporating clonal interactions including (3) a model of clonal competition with distinct clones competing for growth advantages in the form of antagonistic evolution and (4) a model of clonal cooperation with a symbiotic relationship between individual clones ([Figure 6](#)).

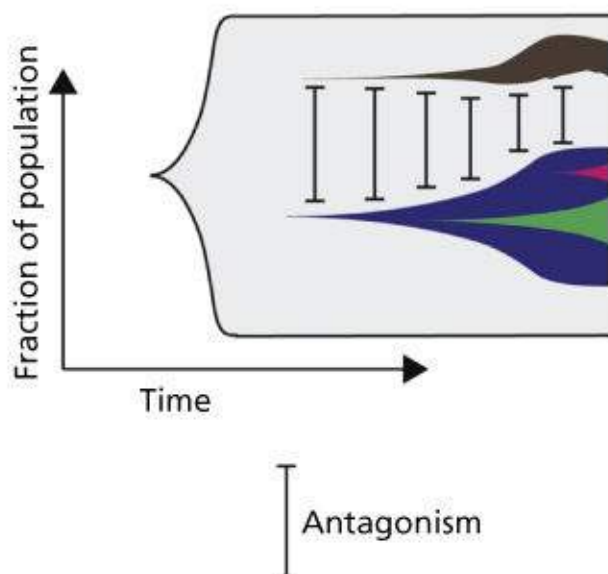

(a) Linear evolution

(b) Clonal separation (allopatric speciation)

(c) Clonal competition (antagononist evolution)

(d) Clonal cooperation (sybiotic evolution)

Figure 6 (a) Linear evolution involves sequential accumulation of mutations over time. As can be seen, linear evolution can result in heterogeneity if a subclone has failed to outcompete its predecessors. (b) Tumor subclones may evolve through a process equivalent to allopatric speciation when subclonal populations are geographically distinct within a tumor. (c) Clonal competition can occur between subclonal populations, where distinct subclones compete for growth advantages (equivalent to an antagonistic relationship). (d) Subclonal populations may cooperate, resulting in a symbiotic relationship.

Understanding of the molecular spectrum and mechanisms of cancer evolution impacts our ability to treat cancer. Molecular heterogeneity and clonal evolution limit the benefits derived from targeted treatments. The repertoire of clones with distinct molecular signatures within each patient's tumor(s) allows for treatment-driven selection, manifesting as acquired therapeutic resistance even in patients who initially respond to treatment. Pre-existing somatic mutations (even passenger events) or new mutations acquired during therapy can drive therapeutic resistance. While improvements in experimental models have enhanced our ability to understand and perturb complex patterns of clonal evolution in the laboratory, development of methods such as ctDNA analysis in plasma can allow monitoring of clonal evolution in the clinic.²⁶² In patients who progress on targeted therapies, multiple studies have shown that somatic mutations driving resistance are detectable in plasma. For instance, lung cancer patients treated with

erlotinib or gefitinib (an EGFR inhibitor) most often develop acquired treatment resistance owing to a second mutation in *EGFR* p.T790M that affects drug binding. This resistance-driving mutation is detectable in ctDNA up to 16 weeks before disease progression is evident on routine imaging.²³⁹ Similar data has been reported for patients with colorectal cancer who progress on cetuximab (an anti-EGFR antibody) where *KRAS* mutations are evident weeks before disease progression.²⁶³ A recent study of colorectal cancer patients confirmed that if targeted therapy is discontinued upon disease progression (a drug holiday) and replaced with chemotherapy, circulating levels of the *KRAS* mutation in ctDNA recede (suggesting recession of *KRAS*-mutation bearing tumor subclone).²⁶⁴ While these studies used deep targeted sequencing strategies to investigate hypothetical genes driving treatment resistance, hypothesis-free genome-wide analysis to discover novel drivers of treatment resistance has also been described.²⁶⁵ These proof of principle results describing ctDNA analyses to track clonal evolution warrant investigation of ctDNA-based, personalized adaptive, sequential, or combination treatment strategies.

Cancer genomics and evolution in clinical practice: A case study in melanoma

Background

Malignant melanoma is the sixth most common cancer in the United States and is one of few that is increasing in incidence.²⁶⁶ Although detection and surgical resection of early-stage disease can be curative, a tumor thickness of merely 4 mm portends metastatic disease and an abysmal prognosis. Dramatic recent progress in melanoma precision medicine powerfully illustrates the potential for genomics to impact clinical cancer management. In this section, we will focus on this progress and its impact on melanoma treatment while clinical features will be discussed in detail in [Chapter 111](#). Melanoma is a disease of transformed melanocytes and is clinically subdivided by anatomic location, histopathology, sun exposure, and progression (using tumor-node-metastasis staging).²⁶⁷ By site, cutaneous melanoma most commonly originates on sun-exposed skin and is further categorized based on type of sun exposure of the primary site including areas with chronic sun exposure (e.g., face and forearms) and those with intermittent sun exposure (e.g., back). Less common subtypes include acral melanoma, occurring on non-hair-bearing areas of skin on hands and feet; ocular melanoma, which is predominantly uveal with a smaller proportion of conjunctival melanomas; mucosal (nasopharyngeal, bowel, anorectal, or vulvovaginal) and primary CNS melanoma. This categorization has implications for prognosis and treatment, although it is sometimes unable to predict outcome or treatment response. Further, until the discoveries of the past decade, metastatic melanoma was uniformly treated with cytotoxic chemotherapy to limited effect.²⁶⁸

The genetic basis of melanoma

Where variation in clinical course by melanoma histopathologic subtype is confounding, genomic characterization is now helping to clarify etiology, biology, and optimal treatment. Just as breast cancer can best be characterized according to ER, PR, and Her2 status, genotype should now take a prominent role in the clinical approach to melanoma owing to its implications for treatment. Although melanomagenesis is still poorly understood, melanoma is known to occur through the stepwise accumulation in melanocytes of mutations in cancer genes ([Figure 7](#)).²⁶⁹ Most melanomas are sporadic with 5–10% of cases due to familial predisposition predominantly driven by germline variants in the first familial melanoma gene identified—the tumor suppressor *CDKN2A* (40% of familial cases).^{270–272}

Additional rare variants in other cancer genes have since been found in familial cases (*CDK4*, *BRCA2*, *BAP1*, *TERT* promoter, *MITF*, and *POT1*).^{273–278} Beyond heredity, UV radiation is recognized as the greatest risk factor for cutaneous melanomas, although not for sun-shielded mucosal, acral, or ocular disease.²⁷⁹ In keeping with UV etiology, additional melanoma risk factors include fair skin, increased freckling and benign nevi, *MC1R* germline variants, and tanning.^{280–283}

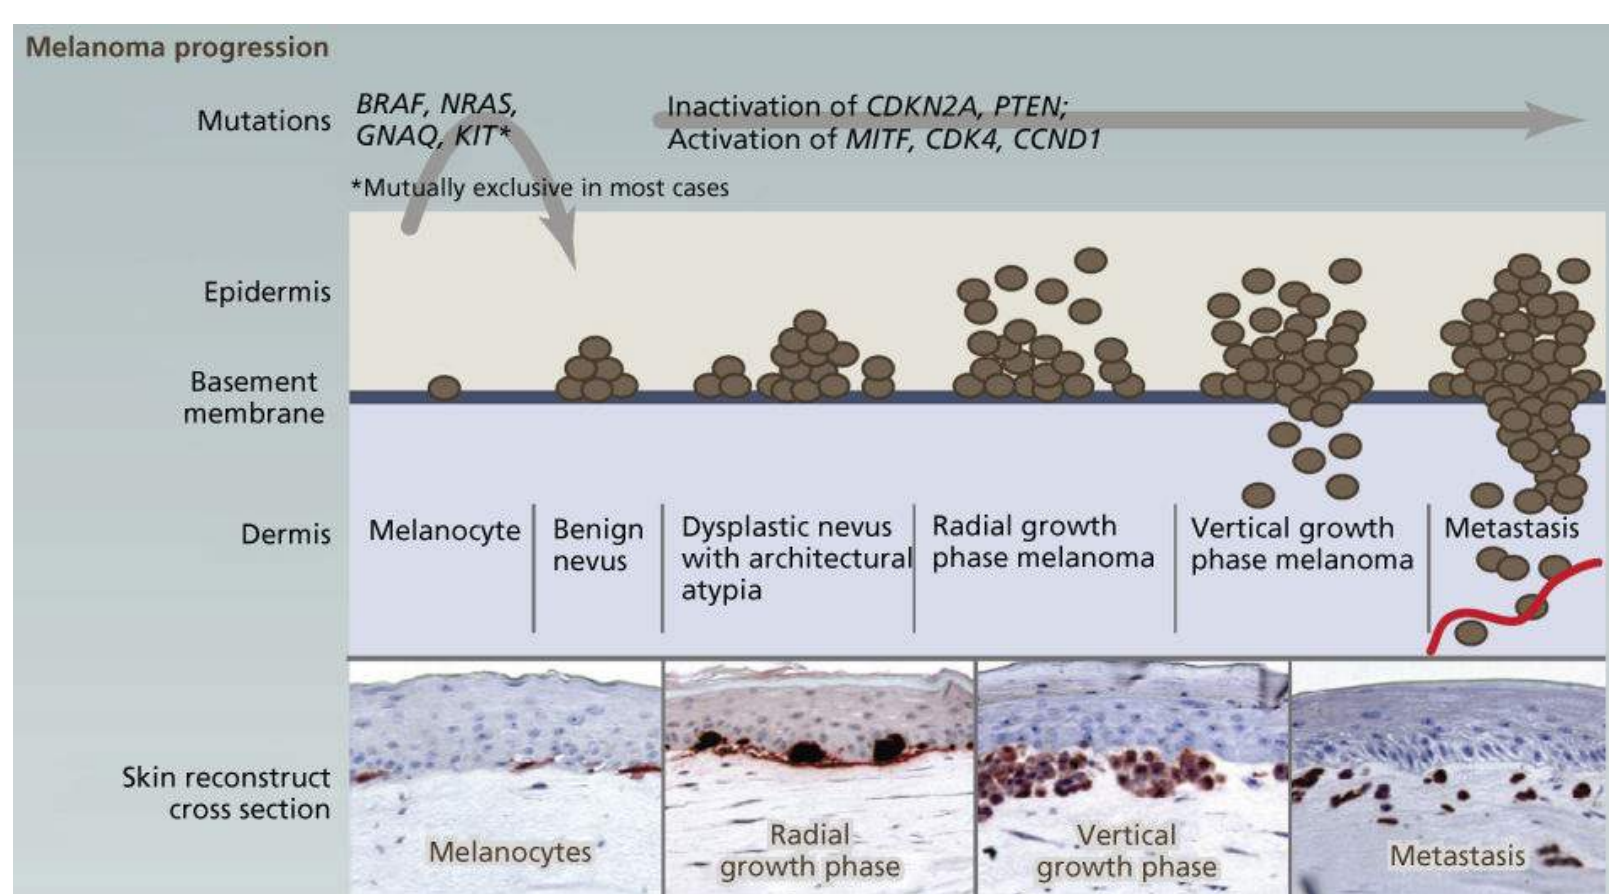

Figure 7 The genetic basis of cutaneous melanoma. Melanoma, the deadliest of skin cancers, is caused by the transformation of melanocytes (pigment-producing cells) that accumulate genetic alterations, leading to abnormal proliferation and dissemination. Clinically, melanoma lesions can be classified based on location and progression, ranging from benign nevi to metastatic melanoma. Important driver genes in melanomas are shown in the figure. MAPK signaling is often constitutively activated through alterations in membrane receptors or through mutations of RAS or BRAF.

Early genetic and functional characterization of melanoma determined that it is driven both by mutations that inactivate cell cycle gatekeepers and by those that activate cell proliferation pathways. Building on discovery of familial mutations in *CDKN2A*, a locus that regulates the p53 and RB proteins, these tumor suppressors were found to be frequently disrupted by disparate mutations that enable unconstrained cell growth such as *CDKN2A*, *CDK4*, *RB1*, *TP53*, and *MDM2* mutations.^{284–288} Meanwhile frequent mutations in the proliferation pathway genes *BRAF*, *KIT*, *NRAS*, and *PTEN* were identified and found to cooperate with inactivation of cell cycle tumor suppressors to promote malignancy.^{115, 119, 289–302} Cytogenetic and molecular studies further pointed to as-yet unidentified genes in recurrently altered regions of chromosomes 1p, 6q, 7p, and 11q.^{288, 303–311} As with many early genetic analyses of human cancers, these studies were typically performed in disparate small cohorts or model systems, focused on only one or several genes in a single clinical subtype, and often produced inconclusive results.

Melanoma genomic landscapes

The striking genetic complexity between subtypes and within individual tumor genomes revealed by the above analyses was soon confirmed at high resolution through a succession of genomic studies. Genome-wide aCGH profiling and targeted sequencing of *BRAF* and *NRAS* in 126 tumors first revealed distinct patterns of somatic mutation based on subtype. *BRAF* and *NRAS* mutations were found to be enriched in intermittently sun-exposed and cutaneous melanoma but rare in chronically sun-exposed, mucosal, and acral melanoma. Patterns of mutation also varied by subtype with CNVs enriched in mucosal melanoma. Subsequent analyses identified patterns of CNV correlating with poor prognosis^{49, 289} as well as subtype-specific *KIT* mutations occurring in 10–20% of mucosal and acral as well as at low frequency in cutaneous melanoma in sun-damaged sites.^{48, 312} The existence of molecular subsets of disease was also borne out by gene expression microarray studies^{84, 313, 314} and such molecular subsetting of clinical melanoma categories seeded hope that these types could be tied to clinical outcome or exploited for therapeutic targeting.³¹⁵

A spate of massively parallel sequencing studies beginning in 2011 spurred explosive growth in the genomic understanding of cutaneous melanoma, recently culminating in two large multiplatform studies that jointly span over 500 cases.^{142, 275, 315–325} These studies not only corroborate prior identification of important melanoma drivers (*BRAF*, *NRAS*, *NF1*, *TP53*, *CDKN2A*, and *RB1*) but also point to new genes not previously linked to the disease including *RAC1*, *PREX2*, *PPP6C*, *ARID2*, *TACC1*, *GRM3*, *MAP3K4*, *MAP3K9*, *IDH1*, *MRPS31*, *RPS27*, and the *TERT* promoter. Melanoma is now predominantly categorized according to *BRAF*, *RAS*, and *NF1* status, all of which, when mutated, constitutively activate the mitogen-activated protein kinase (MAPK) pathway, a central regulator of cell proliferation ([Figure 8](#)).¹⁴² These mutations tend to be mutually exclusive and account for all but 10% of cases, suggesting four genomic subtypes: *BRAF*, *NRAS*, *NF1*, and triple wild type (TWT). Genome-wide sequencing has also enabled characterization of mutation signatures in melanoma, shedding further light on the role of UV radiation in various subtypes. Melanomas on sun-exposed skin are characterized by UV signature mutations—cytosine to thymine (C > T) substitutions occurring in dipyrimidines as more than 60% of the total mutation burden.^{142, 318, 326} Curiously, most common mutations in *BRAF* and *NRAS* are not C > T substitutions despite their driver roles in the majority of sun-exposed melanomas.³¹⁷ While it is often noted that melanoma has the highest average mutational burden of any cancer type, the mutation frequency can range from 0.1–100 mutations per megabase.¹⁶⁹ This marked heterogeneity tracks with the clinical heterogeneity of the disease, with the highest mutational rate in melanoma on sun-exposed skin at >100/Mb, intermediate rates in mucosal melanoma at 2–5/Mb, and the lowest rates in uveal and CNS melanoma at <0.1/Mb.^{316, 327, 328}

Figure 8 The genomic landscape of cutaneous melanoma. Total number of mutations, age at melanoma accession, and mutation subtype (*BRAF*, *RAS* [N/H/K], *NF1*, and Triple-WT) are indicated for each sample (a). (Not shown are one hypermutated and one co-occurring *NRAS* *BRAF* hot-spot mutant). Color-coded matrix of individual mutations (specific *BRAF* and *NRAS* mutations indicated) (b), type of melanoma specimen (primary or metastasis), and mutation spectra for all samples (c) are indicated. For the two samples with both a matched primary and metastatic sample, only the mutation information from the metastasis was included.

Source: The Cancer Genome Atlas Network. 2015.¹⁴² Reproduced with permission of Elsevier.

Cutaneous *BRAF* melanomas account for over 50% of tumors and predominantly bear the hotspot missense mutation V600E, although other activating *BRAF* mutations, amplifications, and even fusions do occur. They are characterized by incidence in younger patients, UV signature in 91%, relatively fewer CNVs compared to TWT, amplifications of *BRAF*, *MITF*, PD-1, and PD-L1, enrichment for *TP53* mutations, and more frequent *PTEN* deletions. *RAS* melanomas are the second most common (30%), typically *NRAS* Q61R/K/L and with occasional mutations in *K-* or *H-RAS*. These mutations are nearly always mutually exclusive with *BRAF* mutations although molecular features of this category otherwise resemble the *BRAF* subtype. *NF1* melanomas comprise 15% of cases, the majority of which contain inactivating *NF1* mutation. This subtype bears the highest SNV burden, occurs in older patients, and contains a UV signature. It can co-occur with *BRAF* and *NRAS* mutations and tends to show a pattern of co-occurrence with other mutated “RASopathy” genes such as *RASA2*.³¹⁹ Similar to *BRAF* and *RAS* mutations, most *NF1* mutations drive *RAS* and *MAPK* pathway activation. Finally, TWT melanoma is a heterogeneous subtype that lacks recurrent driver mutations although *KIT*, *CTNNB1*, *GNAQ*, *GNA11*, and *EZH2* mutations have been found at low frequency. Notable characteristics of this subtype include higher

numbers of SVs, fusions and CNVs, only 30% containing UV signatures, amplifications containing *KIT*, *PDGFRA*, *KDR*, *CDK4*, *CCND1*, *MDM2*, and *TERT*, and only few (7%) with *TERT* promoter mutations.¹⁴² It is important to highlight that despite diversity across genomic subtypes, the vast majority of melanoma driver mutations converge on the MAPK and PI3K pathways, such that approximately 91% of cutaneous melanomas depend on aberrant activation of this single pathway.³²⁹

Despite exhaustive characterization of cutaneous melanoma, genomic landscapes of less-common clinical subtypes remain poorly characterized. Several small studies of uveal, acral, desmoplastic, and mucosal melanoma have identified recurrent mutations, but much still remains unknown. Uveal melanoma, the most common ocular tumor, has been shown in studies encompassing nearly 80 cases to have one of the lowest melanoma mutation burdens and to be characterized by mutations in *GNAQ* (50%) as well as frequent *BAP1*, *EIF1AX*, and *SF3B1* mutations in tumors with high metastatic propensity.^{324, 325, 330–332} Acral melanoma occurs on non-hair-bearing skin of the palms, soles, and nail beds, is the most common melanoma subtype in non-Caucasians, and has a poorer prognosis than cutaneous melanoma on hair-bearing skin owing to later diagnosis.³³³ Although known for nearly a decade to be largely *BRAF* wild type, it is rarely included in larger cutaneous genomics studies and limited focused data sets are available. In total, 38 acral melanomas have been characterized across six studies that have identified the following characteristics: about 30% *KIT*-mutant, 20% *BRAF*-mutant, 10% *NRAS*-mutant, low SNV burden, high CNV and SV burden, and absence of UV signature.^{49, 316–318, 332, 334, 335} Data on mucosal melanoma, another rare and aggressive subtype that is predominantly *BRAF* wild type, is more sparse with only 10 cases comprehensively assessed in a single study.³²⁷ This study largely confirmed prior targeted and cytogenomic analyses, showing a low SNV frequency, high CNV and SV burden, absence of UV signature, and recurrent mutations in *KIT*, *PTEN*, and other putative cancer genes in two or fewer samples. Desmoplastic melanoma, a rare and invasive fibrous form of dermal melanoma has also recently been characterized (62 cases) and preliminary results reveal a notably high SNV burden (one of the highest to date at 62 mutations/Mb), UV signatures, absence of *BRAF* or *NRAS* mutations, and a diverse array of mutations that activate the MAPK and PI3K pathways.³³⁶ Notable similarities and differences between these rare tumor types support their potentially distinct etiology and may help guide therapeutic management.

Clinical implications of melanoma genomics

Although no definitive correlation with outcome has been identified based on the above-mentioned genomic subtyping or other molecular classifications in melanoma, these genomic subtypes have direct bearing on treatment of advanced metastatic melanoma ([Table 6](#)). The *BRAF* subtype carries the greatest array of clinical options. Mutant *BRAF* has now proven to be an effective therapeutic target, with *BRAF*V600E/K and K601 targetable by inhibitors of *BRAF* or *MEK*. As of 2015, three such small molecule inhibitors have demonstrated an overall survival (OS) benefit in randomized clinical trials. Vemurafenib and dabrafenib are *BRAF* inhibitors (BRAFi) with demonstrated response rates greater than 90% in *BRAF* melanoma.^{224, 337} Trametinib is a *MEK* inhibitor (MEKi) which, while less dramatically effective than BRAFi, nevertheless triples progression-free survival (PFS) versus chemotherapy.³³⁸ The best results to date from trials of targeted agents in *BRAF* melanoma have come from combined BRAFi and MEKi with dabrafenib and trametinib, a combination with marked improvement in PFS and OS with an overall reduction in toxicity.^{339, 340}

Table 6 Therapeutic options in melanoma by genomic subtype

Genotype	Approved treatments	Selected phase I or II data
BRAF mutant	Targeted—vemurafenib, dabrafenib, and trametinib Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	Cobimetinib
RAS mutant	Targeted therapy—none Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	Trametinib, MEK162
NF1 mutant	Targeted therapy—none Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	None
Triple wild type (TWT) ^b	Targeted therapy—none Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	None
TWT — KIT mutant or overexpressed	Targeted therapy—none Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	Imatinib, nilotinib
TWT — GNAQ/GNA11 mutant	Targeted therapy—none Immunotherapy ^a —ipilimumab, nivolumab, and pembrolizumab	Selumetinib, trametinib, MEK 162

^a Phase III studies for immunotherapy have not included genotyping beyond BRAF. FDA approval for these does not specify genotype and thus is inclusive of all genotypes.

^b No trials to date have specifically identified TWT patients, although KIT and GNAQ/GNA11 cases do occur in this category.

Development of targeted agents for RAS, NF1, TWT, and rare histological melanoma subtypes has lagged behind that for BRAF melanoma, with no completed phase III studies. Nevertheless, early phase studies have shown sufficient efficacy to encourage ongoing efforts at developing agents for these patients. RAS melanoma has been treated with a variety of MEK inhibitors in clinical trials including trametinib,³⁴¹ MEK162,³⁴² and selumetinib.³⁴³ Of these, only MEK162 has shown a significant response rate (around 20%), with the others showing a best response of stable disease. No trials have been conducted specifically in NF1 melanoma, in part due to the emerging understanding of this subtype and overlap with RAF and RAS subtypes. Conflicting preclinical reports have suggested NF1 mutation and loss confers sensitivity or resistance to MEKi and that this relationship is also dependent on RAF/RAS status.^{319, 344–346} *KIT*-mutant melanoma (which is common in TWT cutaneous as well as acral and mucosal subtypes) has been shown in two randomized phase II studies to have an overall response rate to imatinib of 19–29%, with the best responses in cases with canonical *KIT* SNVs rather than amplifications.^{286, 347} The most robust data in *GNAQ/GNA11*-mutant disease comes from a randomized phase II study with the MEKi selumetinib.³⁴⁸ Selumetinib induced tumor regression in 49% of patients and led to a nonstatistically significant improvement in OS to 11.8 versus 9.1 months. Additional agents in development that are relevant to many subtypes and/or may motivate additional subtyping include CDK, MDM2, and PI3K/Akt/mTOR inhibitors in clinical trials in addition to ERK, IDH1, EZH2, and aurora kinase

inhibitors in preclinical development.¹⁴²

Little is known about the impact of genomics on immunotherapy. Immunotherapy with the CTLA-4 inhibitor ipilimumab and the PD1 inhibitors pembrolizumab and nivolumab have revolutionized melanoma care with long-term survival even in advanced disease, but the role of genomics as predictive or prognostic for immunotherapy remains to be fully elucidated.^{349–351} While there is interest in mutational burden as a predictor of response to immunotherapy based on the hypothesis that immunogenicity is a probabilistic aggregate that increases in proportion to total mutation burden, to date no prospective data bears this out. While the hypothesis is supported by the fact that PD1 inhibitors were first approved in melanoma and then lung cancer (the two cancers with the highest mutational burdens), renal cell carcinoma has a very low mutational burden but has demonstrated responsiveness to PD1 inhibitors in phase II studies. Only a minority of patients on the registration studies for pembrolizumab and nivolumab had noncutaneous melanoma and ocular melanomas were excluded. While 20–35% of patients had *BRAF* V600 mutations, genotyping was not routinely done so that the rate of *NRAS* mutant and TWT patients is unknown.

Drug resistance and evolution in melanoma

Despite the activity of targeted agents in *BRAF* melanoma, drug resistance (both innate and acquired) remains a key challenge. Only about 50% of patients respond to BRAFi and in those who do respond, acquired resistance to BRAFi invariably develops.²²⁴ BRAFi resistance is driven by a diverse range of mechanisms, most of which reactivate MAPK activity or redirect proliferative signaling through the PI3K pathway. Resistance can occur through further mutation in *NRAS*,³⁵² *MEK1*,^{353, 354} *MEK2*,³⁵⁴ *NF1*,³⁴⁴ or *BRAF* (via amplification).³⁵⁵ *BRAF* splice variants,³⁵⁶ *EGFR* activation,^{357, 358} and *COT* activation³⁵⁹ have also been implicated. Activation of other receptor tyrosine kinases such as *PDGFR-β* and *IGF-1R* or loss of *PTEN* has also been demonstrated in laboratory models.^{354, 360–364} Clinical trials are ongoing to test whether identification of these resistance mechanisms in the clinical setting will allow for targeted therapeutic approaches that may circumvent resistance to BRAFi. Hypothetical approaches to circumvent specific resistance mechanism after progression on dual inhibition with BRAFi and MEKi are given in [Table 7](#).

Table 7 Hypothetical treatment approaches to acquired BRAFi/MEKi resistance

Mechanism of resistance	Therapeutic strategy
EGFR activation	EGFR inhibitor—erlotinib, gefitinib, afatinib, and dasatinib PIK3 inhibitor—in trials
IGF-1R activation <i>PTEN</i> loss <i>PTEN</i> mutation PIK3CA activation	PIK3Ca inhibitor—in trials
cMET activation	cMET inhibitor—crizotinib
PDGFR-β activation	RTK inhibitor—dasatinib, sunitinib
FGFR activation	FGFR inhibitors—ponatinib, dasatinib
COT activation	ERK inhibitor—in trials

With the recent approval of new targeted and immunologic therapies for metastatic disease, it is now

critically important that the clinician clearly identify the genetic signature of the patient's disease in order to optimize outcomes. Similarly, genomic testing can accelerate new drug development and target identification for the less common subtypes of melanoma and potentially lead to identification of resistance pathways to guide drug selection in individual patients. Thus, the genomic landscape of melanoma conforms to the clinical heterogeneity of the disease, with melanomas of different locations having markedly different genotypic signatures that speak to distinct etiologies. The challenge, then, is to use available genomic technologies in a real time clinical setting. In theory, one could identify the evolutionary mechanisms active in the individual patient to guide treatment selection.

In addition to molecular diversity across melanoma subtypes and even between individual patients with the same disease subtype, a higher order of complexity is becoming apparent. As outlined in the previous section on cancer evolution, recent data indicates that development of melanoma cannot be fully explained by a linear model of accumulating mutations leading to an increasingly aggressive phenotype. Instead, an emerging picture points to cancer as a complex ecosystem driven by the process of branched clonal evolution. As a result, multiple related, but distinct clonal lineages may exist within a single patient,²⁵¹ with some lineages being more likely to progress and metastasize.²⁵² Furthermore, this diversity may provide an escape mechanism leading to therapeutic resistance. This is well illustrated by almost universal development of resistance to BRAF inhibition in melanoma, where rapidly relapsing disease can harbor multiple resistance mechanisms differing between individual subclones even within a single patient.³⁶⁵ This challenge is potentiated by the fact that, while some mechanisms of resistance are driven by mutations, others appear to be mediated through epigenetic or posttranslational processes.³⁶⁶ The obvious and critical question raised by these observations is whether a single tumor biopsy in a metastatic setting can capture the full spectrum of disease heterogeneity, its drivers, and potential therapeutic targets. The solution to this conundrum may lie in approaches with the potential to monitor the clonal complexity on a larger scale, such as “liquid biopsies” that attempt to molecularly characterize circulating tumor DNA in the patient's bloodstream. Emerging data describing detection of ctDNA and concordance of BRAF mutation status between tumor and plasma samples is encouraging.^{246, 367, 368} In addition, anecdotal evidence suggests that serial ctDNA analysis may be a useful marker of treatment response to immunotherapy.²⁴⁰

Summary

Detailed characterization of the genomic lesions underlying cancer has led to identification of biological pathways driving tumorigenesis, improved cancer diagnosis through molecular classification, enhanced selection of therapeutic targets for drug development, promoted the development of faster and more efficient clinical trials using targeted agents and sophisticated biomarkers, and created markers for early detection and recurrence surveillance. Yet, gaps nonetheless remain in our knowledge of the causative mutations underlying some cancers, in our understanding of the biology of the mutations we have identified, in developing drugs capable of targeting many of these diverse mutations, and in fending off the inevitable emergence of drug resistance. As summarized in this chapter, genomics has already made extraordinary contributions to our understanding of cancer biology and cancer medicine. Nevertheless, the enormous potential of cancer genomics has only just begun to be realized.

Acknowledgments

The authors thank the patients who have supported these studies. We also thank Matthew Taila and Victoria Zismann for assistance in preparation and proofreading of this chapter as well as Jeffrey Watkins for assistance in creation of figures. WPDH, AS, AHB, and JMT received research support from a Stand Up To Cancer—Melanoma Research Alliance/Melanoma Dream Team Translational Cancer Research Grant (SU2C-AACR-DT0612). Stand Up To Cancer is a program of the Entertainment Industry Foundation administered by the American Association for Cancer Research (AACR). WPDH, AS, PR, and JMT are supported by NIH R01CA195670. Glossary

Array comparative genomic hybridization (CGH)

Microarray platform optimized to identify genome-wide DNA copy number changes.

Chromothripsis

Phenomenon by which extensive chromosomal rearrangements occur in a single event in one or a few chromosomes.

Copy number variant (CNV)

Change in DNA copy number such as amplification or deletion relative to a reference sequence.

Driver mutation

A mutation that confers a selective growth advantage on the cell in which it occurs.

Epigenomics

Global study of epigenetic changes throughout the genome.

Exome sequencing

Application of NGS for the parallel sequencing of many exons (coding areas of the genome).

Fluorescence *in situ* hybridization (FISH)

Cytogenetic technique for detecting specific DNA sequences on chromosomes using fluorescent probes.

Gene expression array

Oligonucleotide microarray platform designed to probe for the transcriptome-wide abundance of RNA messages.

Genomics

Study of the structure, function, evolution, and sequence of genomes.

Germline mutation

Mutation in the germ cell lineage present in all cells of the body and transmitted to offspring.

Loss of heterozygosity

Loss of the normal, functional allele at a heterozygous locus via deletion or other mutational event.

Massively parallel sequencing (also known as next generation sequencing or NGS)

High-throughput sequencing methodologies based on simultaneous sequencing of large numbers of

genes or entire genomes.

Mutational hills

Mutations that occur at low frequency.

Mutational mountains

Mutations such as BRAF V600E that are frequent in a single cancer type or across multiple cancer types.

Single nucleotide polymorphism (SNP) array

Microarray platform that probes for genome-wide SNPs used to characterize allelic variation, LOH, or CNVs in cancers.

Oncogene

Gene that, when activated by mutations, promotes cancerous phenotype.

Passenger mutation

A mutation that does not confer a selective growth advantage to the cell in which it occurs.

Sanger sequencing

An approach for targeted DNA sequencing of individual genes or sets of genes using dideoxy chain termination and agarose gel electrophoresis.

Single nucleotide polymorphism (SNP)

Single nucleotide sequence difference occurring in germ lines of individuals across populations.

Single nucleotide variant (SNV)

Change in the DNA sequence relative to a reference sequence including point mutation and small insertions and deletions.

Somatic mutation

Mutation acquired somatically in a subset of cells (e.g., in a cancer).

Structural variant (SV)

Structural DNA changes such as rearrangements, translocations, inversions, etc.

Transcriptomics

Study of all RNA transcripts in a cell or population of cells.

Tumor suppressor

A gene safeguarding cellular processes that, when inactivated, facilitates oncogenesis.

Chapter 8

Chromosomal aberrations in cancer

David J. Vander Weele, MD, PhD ■ Megan E. McNerney, MD, PhD ■ Michelle M. Le Beau, PhD

Overview

The malignant cells of most patients who have leukemia, lymphoma, or a solid tumor have acquired clonal chromosomal abnormalities, the identification of which can aid in establishing the correct diagnosis and prognosis and in the selection of therapy. Today, our arsenal of approaches to characterize an individual's malignant disease combines pathologic evaluation, cytogenetic analysis, and molecular studies, typically focused on a few key genes. The advent of high-throughput methods, such as next-generation sequencing, capable of surveying the entire genome or large panels of cancer-related genes, presents new options for a revolutionary change in the way we diagnose, characterize, and treat cancer. The vision for the future entails an integrated molecular profile, that is, chromosomal pattern, gene/miRNA expression, DNA methylation/epigenomic pattern, gene mutation status, and chemosensitivity of each patient's tumor, as well as predisposition to disease, facilitating the development of an individualized treatment plan with decreased toxicities and prolonged survival.

Introduction

Cancer is a heterogeneous group of diseases caused by the stepwise accumulation of numerous genetic and epigenetic aberrations altering the function of genes that regulate genome stability, cell proliferation and differentiation, cell death, adhesion, angiogenesis, invasion, and metastasis in complex cell and tissue microenvironments. The analysis of metaphase chromosomes provided our first broad glimpse into the genetic anatomy of a malignant cell and identified many of the basic abnormalities that characterize cancer, such as deletions, translocations, and gene amplifications. Specific cytogenetic abnormalities have been identified that are very closely, and sometimes uniquely, associated with morphologically distinct subsets of leukemia, lymphoma, or solid tumors.^{1, 2} The detection of one of these recurring abnormalities is helpful in establishing the diagnosis and adds information of prognostic importance. In the hematologic malignancies, patients with favorable prognostic features benefit from standard therapies with a well-known spectra of toxicities, whereas those with less favorable clinical and cytogenetic characteristics may be better treated with more intensive or investigational therapies. The disappearance of an abnormal clone is an important indicator of complete remission following treatment, whereas the appearance of new abnormalities signals clonal evolution and, often, more aggressive behavior. Similarly, in solid tumors, the detection of a recurring cytogenetic abnormality or genetic change may inform the selection of targeted therapy or an investigational clinical trial. Given the rapid progress in genomic analysis, one can envision a new approach to patients with cancer based on molecular profiling of the malignant cells as well as host factors that influence the development and treatment of the disease.³ This chapter focuses on the key role of cytogenetic analysis in the context of diagnosis, prognosis, and molecular pathobiology of human tumors.

Genetic consequences of genomic rearrangements

Recurring chromosomal translocations result in alterations of the genes located at the breakpoints and play an integral role in the process of malignant transformation.² The altered genes fall into several functional classes, including tyrosine or serine protein kinases, cell surface receptors, growth factors and, the largest class, transcription regulators, which regulate growth and differentiation via the induction, or repression of gene transcription. There are two general mechanisms by which chromosomal translocations result in altered gene function in a dominant manner. The first is deregulation of gene expression, characteristic of the translocations in lymphoid neoplasms that involve the immunoglobulin genes in B lineage tumors and the T cell receptor genes in T lineage tumors, that results in the inappropriate or constitutive expression of an oncogene. The second mechanism is the expression of a novel, fusion protein, resulting from the juxtaposition of coding sequences from two genes, typically located on different chromosomes. Thus, these tumor-specific fusion proteins are therapeutic targets. Examples are the chimeric BCR-ABL1 protein resulting from the t(9;22) in chronic myelogenous leukemia (CML) or the anaplastic lymphoma kinase (ALK) fusion proteins in lung cancer.

A number of human tumors, particularly solid tumors, result from homozygous, recessive mutations. The hallmark of these genes, known as “tumor suppressor genes” (TSGs), whose normal role(s) is to limit cellular proliferation, promote differentiation, or repair DNA, is the loss of genetic material, resulting from chromosomal loss or deletion, as well as by other genetic mechanisms.² A growing number of TSGs act by haploinsufficiency, whereby loss of one allele results in a reduction in the level of the protein product by half, perturbing normal cellular processes.⁴ This mechanism is common in the recurring deletions in myeloid neoplasms. Conversely, alterations in copy number resulting from gain of a whole, or part of a chromosome, or from gene amplification, for example, *ERBB2/HER2* in breast cancer, result in increased expression of one or more critical genes.

More than one mutation is required for the pathogenesis of human tumors; thus, an important aspect of cancer biology is the elucidation of the spectrum of chromosomal and molecular mutations that cooperate in the pathways leading to disease. Where known, we describe the cooperating mutations associated with specific cytogenetic subsets of leukemia, lymphoma, or solid tumors.

Chromosome nomenclature

Chromosomal abnormalities are described according to the International System for Human Cytogenetic Nomenclature ([Table 1](#)).⁵ The total chromosome number is listed first, followed by the sex chromosomes, and numerical and structural abnormalities in ascending order. The observation of at least two cells with the same structural rearrangement, for example, translocations, deletions, or inversions, or gain of the same chromosome, or three cells each showing loss of the same chromosome, is considered evidence for the presence of an abnormal clone. An exception to this is a single cell characterized by a recurring structural abnormality, which likely represents the karyotype of the malignant cells. One cell with a normal karyotype is considered evidence for a normal cell line.

Table 1 Glossary of cytogenetic and genetic terminology^a

Amplification	An increase in the number of copies of a DNA segment
Aneuploidy	An abnormal chromosome number, owing to either gain or loss
Banded	Each chromosome pair has a unique pattern of alternating dark and light segments due to

chromosomes	special stains or pretreatment with enzymes before staining
Breakpoint	A specific site on a chromosome that is involved in a structural rearrangement, such as a translocation or deletion
Centromere	The chromosome constriction that is the site of the spindle fiber attachment, enabling chromatid separation by shortening of the spindle fibers attached to opposite poles during mitosis
Clone	Defined as two cells with the same additional or structurally rearranged chromosome, or three cells with loss of the same chromosome
Deletion	A segment of a chromosome is missing, typically as the result of two breaks and loss of the intervening piece (interstitial deletion)
Diploid	Normal chromosome number and composition of chromosomes
Epigenetics	The study of the heritable changes in gene function that result from modifications to the genome, such as DNA or histone methylation, rather than changes in the primary DNA sequence
Fluorescence <i>in situ</i> hybridization	A molecular-cytogenetic technique based on the visualization of fluorescently labeled DNA probes hybridized to complementary DNA sequences from metaphase or interphase cells, used to detect numerical and structural abnormalities
Haploid	Only one-half the normal complement, that is, 23 chromosomes
Hyperdiploid	Additional chromosomes; therefore, the modal number is 47 or greater
Hypodiploid	Loss of chromosomes with a modal number of 45 or less
Inversion	Two breaks occur in the same chromosome with rotation of the intervening segment
Isochromosome	A chromosome that consists of identical copies of one chromosome arm (separated by the centromere) with loss of the other arm
Karyotype	Arrangement of chromosomes from a cell according to a internationally established system, such that the largest chromosomes are first and the smallest ones are last. A normal female or male karyotype is described as 46,XX or 46,XY, respectively
Loss of heterozygosity (LOH)	Typically results from a gross chromosomal abnormality, such as a deletion, that results in loss of one parental copy of a locus or segment (also called hemizygosity). Copy-neutral LOH is the presence of two copies of a chromosome (or segment) originating from one parent, with loss of the copy contributed by the other (also called uniparental disomy)
Single nucleotide polymorphisms (SNPs)	These are common, heritable DNA sequence variations that occur when a single nucleotide (A, T, C, or G) is changed, occurring every 100–300 base pairs
Pseudodiploid	A diploid number of chromosomes accompanied by structural abnormalities
Recurring abnormality	A numerical or structural abnormality noted in multiple patients who have a similar neoplasm
Translocation	A break in at least two chromosomes with exchange of material
<i>Nomenclature symbols</i>	
p	Short arm

q	Long arm
+	Indicates a gain of a whole chromosome (e.g., +8)
–	Indicates a loss of a whole chromosome (e.g., –7)
t	Translocation
del	Deletion
inv	Inversion
i	Isochromosome
mar	Marker chromosome
r	Ring chromosome

^a Modified from Ref. 2.

Methods that complement karyotype analysis

Fluorescence *in situ* hybridization (FISH)

Fluorescence *in situ* hybridization (FISH) is widely used in cancer diagnostics and is based on the ability of a labeled DNA probe to anneal to complementary DNA from interphase cells or metaphase chromosomes that are affixed to a glass microscope slide.⁶ FISH can be performed on marrow or blood smears, or fixed and sectioned tissue, for example, formalin fixed paraffin-embedded (FFPE) tissue, as it does not require dividing cells. Probes are now commercially available for most clinically relevant abnormalities, such as centromere-specific probes to detect numerical abnormalities as well as the sex chromosome complement in the stem cell transplant setting, and locus-specific probes to detect translocations, deletions, and amplifications ([Figure 1](#)a–e). Advantages of FISH include (1) the rapid nature of the method; (2) its high sensitivity and specificity—cytogenetic abnormalities have been identified by FISH in samples that appeared to be normal by conventional cytogenetic analyses; and (3) the ability to obtain cytogenetic data from samples with a low mitotic index or terminally differentiated cells. The major disadvantage is the inability to interrogate more than a few abnormalities. FISH is often used to assess therapeutic efficacy by evaluating abnormalities identified by karyotyping at diagnosis, for example, detection of the *BCR-ABL1* fusion in CML patients following therapy with an oral tyrosine kinase inhibitor (TKI). Applications in solid tumors include the detection of gene amplification, for example, *ERBB2* in breast cancer and *EGFR* or *ALK* in lung cancer, or the UroVysion™ test in bladder cancer.

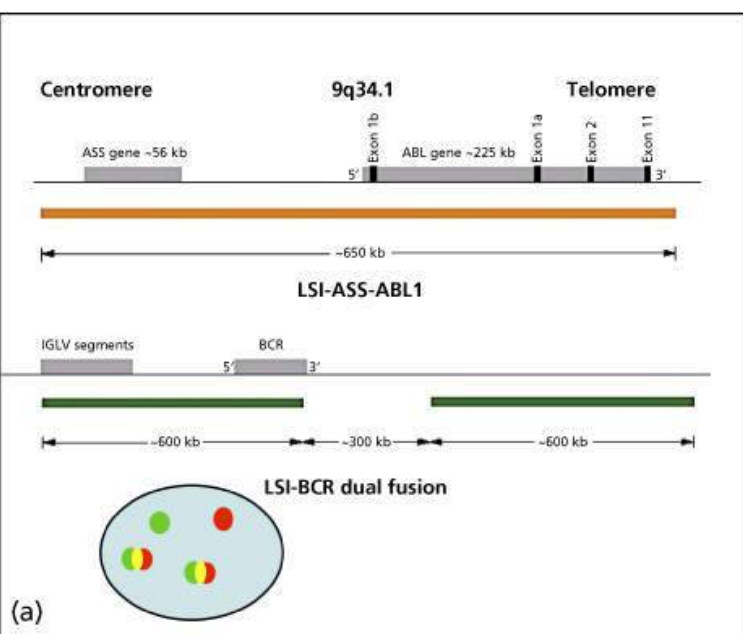

Figure 1 Fluorescence *in situ* hybridization and SNP array analysis. Panels (b), (d), and (e) illustrate images of metaphase or interphase cells following FISH; the cells are counterstained with 4,6-diamidino-2-phenylindole-dihydrochloride (DAPI). (a) Schematic diagram of the genomic origin of the *BCR* and *ABL1* dual fusion probe (Abbott Molecular), and configuration of signals in interphase cells. (b) In cells with the t(9;22), one green and one red signal is observed on the normal 9 and 22 homologs, and two yellow fusion signals (arrows) are observed on the der(9) and the der(22) (Ph) chromosomes as a result of the juxtaposition of the *ABL1* and *BCR* sequences. (c) Schematic diagram of the *KMT2A/MLL* break-apart probe (Abbott Molecular), and configuration of signals in interphase cells. (d) In cells with a translocation of 11q23.3, a yellow fusion signal is observed for the germ-line configuration on the normal chromosome 11 homolog, a green signal is observed on the der(11) chromosome, and a red signal is observed on the partner chromosome. (e,f) Detection of gene amplification. (e) SNP array analysis for DNA copy number aberrations in a glioblastoma reveals amplification of the *EGFR* locus. (f) FISH analysis for *ERBB2/HER2* amplification in breast carcinoma. The probe labeled with Spectrum Green (green signal) is a centromere-specific probe for chromosome 17 (CEP17). Most cells have two copies of the centromere of chromosome 17; however, polyploid cells have more copies. The probe labeled with spectrum orange (red signal) is a locus-specific probe for the *ERBB2/HER2* gene, with an estimated average of 10–20 copies per cell (Abbott Molecular). The *ERBB2/HER2*:CEP17 ratio was reported as ≥ 2.0 .

Source: Dr. Carrie Fitzpatrick, Department of Pathology, University of Chicago.

Other low-throughput methods

In addition to FISH, other low-throughput tests, such as ISH, RT-PCR (reverse transcription polymerase chain reaction), and immunohistochemistry (IHC), comprise the bulk of clinical molecular tests to detect translocations or copy number aberrations (CNAs). For example, they provide rapid diagnosis of acute promyelocytic leukemia (APL), diagnosis of ER/PR and *ERBB2* status in breast cancer. The main disadvantage of these assays is that the number of clinically relevant gene alterations per tumor has grown to the extent that high-throughput assays are becoming more efficient and cost-effective.

Single nucleotide polymorphism (SNP) arrays

Single nucleotide polymorphism (SNP) arrays probe for the presence of common SNPs genome wide. They provide sensitive detection of CNAs, on the order of kilobases, providing higher resolution than karyotyping (3–5 Mb resolution) ([Figure 1f](#)). Unlike karyotyping, they do not require dividing cells, an advantage for solid tumors. SNP arrays also detect copy-number neutral loss-of-heterozygosity (CN-LOH) but not balanced translocations. SNP arrays are available as an adjunct test to karyotyping and FISH analysis of leukemias and lymphomas, and they facilitate detection of genomic abnormalities in a substantial proportion of cases with a normal karyotype.

Next-generation sequencing (NGS)

Next-generation sequencing (NGS) is sequencing in a massively parallel manner, analyzing over one billion DNA fragments simultaneously, and has revolutionized clinical cancer diagnosis. NGS enables the most comprehensive testing, providing data on the spectrum of genetic alterations, including CNAs, LOH, translocations, single nucleotide mutations, small insertions and deletions (indels), germ-line predisposition variants, pharmacogenomic information, and oncogenic virus identification. Assays are evolving rapidly, driven by advances in instrumentation, design, software, and decreasing cost. NGS is routine at some centers and is expected to become widely used in oncology.

DNA or RNA can be obtained from fresh tissue, FFPE tissue, slide scrapings, or biopsies. Generally, small amounts of material are required, and some tests are available even for fine needle aspirates. High tumor cellularity is preferred, although lower cellularity can be compensated for by greater sequencing depth.⁷ Extracted nucleic acids are converted into sequencing libraries and 75–250 bp paired-end reads are generated, which are then aligned to the reference genome.

CNAs are detected by counting the number of reads that align to a region, and comparing that number to data collected from a panel of normal diploid samples ([Figure 2a](#)). Regions of LOH are determined by examining SNP allele frequencies within the region. Homozygous deletions and amplifications greater than seven have been detected with 99% sensitivity and 100% specificity by NGS, comparing favorably to IHC and FISH.⁷ Of note, NGS provides average DNA content, similar to arrays. In contrast, ISH is performed on a cell-by-cell basis; thus, ISH may have higher sensitivity for samples with low tumor cellularity. Translocations can be characterized by (1) read pairs that map to discordant portions of the genome or (2) reads that map directly to a breakpoint ([Figure 2b](#)). Although NGS can achieve comparable sensitivity and specificity as FISH and provides finer-scale information,⁸ FISH is currently the gold standard for translocation identification.

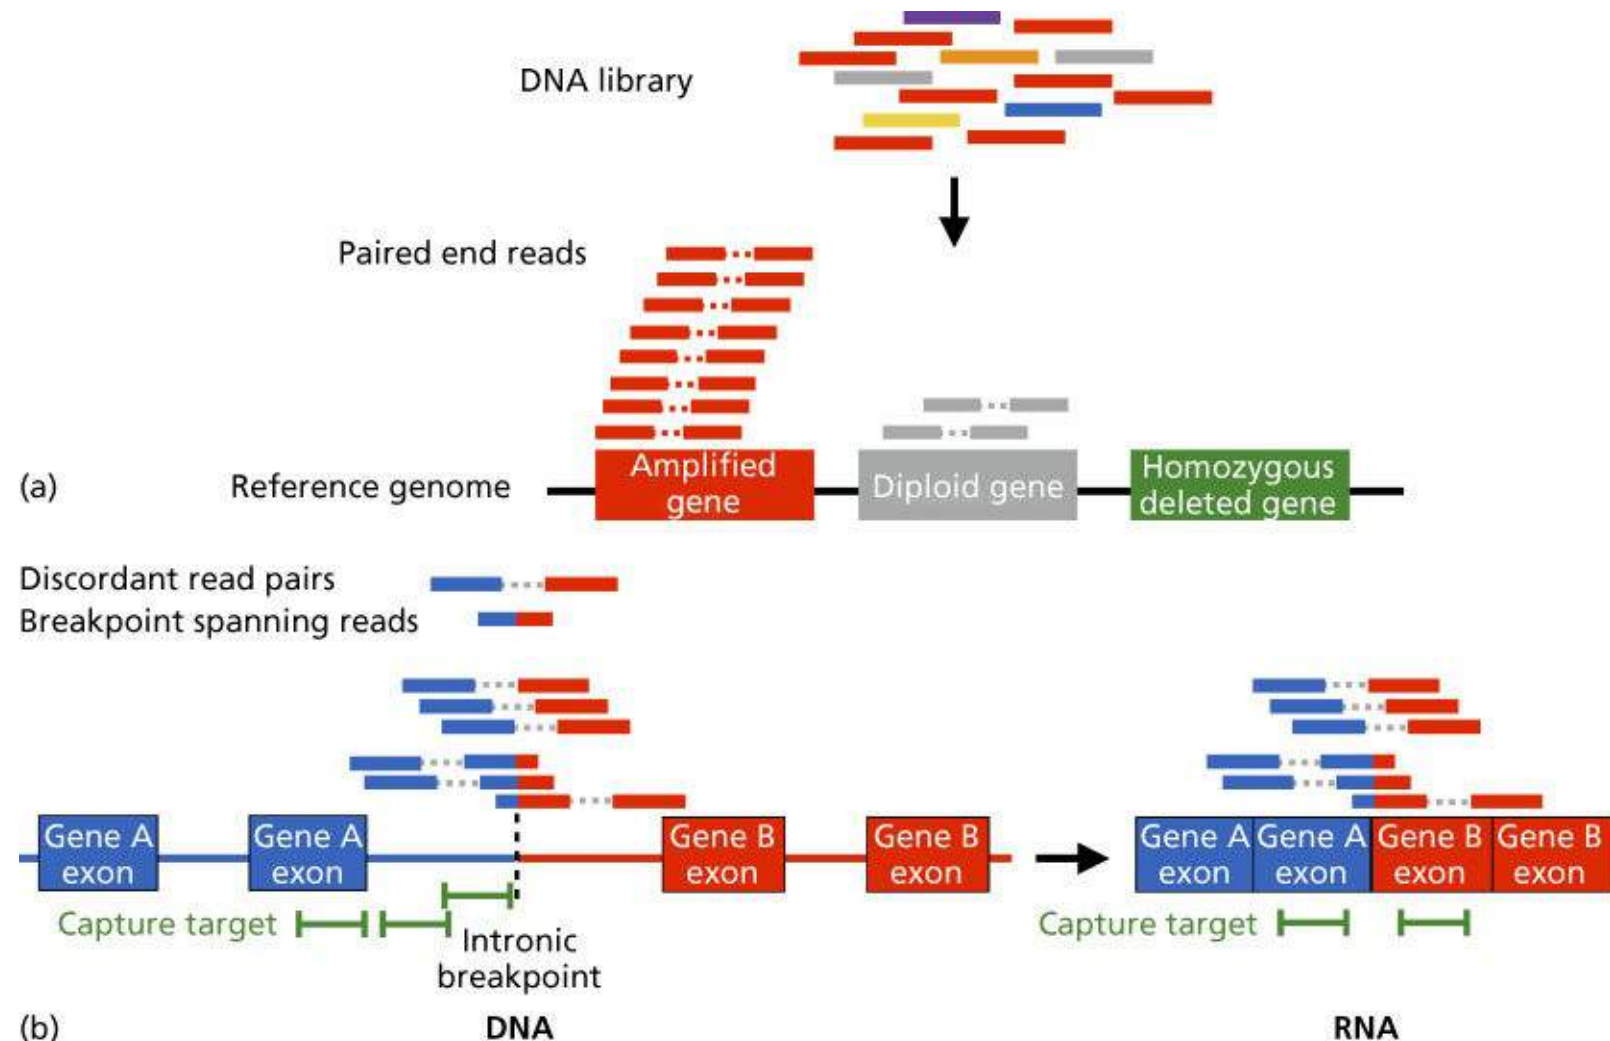

Figure 2 Detection of chromosomal aberrations by next-generation sequencing (NGS). (a) Copy number alterations are determined from a DNA library, that can be derived from whole genome DNA, or enriched by exome capture or a smaller, targeted gene panel. Paired-end or single-end (not shown) NGS is performed on the tumor sample, and reads are aligned to a reference human genome. The number of reads that align to a region are compared to either normal tissue from the same patient, or a database of normal, diploid patient samples. Regions of amplification will have a higher number of reads as compared to normal. Regions with heterozygous or homozygous deletions will have relatively fewer reads than expected. (b) Translocations can be identified by discordant read pairs that map to two different regions of the genome, or from reads that span breakpoints. Structural changes can be detected from DNA (left panel) or RNA (right panel). In the case of DNA, translocations can be identified by whole genome sequencing or by an initial capture step. As translocations involving two genes often have heterogenous breakpoints occurring in large regions of intronic sequence, capture probes have to be designed to span this intervening sequence. The advantage of using RNA is that the introns are spliced out; thus, capture probes are only required for exons, which are shorter than introns.

Targeted gene panels

Targeted gene panels cover <0.05% of the genome and are composed of tens to hundreds of clinically significant genes. Some panels are comprehensive, whereas others are tailored for the tumor type. Compared to whole genome sequencing, they are cost-effective, provide greater sequencing depth, high sensitivity, the shortest turn-around-time, and decreased bioinformatics burden, as well as circumventing issues of incidental findings.

For identification of CNAs, target genes are typically enriched from DNA by probe hybridization.

Targeting translocations is less straightforward because most translocations have breakpoints in introns, which can be significantly longer than NGS reads. Thus, capture probes for DNA must target introns, which increases the territory of DNA surveyed ([Figure 2a](#)). RNA-based sequencing avoids the problem of intervening introns, but is limited to detecting expressed chimeric fusion transcripts, and will fail to detect common translocations such as *IGH/MYC*. In addition, RNA suffers degradation in FFPE specimens.

Exome sequencing

Exome capture is enrichment by hybridization capture of all protein coding DNA, ~1% of the genome. Some clinical laboratories offer this as an unbiased assay of mutations and CNAs in all potentially pathogenic genes. The cost is lower than whole genome sequencing, but there is limited utility in detecting translocations.

Whole genome sequencing (WGS)

Whole genome sequencing (WGS) is sequencing of the entire tumor genome without a prior enrichment step and identifies all structural changes in coding and noncoding regions. Although used for research purposes and some clinical trials,⁹ WGS is encumbered by cost, data size, and computational requirements. As sequencing costs decrease and laboratories gain more experience with NGS data, WGS may become more widely used.

Specific clonal disorders

Chronic myelogenous leukemia (CML)

The first consistent chromosomal abnormality in any malignant disease was identified in CML.¹⁰ The Philadelphia (Ph) chromosome results from a reciprocal $t(9;22)(q34.1;q11.2)$ ([Figures 1a,b](#), [4a](#)) and arises in a pluripotent stem cell that gives rise to both lymphoid and myeloid lineage cells. The standard $t(9;22)$ is identified in about 92% of CML patients, whereas 7% have variant translocations that also involve a third chromosome. The genetic consequences are to move the 3' portion of the *ABL1* oncogene on chromosome 9 next to the 5' portion of the *BCR* gene on 22. Rare patients with CML who lack the $t(9;22)$ have a rearrangement involving *ABL1* and *BCR* that is detectable only at the molecular level (~0.5% of cases).¹¹

The $t(9;22)$ and resultant *BCR-ABL1* fusion is the *sine qua non* of CML.¹¹ The BCR-ABL1 fusion protein acquires a novel function in transmitting growth-regulatory signals to the nucleus via the RAS/MAPK, PI3K/AKT, and JAK/STAT pathways. The tyrosine kinase activity of BCR-ABL1 can be inhibited by several commercially available oral TKIs: imatinib mesylate (Gleevec/STI571, Novartis Pharmaceuticals), dasatinib (Sprycel, BMS-354825, Bristol-Myers Squibb), and nilotinib (Tasigna, AMN107, Novartis Pharmaceuticals).^{12, 13} Additional oral agents are being tested in clinical trials.¹⁴ Imatinib has shown remarkable activity in all phases of CML and is the preferred therapy for most patients with newly diagnosed CML, who can be monitored by FISH analysis or qRT-PCR.^{15, 16} Several types of genetic changes are associated with imatinib resistance, including point mutations leading to amino acid substitutions in the ABL1 kinase domain that interfere with imatinib binding, as well as the acquisition of additional copies of the Ph chromosome or *BCR-ABL1* gene amplification, both of which can be detected by FISH.¹⁵

Historically, most CML patients in the accelerated or acute phases (80%) showed karyotypic evolution, commonly a gain of chromosomes 8 or 19, or a second Ph (by gain of the first), or an $i(17q)$, as well as

mutations in the *TP53*, *RB1*, *MYC*, *CDKN2A (p16)*, *KRAS/NRAS*, or *RUNX1/AML1* genes.¹¹ With the advent of TKI therapy, the natural history of CML has been altered, and the karyotype in blast phase differs, but is not yet well described.

Interestingly, because each of the oral TKIs blocks kinase activities in addition to *ABL1*, they have proven to be effective in other hematologic malignancies, including myeloproliferative neoplasms (MPNs) with rearrangements of *PDGFRB*, a myeloproliferative variant of hypereosinophilic syndrome that expresses the *FIP1L1-PDGFR*A fusion protein, and in patients with mast cell malignancies that demonstrate *KIT* activation, as well as in some solid tumors, for example, *KIT*-mutated melanoma and GIST.¹⁷

Other myeloproliferative neoplasms (MPNs)

A cytogenetically abnormal clone is present in 15% of untreated and 40% of treated polycythemia vera (PV) patients, compared with 100% when the disease progresses to acute myeloid leukemia (AML) (Table 2).^{18, 19} Common changes are +8 or +9, del(13q), or del(20q), noted in 30% of patients.¹⁸ A del(5q) (40%) or -7 (20%) is often observed in the leukemic phase. Cytogenetic analysis has revealed clonal abnormalities in 60% of primary myelofibrosis (MF), commonly +8, -7, or a del(7q), del(11q), del(13q), and del(20q).¹⁸ A change in the karyotype may signal evolution to AML. *JAK2*^{V617F} mutations leading to activation of the STAT, PI3K, and MAPK signaling pathways occur in PV (90–95%), essential thrombocythemia (ET, 50–70%), and MF (40–50%).^{20, 21} More recently, the majority of ET and MF cases with nonmutated *JAK2* have been shown to carry somatic mutations in the calreticulin gene (*CALR*).^{22, 23}

^a AML, acute myeloid leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; MDS, myelodysplastic syndrome.

^b Genes are listed in order of citation in the karyotype, for example, for CML, *ABL1* is at 9q34.1 and *BCR* at 22q11.2.

^c Rare patients with CML have an insertion of *ABL1* adjacent to *BCR* in a normal appearing chromosome 22.

^d Considered in the WHO 2008 Classification as presumptive evidence of MDS in patients with persistent cytopenias(s), but with no dysplasia or increased blasts.

Primary myelodysplastic syndromes (MDS)

The myelodysplastic syndromes (MDSs) are a heterogeneous group of diseases.^{24, 25} Clonal chromosome abnormalities can be detected in marrow cells of 40–60% of patients with primary MDS at diagnosis, including refractory cytopenia with unilineage dysplasia (25%), refractory anemia with ring sideroblasts (RARS, 10%), refractory cytopenia with multilineage dysplasia (RCMD, 50%), refractory anemia with excess blasts (RAEB–1,2, 50–70%), MDS with isolated del(5q) (100%), MDS unclassifiable, and childhood MDS (Table 2).^{26–28} The common changes, +8, del(5q), –7/del(7q), and del(20q), are similar to those seen in AML *de novo* (Figure 3a). The recurring translocations that are closely associated with the distinct morphologic subsets of AML *de novo* are almost never seen in MDS.

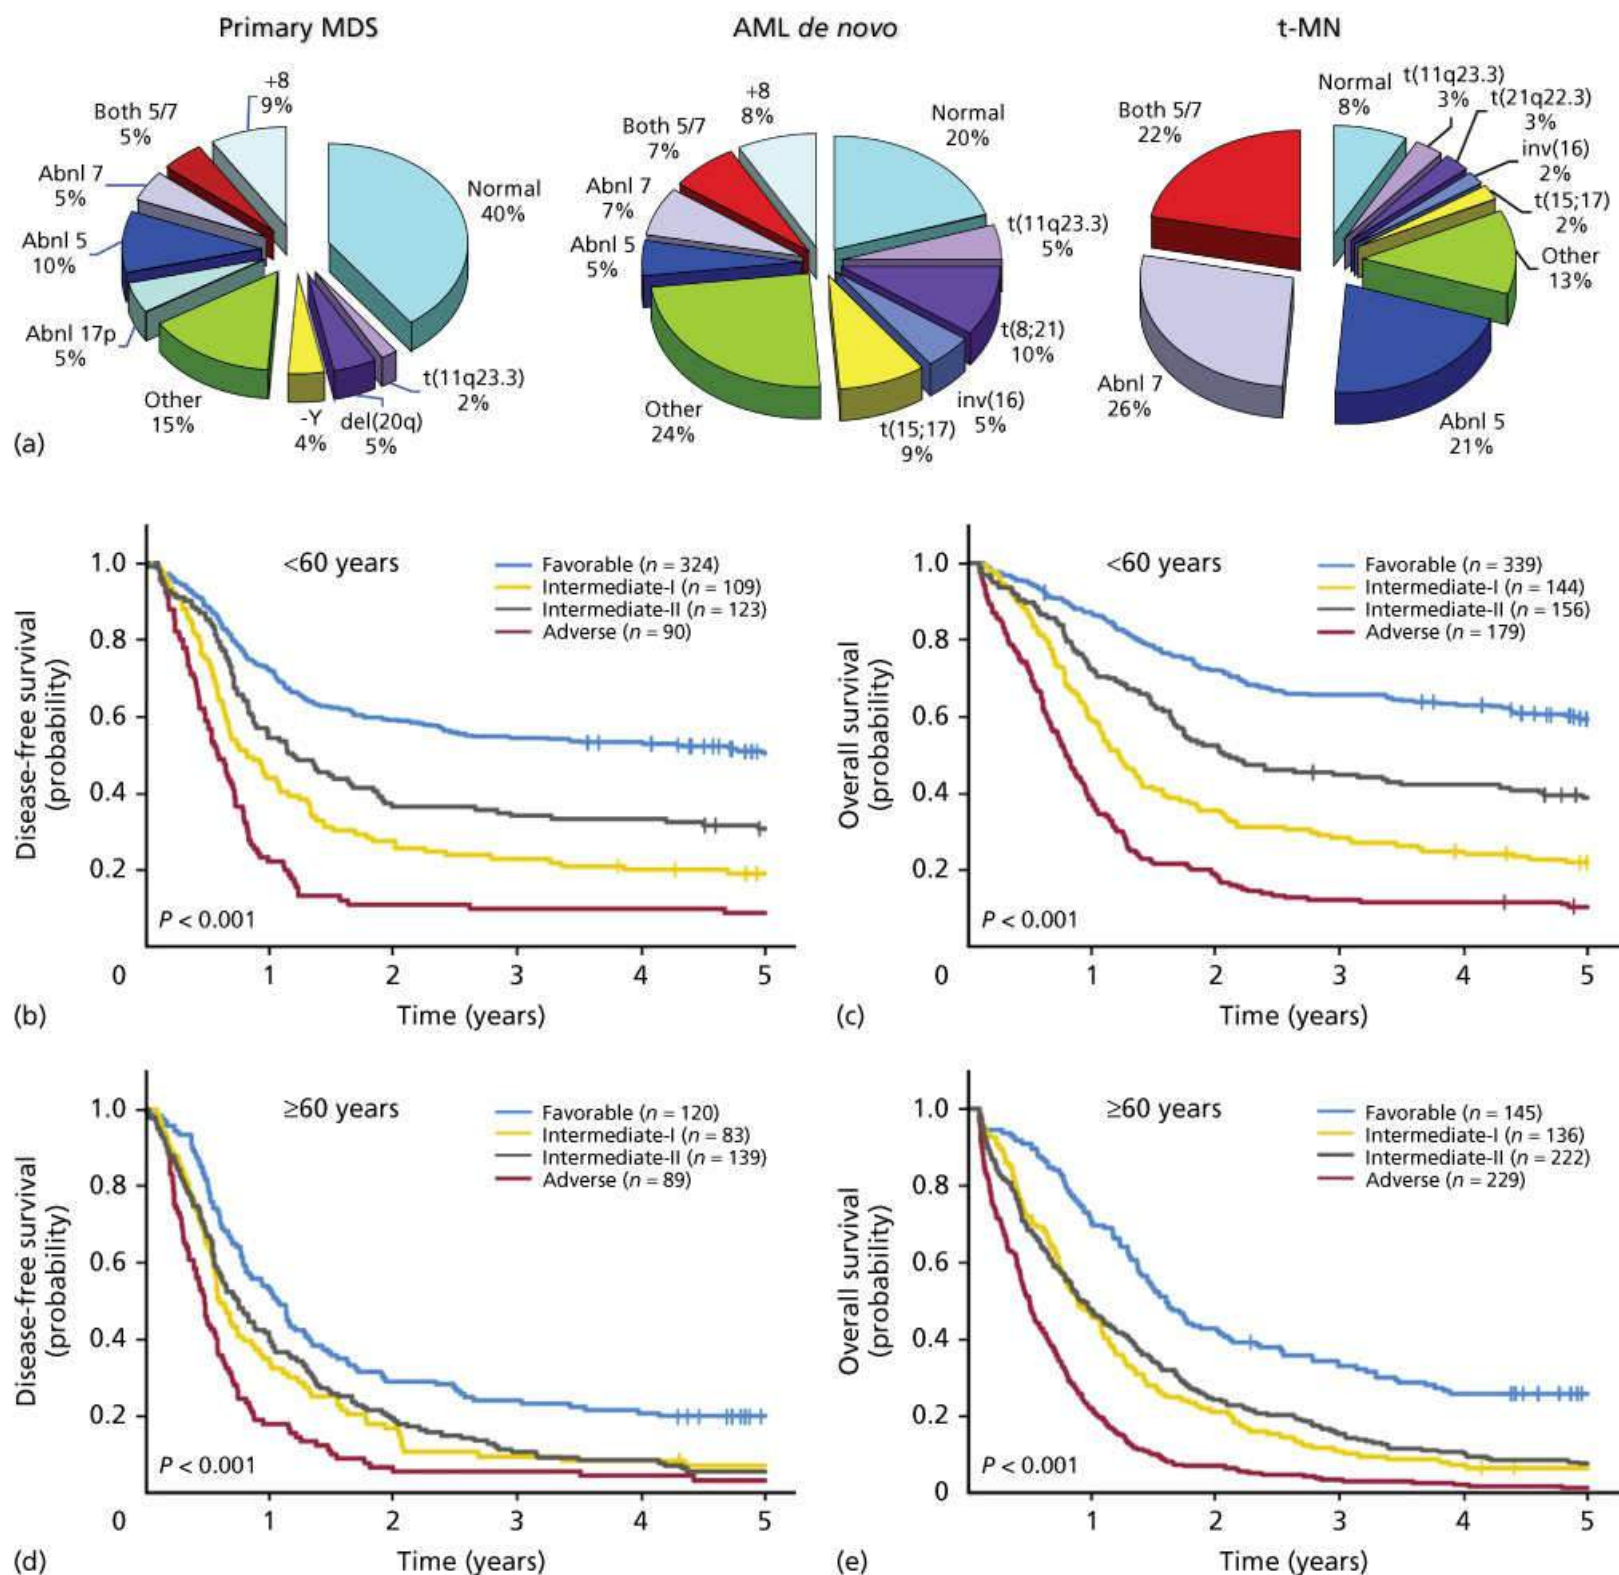

Figure 3 (a) Frequency of recurring chromosomal abnormalities in MDS, AML *de novo*, and t-MN. (b–e) Outcome of patients with AML classified according to the four European LeukemiaNet groups. (b) Disease-free survival and (c) overall survival of AML patients younger than 60 years of age. (d) Disease-free survival and (e) overall survival of patients aged 60 years or older.

Source: Mrozek et al.²⁹ Reproduced with permission of American Society of Clinical Oncology.

MDS with isolated del(5q) occurs in a subset of older patients, frequently women, with RA, generally low blast counts, and normal or elevated platelet counts.³⁰ These patients have an interstitial deletion of 5q as the sole abnormality or with one additional abnormality and typically have a relatively benign course that extends over several years.²⁹ Haploinsufficiency of *RPS14*, encoding an essential component of the 40S ribosomal subunit, appears to be responsible for the defect in erythropoiesis,³¹ whereas two

adjacent micro-RNAs, *miR-145* and *miR-146a*, cooperate with loss of *RPS14* and mediate the megakaryocytic dysplasia seen in this disease.^{32, 33}

SNP microarrays can detect abnormalities in 10–15% of cases with a normal karyotype. Of these, LOH of 7q, 11q, and 17p are associated with a poor outcome.^{34, 35} As defined by the International Prognostic Scoring System Revised, patients with a “very good outcome” have $-Y$ or $\text{del}(11q)$ as the sole abnormality; those with a “good outcome” have normal karyotypes, $\text{del}(5q)$ alone or with one additional abnormality, $\text{del}(12p)$ alone, or $\text{del}(20q)$ alone; those with an “intermediate outcome” have $\text{del}(7q)$, $+8$, $+19$, $\text{i}(17q)$ or any other single or double abnormality; those with a “poor outcome” have -7 , $\text{inv}(3q)/\text{t}(3;3)$ double abnormalities, including $-7/\text{del}(7q)$, and complex karyotypes with 3 abnormalities; and those with a “very poor outcome” have complex karyotypes with >3 abnormalities, typically with abnormalities of chromosome 5.^{26, 36, 37}

Acute myeloid leukemia (AML) *de novo*

Clonal chromosomal abnormalities are detected in ~75% of patients with AML and have prognostic and therapeutic implications.^{38–41} The most frequent abnormalities are $+8$ and -7 (Figure 3a).² The recurring translocations occur in younger patients with a median age in the 30s, whereas other abnormalities, such as $\text{del}(5q)$ or $-7/\text{del}(7q)$, occur in patients with a median age over 50. The WHO classification now recognizes specific recurring abnormalities together with their molecular counterparts as separate disease entities within AML (Table 2).² These entities include the core-binding factor (CBF) leukemias characterized by the $\text{t}(8;21)(q22;q22.1)$ (Figure 4b) occurring in 5% of AML, and the $\text{inv}(16)(p13.1q22)$ (Figure 4c) in 5% of AML (25% of AMMoL), the $\text{t}(15;17)(q24.1;q21.2)$ (Figure 4d) in APL, and the $\text{t}(9;11)(p21.3;q23.3)$ (Figure 4e).² At the molecular level, CBF rearrangements disrupt the two genes encoding the subunits of the CBF transcription factor (*RUNX1* at 21q22.1 and *CBFB* at 16q22) essential for hematopoiesis.⁴² CBF-AML has a favorable prognosis in adults (overall 5-year survival of 70% for $\text{t}(8;21)$; 60% for $\text{inv}(16)$), but the outcome in children with a $\text{t}(8;21)$ is poor.⁴² Secondary mutations of *KIT*, *KRAS*, and *NRAS* are common in CBF-AML, although only *KIT* mutations confer a poor prognosis.⁴²

Figure 4 Partial karyotypes from trypsin-Giemsa-banded metaphase cells depicting select recurring chromosomal rearrangements observed in myeloid leukemias. The rearranged chromosomes are identified with arrows. (a) $\text{t}(9;22)(q34.1;q11.2)$, CML. (b) $\text{t}(8;21)(q22;q22.1)$, AML-M2. (c) $\text{inv}(16)(p13.1q22)$, AMMoL-M4Eo. (d) $\text{t}(15;17)(q24.1;q21.1)$, APL. (e) $\text{t}(9;11)(p21.3;q23.3)$, AMoL-M5. (f) $\text{del}(5)(q15q35)$, t-MN.

The t(15;17) results in a fusion retinoic acid receptor-alpha protein (PML-RARA), the oncogenic potential of which results from the aberrant repression of RARA-mediated gene transcription through histone deacetylase (HDAC)-dependent chromatin remodeling.⁴³ *FLT3* internal tandem duplications (ITDs) are observed in 35% of patients. Establishing the diagnosis of APL with the typical t(15;17) is important because this disease is sensitive to therapy with all-trans retinoic acid (ATRA). Translocations of 11q23.3 are associated with acute monoblastic leukemia and are 4-times more common in children less than 1 year of age than in adults.^{41, 44} They result in fusion proteins of *KMT2A/MLL*, which encodes a histone methyltransferase that regulates transcription of target genes, for example, *HOX* genes, via chromatin remodeling.⁴⁵

In an international effort, the European LeukemiaNet (ELN) has recently proposed a standardized system integrating cytogenetic and molecular abnormalities.³⁸ The favorable group includes patients with the t(8;21), inv(16), mutated *NPM1* without *FLT3-ITD* (normal karyotype), and mutated *CEBPA* (normal karyotype); Intermediate-I includes patients with a normal karyotype with mutated *NPM1* and *FLT3-ITD*, wild-type *NPM1* with or without *FLT3-ITD*; Intermediate-II includes patients with the t(9;11) or abnormalities not classified as favorable or adverse; and the adverse group includes patients with the inv(3q)/t(3;3), t(6;9), t(11q23.3), del(5q), -7, loss of 17p, or complex karyotype (≥ 3 abnormalities). Several large studies have validated this classification in predicting outcome and support the view that these genetic groups should be applied to younger (<60 years old) and older (≥ 60 years old) patients separately (Figure 3b–e).²⁹ Recent studies have provided evidence that the mutation analysis of additional genes, that is, *DNMT3A*, *TET2*, *ASXL1*, and *RUNX1*, may refine the ELN risk stratification.^{46–49}

Therapy-related myeloid neoplasms (t-MN)

t-MN (therapy-related myeloid neoplasms), composed of t-MDS/t-AML, is a late complication of cytotoxic therapy used in the treatment of both malignant and nonmalignant diseases.⁵⁰ Loss of part of chromosome 5, del(5q) (Figure 4f), and/or part or all of chromosome 7 [–7/del(7q)] are characteristic in patients who received alkylating agents (Figure 3a). Clinically, these patients have a long latency period (5 years), present with MDS, which often progresses rapidly to AML with multilineage dysplasia and a poor prognosis (median survival 8 months). In our experience, 92% of t-MN patients had an abnormal karyotype and 70% had an abnormality of one or both chromosomes 5 and 7,⁵¹ and these observations have been confirmed in other series.⁵² In contrast, only about 20% of patients with AML *de novo* have a similar abnormality of chromosomes 5 or 7 or both.² Molecular analysis of the genes within the deleted segment of chromosome 5 (band 5q31.2) is compatible with a haploinsufficiency model in which the coordinate loss of more than one gene on 5q in HSCs cooperates in disease pathogenesis, and several haploinsufficient myeloid leukemia genes (*EGR1*, *APC*, *RPS14*, and *miR-145/miR-146a*) have been identified.^{53, 54}

A second subtype of t-AML is seen in patients receiving drugs known to inhibit topoisomerase II, for example, etoposide, teniposide, and doxorubicin. Clinically, these patients have a shorter latency period (1–2 years), present with overt leukemia, often with monocytic features, without an antecedent MDS, and have a more favorable response to intensive induction therapy. Translocations involving *KMT2A* at 11q23.3 or *RUNX1* at 21q22.1 are common in this subgroup.⁵⁰

Acute lymphoblastic leukemia (ALL)

The identification of prognostic subgroups based on recurring cytogenetic abnormalities (Table 3, Figure 5) and molecular markers has resulted in the application of risk-adapted therapies in acute lymphoblastic

leukemia (ALL).^{55, 56} The Children's Oncology Group has defined four risk groups: low risk (5-year event-free survival (EFS), at least 85%), with either the *ETV6-RUNX1* fusion or simultaneous trisomies of chromosomes 4, 10, and 17; standard and high risk (those remaining in the respective National Cancer Institute risk groups); and very high risk (5-year EFS, 45% or below) with extreme hypodiploidy (<44 chromosomes) or the *BCR-ABL1* fusion and induction failure.⁵⁷ Genome-wide profiling studies using CMA have revealed a high frequency of submicroscopic CNAs in pediatric ALL, including deletions of *PAX5* (32%), *IKZF1* (*IKAROS*, 29%), *CDKN2A/B* (50%), *BTG1*, and *EBF1* (8%), that disrupt genes and pathways controlling B cell development and differentiation.⁵⁸ Genetic alterations of *IKZF1* are associated with a very poor outcome in B cell progenitor ALL.⁵⁹

^a DLBCL, diffuse large B cell lymphoma; MCL, mantle cell lymphoma; LPL, lymphoplasmacytoid lymphoma; MALT, mucosa-associated lymphoid tumor; PCFCL, primary cutaneous follicular center lymphoma; ALCL, anaplastic large cell lymphoma.

^b The percentage refers to the frequency within the disease overall. The number in the parentheses refers to the frequency within the morphological or immunological subtype of the disease.

^c Genes are listed in order of citation in the karyotype, for example, for precursor B ALL, *ETV6* is at 12p13.2 and *RUNX1* is at 21q22.3.

^d TF, transcription factor.

^e By cytogenetic analysis, the frequency in children is about 5% and in adults is about 25%; using molecular probes, this frequency is 30% in adults overall and 50% in adults over 60 years of age.

Figure 5 Frequency of recurring chromosomal abnormalities in ALL, CLL, and NHL.

Translocation 9;22

The incidence of the t(9;22) in ALL is 30% in adults overall, ~50% in adults over 60 years of age, and 5% in children and is associated with a very poor prognosis. About 70% of the patients show additional abnormalities, commonly with +der(22)t(9;22), +21, or -7 (associated with a poorer outcome).⁶⁰ Most cases have a B lineage phenotype (CD10+, CD19+, and TdT+), but there is frequent expression of myeloid-associated antigens (CD13 and CD33). In over half of the patients, the break in *BCR* is more proximal, resulting in a smaller BCR-ABL1 fusion protein with even greater tyrosine kinase activity (BCR-ABL1^{p190}). Genetic alterations of the *IKZF1* gene are detectable in up to 80% of Ph+ ALL cases and are associated with an unfavorable outcome even with the use of TKIs.⁶¹

Translocations involving 11q

Translocations involving the *KMT2A* gene at 11q23.3 are observed in 5% of ALL patients but in 80% of ALL in infants.⁶² Of these, the most common is the t(4;11)(q21.3;q23.3) (Figure 6a), followed by the t(11;19)(q23;p13.3). Patients with the t(4;11) have a pro B phenotype (CD10-, CD19+), with co-expression of monocytic (CD15+) or, less commonly, T cell markers, and a poor response to conventional chemotherapy (adults: remission rate of 75% with EFS of only 7 months).⁶²

Figure 6 Partial karyotypes of trypsin-Giemsa-banded metaphase cells depicting select recurring chromosomal rearrangements observed in lymphoid neoplasms. The rearranged chromosomes are identified with arrows. (a) $t(4;11)(q21.3;q23.3)$ in ALL. (b) $t(1;19)(q23;p13.3)$ in pre-B cell ALL. (c) $t(8;14)(q24.2;q32.3)$ in B cell ALL and Burkitt lymphoma. (d) $inv(14)(q11.2q32.3)$ in T cell leukemia/lymphoma. (e) $t(8;14)(q24.2;q11.2)$ in T cell leukemia/lymphoma. (f) $t(14;18)(q32.3;q21.3)$ in B cell lymphoma.

Translocation 12;21

The $t(12;21)(p13.2;q22.3)$ has been identified in a high proportion (~25%) of childhood precursor B leukemia but is uncommon in adults (~4% of ALL cases).⁶³ This cryptic translocation is not detectable by cytogenetic analysis but can be detected reliably using RT-PCR or FISH analysis. The $t(12;21)$ defines a distinct subgroup of patients aged 1–10 years, with a B lineage immunophenotype (CD10+, CD19+, HLA-DR+), and a favorable outcome (5-year EFS of 91% vs 65% for other ALL). The $t(12;21)$ results in a fusion protein containing the N-terminus of ETV6/TEL, a transcriptional repressor of the ETS family, and most of the RUNX1 transcription factor.

Hyperdiploidy

The leukemia cells of some patients with ALL are characterized by a gain of many chromosomes. Two distinct subgroups are recognized: a group with 1–4 extra chromosomes,^{47–50} and the more common group with >50 chromosomes (typically 51–60 chromosomes). The latter subgroup is common in children (~30%) but is rarely observed in adults (<5%). Certain additional chromosomes are common (X chromosome, and chromosomes 4, 6, 10, 14, 17, 18, and 21). Patients with >50 chromosomes with +4, +10, and +17 have favorable clinical features, including age between 1 and 9 years, low white blood cell count (median 6700/L), and favorable immunophenotype (early pre-B or pre-B).⁶⁴

Translocation 1;19 and translocation 8;14

The $t(1;19)(q23;p13.3)$ is associated with a good prognosis and has been identified in about 6% of children with a B lineage leukemia (Figure 6b). The leukemia cells have cytoplasmic immunoglobulin and are CD10+, CD19+, CD34–, and CD9+. The $t(8;14)(q24.2;q32.3)$ is observed in mature B cell ALL (Figure 6c). These patients have a high incidence of central nervous system involvement and/or abdominal nodal involvement at diagnosis. Historically, the outcome has been poor, but the use of high-intensity chemotherapy has markedly improved the outcome (EFS of 80% in children).

Ph-like ALL

Ph-like ALL is a novel subgroup of high-risk ALL (15% of pediatric and 30% of adult ALL), characterized by increased expression of HSC genes, a similar gene expression profile to Ph-positive ALL, and by a high frequency of *IKZF1* deletions and mutations, which confer a poor prognosis. Genetic alterations responsible for the activated kinase and cytokine receptor signaling signature in Ph-like ALL include point mutations and gene fusions affecting *CRLF2*, *JAK2*, *ABL1*, *PDGFRB*, *EPOR*, *EBF1*, *FLT3*, *IL7R*, *SH2B3*, and other genes.^{65, 66}

T-cell acute lymphoblastic leukemia

T lymphoblastic leukemia/lymphoma has a distinct pattern of recurring abnormalities, involving the T cell receptor loci at 14q11.2 ([Figure 6d,e](#)) and two regions of chromosome 7 (7q34) and 7p14) ([Table 3](#)).^{67, 68} The most common are the t(10;11)(q24.3;q11.2) (7% of childhood and 30% of adult patients, *TLX1* gene) and the cryptic t(5;14)(q35.1;q32.1) (*TLX3*, 20% of childhood, and 10–15% of adult cases). About 30% of patients have activating mutations of the *NOTCH1* gene. Patients with T-cell ALL are most often young males and often have a mediastinal tumor mass, high white blood cell count, and leukemia cells in the cerebrospinal fluid.

Chronic lymphocytic leukemia (CLL)

Only 50% of chronic lymphocytic leukemia (CLL) patients have detectable abnormalities by cytogenetic analysis, which increases to 80% when FISH analysis is used ([Table 3](#), [Figure 5](#)).⁶⁹ The most frequent changes seen by FISH are: -13/del(13q) (55%), deletion of *ATM* on 11q (18%), +12 (16%), deletion of *TP53* on 17p, and deletion of 6q (6%).⁷⁰ The median survival is shorter in patients with 17p (32 months) or 11q (79 months) loss, than in those with no detectable abnormality (111 months), +12 (114 months), or -13/del(13q) (133 months). ZAP-70, an enzyme critical for T cell activation, is upregulated in CLL cells that contain unmutated *IGH* genes, conferring a poor prognosis.⁷¹ Patients whose CLL cells have mutated *IGH* and lack expression of ZAP-70 and CD38 have the longest treatment-free period after diagnosis.⁷²

T-cell CLL and large granular lymphocytic leukemia are uncommon disorders. Rearrangements involving 14q11.2, with or without an accompanying break in 14q32.3, have been reported in T-CLL as well as in T-cell lymphomas ([Table 3](#)).⁶⁷ The most common is inv(14)(q11.2q32.3) ([Figure 6d](#)).

Non-Hodgkin lymphoma (NHL)

More than 90% of non-Hodgkin lymphoma (NHL) cases are characterized by clonal chromosomal abnormalities, which correlate with histology and immunophenotype ([Table 3](#), [Figure 5](#)).^{73, 74} For example, the t(14;18) is observed in a high proportion of follicular small cleaved cell lymphomas (70–90%). Most patients with a t(3;22)(q27;q11.2) or t(3;14)(q27;q32.3) have diffuse large B cell lymphomas (DLBCLs), and patients with a t(8;14)(q24.2;q32.3) have either small noncleaved cell or DLBCL. *IGH* at 14q32.3 is frequently involved in translocations in B-cell neoplasms (~70%). Similarly, a large proportion of T cell neoplasms are characterized by rearrangements of the TCR genes at 14q11.2, 7q34, or 7p14. Gene expression profiling has proven useful in distinguishing unique genetic subtypes of lymphoma.⁷⁵ For example, gene expression profiling has shown that DLBCL comprises at least three different subtypes (Germinal Center B-cell like, activated B-cell like, and primary mediastinal B-cell lymphoma), each with a distinct oncogenic mechanism, prognosis, and response to therapies.⁷⁶

The t(8;14) or variant t(2;8) or t(8;22) is characteristic of both endemic and nonendemic Burkitt tumors,

as well as Epstein–Barr virus-negative and -positive tumors ([Figure 6c](#)). Moreover, the t(8;14) has been observed in other lymphomas, particularly small noncleaved cell (non-Burkitt) and large cell immunoblastic lymphomas, HIV-associated BL (100%) and HIV-related DLBCL (30%).⁷⁷ The t(8;14) results in constitutive expression of *MYC* (8q24.2) via juxtaposition of the coding exons with *IGH* sequences (14q32.3). *MYC* is a transcription factor that plays a critical role in a number of cellular processes, including DNA replication, proliferation, and apoptosis.

Between 70% and 90% of follicular lymphomas and 20% of DLBCL have the t(14;18) ([Figure 6f](#)), in which the *BCL2* gene at 18q21.3 is juxtaposed to the *IGH* J segment, leading to the deregulated expression of *BCL2*, an anti-apoptotic mitochondrial membrane protein.⁷⁸ Common secondary abnormalities include -7, +18, and del(6q). Double-hit lymphomas arising from the progression of a follicular lymphoma to a DLBCL have both a *BCL2* and *MYC* translocation.⁷⁹

The t(11;14) (q13.3;q32.3) is observed in virtually all cases of mantle cell lymphoma (MCL), a poor prognostic group with a median survival of 3 years, in 3% of myeloma, and in up to 20% of prolymphocytic leukemias.⁸⁰ This translocation results in the activation of the cyclin D1 (*CCND1*) gene, located 100–130 kb away from the breakpoint, by the *IGH* gene. The D-type cyclins act as growth factor sensors, regulating cell division via phosphorylation and inactivation of RB1.

Rearrangements leading to overexpression of *BCL6* at 3q27 occur in 40% of DLBCL and in up to 10% of follicular lymphomas and result most commonly from a t(3;22)(q27;q11.2) or t(3;14)(q27;q32.3).⁷³ *BCL6* is a 96 kD POZ/Zn finger transcriptional repressor and may suppress genes involved in lymphocyte activation, differentiation, cell cycle arrest, and apoptosis. Somatic mutations have been identified in the 5' regulatory regions of *BCL6* in ~20% of DLBDL without translocations, suggesting that overexpression of *BCL6* is more broadly involved than initially recognized.⁸¹

Extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT lymphoma) are composed of several genetic subgroups, one characterized by +3 plus other abnormalities (60%), and another by the t(11;18)(q21.2;q21.3) (25–50%) and its variants.⁸² The t(11;18) results in the fusion of the apoptosis-inhibitor gene *BIRC3* (*API2*) to a novel gene at 18q21.3, *MALT1*, whose product activates the NFκB pathway.

Anaplastic large cell lymphoma (ALCL) is characterized by a young age at presentation and skin and/or lymph node infiltration by large, often bizarre lymphoma cells, which preferentially involve the paracortical areas and lymph node sinuses. The majority of such tumors express one or more T-cell antigens, a minority express B-cell antigens, and some express both T- and B-cell antigens (the null phenotype). The t(2;5)(p23.2;q35.1), t(1;2)(q25;p23), or variant rearrangement involving the *ALK* tyrosine kinase gene at 2p23 occurs at a high frequency in ALCL of either T-cell or null phenotype.⁸³ The tumor cells are positive for CD30 on the cell membrane and in the Golgi region, and *ALK* expression is detectable in 60–85% of cases, where it confers a more favorable outcome (5 year survival, 80% in *ALK*+ vs 40% in *ALK*-tumors).

Multiple myeloma

The application of FISH in combination with plasma cell enrichment techniques has led to the discovery of abnormalities in a high proportion of myeloma, a monoclonal malignancy of post-follicular B cells, preceded by a premalignant monoclonal gammopathy of undetermined significance (MGUS) ([Table 3](#)).⁸⁴ ⁸⁵ MGUS is characterized by chromosomal aneuploidy, *IGH* translocations (45%), hyperdiploidy, and deletions of 13q (15–50%), leading to dysregulation of the cyclin D/RB1 pathway, also seen as the

earliest changes in plasma cell myeloma.^{84, 86–88}

A molecular cytogenetic classification for myeloma recognizes three major groups: (1) nonhyperdiploid with *IGH* translocations (40% of myeloma patients and 10% of MGUS patients); (2) hyperdiploid; and (3) other abnormalities.^{84, 86} The t(11;14)(q13.3;q32.2) is found in 15% of cases and results in *CCND1* overexpression. The t(4;14)(p16.3;q32.3) is noted in about 15% of patients and deregulates the expression of the fibroblast growth factor receptor 3 gene (*FGFR3*) translocated to the der(14), and the *WHSC1/MMSET* domain remaining on the der(4) chromosome. The t(14;16)(q32.3;q23), noted in 5% of cases, results in the overexpression of the *MAF* transcription factor gene. The t(4;14) and t(14;16) are both associated with a poor clinical outcome, whereas the t(11;14) confers a favorable prognosis. Nearly half of myeloma cases are hyperdiploid (45%), most commonly with 49–56 chromosomes, including trisomy for three or more odd-numbered chromosomes (chromosomes 3, 5, 7, 9, 11, 15, 19, or 21), a genetic subgroup that is associated with older patients and a more favorable outcome.

Deletions of *TP53* on 17p are noted by FISH in 10% of myeloma and are associated with a poor prognosis (37% of these patients also have mutations of *TP53*). Chromosome 1 abnormalities frequently resulting in both gain of 1q and loss of 1p (*CDKN2C*) are associated with a shorter survival.⁸⁹ Thus, a comprehensive FISH testing panel for myeloma should include probes for 1p and, particularly, 1q.

Additional events occur with disease progression in myeloma, including mutations of *NRAS* and *KRAS* (30–40%), *MYC* deregulation, and epigenetic alterations. Several genes are silenced through aberrant promoter hypermethylation in both MGUS and multiple myeloma, including *DAPK1* (67%), *SOCS1*, *CDKN2B* (*p15*), and *CDKN2A* (*p16*).⁸⁶

Solid tumors

In contrast to the hematologic malignancies, our understanding of the contribution of chromosomal alterations to solid tumors has lagged behind, largely due to technical constraints. With recent advances in genetic analysis, however, chromosomal changes clearly play a significant role in solid tumors ([Table 4](#)). Although simple karyotypes with disease-specific gene fusions are the norm in hematologic malignancies and sarcomas, chromosomal aberrations in other solid tumors often involve a larger fraction of the genome. Indeed, the median number of somatic CNAs in solid tumors is 39, a much higher number than in hematologic malignancies.⁹⁰ Extreme cases of CNAs have been described as “chromothripsis” and “chromoplexy,” involving highly complex rearrangements,^{91, 92} that are frequently associated with *TP53* mutations and a poor prognosis.⁹³ As with hematologic malignancies, many recurring alterations in solid tumors involve genes encoding transcriptional regulators or tyrosine kinases, the latter creating potentially druggable proteins. In addition to providing potential therapeutic targets, chromosomal alterations can give insight into the biology of solid tumors, improve disease classification, predict response to therapy, and inform our understanding of prognosis. Representative diseases and associated recurring chromosomal aberrations are discussed in the following sections.

Table 4 Recurring chromosomal abnormalities in solid tumors

^a Genes are listed in order of citation in the karyotype, for example, for bladder cancer, *DIP2B* is at 12q13.1 and *ERBB2* at 17q12.

Sarcomas

Sarcomas are a heterogeneous group of diseases that over time have come to be recognized as comprising an increasing number of distinct entities. Histologic similarity does not always translate to similar clinical behavior, and knowledge of the genetic basis of these diseases has assisted in improving disease classifications and contributed to our understanding of how these separate diseases are related.

In 1983, the t(11;22)(q24.3;q12.2) was identified in Ewing sarcomas.^{94, 95} This translocation results in an in-frame fusion of Ewing Sarcoma Breakpoint Region 1 (*EWSR1*), a member of the FET family, and Friend Leukemia Virus Integration Site 1 (*FLI1*), a member of the ETS transcription factor family. The resultant EWS-FLI1 fusion protein consists of the *N*-terminal transactivation domain of EWS fused with the DNA-binding domain of FLI1, forming an oncogenic transcription factor that upregulates or downregulates thousands of genes and is required for tumorigenesis.^{96–98} The fusion breakpoint is variable and the functional significance of the different fusion products is not entirely characterized.⁹⁹

A decade later, the *EWSR1* and ETS-related gene (*ERG*) fusion was identified in ~10% of Ewing sarcomas. *ERG* encodes another ETS family member that has 98% identity with *FLI1* in the DNA-binding ETS domain.¹⁰⁰ Together with EWS-FLI1, these account for 95% of Ewing sarcomas. The remaining 5% contain other fusions of FET family members, particularly *EWSR1* or *FUS*, with ETS family members, including *FLI1*, *ERG*, *ETV1*, *ETV4*, or *FEV*.¹⁰¹ These fusions are mutually exclusive, suggesting that the resulting proteins function in a similar manner.

Ewing-like sarcomas are histologically similar to Ewing sarcomas but do not contain a detectable FET/ETS chromosomal rearrangement. They are characterized by other rearrangements, involving *EWSR1* and non-ETS family members.¹⁰² It is likely that diagnostic definitions of these diseases will change as we improve our understanding of the fusion genes and the associated disease. Complicating the diagnostic challenge is the association of *EWSR1* rearrangements with other sarcomas, including *EWSR1-ATF1* and clear cell sarcoma, *EWSR1-WT1* and desmoplastic round cell tumor, *EWSR1-NR4A3* and extraskeletal myxoid chondrosarcoma, *EWSR1-DDIT3* and myxoid liposarcoma, and *EWSR1-ZNF278* and small round cell sarcoma. As with Ewing Sarcoma, a single rearrangement is most common for each diagnosis, but one or both of the genes involved can also form fusion partners with other genes.

A translocation involving *SS18* at 18q11.2 and *SSX1* at Xp11.23 was identified in synovial sarcoma in 1986.¹⁰³ A large family of genes and pseudogenes is homologous with *SSX1* and many of them can form fusion oncogenes with *SS18*. The resulting fusion proteins regulate transcription through interactions with the SWI-SNF chromatin remodeling complex and the polycomb group protein complex.^{104–106} The various fusion gene products appear to have subtle functional differences and result in morphologically distinct tumor variants.

Renal cell carcinoma

Conventional renal cell carcinoma (RCC) refers to clear cell carcinoma, which comprises ~85% of cases. Almost all clear cell RCCs are associated with disruption of *VHL*, through deletion, mutation, and/or epigenetic silencing. It is typically altered in every cell within the tumor, indicating that these genetic changes occur in the parental clone and are likely to be essential for tumor initiation.¹⁰⁷ In addition to loss of *VHL*, 90% or more of clear cell RCCs harbor a deletion of other genes located on 3p, including *PBRM1*, *SETD2*, and *BAP1*.¹⁰⁸

Oncocytomas and chromophobe RCCs are thought to originate from the intercalated cells of the collecting ducts and they can be difficult to distinguish histologically. Oncocytomas rarely metastasize, however, suggesting that prior reports of metastatic oncocytomas may have been diagnosed incorrectly.¹⁰⁹ Both can harbor a variety of chromosomal abnormalities; oncocytomas, but not chromophobe RCC, frequently have rearrangements leading to overexpression of *CCND1* (11q13). Identifying these alterations can have a major impact on predicting risk of metastatic potential and, therefore, clinical management.¹¹⁰

Gliomas

Oligodendrogliomas are well-differentiated tumors that are associated with an unbalanced translocation involving 1q and 19p, with subsequent loss of 1p and 19q. Anaplastic oligodendrogliomas and oligoastrocytomas are somewhat less differentiated, and their prognosis appears to be related to the presence of the codeletion. Among oligodendrogliomas, those that harbor this codeletion are sensitive to chemotherapy and patients have a median survival that exceeds 10 years. In contrast, tumors without these changes are more likely to have astrocytic features and shorter survival (2–3 years).¹¹¹ Thus, assessment for the codeletion is recommended for all oligodendrogliomas at the time of diagnosis.

Non-small-cell lung cancer (NSCLC)

In addition to predicting response to cytotoxic therapy, the protein products resulting from many chromosomal alterations have emerged as drug targets. A decade ago, small molecule inhibitors of EGFR were found to be effective for ~10% of patients with non-small-cell lung cancer (NSCLC), a subset that appeared to be composed of never-smokers with adenocarcinoma, especially in Asian patients.^{112, 113} Subsequently, most responders were found to have *EGFR* mutations with frequent amplification of the mutated allele.¹¹⁴ Before this discovery, *KRAS* mutations were the sole driver mutation identified in NSCLCs, presenting a challenging drug target. In 2007, the *EML4-ALK* fusion oncogene was identified in ~5% of patients, typically in young, never or light smokers.¹¹⁵ Just 4 years later, crizotinib was approved by the FDA for patients with *EML4-ALK* translocations. In patients with genetic alterations predicting response, targeted inhibitors of EGFR and ALK are preferred over cytotoxic therapy.

Although the percent of patients with each driver oncogene is low, there is a growing number of driver oncogenes in adenocarcinomas ([Figure 7](#)). These include fusions of *ALK* with other fusion partners; *CD74-ROS1*, *SLC34A2-ROS1*, and other fusions involving *ROS1*; *KIF5B-RET* and other *RET* fusions; fusions involving *NTRK1*; and others. Recent sequencing efforts have identified amplifications of *MET* and *ERBB2*.¹¹⁶ *FGFR3-TACC3* mutations were first identified in glioblastoma but have been found also in squamous cell carcinoma of the lung and urothelial cancers.¹¹⁷ Patients with fusions involving *ALK*, *ROS1*, and, possibly, *NTRK1* respond to crizotinib. Various RET inhibitors are being tested in patients with *RET* fusions and tumors with *FGFR* family fusions are likely to be sensitive to FGFR inhibitors. Testing for alterations of driver genes is recommended for patients with newly diagnosed NSCLC, especially those with adenocarcinoma or young age at diagnosis. As the number of identified driver mutations has grown, multiplex evaluation or more comprehensive sequencing techniques have replaced PCR-based assays of individual genes.

Figure 7 Frequency of driver gene alterations in lung adenocarcinoma. Genes that are involved in chromosomal abnormalities are identified with bold text.

Prostate cancer

Given the high prevalence of prostate cancer, the *TMPRSS2-ERG* fusion found in ~40–50% of patients with prostate cancer is the most common gene fusion in human neoplasms.^{118, 119} It leads to high expression of *ERG*, driven by the androgen receptor-regulated *TMPRSS2* promoter, which is otherwise expressed at very low levels. Similar to the *EWSR1* fusion genes in sarcoma, multiple other *ETS* family members also form fusion genes in prostate cancer, including *ETV1*, *ETV4*, *ETV5*, and *ELK4*, and these fusions are mutually exclusive. Each of these *ETS* family members can form fusions with 5' fusion partners, including *TMPRSS2* or *SCL45A3* or other fusion partners. In total, 60% of prostate cancers harbor *ETS*-family fusions ([Figure 8](#)).

5' fusion partner	3' fusion partner	Frequency
<i>TMPRSS2</i>	<i>ERG</i>	~40–50%
<i>TMPRSS2</i>	<i>ETV1</i>	} 5–10%

<i>SCL45A3</i>	<i>ELK4</i>	
<i>SCL45A3</i>	<i>SCL45A3</i>	} 1–2%
<i>ESRP1</i>	<i>ESRP1</i>	
<i>AGTRAP</i>	<i>AGTRAP</i>	

Figure 8 Fusion genes identified in prostate cancer.

ETS-family rearrangements appear to be an early event in tumor initiation and have been demonstrated in preneoplastic prostatic intraepithelial neoplasm (PIN) lesions.¹²⁰ Initially, ETS-family rearrangements were associated with a poor prognosis; subsequent reports refuted this finding and it remains a topic of debate. Recent preclinical data have demonstrated sensitivity of *ETS*-rearranged cell lines and xenograft models to PARP1 inhibitors, now under evaluation in clinical trials.¹²¹

Approximately 1% of prostate cancers harbor fusions involving each of *CRAF* and *BRAF* and are sensitive to sorafenib.¹²² Virtually, 100% of advanced prostate cancers are estimated to harbor alterations in the PTEN-PI3K-Akt pathway and *PTEN* deletion in localized prostate cancer portends a worse prognosis.¹²³ *PTEN* deletion together with *MYC* amplification predicts a 50-fold increase in prostate cancer mortality compared to the absence of both abnormalities.¹²⁴ To date, however, PI3K and AKT inhibitors have not demonstrated clinical benefit.

Approximately 5% of localized prostate cancers have amplifications of *AURKA* or *MYCN*. In the aggressive neuroendocrine variant, however, the amplification rate is ~40%.¹²⁵ Preclinical models have demonstrated sensitivity of neuroendocrine tumors to AURKA inhibitors and ongoing clinical trials are testing these agents for this aggressive subtype. Although evaluation for chromosomal aberrations in prostate cancer seldom occurs outside of a clinical trial, more widespread analysis will likely occur with the implementation of next-generation sequencing and fusion-specific panels.

Chapter 9

MicroRNA expression in cancer

Serge Patrick Nana-Sinkam, MD ■ Mario Acunzo, PhD ■ Carlo M. Croce, MD

Overview

In the last two decades, researchers have identified a novel group of noncoding RNAs (ncRNAs) classified according to their function and size. The best studied of these ncRNAs termed microRNAs (miRNAs) are short noncoding RNAs that are approximately 22 nucleotides in length and play a key role in the regulation of a large number of biological processes and diseases, including cancer. Since the initial description of an association between miRNA and cancer in 2002, miRNAs have emerged as central regulators of processes fundamental to the initiation and progression of cancer. More recently, miRNAs have been detected in bodily fluids including blood, sputum, and urine, thus making them potential noninvasive diagnostic and prognostic biomarkers of disease. The application of miRNAs in human cancer therapy has become a fascinating field of study, representing one of the newest frontiers for cancer treatment. However, our knowledge for these small molecules and their application to human cancers is still growing. In this chapter, we provide an overview of the connection between miRNAs and cancer with a focus on translation to human application.

Background

As investigators increasingly recognize the inherent complexities of cancer, they continue to search for novel molecular pathways in cancer that may be leveraged for the development of novel biomarkers and therapeutics, with the ultimate goal of saving lives. For decades, investigators have held the belief that a large percentage of the human genome was composed of “junk-DNA” or “dark matter” due to its inability to code for proteins. In the last two decades, researchers have now identified functions for regions of the human genome previously considered to be nonfunctional. Some genes located within these regions indeed encode for noncoding RNAs (ncRNAs), with microRNAs (miRNAs) representing the most researched member of this group. Since their initial discovery two decades ago in *Caenorhabditis elegans*, miRNAs have emerged as key regulators of biological processes fundamental to the initiation and progression of cancers.^{1, 2} Approximately, 22 nucleotides (nt) in length, miRNAs tend to be highly conserved across species and often demonstrate global deregulation in solid and hematological malignancies.^{3, 4} By directly binding to either the 3' or 5' untranslated region (UTR) of target mRNAs, miRNAs can either degrade target mRNA or inhibit translation. In addition, based on their relatively short size, miRNAs have the capacity for the simultaneous regulation of tens to hundreds of genes, thus interdicting in numerous biological pathways. In fact, the estimate that miRNAs may regulate up to 60% of the human genome is probably wrong and miRNA may regulate over the 90% of the protein-coding genes^{4, 5}). miRNAs are often located in fragile regions of the chromosome and thus susceptible to regulation through chromosomal amplifications, deletions, or rearrangements.⁶ The mechanisms for the regulation of miRNAs in the setting of cancer are complex and remain only partially understood. However, increasing lines of investigation indicate that miRNA regulation may occur by several mechanisms including

alterations in key components of processing, epigenetic silencing, and polymorphisms in either miRNAs or target mRNAs interfering with binding and regulation.⁷ The mechanisms for miRNA regulation and function are further complicated by their tumor and cell specificity. We are now approaching the identification of nearly 3000 miRNAs. miRNAs may function either as tumor suppressors or oncogenes depending on tumor and cell type and regulate processes fundamental to tumorigenesis (hallmarks of cancer) including differentiation, proliferation, and angiogenesis.⁸ The mechanisms that regulate miRNAs in cancer, as well as their roles in cancer initiation and progression, are only beginning to be uncovered. While the use of high-throughput profiling strategies for the identification of clinically relevant miRNA-based biomarkers has been useful, this approach to miRNA investigation remains limited by issues of reproducibility and the need for improved algorithms for miRNA-target prediction and validation. Thus, there is still considerable work required to translate miRNAs into markers for clinical decision-making. One must also consider the inherent difficulties in achieving tumor-specific miRNA delivery. As miRNA biology transitions to the clinic, there is encouraging evidence suggesting that human applications for miRNAs, particularly as therapeutics, are in the not-too-distant future. For instance, nanotechnology-based carriers for miRNA delivery represent a new promising tool for the effective shuttling of miRNAs in the human body. Santaris/miRNA Therapeutics Inc. has tested human delivery of an antagomir against miR-122 for the treatment of hepatitis C. More recently, investigators have initiated trials testing human delivery of miR-34 in hepatocellular carcinoma as well as a phase I trial testing miR-16 replacement in recurrent malignant mesothelioma. Such studies represent the first of hopefully a series of future applications for the treatment of human cancer.

Biogenesis and production of microRNAs

miRNAs are short ncRNAs with a length of approximately 22 nucleotides encoded by evolutionally conserved genes. miRNAs are more frequently located within the introns or exons of protein-coding genes (about the 70%), or in intergenic regions (30%). The expression of intergenic miRNAs is related to their host gene expression, all intragenic miRNAs having independent transcription units.⁹ miRNAs are processed and generated through a well-orchestrated series of interrelated steps, each of which is currently being investigated ([Figure 1](#)). In the first step, a long primary transcript termed the (pri)-miRNA undergoes transcription by RNA polymerase II. The pri-miRNAs are then bound to the double-stranded RNA-binding domain (dsRBD) protein known as DiGeorge syndrome critical region gene 8 (DGCR8) for vertebrates.¹⁰ (An RNase III endonuclease termed The Drosha/DGCR8 complex cleaves the pri-miRNA into a smaller stem-loop ~70-nucleotide (nt) precursor miRNA (pre-miRNA). Pre-miRNAs are then exported from the nucleus to the cytoplasm using the double-stranded RNA-binding protein, Exportin 5 (XPO5).¹¹ Once in the cytoplasm, the pre-miRNA is cleaved into a mature 18–25 nucleotide miRNA by a complex that includes RNAase Dicer, Argonaute 2 (Ago 2), and transactivation-responsive RNA-binding protein (TRBP). The Ago2 protein belongs to the Argonaute family of proteins that bind fragments to guide RNA (including miRNAs). The resultant miRNA sequence, which consists of two strands, is then loaded into the RNA-induced silencing complex (RISC), with the mature strand being maintained while the complementary strand is degraded. The remaining strand possesses complementarity either to the 3' or 5' UTR of a target gene leading to degradation through endonuclease activity or to translational inhibition. Recently, investigators have shown that an miRNA can also bind to the coding sequence of a transcript, leading to translational repression.¹² The degree of complementarity between the "seed" sequence of the mature miRNA and the target is the primary determinant of the biological effect. It is important to recognize that investigators have now identified additional mechanisms for miRNA biogenesis, suggesting that we are just beginning to understand the complexities of this process.

Figure 1 MicroRNA biogenesis.

MicroRNA deregulation in cancer

Calin et al.¹³ made the first observations linking miRNA deregulation to cancer in a study. While investigating the mechanisms for chronic lymphocytic leukemia (CLL), this team of investigators made the startling observation that a pair of miRNAs, miR-15a/16-1 which, along with the deleted in leukemia (DLEU) gene, are located at the chromosomal region 13q14.3, was either deleted or downregulated in 68% of patients with CLL.¹³ In addition, both of these miRNAs were highly expressed in normal CD5+ B cells. Both findings suggested that these miRNAs were in fact important to the pathogenesis of the disease. This initial observation was corroborated by independent investigators who identified a functional link between miR-15a/16-1 and the prosurvival molecule Bcl2. They validated *in vitro* that miR-15a/16-1 targeted Bcl2 to induce apoptosis. Since this initial discovery of miRNAs in CLL, investigators have observed patterns of global dysregulation of miRNAs across both solid and hematological malignancies. In the last few years, researchers have determined that the causes for such dysregulation are multifactorial. For instance, the altered expression and/or function of the proteins involved in the biogenesis of miRNAs, such as Drosha and Dicer, can lead to an aberrant expression of

miRNAs and thus to cancer.¹⁴ A decreased expression level of Drosha and Dicer has been found in a high percentage of ovarian cancer patients.¹⁵ Moreover, epigenetic changes within miRNA promoters such as changes in their methylation can also induce changes in miRNA expression levels.¹⁶ Like other deregulated genes that cover an important role as oncogenes or tumor suppressors, the epigenetic deregulated expression of a single miRNA can be the triggering event for carcinogenesis. One such example involves the intensely studied miR-155 whose dysregulation can induce leukemia in miR-155 transgenic mice.¹⁷ The tumor-suppressor miR-127 in primary prostate cancer and bladder tumors causes the upregulation of the proto-oncogene BCL6, which is a direct target of miR-127.¹⁸ On the other hand, miRNAs can also act as protagonists in the control of the global cellular methylation status by acting on the enzymes responsible for epigenetic control. For example, the miR-29 family is able to modulate methylation levels by affecting the *ex-novo* expression of DNA methyltransferases DNMT3a and DNMT3B in lung cancer.¹⁶ Another important and complex regulative mechanism of miRNAs is related to the transcriptional control of gene expression.¹⁹ The activation of the miR-17/92 cluster induced by the MYC oncogene modulates the anti-apoptotic action of E2F1, thus mediating the MYC proliferative effect.²⁰ Recently, the effect of the membrane tyrosine-kinase receptors on miRNA expression has been studied. For instance, the hepatocyte growth factor receptor c-MET is able, through the transcriptional factor AP1, to induce the expression of the onco-miRNA miR-221/222 cluster, suggesting that the important effect of deregulated c-MET in cancer is at least in part linked to a deregulated miRNA expression pathway.²¹ Finally, considering that the loss of p53 is one of the most represented genetic abnormalities in cancer, the link between the miR-34a family and p53 is another important example of miRNA transcriptional regulation.²² p53 stimulates the transcription of the miR-34 family, inducing apoptosis and senescence. The loss of p53 function induces the downregulation of the miR-34 family in a very high percentage of ovarian cancer patients with a p53 mutation.²³ Hence, the primary theme is that patterns of miRNA expression are globally deregulated in cancer, this event being potentially a cause as well as a consequence of cancer itself. The global deregulation of miRNA in cancer has a dramatic effect on downstream targets of several cellular pathways.

Recently, investigators have also determined that miRNA function may be altered through mutations in target gene seed sequences. Such mutations can render an miRNA incapable of regulating a given mRNA and have been identified as biomarkers of clinical outcome. Mutations in the 3' UTR have been identified in several solid malignancies including ovarian, lung, breast, and colon cancers. Conversely, SNPs in miRNA gene sequences can change miRNA functions. We know that mRNA functional regulation by miRNAs is highly sensitive to base pair mismatches within nucleotides 2–8 of the miRNA, which have been defined as the seed region.²⁴ Therefore a single point mutation on an miRNA gene or a post-transcriptional modification such as RNA editing, can change the function or modify the targetome of an miRNA.^{25, 26} For example, it was determined that a single nucleotide polymorphism (SNP) in a let-7 (lethal-7) miRNA complementary site in the KRAS 3' UTR increases nonsmall-cell lung cancer risk.²⁷ A mutation of let-7 binding site in the Kras 3' UTR has been detected also in juvenile myelomonocytic leukemia (JMML).²⁸

MicroRNA as biomarkers in cancer

Over the last several years, miRNAs have been implicated in virtually every type of cancer. Early studies have focused on applying high-throughput platforms as a means for linking patterns of miRNA deregulation to clinical parameters. One of the first such approaches was made in 2005 by Volinia and colleagues who profiled the miRNA signatures of six human solid tumors, detecting miR-21, miR-17-5p,

and miR-191 overexpressed in some tumors.²⁹ Since that initial study, investigators have conducted similar multiple studies with the primary goals of identifying a prognostic miRNA signature. Yanaihara and colleagues conducted high-throughput profiling of cases of stage 1 adenocarcinoma of the lung. They identified over 40 miRNAs that distinguished lung tumors from adjacent uninvolved lung.³⁰ A broader study conducted on 22 different tumor types showed how an miRNA expression profile is able to classify tumors according to tissue of origin with high accuracy.³¹ Studies have also focused on preselected miRNAs as potential prognostic markers. For example, Nadal et al.³² examined the tumor-suppressive miR-34 as a prognostic biomarker in early-stage adenocarcinoma of the lung. They identified methylation and reduced expression of miR-34b/c in nearly half (46%) of early-stage lung adenocarcinomas and determined that reduced expression and methylation of miR-34b/c correlated with shorter disease-free survival and overall survival. For example, in a separate study, investigators showed that miRNA expression levels may correlate with BCR-ABL kinase activity in chronic myeloid leukemia (CML),³³ suggesting, therefore, a potential application in the adjustment of the therapy during treatment to improve the outcome. Another very intriguing application of miRNAs as biomarkers consists of the integration of both protein-coding and noncoding gene expressions in order to develop a prognostic signature in early stages of cancer. Akagi et al.³⁴ examined 148 cases of stage 1 lung adenocarcinoma for 42 preselected genes as predictive biomarkers. Through testing and subsequent validation in independent cohorts, the authors developed a four-gene classifier (DLC1, XPO1, HIF1A, and BRCA1) that correlates to survival in stage 1 lung adenocarcinoma. In addition, they determined that miR-21 expression was independently associated with survival in the same cohorts. Lastly, the combination of the four-gene classifier and miR-21 expression was superior to either biomarker alone. Despite the multitude of very encouraging miRNA profiling studies, investigators have yet to reach consensus on which miRNAs confer the most accurate prognostic information. A primary reason for the lack of reproducibility is that, similarly to other high-throughput analyses, miRNA profiling studies are susceptible to certain biases, including small cohort sizes, varying platforms (array, sequencing, RT-PCR), and variability in data interpretation.

MicroRNAs as noninvasive biomarkers in cancer

The development of noninvasive biomarkers in cancer that may inform clinical decision-making remains elusive and the subject of continued study. Several studies have demonstrated that miRNAs exist in body fluids (serum, plasma, urine, sputum, cerebrospinal fluid, and bronchoalveolar lavage) in a relatively stable form at different conditions of pH and temperature.^{35–37} miRNAs are also present in blood, where they were detected in plasma, platelets, erythrocytes, and nucleated blood cells. One of the earliest studies revealed that miRNAs were detectable in circulation in prostate cancer.³⁸ Shen et al.³⁹ demonstrated that plasma-based miRNAs could be used as biomarkers to distinguish solitary lung nodules. A subsequent larger study further validated the concept that circulating miRNAs could be used in the setting of lung cancer early detection.⁴⁰

The compartment specific location of miRNAs in circulation remains the subject of debate. However, circulating miRNAs have been found packaged in extracellular vesicles (EVs) as well as associated with RNA-binding proteins like Argonaute 2 or lipoprotein complexes, which prevent their degradation (Figure 2).^{41–44} EVs are small membrane-encapsulated fluid particles comprised of a family shedding vesicles and exosomes that are released from a wide variety of cell types by entirely independent cellular mechanisms.⁴⁵ Investigators to date have focused primarily on exosomes, which are ~40 to 100 nm vesicles. These particles consist of a lipid bilayer, generated from secretory multivesicular bodies (MVB) that fuse with the plasma membrane for release into the extracellular environment. Exosomes

contain various molecular constituents of their cell of origin including lipids, proteins, messenger RNA (mRNA), and miRNA, which may be transferred from donor to target cells to facilitate direct cell-to-cell contact and subsequent reprogramming of the tumor microenvironment.⁴² In pathological states, such as cancer, exosomes cross-talk, and/or influence major tumor-related pathways such as epithelial-mesenchymal transition (EMT), cancer stemness, angiogenesis, and metastasis involving many cell types within the tumor microenvironment.^{46–49} Exosomes have also been detected in a number of human body fluids including plasma, urine, breast milk, amniotic fluid, malignant ascites, and bronchoalveolar lavage fluid, suggesting their potential importance as biomarkers of disease.⁵⁰

Figure 2 Process of extracellular vesicles release from cells. Apoptotic cells release apoptotic bodies.

Selected miRNAs implicated in cancer

Following a multitude of miRNA in cancer studies, several miRNAs, including miR-155, let-7, miR-21, and miR-34, for example, have emerged as fundamental contributors to tumor development. These miRNAs are now being integrated into clinical trials as biomarkers for clinical diagnosis and therapy.

LET-7

The let-7 gene was first discovered in *C. elegans* as a key regulator of development.⁵¹ The mature form of let-7 family members is highly conserved across species. let-7 miRs family plays an essential role in regulating cell proliferation and differentiation during development in different species. In addition, let-7 is a marker of fully differentiated cells while undetectable in stem cells.⁵² The human let-7 family contains 12 members located on nine different chromosomes, they map to fragile sites associated with different types of solid cancers.⁵³ Indeed, the deregulation of these miRs has been shown as a feature of many types of cancer.^{54–56} One of the most studied let-7 targets and regulators is the c-Myc oncogene,

given, moreover, the well-known double-negative feedback between them.

MiR-21

MiR-21 is one of most studied oncomiRs, as most of its validated targets are tumor suppressors (i.e., PTEN, Bcl2, and Sprouty1 and 2). This miR is probably one of the most dynamic miRNAs, being responsive to various stimuli given its involvement in positive and negative feedback loops. miR-21 is one of the most altered miRNAs in solid tumors including breast, ovaries, cervix, colon, lung, liver, brain, esophagus, prostate, pancreas, and thyroid.^{29, 57–59} miR-21 is also upregulated in leukemic cancers,⁶⁰ indicating an important key role for this miRNA in cancer development and progression. Moreover, a recent study established circulating miR-21 as a biomarker of various carcinomas, unveiling its potential as a tool for cancer diagnosis.⁶¹

MiR-34

The miR-34 family consists of three highly related miRNAs: miR-34a, miR-34b, and miR-34c. miR-34a is expressed at higher levels than miR-34b/c in all tissues, particularly brain, with the exception being the lung.⁶² These miRNAs are directly induced by p53 in response to DNA damage or oncogenic stress⁶³ and contribute to the p53 downstream effect by targeting c-Myc, Bcl2, C-Met, and Src.⁶⁴ MiR-34a plays a fundamental role not only in tumor suppression but also in modulation of drug response in a number of cellular models, including HCC, breast, bladder, HNSCC, and NSCLC (e.g., an overexpression of miR-34a, downregulating PDGFR, restores TRAIL-induced apoptosis in NSCLC cell lines).⁶⁵

MiR-200 family

The miR-200 family consists of five members: miR-200a, miR-200b, miR-200c, miR-141, and miR-429. These miRs are highly expressed in epithelial tissues and are involved in tumor suppression by inhibiting EMT, migration, invasion, tumor cell adhesion, and metastasis.⁶⁶ Among miR-200 family targets, ZEB1 and ZEB2, two central mediators of EMT, are two of the most studied. Moreover, there is a double-negative ZEB/miR-200 feedback loop, given the ability of ZEB1 to suppress the expression of miR-200 family members.⁶⁷ Furthermore, there is evidence that breast cancer metastases may be under the control of the Akt-miR200-E-cadherin axis. Specifically, the balance of the three Akt isoforms can control the expression of miR-200 and that of the E-cadherin mRNA in primary and metastatic human breast cancers.⁶⁸

Therapeutic targeting and miRNA

Given that deregulation of a single or group of miRNAs can drive malignancy, it is hypothesized that through directed targeting of their deregulation, at least *in vitro*, one can attenuate carcinogenesis. Alternatively, patterns of miRNA deregulation may drive chemoresistance to traditional agents. For example, strategies aimed at using global miRNA expression profiling of selectively created drug-resistant cell lines have been utilized to identify which specific miRNAs are responsible for the acquired resistance. These findings have translated to miRNAs serving both as directed targets and predictors of response to chemotherapeutic agents. Importantly, the contribution of specific miRNAs to chemoresistance can be highly cell tumor specific. As mentioned, miRNAs have the capacity to simultaneously target and regulate multiple biological pathways. In the case of CLL, selected patterns of miRNA expression could clinically predict which patients would respond to the selected agent

fludarabine.⁶⁹ In solid tumors such as lung cancer, miRNAs including miR-21, miR-30, miR-221, and miR-222 have been associated with response to chemotherapeutic agents. Recently, Vecchione et al.⁷⁰ profiled an miRNA signature that is able to define chemoresistance in ovarian cancer. It has been reported that an miRNA profiling is useful to identify a subtype of temozolomide-resistant glioblastoma.⁷¹

In the last few years, the majority of applications of miRNAs as directed therapies in human disease have taken place in *in vitro* and murine models of disease settings. The primary goal of directed therapeutics is to manipulate miRNAs that are known to be deregulated in tumors and thus alter their downstream targets and biological pathways. This approach may occur through the selected targeting of an miRNA or as a strategy for augmenting the effects of an established therapeutic agent. The manipulation of miRNAs via either selective gain of function (e.g., mimics) for the purposes of repletion or silencing (e.g., antagonists) has been applied with variable results. miRNAs may be delivered by several modalities including viral vectors and nanoparticles (NPs). Viral-based carriers have been effectively used to deliver miRNAs in solid tumors including let-7 in lung cancer.⁷² However, viral carriers for small molecule delivery are not without limitations including the potential immunogenic and toxic effects of the carrier to the host. More recently, investigators have employed lipid-based NPs as carriers for small molecules including miRNA. NPs represent smaller engineered particles that are particularly suitable for drug delivery based on their modifiable composition allowing for optimal binding and absorption. Several recent studies have demonstrated the efficacy of NPs as vehicles for miRNA delivery *in vivo*. For example, Wu et al. recently showed that lipid-based NPs could be utilized to effectively deliver miR-29 in lung cancer both *in vitro* and *in vivo*.⁷³ In an independent study, Trang et al. showed that delivery of let-7 could reduce tumor growth and many oncogenes.⁷⁴ Issues of off-target effects, stability of carriers, and toxicity all remain germane to miRNA-based therapeutics. The use of miRNA sponges represents an alternative strategy to antagomirs. RNA sponges are able to simultaneously repress a large number of miRNA molecules. The existence of circular RNA (circRNA) has been already established in nature and can represent an example of miRNA sponge. circRNA is a type of RNA, which forms a covalently closed continuous loop, forming a circRNA whereby the 3' and 5' ends are attached together forming a round RNA molecule. This structural characteristic confers stability to circRNAs in the cytosol, while also ensuring the ability to bind simultaneously a variable number of miRNA molecules thus inhibiting their action. circRNAs are derived from protein-coding genes but do not encode for any protein and are thus classified as ncRNA.⁷⁵ Recently, investigators determined that a circRNA called R1as/CiRS-7 could serve as sponge for miR-7. This circRNA was able to downregulate miR-7 by acting as a specific sponge for it through 63 miR-7 binding sites.⁷⁶ The design of synthetic sponges able to mimic natural circRNA action represents a novel approach for the modulation of aberrant miRNA expression in cancer. This technology is very useful in satisfying the need to simultaneously downregulate several miRNAs or miRNA families.⁷⁷

Recently, investigators have developed novel computational tools for the design of synthetic miRNAs capable of effectively and simultaneously targeting multiple specific mRNAs of choice (multitarget, multisite targeting). Lagana et al.⁷⁸ in 2014 developed and validated a bioinformatic tool termed “miR-Synth,” which represents a single synthetic miRNA able to simultaneously target MET and EGFR. Interestingly, this tool can be applied to create synthetic miRNAs for a wide variety of different target combination choices. The concept of modulating miRNA in cancer through the reintroduction or the repression of deregulated miRNAs combined with the use of synthetic technology for the modulation of miRNA expression (miRNA sponges) and, finally, the employment of synthetic miRNA that can modulate simultaneously the expression of different genes of choice does not represent a strategy void of issues. The off-target problem and difficulties in delivery make miRNA-centered cancer therapy a promising technology not yet applicable.

Human applications for miRNAs

While the majority of miRNA-focused lines of investigation have been laboratory based, an increasing number of human clinical trials have begun to incorporate miRNAs as with predictive/therapeutic biomarkers or as directed therapeutics. Currently, there are over 100 clinical trials incorporating miRNAs that are either actively recruiting or completed recruiting. The majority of such studies are utilizing miRNAs as potential clinical biomarkers. However, in the last few years, we have witnessed the emergence of clinical studies directed at utilizing miRNAs as therapeutics in humans. The most recognized such study involves the application of an antagomir for miR-122 to treat hepatitis C.⁷⁹ Both phase I and phase II trials have been completed using the agent SPC3649 (Miravirsen) in both healthy volunteers and those with chronic Hepatitis C.⁸⁰ Currently, studies are ongoing to examine the utility of Miravirsen in chronic Hepatitis C nonresponders. In the area of cancers, there are two exciting studies on the horizon that have potential for clinical application. The first such study is an ongoing phase I trial, which is a multicenter phase I trial using a liposomal formulation of miR-34 (MRX34) for primary unresectable liver cancer or advanced metastatic solid malignancies with or without metastases. The second study identified as MesomiR-1 is a phase I trial involving the use of an EGFR-targeting delivery vehicle harboring miR-16 in individuals with malignant pleural mesothelioma or advanced non-small-cell lung cancer who have failed previous therapies.

Chapter 10

Aberrant signaling pathways in cancer

Luca Grumolato, PhD ■ Stuart A. Aaronson, MD

Overview

Most, if not all, human cancers harbor aberrant activation of one or several signaling pathways, contributing to tumor initiation and/or progression. In this chapter, we describe how growth factors signal to receptors with intrinsic tyrosine kinase activity to promote cell proliferation and survival, largely through activation of the phosphatidylinositol-3'-kinase (PI-3-K)/Akt and Ras/MAP kinase pathways. Using different paradigmatic examples of oncogenic alterations in growth factor signaling, we discuss functional implications and relevance of these pathways for human cancer. General cell signaling principles in both normal and tumor cells will be addressed, and we briefly discuss how the initiation and progression of specific cancer types can be affected by the deregulation of certain other pathways, including those mediated by cytokines, the transforming growth factor- β (TGF β) family, Wnt, Hedgehog, Notch, and nuclear receptors.

Finally, we discuss the concepts of oncogene addiction and targeted therapy and provide a few representative examples to illustrate how increased understanding of the mechanisms underlying signaling pathway aberrations in cancer can be translated to the clinic.

Intercellular communication in multicellular organisms is required for processes such as embryonic development, tissue differentiation, and systemic responses to wounds and infections. These complex signaling networks are in large part mediated by growth factors, cytokines, and hormones. Such factors can influence cell proliferation in positive or negative ways, as well as induce a series of differentiated responses in appropriate target cells. Cytoplasmic molecules that mediate these responses have been termed second messengers. The eventual transmission of biochemical signals to the nucleus leads to effects on the expression of genes involved in mitogenic and differentiation responses.

The pathogenic expression of critical genes in growth factor signaling pathways can also contribute to altered cell growth associated with malignancy. The v-sis oncogene of simian sarcoma virus, which encodes a growth factor homologous to the B chain of human platelet-derived growth factor (PDGF-B), is the paradigm for such genes.¹ The normal counterparts of other retroviral oncogenes were subsequently shown to encode membrane-spanning growth factor receptors.^{2, 3} Other genes that act early in intracellular pathways of growth factor signal transduction have been implicated as oncogenes as well. Present knowledge indicates that the constitutive activation of growth factor signaling pathways through genetic alterations affecting these genes contributes to the development and progression of most, if not all, human cancers.

Because of space limitations, this chapter primarily focuses on growth factor signaling mediated by receptors with intrinsic tyrosine (Tyr) kinase activity. However, we briefly highlight other ligand-triggered pathways relevant to cancer biology.

Growth factor receptors with Tyr kinase activity

Hormones that act at great distances from the cells producing them have been known for many years. Hormones as signaling molecules were isolated from tissue fluids and readily characterized by their *in vivo* effects. The initial discoveries of growth factors indicated more subtle activities capable of stimulating the growth of chicken embryonic nerve cells in the case of nerve growth factor (NGF)⁴ or promotion of eyelid opening and incisor eruption in the case of epidermal growth factor (EGF).⁵ An important discovery concerning growth factors came from the demonstration of a unique enzymologic activity associated with binding of EGF to its receptor.⁵ Studies of the product of the viral oncogene, *v-src*, had led to the demonstration of its ability to act as a protein kinase.^{6, 7} Many protein kinases had been previously identified, but these had the capacity to phosphorylate serine (Ser) and/or threonine (Thr) residues. Moreover, it was well established that phosphorylations and dephosphorylations affected the activities of a variety of proteins. However, the *src* product was subsequently shown to have a unique specificity as a protein kinase in that it was capable of phosphorylating Tyr residues.⁸ Cohen then showed that addition of EGF led to phosphorylation of its purified receptor on Tyr residues.⁵ Subsequent studies have demonstrated that Tyr kinase activity is central to the functions of a large number of mitogenic signaling molecules.

More than 50 receptor Tyr kinases (RTKs) belonging to at least 18 different receptor families have been identified^{9, 10} ([Figure 1](#)). All RTKs contain a large, glycosylated, extracellular ligand-binding domain, a single transmembrane region, and a cytoplasmic portion with a conserved protein Tyr kinase domain. In addition to the catalytic domain, a juxtamembrane region and a carboxyl-terminal tail can be identified in the cytoplasmic portion. Because of their structure, RTKs can be visualized as membrane-associated allosteric enzymes with the ligand-binding and protein Tyr kinase domains separated by the plasma membrane. Their role is to catalyze the transfer of the γ -phosphate of adenosine triphosphate (ATP) to Tyr residues of exogenous substrates, as well as within their own polypeptide chain. Tyr phosphorylation represents the language that these receptors use to transduce the information carried by the growth factor.

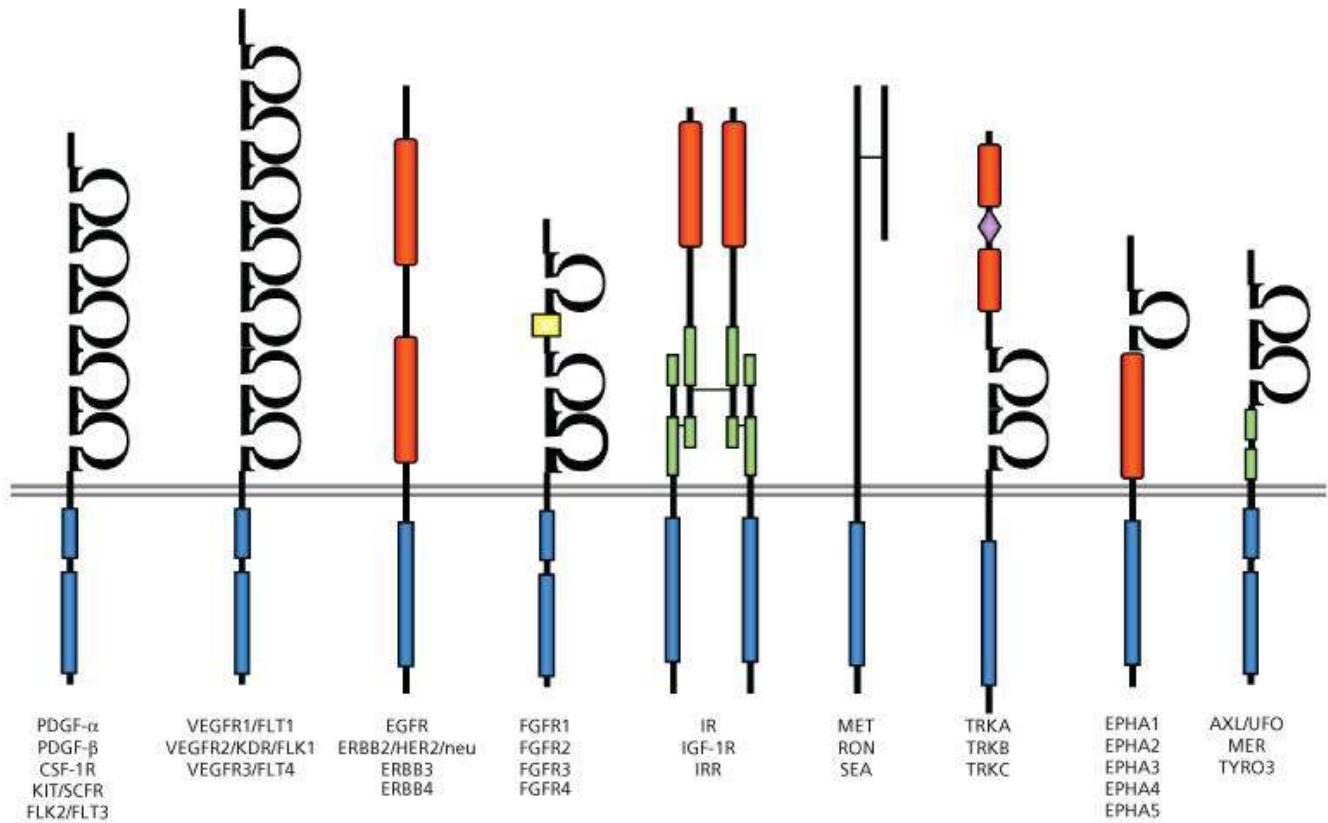

Figure 1 Families of receptor tyrosine kinases.

RTKs are activated by their ligands through receptor oligomerization, which stabilizes interactions between adjacent cytoplasmic domains and controls the activation of kinase activity.¹⁰ Dimerization can take place between two identical receptors (homodimerization), between different members of the same receptor family, or, in some cases, between a receptor and an accessory protein (heterodimerization),¹⁰ thus expanding both the repertoire of ligands recognized by each receptor and the diversity of effector pathways stimulated by a given receptor.

How ligands bind to induce receptor oligomerization varies for each class of RTKs.^{10, 11} PDGF, for example, induces receptor dimerization by virtue of its dimeric nature.¹² EGF induces instead a conformational change in the extracellular domain of the epidermal growth factor receptor (EGFR), resulting in the exposure of a dimerization domain that is masked in the absence of the ligand.¹⁰ Fibroblast growth factor, which is a monomeric ligand like EGF, needs an accessory molecule, heparan sulfate proteoglycan, to induce receptor dimerization.^{13, 14} In contrast, the insulin receptor family exists as disulfide-bonded homo- or heterodimers of receptor subunits, and ligand binding causes a conformational change in the preformed dimeric receptor, which leads to receptor activation.^{15, 16}

The activation of intrinsic protein kinase activity results in autophosphorylation of specific Tyr residues in the cytoplasmic portion of the RTK. Moreover, Tyr phosphorylation in the kinase domain stimulates the intrinsic catalytic activity of the receptor. Biochemical and structural studies have revealed some of the molecular mechanisms that mediate such activation. There is substantial evidence that autophosphorylation occurs in *trans* by a second RTK after dimerization induced by ligand binding. In the unphosphorylated state, the receptor possesses a low catalytic activity due to the particular conformation of a specific domain in the kinase region, which interferes with the phosphotransfer event. Phosphorylation of the kinase domain removes this inhibition, and the catalytic activity is enhanced and persists for some time independently of the presence of the ligand. Although kinase activity is at a low basal level in the monomeric state, this activity is sufficient to induce *trans*-autophosphorylation once the dimer forms. In addition to this mechanism, different RTKs contain *cis*-inhibitory elements outside the kinase domain, such as in the juxtamembrane domain (e.g., in KIT and MuSK) or the C-terminal tail (e.g., in Tie2), that can be disrupted by *trans*-phosphorylation following receptor dimerization. Besides the regulation of receptor catalytic activity, the other major function of RTK autophosphorylation is to create specific docking sites for downstream molecules that participate in the transduction of the signal (see the following section).

Aberrations affecting growth factor receptors in tumor cells

Although growth factor receptors can be constitutively activated by autocrine/paracrine loops, a number of other mechanisms have been identified by which growth factor receptors can become transforming. The paradigm for such alterations is the avian erythroblastosis viral oncogene *v-erbB*, which corresponds to a truncated form of EGFR, in which deletion of the ligand-binding domain results in the constitutive activation of the receptor.² Alterations affecting a large number of RTKs have been implicated in different human malignancies. One mechanism involves the amplification or overexpression of a normal receptor, such as in the case of EGFR, ErbB-2, and MET.^{17–20} *ErbB-2* was initially identified as an amplified gene in a primary human breast carcinoma and a salivary gland tumor.^{21, 22} Clinical studies have indicated that the normal *ErbB-2* gene is frequently amplified and/or overexpressed in human breast carcinomas and in ovarian carcinomas,²³ and detection in breast carcinomas of high ErbB-2 levels was initially a prognostic

indicator of poor survival.^{17, 18} While ErbB-2 overexpression has been observed primarily in adenocarcinomas, the overexpression of a normal EGFR has been reported frequently in squamous cell carcinomas and glioblastomas.^{17, 24} In many cases, the EGFR appears to be activated by autocrine stimulation by one of its ligands, most commonly transforming growth factor- α .

Genomic alterations, such as mutation or rearrangement, have also been shown to activate the transforming capacity of RTKs in different human malignancies.²⁵ For example, deletions within the external domain of the EGFR receptor or mutations in its Tyr kinase domain^{26, 27} are associated with its constitutive activation in some glioblastomas, lung and breast cancers.^{17, 24} The *ret* gene is activated by rearrangement, as a somatic event, in about one-third of papillary thyroid carcinomas, whereas germline mutations of cysteine residues in the extracellular region, which affect receptor dimerization, are responsible for multiple endocrine neoplasia (MEN) 2A and for the familial medullary thyroid carcinoma syndrome. Of note, point mutations in the RET kinase domain are associated with MEN 2B,²⁸ indicating that the catalytic function of an RTK can be upregulated by oncogenic alterations affecting distinct domains of the receptor. Another example of an RTK activated by genetic alterations in the germline is the receptor for hepatocyte growth factor, MET, which is responsible for hereditary papillary renal carcinomas. Aberrant activation of MET through amplification/overexpression or mutations is also found in a variety of sporadic tumors including renal, liver, and gastric cancer.²⁰ Finally, several other receptors, including the anaplastic lymphoma kinase (ALK), ROS1 and TrkA, have been shown to be oncogenically activated in human malignancies by chromosomal rearrangements that lead to fusion products containing the activated TK domain.²⁵

Key Points

- RTKs are activated by growth factors through receptor dimerization and subsequent trans-phosphorylation.
- Tyr phosphorylation represents the language used by these receptors to transduce their signals, allowing specific recruitment of different effector or adaptor proteins.
- Different mechanisms are responsible for constitutive RTK activation in tumor cells. These include receptor/ligand overexpression, RTK amplification/mutation, and chromosomal translocation, which results in the formation of constitutively active fusion protein.

Signaling pathways of Tyr kinase receptors

Molecules, known as adaptor and scaffolding proteins,²⁹ play an integral role in intracellular signaling by both recruiting various proteins to specific locations and assembling networks of proteins particular to RTK cascades. These adaptor proteins often contain a variety of motifs that mediate protein–protein interactions, including Src homology 2 (SH2) and phosphoTyr-binding domains, which bind to specific phosphorylated Tyr containing sequences, or SH3 domains, which recognize and bind to proline-rich sequences in target proteins.^{29, 30} One such adaptor, Grb2, is important in the activation of the small G-protein Ras ([Figure 2](#)).

Figure 2 Intracellular effectors of receptor tyrosine kinases.

The PDGF system has served as the prototype for identification of the components of signaling cascades. Certain molecules become physically associated and/or phosphorylated by the activated PDGF receptor (PDGFR) kinase. These include phospholipase C- γ ,³¹ PI-3-K regulatory subunit (p85),³² NCK,³³ the phosphatase SHP-2,³⁴ Grb2,³⁵ CRK,³⁶ RAS p21 GTPase-activating protein (GAP),³⁷ SRC, and SRC-like Tyr kinases.³⁸ Many of these molecules contain SH2 or SH3 domains.

PI-3-K and survival signaling

The regulation of cell survival and cell death is essential for both normal development and tissue homeostasis in adult organisms, where damaged cells must be removed and terminally differentiated cells must be sustained. A failure for this to occur may result either in the accumulation of mutations leading to cancer or to degenerative diseases.

PI-3-K is a lipid kinase that catalyzes the transfer of the γ -phosphate from ATP to the D3 position of the phosphoinositide (PtdIns), generating PtdIns(3,4,5)P3. These lipids can act in a variety of cascades, promoting the activation of several proteins ([Figure 2](#)). PI-3-K activation has been demonstrated to play an important role in survival signaling in a number of cell types.^{39, 40} The prototypical class 1 PI-3-K consists of two tightly associated subunits encoded by two distinct loci: a regulatory and a catalytic subunit. The classic mode of PI-3-K activation involves binding of the regulatory subunit to the phosphorylated Tyr residues of RTKs through SH2 domains, resulting in a conformational change that facilitates activation of the catalytic subunit. There are several known downstream effectors of PI-3-K. These include Rac, certain isoforms of protein kinase C, and, most relevant to cell survival, Akt, the cellular homolog of the viral oncogene *v-Akt*.^{39, 40} Three human homologs encode 57 kDa Ser/Thr kinases that contain an *N*-terminal pleckstrin homology (PH) domain, which binds to the activated PtdIns products

of PI-3-K. These lipids are believed to mediate the localization of Akt to the plasma membrane. In addition, phosphorylation of two residues, Thr 308 and Ser 473, is required for its full activation.^{39, 40}

Akt promotes survival and prevents apoptosis in various cell types through the regulation of different downstream pathways and effectors⁴¹ ([Figure 2](#)). Akt phosphorylates the pro-apoptotic protein BAD (BCL2-associated agonist of cell death), thus creating a docking site for the cytosolic protein 14-3-3, which sequesters BAD and inhibits its activity. Akt also phosphorylates FOXO transcription factors creating a binding site for 14-3-3, which retains them in the cytoplasm and inhibits their transcriptional targets, including pro-apoptotic proteins such as BIM and FAS ligand. Moreover, Akt can increase p53 degradation through phosphorylation of MDM2, and there is evidence that Akt can increase the pro-survival functions of the nuclear factor- κ B (NF- κ B) transcription factor complex and inhibit the pro-apoptotic c-Jun *N*-terminal kinase (JNK) and p38 pathways.⁴¹ Besides promoting cell survival, Akt can also exert positive effects on cell growth through inhibitory phosphorylations of the tuberous sclerosis complex 2, resulting in the activation of the mTOR pathway, or GSK3, which normally targets cyclin D1 for degradation^{41, 42} ([Figure 2](#)).

PI-3-K signaling in cancer

PIK3CA, which encodes the p110 α catalytic subunit, was originally found to be amplified in a high percentage of ovarian tumors and ovarian tumor cell lines.⁴³ Later studies revealed that PIK3CA is one of the most frequently mutated oncogenes in human cancer, particularly in colon, breast, endometrial, brain, and gastric tumors.^{44, 45} While far less frequently mutated in cancer, Akt can also play a role in human malignancies. Akt1 was found to be amplified 20-fold in a primary gastric adenocarcinoma.⁴⁶ Additional studies have shown genomic amplification and overexpression of Akt2 in pancreatic and ovarian carcinoma cell lines, as well as in some ovarian and breast carcinomas.⁴⁷ Overexpression of Akt2 occurs more frequently in undifferentiated and, thus, more aggressive tumors. Missense mutations in the Akt1 PH domain were identified in breast, colon, and ovarian cancers, resulting in prolonged Akt activation owing to its pathological localization to the plasma membrane.⁴⁸

Further evidence of the involvement of the PI-3-K/Akt pathway in cancer stems from the discovery of the phosphatase and tensin homolog (PTEN) tumor suppressor, a gene inactivated by mutation in a high fraction of glial and endometrial tumors, as well as in melanoma, prostate, renal, and small-cell lung carcinomas.^{42, 45, 49} By dephosphorylating the three position of phosphatidylinositol, PTEN directly opposes PI-3-K activity, thus inhibiting Akt activation.

Ras

Ras proteins are a major point of convergence in RTK signaling and are important components of the cellular machinery necessary to transduce extracellular signals ([Figure 2](#)). These small GTP-binding proteins are membrane-bound intracellular signaling molecules that mediate a wide variety of cellular functions, including proliferation, differentiation, and survival. Ras acts as a molecular switch alternating from an inactive GDP-bound state to an active GTP-bound state. The paradigm for Ras activation involves the recruitment of a guanine nucleotide exchange factor (GEF) to the membrane in response to growth factor binding and subsequent activation of an RTK.⁵⁰ GEFs promote the release of GDP from the catalytic pocket of Ras, and the relative abundance of intracellular GTP as compared to GDP ensures preferential binding of GTP. The best example of a Ras GEF is son of sevenless, which is brought to the membrane by its stable association with the adaptor protein Grb2.⁵¹ Although Ras is a GTPase, its intrinsic GTPase activity is actually quite low and requires additional proteins known as GAPs to

promote GTP hydrolysis. GAPs can accelerate GTP hydrolysis by several orders of magnitude and are, thus, negative regulators of Ras functions.^{50, 52} An example of a Ras GAP is neurofibromin, encoded by the *NF1* gene, which is frequently inactivated by mutation in different types of cancer, including glioblastoma and lung cancer, as well as in patients with the familial tumor syndrome, neurofibromatosis type I.^{50, 53}

Ras mediates its multitude of biologic effects via a number of downstream effectors. Several proteins have been shown to directly bind to Ras in a GTP-dependent manner, including Raf, Ral, and PI-3-K.⁵² In fact, Ras can activate PI-3-K independently of RTKs, providing a direct connection between Ras and PI-3-K prosurvival signaling.⁵⁰

Ras and cancer

Ras has been shown to be oncogenically activated by mutations in over 15% of all human tumors, and in some cancers, such as pancreatic carcinoma, the frequency is as high as 60%.^{52, 54} The initial evidence for Ras involvement in cancer came from the discovery of transforming retroviruses, Harvey and Kirsten sarcoma viruses, which contained *H-* and *K-ras* cellular-derived oncogenes. The first human oncogenes were identified by transfecting genomic DNA from human tumor cell lines into NIH3T3 mouse fibroblasts and isolating the DNA fragments from the transformed foci. These were shown to be the human homologs of the viral *ras* genes.⁵⁵

The major hotspots for activating Ras mutations decrease the intrinsic rate of GTP hydrolysis by Ras and make the molecule significantly less sensitive to GAP-stimulated GTP hydrolysis. Thus, the outcome is a predominantly GTP-bound form that is constitutively active and essentially independent of growth factor stimulation.^{52, 54}

Signaling downstream of Ras: Ras>Raf >MAPKinase cascade

The most well-studied effector of Ras is the Ser/Thr kinase Raf. Raf has been shown to bind to Ras and, in many cases, has been demonstrated to be indispensable for Ras functions, such as cellular transformation.^{56, 57} There are three known mammalian Raf isoforms, designated A-, B-, and C-Raf (also known as Raf-1), displaying distinct expression patterns.⁵⁷ Ras-GTP binds to the amino terminus of Raf and promotes its activation, resulting in Raf homo- or heterodimerization and the phosphorylation of different Ser/Thr and Tyr residues participating in the regulation of Raf activity.^{57, 58} Once activated, Raf can phosphorylate the mitogen/extracellular-signal regulated kinase (MEK), also known as MAP kinase kinase (MKK), a dual specificity kinase, leading to its activation^{56, 58} ([Figure 2](#)). MEK can, in turn, activate MAP kinase or extracellular signal-regulated kinase (ERK) through tandem phosphorylations on both Thr 183 and Tyr 185. ERK then translocates to the nucleus, where it can activate a variety of proteins through phosphorylation on Ser or Thr, including the ETS family of transcription factors and the kinase p90 RSK, involved in protein translation.^{58, 59} Activation of the Ras-Raf-MAPK pathway results in an increase of DNA synthesis and cell proliferation, exemplified by the induction of cyclin D1,⁶⁰ a major regulator of early cell cycle progression. In fact, cyclin D1 is also one of the most frequently amplified genes in cancer.⁶¹

Raf and cancer

The direct implication of Raf in human cancer came relatively recently with the identification of B-Raf mutations in more than half of melanoma cell lines and primary tumors.⁶² B-Raf mutations, which generally affect few specific residues, such as valine 600, were subsequently found in other malignancies,

including thyroid (60%), colorectal (10%), and lung (6%) cancer.⁵⁶ While B-Raf is one of the most commonly activated oncogenes, mutated in about 8% of all cancers, the frequency of A-Raf and C-Raf mutations is far lower, probably because of their weaker basal kinase activity compared to B-Raf.⁵⁶ Of note, oncogenic activation of B-Raf can also occur following chromosome translocations, which result in the expression of fusion proteins containing the catalytic carboxy terminus of B-Raf. Such translocations have been found in pediatric astrocytoma, glioma, and thyroid cancers.⁵⁶

Other MAP kinases

In addition to the ERKs, there are other MAP kinases belonging to distinct MAPK cascades with both different upstream activators and downstream effectors. JNK and p38 are stress-activated kinases involved in the cellular responses to a wide variety of extracellular stimuli, including mitogens, inflammatory cytokines, and UV irradiation.⁶³ In contrast to its ability to activate the MAPK/ERK cascade, Ras only minimally perturbs JNK and p38, whose activity is mainly induced by the Rho family of small G-proteins, including Rac1, Cdc42, and RhoA. The pathways leading to JNK or p38 activation mirror those seen for ERK, with a variety of MKKs that can phosphorylate the various JNK isoforms.⁶³

As with the ERKs, the end result of JNK and p38 activation is the phosphorylation of different transcription factors, resulting in increased expression of their target genes. Examples of transcription factors directly phosphorylated by either JNK or p38, or both, include ATF2, ELK1, JUN, MYC, and MEF2.^{63, 64} Of note, some of these factors were initially discovered as retroviral oncogenes.

Key Points

- Activated RTKs promote PI-3-K-mediated synthesis of PtdIns3P, resulting in the recruitment and activation of the kinase Akt. Through the regulation of different downstream effectors, Akt promotes survival in various cell types.
- RTKs stimulate cell proliferation largely through activation of the Ras/Raf/MAPK pathway.
- In human cancer, these downstream pathways can be frequently activated independently of RTKs, generally through mutations in the genes encoding various key effectors, including PI-3-K, Ras, and Raf.

Other signaling pathways aberrantly deregulated in cancer

While activation of the RTK pathway is common in most, if not all, types of cancer, other signaling pathways can also play instrumental roles in tumor initiation and progression. During embryonic development and in adulthood, these pathways exert diverse physiological functions, but, as with RTK signaling, they can be aberrantly activated (or inactivated) in cancer, as a result of mutations, chromosomal rearrangements or other mechanisms.

Although RTKs represent the largest family of cell surface receptors possessing an enzymatic activity, there are other classes of receptors with such activities. For example, transforming growth factor- β (TGF β) induces the formation of a tetrameric complex containing two type I and two type II TGF β receptors, both Ser/Thr kinases. Type II receptors then phosphorylate type I receptors, which propagate

the signal through binding and phosphorylation of the SMAD transcription factors, resulting in SMAD activation.⁶⁵ Depending on cellular context, the TGF β pathway can play a role in either tumor suppression or progression. In pre-malignant cells, TGF β signaling can promote apoptosis, thus explaining the frequent inactivating mutations of TGF β receptors or SMADs found in certain tumors, including colorectal and pancreatic carcinomas. Other tumors, including glioma, melanoma, and breast carcinoma, can use other mechanisms to circumvent this tumor-suppressive activity of TGF β , while maintaining a functional pathway, which, in more advanced tumors, can favor progression and metastasis through crosstalk between tumor cells and their microenvironment.⁶⁵

Other surface receptors lack an intrinsic catalytic activity but instead directly interact with enzymatic adaptor proteins that mediate propagation of the signal. This is the case, for example, with cytokine receptors, which bind to the Janus kinase (JAK) family of Tyr kinases.⁶⁶ Upon cytokine-induced dimerization of their receptors, JAKs transphosphorylate each other, as well as the C-terminus of the receptors, thus creating docking sites for a family of transcription factors, the signal transducers and activators of transcriptions (STATs). Following JAK-mediated phosphorylation, STATs form homo- or heterodimers through their SH2 domains and translocate to the nucleus to transcriptionally activate their target genes.^{66, 67} Activating mutations of JAK2 are common in patients with different types of myeloproliferative neoplasms, including polycythemia vera and essential thrombocythemia, resulting in cytokine hypersensitivity and cytokine-independent proliferation.⁶⁸ While STAT mutations are far less common, different mechanisms have been shown to promote STAT3 and STAT5 activation in various cancers, affecting tumor growth and invasion, as well as tumor interactions with the immune system.⁶⁷ Another example of receptors directly interacting with proteins possessing enzymatic activity are the G-protein-coupled receptors (GPCRs), a large family of seven membrane-spanning domain proteins, which are activated by very different types of ligands, including hormones, neurotransmitters, and chemokines.⁶⁹ While certain tumors contain mutations in GPCRs or their G proteins, the most common mechanism of aberrant activation of this signaling pathway in cancer is through receptor overexpression and autocrine stimulation.⁶⁹ The GPCR pathway is particularly relevant in tumors of the endocrine system, and ligands signaling through these receptors, such as certain chemokines, are major modulators of the tumor microenvironment.⁷⁰

Activation of other signaling pathways with well-established roles in cancer occurs through more complex mechanisms involving different co-receptors, adaptor proteins and cytoplasmic complexes with or without enzymatic activity. This is the case with Wnt, Hedgehog, Hippo, Notch, and tumor necrosis factor (TNF)/NF- κ B signaling. A common feature of these diverse signaling pathways is that ligand activation of the receptor results in stabilization or activation at or near the cell membrane of a transcription or co-transcription factor, for example, NF- κ B (TNF),⁷¹ GLI (Hedgehog),⁷² YAP/TAZ (Hippo)⁷³ and β -catenin (Wnt).⁷⁴ A variation on this theme is represented by the Notch pathway, where binding by Delta/Jagged ligands induces cleavage of the Notch receptor and release of its cytoplasmic domain, which translocates to the nucleus and activates the CBF1, Suppressor of Hairless, Lag-1 transcription factors.⁷⁵ These highly conserved signaling pathways regulate fundamental physiological processes required for normal embryonic development and stem/progenitor cell maintenance in the adult. Their capacity to regulate cell proliferation, survival, and differentiation helps to explain why these pathways are frequently targeted in tumorigenesis. For example, mutations of different genes resulting in aberrant activation of Wnt/ β -catenin signaling can be found in almost all colorectal carcinomas.^{74, 76, 77} Of note, aberrant activation of Wnt signaling through different mechanisms has also been identified at significant frequency in diverse tumor types including breast, adrenocortical, and hepatocellular carcinoma.^{74, 78–80}

A different class of signaling molecules can cross the cell membrane and binds in the cytoplasm or in the nucleus to a large family of transcription factors, which serve as receptors for such ligands. Once bound to their ligands, these nuclear receptors can activate, as homo- or hetero-dimers, the expression of specific target genes through interaction with different co-activators.⁸¹ The nuclear receptor family includes around 50 members and regulates diverse physiological processes, which can play a crucial role in some types of cancer. For example, the proliferation and growth of a large fraction of breast and prostate tumors depends on sex hormone receptors, that is, estrogen/progesterone and androgen receptors, respectively. These findings have important implications for the treatment of such tumors, which respond to sex hormone antagonists or inhibitors of sex hormone synthesis.^{82–84} Another example of the involvement of nuclear receptors in cancer is the chromosomal translocation of the *promyelocytic leukemia* (*PML*) and the *retinoid acid receptor α* (*RAR α*) genes resulting in a PML-RAR fusion protein. This fusion protein enhances the recruitment of co-repressors to the regulatory regions of RAR α target genes, inhibiting normal differentiation of the myeloid lineage. This results in accumulation of immature granulocytes precursors and to a deadly form of blood malignancy, acute promyelocytic leukemia (APL). The discovery of this tumorigenic mechanism translated into the design of a new therapy based on treatment with all-trans RA, which can result in cure of 70–80% of APL patients.⁸⁵ The example of APL illustrates how signaling pathways aberrantly activated in cancer can be specifically targeted in the clinic to block or restrain the growth and/or the spread of tumors, a concept discussed further in the following text.

Key Points

- Other ligand families signal through their receptors to activate diverse effector pathways.
- In most cases, such receptors directly or indirectly activate specific transcription factors at or near the cell surface, and these factors regulate the expression of specific target genes.
- Certain ligands penetrate the cell to bind their cognate receptors, which function as bona fide transcription factors.
- These pathways control a wide range of physiological processes, and their aberrant deregulation through different mechanisms plays an instrumental role in the initiation and/or progression of various tumors.

Growth factor signaling and cancer therapy

As many of the signaling pathways involved in cellular transformation by oncogenes have been elucidated, efforts have been made to develop therapeutic strategies that target such oncogenically activated signaling molecules or their downstream effectors. One of the important advantages of rationally based targets is that approaches are generally available to monitor *in vivo* inhibition of the target molecule. This makes correlation of clinical response with pharmacodynamic analysis of target suppression feasible to speed the process of clinical testing. Another advantage is that some of these agents appear to have less inherent toxicities than standard chemotherapeutic regimens. Such approaches rely on the concept of “oncogene addiction,” which implies that tumor cells, despite their complex pattern of mutational events, can become particularly dependent on one or a few signaling pathways for their growth and/or survival.⁸⁶ These pathways are thought to counterbalance other pro-apoptotic signals also

triggered by oncogenic alterations in the tumor: once the pro-survival signal is blocked, the tumor cell undergoes what has been defined as “oncogenic shock” and dies.⁸⁷ This idea is supported by studies with tumor cell lines,⁸⁸ as well as in genetically modified mice, in which complete regression of tumors induced by oncogenes, such as K-Ras, was achieved by switching off expression of the oncogene.⁸⁹ Treatments targeting aberrantly activated signaling pathways, either alone or in combination with traditional chemo- or radiation therapy, have yielded extraordinary clinical benefit for certain types of malignancies. However, additional genetic lesions, often activating the same signaling pathway, have been shown in many cases to eventually by-pass the targeted oncogene with associated disease progression (see the following sections).

Monoclonal antibodies

One possible target for therapeutic intervention is the initial triggering of growth factor signaling at the surface of tumor cells. Monoclonal antibodies have been generated to specifically neutralize the activities of growth factors or interfere with ligand receptor interactions. Monoclonal antibodies have also been applied to interfere with receptors overexpressed in certain types of cancer⁹⁰ ([Table 1](#)). Trastuzumab (herceptin, Genentech), a humanized monoclonal antibody against ErbB2, became the first clinically approved drug targeting an oncogene product. Experimental evidence further indicated that trastuzumab enhances the responsiveness of ErbB2 overexpressing breast cancer cells to taxanes, anthracyclines, and platinum compounds.⁹¹ Cetuximab (erbitux, ImClone Systems), a chimeric monoclonal antibody against the EGFR has been approved for the treatment of colorectal and head and neck cancers in combination with chemotherapy and radiotherapy, respectively.^{91–93} Of note, it was shown that cetuximab significantly increased the survival of colorectal cancer patients with wild-type *K-Ras*. However, it had no benefit in the presence of *K-Ras* mutations, accounting for 40% of the tumors,⁹⁴ thus emphasizing the need to identify the particular genetic context required for successful therapeutic intervention.

Table 1 Cancer therapeutics targeting aberrant signaling pathways

Cancer drug	Target	Disease
Monoclonal antibodies		
Bevacizumab (Avastin)	VEGF	Colorectal cancer, NSCLC, RCC, glioblastoma, and cervical cancer
Cetuximab (Erbix)	EGFR	Colorectal cancer, head, and neck cancer
Denosumab (Xgeva)	RANKL	Giant cell tumor of the bone
Panitumumab (Vectibix)	EGFR	Colorectal cancer
Pertuzumab (Perjeta)	ErbB2	Breast cancer
Ramucirumab (Cyramza)	VEGFR2	Stomach adenocarcinoma
Siltuximab (Sylvant)	IL-6	Lymphoma

Trastuzumab (Herceptin)	ErbB2	Breast cancer and gastric cancer
<i>Fusion protein</i>		
Aflibercept (Zaltrap)	VEGFA, VEGFB, and PGF	Colorectal cancer
<i>Small molecule inhibitors</i>		
Abiraterone (Zytiga)	Testosterone synthesis	Prostate cancer
Afatinib (Gilotrif)	EGFR, ERBB2, and ERBB4	NSCLC
Anastrozole (Arimidex)	Estrogen synthesis	Breast cancer
Axitinib (Inlyta)	VEGFR, PDGFR, and c-KIT	RCC
Bosutinib (Bosulif)	Abl, Src	CML
Cabozantinib (Cometriq)	c-Met, RET, VEGFR, c-KIT, FLT-3, TIE-2, TRKB, and AXL	Thyroid cancer
Ceritinib (Zykadia)	ALK	NSCLC
Crizotinib (Xalkori)	ALK and c-Met	NSCLC
Dabrafenib (Tafinlar)	B-Raf	Melanoma
Dasatinib (Sprycel)	Abl and Src	CML, ALL
Enzalutamide (Xtandi)	AR	Prostate cancer
Erlotinib (Tarceva)	EGFR	NSCLC, pancreatic carcinoma
Everolimus (Afinitor)	mTOR	RCC, astrocytoma, PNET, breast cancer
Exemestane (Aromasin)	Estrogen synthesis	Breast cancer
Fulvestrant (Faslodex)	ER	Breast cancer
Gefitinib (Iressa)	EGFR	NSCLC
Ibrutinib (Imbruvica)	BTK	CLL, mantle cell lymphoma

Idelalisib (Zydelig)	PI-3-K	CLL
Lapatinib (Tykerb)	EGFR and ERBB2	Breast cancer
Letrozole (Femara)	Estrogen synthesis	Breast cancer
Imatinib (Gleevec)	Abl, PDGFR, and c-Kit	CML, GIST, ALL, and dermatofibrosarcoma protuberans
Nilotinib (Tasigna)	Abl, PDGFR, and c-Kit	CML
Pazopanib (Votrient)	VEGFR, PDGFR, and c-KIT	RCC, soft tissue sarcoma
Regorafenib (Stivarga)	VEGFR, Ret, Kit, PDGFR, and Raf	Colorectal cancer, GIST
Sorafenib (Nexavar)	VEGFR, PDGFR, FLT3, c-Kit, Raf, and Ret	RCC, hepatocellular carcinoma, and thyroid cancer
Sunitinib (Sutent)	VEGFR, PDGFR, FLT3, c-Kit, and Ret	GIST, RCC, and PNET
Tamoxifen	ER	Breast cancer
Temsirolimus (Torisel)	mTOR	RCC
Toremifene (Fareston)	ER	Breast cancer
Trametinib (Mekinist)	MEK	Melanoma
Vandetanib (Caprelsa)	VEGFR, EGFR, and Ret	Thyroid cancer
Vemurafenib (Zelboraf)	B-Raf	Melanoma
Vismodegib (Erivedge)	Smoothened	BCC
<i>Ligand analogs</i>		
Alitretinoin (Panretin)	RAR and RXR	Kaposi sarcoma
Bexarotene (Targretin)	RXR	Cutaneous T-cell lymphoma
Tretinoin (Vesanoid)	RAR	APL

ALK, anaplastic lymphoma kinase; ALL, acute lymphoblastic leukemia; APL, acute promyelocytic leukemia; AR, androgen receptor; BCC, basal cell carcinoma; BTK, Bruton's tyrosine kinase; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; ER, estrogen receptor; GIST, gastrointestinal stromal tumor; IL6, interleukin 6; MEK, mitogen/extracellular signal-regulated kinase; NSCLC, non-small-cell

lung carcinoma; PGF, placental growth factor; PI-3-K; phosphatidylinositol-3'-kinase; PNET, pancreatic neuroendocrine tumor; RAR, retinoic acid receptor; RANKL, receptor activator of NF- κ B ligand; RCC, renal cell carcinoma; and RXR, retinoid X receptor.

Drugs included in this table have been approved by the Food and Drug Administration (FDA).

Another example is bevacizumab (avastin, Genentech), a monoclonal antibody targeting vascular endothelial growth factor (VEGF), a ligand that promotes angiogenesis. The FDA has approved bevacizumab for treatment of glioblastoma, colorectal, renal, and lung cancer. Contrary to trastuzumab and cetuximab, bevacizumab acts on vascular endothelial cells in the tumor microenvironment. Advantages include that drug resistance in such normal cells is less likely to develop than in genetically unstable tumor cells and that such therapy may be applicable to a wider range of tumors.⁹⁵ Of note, recent findings suggest that targeting VEGF may also directly affect some tumor cells, which express VEGF receptors.⁹⁶

Tyr kinase inhibitors

Increased understanding of the important role of growth factor signal transduction in cancer has also led to intensive efforts focused on the development of small molecule inhibitors of constitutively activated Tyr kinases ([Table 1](#)). The most striking example is imatinib (gleevec, Novartis), a small molecule inhibitor of the non-RTK Abl. *Abl* is translocated in chronic myelogenous leukemia (CML) as part of the Philadelphia chromosome to create the *Bcr-Abl* oncogene.⁹⁷ Imatinib interacts with the ATP-binding pocket of the Abl kinase domain and stabilizes a catalytically inactive conformation of this oncogene product.⁹⁸ Clinical trials rapidly confirmed the efficacy of this agent in CML and *Bcr-Abl* as a therapeutic target in this disease. Remarkable responses were observed in the chronic phase of the disease with complete clearing of Ph⁺ cells from the circulation in 95% of patients, who had failed standard therapy. Only 9% of patients relapsed over a median follow-up of 18 months,⁹⁹ leading to regulatory approval. Imatinib is most effective in the chronic phase, with fewer responses and more relapses with patients in myeloid blast crisis. Unfortunately, during the progression of the disease, tumor cells often develop resistance, either through mutations that interfere with the binding of imatinib to Abl or by *Bcr-Abl* gene amplification.⁹⁸ Imatinib was subsequently shown to inhibit related RTKs, in particular Kit and PDGFR, for which activating mutations have been identified in gastrointestinal stromal tumor (GIST), leading to FDA approval for its use in therapy of this tumor type as well.

Examples of other small molecules targeting RTKs include gefitinib (iressa, AstraZeneca) and erlotinib (tarceva, OSI/Genentech), which were approved for the treatment of lung cancers displaying EGFR mutations.¹⁰⁰ Crizotinib (xalkori, Pfizer) inhibits ALK, a receptor activated by chromosome translocations or mutations in tumors including lung cancer and neuroblastoma.¹⁰¹ Other more promiscuous small molecule inhibitors that target different Tyr kinases involved in both tumorigenesis and angiogenesis, such as sorafenib (nexavar, Bayer) and sunitinib (sutent, Pfizer), have been approved for the treatment of certain cancers, including advanced renal cell carcinoma, hepatocellular carcinoma, and imatinib-refractory GIST ([Table 1](#)).

Inhibition of growth factor downstream signaling

Downstream components of growth factor signaling pathways activated in cancer cells are also potential therapeutic targets. While extensive efforts to generate efficient and specific Ras inhibitors for the clinic have not been successful, this approach has paid off with the recent approval of new small molecules targeting downstream effectors of RTK signaling ([Table 1](#)). One striking example is vemurafenib (zelboraf, Plexxikon/Roche), approved in 2011 for the treatment of melanomas harboring B-Raf V600E mutations. Vemurafenib is paradigmatic in that it was specifically developed to selectively block the

mutant, but not wild-type B-Raf. Similar to other targeted therapeutic agents, after an initial response, these tumors often become unresponsive to the inhibitor. Several mechanisms have been described for the acquired resistance to vemurafenib, including mutation of Ras, expression of particular B-Raf splice-variants or the overexpression of RTKs, such as the PDGFR.⁵⁶ Recent evidence indicates that melanoma cells resistant to vemurafenib may show a decreased fitness in the absence of the B-raf inhibitor. Thus, intermittent vemurafenib dosing may forestall the clonal expansion of resistant cells, preventing or delaying the onset of drug-resistant disease.¹⁰²

The recent advances in targeting specific growth factor signaling aberrations in human cancer cells argue strongly that knowledge gained on the important role of growth factor signaling in cancer is leading to a promising new era in cancer therapeutics. Increasing understanding of the molecular basis for the selectivity of the successful targeted drugs, as well as the mechanisms of acquired resistance to these therapies, strongly suggests that therapies will be individually tailored based on the genetic profile of the tumor. The astonishing advances in genome sequencing,¹⁰³ combined with the ability to isolate and DNA sequence primary tumors and circulating cancer cells,^{104, 105} offer powerful new approaches in this regard that would be deemed to belong in the realm of fantasy only a decade ago.

Key Points

- Tumor cells can become dependent or addicted to a particular signaling pathway for their growth and survival.
- The pathways aberrantly deregulated in tumor cells may be specifically targeted in the clinic through different therapeutic strategies, including monoclonal antibodies, Tyr kinase inhibitors, and inhibitors of downstream effectors.

Summary

In multicellular organisms, physiological processes are regulated through a complex and interconnected network of signaling pathways, generally mediated by hormones, cytokines, and growth factors. These molecules normally act in a timely and precise manner to specifically control the phenotype of a well-defined population of cells, including their proliferation, differentiation, survival, and motility. When a signaling pathway goes awry, this tight regulation is lost, resulting in an aberrant cell behavior that can lead to cell transformation. Most, if not all, human cancers contain aberrant activation (or, less commonly, inhibition) of more than one such pathway, contributing to increased proliferation, survival, invasiveness, and metastatic spread. Such aberrations occur through different mechanisms, including autocrine/paracrine deregulation or genetic alterations affecting a particular component of the pathway. In this chapter, we discuss growth factor signaling through receptors exhibiting intrinsic tyrosine kinase activity and focus on two major downstream pathways activated by these receptors to promote cell proliferation and survival, that is, the PI-3-K/Akt and Ras/MAP kinase pathways. We will provide different paradigmatic examples, with special emphasis on the functional implications of such aberrations for tumorigenesis. General principles in cell signaling in both normal and tumor cells are addressed, and we briefly discuss how the initiation and progression of particular types of cancer can be affected by the deregulation of several other signaling pathways, including those mediated by cytokines, the TGF β family of

ligands, Wnt, Hedgehog, Notch, and nuclear receptors.

Finally, we discuss the concepts of oncogene addiction and targeted therapy, providing representative examples to illustrate how increased understanding of the mechanisms responsible for aberrant deregulation of particular signaling pathways in cancer can be translated to the clinic.

Chapter 11

Differentiation therapy

Sai-Juan Chen, MD, PhD ■ Xiao-Jing Yan, MD ■ Guang-Biao Zhou, MD ■ Zhu Chen, PhD

Overview

Abnormal differentiation is one of the main features of human cancers, especially in hematological malignancies. Many aberrant genetic and epigenetic factors have been shown to disrupt the regulation of cell differentiation in a variety of cancers and play an important role in oncogenesis. Differentiation therapy refers to the application of therapeutic agents selectively targeting the key molecules involved in the process of cell differentiation, leading to the restoration of normal cellular homeostasis and the eventual clearance of cancer cells. Over the past four decades, investigations of the molecular mechanisms underlying cancer cell differentiation arrest or blockage have allowed the identification of an array of drug targets. On the other hand, many physiological or pharmacological agents have been tested using *in vitro* and *in vivo* systems as the inducers of differentiation and maturation of cancer cells. The translational research in this field has gradually turned the differentiation therapy from a concept to clinical practices. The most successful model of cancer differentiation therapy is the development of synergistic targeted treatment of acute promyelocytic leukemia (APL) with all-trans-retinoic acid (ATRA) and arsenic trioxide (ATO). This chapter discusses the basic theories of differentiation therapy and the clinical achievements of this therapeutic approach.

Molecular mechanisms underlying differentiation blockage in cancer

It has long been recognized that in human cancers, there exist some relationship between the clinical aggressiveness and their differentiation status, with poorly differentiated tumors being usually more aggressive. To understand the biology of differentiation arrest or blockage in cancer, it is necessary to elucidate how the related functions are regulated in normal cells and how they become disrupted in cancer cells. These studies are of importance for identifying meaningful therapeutic targets.

It is well established that pluripotent embryonic stem cells are capable of self-renewal and differentiating into various cells with specific functions in an organism. These cells can then develop into distinct cell types, tissues, and organs, which are under accurate regulation in a finely organized manner. A large body of evidence has been obtained that the underlying mechanisms entail the sequential action of cell-/tissue-specific or time-specific transcription factors (TFs) that activate or repress the differentiation-associated genes under appropriate conditions.^{1–3} The transcriptional expression of genes is also orchestrated by complex mechanisms designated as epigenetic regulation. Notably, many pathways and networks that regulate cell differentiation during normal development are affected by genetic and epigenetic abnormalities during tumorigenesis. As a result, cancer cell population generally bears an aberrant expression of regulators for embryonic morphogenesis and maintains a subset with properties of stem cells. Meanwhile, cancer cells often show defects in programs that keep cells in differentiated state

([Figure 1](#)).

Figure 1 Differentiation blockade and differentiation therapy in cancer. In addition to self-renewal, normal stem cells are capable of differentiating into specific mature cells, while differentiation blockade may lead to the development of cancer. Cancer stem cells may originate from normal stem cells acquiring genetic and/or epigenetic abnormalities, or from normal progenitor or differentiated cells undergoing de-differentiation and reprogramming also due to genetic and/or epigenetic abnormalities. Differentiation therapy exerts therapeutic efficacy by inducing differentiation of cancer stem cells and undifferentiated cancer cells.

Transcriptional factors (TFs)

Cellular differentiation can be defined by a sequential process of acquisition of different functions, and cell fate is largely determined by control of gene expression through the combination of TFs and epigenetic modifiers.^{3, 4} TFs are nuclear proteins capable of DNA binding and trans-activating or trans-repressing the transcription of target genes. They are often assembled into multiprotein complex with cofactors (activators or repressors) and play decisive roles in regulating the gene expression profiles of stem/progenitor cells and determining their ability to differentiate into mature cell lineages.⁵ TFs are also essential for control of cell proliferation and programmed cell death (apoptosis). Recently, cellular reprogramming and induction of pluripotency across differentiated lineages have been achieved using

combinations of TFs, which provide strong evidence for the key role that TFs play in the decisions of cell fate.^{6–11} In addition, that cell differentiation can be directed by lineage-specific TFs has also been supported by a large amount of experimental data.^{3, 5, 12} In contrast, abnormalities of differentiation-associated TFs due to dysregulated expression or aberrant functions imposed by gene point mutations or fusions may disturb the differentiation program of normal stem/progenitor cells.⁵ As a result, immature descendants with growth and survival advantages may be produced, eventually leading to the development of cancer.

The cancer-associated TFs can be divided into distinct classes according to structural and/or functional features,¹² such as leucine zipper factors (bZIP, e.g., c-JUN), helix-loop-helix factors (bHLH, e.g., MYC), Cys4 zinc fingers [e.g., nuclear receptors (NRs), GATA factors], helix-turn-helix factors (HTH, e.g., HOX family, OCT-1/2), and Rel homology region (e.g., NF- κ B). These TFs are considered as key regulators of cell proliferation, differentiation, and apoptosis, and their mutations and/or aberrant expression have been shown to play an essential role in malignant transformation. A special class of ligand-activated zinc finger proteins known as superfamily of NRs is worth particular attention, as they are major regulators in the initiation and/or maintenance of differentiated status of many cell/tissue types.¹³ This family contains the receptors for different ligands including steroid/thyroid hormones, retinoids, vitamin D3, and certain fatty acids. Notably, many of these receptors are subject to dysregulated expression or structural abnormalities in various cancers. These abnormalities subsequently lead to undesired activation of the normally hormone-regulated genes in a hormone-independent way, or even activation of some genes unrelated to hormone regulation, which will be discussed in detail in the section entitled “Agents targeting aberrant TFs.”

For long time, hematopoiesis has been at the frontline of research in the biology of normal and abnormal cell differentiation,^{5, 14, 15} owing to the discoveries of hematopoietic hormones and related signaling pathways and the specific TFs that regulate the fate of hematopoietic stem/progenitor cells (HSPC) ([Figure 2](#)). Each stage of myeloid and lymphoid differentiation shows particular TFs signatures that function in networks. For example, RUNX1, GATA1, C/EBP α , C/EBP β , MYB, E2A, PAX5, TAL1/SCL, or PU.1 are turned on or turned off in an orchestrated manner to ensure blood cell lineage specification.^{3, 15} Some of these TFs were originally identified following the molecular characterization of gene point mutations or fusion in leukemia, such as C/EBP α in *CEBPA* mutation of acute myeloid leukemia (AML), RUNX1 in the *RUNX1(AML1)–ETO* fusion gene of t(8;21) AML, and SCL(TAL1) in t(1;14) T-cell acute lymphoblastic leukemia (ALL).^{16–18} Disruption of these hematopoietic TFs in leukemia blocks hematopoietic cells in their early stages of differentiation.

APL, acute promyelocytic leukemia; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; GMP, granulocyte-macrophage progenitor; HSC, hematopoietic stem cell; LT, long-term; MEP, megakaryocyte-erythroid progenitor; MPP, multipotent progenitor; PMLC, promyelocyte; ST, short-term

Figure 2 Signaling pathways and transcriptional factors (TFs) regulating the differentiation of hematopoietic stem/progenitor cells (HSPC). Differentiation block may result in leukemia, exemplified by development of acute promyelocytic leukemia (APL), a subtype of acute myeloid leukemia (AML) characterized by accumulation of abnormal promyelocytes in bone marrow/peripheral blood, the presence of $t(15;17)/PML-RAR\alpha$ fusion gene, and severe bleeding syndrome. In fact, almost all the listed signaling molecules and TFs are subject to mutations (gene fusions, point mutations, gene amplifications/deletions) and/or dysregulation of expression in hematological malignancies.

The fact that abnormal TFs disturbing cell differentiation are “drivers” in oncogenesis has aroused interest for these proteins to be potential targets for therapeutic intervention. However, most current anticancer research activities are concentrated on cell-surface receptors because they offer a relatively straightforward way for drugs to affect cellular behavior, whereas agents acting at the level of transcription need to penetrate the cell membrane and enter into the nucleus. Efforts should be supported to design drugs affecting cancer-associated transcriptional patterns for re-establishing differentiation. Small molecule drugs directed against well-defined interacting sites between TFs and DNA or between TFs and other proteins in transcription machinery can be developed, so as to modulate the key TF target genes. On the other hand, the re-introduction of differentiation-related wild-type TFs with gene therapy might also serve as a strategy for cancer differentiation therapy.

Epigenetic modifiers

Epigenetic regulation constitutes crucial mechanisms governing the variability in gene expression, which is heritable through mitosis and potentially also meiosis, without changes of genomic sequence.^{19, 20} All cells of an organism share the same genome information but exhibit different phenotypes with diverse

functions. This phenotypic diversity is due to distinct gene expression patterns among different cell types. It is well established that chromatin states are primary determinants for the turn-on or turn-off of genes. The assembly and compaction of chromatin require multiple regulatory mechanisms, including DNA methylation (cytosine methylation and hydroxymethylation) or demethylation, post-translational modifications of histones (phosphorylation, acetylation, methylation, and ubiquitylation), and noncoding RNA-mediated pathways.^{20–22} A large number of enzymes have been identified to be regulatory factors in the mechanisms, such as DNA methyltransferases (DNMTs) and DNA demethylases (DNDMs), histone deacetylases (HDACs) and histone acetyltransferases (HATs), and histone methyltransferases (HMTs) and histone demethylases (HDMs) (Figure 3a and b). The different modifications of DNA or histones are closely interrelated and can both reinforce each other and inhibit each other. Many histone-modifying enzymes are components of cofactor complexes and function cooperatively with TFs to modulate gene expression (Figure 3c).

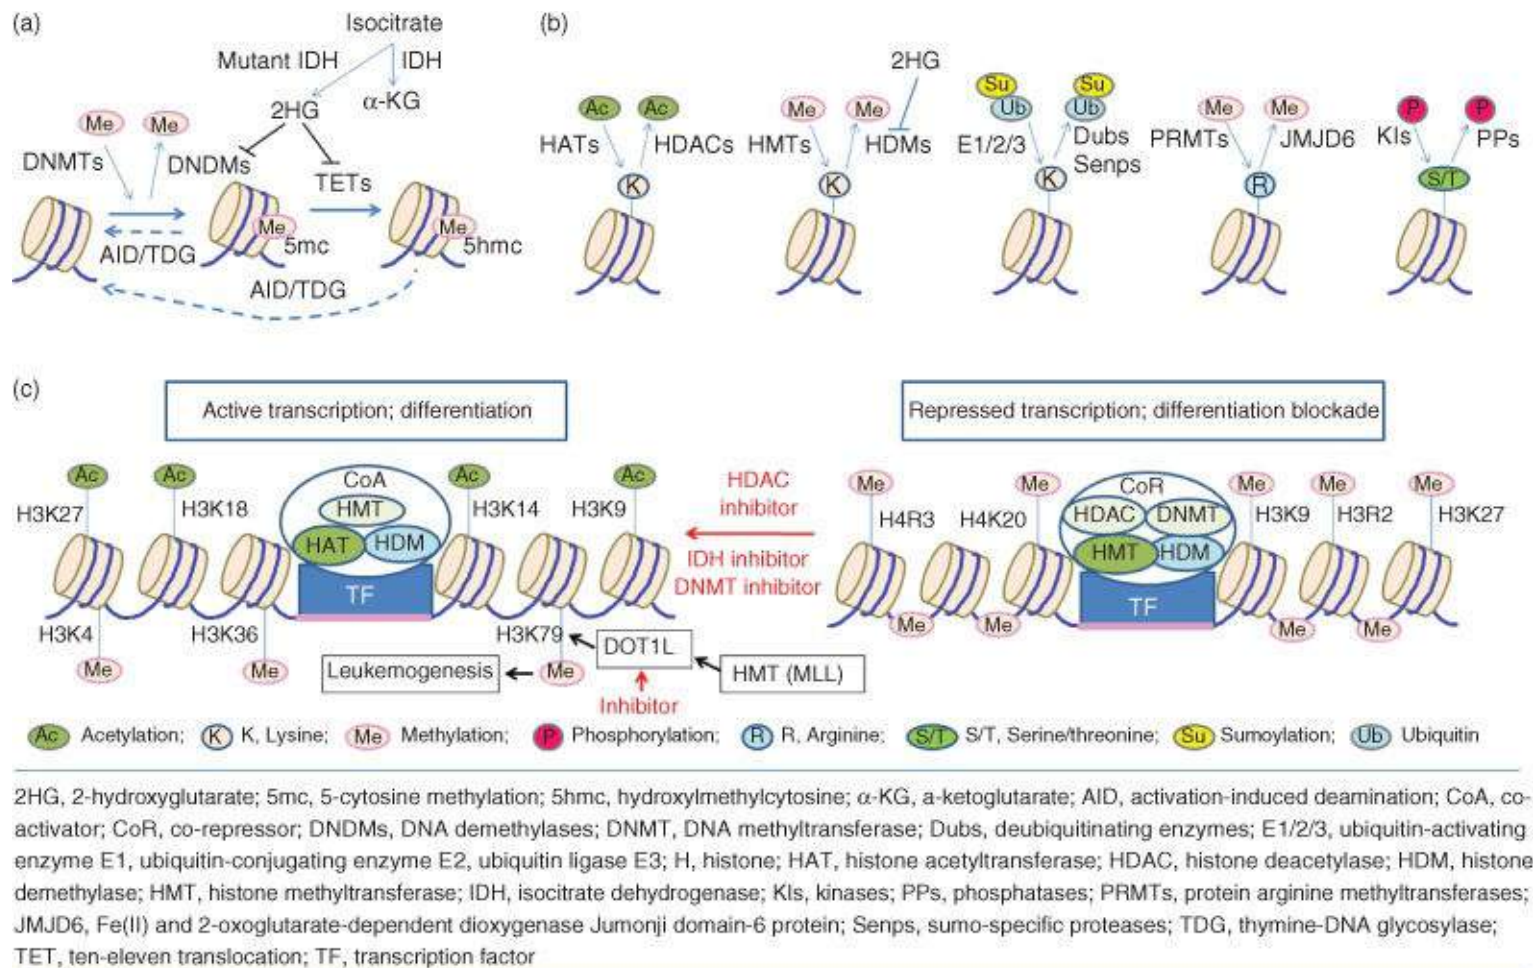

Figure 3 Epigenetic regulation involved in the cell differentiation and tumorigenesis. (a) DNA methylation (cytosine methylation and hydroxymethylation) are regulated by different enzymes DNMTs, TETs, and IDH. (b) Post-translational modifications of histones include phosphorylation, acetylation, methylation, and ubiquitylation or sumoylation, which are regulated by a variety of factors HATs, HDACs, HMTs, HDMs, and so on. Notably, most of these epigenetic modifier genes have been found to be mutated in human cancers including solid tumors and hematological malignancies. (c) Gene expression is controlled in the promoter regions by a combination of chromatin modification and transcriptional factor (TF). In tumor cells, gene expression is silenced by condensing chromatin, methylating DNA, and deacetylating histones, which results the differentiation blockade. Inhibition of HDACs, DNMTs, and IDH may result in active transcription and differentiation of cancer cells. Some HMTs (e.g., MLL and related fusion proteins) may enhance H3K79 methylation by promoting DOT1L to activate transcription of some leukemogenic genes, and inhibitor of DOT1L may suppress the leukemogenic genes to treat leukemia.

Recently, new technological platforms have allowed comprehensive epigenomic map to be made in pluripotent and differentiated cells, which provide further support to the concept that cell differentiation is accompanied by dynamic features of chromatin states.^{22–25} Genetic studies in different model organisms have shown the importance of chromatin regulators in key developmental transitions and cell fate decision. Cancer cells are characterized by typical genome-wide aberrations at the epigenetic level, such as the hypomethylation, the hypermethylation of specific promoter regions, the histone deacetylation, the downregulation of microRNAs (miRNAs), and the dysregulation of certain components of epigenetic machinery.^{20, 21, 26} Recently, somatic alterations of many epigenetic modifiers have been identified as common genetic events in cancers including solid tumors and hematopoietic malignancies.^{27–30} In acute leukemia and myelodysplastic syndrome (MDS), besides the already known aberrations of mixed lineage leukemia (*MLL1*) located on 11q23, mutations in a subset of epigenetic modifiers, including other SET domain-containing proteins (*MLL2*, *SETD2*),³¹ tet methylcytosine dioxygenase 2 (*TET2*),^{32–34} isocitrate dehydrogenase (*IDH1/IDH2*),³⁵ additional sex combs-like 1 (*ASXL1*),^{36, 37} enhancer of zeste homolog 2 (*EZH2*),^{38, 39} and DNA methyltransferase 3A (*DNMT3A*),^{40, 41} have been discovered. These mutations have been shown not only to contribute to the leukemogenesis but also serve as the biomarker of clinical prognosis since they often predict a poor overall survival (OS) of patients.^{28–30} The aberrations of epigenetic modification together with those of genetic regulation result in permanent changes in the gene expression patterns that confer a selective advantage to differentiation block, apoptotic deficiency, and uncontrolled cell growth. Because the epigenetic modifications are usually reversible, therapies targeting epigenetic modifiers hold the promise of being clinically effective.

Cancer stem cells (CSCs)

Most cancers are heterogeneous in terms of cell proliferation and differentiation status. In recent years, evidence has been accumulated to suggest the existence of less-differentiated, stem cell-like cells within the cancer cell population in solid tumors (lung, colon, prostate, ovarian, and brain cancers and melanoma) and leukemia.^{42–45} These cells are now referred to as cancer stem cells (CSCs) or tumor-initiating cells capable of self-renewal and giving rise to the entire cancer bulk.⁴⁶ Indeed, a single leukemia-initiating cell (LIC) from human being can cause a full-blown AML in animal model.⁴⁷ As a result, malignant cells in a given cancer are highly hierarchical, with the unique self-renewing CSCs at the top of the hierarchy, while all other cells are derived from differentiated CSCs ([Figure 1](#)).

Investigation of the properties of CSCs and their roles in disease mechanisms occupies a central position in cancer research nowadays. Generally speaking, CSCs represent the driving force behind cancer initiation, progression, metastasis, recurrence, and drug resistance.^{43, 48} It is nevertheless not easy to define the phenotypes of CSCs in that they are variable from one cancer to another and are affected by the initial transformation as well as different stages of neoplastic development. Currently, fluorescence-activated cell sorting using cell surface markers or intracellular molecules represents the common method to identify CSCs.^{42, 43} There are still problems to be tackled: CSC biomarkers are lacking in some cancers; not all CSCs express the markers or marker sets; some differentiated cancer cells also express the same marker sets as CSCs do; some currently used marker sets are not specific to CSC since they are also expressed by stem/progenitor cells in normal tissues. On the other hand, gene expression patterns may be of value because dysregulation of certain pathways or networks can be seen in CSCs but not in differentiated cancer cell compartments, which can eventually be used as new CSC markers. So far, PI3K/Akt, PTEN, JAK/STAT, TGF- β , Wnt/ β -catenin, hedgehog, Notch, NF- κ B, and Bcl-2 have been included into the pathways that are involved in the control of self-renewal and differentiation of CSCs.^{42,}

Traditional cytotoxic chemotherapy (CT) or radiation therapy is designed to target cancer cells with rapid proliferative or dividing abilities. These therapies are usually unable to eliminate CSCs, which are in relatively quiescent state and divide slowly, and can consequently regenerate cancers and drive disease recurrence.^{48–50} It is believed that only when CSCs are eradicated can cancer patients be actually cured. In recent years, great attention has been given to the characteristics of CSCs by both scientific and medical communities because these cells provide a unique target for cancer treatment. CSCs-targeted strategy focuses on the elimination of CSCs by acting on specific surface molecules, signaling pathways, or microenvironments, which are indispensable for the maintenance of stem cells, or by inducing CSCs into the more differentiated state.^{4, 45, 48, 49} A number of existing agents have been investigated in this regard and high-throughput screening of chemical libraries has also been used to find novel CSC-targeted chemicals.^{51, 52}

Potential cancer cell differentiation-inducing agents

Cancer differentiation therapy aims at using appropriate therapeutic agents to induce cell cycle arrest and a commitment to the cell differentiation program toward terminal cell division, specific function gaining, and ultimately apoptosis.⁵³ This concept applies relatively clearly to hematologic malignancies, whereas “authentic” differentiation therapy for solid tumors is sometimes difficult to define and often refers to the processes that convert malignant cells to a more benign phenotype, accompanied by diminished proliferative and metastatic abilities and the expression of mature cell markers.⁴ Interestingly, some initially defined differentiation inducers have turned out to be compounds targeting oncoproteins, while some newly developed targeting therapeutics have been found to trigger significant differentiation of cancer cells. Thus far, about 80 agents of differentiation induction have been identified and biosynthesized, and most of them are under investigations *in vitro* or on animal models, among which only a fraction have been used in clinical practice.

Agents targeting aberrant TFs

As discussed previously, TFs play a powerful role in physiological cellular differentiation and can be abnormally regulated or functionally disturbed in cancers. The modulation and/or restoration of the functions of differentiation-associated TFs constitute one of the main strategies for cancer differentiation therapy. Here, we introduce some differentiation-induction agents, which specifically target hormone-regulated TFs.

Retinoids

Retinoids are a group of vitamin A derivatives. Retinoic acids (RAs) are the physiologically existing active metabolite of retinol, which regulate a wide range of biological processes including development, differentiation, proliferation, and apoptosis in normal or cancer cells.^{13, 54–56} The most important isomers of RAs are all-trans-retinoic acid (ATRA), 13-cis-retinoic acid (13-cRA), and 9-cis-retinoic acid (9-cRA), which have different spectrums of biological activity and ligand affinity.^{57, 58} Synthetic retinoids include bexarotene and fenretinide. The effects of RAs on cell differentiation are exerted mostly via their NRs. Two types of receptors, the retinoic acid receptors (RARs, with three major isoforms RAR- α /- β /- γ) and the retinoid X receptors (RXRs, with three main isoforms RXR- α /- β /- γ), mediate RA signaling as heterodimer RAR/RXR.^{13, 56} These receptor heterodimers are able to bind, at genomic level, to the specific motifs defined as retinoic acid response elements (RAREs) on the promoters of target genes. RAR/RXR differentially activates or represses gene transcription while recruiting co-activators (CoA) or

co-repressors (CoR) complexes. These different modes of action depend on the presence or absence of the ligands, RAs. Physiological concentrations of RA (1 pmol/L) are able to release CoR (such as N-CoR/SMRT complex and the chromatin remodeling complexes, e.g., HDACs, DNMTs) from the RAR/RXR and recruit CoA (such as p300/CBP complex with HAT activity), leading to the transcriptional activation of genes involved in cell differentiation (e.g., C/EBP α and PU.1), growth, and apoptosis.^{56, 59–65}

Retinoid signaling is often disrupted during carcinogenesis, suggesting that restoration of this pathway may be a viable option for cancer treatment.^{54, 55, 58, 66} The effects of RA-induced differentiation are particularly observed on promyelocytic leukemia cell-like cell lines such as HL60 and NB4, or fresh primary APL (acute promyelocytic leukemia) cells.^{67, 68} These cells can undergo terminal differentiation to morphologically and functionally mature granulocytes after incubation with pharmacological concentrations (0.1–1 μ mol/L) of RAs, especially ATRA.⁶⁷ Myeloblasts from other AML subtypes are generally not affected by RAs, whereas only limited differentiating effects of retinoids are seen on cell lines such as THP-1 (monoblastic leukemia), K562 (blastic phase of CML), HEL (erythroleukemia), and U937 (monocytic leukemia).^{59, 68} Until now, the most successful clinical practice of differentiation therapy is the use of ATRA in APL, which will be discussed in details in the following section.

Retinoids have been reported to induce the differentiation of many solid tumor cell lines *in vitro* and suppress carcinogenesis in tumorigenic animal models, including human teratoma, melanoma, neuroblastoma, osteosarcoma, and rhabdomyosarcoma.^{57, 69, 70} In thyroid carcinoma cell lines, retinoids were shown to induce the expression of type I iodothyronine-5'-deiodinase and sodium/iodide symporter, which are the thyroid differentiation markers.^{71–73} In early clinical studies, patients with poorly differentiated, inoperable thyroid carcinoma with lacking or insufficient iodine uptake were treated with 13-cRA at oral doses of 0.3–1.5 mg/kg/day over 5 weeks and up to 9 months. The results showed an increased radio iodide uptake in 20–40% of patients.^{73–75} In some of these trials, aflurine-18 fluorodeoxyglucose positron emission tomography (18 F-FDG PET) was used for the evaluation of therapy with 13-cRA in thyroid cancer. These data indicate retinoids as promising differentiation therapy agents for the treatment of thyroid cancer.

In addition to induction of differentiation, retinoids exert antitumor effects through other modes of action: repressing cell proliferation, promoting cell apoptosis, and inhibiting angiogenesis and metastasis.^{56, 57} Notably, retinoids are used effectively in the treatment of certain cutaneous premalignancies and malignancies with good results.⁷⁶ Bexarotene, the first synthetic highly selective RXR agonist, has been shown to induce apoptosis of cutaneous T-cell lymphoma (CTCL) cells with downregulation of its receptors and of survivin, an inhibitor of apoptosis.⁷⁷

In clinical practice, systemic retinoids are approved by the US Food and Drug Administration (FDA) for the treatment of APL and CTCL.

Vitamin D compounds

Vitamin D is known to have a variety of actions at cell proliferation and differentiation.⁷⁸ These actions are mainly mediated by vitamin D receptor (VDR), a member of NR superfamily. While performing physiological functions, VDR forms heterodimer with RXR. The VDR/RXR heterodimer binds to vitamin D response elements (VDREs) in the promoter regions of target genes.⁷⁹ In the absence of physiologically active form of vitamin D, 1,25 dihydroxy vitamin D3 [1,25(OH)₂D₃](1,25D), the VDR/RXR heterodimer recruits co-repressors including HDACs and results in transcriptional repression.⁶⁶ However, once the ligand binds to VDR/RXR, the resultant conformational change of the receptor heterodimer triggers the

transcriptional activation of the target genes. It has been demonstrated that the recruitment of several coactivators to VDR/RXR is indispensable for this trans-activation. The VDR also directly interacts with a number of other proteins (e.g., β -catenin) and regulate their activities.⁸⁰ Besides, 1,25D can trigger “rapid responses” via activating membrane initiated signaling pathways, such as MAPK pathways, the lipid signaling pathways, or PI3K/AKT pathway.^{79, 81, 82}

Similar to the differentiation-inducing effects of retinoids, 1,25D has been shown to dispose differentiating actions on various types of human AML cells,⁷⁸ including HL-60, U937, NB4, THP-1, and KG-1. Animal model studies have shown that 1,25D strongly promotes cell differentiation and thereby significantly prolongs the survival of mice transplanted with leukemic cells. However, the results of clinical trials are unsatisfactory. Neither 1,25D nor vitamin D analogs (VDAs) show clear beneficial effects on patients with AML or MDS.^{83, 84} An important issue for these failures could be the heterogeneous nature of the diseases. The clinical utility of 1,25D has also been limited by the severe toxicity of its therapeutic doses, primarily due to fatal drug-induced hypercalcemia.⁸⁵

Some types of solid tumors, such as colon, breast, and prostate cancers and osteosarcoma, were also reportedly to respond to *in vitro* applied VDAs.^{86, 87} Nevertheless, little is known about how VDAs mediate their antiproliferation or pro-differentiation activity.⁸⁶ Moreover, the results of clinical trials of VDAs across a variety of cancers have been disappointing with regard to efficacy.⁸⁸ Thus, the routine recommendation of vitamin D for cancer treatment is premature.

PPAR γ agonists

Peroxisome proliferator-activated receptor gamma (PPAR γ) is also a member of the NR superfamily.⁸⁹ PPAR γ forms heterodimer with RXR, which then binds to PPAR γ response elements in the promoter regions of target genes. It is well established that PPAR γ is important in the regulation of proliferation, differentiation, and apoptosis in many cell types.⁸⁹ Synthetic PPAR γ agonists have been developed, including drugs used in the treatment of type 2 diabetes [e.g., troglitazone, rosiglitazone (TGZ)] and nonsteroidal anti-inflammatory agents (e.g., indomethacin).^{59, 69}

Activation of PPAR γ with agonists can suppress the growth and induce the differentiation of several types of tumors *in vitro* and in animal models for colon, breast, prostate, and thyroid cancers, liposarcoma (LPS), pituitary adenomas, and acute leukemia.^{90–92} Antitumor effects of PPAR γ agonists may also be associated with regulation of cell cycle, apoptosis, and expression of tumor suppressor genes (TSGs, e.g., *PTEN* and *BRCA1*).^{59, 93, 94} Besides, there has been evidence for “off-target” effects of PPAR γ agonists, which is independent on the PPAR γ receptor activity.⁵⁹

Clinical trials of PPAR γ agonists have been carried out in several human malignancies. A few studies have reported that TGZ could induce the differentiation of cancer cells in patients with LPS.⁹⁵ It was initially found that terminal adipocytic differentiation was induced in a few patients with intermediate to high-grade LPS. However, such responses and clinical benefit could not be confirmed in a subsequent trial.⁹⁶ Clinical investigations in breast, prostate, colon, lung, and thyroid cancers and LPS did not reveal a meaningful benefit of TGZ therapy.^{59, 73, 96–98} Although the clinical effects of PPAR γ agonists have not been convincing, their low toxicity profile and potential additive or synergistic effects combined with other anticancer agents such as retinoids make them reasonable candidates in combination therapy trials.

Agents targeting epigenetic modifiers

It has been shown that the aberration of epigenetic regulation and TFs governing differentiation occurs in

many cancers. Recurrent somatic alterations in epigenetic modifiers are also observed in solid tumors and hematological malignancies. Hence, there has been substantial interest in preclinical and clinical studies for epigenetic regulating agents to be considered as differentiation inducers.⁹⁹ A large amount of epigenetic agents are currently under investigation and a few have received FDA approval. Promising results have been already yielded in certain cancer types.

DNMTs inhibitors

DNA methylation is the most characterized epigenetic modification and is described as a stable epigenetic marker.¹⁰⁰ The enzymes catalyzing DNA methylation are known as DNMTs. As hypermethylation of TSGs and over-expression of DNMTs have been established as the key factors in carcinogenesis, demethylating agents seem to be especially promising as anticancer drugs.^{101, 102} To date, 5-azacytidine (5-Aza) and 5-aza-2'-deoxycytidine (decitabine) are the most successful DNMTs inhibitors, already approved by FDA for the treatment of patients with MDS or AML, and 5-Aza has also been approved by the FDA and the European Medicines Agency (EMA) for the treatment of chronic myelomonocytic leukemia (CMML).¹⁰¹ The mode of action seems dose-dependent and a “dual mechanism” has been identified: the cytotoxicity and/or the inhibition of cell proliferation at high doses, and the DNA hypomethylation effect on the induction of gene expression at low doses.^{101, 102} Numerous studies have described terminal differentiation of AML cells treated with 5-Aza or decitabine.^{102–104} Moreover, it has been demonstrated that decitabine-induced killing of myeloid leukemia cells is independent on DNA damage and apoptosis.¹⁰² In some solid tumor cells, 5-Aza or decitabine induces cancer cell apoptosis and senescence through multiple mechanisms.¹⁰⁵

Recent clinical studies indicated that repeated exposure at low doses (decitabine: 20 mg/m² for 5 days every 28 days; 5-Aza: 75 mg/m² for 7 days every 28 days) to these agents can induce DNA demethylation with a better antineoplastic effect than when used at higher doses (decitabine: 45 mg/m² for 3 days every 42 days).^{102, 106–109} In MDS patients, 5-Aza induces an overall response rate of 20–30% and significantly improves survival compared with standard care, while decitabine induces cytogenetic remission (Cyt-CR) rates of 35–50% at optimal doses and prolongs survival when compared with historical controls.^{102, 106–108, 110, 111} Clinical trials of DNMTs inhibitors in combination with other agents have also obtained promising results in solid tumors such as nonsmall-cell lung cancer and refractory ovarian cancer.^{105, 112, 113} Therefore, rational use of the existing DNMTs inhibitors are to be encouraged and efforts to develop new compounds targeting more selectively DNMTs and with less toxicities should be continued.

HDAC inhibitors

As enzymes catalyzing the deacetylation of histones, HDACs are involved in the control and regulation of cell growth and differentiation. Abnormal expression or mutations of HDACs, together with aberrant histone acetylation patterns, have been found in a broad range of cancer types.¹¹⁴ HDACs have thus become a novel class of targets in cancer therapy ([Figure 3c](#)). Histone deacetylase inhibitors (HDACIs) comprise diverse compounds such as suberoylanilide hydroxamic acid (SAHA, vorinostat) or valproic acid (VPA). It has been reported that HDACIs promote growth arrest, differentiation, and apoptosis of many solid tumor cells (e.g., lung, prostate, thyroid, and breast cancers, chondrosarcoma, and glioblastoma) and cell lines of hematopoietic malignancy, and exhibit only minimal effects on normal tissues.^{69, 115–121} For instances, SAHA and VPA are able to induce *in vitro* myeloid differentiation and early apoptosis of Kasumi-1 AML cells, which express AML1-ETO. Similar effects were also reported in a murine xenograft tumor model.

Inspired by preclinical data, many researchers have investigated the effects of HDACIs in clinical trials. Early study of SAHA showed efficacy in a panel of hematologic diseases.¹²² The compound has been successfully applied to the treatment for refractory CTCL and becomes the first HDACI approved by FDA for this disease. A pilot study combining VPA and ATRA in eight refractory or high-risk AML patients demonstrated clinical benefits in seven cases, with myelomonocytic differentiation of circulating blasts. Although promising results have been obtained in hematological malignancies, clinical data for HDACIs in patients with solid tumors are inadequate.¹²³ In future, the effects of the combination of HDACI with conventional cancer treatment should be explored in solid tumor.

DOT1L inhibitor

MLL gene is one of the epigenetic modifier genes identified through molecular cloning of chromosomal translocations involving 11q23. This gene encodes a SET domain histone methyltransferase, which catalyzes the methylation of lysine 4 of histone H3 (H3K4) at specific gene loci.¹²⁴ *MLL* is essential for fetal and adult hematopoiesis in that it regulates the expression of HOX genes and some cofactors key to the expansion and differentiation of HSPCs.^{125–127} Abnormalities of *MLL* gene account for over 70% of infant leukemia and approximately 10% of adult AML, and are correlated to a particularly worse clinical outcome.¹²⁸ In addition to *MLL* translocations, *MLL* partial tandem duplication (PTD) is also reported as a recurrent genetic defect. In the chimerical genes, the catalytic SET domain of *MLL* is lost and the fusion partners are capable of interacting with a histone H3K79 methyltransferase DOT1L.^{129, 130} As a result, fusion products not only retain gene-specific recognition elements within the *MLL* moiety, but also gain the ability to recruit DOT1L to these locations. The ectopic H3K79 methylation due to recruitment of DOT1L leads to enhanced expression of leukemogenic genes, such as *HOXA9* and *MEIS1*.¹³¹ Of particular interest is that DOT1L contributes to the transforming activity of *MLL* fusion and thus functions as a catalytic driver of leukemogenesis.

It has been proposed that inhibition of DOT1L may provide a pharmacologic basis for therapeutic intervention in *MLL*-related leukemia ([Figure 3c](#)). *In vitro* and *in vivo* experiments have demonstrated that EPZ-5676, a specific inhibitor of DOT1L, can selectively kill cells carrying on the *MLL* gene translocation by causing cell cycle arrest and promoting cell differentiation.¹³² Data of phase 1 clinical trial of EPZ-5676 for the treatment of refractory or relapsed *MLL* rearranged acute leukemia patient reported that the compound was generally safe and well tolerated (NCT01684150). Eight of the 34 *MLL*-related patients showed biological or clinical responses,¹³³ including two complete responses (CRs) and one partial response (PR). Other DOT1L inhibitors such as EPZ4777 and SYC-522 also have been documented to promote differentiation and apoptosis.^{134–136} Interestingly, bioinformatics analysis suggested that DOT1L may play a role in the pathogenesis of breast cancer. *In vitro* study has shown that DOT1L inhibition selectively inhibited proliferation, self-renewal, and metastatic potential of breast cancer cells and induced cell differentiation.¹³⁷

Inhibitors of isocitrate dehydrogenase (IDH)

Somatic mutations of the metabolic enzyme IDH have recently been reported in human glioma, melanoma, thyroid cancer, chondrosarcoma, and AML.^{35, 138–140} All mutations are located at arginine residues in the catalytic pockets of IDH1 (R132) or IDH2 (R140 and R172) and thus confer on the enzymes a new activity: catalysis of α -ketoglutarate (α -KG) to 2-hydroxyglutarate (2-HG).^{140, 141} High concentrations of 2-HG, known as an “oncometabolite,” have been shown to inhibit α -KG-dependent dioxygenases, including histone and DNA demethylases, which are main modifiers of the epigenetic state of cells ([Figure 3a](#)).^{140–143} It has been suggested that cancer-associated IDH mutations may induce a block of

cellular differentiation to promote tumorigenesis and therefore may be potential targets of differentiation therapy.^{143, 144} Indeed, it has been shown that a selective IDH1/R132H inhibitor (AGI-5198) induces the expression of genes associated with gliogenic differentiation and triggers astroglial differentiation of IDH1/R132H mutant (mIDH1) cells.¹⁴⁵ Moreover, blockade of mIDH1 suppresses the growth of glioma cells with IDH1/R132H, but not those with wild-type IDH1 *in vitro* or in IDH1/R132H glioma xenograft mice. It is worth noting that AGI-6780, a small molecule that potently and selectively inhibits the tumor-associated mutant IDH2/R140Q, has also been developed. AGI-6780 is capable of inducing differentiation of TF-1 erythroleukemia and primary human AML cells *in vitro*.¹⁴⁶ These findings provide proof-of-concept that inhibitors targeting mutant IDH1 or IDH2 may have potential applications as cancer differentiation inducers.

Recently, promising results of early phase clinical studies on AG-120 (the first inhibitor of mutated IDH1) and AG-221 (the inhibitor of the mutated IDH2 protein) were reported (<https://www.clinicaltrials.gov/>).¹⁴⁴ AG-120 was well tolerated and showed encouraging clinical efficacy in patients with advanced *IDH1*-mutation positive AML. The compound seemed able to reduce 2-HG levels in diseased cells to normal levels and allow leukemia cells to mature into granulocytes. Among 14 evaluable cases out of 17 patients, 7 patients responded to the drug, with 4 CR (Daniel Pollyea, the 26th European Organization for Research and Treatment of Cancer Symposium). Consistent with the clinical observation, AG-120 reduces intracellular 2-HG and induces cellular differentiation in TF-1 R132H cells and primary human *IDH1* mutant AML patient samples treated *ex vivo* (56th ASH meeting, abstract 70455). The ongoing phase 1 study of AG-221 as a single agent in patients with *IDH2*-mutant positive advanced hematologic malignancies also showed a favorable safety profile as well as durable clinical benefits (56th ASH meeting, abstract 70721). Out of 48 patients enrolled, 20 patients achieved objective responses, including 12 CRs and 8 PRs. Responses were durable, with durations up to 8 months. Interestingly, AG-221 induces differentiation and impairs self-renewal of IDH2-mutant leukemia cells in murine models of IDH2-mutant leukemia and primary human AML xenograft models (56th ASH meeting, abstract 70656 and 76334).

Actually, the studies on cancer differentiation inducers gradually take momentum. Of particular interest is the model disease APL, where differentiation-inducing agents have been demonstrated to exert a curative effect in the great majority of patients. Besides, some other differentiation-induction agents have shown promising effects in preclinical experiments and clinical trials. Differentiation therapy for cancers, although still in its relative infancy, has given hope to millions of cancer patients.

APL as a successful model of cancer differentiation therapy

APL is the M3 subtype of AML, characterized not only by distinct clinical manifestations but also by unique molecular pathogenesis and effective target-based differentiation therapy.

Clinical treatment strategies in APL

APL was first described in 1957 as the most malignant form of acute leukemia.¹⁴⁷ Patients with APL show specific features: a very rapid fatal natural course of only a few weeks' duration, an accumulation of abnormal promyelocytes in bone marrow, and a severe bleeding syndrome due to disseminated intravascular coagulation (DIC) or hyperfibrinolysis. In the era before ATRA-based therapy, only 23–35% of the APL patients could have a 5-year survival by CT.¹⁴⁸ Inspired by the Chinese philosophy of educational approach in health maintenance and the Western medical science of induction of cancer cell differentiation, scientists from Shanghai Institute of Hematology (SIH) carried out the research on

leukemia differentiation therapy since the late 1970s.¹⁴⁸

In 1980, a group from United States published the results of *in vitro* terminal differentiation of HL-60 cells upon the effect of 13-cRA.⁶⁷ Clinical improvement or CR after treatment with 13-cRA in a few isolated cases of APL were then reported, accompanied by maturation of promyelocytes with disappearance of signs of coagulopathy.^{149–151} The SIH group, on the other hand, was focused on the potential therapeutic effects of ATRA. The first clinical trial of ATRA was reported in 24 APL cases (16 newly diagnosed and 8 anthracycline refractory cases) who were treated with ATRA alone.¹⁵² CR was achieved in all patients and the evidence of *in vivo* blast differentiation with Auer's rods in polynucleated granulocytes was documented. The results have been quickly confirmed by a large amount of clinical practices around the world.^{59, 148} ATRA therapy became the standard for induction of newly diagnosed APL patients, which was then further improved stepwise through the effective combination regimen of ATRA with CT. Moreover, the roles of ATRA and CT in consolidation or maintenance therapy have been verified to reduce the incidence of relapse. By using this protocol, 5-year OS was up to about 70%.^{69, 148, 153–155} The routine prescription of ATRA is 45 mg/m²/day, while the recommendation dosage of ATRA in the SIH is 25 mg/m²/day. The reason to reduce the initial dose of ATRA is to avoid ATRA toxicity but to achieve the same therapeutic effects as the conventional dosage.¹⁵⁶

Even though the ATRA/CT combination was considered very efficient anti-APL therapy, up to about 30% of APL patients still ended with relapse.^{157–159} The introduction of arsenic trioxide (ATO) since the early 1990s has further changed the clinical landscape of APL. *In vitro* studies showed that ATO exerts dose-dependent effects on APL cells including differentiation and apoptosis, although the differentiation is only a partial one compared with that induced by ATRA.¹⁶⁰ Clinically, refractory or relapsed APL after ATRA/CT therapy as well as newly diagnosed APL could achieve CR, suggesting an absence of cross-resistance between ATRA and ATO.¹⁶¹ Therefore, new therapeutic strategies have focused on minimizing CT and administering ATRA plus ATO as primary therapy. Indeed, the ATRA-/ATO-based protocol yielded a much longer survival in newly diagnosed APL compared with therapy with ATRA or ATO alone.^{148, 162, 163} These outcomes were even not influenced by FLT3 mutation status, which was a poor prognostic factor in APL patients treated with ATRA and CT.¹⁶⁴ Combination of ATRA and ATO have obtained about 95% of CR rate and 5-year DFS and OS were near 90%.¹⁶² Of note, the combination therapy without CT was associated with very high 2-year EFS and OS rates (97% and 99%, respectively) in nonhigh-risk APL by Sanz Score ([Table 1](#)).^{158, 165} Thus, in some newly updated authoritative guidelines, the ATRA-/ATO-based therapy has been the first-line strategy for APL patients. Although consensus has not yet been reached on the details of specific consolidation or maintenance therapy, it has been widely accepted that ATRA, ATO, and anthracycline-based CT should be given sequentially. The recommendation of APL treatment is listed in [Tables 2](#) and [3](#).

Table 1 Sanz score for APL risk stratification

Characteristic	Low risk	Intermediate risk	High risk
WBC (×10 ⁹ /L)	≤10	≤10	>10
Platelets (×10 ⁹ /L)	>40	≤40	≤40

Source: Data from http://www.nccn.org/professionals/physician_gls/f_guidelines.asp.

The conventional administration of ATO is the intravenous route. An oral formulation of ATO was also found to be active in relapsed APL and has subsequently been evaluated in upfront management. Another formulation of arsenic in advanced clinical investigation is tetra-arsenic tetra-sulfide (AS₄S₄) and an oral

As₄S₄-containing formula named the Realgar–Indigo naturalis formula (RIF) in traditional Chinese Medicine was used in APL patients.^{167, 168} No significant differences were noted between the RIF and intravenously administered ATO groups with regard to the CR rate, the 3 year of OS or the 2 years of DFS at 2 years.^{169, 170} These two trials have established the feasibility and safety of prolonged oral arsenic administration, but long-term safety data are still required. Oral arsenic formulations are not currently available in the United States or Europe.

As the prognosis of APL patients is getting much better, the issues of early mortality [related to bleeding, differentiation syndrome (DS), or infection] and relapse [including central nerve system (CNS) relapse] becomes increasingly important. In patients with clinical and pathologic features of APL, ATRA should be started upon first suspicion of APL without waiting for genetic confirmation of the diagnosis.¹⁶⁶ Early initiation of ATRA may prevent the lethal complication of bleeding. DS is a common complication in the ATRA or ATO treatment, with a frequency being around 25% both in United States and in Europe,^{171, 172} but relatively rare in East Asian populations (5–10%).^{154, 162} Signs and symptoms of this syndrome include hyperleukocytosis, dyspnea with interstitial pulmonary infiltrates, peripheral edema, unexplained fever, weight gain, hypotension, and acute renal failure. The mortality could be down to 3% or lower if DS is recognized early and treated promptly with CT and high dose of dexamethasone (10 mg twice daily).^{172, 173} In addition, patients with a high white blood cell count (WBC > 30 × 10⁹/L) at diagnosis may benefit from prophylactic steroids. A common practice to avoid CNS prophylaxis (methotrexate 5–10 mg, cytarabine 40–50 mg, and dexamethasone 5 mg) for APL patients are recommended, 4–6 times for nonhigh-risk APL and 6–8 times for the patients with high WBC counts.¹⁶⁶ Another issue is side effects of ATO because the compound has long been considered as a very strong poison. In fact, the protocol incorporating ATO proves to be quite safe. The common adverse effects such as minor bone marrow myelosuppression, hepatotoxicity, gastrointestinal reactions, and neurotoxicity can be controlled and are generally reversible without need of the discontinuation of the drug.^{162, 166} In very rare situation, clinically significant arrhythmias due to prolongation of the QT interval on the ECG are observed, which can be avoided with appropriate precautions and withdrawal of the medicine.¹⁷⁴ At the same time, arsenic concentrations in the urine of patients who had ceased maintenance treatment for 2 years were below the safety limits recommended by government agencies in several countries or regions, whereas arsenic levels in plasma, nails, and hair were only slightly higher than those found in healthy controls.¹⁶²

Leukemogenesis and therapeutic mechanisms of APL

It has been well known that PML-RAR α resulting from t(15;17)(q22;q21) translocation is the key driver of APL leukemogenesis, which exerts dominant negative effects on RAR α - and PML-related pathways.¹⁷⁵ The fusion protein represses the transcriptional expression of target genes essential for hematopoietic differentiation and yields an increasing proliferation and self-renewal of LICs.^{175–177} The PML-RAR α fusion protein binding to RXR co-receptor functions as a constitutive transcriptional repressor at RAREs of target genes through recruitment of CoR, which leads to the characteristic differentiation block.^{148, 176, 178} In normal cells, PML proteins multimerize to form multiprotein subnuclear structures called PML-nuclear bodies (PML-NBs).¹⁷⁹ PML-NBs have been shown to play an important role in DNA damage repair, apoptosis, growth, senescence, and angiogenesis, and more recently, in the maintenance of HSPCs. In APL cells, PML-NBs are disrupted owing to the formation of PML/PML-RAR α heterocomplex, interfering with the normal biological functions of PML.¹⁸⁰ This mechanism probably cooperates with the disruption of RAR/RXR pathway to enforce the APL-specific differentiation block and acquisition of self-renewal, thus transforming the committed HSPCs into immortal, fully transformed LICs ([Figure 4](#)).

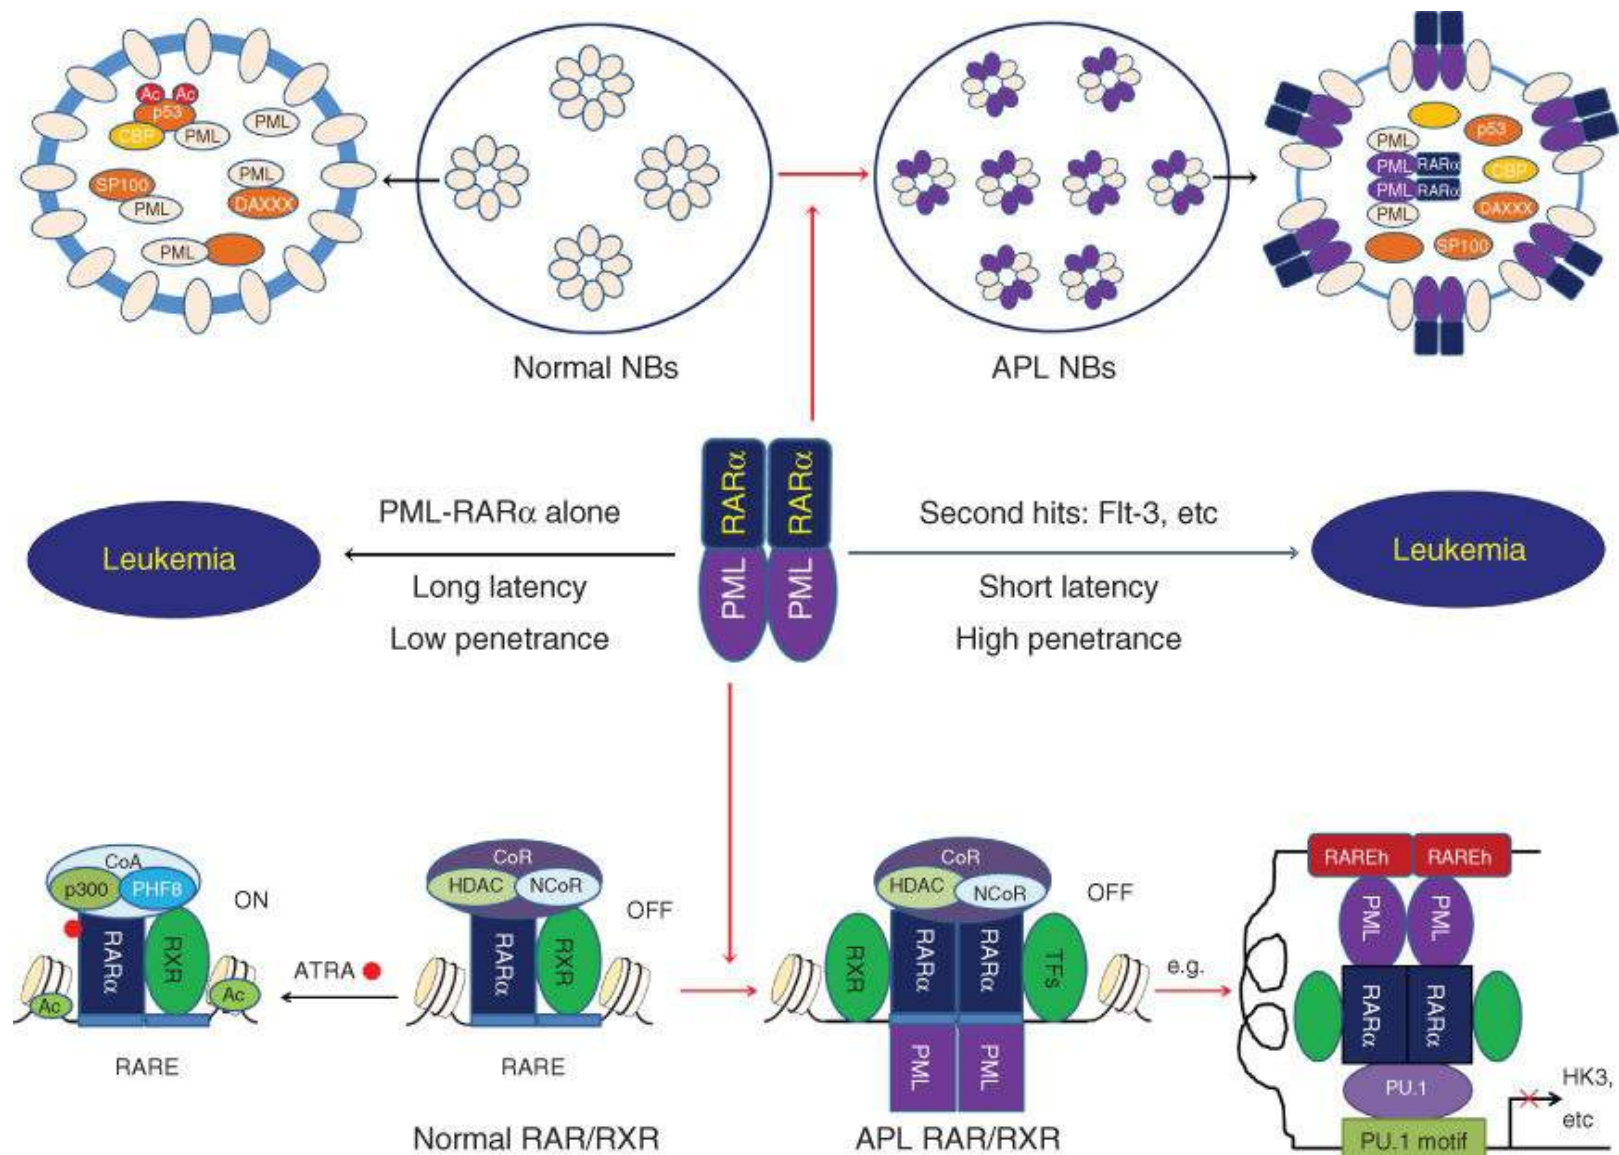

Figure 4 Molecular pathogenesis of APL. PML-RAR α plays a key role in leukemogenesis of APL, which exerts dominant negative effects on RAR α - and PML-related pathways. Under physiological condition, RAR/RXR heterodimers bind to the specific motifs defined as retinoic acid response elements (RAREs) on the promoters of target genes and differentially activates or represses gene transcription while recruiting co-activators (CoA) or co-repressors (CoR) complex depend on the presence or absence of the ligands, such as ATRA. The fusion protein binding to RXR co-receptor functions as a constitutive transcriptional repressor at RAREs of target genes through recruitment of CoR. In other hand, PML proteins multimerize to form multiprotein subnuclear structures called PML-nuclear bodies (PML-NBs) in normal cells. In APL cells, PML-NBs are disrupted owing to the formation of PML/PML-RAR α heterocomplex.

Combining the discovery of PML-RAR α in APL pathogenesis with special effective treatment of ATRA and ATO has pointed to a possible molecular mechanism underlying PML-RAR α -specific therapy. Indeed, a large number of studies have revealed that ATRA and ATO act through distinct but complementary mechanisms, providing a biologic rationale for the two agents to be used in combination to achieve synergistic efficacy with low toxicity.

At pharmacological level (10^{-7} – 10^{-6} mol/L), ATRA binds to the ligand-binding domain (LBD) of RAR α portion in the fusion protein and induces a conformational change of the chimerical receptor.^{181, 182} This leads to displacement of CoR complexes and recruitment of CoA complexes and clearance of PML-RAR α from promoters of target genes, thereby restoring wild-type RAR α function and subverting the

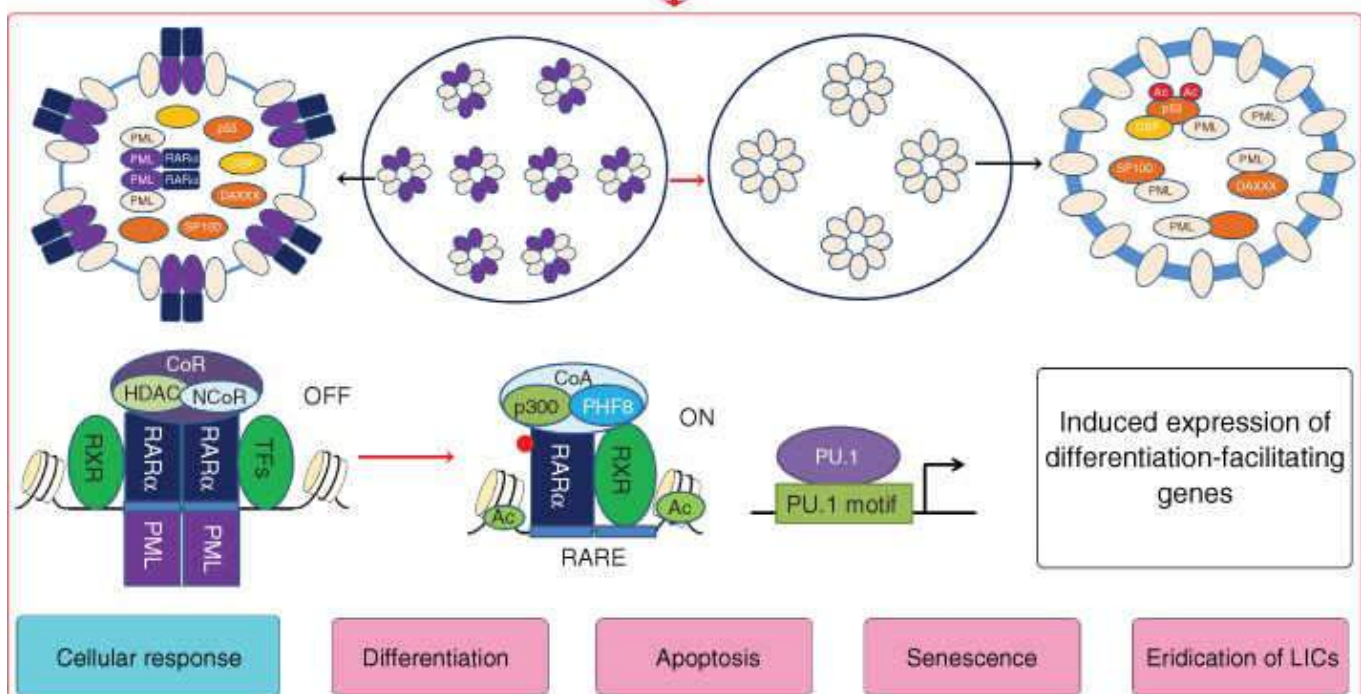

differentiation block.^{63, 148, 178, 183} ATRA also leads to the degradation of PML-RAR α oncoprotein,^{184–186} which may contribute to the response, and generate a restoration of nuclear architecture with reformation of PML-NBs. Re-establishment of RAR α signaling allows differentiation of APL blasts and yields short-term disease management. Even though ATRA and anthracyclines are very efficient anti-APL therapies, APL patients can relapse, perhaps due to ATRA failing to affect LICs.

ATO exerts dose-dependent effects on APL cells in initial cellular and molecular mechanistic studies.^{160, 187} At low concentrations, ATO induces partial morphologic differentiation in APL cells, whereas at high concentrations, apoptosis induction occurs predominantly. Both effects are associated with a degradation of PML-RAR α . ATO efficiently triggers the degradation of PML-RAR α and PML through direct binding to the RBCC domain of PML moiety, which induces the conformational changes of PML proteins, leading to protein–protein aggregation and sumoylation of these proteins.¹⁸⁸ In addition, ATO-induced oxidative stress promotes PML homodimerization by cross-linking PML via disulfide bonds.¹⁸⁹ Sumoylated PML and PML-RAR α recruit the ubiquitin ligase RNF4 and subject to proteasome-mediated proteolysis.^{190, 191} Besides, arsenic can act through other mechanisms independent of PML-RAR α status, such as pro-apoptotic effects mediated by the mitochondria-mediated pathway, DNA damage, telomerase activity, autophagy, and so on.^{148, 192} Notably, ATO could induce LIC eradication in APL through several pathways, which may be a key factor in the success of ATO for APL patients.^{148, 177, 183, 192, 193} Sufficient and rapid degradation of PML and PML-RAR α is required for LIC clearance and long-term disease eradication,^{194, 195} which can be obtained by ATO treatment. Arsenic can also facilitate elimination of LICs through inhibiting Notch pathway, antagonizing the Hedgehog–Gli pathway, and repressing NF- κ B and β -catenin. The pleiotropic behaviors may be the reason why arsenic is very active in APL, as a single agent as well as in combination.

Because ATRA and ATO target respectively the C- and N-terminals of PML-RAR α , enhanced degradation of PML-RAR α oncoprotein might provide a plausible explanation for the superior efficacy of combination therapy in patients. Intriguingly, consistent with the mechanistic researches, genetic mutations in the LBD of the RAR α moiety that interfere with ATRA binding or nuclear coregulators binding are observed in about 40% of relapsed APL patients treated with ATRA/CT,^{196–198} while genetic mutations in the PML moiety of the PML-RAR α oncogene that probably impair the direct binding of ATO to PML-RAR α in patients with clinical ATO resistance have been described after treatment with ATRA/ATO/CT.^{199, 200} A small number of APL patients harbor PLZF-RAR α fusion gene resulting from t(11;17)(q23;q21), which are resistant to ATRA and ATO therapy.^{201, 202} These data further support that PML-RAR α is the direct target of both ATRA and ATO. Several groups have shown that ATRA and ATO display a synergy in many pathways including TFs and cofactors, activation of calcium signaling, stimulation of the IFN pathway, activation of the proteasome system, cell cycle arrest, gain of apoptotic potential, downregulation of telomerase and telomere length, upregulation of cAMP/PKA activity, and enhanced arsenic uptake by APL cells through induced expression of cell membrane arsenic transporter (AQP9).^{148, 176, 203, 204} Recent studies have shown that the ATRA/ATO combination rapidly clears PML-RAR α + LICs, resulting in APL eradication and dramatically prolong survival in murine models.^{177, 194} All these findings may contribute to the dramatically improved response from APL patients under the treatment of ATRA and ATO combination.

In conclusion, ATRA and ATO exert different but cross-linked actions on APL cells. ATRA mainly works through transcriptional modulation, and the main effects of ATO occur at the protein level, while both agents target PML-RAR α . These data may further explain the lack of cross-resistance between the two agents ([Figure 5](#)). Therapy of APL with ATRA and ATO is to date the most successful example of cancer

differentiation therapy, and key factor can be the synergistic targeting of the oncoprotein by the two agents. This scientific history may hence serve as a template for subsequent development of similar treatments in other leukemias and solid tumors. More importantly, the story of APL provides new way for thinking that differentiation therapy is essentially target therapy on the molecules affecting differentiation pathway and combination or synergistic targeting strategy is highly effective to eliminate CSCs.

 UBC9 UBC9 Ubiquitin Ubiquitin

Figure 5 Therapeutic mechanism of APL. ATRA and ATO target respectively the C- and N-terminals of PML-RAR α , enhancing degradation of PML-RAR α oncoprotein. ATRA binds to the ligand-binding domain (LBD) of RAR α portion in the fusion protein and ATO binds to the RBCC domain of PML moiety, which induces the conformational change and the consequential degradation of the fusion protein. The degradation of PML-RAR α generates a restoration of nuclear architecture with reformation of PML-NBs. ATRA binding also leads to displacement of CoR complexes and recruitment of CoA complexes and clear PML-RAR α from promoters of target genes, thereby restoring wild-type RAR α function. The synergistic effects of ATRA and ATO result in a variety of cellular response including differentiation, apoptosis, and senescence of leukemic cells, and importantly, the eradication of leukemia-initiating cell (LIC).

Perspectives

Taken together, differentiation therapy against cancer has the potential to make tumor cells convert from a malignant path to a benign course, which has given hope to scientists and clinicians on a much better cancer treatment outcome. However, interest and application of differentiation-based therapy for solid tumors and hematological malignancies other than APL are just at the beginning. One major challenge is the complexity of histopathological subtypes and clinical stages of cancers, resulting in the absence of developmental models of cancer progression. The re-establishment of the genotype that characterizes the original tissue types and the morphological transformation of tumor cells to the normal cells may help to determine more successful differentiation induction. In addition, there have not yet been definite markers for evaluating the effects of differentiation inducers. Assessment of the precise therapeutic role of agents is often hampered by the difficulties in distinguishing *in vivo* cytotoxicity from differentiation. The classic evaluation of therapeutic responses mainly focuses on the shrinkage of the tumor mass, but this is not suitable for the response evaluation of differentiation therapy that just restores the differentiation program of tumor cells. Consequently, identifying accurate novel biomarker sets of response to differentiation therapy becomes urgent for clinical application. Recent evidence suggests that targeting of leukemia driver proteins other than PML-RAR α can induce cell differentiation in some other types of AML and can eventually yield high-quality CR, paving the way of enlarging this approach in hematological malignancies. Nevertheless, solid tumors are still viewed as much more heterogeneous aberrant tissues than most leukemia, and much more complex molecular mechanisms are involved in their pathogenesis. Hence, the development of differentiation therapy in solid tumors may need more comprehensive approach to combine CT, immunotherapy, and differentiation agents in order to produce multiplied synergistic targeting effects.

Summary

Most human cancers show characteristics of abnormal cell differentiation, often coupled with dysregulation of proliferation and/or apoptosis. Cancer cells may be blocked at a particular stage of differentiation along with the involved cellular lineage, or they may differentiate into an inappropriate cell type. Hence, cancer differentiation therapy represents the approach aimed at the re-activation of endogenous differentiation programs or subverting differentiation/maturation blockage within cancer cells, often accompanied by the loss of malignant phenotype and the restoration, at least in part, of the normal phenotype.

The concept of differentiation therapy was pioneered by the work of Pierce and Verneyin 1961 when

they observed differentiation of teratocarcinoma cells.²⁰⁵ In 1970s, important reports were made to demonstrate the differentiating capability of DMSO on erythropoiesis, the differentiation of neuroblastoma cells with some inducers, and the morphologic and functional maturation of leukemia cells induced by certain agents.^{59, 67, 206–208} Many substances have thus been shown to possess the potential of cancer differentiation inducer with *in vitro* cell line experiments. To trigger malignant cells to overcome their differentiation block and to enter the apoptotic pathways has become an elegant alternative to the therapies simply killing malignant cells. However, differentiation therapy had historically been hampered by many factors, especially due to the insufficient understanding of the pathways of normal cell differentiation and the much higher complexity of the process of cancer cell reversion to “normal” cells/tissues induced by differentiation therapy than the cytotoxic approaches.⁶⁹

The advancement of differentiation therapy to a real successful clinical practice was not realized until the use of ATRA and ATO in the treatment of APL.⁵³ This breakthrough has transformed APL from once a fatal disease to one of the most curable human cancers, with 5-year OS rates of 85–90%.¹⁴⁸ In addition, over the past several years, progress has been made in understanding the differentiation pathways that are also cross-talking with those of the regulation of cell proliferation and survival, and the development of some targeted therapies on other types of leukemia has already yielded promising differentiation-inducing effects, which need to be further explored clinically.

This chapter focuses on the basic theories of differentiation therapy, and the clinical achievements of this novel therapeutic approach.

Chapter 12

Cancer stem cells

Yadwinder S. Deol, PhD ■ Jill Granger, BSc, MSc ■ Max S. Wicha, MD

Overview

There is substantial evidence that many if not most tumors contain a subpopulation of cells that display stem cell properties. These “cancer stem cells” (CSCs) play an important role in tumor initiation and propagation. Furthermore, these cells may mediate resistance to cancer therapeutic agents and therefore play a fundamental role in cancer relapse. This highlights the importance of developing therapeutic approaches to target this cell population. In this chapter, we will review current thoughts on the role of tissue stem cells in carcinogenesis, the pathways that regulate these cells, and current progress in development of CSC targeting therapeutic agents. We will then review clinical implications of CSC models.

Cancer stem cell hypothesis

The idea that cancer originated from “primitive embryonic-like cells” dates back over a hundred years.¹ However, it is only within the past several decades that cellular and molecular technologies have permitted the direct testing of these concepts. The “cancer stem cell (CSCs) hypothesis” consists of two separate but inter-related concepts. The first concerns the cellular origins of cancer and the second the cellular organization of established cancers.

Models of carcinogenesis and cellular origin of cancer

Currently, two main models of carcinogenesis have been proposed, which are summarized in [Figure 1](#). The classical “stochastic” model proposes that cancer may arise from any cell and that carcinogenesis evolves through random “stochastic” processes of mutation followed by clonal selection. As illustrated in the sequential accumulation of mutations during carcinogenesis ([Figure 1b](#)), disease development is driven by Darwinian selection of the fittest clones of cancer cells. In contrast to stochastic models, the CSC model posits that this process originates in those cells that possess or acquire the stem cell property of self-renewal. It is important to emphasize that the CSC model does not hold that tissue stem cells are the sole cellular source of cancer initiation. Although cancers may arise in normal tissue stem cells,^{2, 3} there is evidence that some cancers arise in tissue progenitor cells through mutations that endow these cells with self-renewal capabilities.⁴ This process generates tumors that display a degree of hierarchical organization. At the apex of this hierarchy are CSCs, which are operationally defined as cancer cells that maintain the ability to self-renew ([Figure 1a](#)). These CSCs are capable of generating tumors that recapitulate the phenotypic heterogeneity of the original tumor when transplanted into mouse models.

Figure 1 Schematic representation of two models of tumorigenesis. (a) Depicts “cancer stem cell” model where tumors arise in cells with stem cell properties generating hierarchically organized tumors driven by “cancer stem cells” at the top of hierarchy. These cells then generate differentiated clonal progeny that form the tumor bulk. (b) Depicts stochastic or classical model of tumorigenesis where random mutations in any cell generates cancerous clonal populations, which evolve through further mutation.

Although the “stochastic” and “CSC model” were initially described as mutually exclusive, more recent research suggests that elements drawn from both models might better describe tumor development. Recent reports by the Vogelstein suggest that the incidence of cancers in many organs is directly proportional to their number of tissue stem cell divisions.⁵ The latter is reflective of their stem cell frequency and division rate. As tissue stem cell mutations are themselves stochastic, this work provides a unifying model of carcinogenesis, whereby stem cells may be a functional unit of mutation and subsequent clonal selection. Furthermore, CSCs may undergo mutation during tumor evolution, generating tumors that contain multiple CSCs and their clonal progeny. The combination of these concepts, derived from both models of carcinogenesis, may provide a molecular explanation for the generation of intratumor heterogeneity; a phenomenon with considerable therapeutic implications.

Cancer stem cells as a unifying concept in multiple cancers

CSCs were first identified in human leukemia in 1997.⁶ In seminal studies, John Dick et al. demonstrated that only a small fraction of primary human leukemia cells were capable of regenerating the leukemia when transplanted into immune-suppressed NOD/SCID (nonobese diabetic/severely compromised immunodeficient) mice.⁶ Further, these tumor-initiating leukemia cells were prospectively identified by virtue of their phenotypic characterization as CD34⁺/CD38[−], a phenotype resembling that found on normal hematopoietic stem cells. Although the frequency of these leukemia initiating cells was found to be approximately 1 in 250,000, the leukemias generated in transplanted mice recapitulated the phenotypic heterogeneity of the initial tumor. Utilizing similar tumor transplantation technologies, investigators have

subsequently identified CSC in a wide variety of solid tumors. These include cancers of the breast,⁷ brain,⁸ prostate,^{9, 10} colon,^{11, 12} pancreas,¹³ liver,^{14, 15} lung,¹⁶ melanoma,¹⁷ and head and neck.¹⁸ In fact, evidence suggests that the majority of tumors are hieratically organized and contain cell populations that display stem cell properties.

Isolation, identification, and characterization of CSCs

In order to study the basic attributes of CSCs, it is necessary to first identify, isolate, purify, and characterize these cells by employing techniques that enable one to distinguish them from the bulk tumor cell population. The functional characteristics of CSCs, including self-renewal capability and differentiation potential, can be exploited by various *in vitro* and *in vivo* assays to identify and characterize this important cell population. Several methods or techniques exist to identify and isolate stem cell-like cancer cells; flow cytometry detecting expression of CSC-related markers, dye exclusion, ALDH (aldehyde dehydrogenase) assay, label retention (PKH staining), and a recent novel method of using autofluorescence in presence of riboflavin. CSCs, enriched by these techniques, may be functionally validated by sphere formation assays or serial transplantation assays *in vivo* for evaluation of tumorigenic and self-renewal potential. The details of the methods are listed in the following sections.

CSC marker expression

The first CSCs in solid tumors were described in human breast cancer based on cellular expression of CD44 and lack of expression of CD24 (i.e., CD44+/CD24-).⁷ Interestingly, these markers have proven useful for the isolation of CSC from a variety of other solid tumors. In parallel, CD133 has been shown to be useful in enriching for CSC in brain and lung cancers.^{8, 16} Another stem cell marker, ALDH, is also used along with CD44/CD24 or CD133 to identify the CSC population in several tumors. ALDHs are a family of enzymes that are involved in the oxidation of retinol to retinoic acid.¹⁹ ALDH activity can be readily determined using the commercially available Aldefluor assay and was shown to be a useful CSC marker in cancers of the breast,²⁰ ovary,²¹ colon,²² head and neck,²³ and recently melanoma.²⁴

Dye exclusion assays

Dye exclusion is based on the ability of stem cells to efflux lipophilic dyes, such as Rhodamine or Hoechst, owing to the high expression of the ATP-binding cassette transporter proteins such as ABCG2/BCRP1.²⁵ Utilizing flow cytometry analysis, cells that do not retain dye are observed as a side population.²⁶ Several studies have demonstrated that such side populations are enriched in cells with tumor-initiating capacity and are capable of regenerating heterogeneous cell populations.²⁷ This stem cell-like side population has been observed in several cancer types, as well as bone marrow and normal solid tissues.^{28, 29} The cellular toxicity of Hoechst dye limits their ability to be combined with functional studies.

Label retention

Another dye-based method used to characterize CSCs *in vitro* is the cell membrane, label-retaining assay using fluorescent PKH dye. This dye consists of a fluorophore that binds to the cell membrane lipid bilayer.³⁰ Upon cell division, the dye becomes distributed equally among daughter cells. Subsequent continuous cell divisions lead to decreased intensity.³¹ Stem cells, including CSCs, normally undergo an asymmetric self-renewal process generating a stem cell and a daughter cell. The generated stem cells are quiescent and thus retain PKH dye for a longer time period, whereas the daughter cells proliferate and

differentiate leading to decreased intensity of PKH dye. These daughter cells are then identified and sorted by flow cytometry. This method has been used successfully to isolate murine hematopoietic and mammary stem cells.³²

Recently, it was reported that CSCs demonstrate autofluorescence in the presence of riboflavin.³³ The authors isolated this population using flow cytometry, distinguished these cells from the side population, and demonstrated that these putative CSCs had a greater tumor sphere-forming ability, increased chemoresistance, were highly metastatic, and possessed long-term *in vivo* tumorigenicity. Further, in support of the cancer stem model, this autofluorescent CSC-like population was detected in several cancers.³³

Sphere formation assays

The sphere formation assay is another *in vitro* assay that has proven useful for the identification of CSC populations. This is based on a property shared by both normal and malignant stem cells: survival when cultured in suspension and generation of spheroids at clonal density.³⁴ These spheres can be serially passaged and display stem cell properties with each passage. It has also been possible to combine a number of *in vitro* CSC assays. For instance, the addition of PKH dye during sphere formation results in the formation of spheres that often contain a single label-retaining sphere-initiating cell.³⁵

In vivo serial dilution CSC assays

Although the use of CSC markers and *in vitro* assays has proven useful in the isolation and characterization of CSC, all of these techniques have limitations. The expression of CSC markers is variable and may be influenced by culture conditions or the tumor microenvironment.³⁶ Further, sphere formation assays may not correlate with tumor initiation capacity.³⁷ In light of these limitations, the “gold standard” for CSC identification is demonstration of tumor initiation upon implantation into immunosuppressed mice.³⁷ The tumor-initiating frequency in any cell population may be assessed by the ability of cells to initiate tumor development in mice using limiting dilution of cell suspensions. Thus, the definition of “CSCs” is ultimately an operational one.

It is important to note that immunosuppressed mouse models also have limitations. In human melanoma, the frequency of tumor-initiating cells was strongly influenced by the degree of immune competence of the mouse model utilized.³⁸ Recent studies have indicated that the immune system may actually play an important role in CSC regulation.^{39, 40} Studies elucidating these roles have been carried out in mouse tumors transplanted into syngeneic immune-competent mice. Such studies have confirmed the existence of CSC as determined by serial transplantation.⁴¹

Lineage tracing studies

One criticism of all transplantation studies is that they perturb the normal microenvironment where tumors develop. To circumvent this limitation, a series of studies using cell markers and lineage tracing have been performed. Such studies have confirmed the existence of CSC in tumors of the skin,⁴² brain,⁴³ and colon.⁴⁴

EMT/MET and cancer stem cells

Epithelial–mesenchymal transition (EMT) is a physiological process of particular importance during embryonic development whereby epithelial cells acquire mesenchymal properties, are characterized by a loss of cell adhesion and the acquisition of invasive properties. The EMT process was initially described

during development, where it induced the migration of mesodermal cells during gastrulation or the delamination of the neural crest cells from the dorsal neural tube.⁴⁵ Similarly in cancer, EMT has been associated with the process of metastasis where epithelial cells from the primary tumor acquire mesenchymal phenotype and invade to other tissues.⁴⁶

EMT is regulated by signals from the microenvironment that mediate epigenetic alterations driven by core transcription factors. Microenvironmental factors include tissue hypoxia, TGF- β (transforming growth factor- β), and other inflammatory molecules with subsequent induction of EMT-related transcription factor expression such as TWIST1, TWIST2, SNAI1, SNAI2, ZEB1, and ZEB2, among others.^{47, 48} Overexpression of these transcription factors induce a mesenchymal and invasive phenotype through repression of cell adhesion molecules, such as E-cadherin.⁴⁹ Twist1, which is involved in mesenchymal development during embryogenesis, has been shown to induce metastasis in breast cancer.⁵⁰ Several studies suggest that the EMT process generates CSC-like cells.^{51, 52} In this regard, overexpression of SNAI1 or TWIST1 alone was shown to induce EMT in MCF10A and immortalized human mammary epithelial cells.⁵³ In addition, there was increased expression of the stem cell marker CD44 and a decrease in CD24 expression, which suggests induction of CSC-like phenotype. Moreover, TWIST1 has been associated with an increased ability of breast cancer cells to form mammospheres and secondary tumors in an oncogenic HRAS-g12V model.⁵⁴ Based on the molecular classification of breast cancer, a basal subtype, particularly claudin-low are known to possess an EMT-like gene expression signature. Such cancers have a high proportion of CD44⁺/24⁻ cells that are locked within the mesenchymal state. These tumors display a highly aggressive behavior accompanied by a greater propensity to develop metastasis. Further, TWIST1 upregulated BMI expression, when suppressed by the miR-200 microRNA cluster, decreased CSC self-renewal, and cellular differentiation. Similarly, BMP signaling induced MET via induction of miR-205 and the miR-200 family of microRNAs that are key regulators of MET.⁵⁵

The aforementioned studies strongly suggest the role of EMT in the acquisition of a stem cell phenotype. It is plausible that the CSC possesses alternative phenotypes; one involved in tumor invasion and metastasis while another state maintains the bulk of the tumors. This is evident from the recent study that used gene expression analysis to compare ALDH⁺ and CD44⁺/24⁻ BCSCs isolated from different subtypes of breast cancer. This comparative gene expression analysis suggested that, although each population was independently capable of tumor initiation in NOD/SCID mice, yet they were quite distinct both functionally and anatomically in the original primary tumors. ALDH⁺ CSCs usually populated the interior of the tumors where they self-renewed and proliferated at a higher rate, whereas CD44⁺/24⁻ CSCs were more mesenchymal, displayed an EMT phenotype located on the tumor margins or invasive front, and were more quiescent.⁵⁶ Further characterization of these two populations showed that CD44⁺/24⁻ cells were highly vimentin positive and E-cadherin negative, whereas an ALDH⁺ population was highly positive for E-cadherin and negative for vimentin. Therefore, these CD44⁺/24⁻ cells were more EMT-like, and may be poised to invade the blood vessels when triggered by stromal factors such as hypoxia, TGF- β , and other inflammatory agents.

These studies also demonstrated that BCSCs maintain the plasticity to transition between EMT and MET states in a process regulated by the tumor microenvironment. The interconversion of BCSCs from the EMT-like to MET-like state has also been shown to be regulated by microRNA networks. Such networks included EMT-inducing mir-9, mir-100, mir-221, and mir-155 as well as MET-inducing mir-200, mir-205, and mir-93.⁵⁷ The plasticity of BCSCs from a quiescent mesenchymal state to a proliferative epithelial-like state is critical for formation of tumor metastases at distant sites. The knockdown of TWIST1 in a spontaneous squamous-cell carcinoma model reversed EMT and allowed cells to

proliferate and form metastasis.⁵⁸ Similarly, the loss of the EMT inducer Prrx1 was required for cancer cells to form lung macrometastasis.⁵⁹ In addition, MET-promoting factors, such as miR-200 family members, were found to promote metastatic colonization of breast cancer cells and induce epithelial differentiation.⁶⁰ Furthermore, expression of Id1 gene in breast cancer cells reconverted EMT cells into MET by downregulating TWIST1, which is required for establishing macrometastasis.⁶¹ The above studies provide evidence that two alternative states of CSCs display plasticity and are regulated by microenvironmental factors that modulate the genetic regulators and several transcription factors. The existence of multiple CSC states has important therapeutic implications as elimination of CSC may require successful targeting of multiple CSC populations.

Signal transduction pathways in cancer stem cells and their therapeutic targeting

Like their normal counterparts, a number of evolutionarily conserved developmental pathways play a significant role in the regulation of CSCs in several cancer types. The conservation of these pathways in CSCs of different tumor types further strengthens the cancer stem model. Moreover, these pathways could provide common potential therapeutic targets irrespective of the tumor type.

Hedgehog signaling

The Hedgehog (Hh) family of proteins controls cell growth, survival, pattern of the vertebrate body, and stem/progenitor cell maintenance. Dysregulation of Hh signaling, including that arising from somatic mutation, has been linked to several cancer types. The binding of Hh proteins to the receptor Patched (Ptc) activates a signaling cascade that leads to the upregulation of a zinc-finger transcription factor GLI1–3 and its downstream gene targets.^{62–64} Of the three mammalian Hh ligands, sonic hedgehog (SHH), Indian hedgehog (IHH), and desert hedgehog (DHH), SHH is the most highly expressed Hh signaling molecule and is involved in the regulation of many epithelial tissues. Aberrant activation of Hh signaling has been linked to basal cell carcinoma,^{65, 66} medulloblastoma,^{67, 68} rhabdomyosarcoma,⁶⁹ and other cancers, such as glioma, breast, esophageal, gastric, pancreatic, prostate, and small-cell lung carcinoma.⁷⁰ GLI1 amplifications are also known to occur in gliomas.⁷¹

The Hh signaling pathway plays a major role in mammary gland development both in humans and in mice. In mice, constitutive activation of Gli1 or inactivation of Gli3 resulted in mammary bud formation defects.⁷² Ectopic expression of Gli1 has been shown to induce the nuclear Snail expression resulting in loss of E-cadherin expression in mouse mammary glands tissue during pregnancy.⁷³ In addition, the transcription factor FOXC2 also promoted mesenchymal differentiation via the Hh pathway and Snail upregulation.⁷⁴ Similarly, SHH overexpression in mouse mammary glands leads to mammary bud defects.⁷⁵ Perturbation of other Hh pathway molecules, such as activation of SMO or loss of PTCH1, has resulted in terminal end bud abnormalities.⁷⁶ Normal human mammary stem cells expressed PTCH1, Gli1, and Gli2 during mammosphere formation, a pathway that is downregulated during the process of differentiation. Hh signaling played an important role in stem cell regulation as activation of Hh signaling through Hh ligand, or Gli1/Gli2 overexpression, increased mammosphere formation and size through activation of BMI-1, a member of the polycomb gene family.⁷⁷ The similar activation of SMO, driven by an MMTV (mouse mammary tumour virus) promoter, increased mammosphere formation of primary mammary epithelial cells in transgenic mice.⁷⁶ Hh ligands are also known to exert mitogenic effects on mammary stem cells through paracrine interactions. This process may be involved in the regulation of

mammary differentiation during pregnancy, in a process regulated by TP63.⁷⁸ Apart from TP63, the transcription factor Runx2 has been shown to regulate the expression of Hh ligands.⁷⁹

Hh signaling pathway members SHH, PTCH1, and GLI1 were highly expressed in invasive breast carcinomas suggesting a role for this pathway in human breast cancers.⁸⁰ Further, Hh ligand expression was associated with basal-like breast cancer; an aggressive phenotype with relatively poor outcome. These findings were corroborated in mouse models where ectopic expression of Hh ligand in BLBC mice induced high-grade invasive tumors.⁸¹ Similarly, SHH upregulation due to hypomethylation of the SHH promotor has been observed in breast carcinomas that were associated with expression of NF- κ B in breast cancer clinical samples.⁸² Hh signaling has also been linked to bone metastasis in this disease. In bone metastases, secretion of Hh ligand by tumor cells activates the transcription of **osteopontin (OPN)** by bone osteoclasts. This further promotes osteoclast maturation and resorptive activity, facilitating metastasis.⁸³

The most commonly used antagonist of the Hh pathway is the plant alkaloid cyclopamine that binds to SMO and downregulates Gli1.⁸⁴ Other antagonists that bind to SMO include SANTs 1–4;⁸⁵ KAAD-cyclopamine,⁸⁴ compound-5 and compound-Z,⁸⁶ and Cur-61414.⁸⁷ Further, 5E1 monoclonal antibody targeting SHH treated tumors in small-cell lung carcinoma.⁸⁸ GDC-0449 (Vismodegib, trade name: Erivedge®), the first Hh pathway inhibitor approved by FDA, was used in clinical trials in combination with the Notch signaling inhibitor RO4929097 (a γ -secretase inhibitor, GSI).⁸⁹

Notch signaling

Notch is another evolutionarily conserved signaling pathway that is involved in the regulation of cell fate determination, proliferation, and differentiation in many tissues. The core components of the Notch signaling cascade include the ligands-Delta-like-1, -3, and -4 (DLL1, DLL3, and DLL4), Jagged-1 and -2 (JAG1 and JAG2), and four transmembrane receptors (Notch 1 to Notch 4). After ligand binding, the receptor undergoes two proteolytic events. First, cleavage occurs in close proximity to the extracellular side of the plasma membrane. This is followed by a second cleavage within the transmembrane domain, mediated by a γ -secretase complex, which leads to the release of the intracellular domain of the receptor from the membrane. Upon cleavage, the intracellular Notch domain translocates to the nucleus where it forms a complex with the ubiquitously expressed transcription factor CSL and recruits co-activators such as mastermind-like (MAML-1, -2, and -3).⁹⁰ The transcriptional targets of Notch signaling include not only differentiation-related factors, such as Hairy/enhancer of split (Hes) and Hes-related (HRT/HRP/Hey) families, but also cell cycle regulators (p21 and cyclin D1) and regulators of apoptosis.^{90, 91}

The oncogenic role of Notch 1 was first discovered in T-ALL where the translocation of t(7;9) (q34;q34.3) led to juxtaposition of Notch 1 with TCR- β (T cell receptor-beta). This translocation led to the ligand-independent activity and deregulated expression of intracellular Notch 1 regulated by TCR- β that impacted T-cell differentiation.⁹² Overexpression of Notch 4 in mouse mammary glands utilizing an MMTV promotor blocked cellular differentiation with aberrant lactation and poorly differentiated mammary and salivary adenocarcinomas occurred between two and seven months of age.⁹³ This evidence again underscores the role that Notch signaling plays in the differentiation and tumorigenesis of several tissues. A correlation between Ras overexpression and elevated Notch 1 levels has been reported.⁹⁴ Furthermore, expression of Numb, a negative regulator of Notch signaling, was lost in approximately 50% of primary human mammary carcinomas and these tumors showed increased Notch 1 activity.⁹⁵ Overexpression of several Notch signaling molecules was reported in several tumors such as pancreatic

cancer, renal cell carcinoma, prostate cancer, multiple myeloma, and Hodgkin's and anaplastic lymphoma.^{96–100} In lung cancer, Notch signaling had a differential effect based on the cell type: in small lung cancer, Notch signaling is inactive but Hes1 and Hash1 are active¹⁰¹ and introduction of constitutively active intracellular Notch induces Notch signaling resulting in growth arrest.¹⁰² In contrast, Notch signaling is active in nonsmall lung cancer with high expression of Hes1 and Hey1.¹⁰¹

CD24⁺/24[–] breast CSCs has been reported to display Notch pathway activation.¹⁰³ Notch 3 was found to be upregulated in CD44⁺ populations of normal and breast cancer cells via SAGE analysis.¹⁰⁴ Other studies have suggested that Notch 4 is the most important regulator of breast stem cells.¹⁰⁵ Moreover, aberrant activation of Notch signaling is an early event in breast cancer, as this has been observed in ductal carcinoma *in situ* (DCIS). Treatment of primary DCIS tissue with a γ -secretase inhibitor significantly reduced the mammosphere formation.¹⁰³ Similarly, in an *in vitro* mammosphere culture system, activation of Notch signaling via a DSL peptide promoted self-renewal and branching morphogenesis in three-dimensional Matrigel cultures,¹⁰⁶ a process that was inhibited by a Notch 4 blocking antibody or a γ -secretase inhibitor. Therefore, activated Notch signaling may maintain the epithelial cells in a proliferative state instead of differentiation leading to carcinoma.

Regulation of Notch pathways has also been attributed to epigenetic regulation through hypermethylation and hypomethylation. Notch ligand DLL1 gene is hypermethylated resulting in decreased NOTCH1 expression.¹⁰⁷ Similarly, reduced methylation of NOTCH4 gene promoter in tumors compared to surrounding tissue was observed.¹⁰⁸ Overexpression of JAG2 in multiple myeloma cells was correlated with hypomethylation in malignant cells from multiple myeloma patients and cell lines.¹⁰⁹ Knockdown of the canonical Notch effector Cbf-1 in mammary stem cells increased stem cell activity, whereas constitutive Notch signaling increased luminal progenitor cells, leading to hyperplasia and tumorigenesis.¹¹⁰ In addition, co-expression of JAG1 and NOTCH1 was associated with poor overall survival.¹¹¹ In ESA⁺ CD24-CD44⁺ BCSCs, activity of Notch 4 and Notch 1 were eightfold and fourfold higher, respectively, compared to the differentiated bulk tumor cells and inhibition of this activity resulted in reduce tumor growth.¹⁰⁵

The complexity of the Notch pathway increases through interaction with other oncogenic pathways such as ErbB2, Jak/Stat, TGF- β , NF- κ B, Wnt, and Hh.¹¹² As ErbB2 induces Notch 1 activity through Cyclin D1,¹¹³ combined treatment of DAPT and Lapatinib targeted stem/progenitor cells both *in vitro* and *in vivo* in DCIS.¹¹⁴ The Wnt pathway also interacts with Notch through Jagged-1 (target of WNT/TCF pathway) and Mel-18, a negative regulator of Bmi-1. Knockdown of Mel-18 has been shown to enhance the self-renewal of BCSCs through upregulation of Jagged-1, consequently activating the Notch pathway.¹¹⁵ The activation of Notch activity further activates the Hh pathway and increases expression of Ptch and Gli.⁷⁷ Taken together, these studies suggest that treatments aimed at targets affecting multiple stem cell pathways could present a novel strategy for targeted therapies. A variety of agents that inhibit Notch signaling are in early phase clinical trials. These include γ -secretase inhibitors that block Notch processing,¹¹⁶ antibodies against specific Notch receptors,^{117, 118} and antibodies against the Notch ligand DLL4.^{119, 120}

Wnt signaling

The Wnt/ β -catenin/TCF pathway is another complex evolutionarily conserved pathway involved not only in development and maintenance of adult tissue homeostasis but also cell proliferation, differentiation, migration, and apoptosis.¹²¹ It also regulates the self-renewal and maintenance of embryonic and tissue-specific stem cells.^{122–124} Dysregulation of Wnt signaling is a hallmark of several cancers where

molecules involved in pathway could act as either tumor suppressors or enhancers depending on their activation status.^{125–127} Wnt signaling involves both canonical and noncanonical pathways. The canonical Wnt pathway involves activation of β -catenin/TCF complex, resulting in its dissociation from APC (adenomatous polyposis coli) with subsequent translocation into the nucleus leading to activation of transcriptions including TCF/LEF.¹²⁸ This in turn leads to upregulation of oncogenic targets such as c-myc and cyclin D1. This canonical pathway has been extensively studied and found to be deregulated in many cancers. Noncanonical Wnt signaling involves a planar-cell polarity pathway that regulates the cytoskeleton and a Wnt-calcium-dependent pathway that regulates intracellular calcium levels.^{129, 130} Mutation of APC (Wnt pathway molecule regulating β -catenin stability) is associated with the majority of sporadic colorectal cancers.^{131, 132} Germline mutations in APC have been shown to be involved in familial polyposis syndromes, a condition associated with development of numerous intestinal polyps with a high propensity for further neoplastic transformation. In addition to colon cancer, oncogenic mutations in β -catenin have been described in cancers of the liver and colon, as well as in melanoma, thyroid, and ovarian cancers.¹³³ Epigenetic silencing through methylation of Wnt antagonist genes such as the secreted frizzled-related proteins (SFRPs) has been reported in colon, breast, prostate, lung and other cancers.¹²¹

Wnt signaling has been shown to be involved in maintenance of CSCs in several cancers. In a transgenic mouse model, LRP5 (a key component of the Wnt co-receptor group) knockdown significantly reduced stem/progenitor cells.¹³⁴ In addition, transgenic mice overexpressing Wnt-1 developed mammary glands that were enriched for epithelial cells expressing keratin 6 and Sca1 markers of mammary stem cells. This suggests that mammary carcinogenesis may involve stem cell expansion secondary to Wnt activation. Wnt/ β -catenin signaling is also involved in EMT regulation through downregulation of E-cadherin and upregulation of Snail and Twist.¹³⁵ EMT has been shown to induce stem cell-like phenotype in breast cancer cells.⁵² Wnt signaling has also been demonstrated to maintain pluripotency and neural differentiation of embryonic stem cells.¹³⁶ Wnt signaling may also contribute to stem cell expansion induced by tumor hypoxia, a process mediated by Hif 1- α .¹³⁷

A number of drugs that inhibit Wnt signaling are in development. In preclinical models, two nonsteroidal anti-inflammatory drugs (NSAIDs), sulindac¹³⁸ and celecoxib,^{139, 140} have been found to inhibit Wnt signaling by targeting Dvl and cyclo-oxygenase, respectively. Sulindac is currently being investigated in phase II trials.¹⁴¹ In addition, several non-NSAID inhibitors such as NSC668036 and PCN-N3, among others, have been shown to degrade β -catenin by inhibiting DVL and hence, stabilizing the destruction complex.^{142, 143} Further, antibodies targeting Wnt pathway members are also under development. A Wnt3A neutralizing antibody was shown to reduce proliferation and enhance apoptosis in prostate cancer mouse models.¹⁴⁴ Another monoclonal antibody-OMP-54F28 has been shown to inhibit patient-derived xenograft tumor growth by specifically targeting CSCs. A Wnt decoy receptor¹⁴⁵ and an antibody to the Wnt co-regulator R spondin¹²² are also in development. These aforementioned Wnt inhibiting drugs are currently being tested in several early phase clinical trials.

Clinical significance of cancer stem cells and future perspectives

There is now substantial evidence that CSC plays an important role in treatment resistance; in addition to their role in tumor propagation and tumor metastasis, resistance of CSC to cytotoxic chemotherapy was first demonstrated in preclinical models^{146, 147} and later confirmed in clinical trials.¹⁴⁸ The relative

resistance of CSC to radiation therapy has been demonstrated in a number of tumor types. In patients, it has been shown that the relative proportion of cells expressing CSC markers increases following chemotherapy or radiation therapy.¹⁴⁸ A number of mechanisms have been described that contribute to this resistance. These include alterations in cell cycle kinetics, increased expression of anti-apoptotic proteins, increased in cellular transporters, and increased efficiency of DNA repair, as reviewed in Ref. 149. In addition to the relative therapeutic resistance of CSC, these cells may actually be stimulated by chemotherapy via stimulation of cytokine loops activated by these treatments. These inflammatory cytokines include IL-8 and IL-6. Inhibitors to these cytokines and their receptors have been developed, and several are entering clinical trials.

The CSC model has significant clinical implications. In addition to emphasizing the importance of successfully targeting these cells, acknowledgement of their existence implies a critical role in the tumor microenvironment, which merits thoughtful consideration for the future design of therapeutic trials and development of appropriate clinical endpoints. Currently, tumor shrinkage as assessed by RECIST (response evaluation criteria in solid tumors) is considered an important endpoint for accessing treatment efficacy. However, tumor shrinkage is only poorly correlated with ultimate patient survival across a wide spectrum of tumor types.¹⁵⁰ Tumor shrinkage is a measure of effects of treatments on bulk tumor populations. As CSC constitute only a minority of the tumor bulk, successful targeting of these cells will not necessarily lead to tumor shrinkage. For that reason, the current approach for CSC drug development involves accessing toxicity in Phase I trials followed by combining CSC-targeting drugs with more traditional agents that target bulk populations. As many of the pathways utilized by CSC are shared with normal tissue stem cells, caution is required when introducing such therapeutics in the clinic to assess their safety profile. With this cautionary note, a number of CSC-targeting drugs summarized in [Figure 2](#) are now in early phase clinical testing. Interestingly, preliminary data suggests that these agents are well tolerated at doses that reduce CSC number in serial biopsies.¹⁵¹ This suggests that CSC may be more dependent on these pathways than their normal tissue stem cells counterparts, providing an advantageous therapeutic window. Novel methods are under development to achieve more direct measurement of CSC targeting agents' effects. These include accessing CSC by marker expression in circulating tumor cells (CTC) assays. Studies have demonstrated that CTCs are highly enriched for CSCs supporting the important role these cells play in mediating tumor metastasis.^{152–154}

CSC targeting agents

Figure 2 Cancer stem cell-targeted drugs and their cellular targets currently being evaluated in early phase clinical trials or FDA approved for other purposes.

Another important prediction of the CSC model is that CSC-targeted therapies should have their greatest effect when they are deployed in the adjuvant setting. This is the case because the CSCs are unique in that they possess a sufficient self-renewal capacity to generate clinically significant disease from micrometastases. The efficacy of adjuvant therapies is directly related to their ability to eliminate micrometastasis. This concept is supported by studies demonstrating the remarkable ability of Her 2-targeting drugs, such as trastuzumab, to prevent recurrence when utilized in the adjuvant setting in Her2+ breast cancer.¹⁴⁸ The clinical importance of Her2 in breast cancer may be due to its role as an important regulator of CSC in these tumors.¹⁵⁵

One of the most exciting areas in cancer therapy is the development of cancer immunotherapies including immune checkpoint blockers. Interestingly, there is evidence that CSC may be particularly competent at evading immune surveillance. Several mechanisms have been proposed, including the high expression of PDL-1 or secretion of immunosuppressive TGF- β . A number of approaches utilizing the immune system to target CSCs are being developed to circumvent these processes. These include CSC-based vaccines and peptides. In the future, such approaches may be combined with immune checkpoint blockers to more effectively target CSCs.

Worldwide, there are currently over 70 clinical trials utilizing novel CSC targeting agents. Most of these studies are in their early stages but the next several years should yield exciting and potentially significant

results. Ultimately, carefully controlled randomized clinical trials will be required to conclusively determine if the successful targeting of CSCs improves patient outcome.

Summary

Despite considerable progress in delineating the molecular underpinnings of cancer, this increased understanding has yet to translate into significant improvements in survival for patients with advanced disease. For most common cancers, the development of metastasis renders them incurable. There is now substantial evidence that many cancers are hierarchically organized and driven by a population of cells that display stem cell properties. These properties include the ability to self-renew and differentiate, forming the cells that constitute the tumor bulk. These cells, termed “tumor-initiating cells” or “cancer stem cells,” may mediate tumor metastasis and contribute to treatment resistance. The existence of as well as understanding of molecular mechanisms regulating cancer stem cells is of clinical significance in that additional therapies targeting stem cell populations may be required to limit metastasis and significantly improve patient survival.

Chapter 13

Cancer and cell death

John C. Reed, MD, PhD

Overview

Cell death is a normal facet of human physiology, ensuring tissue homeostasis by offsetting cell production with cell demise. Neoplasms arise in part because of defects in physiological cell death mechanisms, contributing to pathological cell expansion when genetic or epigenetic alternations impart a selective survival advantage to premalignant or malignant cells. Defects in normal cell death pathways also contribute to cancer progression by permitting progressively aberrant cell behaviors, while also desensitizing tumor cells to immune-mediated attack, radiation, and chemotherapy. Multiple mechanisms that account for dysregulation of cell death mechanisms in human malignancies have been identified, providing insights into cancer pathogenesis and suggesting targets for therapeutic intervention based on the concept of restoring sensitivity to natural pathways for triggering cell suicide.

Introduction

Evasion of endogenous cell death processes represents one of the cardinal characteristics of cancer.¹ Enormous amounts of cell death occur on a daily basis within the human body, estimated at 50–70 billion cells per day for the average adult. In bulk terms, this amounts to a mass of cells equal to an entire body weight annually. This “programmed” cell death offsets daily cell production resulting from cell division, achieving tissue homeostasis. Cell death can proceed by several distinct mechanisms. Apoptosis and necrosis are the two broadest categories of cell death mechanisms, but specialized forms of cell death have also been described, including necroptosis, pyroptosis, ferroptosis, and autophagic cell death. Apoptosis is the most common nonpathological route of cell demise in the context of normal tissue homeostasis and mammalian development.^{2–4}

During recent years, numerous examples have been delineated whereby cancer cells place roadblocks in the way of endogenous cell death mechanisms, thus endowing neoplastic cells with a selective survival advantage. Several molecules that create barriers to cell death within tumors have been identified, providing insights into pathogenic mechanisms of human neoplasia and cancer—in addition to suggesting targets for drug discovery, with the aim of restoring the integrity of natural pathways for cell suicide and thereby stimulating auto-destruction of cancer cells.^{5, 6} Alternatively, malignant cells can escape demise by silencing or neutralizing endogenous activators of cell death, with several examples of such mechanisms already elucidated. Replacing or reawakening these endogenous stimulators of programmed cell death (PCD) defines another emerging strategy for potentially eradicating tumors.^{7, 8}

Defects in the natural mechanisms regulating cell death aid cancers in many ways.^{2, 5, 6} First, activation of oncogenes such as *C-MYC* drives proliferation of transformed cells and also promotes apoptosis, unless counteracted by cell survival proteins—thus constituting a type of oncogene “complementation.”⁹ A second, closely related, benefit to tumors of defective cell death is that various cell cycle “checkpoints”

trigger apoptosis of cells undergoing aberrant cell replication or division. Thus, defects in apoptosis and other cell death mechanisms can permit aberrant cell division. Third, genomic instability is also aided by defects in cell death mechanisms because mutations introduced by DNA replication errors and chromosome segregation errors would normally trigger cell suicide. Fourth, defects in cell death mechanisms allow growth factor (or hormone)-independent cell survival, thus helping transformed cells to escape normal paracrine and endocrine growth control mechanisms. Fifth, cell death induced by hypoxia and metabolic stress, conditions that occur in the microenvironments of most rapidly growing solid tumors, are neutralized by defects in cell death machinery that occur in cancers. Sixth, invasion and metastasis of solid tumors may also be enabled by defects in cell death mechanisms, given that epithelial cells normally undergo apoptosis when they lose their attachment to extracellular matrix through integrins.¹⁰ Seventh, defects in cell death mechanisms contribute to avoidance of immune surveillance mechanisms by making it more difficult for cytolytic T-cells (CTLs) and natural killer (NK) cells to kill tumor cells.

In this chapter, the major pathways for cell death are reviewed and examples of their defects in cancers are described, including hypoexpression (hypoactivity) of pro-death genes and overexpression (hyperactivity) of cytoprotective genes. Insights into the mechanisms that lead to cell death dysregulation in cancers have also sparked a variety of oncology drug discovery and development efforts, which are also described briefly. With apology to the many contributors to the field of cell death biology, only representative references are cited for purposes of brevity.

Pathways for cell death

Several endogenous pathways for triggering cell suicide have been delineated and a variety of ways for cataloging these cell death mechanisms have been utilized by the research community.^{11, 12} A general construct for categorizing cell death mechanisms can be attributed to the essential involvement of a family of intracellular proteases called “Caspases” (cysteine-dependent aspartate-specific proteases).¹³ Broadly, cell death mechanisms can thus be divided into Caspase-dependent versus Caspase-independent, though mixtures of these two basic mechanisms are commonly observed in various settings.

Caspase-dependent cell death

Caspase-dependent cell death culminates in the constellation of morphological changes meeting criteria for “apoptosis,” where cells detach from extracellular matrix, become rounded and shrunken in volume, with nuclear chromatin condensation, nuclear fragmentation, and the membrane “bubbling” with membrane protrusions (blebs) that can bud off to create apoptotic bodies. These morphological changes can be attributed directly or indirectly to the multitude of proteolytic cleavage events mediated by Caspases, a full accounting of which is still under investigation using comprehensive proteomics methods.¹⁴

Caspases operate in hierarchical networks of upstream initiators and downstream effectors, where they cleave and activate each other to create amplifiable cascades of proteolysis.^{15, 16} These proteases are present as inactive zymogens within the cytosol of essentially all animal cells. Activation of the most proximal Caspases typically occurs through protein interactions that encourage clustering of the inactive zymogens.¹⁶ Once activated, these upstream initiators then cleave and activate downstream effector Caspases. The upstream initiator Caspases contain N-terminal prodomains that mediate protein interactions with other proteins involved in Caspase regulation—namely, CARDs (Caspase-associated recruitment domains) and DEDs (death effector domains) ([Table 1](#)). Genomic mutations that inactivate

Caspases have been described in a variety of cancers, though overall they are relatively rare.

Table 1 Domains associated with cell death proteins

Domain	Proteins (<i>examples</i>)
Caspase catalytic domain	Caspase family cysteine proteases
Caspase-associated recruitment domain (CARD)	Caspases-1, -4, -5, -9; Apaf1; ASC; NLRP1, 4
Death domain (DD)	TNFR1, FAS, DR4, DR5, TRADD, RAIDD, RIP1
Death effector domain (DED)	Caspases-8, -10; FADD; c-FLIP
Baculovirus IAP repeat (BIR)	XIAP, c-IAP1, c-IAP2, Livin, Apollon, ML-IAP, NAIP
Bcl-2 homology (BH)	Bd-2, Bcl-XL, Mcl-1, Bax, Bak, Bim, Bid

Multiple pathways that lead to Caspase activation and that thereby cause apoptosis or variations of apoptosis have been delineated ([Figure 1](#)). For example, CTLs and NK cells introduce apoptosis-inducing proteases, particularly Granzyme B (a serine protease), into target cells via perforin-mediated pores.¹⁷ Enzymologically, Granzyme B is a serine rather than a cysteine protease. However, similar to the Caspases, Granzyme B cleaves its substrates at Asp residues.¹⁸ Granzyme B is capable of cleaving and activating multiple Caspases. Tumors overcome this pathway for cell death by expressing various immune ligands for checkpoint receptors expressed on T cells (PD1, Tim3, LAG3, etc.) that suppress T-cell activation or by expressing ligands for inhibitory NK receptors (killer immunoglobulin-like receptors (KIRs)).

Figure 1 Caspase activation pathways. The major pathways for Caspase activation in mammalian cells are presented. The schematic represents an oversimplification of the events that occur *in vivo*. The extrinsic (left, upper) is induced by members of the TNF- family of cytokine receptors such as TNFR1, Fas, and the TRAIL Receptors, DR4 and DR5. These proteins recruit adapter proteins to their cytosolic DDs, including FADD, to assemble “death-inducing signaling complexes” (DISCs), which bind DED-containing pro-Caspases, particularly pro-Caspase-8, inducing their activation. Caspase-8 (and Caspase-10 in humans) cleaves downstream effector proteases, such as Caspases-3, -6, and -7, as well as pro-apoptotic Bcl-2 family member Bid, which is an agonist of MOMP-inducing Bax and Bak. CTLs and NK cells introduce the protease Granzyme B into target cells (right, upper). This protease cleaves and activates multiple members of the Caspase-family, as well as Bid. The intrinsic pathway (left, lower) is initiated by release of Cyt-c from mitochondria, induced by various stimuli, including elevations in the levels of pore-forming pro-apoptotic Bcl-2 family proteins such as Bax and Bak. In the cytosol, Cyt-c binds and activates Apaf-1, allowing it to associated with and activate pro-Caspase-9, forming “apoptosomes.” Active Caspase-9 directly cleaves and activates the effector proteases, Caspase-3 and -7. Exogenous pathogen-associated molecular patterns (PAMPs) and endogenous danger-associated molecular patterns (DAMPs) activate NLR family proteins to cause their oligomerization and assembly of “inflammasomes” that may contain PYD-containing adapter protein ASC in many cases, which binds pro-Caspase-1. Activated Caspase-1 cleaves a variety of cellular proteins, including cytokines as well as plasma membrane proteins that promote osmotic stress and cell death.

Another Caspase-activation pathway is stimulated by tumor necrosis factor (TNF)-family receptors. Eight of the ~30 known members of the TNF family in humans contain a so-called death domain (DD) in their cytosolic tails.^{19, 20} Several of these DD-containing TNF-family receptors use Caspase activation as a signaling mechanism, including TNF receptor-1 (TNFR1)/CD120a; Fas/APO1/CD95; death receptor-3 (DR3)/Apo2/Weasle; DR4/TrailR1; DR5/TrailR2; and DR6. Ligation of these receptors at the cell surface results in receptor clustering and recruitment of several intracellular proteins, including certain pro-Caspases, to the cytosolic domains of these receptors, forming a “death-inducing signaling complex” (DISC) that triggers Caspase activation and leads to apoptosis.²¹ The specific Caspases recruited to the DISC are Caspase-8 and, in some cases, Caspase-10. These Caspases contain DEDs in their N-terminal prodomains that bind to a corresponding DED in FADD, a bipartite adapter protein containing a DD and a DED. FADD functions as a molecular bridge between the DD and DED domain families, and is in fact the only protein in the human genome with this dual domain structure. Consequently, cells from mice in which the *fadd* gene has been knocked out are resistant to apoptosis induction by TNF-family cytokines and their receptors. Cells derived from *Caspase-8* knockout mice also fail to undergo apoptosis in response to ligands or antibodies that activate TNF-family death receptors, demonstrating an essential role for this Caspase in this pathway.^{22, 23} However, mice lack the highly homologous protease, Caspase-10, which is found in humans, having arisen from an apparent gene duplication on chromosome 2.¹⁵ Thus, Caspases-8 and -10 may play redundant roles in human cells. Genomic mutations in genes encoding TNF-family ligands or receptors have been documented in some types of cancer. For example, somatic mutations in the *FAS* (*CD95*) gene have been found in lymphoid malignancies.^{24, 25} Missense mutations within the DD of Fas (*CD95*) are associated with retention of the wild-type allele, suggesting a dominant-negative mechanism, whereas missense mutations outside the DD are associated with allelic loss.

Mitochondria also play important roles in apoptosis, releasing Cytochrome-c (Cyt-c) into the cytosol, which then causes assembly of a multiprotein Caspase-activating complex, referred to as the *apoptosome*.^{26–29} The central component of the apoptosome is Apaf1, a Caspase-activating protein that oligomerizes upon binding Cyt-c and which specifically binds pro-Caspase-9. Apaf1 and pro-Caspase-9 interact with each other via their CARDs. Such CARD–CARD interactions play important roles in many steps in apoptosis pathways. The central importance of the Cyt-c-dependent pathway for apoptosis is underscored by the observation that cells derived from mice in which either the *apaf1* or *pro-Caspase-9* genes have been ablated are incapable of undergoing apoptosis in response to agents that trigger Cyt-c release from mitochondria.^{30, 31} Nevertheless, such cells can die by non-apoptotic routes,³² demonstrating that mitochondria control both Caspase-dependent and Caspase-independent cell death pathways (see below). Mitochondria can also participate in cell death pathways induced via TNF-family death receptors, through cross-talk mechanisms involving proteins such as Bid, which become activated upon proteolytic cleavage by Caspase-8 and then stimulate Cyt-c release from mitochondria.³³ However, mitochondrial (“*intrinsic*”) and death receptor (“*extrinsic*”) pathways for Caspase activation are fully capable of independent operation in most types of cells.³⁴ Tumor cells can evolve a variety of mechanisms for averting mitochondria-dependent apoptosis, as outlined below.

Activation of Caspase-1 in the context of infection and inflammation has been shown to stimulate a Caspase-dependent form of cell death called *pyroptosis*.³⁵ Caspase-1 has a CARD-containing prodomain that can bind directly to the CARDs of NLR (nucleotide-binding domain and leucine-rich repeat domain) proteins, such as NLRP1 (NALP1). Alternatively, the CARD of Caspase-1 can bind the CARD of a bipartite adapter protein ASC (Pycard), which also contains a PRYIN domain (PYD) that binds PYDs of NLR family proteins such as NLRP3 (NALP3) or proteins such as AIM2. NLRs oligomerize in response to binding components of pathogens or molecules elaborated during tissue injury, forming

“*inflammasomes*” that recruit and activate Caspase-1.^{36–38} The relevance of pyroptosis to cancer biology is largely unknown.

Caspase-2 is another CARD-carrying member of the Caspase family. Its CARD interacts specifically with the CARD of the bipartite adapter protein RAIDD, which additionally carries a DD.³⁹ Caspase-2 activation has been linked to genotoxic stress via a pathway whereby tumor suppressor p53 induces expression of PIDD, a DD-containing protein that binds the DD of RAIDD, oligomerizes, and assembles into a multiprotein complex termed the “PIDDosome”.⁴⁰

Additional Caspase activation mechanisms have been elaborated, though it is less clear how prominently they figure in the pathophysiology of cell death.^{41–44}

Caspase-independent cell death

Multiple Caspase-independent cell death mechanisms have been identified, with a few prominent examples mentioned here ([Figure 2](#)). *Necrosis* can be initiated by many stimuli. It occurs when cells are incapable of maintaining osmotic equilibrium such that plasma membrane integrity is compromised, resulting in cell swelling and rupture. Organelles within cells during necrosis also typically swell and rupture, including mitochondria and lysosomes, releasing molecules that promote cell death. Initiators of necrosis include circumstances that compromise bioenergetics such as hypoxia and hypoglycemia, resulting in inadequate adenosine triphosphate (ATP) concentrations for powering plasma membrane ionic pumps, as well as insults to the plasma membrane such as serum complement factors that create pores. Necrosis is relevant to cancer biology in the context of rapidly growing tumors that outstrip their vascular supply (insufficient angiogenesis), creating regions of hypoxia and nutrient insufficiency.

Figure 2 Caspase-independent cell death pathways. The TNFR1-mediated pathway for necrosis (necroptosis) involves a cascade of events that include recruitment of Rip1, which in turn activates Rip3, which activates MLKL and which causes mitochondrial and probably lysosomal changes that stimulate ROS generation and lead to necrosis. The cytosolic DD of TNFR1 binds the DD-containing adapter protein TRADD, which binds the DD of Rip1. The kinase cascade involves Rip1, followed by Rip3, followed by MLKL. Mitochondria release proteins stored in the intermembrane space, including Cyt-c, Endonuclease G, and AIF. Release can be induced by MOMP (*upper*), which is regulated by Bcl-2 family proteins and which does not involve organelle swelling. Alternatively, release of mitochondrial can occur as a result of by MPTP complex opening, which leads to organelle swelling and loss of the electrochemical gradient ($\Delta\Psi_m$). MPTP opening is induced by Ca^{2+} influx and oxidative stress, among other stimuli. Accumulation of unfolded proteins in the ER results in UPR signaling, including activation of IRE1 α , which splices XBP1 mRNA to generate XBP1 protein (transcription factor) and activation of the kinase PERK, which stimulates phosphorylation events that promote ATF4 mRNA translation and production of transcription factor ATF4. The UPR transcription factors (XBP1, ATF4, and (not shown) ATF6) converge on the promoter of the *CHOP* gene, which encodes a transcription factor that upregulates pro-apoptotic gene *BIM* and downregulates anti-apoptotic gene *BCL-2*. Autophagic vesicles emerge from the ER, form double membrane vesicles, which fuse with lysosomes (*bottom, right*).

Mitochondria-initiated cell death pathways can also lead to Caspase-independent cell death, in addition to the aforementioned Caspase-dependent pathway downstream of Cyt-c.⁴⁵ In addition to Cyt-c, mitochondria also release several other proteins of relevance to apoptosis, including Endonuclease G, AIF (an activator of nuclear endonucleases), and Smac (Diablo) and Omi (HtrA2), antagonists of a family of Caspase-inhibitory proteins known as the inhibitor of apoptosis proteins (IAP)s (see below).^{46, 47} Moreover, distinguishing mitochondria-driven apoptotic from non-apoptotic cell death can be challenging in many contexts due to the similar morphological features caused probably by some of the proteins

released from these organelle such as EndoG and AIF, which promote chromatin condensation and DNA fragmentation. The mitochondrial mechanisms for apoptotic and non-apoptotic cell death are activated by myriad stimuli, including growth factor deprivation, oxidants, Ca^{2+} overload, DNA-damaging agents, microtubule-modifying drugs, and much more. In this sense, mitochondria are sometimes viewed as central integrators of cell stress signals that ultimately dictate cell life and death decisions.^{48–50}

Uniformly, these mitochondrial cell death mechanisms involve compromises of mitochondrial membrane integrity, but the membrane permeability change can occur via different mechanisms.⁵¹ In the context of insults such as ischemia-reperfusion injury (where oxidative stress occurs due to reactive oxygen species (ROS) and nitrosyl free radicals) and Ca^{2+} dysregulation where cytosolic free Ca^{2+} levels rise (due to loss of plasma membrane integrity or escape from the endoplasmic reticulum [ER]), osmotic homeostasis of mitochondria is perturbed due to opening of the *mitochondrial permeability transition pore* (MPTP) complex that spans inner and outer membranes at contact sites where they come into close apposition.^{52–54} The change in permeability in the inner membrane of mitochondria allows water and electrolytes to enter the protein-rich matrix of mitochondria, resulting in swelling of the organelle and eventually popping of the outer membrane, whose surface area is smaller than the extensively folded inner membrane with its cristae. During pathological opening of the MPTP complex, the electrochemical gradient (proton gradient) that is essential for ATP production is lost, and thus bioenergetics is severely compromised. An essential component of the MPTP complex is the adenine nucleotide translocator (ANT), which is thought to be chiefly responsible for the permeability transition that leads to mitochondrial swelling.

Alternatively, cell death mechanisms can involve the phenomenon of *mitochondrial outer membrane permeabilization* (MOMP), where the outer membrane becomes selectively permeabilized, allowing release of Cyt-c and other proteins that reside in the intermembrane space.^{51, 55, 56} With MOMP, the electrochemical gradient is preserved and mitochondrial osmotic homeostasis is maintained. MOMP is caused by pro-apoptotic members of the Bcl-2 family (see below), namely Bax and Bak (possibly also Bok).^{57–60} Though others may exist, an established mechanism for triggering MOMP entails interaction of pro-apoptotic proteins such as Bid, Bim, and Puma with Bax and/or Bak, causing oligomerization of Bax and Bak in the mitochondrial outer membrane and the formation of ill-defined pores that permit escape of Cyt-c and other proteins. MOMP induced by Bax and/or Bak thus initiates the mitochondrial pathway for Caspase-dependent cell death and apoptosis by releasing Cyt-c, but it also secondarily causes Caspase-independent necrotic cell death by uncoupling of oxidative phosphorylation (when Cyt-c becomes limiting) and causing diversion of electrons from the respiratory chain into production of toxic free radicals.⁶¹

Given the diversity of cell death mechanisms initiated by mitochondria, it is not surprising that tumors evolve a variety of alternations in these organelles and their regulation. The metabolic changes that convert the bioenergetic signature of tumor cells from dependence on aerobic respiration to non-aerobic glycolysis are well known (Warburg effect), and could be argued to make tumor cells less dependent on mitochondria. Indeed, some tumors seem to have a diminution in the numbers of mitochondria compared to normal cells of the same cell lineage.⁶²

Cell death induced by CTCs and NK cells can also occur via Caspase-independent mechanism. In this regard, Granzyme B directly cleaves some of the same substrates as Caspases,^{63, 64} thereby potentially bypassing the need for Caspases to cause proteolytic events associated with apoptosis. Also, the cytotoxic granules of CTLs and NK cells contain several other death-promoting molecules besides Granzyme B.¹⁷ Moreover, the perforin-mediated pores created in the plasma membrane of target cells by CTLs and NK cells can also lead to osmotic disequilibrium and thus Caspase-independent cell death. The

diversity of cytolytic mechanisms invoked by CTLs and NK cells bodes well for attempts to harness the immune system as a weapon for attacking cancers, since specific blocks to cell death in tumors (see below) might be overwhelmed by the multiple parallel cytotoxic mechanisms initiated by these immune cells.

Necroptosis is the term that has been applied to a Caspase-independent cell death mechanism initiated by TNFR1. When Caspase-8 is incapacitated, TNFR1 can stimulate a non-apoptotic cell death signaling pathway that involves the serine/threonine protein kinases Rip1, Rip3, and MLKL (mixed lineage kinase domain-like).^{65–67} Rip3-dependent necroptosis occurs through a process involving ROS generated by mitochondria. Necroptosis was initially identified by studies of tumor cells where TNF α was shown to kill via a Caspase-independent mechanism, suggesting that this cell death pathway could provide a conduit for attacking cancers.

Both Caspase-dependent and Caspase-independent cell death signaling mechanisms have been implicated in endoplasmic reticulum stress (*ER stress*). A wide variety of microenvironmental conditions (including those relevant to the tumor microenvironment) can cause the accumulation of unfolded proteins in the ER, triggering an adaptive signal transduction response called the *unfolded protein response* (UPR).^{68–70} Among these UPR events is increased transcription of a gene encoding the pro-apoptotic transcription factor CHOP, which in turn stimulates expression of the gene encoding DR5 (death receptor 5; TRAIL Receptor-2), causing Caspase-8-dependent apoptosis. In addition, CHOP has been reported to directly stimulate transcription of the gene encoding Bim, a pro-apoptotic member of the Bcl-2 family (see below) that stimulates Bax/Bak oligomerization in mitochondrial membranes to induce MOMP and release Cyt-c and other proteins from mitochondria. Thus, ER stress has multiple potential routes of stimulating both Caspase-dependent and Caspase-independent cell death, with the predominant pathway probably varying among cell types and pathophysiological contexts.

Furthermore, the important role that the ER plays in regulating intracellular Ca²⁺ homeostasis provides another potential link to cell death mechanism where changes in cytosolic free Ca²⁺ contribute (reviewed in^{70–72}). When extreme, liberation of Ca²⁺ from the lumen of the ER can trigger a variety of downstream signaling events that promote cell death. Also, the ER collaborates with mitochondria in many ways that can either promote cell life or cause death. ER membranes form close contacts with mitochondria to create structures where Ca²⁺ effluxes from ER into mitochondria, aiding bioenergetics. However, too much Ca²⁺ entry into mitochondria triggers opening of the MPTP complex, such that mitochondria swell and eventually rupture.

Autophagy (“self-eating”) is a catabolic mechanism where senescent proteins and organelles become entrapped in double membrane vesicles that bud off from the ER and that are transported to lysosomes for degradation of their contents. The physiological roles of autophagy include protein homeostasis, supplementing the ubiquitin-proteasome system for removal of unfolded, defective, and aged proteins, as well as providing a source of substrates for maintaining metabolism during times of nutrient deprivation.^{73, 74} In the context of nutrient deprivation, autophagy can contribute to cell survival and is thought to aid tumors at some points in their evolution. However, when taken to an extreme, mechanisms that rely on components of the autophagy machinery have been reported to cause cell death via a process called autophagic cell death, which is Caspase independent.⁷⁵ Under some conditions, exposure of tumor cells to cytotoxic chemotherapeutic drugs can trigger autophagic cell death.⁷⁶

Additional Caspase-independent cell death mechanisms have been described, including lysosome-dependent cell death,⁷⁷ iron-dependent cell death (ferroptosis),⁷⁸ and others,¹¹ which are not reviewed here. All of them may be relevant to cancer biology at some level in some contexts.

Cell death resistance mechanisms used by cancers

Cancer cells have been shown to put the brakes on Caspases and thereby suppress apoptosis by at least three fundamental mechanisms—(1) preventing activation of Caspase zymogens (pro-enzymes); (2) neutralizing active Caspases (active enzymes); and (3) suppressing expression of genes encoding Caspases or Caspase-activating proteins (see below). Malignant cells also develop a variety of ways of counteracting Caspase-independent cell death mechanisms. Some of the more prominent examples understood to date are outlined here.

IAPs

Endogenous suppressors of Caspases include IAPs ($n = 8$ in humans),^{15, 79, 80} an evolutionarily conserved family of proteins that directly bind active Caspases and that either suppress their protease activity or that target active Caspases for destruction.^{79, 81, 82} Overexpression of IAPs occurs in cancers and leukemias, making it more difficult to propagate the Caspase-dependent proteolytic events necessary for apoptotic cell death.

IAPs are characterized by the presence of protein interaction domains called BIRs (baculovirus internal repeats), numbering between 1 and 3 per protein⁸³ ([Table 1](#)). Most IAPs also carry RING domains that endow them with E3 ligase activity through interactions with ubiquitin-conjugating enzymes (UBCs). Some of the apoptogenic proteins released from mitochondria, notably SMAC and HtrA2,^{84, 85} bind certain BIRs and thereby compete for protein interactions on the surface of IAPs. In many cases, Smac binding to IAPs induces their polyubiquitination and proteasomal degradation. Thus, factors that cause MOMP take the brakes off the Caspases by eliminating various IAP family proteins.

The most established Caspase inhibitor among the IAP family members is XIAP (so called because its encoding gene resides on the X-chromosome). The XIAP protein contains 3 BIR domains. BIR2 of XIAP (and an adjacent segment) binds downstream effector proteases, Caspases-3 and -7, to potently suppress apoptosis at a distal point. BIR3 of XIAP binds upstream initiator protease, Caspase-9, to suppress an apical step in the mitochondrial pathway for apoptosis. Overexpression of XIAP mRNA and protein has been reported in cancers and leukemias, apparently caused by epigenetic mechanisms rather than genomic lesions to the *XIAP* gene. XIAP protein stability may also be increased in tumors with Akt hyperactivity.⁸⁶

The c-IAP-1 (BIRC2) and c-IAP2 (BIRC3) proteins are also capable of binding to Caspases-3, -7, and -9, though they are far less potent as direct enzymatic inhibitors and may rely on their E3 ligase activity for controlling Caspase degradation. However, these IAP family members also participate in other cell-death-relevant mechanisms by impacting signal transduction by TNF-family receptors.^{65, 66, 87} Binding of cytokine TNF α to TNFR1 can trigger at least three different signaling pathways, each involving overlapping but distinct protein complexes that are assembled at the receptor.⁸⁸ In addition to the pathways for Caspase-dependent and Caspase-independent cell death outlined above, TNFR1 also stimulates a cell survival pathway in which c-IAP1 and c-IAP2 participate. In this regard, the BIR3 domains of c-IAP1 and c-IAP2 directly bind the kinase Rip1. In the TNFR1-mediated survival pathway, Rip1 forms protein complexes that contain the E3 ligases c-IAP1, c-IAP2, and TRAF2, stimulating noncanonical (lysine 63, rather than lysine 48) ubiquitination of Rip1 to initiate a signal transduction pathway that causes activation of transcription factor NF- κ B.^{89, 90} NF- κ B influences the expression of many target genes involved in host defenses and immune regulation, among which are several genes that suppress apoptosis⁹¹ (see below). As a result, this NF- κ B pathway nullifies the Caspase pathway, negating apoptosis, in addition to accounting for the untoward inflammatory actions of this cytokine. In

addition, the Rip3-dependent pathway for necroptosis is suppressed by c-IAP1 and c-IAP2, probably via their roles as E3 ligases and possibly involving ubiquitin-/proteasome-mediated reductions in Rip3 protein levels. In human cancers, chromosomal translocations that deregulate c-IAP2 by creating a chimeric protein mucosa-associated lymphoid tissue (MALT-c-IAP2) have been described in lymphomas.^{92, 93} In addition, the genomes of some cancers have amplification of the gene encoding TRAF2, the c-IAP1/c-IAP2-binding protein implicated in TNF-family receptor signaling. Overexpression of c-IAP1 and c-IAP2 mRNAs and proteins, presumably via epigenetic mechanisms, is also reported. In this regard, *c-IAP2* is among the direct transcriptional targets of NF- κ B, and hyperactivity of the canonical (RelA) and alternative (RelB) pathways is well established in human malignancies of various types.

Additional members of the IAP family, not described here (Survivin, Apollon/Bruce, ML-IAP, etc.), also have interesting mechanisms of interacting with components of cell death pathways; and they can have other roles beyond cell death regulation. For example, the Survivin protein plays a fundamental role in chromosome segregation and cytokinesis.⁹⁴

c-FLIP

The c-FLIP protein provides another example of an endogenous modulator of Caspases whose overexpression is a common occurrence in tumors.^{95, 96} FLIP is structurally similar to certain Caspases, containing a pair of DEDs analogous to Caspases-8 and -10. It directly binds and suppresses activation of Caspases-8 and -10 in the context of TNF-family death receptor signaling. However, the role of c-FLIP is more complex than merely suppressing Caspase-8 or -10 activation, as it also collaborates with these Caspases in poorly understood ways (probably involving Caspase-8, MALT, and Bcl-10) to promote NF- κ B activation.⁹⁷ Testimony to this complex interaction is also found in the observation that knockout of the genes encoding either c-Flip or Caspase-8 in mice results in similar embryonic lethal phenotypes. In addition to promoting NF- κ B activation, the *c-FLIP* gene is itself also a direct transcriptional target of NF- κ B, whose expression is strikingly upregulated (positive feedback).⁹⁸

Bcl-2

Among the central regulators of MOMP are members of the Bcl-2 family, evolutionarily conserved proteins that either promote (e.g., Bax; Bak) or suppress (e.g., Bcl-2, Bcl-XL) MOMP.^{99–101} The Bcl-2-family proteins ($n = 26$ in humans)¹⁵ physically interact with each other, forming complex networks of homo- and heterodimers that steer the cell toward either life or death.^{102, 103} Numerous examples of altered expression and function of Bcl-2-family proteins have been identified in cancers, accounting for intrinsic resistance to cell death induced by myriad stimuli, including most cytotoxic anticancer drugs and x-irradiation, growth factor deprivation and therapeutic inhibitors of growth factor receptor signal transduction pathways.

Many members of the Bcl-2-family have a hydrophobic stretch of amino acids near their carboxyl-terminus that anchors them in the outer mitochondrial membrane. In contrast, other Bcl-2-family members such as Bid, Bim, and Bad lack these membrane-anchoring domains, but dynamically target to mitochondria in response to specific stimuli. Still others have the membrane-anchoring domain but keep it latched against the body of the protein, until stimulated to expose it (e.g., Bax).

Based on their predicted (or experimentally determined) three-dimensional structures, Bcl-2 family proteins can be broadly divided into two groups. One subset of these proteins is probably similar in structure to the pore-forming domains of bacterial toxins, such as the colicins and diphtheria toxin.^{104–106}

These α -helical pore-like proteins include both anti-apoptotic proteins (Bcl-2, Bcl-X_L, Mcl-1, Bfl-1, Bcl-W, Bcl-B), as well as pro-apoptotic proteins (Bax, Bak, Bok, and Bid). Most of the proteins in this subcategory can be recognized by conserved stretches of amino acid sequence homology, including the presence of Bcl-2 homology (BH) domains, BH1, BH2, BH3, and sometimes BH4 ([Table 1](#)). However, this is not uniformly the case, as the Bid protein contains only a BH3 domain but has been determined to share the same overall protein-fold with Bcl-X_L, Bcl-2, and Bax. Where tested to date, these proteins have all been shown to form ion-conducting channels in synthetic membranes in vitro, including Bcl-2, Bcl-X_L, Bax, and Bid,¹⁰⁷ but the significance of this pore activity remains largely unclear. The other subset of Bcl-2 family proteins appears to have in common only the presence of the BH3 domain, including Bad, Bik, Bim, Hrk, Bcl-G_s, p193, APR (Noxa), and PUMA. These “BH3-only” proteins are uniformly pro-apoptotic. Their cell-death-inducing activity depends, in most cases, on their ability to dimerize with anti-apoptotic Bcl-2 family members, functioning as trans-dominant inhibitors of proteins such as Bcl-2 and Bcl-X_L.^{101, 102} However, a select group of them (Bim, Bid, Puma) interact with pro-apoptotic proteins Bax and Bak, functioning as agonists that induce their oligomerization in mitochondrial membranes to stimulate MOMP.

The BH3 domains mediate dimerization among Bcl-2 family proteins ([Figure 3](#)). This domain consists of an amphipathic α -helix of ~16 amino acids length that inserts into a hydrophobic crevice on the surface of anti-apoptotic proteins such as Bcl-2 and Bcl-X_L.^{104, 105} The BH3-only proteins link a wide variety of environmental and iatrogenic stimuli to the mitochondrial pathway for apoptosis (see below).

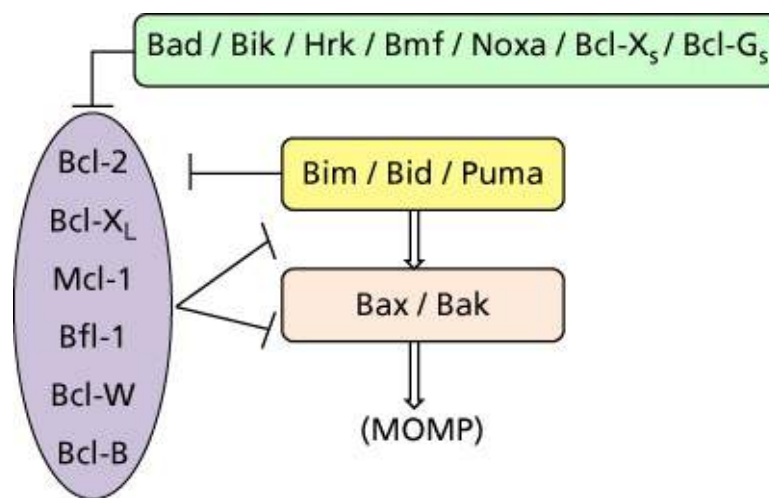

Figure 3 Network of interactions among Bcl-2-family proteins. The functional and physical interactions among pro-apoptotic and anti-apoptotic Bcl-2-family proteins are depicted as pertains to their regulation of MOMP.

While Bcl-2 family members clearly regulate MOMP, it has been proposed that they also regulate other aspects of mitochondrial biology. For example, components of the MPTP complex, including ANT and the voltage-dependent anion channel (VDAC), reportedly interact with Bcl-2 family members, with anti-apoptotic proteins suppressing and pro-apoptotic facilitating MPTP complex opening.¹⁰⁸ In addition, VDAC has been proposed as a facilitator of Cyt-c release from mitochondria, via a Bcl-2 suppressible mechanism¹⁰⁹ while Bcl-XL has been reported to enhance delivery of ATP to the cytosol via effects on ANT and thereby support cell survival in the context of growth factor deprivation.¹¹⁰ Anti-apoptotic Bcl-XL also may regulate mitochondrial metabolism through poorly understood mechanisms to reduce production of acetyl-CoA.¹¹¹ The significance of this reduction in acetyl-CoA has been attributed to reduce N-acetylation of apoptosis-relevant proteins, including certain Caspases, which may make it more

difficult to activate these proteases. Bcl-2 has also been proposed to regulate mitochondrial redox metabolism, though mechanistic details remain largely unclear.¹¹²

In addition to mitochondria, mechanistic links for Bcl-2 family proteins to ER stress have also been delineated.¹¹³ For example, Bax and Bak can bind the ER stress signaling protein, IRE-1 α , a central component of UPR signaling.¹¹⁴ IRE-1 α spans the ER membranes and possesses a protein kinase domain and a ribonuclease domain that reside on the cytosolic face of the ER membrane. Bax and Bak stimulate the intrinsic autokinase activity and the endoribonuclease activity of IRE1 α , thus stimulating production of CHOP-inducing transcription factor XBP-1 (by RNA splicing mechanisms) and also stimulating stress kinase activation (Ask1, p38MAPK, JNK1, etc.). Pro-apoptotic (Bak/Bax) and anti-apoptotic (Bcl-2/Bcl-XL) family members also have opposing effects on basal ER Ca²⁺ levels, probably via effects on Ca²⁺ channel proteins in ER membranes (e.g., IP₃Rs, BI-1 and TmBim3).⁷²

In addition to mitochondria- and ER-initiated cell death pathways, Bcl-2-family proteins have also been implicated in control of autophagic cell death. Anti-apoptotic protein Bcl-2 binds the autophagy protein Beclin, preventing it from forming complexes with downstream autophagy proteins (e.g., ATG5) and apparently sequestering Beclin to preclude its participation in autophagy.¹¹⁵ During nutrient deprivation, Bcl-2 can suppress cell death mechanisms that depend on components of the autophagy pathway.¹¹⁶ Beclin has recently been recognized as a haplo-insufficient tumor suppressor gene,¹¹⁷ suggesting that suppression of autophagy contributes to tumorigenesis. These recent findings concerning links between autophagy, tumorigenesis, and anti-apoptotic Bcl-2-family proteins indicate a master-switch role for Bcl-2-family proteins in controlling cell life and death decisions.

Genomic lesions involving members of the Bcl-2 family are well documented in human cancers.^{6, 118–120} These mechanisms include hyperactivation of anti-apoptotic Bcl-2 family members by chromosomal translocations that cause overproduction of transcripts and proteins (Bcl-2), gene amplification (Bcl-2, Bcl-X, Mcl-1), and deletion/mutational inactivation of microRNAs (miRs) that suppress expression of anti-apoptotic Bcl-2 family genes (miR15-16 targeting Bcl-2 mRNA). Conversely, mutations inactivating pro-apoptotic members of the Bcl-2 family also occur in some human cancers (Bax). In addition, a wide and diverse array of epigenetic mechanisms contribute to dysregulation of Bcl-2 family gene expression in cancers and leukemias, some of which are outlined below.

Signal transduction pathway alterations in cancers—impact on cell death machinery

Various receptor-mediated signal transduction pathways converge on the core components of the cell death machinery outlined above, including tyrosine kinase growth factor receptors and their downstream signaling pathways that become deregulated in many cancers. Some examples of the intimate links between growth factor receptor-mediated signal transduction and cell death pathways are described here ([Figure 4](#)).

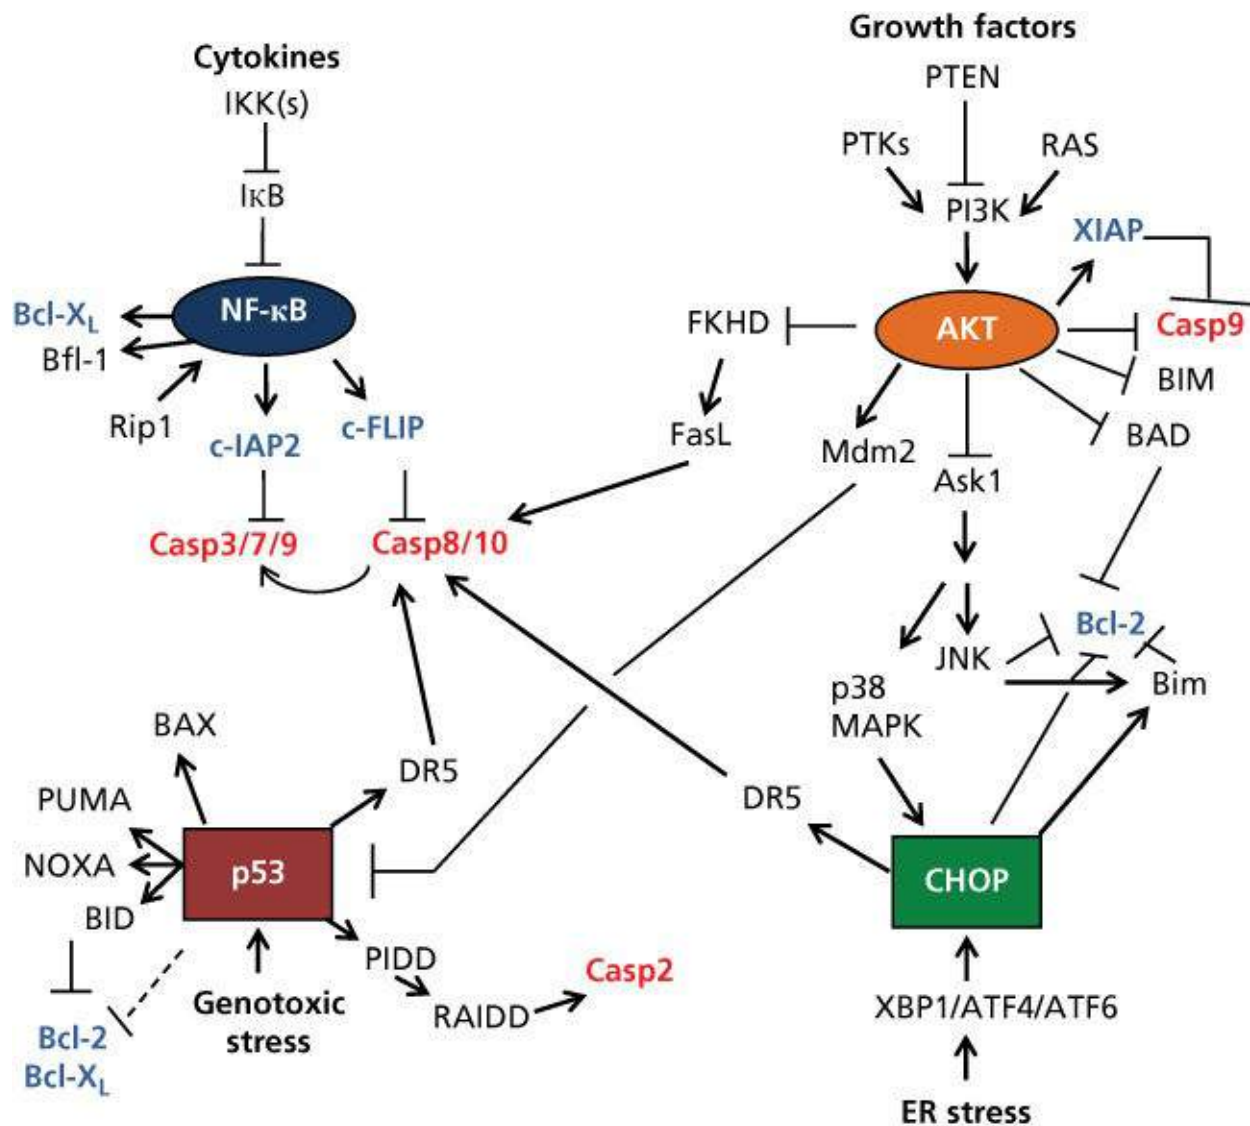

Figure 4 Signal transduction and cell death regulation. Some of the transcription factors and kinases that play prominent roles in apoptosis regulation are depicted, including kinases Akt (PKB) and the transcription factors p53, NF-κB, and CHOP. Illustrative examples of the connections to apoptosis-regulating proteins and genes are shown, without attempting to be comprehensive. The protein kinase Akt (PKB) is activated in response to second messengers produced by PI3K, a lipid kinase that is activated by many growth factor receptors and oncoproteins. PTEN is a lipid phosphatase that prevents accumulation of these second messengers, the expression of which is lost in many tumors through gene deletions, gene mutations, and other mechanisms.⁸⁹ Akt can phosphorylate and either activate (arrows) or inactivate (⊥) multiple proteins directly or indirectly relevant to apoptosis.¹²¹ Expression of the transcription factor CHOP is stimulated by transcription factors that are elaborated during ER stress, including XBP1, ATF4, and ATF6. See text for additional details.

Protein kinases

By catalyzing phosphorylation of tyrosines on themselves and on various substrates, protein tyrosine kinase (PTK) growth factor receptors uniformly transduce signals that lead to activation of the (1) phosphatidyl inositol 3' kinase (PI3K) and Akt pathway and (2) Raf/MEK/Erk pathway (*reviewed elsewhere in this book*). One or both of these pathways is also activated by most non-receptor PTKs (Src-family, Jak-family, c-Abl, etc.) and Ras-family GTPases.

The murine gene encoding Akt was first discovered by virtue of its similarity to the *v-akt* oncogene found in some murine leukemia viruses, where it becomes activated in thymomas caused by retrovirus insertions

near the *c-akt* gene.¹²² Humans contain three *AKT* genes. Akt can phosphorylate multiple proteins within the core apoptosis machinery.¹²³ For example, the pro-apoptotic Bcl-2 family member Bad is a target of Akt, where phosphorylation of Bad causes its sequestration by 14-3-3 family proteins, thus inhibiting Bad from heterodimerizing with Bcl-X_L.¹²⁴ Akt also phosphorylates Bax on serine 184, inhibiting its translocation from cytosol to mitochondrial membranes,¹²⁵ as well as Bim, suppressing its pro-apoptotic activity.¹²⁶ Akt also can phosphorylate human Caspase-9, blocking apoptosis downstream of mitochondria.¹²⁷ Forkhead transcription factors (FKHDs) are another class of substrates of Akt relevant to apoptosis. Some FKHD family members such as Foxo-3 appear to control apoptosis, perhaps by affecting transcription of genes encoding Fas-ligand (FasL) and Bim.¹²⁸ Phosphorylation of FKHD by Akt prevents its entry into the nucleus. Akt also reportedly causes phosphorylation of XIAP, promoting stability of the XIAP protein probably by reducing ubiquitin-dependent proteasomal degradation.⁸⁶

Several growth factor receptors and lymphokine receptors signal via Jak/STAT pathways. STAT family transcription factors are known to stimulate transcription of the *BCL-X* gene as at least one of their mechanisms of suppressing apoptosis.¹²⁹ In addition, Jak family non-receptor PTKs are capable of stimulating PI3K activity, which in turn causes activation of Akt family kinases. These signaling mechanisms are also relevant various oncogenes such as BCR-ABL, the oncogenic driver of certain types of leukemia.¹³⁰

The Raf/MEK/Erk signaling pathway has important links to the cell death machinery. For example, phosphorylation by Erk of pro-apoptotic protein Bim on serine 69 promotes Bim protein degradation via proteasomal-dependent mechanisms.¹³¹ Inhibitors of the Raf/MEK/Erk pathway therefore help promote apoptosis by enabling accumulation of Bim protein levels. MEK-dependent phosphorylation of anti-apoptotic protein Bcl-2 has also been described, purportedly enhancing its survival-promoting function through unclear mechanisms.¹³²

Protein acetylation

Acetylation of lysines in histones is a well-established mechanism for controlling chromatin structure and thus transcription of genes. However, acetylation of non-histone proteins is increasingly recognized as a mechanism for impacting biological processes through diverse mechanisms. In terms of cell death regulations, examples of dysregulated protein acetylation impacting the core components of the cell death machinery are only just emerging. For example, acetylation of transcription factor FoxO1 was reported to be required for induction of Bim expression in the context of treatment of cancer cells with histone deacetylase (HDAC) inhibitors.¹³³ Acetylation also indirectly impacts the expression of multiple apoptosis and cell-death-relevant genes through modification of lysines on a variety of other transcription factors, including STATs, NF-κB, and p53.¹³⁴ In addition, acetylation of tumor suppressor p53 has also been reported to be required for a transcription-independent mechanism of Bax activation.¹³⁵ Acetylation of DNA damage repair protein Ku70 neutralizes its anti-apoptotic functions by interfering with interactions with proteins constituting core components of the cell death machinery (see below). As mentioned above, via effects on mitochondrial acetyl-CoA production, Bcl-XL may also broadly impact N-alpha-acetylation of proteins, including certain Caspases that require this post-translational modification for interactions with upstream activators.¹¹¹

Transcription factors

As expected, epigenetic dysregulation of expression of cell death genes is a common occurrence in human

cancers, with mechanisms too abundant to catalog here. Among the cancer-relevant connections are steroid hormone receptors including estrogen, androgen, and vitamin D receptors, which regulate the expression of various cell death and cell survival genes. For example, estrogen receptor (ER) is a prominent transcriptional regulator of the *BCL-2* gene expression in mammary epithelial cells and in ER-positive breast adenocarcinomas.¹³⁶ Retinoid receptors and other nuclear receptors also regulate the expression of various cell death and cell survival genes through transcriptional mechanisms.¹³⁷ The roles of transcription factors such as FKHD family members (Foxo-3, FoxO1), CHOP, NF- κ B family members, and p53 have been cited above. Precedence also exists for nontranscriptional mechanisms of regulating cell death proteins, where transcription factors leave the nucleus and physically interact with Bcl-2 family members on the surface of mitochondria.¹³⁸ Chromatin-modifying enzymes responsible for histone acetylation and deacetylation have also been implicated in controlling core components of the cell death machinery. Therefore, cancer-associated aberrations in the regulation of transcription factors and chromatin-modifying enzymes are connected ultimately to perturbations in the core cell death machinery.

Cytotoxic chemotherapeutic oncology drugs

Chemotherapeutic cytotoxic drugs remain a foundational component of cancer therapy today, though giving way to more targeted agents. These chemical agents were designed to interfere with replication of rapidly dividing cells by inhibiting DNA synthesis, inducing DNA damage, or crippling microtubules. The cellular injuries induced by classical chemotherapeutic anticancer drugs, and x-irradiation, trigger molecular events with connections to the core cell death machinery. Some examples are described here. Cytoprotective proteins that blunt cell death pathways thus play important roles in chemoresistance.

Radiotherapy and DNA-damaging anticancer drugs potently stimulate activation of the tumor suppressor p53, one of the principal mediators of apoptosis induced by genotoxic stress. The p53 protein is a tetrameric transcription factor, whose levels are controlled by the E3 ligase Mdm2. This transcription factor directly induces expression of BH3-only proteins Bim, Bid, and PUMA, and the MOMP-inducing protein Bax, thus linking p53 to the death machinery.^{139–142} Active p53 also stimulates transcription of DR5, a TNF-family death receptor, thus rendering tumor cells more sensitive to its ligand TRAIL.¹⁴³ Loss of p53 activity occurs in many human malignancies by a variety of mechanisms, including gene deletion, gene mutations that result in mutant p53 proteins lacking transcriptional activity, and *MDM2* gene amplification. Small-molecule drugs that block Mdm2 protein interaction with p53 have shown promising preclinical activity against hematological malignancies¹⁴⁴ and are synergistic with Bcl-2 inhibitors.¹⁴⁵

Interestingly, in addition to its role as a nuclear transcription factor, evidence has emerged suggesting that p53 may promote apoptosis also via nontranscriptional mechanisms under some circumstances. Specifically, a cytoplasmic pool of p53 reportedly associates with mitochondria, directly inducing activation of the Bax and inhibiting Bcl-2 and Bcl-XL.^{146, 147} Importantly, even mutant p53 is capable of activating this cell death pathway, raising hopes of finding pharmacological interventions that agonize this mechanism for promoting cell death.

DNA damage is also linked to regulation of the core cell death machinery via p53-independent mechanisms. For example, Ku70 plays an important role in repairing double-strand DNA breaks. Ku70 binds Bax and suppresses its translocation to mitochondria; but after DNA damage, Ku70 becomes acetylated and dissociates from Bax.^{148, 149} Ku70 also interacts with c-FLIP and suppresses its ubiquitination and proteasomal degradation, where Ku70 acetylation releases c-FLIP and allows its degradation to promote apoptosis.¹⁵⁰ Another DNA repair protein RAD9 has been reported to translocate

from nucleus to mitochondria following DNA damage, where it reportedly binds and neutralizes anti-apoptotic proteins Bcl-2 and Bcl-XL to promote cell death.¹⁵¹

Anti-microtubule drugs impact the cell death machinery via a variety of mechanisms. For example, the pro-apoptotic Bcl-2 family member Bmf-1 is sequestered on microtubules. When microtubules are disrupted by anticancer drugs, Bmf is released from microtubule-binding proteins (dynein light chains), allowing it to engage and neutralize anti-apoptotic members of the Bcl-2 family.¹⁵² A role for Bim in cell death induced by microtubule-targeting drugs has also been identified, facilitated perhaps by other BH3-only proteins Bmf and Puma.¹⁵³ Microtubule-targeting drugs also stimulate a stress kinase cascade that results in multisite phosphorylation of Bcl-2, which is proposed to impair its anti-apoptotic function.^{154, 155}

Cancer drug discovery by targeting the cell death machinery

Multiple efforts have been made to devise therapeutics that neutralize anti-apoptotic or activate pro-apoptotic components of the core cell death machinery. All drug targets can be approached by at least three means, involving attack at the level of the gene, mRNA, or protein. The relative attractiveness of these alternative strategies depends on the nuances of the target and its biology. Discussion here is limited to therapeutic strategies that modulate protein targets, though nucleic acid-based therapeutics (RNA therapeutics, gene therapy) have been explored preclinically and some even taken into advanced clinical trials. Also, while a wide variety of signal transducing proteins (e.g., protein kinases, transcription factors) provide inputs into cell death pathways described above and thus are attractive targets for indirectly promoting tumor cell death, the focus here is limited to direct modulators of components of the core cell death machinery.

Bcl-2-family inhibitors

In humans, six anti-apoptotic members of the Bcl-2-family have been identified (Bcl-2, Bcl-XL, Mcl-1, Bcl-W, Bfl-1, Bcl-B), with overexpression of various individuals occurring in a variety of cancers. Simultaneous overexpression of two or more anti-apoptotic members of the Bcl-2 family in tumors has also been documented in some cases, raising the issue of redundancy. Overexpression of Bcl-2 or other anti-apoptotic members of the Bcl-2 family has been associated with chemoresistant states, due to the ability of these proteins to block cell death induced by DNA-damaging agents, microtubule-modifying drugs, and antimetabolites. Thus, restoring chemosensitivity by nullifying Bcl-2 and related proteins has emerged as an attractive strategy for improving cancer therapy.

Chemicals that bind regulatory sites on anti-apoptotic Bcl-2-family proteins and that directly neutralize the cytoprotective actions of these proteins have been identified and brought into clinical development. Some have progressed into advanced human clinical trials, and at least one molecule (venetoclax) has produced sufficiently compelling data that the U.S. Food & Drug Administration (FDA) has granted approval for treatment of some forms of leukemia. The compounds described to date target a crevice on the surface of anti-apoptotic Bcl-2-family proteins that serves as a receptor for the BH3 peptidyl motif present in endogenous antagonists of the anti-apoptotic Bcl-2 family proteins.^{6, 104, 120} Compounds that mimic the BH3 peptidyl structure suppress anti-apoptotic Bcl-2-family proteins, tapping into a natural pathway for defending against excessive Bcl-2. Several natural products and synthetic chemicals have been reported to occupy the BH3-binding site on Bcl-2 or Bcl-XL, and some of them have been shown to promote apoptosis of tumor cells in culture and to suppress tumor growth in mouse models.^{156–162} The strategies for generating chemical antagonists of anti-apoptotic Bcl-2 family proteins have ranged from

highly selective inhibitors, which neutralize only 1 of the 6 human anti-apoptotic Bcl-2 family proteins, to broad-spectrum that cross-react with multiple family members. The trade-offs with these opposing strategies are efficacy versus drug safety. For example, development of a chemical inhibitor with activity against Bcl-2, Bcl-XL, and Bcl-W (navitoclax) was stalled because of thrombocytopenia—which has been attributed to the requirement of Bcl-XL for longevity of platelets.^{163–165} In contrast, a selective Bcl-2 inhibitor (venetoclax) is free of the thrombocytopenia side effect; but with a narrower spectrum of activity, its efficacy is likely to be more limited to tumors where Bcl-2 is the major driver of cell survival.

Other approaches to tackling Bcl-2 family proteins for cancer therapy have been proposed, though most of those concepts are less validated. For example, direct agonists of Bax and Bak that mimic the actions of Bid, Bim, and Puma could be envisioned,¹⁶⁶ though this has not been reduced to practice to date. Alternatively, indirect mechanisms for upregulating pro-apoptotic Bcl-2 family members are actively being explored. Small-molecule antagonists of Mdm2, such as idasanutlin, cause an accumulation of p53 protein, which in turn stimulates transcription of several pro-apoptotic Bcl-2 family genes including *BAX*, *NOXA*, *BID*, and *PUMA*. Mdm2 antagonists have progressed to advanced clinical trials, following displays of promising activity for some types of malignancy such as acute leukemia. It remains to be seen whether the Mdm2 inhibitor strategy is applicable only to tumors that retain wild-type p53 versus whether it may also benefit some patients whose malignancies harbor mutants of p53 that still retain the ability to exit the nucleus and directly modulate Bcl-2 family protein activity at the surface of the mitochondria (see above). In addition, chemical inhibitors of MEK (Trametinib, Cobimetinib, etc.) can produce elevations in the levels of Bim protein by reducing its ubiquitination and proteasomal degradation. In an analogous fashion, small-molecule inhibitors of Akt that are currently in advanced clinical development also would be expected to help restore the activity of pro-apoptotic Bcl-2 family proteins that are phosphorylated by this protein kinase (e.g., Bad, Bax, etc.). Finally, compounds that stimulate an orphan member of the nuclear receptor family, Nur77 (NR4A1), have been described; and they cause this transcription factor to exit the nucleus and translocate to mitochondria, where it interacts with Bcl-2, Bfl-1, and Bcl-B to promote cell death.^{138, 167–169}

TRAIL

Cytokines of the TNF family have been extensively evaluated in preclinical studies for anticancer activity. Two general strategies for exploiting this endogenous mechanism for triggering apoptosis have been tested clinically, involving parenteral administration of either recombinant proteins constituting functional fragments of the cytokine ligands or agonistic monoclonal antibodies that bind the TNF-family death receptors and trigger their activation.

Attempts to apply TNF α , the founding member of the TNF family, as a cancer therapy provided highly toxic, due to the proinflammatory activity of this cytokine. At present, TNF α is employed only in rare circumstances for treatment of melanomas and soft tissue sarcomas confined to specific limbs using tourniquet-based methods to prevent systemic exposure.¹⁷⁰ TRAIL (TNF-related apoptosis-inducing ligand) emerged as a possible alternative, owing to its ability to induce tumor cell apoptosis without inducing signals that cause inflammation. Preclinical studies, including data from primates, indicated that a soluble fragment of TRAIL (produced as a recombinant protein) was nontoxic, apparently sparing normal tissues, while showing potent preclinical activity against tumor xenografts in mice.¹⁷¹ Moreover, TRAIL is sometimes synergistic when used in combination with cytotoxic anticancer drugs, at least in preclinical mouse models. Based on these promising data, a recombinant version of TRAIL was taken into clinical trials but lack of efficacy resulted in its eventual termination. Postulated reasons for the poor

efficacy of TRAIL in the clinic are myriad, including intrinsic blocks in cancers to the downstream apoptotic signaling pathways, expression of “decoy” receptors that compete for TRAIL binding to function death receptors on tumor cells, insufficient expression levels of DR4 (TRAIL-R1) and DR5 (TRAIL-R2), and other explanations.¹⁷¹

Agonistic antibodies that bind DR4, DR5, or both have been reported, and several were taken into clinical development.^{172, 173} Clinical responses when tested as monotherapy were rare, and some of these antibodies showed hepatotoxicity,^{174, 175} which was theorized to be due to FcR binding to Kupfer cells in the liver. In this regard, the agonists antibodies were uniformly dependent on FcR-binding to achieve crosslinking of receptors tumor cells, and thus reliant on macrophages, NK cells, or other types of FcR-expressing immune cells to achieve the desired apoptotic signaling. More recently, highly engineered antibodies that utilize FcR-independent mechanisms to achieve death receptor crosslinking have been advanced into clinical studies, awaiting results at the time of this writing.

TRAIL and TRAIL Receptors can induce apoptosis via either mitochondria-dependent or mitochondria-independent pathways, depending on the specifics of how apoptosis pathways are regulated in a given tumor.¹⁷⁶ The mitochondrial-dependent route of signaling entails cleavage by Caspase-8 of and Bid, which activates the protein such that it can interact with Bax and Bak to induce MOMP. The possible advantage of mitochondria-independent apoptosis is that roadblocks to apoptosis created by survival proteins such as Bcl-2 are bypassed, an attractive feature for chemorefractory cancers that often have defects in the mitochondrial pathway. Unfortunately, predicting whether TRAIL operates via a mitochondria-dependent versus mitochondria-independent mechanism in a given tumor is still an empirical process, as no single predictive biomarker has emerged.

Among the roadblocks to TRAIL-induced apoptosis is c-FLIP, a protein that is produced as either longer and shorter isoforms (due to mRNA splicing) that associate with the Caspases normally recruited into the TRAIL receptor complex. The longer c-FLIP proteins is overexpressed in many cancers, and is capable of squelching signaling by TNF-family death receptors by modulating Caspase activation.⁹⁵ Chemical compounds that reduce c-FLIP protein levels have been identified, including HDAC inhibitors such as suberoylanilide hydroxamic acid (SAHA)¹⁷⁷ and synthetic triterpenoids such as Bardoxolone (1[2-Cyano-3,12-dioxoleana-1,9(11)-dien-28-oyl]imidazole [CDDO]) and its analogs.^{178–183} Preclinical studies have shown that Bardoxolone analogs used in combination with recombinant TRAIL can synergistically suppress growth of human tumor xenografts in mice, where the human tumor cells were resistant to treatment with TRAIL alone.¹⁸⁴ Thus, compounds such as CDDO can restore sensitivity of cancer cells to TRAIL (and agonistic anti-TRAIL Receptor antibodies), and therefore might serve as adjuncts to TRAIL therapy. At least in mice, the combination of TRAIL and CDDO analogs is a nontoxic therapy,¹⁸⁴ suggesting that combining these two targeted therapies provides a promising direction for future research. Bardoxolone (CDDO analog) was brought into the clinic for a non-oncology indication but development terminated.

IAP inhibitors

The most common strategy employed for generating small-molecule inhibitors of IAPs is to mimic the effects of endogenous antagonists of IAPs, particularly the proteins SMAC and HtrA2. SMAC- and HtrA2-mimicking agents bind the BIRs of multiple IAP family members, thus disrupting their interactions with Caspases (Caspase-3, -7, -9) and kinases (Rip1, Rip2).¹⁸⁵ The active region of SMAC and HtrA2 has been reduced to a 4 amino acid peptide that is necessary and sufficient to bind IAPs, displace Caspases or kinases, and promote apoptosis or inhibit signal transduction.¹⁸⁶ Several peptidyl compounds

that occupy the same tetramer-binding site on IAPs have been described,^{187–189} as well as at least one natural product. Several of the synthetic compounds were taken into clinical development, and some of them remain actively under investigation at the time of this writing. These SMAC-mimicking compounds show only occasional single-agent activity as apoptosis inducers when applied against cultured tumor cell lines, which has been the reason for termination of several of these drug development programs. However, SMAC mimics often sensitize transformed cells very potently to apoptosis induced by cytotoxic anticancer drugs and TNF-family death receptors such as TRAIL and agonistic antibodies targeting TRAIL Receptors. In this sense, IAP antagonists take the breaks the cell death pathways induced by TNF-family death receptor, providing a solid rationale for combination therapy.

An alternative approach to deriving chemical inhibitors of IAPs involves screening compound libraries using an enzyme derepression assay, where recombinant IAPs are mixed with active Caspases, forming an inhibited enzyme complex, and where chemicals displacing the Caspase are then revealed by cleavage of fluorogenic substrates.^{190, 191} Compounds derived by the latter approach, however, have failed to yield molecules with sufficient affinity (potency) to progress into clinical development.

Finally, an additional strategy for attacking IAPs has been suggested by interrogation of the actions of another apoptogenic protein released from mitochondria called ARTS.¹⁹² The ARTS protein binds certain IAPs, including XIAP, c-IAP1, and c-IAP2. It has been shown to recruit an E3 ligase (Siah-1) to IAPs and promote their degradation.¹⁹³ Short peptides from ARTS purportedly can induce apoptosis,¹⁹⁴ though the translation of these observations into drug-like molecules remains an ambition to date. The structural nature of the ARTS binding site on IAPs also remains to be determined, which would presumably provide important insights into the “druggability” of this protein–protein interface.

Some tumors overexpress simultaneously two or more members of the IAP family, suggesting that broad-spectrum inhibitors that address multiple IAPs may be preferable to selective agents. More extensive comparisons of the therapeutic indices of selective versus broad-spectrum inhibitors are needed to reveal the best path forward.

Conclusions

Dysregulation of PCD mechanisms plays critical roles in cancer pathogenesis and progression. Elaboration of the complex cell death pathways and the networks of proteins that modulate these pathways has provided insights into the underlying mechanisms of cell life–death decisions—though many mechanistic details remain still to be revealed. In several cases, the available information has already sparked efforts to translate the base of information into therapeutic strategies, with new agents for cancer treatment nearing or already reality.

List of abbreviations

BH	Bcl-2 homology domain
CARDs	Caspase recruitment domains
Caspases	Cysteine aspartyl proteases
Cyt-c	Cytochrome-c
CTL	Cytolytic T cells
DD	Death domain
DEDs	Death effector domains
DISC	Death-inducing signaling complex
DR	Death receptor
ER	Endoplasmic reticulum
FasL	Fas-ligand
FKHD	Forkhead transcription factors
IAP	Inhibitor of apoptosis
miRs	microRNAs
MOMP	Mitochondrial outer membrane permeabilization
MPTP	Mitochondrial permeability transition pore
MLKL	Mixed lineage kinase domain-like
MALT	Mucosa-associated lymphoid tissue
MMs	Multiple myelomas
NK	Natural killer
NHLs	non-Hodgkin lymphomas
PI3K	Phosphatidylinositol-3'kinase
PCD	Programmed cell death
ROS	Reactive oxygen species
TNFR1	TNF receptor-1
TNF	Tumor necrosis factor
UBCs	Ubiquitin conjugating enzymes

Chapter 14

Cancer cell immortality: targeting telomerase

Ilgen Mender PhD ■ Zeliha Gunnur Dikmen MD, PhD ■ Woodring E. Wright MD, PhD ■ Jerry W. Shay PhD

Overview

Finding specific targeted agents for cancer therapy remains a challenge. One of the hallmarks of cancer is the limitless proliferation (immortalization) of cancer cells, which correlates with the activation of the ribonucleoprotein enzyme complex called telomerase. As 85–90% of primary human cancers express telomerase activity, while most normal cells do not, telomerase is a unique and almost universal therapeutic target for cancer. Although there have been several approaches developed for telomerase-targeted therapies, there is still no agent that has been approved. This chapter focuses on the pros and cons of the different approaches to target telomerase and summarizes preclinical and clinical results. We will also review novel telomerase-mediated telomere uncapping approaches that target telomerase-expressing cancer cells, but not normal cells.

Telomerase: a universal target for cancer therapy

Telomeres (TTAGGG)_n are repetitive hexameric nucleotide repeats that are found at the ends of linear chromosomes. Telomere length varies in different organisms such as humans (2–15 kb) and mice (up to 100 kb).¹ Telomeres are protected from being recognized as damaged or broken chromosomes by a special protein complex. This is termed the shelterin complex that stabilizes the chromosomal ends with 6 protein components (TRF1, TRF2, Rap1, TIN2, TPP1, and POT1) to protect the telomeric ends from exonuclease activity and DNA damage recognition.^{1–3} Shelterin proteins also have a role in the generation of a special lariat-like loop structure at each telomere end called the telomere loop (T-loop). The single-stranded telomeric DNA overhang at the ends of each chromosome bends backward and is believed to strand invade into the telomere DNA duplex structure disrupting the double-stranded TTAGGG repeats and forming a triple-stranded structure called the displacement loop (D-loop). The D-loop is bound by a single-stranded TTAGGG-binding protein called POT1 and this entire T-loop and D-loop structure functions in part by hiding or masking the single- and double-stranded telomeric DNA from being recognized as broken DNA and thus is important in telomere maintenance.⁴

G-quadruplex formation is a secondary structure that is generated between guanine bases in telomeric DNA and is also proposed to protect the ends of chromosomes from degradation.⁵ As normal somatic cells have a limited capacity to divide in culture, they stop proliferating after a finite number of cell doublings (the so-called Hayflick limit), which is related to DNA replication turnover.⁶ Because DNA polymerase is unable to replicate the 3' end of the DNA lagging strand (often referred to as the end replication problem), in the absence of a maintenance mechanism, telomeres shorten with each cell division until they become “uncapped.”⁷ In addition to the end replication problem, oxidative stress and/or other unknown processes may accelerate telomeric shortening *in vitro* and *in vivo*. It is believed that only a few short telomeres with uncapped ends are sufficient to trigger a p53-dependent G1/S cell

cycle arrest, which is known as replicative senescence. When cells enter senescence, the fate of normal cells is to remain in a quiescent phase. If other alterations occur in important cell cycle checkpoint genes such as TP53 or pRB, then senescence can be bypassed and cells continue to proliferate (extended lifespan phase) until many telomere ends become critically shortened leading to end fusions and chromosome bridge fusion breakage cycles (also referred to as crisis). Senescence and crisis are two fundamental mechanisms that protect cells against the early development of cancer. The cells that escape from crisis almost universally express the enzyme telomerase; a ribonucleoprotein cellular reverse transcriptase ([Figure 1a](#)), which has two essential components for the elongation of telomeres: the catalytic component hTERT (telomerase reverse transcriptase) and the telomerase RNA component (hTR or hTERC) ([Figure 1b](#)).^{8,9} Telomerase is active during early human fetal development, then becomes silent in most tissues ([Figure 2a](#)) except embryonic stem cells and some but not all proliferating progenitors (e.g., male germline spermatocytes, activated lymphocytes, and a few other transient amplifying cell types).¹⁰ Telomerase is not absolutely required for cells to become malignant; however, 85–90% of primary human tumors have telomerase activity ([Figure 2a](#)), while the vast majority of normal tissues do not have detectable enzyme activity.⁹ A rarer (3–10%) mechanism to maintain telomere length is called ALT (alternative lengthening of telomeres) and involves intratelomeric recombination and perhaps T-loop resolution.

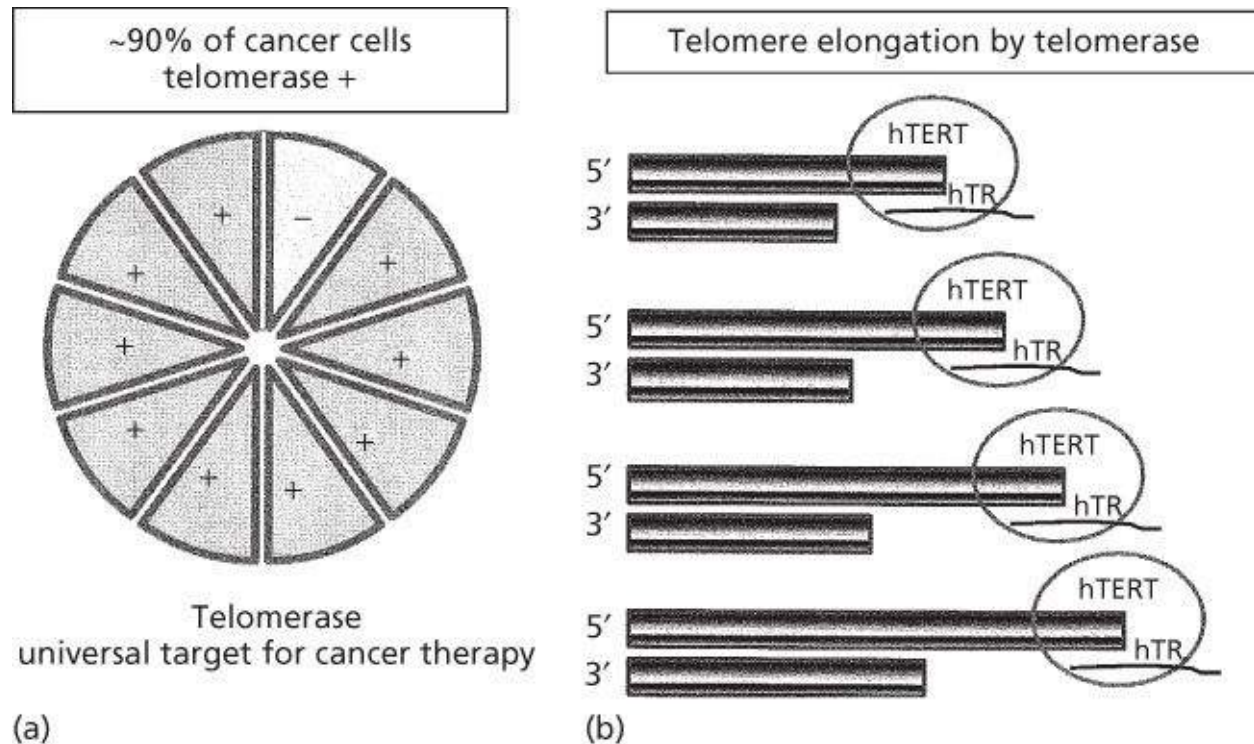

Figure 1 Normal cells that do not express telomerase activity cannot elongate their telomeres, hence their life span is limited whereas telomerase-expressing cancer cells (~90% of cancer cells, a) can elongate their telomeres by telomerase (with hTERT and hTR subunits, b) resulting in unlimited proliferative lifespan (a hallmark of cancer). This important difference between normal and cancer cells make telomerase an almost universal therapeutic target.

Figure 2 Diagram of hypothetical telomere demonstrating the t-loop structure. This structure is similar in normal and cancer cells but as normal cells generally do not express telomerase, telomeres shorten progressively while cancer cells expressing telomerase can maintain their telomeres (a). There are disadvantages of G-quadruplex stabilizers (b), immunotherapy (c), and gene therapy approaches (d). G-quadruplex stabilizers show their toxic effects by binding and stabilizing T-loop structures and they are also found at the other regions of chromosomes beside telomeres. Thus, these agents are likely to be toxic for both normal and cancer cells (b). One of the most important disadvantages for immunotherapy is that when combination chemotherapy is used with vaccines for cancer patients, some agents can block the effect of immunization as most chemotherapeutic agents are immunosuppressive (c). The main challenge for gene therapy is the delivery of the gene vector to the cancer cells (d) throughout the body. In addition, immunologic responses to therapy can also limit dosing. Gene therapies generally require more invasive approaches to delivery and are generally not orally available for systemic delivery.

There have been several studies on changes in telomerase expression/activation in normal and cancer cells. DNA rearrangement breakpoints within the TERT promoter region correlate with increased TERT expression in some cancers.¹¹ In addition, mutations in the TERT promoter can lead to activated telomerase in immortalized, nontumorigenic fibroblasts.¹² Different studies show that the mutations in the TERT promoter¹³ and gene amplifications in TERT^{14, 15} correlate with increased TERT transcriptional activation and expression of telomerase activity. While it is difficult to regulate very low abundant transcripts such as TERT, it has been reported that another mechanism for telomerase regulation is by alternative splicing. Precursor mRNA (pre-mRNA) that is transcribed from DNA is processed to exclude introns (noncoding sequences) and join exons (coding sequences) in order to produce mRNA for mature protein translation. However, during RNA splicing, exons may be included or excluded from the pre-

mRNA to create diverse proteins with multifunctional roles. This process is known alternative splicing¹⁶ and may be important in the regulation of telomerase.

Induction of hTERT cDNA into most normal cells causes reactivation of telomerase and unlimited cell proliferation,^{17, 18} indicating that repression of telomerase activity is primarily regulated by transcriptional mechanisms and generation of full-length hTERT is likely responsible for activation of telomerase.^{19, 20} However, it is also known that posttranscriptional and epigenetic alterations may play an important role in this dynamic process.¹⁹ There remains no known consensus mechanism to repress telomerase during human developmental and to reactivate telomerase during cancer progression. Alternative splicing is one of the potential mechanisms for repression or reactivation of telomerase.^{21, 22} Several groups have found that there are different hTERT splice forms such as minus alpha, minus beta, or minus alpha beta,^{16, 21, 23, 24} which may have a role on regulation of telomerase activity.^{16, 20} hTERT α is one of the known splice variants that inhibits telomerase activity by acting as a dominant-negative inhibitor. Thus, the balance between hTERT α form and full-length hTERT and other splice variants may be important in the regulation of active telomerase.^{19, 25} Recent papers showed that a 1.1-kb region of a 38-bp variable number tandem repeats (conserved among Old World primates) is essential for exclusion of exon 7 and 8 to produce the minus beta splicing form and that RNA:RNA pairing between these repetitive sequences may be used to regulate decisions on hTERT splicing.^{26, 27} Importantly, misregulation of alternative splicing is a hallmark of nearly all cancers. In addition, a recent shift in our understanding of telomerase regulation has occurred. The common paradigm in the field was that hTERT was transcriptionally silenced in normal differentiated human tissues. However, there is increased evidence that hTERT is transcribed in normal cells but spliced to variants that do not have telomerase activity (Andrew Ludlow, unpublished observations). Although hTR (hTERC) is expressed in almost all cells, hTERT is only detected at extremely low levels even in cancer cells. How TERT is regulated to produce an optimal level for telomerase function in stem cells and cancer cells is still largely unknown. However, one could speculate that targeting hTERT at the splicing level may be a novel approach to reduce telomerase activity in cancer cells perhaps with minimal toxicity to normal cells.¹⁶

Compared to normal cells with long telomeres, the vast majority of cancer cells have relatively short telomeres. As normal stem cells generally have longer telomeres compared to cancer cells, this may facilitate cancer cells undergoing apoptosis with telomerase-targeted drug administration without a significant effect on normal cells.²⁸ As an example, the transfection of an hTERT dominant-negative mutant into tumor cell lines resulted in apoptosis and reduced tumorigenic capacity.^{29, 30} The death by apoptosis in tumor cells correlates with initial telomere length, the tumor cells with short telomeres die before those with longer telomeres.³¹ In addition, it has been proposed that tumors are less likely to develop resistance against telomerase-based therapies compared to other cancer targets.³² However, this has not been experimentally observed in ALT or other telomere maintenance mechanisms. All of these factors suggest that targeting telomerase is not only a unique and almost universal cancer target, but it is likely to be a relatively safe anticancer treatment approach with fewer side effects compared to standard chemotherapy. Thus, a more complete understanding of the relationships between telomeres, telomerase, aging, and cancer may increase our knowledge and contribute to new approaches to cancer therapy and basic tumor biology research ([Figure 1](#)).

There are no telomere/telomerase-targeted drugs approved by the Food and Drug Administration (FDA)

Although proof of concept of different approaches against telomerase-based therapies has repeatedly been achieved in the preclinical setting, there are no telomerase inhibitors in clinical trials that have been approved by FDA. The most promising telomere/telomerase-targeted strategies are reviewed in [Table 1](#).

Table 1 Telomere/telomerase-targeted strategies

Therapeutic approach	Inhibitors
G-quadruplex stabilizers	BRACO19, RHPS4, Telomestatin, porphyrin, TMPyP4, CX-3543/quarfloxin, AS1411/ Cytarabine/Ara-C
Immunotherapy	GV1001, VX-001, GRNVAC1/2
Gene therapy	Telomelysin, Ad-hTERT-NTR/CB1954, hTERTp-HRP/IAA
Telomere and telomerase-associated proteins	Geldanamycin (GA), Curcumin
T-oligo approach	PARP inhibitors
Small-molecule inhibitors	BIBR1532
Oligonucleotides	GRN163L
Telomerase-mediated telomere uncapping approaches	Lentiviral mutant hTERC 6-thio-2' deoxyguanosine

G-quadruplex stabilizers

G-quadruplexes are formed by the ability of guanosine self-assembly together with monovalent cations (e.g., potassium) in the presence of guanine tandem repeats. G-quadruplexes may form in telomeres, oncogene promoter sequences, and other biologically relevant regions of the genome.³³ It has been demonstrated that small molecules that target G-quadruplex structure in human telomeres cause telomerase inhibition (perhaps indirectly) and telomeric end disruption.³⁴ Thus, this secondary structure is a popular target to design small-molecule ligands.

Telomestatin is isolated from *Streptomyces anulatus* 3533-SV4 and reported to be a telomerase inhibitor that interacts with G-quadruplex structures.^{35, 36} Nakajima and co-workers³⁷ showed that telomestatin causes telomerase inhibition and induces apoptosis in primary leukemic blasts that were isolated from bone marrow of acute myeloid leukemia (AML-M2) patients. The other reported G-quadruplex ligand is termed TMPyP4. Hurley and colleagues showed that telomestatin caused telomerase inhibition by stabilizing of intramolecular G-quadruplex structures and eventually telomere shortening, whereas TMPyP4 suppressed the proliferation of ALT-positive cells as well as telomerase-positive cells by facilitating the formation of intermolecular G-quadruplexes leading to the induction of anaphase bridges. They also reported that telomestatin more tightly and specifically binds to the intramolecular G-quadruplexes compared to other G-quadruplex interactive compounds such as TMPyP4.³⁸ Another investigated telomeric G4 ligand is termed RHPS4 (pentacyclic acridine). RHPS4 reduces telomerase activity at submicromolar levels through stabilization of G-quadruplex structures formed by single-stranded telomeric DNA.³⁹ Others reported that RHSP4 causes telomere capping alterations in a telomere length-independent manner.⁴⁰ *In vivo* experiments demonstrate that RHSP4 is even more effective when compared with other antineoplastic drugs in terms of antitumoral and antimetastatic effects.⁴¹ Although

BRACO19 (trisubstituted acridine) is classified in the class of G-quadruplex stabilizers due to *in vitro* and *in vivo* anticancer effects,³¹ the utility of this compound is limited because of its low permeability for biological barriers in the airways or intestinal epithelial cell cultures *in vitro*.⁴² Several ligands induce growth inhibition of various cancer cells *in vitro* by causing cellular senescence and/or apoptosis. These ligands also exert short-term effects with telomere uncapping.⁴³ Over the past decade, many G-quadruplex ligands have been described including fluorenones, bisubstituted acridines, cationic porphyrins, a perylenetetracarboxylic diimide derivative, indolo-quinolines. However, the evidence for specificity of these compounds for telomerase is very limited and they poorly bind to the quadruplex structures compared to double DNA.³¹ Thus, many of these compounds may affect quadruplex structures in normal cells as well as cancer cells ([Figure 2b](#)). Any compound that inhibits cell growth will decrease telomerase activity, so it is not sufficient to show telomerase inhibition to suggest specificity without also testing these compounds on normal cells without telomerase.

Some of the proteins that interact with G-quadruplex stabilizers also have the ability to induce senescence and/or apoptosis. Although G-quadruplex structures appear to be good targets for anticancer therapy, they are also observed during replication in chromosome regions besides telomeres. Because G-quadruplexes also have a large planar surface formed by terminal G-tetrad, most of the small molecules designed so far target this common structure instead of a specific target for a particular G-quadruplex. Thus, a general concern about these compounds is safety: while small-molecule ligands toward G-quadruplex structures affect cancer cells, they may also affect the telomere structure of normal cells^{44, 45} ([Figure 2b](#)).

Although there are two quadruplex-related small molecules that have already entered into clinical trials, there remains lack of direct evidence that these small molecules are specific for telomerase-targeted therapy. The first agent CX-3543 (quarfloxin/quarfloxacin, Cylene Pharmaceuticals, San Diego, CA, USA) is a fluoroquinolone derivative, that selectively disrupts nucleolin/rDNA G-quadruplex complexes in the nucleolus by inhibiting Pol1 transcription, resulting in decreased cancer cell proliferation and induction of apoptosis.^{46, 47} However, CX-3543 also interacts with MYC G-quadruplexes,⁴⁶ so the *in vitro* antiproliferative and *in vivo* antitumoral activity in xenograft models may not be related to G quadruplexes at telomeres. In addition, CX-3543 selectively targets Pol1, rather than telomere function, which further suggests that CX-3543 may have indirect or even no effect on telomere function.⁴⁷ The other quadruplex forming agent in clinical trials is AS1411 (Cytarabine/Ara-C, Antisoma Research, London, UK), which specifically targets nucleolin.⁴⁸

Immunotherapy

Tumor-associated antigens (TAAs)-specific immunotherapy has been investigated for several decades. However, as most TAAs immunotherapies have been restricted to only a few tumor types, telomerase-based immunotherapy would theoretically be a good approach owing to the ubiquitous expression of telomerase in most tumor cells.⁴⁹ Degradation of hTERT in proteasomes by E3 ubiquitin ligase generates protein fragments/peptides that may be presented on the tumor cell surface as antigens by the major histocompatibility complex (MHC) class I pathway. Thus, targeting these antigens by a patient's own immune system (CD8+ T lymphocytes) is a direct way to kill the telomerase-expressing tumor cells^{50, 51} (reviewed in Ref. ⁵²). Several hTERT vaccines have already been developed, but GV1001 and GRNVAC1 are the most promising vaccines that are in clinical trials ([Table 2](#)). GV1001 is a 16-mer TERT peptide (aa 611–626) that binds multiple HLA class II molecules. Recent studies showed that vaccination with hTERT-transfected dendritic cells helped to induce telomerase-specific CD4+ and CD8+ T-cell responses⁵³ and also vaccination with GV1001-induced hTERT-specific T-cell responses in

nonresectable pancreatic cancer patients and nonsmall lung cancer patients.^{54, 55} The combination treatment of GV1001 and cyclophosphamide in hepatocellular carcinoma failed to show partial or complete responses to treatment in a phase 2 clinical trial.⁵⁶ GV1001 vaccination with chemotherapy together did not improve overall survival in advanced or metastatic pancreatic cancer in a phase 3 clinical trial.⁵⁷ GRNVAC1 was also designed to induce CD4 and CD8 responses. GRNVAC1 was prepared from autologous dendritic cells transduced with mRNAs encoding a near full-length hTERT protein *ex vivo*. The dendritic cells are reintroduced into the patient and can potentially recognize any hTERT peptide in a patient's tumor.³² Currently, GRNVAC1 is in phase 2 clinical trials for acute myelogenous leukemia patients. As monotherapy is likely to have limited efficacy, combination therapy might be a more effective approach to kill the heterogeneous nature of tumor cells. However, most chemotherapeutic agents are immunosuppressive and they might preclude the immunization effect. For this reason, vaccines should probably not be used in combination with chemotherapeutic agents⁵⁸ ([Figure 2c](#)). Hence, new strategies are required to improve clinical efficacy with enhanced immune response effects of telomerase vaccination during chemotherapy.

Table 2 Telomerase-targeted vaccines in clinical trials

Vaccines	ClinicalTrials.gov Identifier/phase	Condition	Drug intervention	Status
GV1001	NCT01223209/phase 1	Carcinoma	GV1001, LTX-315	Completed
	NCT01247623/phase1/2	Advanced malignant melanoma	GV1001	Completed
	NCT01342224/phase 1	Locally advanced pancreatic adenocarcinoma	Tadalafil and vaccination	Active, not recruiting
	NCT00425360/phase 3	Locally advanced or metastatic pancreatic cancer	Gemcitabine, capecitabine, GV1001	Completed
	NCT01579188/phase 3	Inoperable stage 3 nonsmall-cell lung cancer	GV1001	Not yet recruiting
	NCT00509457/not provided	Nonsmall-cell lung cancer	GV1001	Completed
	NCT00444782/phase 2	Hepatocellular carcinoma	GV1001	Completed
	NCT00358566/phase 3	Advanced unresectable pancreatic cancer	GV1001, gemcitabine	Terminated
GRNVAC1	NCT00510133/phase 2	Acute myelogenous leukemia	GRNVAC1	Active, not recruiting
VX001	NCT01935154/phase 2	Nonsmall-cell lung cancer metastatic	VX001	Recruiting

Gene therapy

Gene therapy is a technique that treats diseases such as cancer by delivering therapeutic DNA into the patient's cells. DNA that encodes a therapeutic effect can be delivered to the target cells. DNA becomes expressed by the cell machinery that ultimately makes a protein that can result in apoptosis. Genes can be

delivered via oncolytic viral vectors and can include enzymes metabolizing prodrugs or suicide genes.⁵⁹ Although gene therapy can be highly tumor specific, there are challenges including manufacture/formulation, which is often complex and clinical trials requiring special expertise⁶⁰ (Figure 2d). Some studies showed the proof of concept in treating cancer, but there are some concerns about off-target effects. Targeting tumor cells in order to have a reduction of tumor burden and durable responses is the main purpose for successful therapy.^{61, 62} There are adenoviral vectors that have been engineered to kill cancer cells by only entering cells that have telomerase activity. These adenoviral vectors have a TERT promoter driving replication of the adenovirus. In this instance, the virus uniquely replicates in telomerase-positive cells, thus sparing most normal cells.⁶³ After replication and amplification of the virus, the tumor cell will lyse and viral particles will spread to adjacent cells.^{63–66} This approach is known as a tumor-specific replication-competent adenoviral (hTERTp-TRAD) gene therapy approach.^{61, 67} One example for telomerase-mediated virus therapy is Telomelysin (OBP-301), which is an hTERT promoter driven modified oncolytic adenovirus. Preclinical studies demonstrated antitumor activity of telomelysin (and similarly engineered adenoviruses) in various cancer cells.^{64, 66, 68, 69} Phase 1 clinical trials did not show significant related toxic events but there were multiple manageable adverse events such as fever, chills, fatigue, and injection site pain. Some patients with solid tumors developed a decreased asymptomatic transient lymphocyte.⁷⁰ Systemic treatment also has the potential effects on telomerase-positive proliferating normal stem cells. Therefore, systemic hTERTp-TRAD may affect transient amplifying stem cells such as proliferating cells in the crypts of the intestine, hematological cells, and a subset of cells in the basal and suprabasal layer of the epidermis.^{8, 60} The other concern is that intratumoral injections may not be sufficient to reduce the tumor burden.⁷¹

Suicide gene therapy (Ad-hTR-NTR), also called “gene directed enzyme prodrug therapy,” targets only tumor cells without affecting normal cells, similar to oncolytic gene therapy.^{32, 72} Three general steps are required for this approach: first is targeting the vector, second is transfecting the vector carrying an enzyme-encoding gene driven by hTERT into the cells, third is a prodrug that is activated by an enzyme, resulting in a release of toxins into the cytoplasm causing death of telomerase-positive cells.⁷² Although gene therapy (suicide gene or oncolytic vector) show some promising results, they do not appear to be as effective as vaccines or oligonucleotides.⁷³ Future directions would be to make multifunctional viral vectors such as those replicating only in p53 mutant cells with telomerase expression. This would potentially reduce the effects on normal proliferating stem cells.

Small-molecule inhibitors and antisense oligonucleotides

Although millions of compounds have been screened during the past decade to identify small-molecule inhibitors of telomerase, there are currently no potent/specific small-molecule inhibitors except one candidate compound, BIBR1532. While BIBR1532 showed promising results in some preclinical models,^{74, 75} it was not effective enough to enter clinical trials perhaps owing to its short binding on/off rate with telomerase.^{76, 77} After many years of screening new drugs, GRN163L (Imetelstat, Geron Corporation) was found as a parallel approach to small-molecule inhibitors. This telomerase-targeted oligonucleotide approach uses a lipid-modified N3' → P5' thio-phosphoramidate oligonucleotide and has shown highly potent telomerase inhibition as a competitive enzyme inhibitor by being designed to complement the hTR template of telomerase that recognizes telomeres.⁷⁸ GRN163L, 13-mer oligonucleotide (not antisense) was generated as a second improved generation of GRN163 to increase cellular uptake with a conjugating lipophilic palmitoyl (C16) group attached to the 5' terminal.²⁸ The effects of GRN163L have been investigated in different cancer cell lines and xenograft models. GRN163L

demonstrates both *in vivo* and *in vitro* effects by inhibiting telomerase activity and resulting in progressive telomere shortening in a variety of cancer cell lines such as hepatocellular carcinoma,⁷⁹ lung cancer,⁸⁰ breast cancer,^{81, 82} bladder cancer,⁷¹ multiple myeloma,⁸³ pancreatic cancer,⁸⁴ colorectal cancer,⁸⁵ glioblastoma,⁸⁶ and esophageal adenocarcinoma.⁸⁷ *In vivo* antimetastatic effects of GRN163L were tested in tumor xenograft models. When A549 lung cancer cells were injected into the nude mice via the tail vein, lung tumor formation was not observed in the animals treated with 15 mg/kg GRN163L (intraperitoneal, three times per week for 3 weeks).⁸⁰ In mice having implanted hepatoma cancer cells, GRN163L inhibited tumor growth and also sensitized tumor cells to conventional chemotherapy.⁷⁹ In a xenograft model of breast cancer and lung metastasis, administration of 30 mg/kg GRN163L for 12 treatments (three times per week, 4 weeks total) effectively reduced the proliferation of breast cancer cells and metastasis to the lungs.⁸² Different studies showed that GRN163L reduced tumor size as well as improved survival in a human myeloma cell-derived xenograft model.⁸³ Although there are many studies showing promising effects of GRN163L *in vitro* and *in vivo*, GRN163L has not succeeded in most clinical trials owing to hematological side effects and liver function abnormalities as well as other adverse events. When patients had dose-limiting toxicities such as thrombocytopenia, owing to GRN163L, interruption of dosing until their platelet numbers returned to the normal range resulted in telomere re-elongating during the drug holiday period.

GRN163L (Imetelstat), is the first telomerase inhibitor in clinical trials, and 17 studies have been completed, including 10 phase 1 and 6 phase 2 trials. These are summarized in [Table 3](#). The preliminary data in 50- to 74-year-old patients with advanced solid tumors (6 colorectal, 3 lung, 2 mesothelioma, 2 pancreas, 7 others) showed aPTT prolongation (active prolonged thromboplastin), gastrointestinal side effects, fatigue, anemia, GGT elevation, and peripheral neuropathy. Although thrombocytopenia is a dose-limiting toxicity at 4.8 mg/kg, one death from unknown reasons was observed at 3.2 mg/kg dose.⁸⁸ Locally recurrent or metastatic breast cancer (MBC) patients were treated with GRN163L in combination with paclitaxel and bevacizumab (3 of 14 patients with *de novo* MBC and 6 of 14 patients with prior (neo) adjuvant taxane). Phase 1 clinical trials showed that the most common toxicities were cytopenia. The majority of patients had dose reduction or delays in treatments with GRN163L and/or paclitaxel owing to neutropenia and/or thrombocytopenia or other adverse effects.⁷³ Main outcome from pediatric patients with solid tumors in phase 1 clinical trials was that the reduction of telomerase activity in PBMCs (peripheral blood mononuclear cells) and telomerase-positive tumors with the recommended phase 2 dose, which is 285 mg/m² (MTD, maximum tolerated dose). In this study intravenous injection was conducted for 2 h on days 1 and 8 of a 21-day cycle. As a result, dose-limiting toxicity levels (DLT; 360 mg/m²) caused myelosuppression leading to a delay in the therapy of more than 14 days. Some patients had anemia, lymphopenia, neutropenia, thrombocytopenia, and catheter related infections depending on their grade level and cycle number of treatment.⁸⁹ The advanced breast cancer phase 2 trial (NCT01256762) was stopped owing to poorer overall survival in patients treated with GRN163L.⁴⁹ As GRN163L is administered on days 1 and 8 of a 21-day cycle, it is possible that telomerase cannot be inhibited sufficiently during this schedule, so that a new telomere equilibrium length for cancer cells emerges.

Table 3 GRN163L in clinical trials

ClinicalTrials.gov Identifier/phase	Condition	Drug intervention	Status
NCT01568632/phase 1	Refractory or recurrent solid tumors/lymphoma	GRN163L	Withdrawn
NCT01273090/phase 1	Refractory or recurrent solid tumors/lymphoma	GRN163L	Completed
NCT01243073/phase 2	Essential thrombocythemia/polycythemia vera (ET/PV)	GRN163L, standard of care	Suspended
NCT00594126/phase 1	Refractory or relapsed multiple myeloma	GRN163L	Completed
NCT01916187/phase 1	Neuroblastoma	GRN163L, 13-cis retinoic acid	Withdrawn
NCT00732056/phase 1	Recurrent or metastatic breast cancer	GRN163L, paclitaxel, bevacizumab	Completed
NCT00310895/phase 1	Refractory or relapsed solid tumor malignancies	GRN163L	Completed
NCT00718601/phase 1	Multiple myeloma	GRN163L, bortezomib, dexamethasone	Completed
NCT01242930/phase 2	Multiple myeloma	GRN163L, standard of care	Active, not recruiting
NCT00510445/phase 1	Advanced or metastatic nonsmall-cell lung cancer	GRN163L, paclitaxel, carboplatin	Completed
NCT01265927/phase 1	Her2+ breast cancer	GRN163L, trastuzumab	Active, not recruiting
NCT00124189/phase 1	Chronic lymphoproliferative disease (CLD)	GRN163L	Completed
NCT02011126/phase 2	Relapsed or refractory solid tumors	GRN163L	Withdrawn
NCT01137968/phase 2	Nonsmall-cell lung cancer	GRN163L, bevacizumab	Completed
NCT01731951/Not provided	Primary or secondary myelofibrosis	GRN163L	Active, not recruiting
NCT01256762/phase 2	Recurrent or metastatic breast cancer	GRN163L, paclitaxel, w/wo bevacizumab	Completed
NCT01836549/phase 2	Recurrent or refractory brain tumors	GRN163L	Recruiting

Challenges for developing telomerase inhibitors

The other potential challenge for telomerase inhibitors, such as GRN163L, is that the response time that is needed to induce senescence or crisis is long as telomere attrition occurs following each cell replication cycle. Therefore, this delayed response limits its utility as a first-line treatment for advanced cancer. It

has been suggested that telomerase inhibitors following conventional therapy might be a good option to block the growth of residual cancer cells.⁶⁵ A phase 2 study used GRN163L in a maintenance therapy setting after initial standard of care doublet chemotherapy for advanced nonsmall-cell lung cancer (NSCLC) has been completed (clinicaltrials.gov: NCT01137968). This study was designed to evaluate whether or not GRN163L, given as maintenance therapy, prolonged progression-free survival (PFS) in NSCLC. Eligible stage IV or recurrent locally advanced NSCLC patients were randomized to GRN163L (9.4 mg/kg over a 2-h IV infusion on day 1 and day 8 of each 21-day cycle) with or without bevacizumab on day 1 of each 21-day cycle, vs. standard of care alone (patients who had received bevacizumab before randomization were continued with bevacizumab maintenance or had no follow-up maintenance treatment). This study, while not achieving statistical significance showed a trend in PFS in the GRN163L arm, most apparent in the cohort of patients with the shortest telomeres at the initiation of the trial.⁹⁰ Experience with these types of trials is important to more fully understand how to provide antitelomerase therapies going forward.

Overexpression of mutant hTERC and wild-type hTERC-targeted siRNA by lentiviral vectors are different types of gene therapy strategies for telomerase-targeted therapies

The other strategy to disrupt telomere maintenance in cancer cells is to express mutant hTR (hTERC) in the template region (mutant-template human telomerase RNA; MT-hTERC). Wild-type telomere repeats contain DNA binding sites for direct telomeric binding proteins such as POT1, TRF1, and TRF2 in humans.^{91, 92} It is predicted that mutated DNA that is directly synthesized by MT-hTERC disrupts the binding of telomeric proteins,^{93–95} which might lead to telomere uncapping. Studies showed that the uncapping of human telomeres by mutating TRF2 can induce growth arrest (p53 dependent) and apoptosis in cells.^{96, 97} Introduction of MT-hTERC via lentiviral vectors into telomerase-positive human cancer cells causes an alteration in the cancer cellular phenotype and reduced tumor growth in xenografts.^{94, 95} In another approach using siRNA (a hairpin short-interfering RNA) expressed from a lentiviral vector-targeted wild-type human telomerase RNA (WT-hTERC) also caused cell growth inhibition and apoptosis (these effects are telomere length independent). Coexpression of MT-hTERC and anti-WT-hTERC-siRNA showed additive or perhaps synergistic effects on cancer cells. Therefore, mutant hTERC and siRNA present promising anticancer therapy strategies owing to the lack of dependency on p53, initial telomere length, or progressive telomere shortening.⁹⁸ However, these are still gene therapy approaches and require high efficiency in targeting to the cancer cells to be effective in the clinical setting.

6-Thio-dG is a small molecule that is a telomerase-based telomere uncapping target that may overcome some of the problems with gene therapy

Ideal cancer targets are those that are expressed in cancer cells, but not in normal cells. Compared to other targets, telomerase is one of the most universal targets expressed in almost all tumor cells, but not in normal cells except some proliferative progenitor stem cells. Therefore, telomerase is an important target to focus on for new therapeutic strategies.

So far, there have been two different therapeutic strategies in telomere biology: telomere or telomerase-targeted strategies. The strategy that targets telomerase inhibition is correlated with telomere length,

whereas telomere-targeted approach is independent from initial telomere length ([Figure 3](#)). This makes an important difference between these two approaches. With only telomerase inhibition, a long lag period is expected (the time between enzyme inhibition and biological effect). Thus treatments will generally be long and depend on significant reduction of telomere length before reduction of tumor growth, senescence, or apoptosis is observed.^{29, 30}

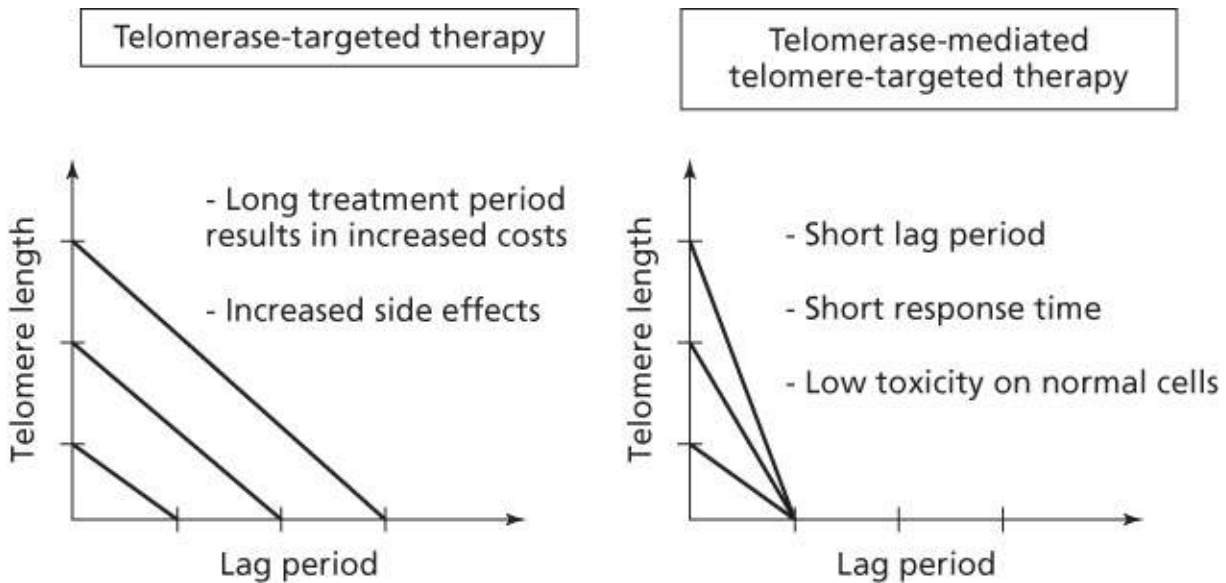

Figure 3 Telomerase-targeted therapeutic responses (such as Imetelstat/GRN163L) are dependent on the initial tumor cell telomere length. Cancer cells have variable telomere lengths. Therefore, cells with long telomeres are predicted to take a longer treatment period to be sensitive to telomerase inhibitors compared to cells with shorter telomeres (left side). As a result, any long-term treatment for telomerase may lead to unwanted side effects, high costs, and potentially re-establishing feedback loops establishing a stable new telomere length. In contrast to telomerase-targeted therapies, telomerase-mediated telomere targeting therapies (such as 6-thio-dG or MT-hTERC gene therapy) do not need long treatment periods as they are independent of the initial telomere length, therefore short response time to tumor burden reduction is a key advantage of these approaches (right side). The other most important advantage is that they may be less toxic to normal cells as most do not express telomerase. However, the MT-hTERC approach has the same obvious limitations of all gene therapy approaches of needing to reach almost all cells and delivery concerns. However, new approaches such as 6-thio-dG nucleoside may be orally available with minimal side effect and have the obvious advantage that all small molecules have.

Some approaches that target telomeres (not directly telomerase) lead to telomere uncapping (e.g., G-quadruplex), which is independent of p53 status and initial telomere length. However, normal tissue toxicity remains a major concern owing to quadruplex formation in other regions of the genome and in normal cells.⁹⁹ Thus, approaches that do not target through telomerase may not have a therapeutic window of efficacy. In addition, using direct telomerase inhibitors or telomere-targeted therapies may need to be combined with other cytotoxic drugs to reduce the potential resistance capacity of heterogeneous tumor cells.⁹⁹ For example, the cells from mTR knock-out mice showed telomere dysfunction by sensitizing cells to some anticancer drugs (e.g., doxorubicin).¹⁰⁰ This result shows that telomerase-targeted therapy in combination with other chemotherapeutic agents may sensitize cells to other chemotherapeutics by resulting in reduced resistant capacity.

In recent work, we focused on a novel approach to identify a small molecule that would uncap telomeres but only in telomerase-positive cells. This theoretical approach using a small molecule obviates some of the problem with gene therapy and also could reduce the lag phase from initiation of treatment to tumor

burden reduction. To test this concept, we decided to focus on nucleoside analogs that are good substrates for telomerase (not inhibitors of telomerase) and also more specific for telomerase than for other polymerases. 6-Thio-2'deoxyguanosine (6-thio-dG) is a new telomere-targeted nucleoside analog that is recognized by telomerase and is used by telomerase as a substrate.¹⁰¹ In our recent studies, we showed that 6-thio-dG causes telomere dysfunction by causing altered telomere structures called telomere dysfunction-induced foci (TIFs) in telomerase-expressing cancer cells of varying telomere lengths and comparing these to normal and ALT cells. Interestingly, beside short-term cell killing effects, 6-thio-dG caused rapid and progressive telomere shortening in surviving cancer cells but not in normal cells. These studies demonstrated that 6-thio-dG targets telomeres by being preferentially used by telomerase as a substrate. In human xenograft models in immunodeficient mice, 6-thio-dG reduced lung cancer growth (no observed side effects, e.g., no death, no weight loss) and caused telomere dysfunction. There were no long-term side effects on normal tissues and hematological, liver, and kidney functions were in the acceptable range. Thus, 6-thio-dG is a promising “telomeric poison” targeting telomeres by using telomerase as a catalyst to change telomeres so they are recognized as DNA damage. Additional, perhaps more potent nucleoside analogs will be the new direction for targeting the cell immortality cancer hallmark.

Summary

Telomeres are protective structures that are found at the ends of linear chromosomes. Telomeres shorten with each cell division owing to the end replication problem. However, telomerase maintenance mechanisms can counteract this progressive shortening process. While most normal cells do not express telomerase activity, it is detected in almost all primary human tumors. Therefore, telomerase is a unique and almost universal target for cancer.

Although there have been promising approaches targeting telomerase for cancer therapies, there are no drugs that have been approved. G-quadruplex stabilizers that target the G-rich DNA sequences in human telomeres cause telomerase inhibition and telomeric end disruption. However, the specificity of these compounds is very limited and may affect quadruplex structures in normal cells as well as cancer cells.

Immunotherapy approaches in clinical trials utilize hTERT GV1001 (peptide vaccine) and GRNVAC1 (dendritic cell priming *ex vivo*). The utility of these vaccines in combination with conventional therapy may be limited owing to immunosuppressive effect of chemotherapeutic drugs.

GRN163L (Imetelstat) is a telomerase-targeted oligonucleotide approach. GRN163L shows highly potent telomerase inhibition, resulting in progressive telomere shortening in cancer cells. Owing to adverse hematological events, clinical trials in solid tumors have not progressed. One of the potential challenges for GRN163L is the response (long lag) time that is needed to induce senescence/apoptosis.

Gene therapy is a well-established technique that targets cancer by delivering therapeutic DNA. Mutant hTERT (dominant-negative approach) or siRNA directed at hTERT are some of the different gene therapy approaches in preclinical studies. In addition, introduction of a mutant hTERC via lentiviral transfer is a telomerase-dependent telomere “upcapping” approach. Gene therapy is a promising anticancer therapy approach but requires high efficiency to target the vast majority of cancer cells.

Typical telomerase inhibitors (GRN163L) require a long lag period between enzyme inhibition and

biological effect. In contrast, telomerase-mediated telomere-targeted therapy is predicted to have a much shorter lag period. One example is 6-thio-dG, a nucleoside analog. 6-thio-dG is a new approach to target telomeres, is preferentially recognized by telomerase and incorporated into telomeres resulting in TIFs. This small-molecule approach results in short-term cell killing effects on telomerase-expressing cells (short lag time) with minimal effects on telomerase silent normal cells (e.g., quiescent stem cells).

Chapter 15

Cancer metabolism

Natalya N. Pavlova, PhD ■ Craig B. Thompson, MD

Overview

Successful cell proliferation is dependent on a profound remodeling of cellular metabolism, required to support the biosynthetic needs of a growing cell. Constitutive signaling through aberrantly activated oncogenes activates pro-growth metabolic circuits that can lock cancer cells into net macromolecular synthesis and resistance to cell death. Oncogenic signaling can induce cellular uptake of metabolic substrates, such as glucose and glutamine, as well as utilization of unconventional nutrient sources. In contrast to nonproliferating tissues, which preferentially oxidize acquired metabolic substrates in mitochondria to fuel the oxidative phosphorylation and energy production, cancer cells prioritize the use of acquired metabolic substrates in anabolic processes, including fatty acid, cholesterol, nonessential amino acid, and nucleotide biosynthesis. The accumulation of these precursors supports the synthesis of the macromolecules necessary to sustain cell growth. Oncogene-directed increases in levels of select metabolites can also influence cellular processes beyond metabolic circuits, resulting in changes to the cellular epigenetic state as well as long-ranging effects on cells within the tumor microenvironment. Recent studies suggest these alterations in tumor cell metabolism can be exploited to improve the diagnosis and treatment of a wide variety of cancers.

Malicious builders

A unifying characteristic of cancer is loss of extrinsic controls over cell proliferation. In normal tissues, the quantities of cells, as well as their relative positions, are maintained by extracellular signaling, which include tissue-specific soluble growth factors as well as signals from the extracellular matrix to which cells adhere. Together, these mechanisms control the timing and the extent of cell survival and proliferation. Basal level of signaling enables day-to-day tissue maintenance, while the upregulation of growth signaling in response to tissue perturbations leads to enhanced production of terminally differentiated cells—for instance, epidermal keratinocytes and dermal fibroblasts in a setting of a cutaneous injury, or T cells in response to infection. In this manner, cell proliferation only takes place in response to a cell-type-specific signal of a sufficient strength and duration, which ensures that the overall structural and biochemical integrity of a metazoan organism is maintained.

In contrast to normal cells, genetic and epigenetic alterations acquired by cancer cells allow them to accumulate within tissues in a manner that is independent of extrinsic growth stimuli, at the same time becoming resistant to antigrowth signals.¹ Together, these adaptations enable survival and proliferation of cancer cells in settings where normal cell proliferation is strictly regimented. Mutations, copy number amplifications, and translocations targeting growth factor receptors are among the most frequently seen growth-promoting genetic alterations in tumors and are thus termed “driver alterations.” For example, activating mutations in EGFR (epidermal growth factor receptor) are found in 10% of nonsmall cell lung carcinoma in United States and up to 35% in Japan,² and amplifications of HER2 are found in 25–30% of

breast carcinomas.³ In addition to growth factor receptors, downstream integrators of growth factor and matrix attachment signals are often aberrantly activated in cancer as well: for instance, up to 70% of breast cancers have mutations in the PI-3 kinase pathway,⁴ up to 90% of pancreatic tumors are driven by activating mutations in KRAS,⁵ and amplification of c-Myc is seen in up to 50% of human cancers regardless of tissue of origin.⁶

A cell that had received a proper growth signal commits to creating two daughter cells. To accomplish this, it must synthesize a complete set of biomolecules sufficient to build a new, functional cell. This set of biomolecules is extremely diverse and includes not only a vast array of proteins, but also lipids and their derivatives for building plasma and organelle membranes, hexose sugars for glycosylation of proteins, as well as pentose sugars and nucleotide bases for genome replication. To ensure that a cell does not attempt to replicate itself without having ample supply of biomolecules, the same signals that control proliferation are in control of nutrient uptake and the biosynthesis of macromolecular precursors. Thus, a growth-factor-stimulated cell undergoes remodeling of its metabolism in order to support the required biosynthesis. First, this remodeling involves acquiring a sufficient amount of building materials from the surrounding environment. Second, a proliferating cell must prioritize the use of these materials for biosynthesis, as opposed to catabolizing them for energy.

Key Points

Constitutive signaling via aberrantly activated oncogenes allows cancer cells to perpetually receive pro-growth stimuli, which for normal tissues are only transient in nature. As a consequence, cancer metabolism is constitutively geared toward supporting proliferation.

This chapter will describe the mechanisms of how oncogenic transformation reshapes cellular metabolism toward nutrient acquisition and biosynthesis. Furthermore, this chapter will demonstrate how altered metabolic state of cancer cells, in turn, exerts profound effects on cellular epigenetic state and on tumor microenvironment, driving tumor expansion and dissemination. To this end, we will explore how alterations in tumor metabolism can be exploited in cancer detection and therapy.

From yeast to mammals—same means to different ends

Metabolic pathways and enzymes that drive their progression are remarkably conserved throughout evolution, yet the way the metabolism of metazoan cells is regulated is fundamentally distinct from unicellular organisms. Unicellular organisms, such as bacteria or yeast, use external nutrient abundance as a signal to begin proliferating.⁷ By attuning their proliferation to the environmental conditions, this strategy allows them to maximize their evolutionary success. For a metazoan organism, on the other hand, an evolutionary goal is not to multiply its cells to no end—which would lead to a physiologic chaos—but to maintain the functionality and structural integrity of its organs and tissues, repair injuries, and fight infections. To serve this goal, metazoans have developed complex and tissue-specific control mechanisms, which regulate cell survival and proliferation, yet allow for rapid induction of proliferation of specific cell populations when needed. Accordingly, the pro-proliferative metabolic state of cancer cells, driven by the loss of tissue-specific control mechanisms, can be best understood by first examining the differences in metabolic regulation in metazoans and in unicellular eukaryotes.

Metabolism of living cells is centered on the acquisition and stepwise biochemical transformation of molecules, which consist of reduced carbon and nitrogen. Glucose is a major metabolic substrate that can be utilized by all living cells as a source of (1) bioenergetic equivalents in a form of high-energy phosphate bonds of adenosine triphosphate (ATP) and (2) carbon building blocks, which can be used to produce a variety of biomolecules. One key chemical constituent that a glucose molecule does not provide is nitrogen. Nitrogen is required for the biosynthesis of amino acids and nucleotide bases, thus, an access to a source of reduced nitrogen is critical for both unicellular eukaryotes and metazoans. Although some bacteria can reduce atmospheric nitrogen to ammonia, most species must acquire a reduced form of nitrogen from the environment. Unicellular organisms can use free ammonia (NH_4^+) as a source of reduced nitrogen. For example, a wild-type, or prototrophic, yeast culture can proliferate in a so-called synthetic complete medium, which consists purely of glucose as a sole carbon source and ammonia as a sole nitrogen source. A yeast cell has all metabolic enzymes to synthesize a complete spectrum of biomolecules from the materials provided.

Metazoan organisms rely on glucose as a preferred carbon source and amino acids as the primary source of reduced nitrogen. In contrast to unicellular organisms, metazoans have lost the ability to synthesize 9 out of 20 amino acids required for protein synthesis (these nine amino acids are termed “essential,” while the rest are termed “nonessential”). The amino acid glutamine, a carrier of two nitrogen atoms, is the predominant “nitrogen currency” for metazoan organisms. Because of its special importance as a reduced nitrogen source, glutamine is a “conditionally essential” amino acid for most proliferating metazoan cells.⁸

The significance of glucose and glutamine as key metabolic substrates for metazoan cells can be illustrated by the fact that in a mammalian organism, nearly constant levels of these two nutrients are maintained in plasma at all times: glucose levels are within the range of 4–6 mM and glutamine, the most abundant amino acid in plasma, ranges within 0.6–0.9 mM.⁹ These steady levels of glucose and glutamine are maintained by a combination of hormone-mediated utilization of glycogen stores in muscle and liver, *de novo* synthesis of glutamine and glucose, as well as the stimulation of feeding behavior.

Unicellular organisms do not have steady levels of carbon and nitrogen sources around them at all times. Instead, they rely on nutrient sensing mechanisms to assess the availability of nutrients in their environment. In yeast, for instance, glucose limitation leads to Snf1 kinase [a homolog of adenosine monophosphate (AMP)-activated protein kinase (AMPK) in mammalian cells] activation, which promotes energy production and suppresses biosynthetic processes.¹⁰ Addition of glucose to a yeast culture triggers a shift toward biosynthetic metabolism and proliferation.^{11, 12} When glucose is abundant, Ras1 and Ras2 GTPases, homologs of the mammalian RAS protein family, become active and promote cell cycle progression. Another signaling mediator downstream of glucose is Sch9 kinase, which is related to Akt and S6 kinases in mammals and plays a role in promoting the use of glucose for biosynthetic processes.¹³ Concurrently, the amino acid status of a yeast cell is measured through Gcn2 serine/threonine kinase, which is homologous to mammalian GCN2. Gcn2 is activated by uncharged tRNA, which accumulates in cells when amino acid levels are insufficient. Activated Gcn2, in turn, inhibits protein translation rates and induces Gcn4 (ATF4 in mammals), a transcription factor that controls expression of a number of enzymes involved in *de novo* synthesis of amino acids.¹⁴ In the absence of glucose, however, active Snf1 represses Gcn4 expression, thus coordinating the metabolism of nitrogen and carbon.¹⁵ As intracellular amino acid levels rise, they, in turn, activate TOR1/2 (mTOR in mammalian cells), which acts as a coordinator of a number of anabolic processes, including protein translation and biosynthesis of fatty acids. If nutrient sources remain plentiful, cell growth is converted into cell division and the process is repeated until the extracellular nutrient supply falls below the

necessary threshold.

Cells within a metazoan organism are surrounded by ample glucose and glutamine in plasma and interstitial fluid, yet in contrast to yeast, they do not proliferate unless a proper extrinsic growth signal is present. First of all, the very access of cells to the extracellular pools of glucose and glutamine is controlled by receptor tyrosine kinases, proteins that are absent in unicellular eukaryotes. We now appreciate that stimulation by a cytokine or a growth factor, for example, directs a cell to take up nutrients, providing it with a supply chain of metabolic substrates. To this end, signals from receptor tyrosine kinases converge on PI-3 kinase/Akt, activation of which triggers rapid translocation of glucose transporters (GLUTs) from the cytosol-localized endosomal vesicles to the plasma membrane,^{16, 17} as well as stimulates GLUT gene expression,¹⁸ driving the entry of glucose into cells. In illustration of this paradigm, PI-3 kinase/Akt signaling facilitates glucose uptake by populations of cells that are induced to undergo proliferative expansion, for example, activated T cells mounting an immune response,¹⁹ or those induced to synthesize massive amounts of macromolecules, such as milk-producing cells of the mammary gland during lactation.²⁰

In addition to effects on glucose transport, growth-factor-stimulated mammalian cells rapidly induce transcription of a set of immediate-early genes, one of which is the transcription factor c-Myc. C-Myc drives expression of a large set of metabolic genes and plays a role as a gatekeeper of cellular access to glutamine—the major metazoan source of nitrogen.²¹ To this end, c-Myc facilitates the expression of glutamine transporters, ASCT2 and SN2,²² as well as a glutaminase enzyme, GLS1, which catalyzes the breakdown of glutamine to glutamate and free ammonia.²³ Through facilitation of glutamine acquisition, c-Myc also indirectly influences the uptake of essential amino acids by the cell. Essential amino acid transport into cells is coupled to the efflux of glutamine into the extracellular space.²⁴ This mechanism allows cells to coordinate the import of essential amino acids to intracellular glutamine status.

Besides signals from receptor tyrosine kinases, cellular anchorage to the extracellular matrix is also needed to facilitate glucose uptake. Glucose consumption is suppressed in cells that are deprived of the matrix attachment even in the presence of soluble growth factors.²⁵ This ensures that not only proliferation, but also positions of cells within the tissue are controlled on a metabolic level.

Taken together, pro-growth signaling through receptor tyrosine kinases has emerged as a control point for nutrient acquisition. Although conserved from yeast to mammals, mammalian RAS is no longer governed by glucose abundance, but by tissue-specific receptors. Similarly, mammalian TOR, while retaining its sensitivity to amino acid levels, have been harnessed by growth signaling control via Akt-dependent phosphorylation and inactivation of TSC2, a negative regulator of mTOR. Next, we will next examine how genetic alterations in growth signaling pathways influence the nutrient uptake in cancer cells.

Key Points

Nutrient abundance is sufficient to stimulate proliferation of unicellular organisms, but not of metazoan cells, which has relegated the control over the ability to access nutrients around them to extrinsic growth stimuli.

Bad table manners of cancer cells

Discovery of the fundamental differences in rates of nutrient uptake between tumors and nontransformed tissues was among the earliest in modern cancer research, predating the discovery of the oncogenes and the role of carcinogens in tumorigenesis. In the 1920s, biochemical characterization of cancer cells from peritoneal ascites and slices of normal, nonproliferating tissues by German physiologist Otto Warburg revealed that the rate of consumption of glucose by tumors far exceeds that of normal tissues.²⁶ Some 30 years later, American pathologist Harry Eagle showed that glutamine requirements of HeLa cells in culture exceed the needs for other amino acids by 10- to a 100-fold, far surpassing the quantity needed for protein synthesis.²⁷

On a signaling level, cellular glucose uptake is controlled through PI-3 kinase/Akt, which targets GLUTs to plasma membrane, as well as promotes their expression on a transcriptional level.¹⁷ Thus, cancer-specific alterations in PI-3 kinase/Akt signaling allow cancer cells to consume glucose constitutively. Activated RAS and c-Src can promote GLUT1 expression as well.²⁸ To match the supply of carbon with a supply of nitrogen, tumor cells concurrently increase their uptake of glutamine. As described previously, the key driver of glutamine uptake and utilization in mammalian cells is c-Myc.^{22, 29} With c-Myc levels aberrantly elevated, cancer cells continuously import and utilize available glutamine for bioenergetic support, nucleotide biosynthesis, and to coordinate essential amino acid uptake and nonessential amino acid biosynthesis in support of protein production.

Tumors originate within the confines of a normal tissue, which is not suited to sustain uncontrolled cellular proliferation. Thus, tumors often lack adequate vasculature, as *de novo* angiogenesis within tissues is negatively regulated by tissue-specific factors.³⁰ Capillaries that do form in response to tumor-secreted pro-angiogenic molecules tend to be underdeveloped and inefficient in delivering oxygen and nutrients to a growing tumor. As proliferation of cancer cells depletes the microenvironment around them of amino acids and glucose, growing tumors face increasingly unfavorable conditions for proliferation. One adaptation that cancer cells use to withstand nutrient limitations is *autophagy*—a regulated process of self-catabolism of proteins, lipids, and even whole organelles as a temporary means of sustaining viability during starvation.³¹ A major cellular bioenergetic sensor, AMPK, initiates the process of autophagy in response to falling ATP/AMP levels, whereas mTOR, on the other hand, acts as an autophagy inhibitor.³² The significance of autophagy for tumor growth *in vivo* has been demonstrated in mutant Kras^{G12D} and Braf^{V600E}-driven lung tumors, in which the genetic knockout of the autophagy machinery component Atg7 dramatically limits tumor cell accumulation and aggressiveness.^{33, 34}

Although autophagy can serve as a temporary means to survive nutrient shortages and maintain cellular bioenergetics, it cannot be used as a source of new biomass. In addition to intracellular proteins, KRAS- and c-Src-transformed cells have been recently shown to recover amino acids from proteins dissolved in extracellular fluid, which are consumed via large (up to 1–2 μm in diameter) vesicles at sites of plasma membrane ruffling.³⁵ These vesicles are called macropinosomes (from latin *pino*—“to drink”). Under conditions of nutrient depletion, macropinosomes are targeted to lysosomes, where engulfed cargo is degraded. This alternative, “scavenging” form of nutrient uptake allows cells to survive amino acid limitations by unlocking otherwise inaccessible amino acid stores. RAS-driven macropinocytosis is an evolutionarily ancient mechanism of acquiring nutrients. In fact, it can be a primary pathway of nutrient acquisition in slime molds, such as *Dictyostelium*.³⁶ Thus, reactivation of macropinocytosis in oncogene-transformed cells can be viewed as yet another example of how cancer cells utilize evolutionarily ancient mechanisms of nutrient uptake.

Another problem that stems from the inadequacies of tumor vasculature is reduced supply of oxygen, or hypoxia. Lack of sufficient oxygen has a profound effect on cellular metabolism as it inhibits those

biochemical reactions in which oxygen is consumed. One reaction that becomes inhibited in hypoxic conditions is stearoyl-CoA desaturase 1 (SCD1)-catalyzed desaturation of fatty acid carbon bonds to create unsaturated fatty acids, which are essential for proper fluidity of plasma and organelle membranes. To circumvent this problem, Ras-transformed cells were shown to be able to bypass the need for SCD1-catalyzed desaturation reaction by scavenging unsaturated lipids from the extracellular environment.³⁷

Key Points

Oncogene signaling allows cancer cells to use conventional metabolic sources, glucose and glutamine, in an unrestricted manner, as well as enables cells to access unconventional sources of biomolecules.

The traveling electrons

Most biochemical reactions within living cells are energetically unfavorable and require catalysis by specific metabolic enzymes. Metabolic reactions can be divided into two types: (1) *catabolic*—in which complex biochemical substrates are degraded to simpler constituents and (2) *anabolic*—in which complex biomolecules, such as amino acids, fatty acids, and nucleotides, are produced from simpler constituents. Catabolic processes involve reactions in which substrates undergo oxidation. Electrons derived from these oxidative steps are captured in a form of hydride anions (:H^-), which are carried by specialized enzyme cofactors NAD^+ and FAD (NADH and FADH_2 in their reduced forms), or NADP^+ (NADPH in its reduced form). The chemical energy of electrons from NADH and FADH_2 is then utilized by a series of enzyme complexes of the *electron transport chain*, which is located at the inner membrane of mitochondria. $\text{NADH}/\text{FADH}_2$ -derived electrons travel down the electron transport chain until they react with oxygen to produce water. The chemical energy of electrons that are being passed along the electron transport chain is used to create a proton gradient between the mitochondrial matrix and the mitochondrial intermembrane space. The resulting build-up of electrochemical potential across the inner mitochondrial membrane, in turn, fuels the activity of ATP synthase, a supramolecular complex that regenerates high-energy phosphate bonds of ATP from ADP. The coupling of electron transport to ADP conversion to ATP is termed *oxidative phosphorylation*.

In living cells, the ratio of ATP to ADP provides the thermodynamic driving force for a myriad of energetically unfavorable cellular processes, as well as for protein and lipid phosphorylation by kinases—a versatile mode of regulating functions of a variety of proteins and transmitting signals within a cell.

The maintenance of an electrochemical proton gradient through the electron transport chain is dependent on the availability of oxygen—the terminal acceptor of electrons, and ADP—a substrate for the ATP synthase. An excessive influx of electrons from $\text{NADH}/\text{FADH}_2$ can deplete the supply of either of these, stopping the oxidative phosphorylation. Consequently, electrons that become stalled in the electron transport chain can be lost over time from their intramembrane carriers, reacting with the aqueous environment of the cell to produce reactive oxygen species (ROS). ROS are avid oxidants, which readily react with a wide spectrum of biomolecules—including lipids, proteins, and nucleotides. To control their redox state, cells produce a variety of ROS-neutralizing molecules, or antioxidants. However, when ROS become elevated beyond the cellular antioxidant capacity, they can cause widespread damage to cellular organelles and DNA.

As noted previously, most catabolic reactions couple the oxidation of their substrates to the reduction of NAD⁺ and FAD to NADH and FADH₂. In contrast, a few metabolic reactions result in a transfer of electrons to a structurally related cofactor, NADP⁺, reducing it to NADPH. Whereas NADH and FADH₂ are mainly used for energy production, NADPH replenishes the cellular antioxidant pool by sustaining the reduced state of glutathione and related sulfhydryl-containing molecules. In addition, the reducing power of NADPH is used in biosynthesis of complex biomolecules, such as fatty acids and nucleotides, which require sequences of reductive reactions. How does a cell choose to prioritize one class of such reactions over others? As it turns out, the allocation of substrates into processes that support bioenergetics versus those with biosynthetic outcomes is coordinated by many of the same pro-growth signals that promote the uptake of biochemical substrates by cells in the first place.

Key Points

A living cell maintains its viability by oxidizing biochemical substrates acquired from the environment. Catabolic reactions produce simple building blocks, which can be consecutively utilized in biosynthetic reactions. In addition, catabolic reactions serve as sources of reducing power to fuel cellular energy production, enable biosynthetic reactions, and bolster the antioxidant defense.

Warburg effect—how to play safe while looking sloppy

Glucose catabolism takes place in two cellular compartments: its first stage, glycolysis, occurs in the cytosol, while the second stage is localized to mitochondria and involves a series of reactions of the tricarboxylic acid cycle (TCA cycle, which is also called citric acid or Krebs cycle). Phosphorylation of glucose by a hexokinase (HK) to produce glucose 6-phosphate is the first committed step of glycolysis ([Figure 1a](#)). The HK reaction prevents the exit of glucose back into the extracellular space. A second committed step of glycolysis is an irreversible phosphorylation catalyzed by phosphofructokinase enzyme (PFK1). Along with targeting the GLUT1 transporter to the plasma membrane, Akt potentiates the action of both HK³⁸ and PFK1,³⁹ thus acting as a coordinator of glucose progression through glycolysis. In fact, the ability of Akt to suppress apoptosis in response to growth factor withdrawal is dependent on glucose;⁴⁰ moreover, overexpression of GLUT1 and HK alone is sufficient to suppress growth factor withdrawal-induced cell death.³⁹ PFK1 activity in cancer cells is further enhanced by frequent overexpression of PFKFB3,⁴¹ an enzyme that produces fructose 2,6-bisphosphate, an allosteric activator of PFK1.

Quiescence

Proliferation

Figure 1 Glycolysis. (a) Catabolism of one glucose molecule via glycolysis yields two molecules of pyruvate, which can then be transported to the mitochondria and used as a source of acetyl-CoA for the TCA cycle. Alternatively, pyruvate can be reduced to lactate and excreted out of the cell. Besides its bioenergetic uses, glycolysis also provides biosynthetic power to cells. Glucose-6-phosphate can be utilized in the PPP to generate NADPH and ribose 5-phosphate for nucleotide biosynthesis; or, its intermediates can be shunted back into glycolysis (shown by gray dashed arrows). In addition, 3-phosphoglycerate can be converted to serine, a carbon donor for the folate (one-carbon) cycle. Folate cycle generates NADPH, as well as provides one-carbon units for the biosynthesis of nucleotide bases and for methylation reactions. GLUT, glucose transporter, HK, hexokinase, PFK1, phosphofructokinase 1, PKM2, pyruvate kinase M2, LDH-A, lactate dehydrogenase A, MCT, monocarboxylate transporter, OxPhos, oxidative phosphorylation. (b) Quiescent cells consume moderate amount of glucose and preferentially catabolize it to pyruvate to fuel oxidative phosphorylation in mitochondria. In proliferating cells, growth factor signaling or constitutively active oncogenes facilitate the increase in glucose uptake. In contrast to a quiescent cell, the majority of glucose consumed by a growth-stimulated cell goes into biosynthetic pathways to produce nucleotides, amino acids, and lipids—or is expelled as lactate.

Downstream of glucose capture and degradation, the various intermediates of glycolysis and the TCA cycle provide the backbones of essentially all the amino acids, acyl groups, and nucleotides a cell can synthesize *de novo* to support macromolecular synthesis. When it was discovered that oncogenic mutations resulted in flooding the cell with glucose that can maintain a supply of these precursors, it became clear why the Warburg effect was selected for during tumorigenesis. A cell engaged in excessive glucose uptake becomes resistant to apoptosis, has virtually unlimited supply of macromolecular precursors, and simply secretes any carbon in excess of its needs by converting the end product of glycolysis, pyruvate, into lactate, which is expelled from the cell. This form of gluttony exhibited by tumors harboring mutations that increase glucose uptake became known as *aerobic glycolysis*—to distinguish it from the well-established increase in glucose uptake exhibited by normal cells when depleted of oxygen, or *anaerobic glycolysis*.

Recently, it has been shown that aerobic glycolysis is not restricted to tumor cells. When stimulated with growth factors, normal cells too, begin to display Warburg-like metabolism.⁴² The discovery that the Warburg effect is a growth-factor-driven phenomenon and not a peculiar “abnormality” of cancer cells warranted exploring whether it may be in fact, a part of a metabolic reprogramming aimed at increasing the cellular capacity for biosynthesis. Thus, it is now becoming appreciated that maximization of the bioenergetic yield from glucose catabolism would run contrary to the biosynthetic priorities of a growth-factor-stimulated cell.⁴³

How can glycolysis help biosynthesis? There are several ways through which glycolytic intermediates can act as substrates for producing both biosynthetic precursors and NADPH (Figure 1a). One such pathway is the *pentose phosphate pathway (PPP)*, which begins with glucose 6-phosphate. Glucose 6-phosphate is oxidized to produce two NADPH molecules, and after a series of interconversions, it produces ribose 5-phosphate—a structural component of nucleotides. Significantly, the PPP enzyme transketolase-like 1 (TKTL1) is required for growth of a number of cancer cell lines and is predictive of poor prognosis in patients.⁴⁴

Another key branch point of glycolysis is at the level of 3-phosphoglycerate. In a series of three consecutive reactions, 3-phosphoglycerate is converted to the amino acid serine. As metabolic studies demonstrate, serine biosynthesis is massively upregulated in tumors beyond the amount necessary for protein biosynthesis.⁴⁵ Moreover, PHGDH gene, encoding the enzyme that catalyzes the limiting step in serine biosynthesis, is frequently amplified in breast cancer and in melanoma, predicts tumor

aggressiveness and is required for tumor growth *in vivo*.^{46, 47} Why do tumors produce so much serine? Serine is not only used as a building block in protein translation, but is also a key substrate in a so-called *one-carbon*, or *folate cycle*, where a serine-donated carbon is passed on to a tetrahydrofolate (THF) molecule. The folate cycle involves a complex series of oxidative–reductive transformations, which involve serine-donated methyl group, and is indispensable for a number of processes that affect cellular growth and proliferation.⁴⁸ In particular, serine-derived carbon is used as (1) a carbon donor for purine synthesis; (2) a donor of methyl groups onto S-adenosylmethionine (SAM), a substrate for histone and DNA methyltransferase enzymes, and (3) a donor of reducing power for the production of NADPH. As a recent study has demonstrated, up to 50% of all cellular NADPH may be generated via one-carbon pathway.⁴⁹ Taken together, diversion of glycolytic intermediates into the pentose phosphate shunt and into the serine biosynthesis pathway both provide building blocks for nucleotide generation as well as produce NADPH.

How does a cell regulate the rate at which glycolytic intermediates are diverted into biosynthetic pathways? Exploration of the interplay between growth factor signaling pathways and metabolism have led to a seminal discovery that has shed light on this question. Specifically, tumor cells express an M2 splice variant of pyruvate kinase M (called PKM2), while their normal counterparts preferentially express the M1 variant.⁵⁰ Pyruvate kinase is a rate-limiting enzyme that catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate ([Figure 1a](#)). Intriguingly, the PKM2 isoform is a less active form of pyruvate kinase than PKM1. Moreover, PKM2, but not PKM1, is susceptible to further inhibition via binding to phosphorylated tyrosine residues through its unique C-terminal sequence.⁵¹ Thus, the activity of PKM2 becomes dampened even further in response to increased tyrosine kinase signaling. Replacement of PKM2 with a PKM1 isoform reduces the tumorigenic potential of cancer cells, promotes oxygen consumption, and inhibits production of lactate.⁵⁰ The lower rate of catalysis by PKM2 creates a “traffic jam” at the level of PEP, facilitating the entry of accumulated glycolytic intermediates into the two pathways described previously.⁵² Reciprocally, products downstream of both PPP (succinylaminoimidazolecarboxamide ribose 5'-phosphate or SAICAR)⁵³ and serine biosynthetic pathway (serine itself)⁵⁴ act as allosteric activators of PKM2, which allows a cell to balance the biosynthetic and bioenergetic uses of glycolysis. Besides its function as a gatekeeper of glycolysis, PKM2 also promotes glucose utilization at the level of gene expression. Thus, in EGF-treated cells, PKM2 becomes phosphorylated by Erk1/2 and is translocated to the nucleus, where it directly controls expression of GLUT1 and lactate dehydrogenase A (LDH-A) genes, further contributing to the Warburg effect.⁵⁵

Increased glycolytic flux allows the growing cell to dynamically regulate the production of diverse biosynthetic intermediates, at the same time secreting any surplus of carbon out of the cell in the form of lactate ([Figure 1b](#)). The previous findings help explain why growth signaling enhances glucose consumption and its entry into glycolysis, but why is glycolysis-derived pyruvate preferentially converted to lactate as opposed to entering the TCA cycle? One explanation of this phenomenon is that a cell with a high rate of glucose consumption must safeguard itself against the overproduction of NADH/FADH₂ in the TCA cycle.⁵⁶ Indeed, a surplus of electron donors would quickly deplete available ADP, overload the electron transport chain, and overproduce ROS. To prevent this from happening, both NADH and ATP act as allosteric inhibitors of the mitochondrial gatekeeper enzyme PDH, attenuating the production of acetyl-coenzyme A (CoA) from pyruvate and ensuring that the electron transport chain does not produce more ATP than a cell can use at the moment.

Besides being allosterically controlled by ATP and NADH, PDH is also negatively regulated via phosphorylation by pyruvate dehydrogenase kinase 1 (PDK1). Expression of PDK1 is induced when cellular production of electron donors for the electron transport chain exceeds the amount that can be

assimilated by the available oxygen. Specifically, PDK1 transcription is upregulated by HIF1 α , a transcription factor induced under these conditions.^{57, 58} Concurrently, HIF1 α activates transcription of LDH-A, re-routing the flux of carbon away from the TCA cycle and toward lactate production.⁵⁹ Even though HIF1 α is classically activated by oxygen deficit, transformed cells exhibiting excess glycolysis induce HIF1 α even in normoxic conditions.⁶⁰ Nor is HIF1 α the only transcriptional activator of PDK1. Indeed, another commonly activated pathway in cancer, the Wnt/ β -catenin pathway, has been shown to promote the Warburg effect by upregulating the expression of PDK1, as well as the lactate transporter MCT1.⁶¹

A damaging effect of an unrestricted pyruvate catabolism has been recently proposed as a metabolic mechanism of oncogene-induced senescence (OIS). OIS is a phenomenon in which overexpression of mutant oncogenes, such as RAS or BRAF, triggers growth arrest, overproduction of ROS, and DNA damage response.⁶² Interestingly, the onset of OIS is dependent on PDH activity. To this end, the modulation of the PDH activity by expressing PDK1 or inhibiting PDH phosphatase PDP2 was found to facilitate cellular escape from OIS.⁶³

A decade ago, it was discovered that the role of mitochondria in the successful evolution of the eukaryotic cells depended more on their contributions to macromolecular biosynthesis than to ATP production. In an evolutionary sense, mitochondria became essential organelles because they supplied a variety of precursors for biosynthetic reactions. In what is referred to as *cataplerosis*, TCA cycle intermediates exit the mitochondria to be used as precursors for a variety of anabolic reactions—including biosynthesis of sugars, nonessential amino acids, and fatty acids. In addition, mitochondria support the synthesis of iron–sulfur (Fe–S) clusters, which are central for the function of a variety of mitochondrial as well as cytosolic enzymes.

Cytosol-localized biosynthesis of fatty acids and cholesterol is particularly essential for proliferating cells. A universal precursor for fatty acid and cholesterol biosynthesis is acetyl-CoA, but because the bulky CoA cannot cross the mitochondrial membrane, a cell cannot directly access the mitochondrial pool of acetyl-CoA for use in biosynthetic reactions. Instead, the TCA intermediate citrate is shuttled out of the mitochondria and into the cytosol, where it is cleaved by ATP-citrate lyase (ACL), regenerating acetyl-CoA ([Figure 2](#)). ACL is essential for tumorigenesis, and its inhibition suppresses tumor growth in mice.^{64, 65} Notably, ACL enzyme becomes activated following Akt induction,⁶⁶ so that Akt not only enables glucose uptake and catabolism, but also diverts carbon flux away from mitochondria and toward fatty acid biosynthesis.

Figure 2 Carbon metabolism in mitochondria. Glycolysis-derived pyruvate serves as a donor of acetyl-CoA for the tricarboxylic acid (TCA) cycle. Cataplerotic efflux of citrate into the cytosol (shown by a maroon arrow) allows maintaining the extramitochondrial pool of acetyl-CoA for fatty acid and cholesterol biosynthesis. Glutamine and pyruvate function as anaplerotic substrates to restock the TCA cycle intermediates (shown by solid green arrows). In conditions when acetyl-CoA is limiting, citrate can be produced from the reductive carboxylation of glutamine-derived α -ketoglutarate (shown by dashed green arrows). Pink circles represent a number of carbon atoms in a molecule. GLUT, glucose transporter, PDH, pyruvate dehydrogenase, PC, pyruvate carboxylase, IDH, isocitrate dehydrogenase, SDH, succinate dehydrogenase, FH, fumarate hydratase, ACL, ATP-citrate lyase, GLS1, glutaminase, ASCT2, glutamine transporter.

Key Points

Pro-growth signals facilitate the uptake of glucose and remodel the glycolytic flux to satisfy the increased biosynthetic demands of a growing cell.

The cavalry arrives!—glutamine and anabolic metabolism

As described previously, besides glucose, many cancer cells (as well as normal cells that have received a signal to proliferate) avidly consume glutamine. Glutamine uptake and its hydrolysis to glutamate, termed *glutaminolysis*, are coordinated by the transcription factor c-Myc; in fact, amplification of c-Myc was shown to make cells critically dependent on glutamine supply. Why is glutamine so essential for dividing cells? First, the carbon skeleton of glutamine is used to restock the TCA cycle when its intermediates exit the mitochondria to participate in anabolic synthesis. Because proliferating cells continuously borrow TCA cycle intermediates, such as citrate, to support biosynthesis, cataplerotic processes must be balanced by the influx of carbons elsewhere in the cycle in a process termed *anaplerosis*. Two major anaplerotic inputs have been described: one is via glutamine-derived α -ketoglutarate and another is via pyruvate carboxylase (PC)-catalyzed carboxylation of pyruvate into oxaloacetate ([Figure 2](#)). Though glutamine is a preferential anaplerotic substrate in cancer cells, cells with high PC activity can use a PC-derived oxaloacetate to survive glutamine deprivation or glutaminase suppression.⁶⁷ In addition, besides replenishing the TCA cycle, glutamine-derived α -ketoglutarate can exit the TCA cycle halfway in the form of malate and become oxidized by malic enzyme (ME) in the cytosol to produce NADPH.⁶⁸ Together, ME, PPP, and folate cycle produce virtually all of the cellular NADPH.

As discussed previously, the entry of glycolysis-derived pyruvate into the TCA cycle may be restricted by negative regulatory inputs into PDH—for example, as a result of upregulated HIF1 α or activation of Wnt signaling. This, however, creates a quandary—if pyruvate is diverted away from the TCA cycle by the coordinate inhibition of pyruvate dehydrogenase and activation of LDH-A and MCT, how can the TCA cycle produce enough citrate for biosynthesis? In fact, some cancer cells have found an unexpected solution to this problem by using glutamine-derived α -ketoglutarate to run a section of the TCA cycle in reverse, producing citrate for fatty acid biosynthesis in conditions where pyruvate-derived acetyl-CoA levels are limiting ([Figure 2](#)).^{69, 70}

Besides contributing its carbon skeleton to the TCA cycle, glutamine is a major donor of reduced nitrogen for cellular needs. Although its amine nitrogen is used primarily in nonessential amino acid biosynthesis, amide nitrogen of glutamine contributes to the biosynthesis of purine and pyrimidine bases. Thus, one molecule of glutamine is needed to build a thymine or a uracil, adenine and cytosine use two, and guanine synthesis requires three glutamine molecules. Notably, together with promoting glutamine uptake for synthesis of nucleotide bases, c-Myc also controls the expression of a number of nucleotide biosynthetic enzymes—namely, thymidylate synthase (TS), inosine monophosphate dehydrogenase 2 (IMPDH2), and phosphoribosyl pyrophosphate synthetase 2 (PRPS2), a rate-limiting enzyme in the biosynthesis of nucleotides.^{71, 72}

In conclusion, the notion that pro-growth signaling is a central facilitator of the acquisition and use of extracellular nutrients by metazoan cells has overturned a long-held view that cellular metabolic networks are self-regulating and exist independently from signaling inputs. However, metabolic circuits themselves are not merely passive recipients of cellular signals. In fact, a cell continuously monitors rising and falling levels of select metabolites and integrates this information so as to coordinate global decisions

including growth and differentiation.

Key Points

Glutamine fuels anabolic metabolism by serving as both a source of carbon to replenish the TCA cycle intermediates and maintain its biosynthetic capacity, as well as providing reduced nitrogen for the biosynthesis of nucleotides and nonessential amino acids.

The nucleus smells what's cooking

Metabolites are known to act as allosteric modulators of specific metabolic enzymes, providing regulatory feedback that allows a cell to adjust the output of its catabolic and anabolic reactions in response to fluctuations in metabolite levels. An example of such regulation is allosteric activation of glycolysis gatekeeper enzyme PKM2 by SAICAR and serine, products of two biosynthetic branches of glycolysis.

Notably, the signaling capacity of some metabolites extends far beyond the regulation of metabolic circuits. Thus, metabolites can act as cofactors or as substrates in a variety of nonmetabolic enzymatic reactions, and through changes in their abundance, convey a regulatory message to these processes.⁷³ Deposition and removal of epigenetic marks in particular is regulated by levels of select metabolites, allowing a cell to coordinately alter its gene expression programs in response to changes in its nutritional status.⁷⁴

Eukaryotic cell chromatin is composed of genomic DNA wrapped around histone octamers. To serve as a template for transcription, select loci within genomic DNA must be temporarily unwound and become accessible to the assembly of transcriptional complexes. The accessibility of genomic loci for transcription is regulated through deposition and removal of epigenetic marks on (1) DNA itself, by covalently attaching methyl groups to carbon 5 of cytosine bases, and (2) select amino acid residues of histones, to which a variety of chemical groups can be added. Acetyl and methyl residues are among the most versatile epigenetic marks that can be deposited on histones. Acetylation marks are predominantly associated with enhanced gene transcription and have a rapid turnover rate (in the order of minutes). Methylation marks have slower turnover rate and can be either activating or repressive, depending on the residue on which the mark is deposited. Combinations of epigenetic marks influence the general accessibility of DNA loci for transcription as well as guide the recruitment and assembly of transcription complexes, thus exerting profound effects on gene expression. Both acetyl and methyl epigenetic marks originate directly from products of metabolic reactions, acetyl-CoA and SAM, respectively. Thus, histone acetyltransferase enzymes deposit acetyl groups of acetyl-CoA onto lysine and arginine residues of histones, whereas SAM, a product of one-carbon (folate) cycle, provides methyl groups for both histone and DNA methyltransferases.

Using metabolic intermediates as precursors for epigenetic marks allows a cell to respond to its “fed” status with targeted upregulation of metabolic genes. As an example, targeted depletion of extramitochondrial acetyl-CoA through genetic repression of ACL profoundly affects histone acetylation patterns, resulting in attenuated expression of GLUTs, HK, PFK1, and LDH-A.⁷⁵ In this manner, by affecting histone acetylation, high levels of acetyl-CoA can promote the utilization of glucose and reinforce the Warburg effect.

Not only the deposition, but the removal of acetyl and methyl marks from histones is guided by the cellular metabolic status as well. Thus, sirtuin deacetylases, which catalyze the removal of acetyl groups from histones, as well as a variety of nonhistone proteins, use an oxidized form of NAD⁺ as a cofactor;⁷⁶ similarly, oxidized FAD serves as a cofactor for a histone demethylase LSD1.⁷⁷ By sensing a shift in NAD⁺/NADH ratio, sirtuins coordinate multiple genetic and post-translational changes aimed at maximizing energy conservation and extraction from metabolic substrates.

A whole host of enzymes—some of which are epigenetic regulators, while others are involved in post-translational modifications of nonhistone proteins—are regulated by the abundance of TCA cycle metabolites: α -ketoglutarate, succinate, and fumarate. Specifically, α -ketoglutarate acts as a cofactor for Jumonji C domain-containing family of histone demethylases, a TET family of methylcytosine hydroxylases, as well as prolyl hydroxylases, a class of enzymes that regulate HIF1 α levels, among other processes. In the course of reactions catalyzed by these enzymes, α -ketoglutarate itself is converted to succinate. Importantly, both succinate and its downstream product fumarate act as inhibitors of α -ketoglutarate-dependent enzymes.⁷⁸ In such a manner, changes in α -ketoglutarate abundance in relation to levels of succinate and fumarate may exert a broad influence on a variety of cellular processes. In fact, select tumor types take advantage of the signaling potential of TCA cycle metabolites by acquiring mutations in metabolic enzymes. These mutations, in turn, lead to unnatural elevations in levels of signaling-competent metabolites, which, in an analogy with oncogenes, are referred to as *oncometabolites*.⁷⁹

To date, three groups of metabolic enzymes have been found to be recurrently mutated in cancer. TCA cycle enzymes succinate dehydrogenase (SDH) and fumarate hydratase (FH) are targeted by loss-of-function mutations, leading to the accumulation of succinate and fumarate, respectively. Biallelic loss of SDH underlies the development of hereditary paragangliomas and pheochromocytomas,⁸⁰ and loss of FH is responsible for the rare familial cancer syndrome HLRCC (hereditary leiomyomatosis and renal cell cancer).⁸¹ Conversely, gain-of-function mutations in isocitrate dehydrogenases 1 and 2 (IDH1 and IDH2) are found in the majority of low-grade glioma cases, as well as in acute myelogenous leukemia (AML), chondrosarcoma, and cholangiosarcoma.^{82–85} Oncogenic mutations in IDH1 and IDH2 convey an unusual neomorphic function to the enzyme. Although the wild-type isocitrate dehydrogenase catalyzes a conversion of isocitrate to α -ketoglutarate, the mutant form reduces α -ketoglutarate to a D-enantiomer of 2-hydroxyglutarate.^{86, 87} Although D-2-hydroxyglutarate levels in cells are normally very low, IDH-mutant cells accumulate this metabolite to millimolar amounts, and owing to its structural similarity to α -ketoglutarate, D-2-hydroxyglutarate acts as a competitive inhibitor of α -ketoglutarate-dependent enzymes.⁸⁸

As many α -ketoglutarate-driven enzymes are involved in epigenetic remodeling, oncometabolite-driven tumors have profoundly altered epigenomes. For instance, SDH loss is associated with the increase in DNA methylation (a so-called hypermethylator phenotype) in SDH-driven paragangliomas as well as in sporadic gastrointestinal stromal tumors, a fraction of which harbors SDH mutations as well.^{89, 90} Similarly, mutant alleles of IDH1 and IDH2 are strongly associated with the hypermethylator phenotype in glioma and AML.^{91, 92} In AML in particular, IDH mutations are mutually exclusive with the loss-of-function mutations in methylcytosine hydroxylase TET2, further strengthening the mechanistic link between the two enzymes.⁹² In various cellular settings, introduction of mutant IDH, or treatment with D-2-hydroxyglutarate, was sufficient to trigger alterations in DNA and histone methylation and suppress cell differentiation.^{93, 94} Conversely, targeted inhibition of mutant IDH enzymes promoted differentiation in glioma and AML cell models.^{95, 96} Taken together, through global remodeling of DNA and histone

methylome, oncometabolites may contribute to tumorigenesis through locking cells in an undifferentiated state.

Key Points

Metabolic adaptations of cancer cells do not only facilitate macromolecular biosynthesis, but can also exert profound nonmetabolic effects on cellular fate.

From petty thieves to ringleaders—how cancer cells corrupt their neighbors

Even though composed of genetically stable cells, the tissue microenvironment in the vicinity of a tumor becomes profoundly altered during tumorigenesis. Most strikingly, its constituents—fibroblasts, endothelial cells, and components of innate and adaptive immunity—convert from being pro-homeostatic into active enablers of tumor growth.⁹⁷ Tumors use a variety of signals to corrupt normal cells, including secreted factors, cell–cell interactions, as well as changes in metabolite levels. Two prominent examples illustrating how altered tumor metabolism affects its microenvironment are discussed as follows.

Increased nutrient consumption by tumors is coupled to the secretion of large amounts of lactate into the extracellular fluid, which has wide-ranging effects on tumor microenvironment. Thus, lactate contributes to the induction of angiogenesis by stabilizing HIF1 α in endothelial cells⁹⁸ and potentiating pro-angiogenic NF- κ B and PI3-kinase signaling,^{99–101} as well as by promoting VEGF (vascular endothelial growth factor) secretion from macrophages.¹⁰² At the same time, lactate attenuates local antitumor immune responses by suppressing migration of monocytes¹⁰³ and activation of T cells and dendritic cells,^{104, 105} as well as affecting the polarization state and localization patterns of tumor-associated macrophages.^{106, 107} Tumor-associated macrophages can assume two functional subtypes: M1, which is associated with secretion of pro-inflammatory cytokines, and M2 subtype, which is involved in immunosuppression and wound repair. Tumor-associated macrophages are predominantly M2-polarized, and M2 subtype has been shown to be directly induced by lactate.¹⁰⁶ Finally, accumulation of lactate contributes to a decreased pH of the tumor extracellular fluid, which, in turn, promotes the activity of numerous matrix-degrading enzymes and promotes invasion.^{108, 109}

Another strategy used by cancer cells to attenuate antitumor immune responses is through the selective depletion of the amino acid tryptophan from their microenvironment.¹¹⁰ To this end, tumors upregulate the expression of tryptophan-degrading enzymes, indoleamine 2,3-dioxygenase (IDO) and tryptophan 2,3-dioxygenase (TDO), which both degrade tryptophan to its derivative kynurenine. Insufficient levels of tryptophan trigger apoptosis of effector T cells;¹¹¹ in addition, accumulation of kynurenine promotes the emergence of immune-suppressive regulatory T cells.¹¹² Finally, kynurenine-mediated signaling enhances invasiveness and extracellular-matrix-degrading capacity of tumor cells themselves.¹¹³

Key Points

Cancer cells use the signaling capacity of select metabolites to influence the state of cells in their

Cancer metabolism comes into the clinic

For over three decades, increased uptake of glucose by cancer cells has been successfully exploited in tumor imaging, where the uptake of 2-deoxyglucose conjugated to ^{18}F , a radioactive isotope of fluorine, is detected by positron emission tomography (PET).¹¹⁴ ^{18}F -Fluorodeoxyglucose (^{18}F -FDG) is transported into cells and is phosphorylated by HK in the same manner as glucose, yet cannot be further catabolized, which leads to its intracellular accumulation. A noninvasive tumor detection approach, ^{18}F -FDG-PET is widely used in the clinic for tumor detection and staging as well as for monitoring tumor response to therapy. However, ^{18}F -FDG-PET has a number of limitations, which include false-positive signals from tissue infiltration by immune cells (for instance, in autoimmune thyroiditis), or inability to detect those tumors that are not markedly glycolytic (as is often the case in prostate cancer). In addition, some tissues, especially brain, exhibit high constitutive levels of glucose uptake, which precludes the detection of tumors localized to brain. Following the success of ^{18}F -FDG, other metabolite-based tracers, such as ^{18}F -fluoroglutamine,¹¹⁵ ^{11}C -acetate,¹¹⁶ and α - ^{11}C -methyl-L-tryptophan,^{117, 118} are currently being developed. Other metabolic imaging approaches, such as ^1H magnetic resonance spectroscopy (MRS) are being developed for the use in the clinic. MRS can detect endogenously abundant metabolites in select tissues. For instance, MRS has been adapted to the detection of gliomas with IDH1 mutation, by using accumulation of D-2-hydroxyglutarate as a marker.¹¹⁹

In addition to tumor imaging, at least two metabolic cancer therapies have been successfully used in the clinic for decades. L-Asparaginase, a recombinant form of a bacterial enzyme that degrades the amino acid asparagine, was approved by the Food and Drug Administration in 1978 as an effective therapy for childhood acute lymphoblastic leukemia.¹²⁰ Leukemic cells lack the capacity to synthesize sufficient asparagine, so that the depletion of plasma asparagine (as well as, potentially, glutamine) sensitizes them to cell death. A class of drugs, which inhibit nucleotide biosynthesis, is another example of a successful metabolic therapy. These agents include 5-fluorouracil, an inhibitor of thymidine synthesis, gemcitabine and hydroxyurea, deoxyribonucleotide synthesis blockers, and an antifolate drug methotrexate, which interferes with dihydrofolate reductase-mediated synthesis of THF, disrupting the folate-cycle-driven synthesis of nucleotides. The therapeutic efficacy of antifolate drugs was first demonstrated by Sidney Farber in Boston in 1940s,¹²¹ followed by the discovery of their mechanism of action in 1958.¹²²

Dependence of cancer cells on glucose metabolism had prompted extensive testing of therapies that target the uptake of glucose or various steps in the glycolysis pathway. However, antiglycolytic interventions, such as, for example, inhibition of HK by a nonmetabolizable glucose analog 2-deoxyglucose or a drug lonidamine, had shown mixed results in trials, and lonidamide had undesirable systemic effects.¹²³ Furthermore, 2-deoxyglucose was shown to trigger compensatory activation of IGF-I receptor-mediated signaling.¹²⁴ A snapshot of therapeutic agents targeting metabolic pathways that are currently being developed are shown in [Table 1](#).

Table 1 Cancer metabolic therapies currently undergoing clinical development

Enzyme target	Targeting compound	Metabolic pathway
GLUT family of glucose transporters	Phloretin and silybin	Glucose uptake
MCT (lactate transporter)	AZD3965	Glycolysis
PDK1	Dichloroacetate	Pyruvate catabolism
Mitochondrial complex I	Metformin	Oxidative phosphorylation
Glutaminase (GLS1)	CB-839	Glutaminolysis
Fatty acid synthase	TVB-2640	Fatty acid biosynthesis
HMGCR	Statins	Sterol biosynthesis
IDH1	AG-120	Oncometabolite production
IDH2	AG-221	Oncometabolite production
IDO/TDO	INCB024360 and indoximod	Tryptophan degradation

Metformin, a standard-of-care antidiabetes drug, had shown clinical promise as both a therapeutic and a chemopreventive anticancer agent. A number of retrospective studies indicate that patients, who were taking metformin as a part of their antidiabetes regimen, had both reduced cancer risk and better treatment outcomes. Effects of metformin were further confirmed in nondiabetic patients.¹²⁵ The mechanism of anticancer activity of metformin is likely to be complex. Metformin impairs mitochondrial oxidative phosphorylation via inhibition of electron transport chain complex I, which leads to an increase in AMP/ATP ratio and activation of AMPK.¹²⁶ In addition, metformin attenuates the production of ROS and reduce DNA damage, which may contribute to its cancer-preventive effects.¹²⁷ Finally, systemic effects of metformin, such as reduction of circulating IGF-I levels and liver gluconeogenesis, may play a role in its anticancer properties as well.

Key Points

The dependence of tumor cells on various aspects of its altered metabolism has formed a basis for a number of imaging and therapeutic strategies.

Conclusions

Discoveries of modern cancer metabolism has elucidated how tumor cells reprogram their metabolism to sustain growth, circumvent nutrient and oxygen limitations, and alter their own fate as well as the fate of neighboring cells. There is, conceivably, a lot more left to learn about how a cell gauges the levels of its many metabolites and the complex ways in which it converts this information into decisions about nutrient acquisition, execution of cell death and differentiation programs, and a cross-talk with the microenvironment as well as the organism as a whole. In addition to macronutrients, the contribution of micronutrients, such as vitamins and metal ions, to metabolism and signaling of cancer cells is only beginning to be unraveled. Our growing understanding of cancer metabolism has already been translated into innovative imaging and therapeutic tools, and the arsenal of these applications will continue to grow in the foreseeable future.

Summary

Proliferation of cells within a metazoan organism is governed by external stimuli, including signals from soluble growth factors as well as from cellular attachments to the extracellular matrix. Pro-growth signals induce a profound shift in the metabolic state of a responding cell, increasing its capacity for *de novo* synthesis of macromolecules—namely, proteins, lipids, and nucleic acids, required for growth. Pro-growth signals directly facilitate the uptake of metabolic substrates from the surrounding environment, ensuring that a proliferating cell has an adequate supply of macromolecular precursors to grow. Pro-growth signals also dictate the downstream metabolic fate of acquired substrates, directing them toward the generation of precursors for a variety of biosynthetic reactions, which include fatty acid, cholesterol, nonessential amino acid, and nucleotide biosynthesis. In contrast to normal tissues, in which pro-growth signals are transient in nature, aberrantly activated oncogenes accumulated by cancer cells lock their metabolism in a constitutive state of nutrient acquisition and macromolecule biosynthesis.

Although pro-growth signals influence the uptake of metabolic substrates and their progression through cellular metabolic pathways, changes in levels of select metabolites, in turn, affect a diverse range of nonmetabolic processes in the cell. For example, intracellular metabolites act either as substrates or as cofactors for several classes of epigenetic enzymes. As a consequence, changes in levels of select metabolites exert changes upon the cellular epigenetic state. Some tumor types take advantage of this form of regulation by acquiring mutations in metabolic enzymes, leading to a newly discovered class of cancer-inducing intermediates, termed oncometabolites. In addition, metabolic alterations of cancer cells influence other cells within the tumor microenvironment, resulting in increased tumor expansion and dissemination.

A number of imaging and therapeutic agents that exploit cancer-specific metabolic alterations have been used in the clinic, and our developing understanding of the complexity of tumor-specific metabolic adaptations holds a promise for expanding the arsenal of such applications in the future.

Chapter 16

Modeling therapy of late or early-stage metastatic disease in mice

Robert S. Kerbel, PhD ■ Marta Paez-Ribes, PhD ■ Shan Man, BSc ■ Ping Xu, PhD ■ Eric Guerin, MD ■ William Cruz-Munoz, PhD ■ John M. L. Ebos, PhD

Overview

An ongoing problem in oncology drug development is the frequent failure of preclinical therapy models involving treatment of tumor-bearing mice, which show positive results, to predict similar success in patients enrolled in clinical trials. There are numerous possible reasons for causing such high rates of false positives. One is the failure to reproduce the clinical circumstances of treating systemic metastatic disease, whether microscopic or macroscopic in nature—but especially the latter. Thus, it is still common practice to treat mice with established primary tumors, whether they are transplanted or spontaneous, of mouse or human origin, or derived from cell lines or tumor tissue grafts—including human patient-derived xenografts (PDXs). In this chapter, we summarize recent progress in developing mouse models of spontaneous metastases, especially of late-stage disease, after surgical resection of primary tumors, including the use of human tumor cell lines, PDXs, and genetically engineered mouse models (GEMMs). Some limited therapy results using such models, and how they retrospectively or prospectively correlated with relevant phase III clinical trial outcomes, are discussed. A limited database indicates the possible benefits of using such models for predictive investigational therapeutic studies relevant to the treatment of patients with metastatic disease. Some limitations of such models are also discussed.

Introduction

The development of new cancer drugs is a painstakingly complex, laborious, and expensive undertaking, associated with an ultimate failure rate much higher than any other therapeutic area; indeed, it has been reported that greater than 60% of all phase III trials in oncology fail to meet their primary endpoint and are thus considered failures.¹ Such long-term and hugely expensive trials almost invariably follow what were highly encouraging preclinical results—usually undertaken in mice—as well as subsequent small phase I and II clinical trials that also suggested encouraging results, thus bolstering the decision to proceed with further development at the pivotal double-blind placebo-controlled randomized phase III clinical trial level. The subsequent high failure rate at the phase III trial level has therefore resulted in a number of critical questions, and among them include the following: (1) what are the reasons for the tendency of preclinical models involving therapy of tumors in mice to overpredict encouraging outcomes, and how might such models be improved for predicting future clinical trial outcomes? (2) what are the reasons for the failure to reproduce positive results detected in phase II clinical trials in subsequent phase III trials—and how might the design of such smaller phase II trials be improved to better predict what will happen at the phase III level?

This chapter will focus with the first question beginning with a discussion of the numerous possible

factors that lead to highly exaggerated “false positives” of therapeutic outcomes obtained in mouse therapy studies, followed by an analysis of some strategies designed to overcome current mouse tumor therapy model limitations. Special emphasis will be placed on one particular approach to improve clinical relevance of mouse tumor models, namely, recapitulating clinical treatment of systemic metastatic disease, early (microscopic) or (overt) late stage, especially the latter.

Some factors that reduce the clinical relevance and hence translatability of most mouse tumor therapy models

Many reviews or commentaries have been published on the limitations of preclinical mouse tumor therapy models for assessing cancer drug activity, at least with respect to clinical relevance and predictive potential.^{2–4} Some factors are well known, but others less so, and hence less appreciated. Among them include the following: (1) it is virtually unknown for therapy studies in mice to be initiated in older animals that would be equivalent to the age of the majority of cancer patients, that is, middle age or elderly.⁵ Instead, it is typical for therapy to be initiated in mice (at least when using transplanted tumor models) at 6–10 weeks of age. As such, this would be the roughly equivalent of undertaking a pediatric oncology clinical trial. However, it is well known that the impact of cancer drugs in children can be vastly different when compared to adults because of critical parameters that impact cancer drug activity such as drug metabolism and pharmacokinetics; (2) in contrast to a typical clinical trial where every patient enrolled is genetically distinct, mouse studies using inbred mouse strains obviously involve a high degree of homogeneity with respect to the population under study. This essentially eliminates or severely reduces the impact in humans of pharmacogenomic heterogeneity on such vital parameters as drug half life and metabolism, which can strongly impact therapeutic outcomes⁶; (3) either the optimal, or maximum tolerated doses (MTDs) of drugs can be very different between mice and humans; for example, the MTD of many different chemotherapy drugs may be much higher in a mouse compared to humans.⁶ This can cause potent tumor response artifacts, especially when using human tumor xenografts for the therapeutic studies; (4) many commonly used transplanted mouse tumor models are highly immunogenic and as a result, this can facilitate the immune system (provided an immunocompetent mouse is used as a host for the therapeutic investigations) to have an influence on therapeutic outcome—but in a way that could distort or exaggerate the degree of efficacy obtained⁷; (5) the endpoints used in preclinical studies are often clinically irrelevant or inappropriate.⁸ For example, a common clinical endpoint, such as progression free survival (PFS) based on imaging, is rarely used to assess efficacy in mice and yet PFS is increasingly used as a primary or secondary endpoint in most phase III clinical trials. Instead, it is typical, especially when using tumor transplants, to simply detect an effect on tumor growth per se, usually involving established primary tumors. A growth delay is often noted in such studies in the absence of any overt tumor regression. From a clinical perspective, growth delays would be viewed as “treatment failure”/progressive disease, and yet such results are often viewed as encouraging by cancer researchers because there is a nontreated control group allowing the benefit between the treated and untreated groups to be observed; (6) as any quick glance through current cancer research journals will indicate, the main way cancer drugs are tested in mice remains very much the same as what was half a century or more ago: tumor cells are transplanted into mice, often subcutaneously, to establish a “primary” ectopic tumor, which is then “staged” to a certain size, and treatment of the tumor-bearing mice subsequently initiated. These transplanted tumors can be of either mouse or human origin. In both cases, especially when using mouse tumors, doubling times can be extremely short owing to a very high tumor cell proliferative rate. This can render the tumor hypersensitive to various cancer drugs, especially cytotoxic chemotherapeutic agents that preferentially target cells in cycle replicating DNA or activating intracellular machinery such as microtubules or various enzymes involved in DNA replication. Moreover, tumor cells in cycle might

also have an impact on their sensitivity to other types of drug such as signal transduction inhibitors. However, such high cell proliferative rates are not typical of most spontaneous human cancers; (7) the clinical circumstance of treating advanced systemic disease in multiple organ sites such as the lungs, liver, brain, and bones is rarely undertaken in preclinical mouse model studies.⁴ Compared to therapy of primary tumors in mice—be they transplanted or spontaneously arising—treating mice with overt metastatic disease is more cumbersome, expensive, and time consuming. However, it is well known that late-stage systemic disease in humans in common solid malignancies is difficult to successfully treat—indeed, it is essentially incurable and associated with very modest gains in PFS or overall survival in “positive” phase III clinical trials. Such gains may be statistically significant and associated with a respectable hazard ratio—but the clinical meaningfulness of such results and their associated cost effectiveness are often marginal.⁹

What follows is a discussion of some of the current attempts to model therapy of metastatic disease in mice; with the emphasis on advanced-stage disease, and also some comment is provided on early-stage (micrometastatic) disease, utilizing transplanted tumors established from either human tumor cell lines or patient-derived xenografts (PDXs) as well as spontaneously arising tumors in genetically engineered mouse models (GEMMs) of cancer.

On the development of postsurgical human tumor xenograft models of advanced visceral metastatic disease using established cell lines

Beginning about a decade ago, attempts were made to develop models of advanced “spontaneous” metastatic disease from resected established primary tumors, virtually the first of their kind.¹⁰ The basic methodology employed involved a variation of the pioneering studies of Fidler¹¹ who first reported the derivation of variant sublines from the B16 mouse melanoma capable of more aggressive metastatic spread, especially to the lungs, after serial selection *in vivo* involving successive intravenous tumor cell inoculations and recovery of resultant “artificial” or “experimental” lung metastases. In these studies, 10 successive intravenous-mediated cell selections were undertaken, thus generating successive sublines of increasing metastatic properties after intravenous inoculation, for example, the B16F1 and B16F10 sublines.¹¹ In our case, we made an attempt to select similar variants capable of spontaneous metastatic spread from an established, but resected orthotopic primary tumor¹⁰ so that the metastatic cells would need to accomplish all of the early and late steps necessary for establishment of a distant metastasis. To achieve this, an established human breast cancer cell line, for example, the “triple-negative” MBA-MD-231 cell line, was implanted into the mammary fat pads of female immune deficient (SCID) mice, a procedure known to promote the rate and extent of distant metastatic spread to sites such as the lungs, compared to ectopic injection of cells into the subcutaneous space.^{12, 13} Once the primary tumors attained a predesignated volume/size, for example, 500 mm³, resection was undertaken. This was considered necessary to allow the mice to survive for a longer period of time, thus increasing the probability that tumor cells seeded from the primary tumor would have sufficient time to establish macroscopic metastases in distant organs, for example, the lungs. Such metastases could be detected by gross inspection beginning after a period of about 4 months, or longer, post surgical resection of the primary tumors.¹⁰ Several such lung metastases were harvested and a cell line established from the pooled population of metastases. These cells were then reinjected once more into the mammary fat pads and the subsequent primary tumors resected approximately 4 weeks later. This resulted in an accelerated rate and degree of pulmonary metastases (and sometimes, variably, extrapulmonary metastases). An individual lung metastasis was harvested and a subline established from it, for example, a more aggressive metastatic variant called LM2.4.¹⁰ It would then be used for experimental therapeutic studies by once

again injecting the cells orthotopically, resecting the resultant primary tumors, allowing the mice to develop overt metastatic disease, which now occurred within about 1 month—mostly confined to the lungs but sometimes involving other sites such as the lymph nodes or liver.¹⁰ It would be at such a late stage of tumor progression that an experimental therapy would be initiated, with survival used as a primary endpoint for assessing therapeutic efficacy.¹⁰ In addition, such variant pro-metastatic sublines can be tagged with markers to monitor disease burden and response to therapy over time. Such markers include luciferase that permits whole body optical/bioilluminant imaging¹⁴ as well as undertaking transduction of the gene for the β subunit of human chorionic gonadotropin (β -hCG), levels of which can be detected in urine as a molecular surrogate of tumor burden.¹⁵ These same procedures have been successfully employed to develop models of advanced metastatic disease not only for human breast cancer but also for human malignant melanoma,¹⁶ renal cell carcinoma,¹⁷ and colorectal carcinoma.¹⁸ In addition, models of advanced intraperitoneal metastatic ovarian cancer had been developed, which did not involve prior serial selection *in vivo*¹⁹ as well as locally advanced orthotopic hepatocellular carcinoma.²⁰

The rationale underlying development of these models was that most experimental therapies would likely have reduced (if any) efficacy when used to treat advanced metastatic disease, when compared to treating the same tumor line in control mice as an established (nonresected) primary tumor. However, we speculated that there might be occasional exceptions to this trend, that is, where a particular drug or therapy could cause meaningful efficacy in the advanced metastatic setting but not, counterintuitively, in the primary tumor treatment setting, or which caused good efficacy in both treatment settings. Such a therapy, it was reasoned, might have a greater probability of showing efficacy (although not necessarily to the same degree) when subsequently tested in patients with advanced metastatic disease. We also adopted a similar strategy for studying adjuvant therapy of earlier-stage microscopic disease.¹⁴ Thus, once the primary tumor was resected, therapy could be initiated very soon after resection at a time when whole body imaging indicated the absence of overt systemic metastases, but where a proportion of the mice would be at risk for developing subsequent metastatic disease.^{14, 17, 18}

A limited body of evidence has suggested the tentative validity of this experimental approach as an improved strategy to assess drug activity for predicting future activity of a given drug or therapy in patients. There are, however, limitations that must also be considered. With respect to the former, that is, supportive evidence for the concept, two observations are particularly noteworthy.

The first observation, or series of results, concerns an attempt to reproduce prior phase III clinical trial outcomes, in particular negative/failed outcomes that were preceded by highly encouraging positive results using conventional mouse tumor therapy models involving treatment of established primary tumors.²¹ Thus, a highly compelling example of phase III clinical trial failures is the combination of an oral antiangiogenic tyrosine kinase inhibitor (TKI) plus conventional chemotherapy.²¹ There are by now over 15 such phase III trials that failed to meet their primary or secondary endpoints and thus considered failures in breast, colorectal, and lung cancers, among others.^{22–24} Perhaps the most discouraging examples are four separate phase III trials evaluating sunitinib in combination with different chemotherapy backbone partners, or when used alone, as reviewed by Guerin et al.²⁴ These trials represent either first or second line therapies. The first line trials were preceded by positive preclinical results involving mostly treatment of established primary tumors in multiple and different models.²⁵ As shown in [Figure 1](#), three different antiangiogenic drugs, namely, sunitinib, another oral TKI (pazopanib), or an antibody that targets vascular endothelial growth factor (VEGF) receptor-2 called DC101 all showed the typical growth delay²⁵ when treating established orthotopic primary tumor xenografts of the

LM2.4 metastatic variant obtained from the MDA-MB-231 breast cancer cell line.^{24, 25} In contrast, in another group of mice where the primary tumors were resected and treatment initiated at the stage of advanced metastatic disease, the efficacy results were assessed to be negative based on a lack of statistically significant benefit in median overall survival.²⁴ Moreover, the results remain negative when an antiangiogenic drug, for example, sunitinib, was combined with standard of care paclitaxel chemotherapy.²⁴ If instead of an oral TKI, the anti-VEGFR-2 antibody was used in conjunction with the same chemotherapy, a benefit in median overall survival was observed, compared to control untreated mice. Although the benefit compared to the paclitaxel treatment group was not statistically significant in terms of an overall survival benefit,²⁴ there was a trend that likely would have translated into a PFS, had this been measured. As such, this particular result seemed to recapitulate a number of positive phase III clinical trials of the VEGF antibody, bevacizumab, combined with chemotherapy, especially with paclitaxel where small but statistically significant benefit in PFS was observed.²⁴

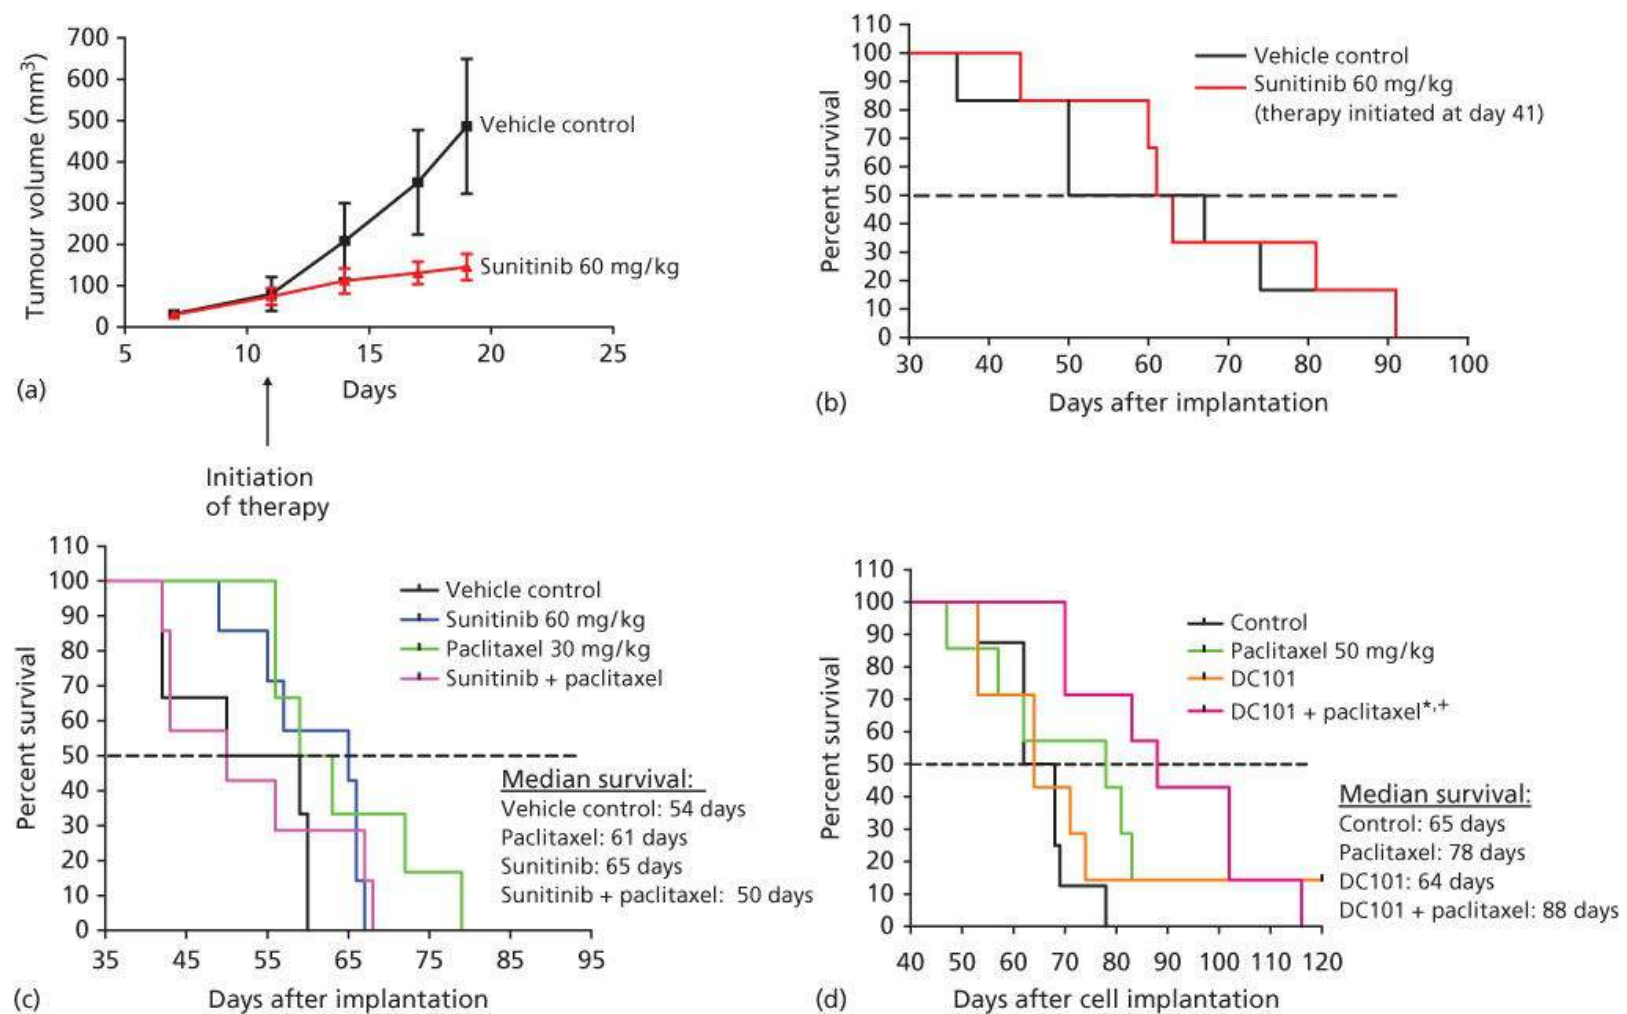

Figure 1 Contrasting outcomes of sunitinib versus DC101 (a VEGF receptor-2 targeting antibody, with or without chemotherapy when treating primary tumors vs overt metastases). A spontaneous metastatic variant of MDA-MB-231 called LM2.4¹⁰ was injected into the mammary fat pads of mice to establish primary tumors (a), or the tumors were resected and the mice allowed to develop extensive metastases, at which point therapy was initiated usually ~20 days after tumor resection (b–d). (a) Sunitinib is active against primary tumors once therapy is initiated (arrow), whereas (b) no impact based on survival using the same dose and schedule of sunitinib in postsurgical mice with advanced metastatic disease. Combination of sunitinib with standard paclitaxel does not improve efficacy of paclitaxel, and in fact worsens outcome (c). In contrast, the DC101 VEGFR-2 antibody improves paclitaxel efficacy (d). Similar results to sunitinib were obtained using pazopanib, which are not shown here. Statistical results and experimental details provided in Guerin et al.²⁴

The second observation concerns the development of spontaneous brain metastases in mice with systemic metastatic disease—either of malignant melanoma or breast cancer—and whose survival was prolonged by a particular treatment strategy. This recapitulates a clinical treatment circumstance that is increasingly being observed, namely, the emergence of CNS metastases in patients with systemic metastatic disease whose survival is prolonged by a particular therapy, for example, trastuzumab plus chemotherapy in women with metastatic breast cancer.²⁶ The basis for the emergence of a higher rate of relapse of brain metastases in such circumstances is that patients with microscopic metastatic disease in the brain developed overt symptomatic lesions as a result of their prolonged survival, this allowed sufficient time for the microscopic metastases to develop into macroscopic lesions. The emergence of spontaneous brain metastases in these therapeutic models resulted in the establishment of models of spontaneous brain metastasis in which cell lines developed from melanoma brain metastases could maintain the spontaneous brain metastatic phenotype upon retransplantation, and moreover, do so without any therapeutic

intervention to prolong survival.¹⁶ This indicated the selection of a subpopulation of metastatic tumor cells capable of spontaneous brain metastasis.¹⁶ Additional studies uncovered some possible molecular drivers of spontaneous brain metastasis, one of which involves increased expression of endothelin receptor B.²⁷ Interestingly, endothelin receptors and endothelins have been implicated as a survival mechanism fostering the growth of brain tumors and metastases as well as their resistance to therapy by Fidler's group.²⁸ As a result, endothelin receptor antagonists are now being evaluated as a potentially promising strategy to treat brain tumors, for example, glioblastomas, and possibly in the future CNS metastatic disease.

“Prospective” studies using metastatic therapy preclinical models: correlation with subsequent clinical outcomes using similar therapies

Two types of study have been undertaken to evaluate the impact of investigational therapies either in the advanced metastatic setting or in the setting of early-stage microscopic disease (as an adjuvant therapy) versions of which were then later evaluated in phase III clinical trials. This allowed, at least to a degree, a prospective analysis of the possible benefits of evaluating drug activity in postsurgical models of metastatic disease. One of these studies involved adjuvant therapy using an antiangiogenic drug (sunitinib) for the treatment of early-stage microscopic breast cancer where sunitinib therapy was initiated on resected LM2.4 primary breast tumors soon after surgical resection, when no overt metastases could be detected by whole body imaging.¹⁴ Using a short course of therapy, and a high dose of the drug known to inhibit the growth of established primary tumors in control experiments, the results indicated no benefit of the adjuvant treatment; indeed, a worsened outcome was observed as shown by the accelerated development of metastases and reduced survival times, compared to “vehicle” control treated mice.¹⁴ As a result of these surprising findings, we suggested caution before undertaking hugely expensive long-term adjuvant trials involving antiangiogenic drugs without more preclinical information indicating that such therapies would likely succeed in the clinic.¹⁴ Since then, numerous adjuvant therapy phase III trials of induction bevacizumab plus chemotherapy followed by maintenance bevacizumab have been undertaken in breast and colorectal cancer^{29, 30} as well as with sorafenib in hepatocellular carcinoma and sorafenib or sunitinib in renal cell carcinoma without any chemotherapy. All of these trials failed to show a benefit in disease free survival and in one case, the outcome was actually worse in the bevacizumab containing arm compared to chemotherapy only.³⁰ Thus, while there is admittedly little evidence for consistent worsened outcomes in these trials, the clinical findings nevertheless support our original contention, based on the preclinical adjuvant therapy model results that it was premature to undertake such adjuvant trials, especially in the absence of preclinical experimental results supporting the concept of adjuvant antiangiogenic therapy.

A second example of (tentative) prospective validation studies stems from the results evaluating low-dose “metronomic” chemotherapy either alone or in combination with an antiangiogenic drug for the treatment of advanced metastatic disease. A number of such preclinical studies have shown the surprisingly potent efficacy of metronomic chemotherapy-based regimens when treating advanced metastatic disease in mice despite the fact that the same therapy showed less-impressive effects when treating primary established tumors,^{4, 10} or similar effects on both primary tumor-bearing mice and mice with advanced metastatic disease.⁴ Such results have helped contribute to the decision to initiate phase II and even randomized phase III clinical trials evaluating metronomic chemotherapy-based regimens. The first such reported phase III trial, called CAIRO3, evaluated metronomic daily lower dose capecitabine plus bevacizumab as a maintenance therapy in first line metastatic colorectal cancer patients.³¹ A marked benefit was noted in PFS, the primary endpoint using the maintenance regimen compared to observation only.³¹ While it is true

that this particular regimen was not evaluated in prior preclinical studies, the results nevertheless would appear to make a case for the preclinical results evaluating metronomic chemotherapy in the advanced metastatic setting as being a harbinger of possible future phase III clinical trial success when treating metastatic patients.³² Additional ongoing phase III trials evaluating metronomic chemotherapy should provide further support for this view—or not.

Developing models of spontaneous metastatic disease using patient-derived xenografts (PDXs)

A major development in trying to improve the predictive power and clinical relevance of preclinical mouse models is the use of PDXs.³³ Many studies are being undertaken to try and validate the hypothesis that such models more accurately predict future clinical impact of cancer drugs, compared to xenografts using established cell lines, as described earlier or other models.³³ Virtually, all PDX studies, however, involve growth and therapeutic response of established primary tumors in immune-deficient mice. We are unaware of PDX investigational therapy studies involving treatment of metastatic disease, whether microscopic or macroscopic in nature. There are only a few reports documenting metastatic disease in PDX models, for example, development of ovarian cancer ascites and metastases in humanized immune-deficient NOD-SCID-IL2R γ null mice.³⁴ Some studies have reported detection of microscopic metastases, for example, in breast cancer PDX models.³⁵ We therefore initiated an attempt to develop such models of overt metastatic PDXs, as shown in [Figure 1](#), beginning with a triple-negative breast-cancer-derived PDX called HCI-002.³⁵ Our experience, albeit limited, indicates several technical difficulties that must be overcome to successfully develop such models and then use them for investigational therapeutics in a practical and meaningful way. First, the growth of most PDXs is usually very slow compared to primary tumor xenografts generated from injection of cells obtained from established cell lines. Thus, the development of overt metastases—if they occur at all in mice whose primary tumors have been resected—can take exceedingly long to emerge. In the case shown in [Figure 1](#), this took 9 months and only occurred in one of 55 mice evaluated. Second, detection of distant metastases, which is easily done using techniques such as whole body bioluminescent imaging of luciferase tagged tumor cell lines, cannot be done using PDX tissues. Thus, other sophisticated imaging methods, for example, MRI using specialized equipment capable of small animal imaging, would be required, and such equipment is usually located outside of animal holding facilities, meaning that once they are removed from within a holding facility they cannot be returned because of the threat of causing infection. Future studies will be required to determine the practicality of developing and utilizing PDX-based metastatic models. For the time being, our unpublished observations suggest serious practical hurdles may have to be overcome ([Figure 2](#)).

Figure 2 Developing a spontaneous metastatic variant from a breast cancer PDX. (a) Tumor fragments of the triple-negative PDX breast cancer tumor called HCI-002³⁵ were implanted in the mammary fat pads (mfp) of SCID mice. The tumor growth rate remained similar after successive passages. (b) After 2 months, primary tumors were resected and the mice maintained for observation of development of distant overt metastases. (c) After 7 months, one mouse (among 55 examined) developed a lung metastasis that was positive for the human leukocyte antigen (HLA) big enough to be implanted into the mfp of new mice. (d) Fragments of this lung metastasis were implanted in the mfp of new SCID mice. These new tumors grew with an accelerated rate when compared to the parental HCI-002 (tumor volumes of 1000 mm³ were reached after 6 weeks). (e) The tissue architecture of this new variant remained similar to that of the parental tumor. The growth rate of this new variant was also consistently maintained after successive passages. (f) Mouse-derived thymic lymphomas also appeared in the 15.9% of the mice implanted with PDX tumors. These tumors (which were negative for HLA, with no human component) showed high rates of proliferation and were positive for the hematopoietic progenitor cell antigen CD34. The arrow shows a mouse thymoma. Scale bars, 150 μ m. Thus, the results indicate the rarity of development of overt distant metastases using PDXs, the protracted time frame for an overt spontaneous metastasis to develop and the complication of the appearance of the novo mouse thymomas in older SCID mice. Development of metastatic models for investigational therapeutics using genetically engineered mouse models (GEMMs) of spontaneous mouse tumors

The use of GEMMs for preclinical investigational therapeutics represents a major initiative in early oncology drug development. The advantages of these models have been described and include no species difference between the tumors which arise in such mice and the host stroma, and the fact that such mice are immune competent, thus making it possible to undertake immunotherapy studies in a more practical way compared to human tumor xenograft models involving immune suppressed mice. This now has to be viewed as a major advantage over xenograft models given the remarkable clinical results recently reported using immune checkpoint control antibodies such as ipililumab or nivolumab. Use of “humanized” immune suppressed mice may be a strategy to allow immunotherapy studies to be undertaken in immune-deprived mice lacking a murine immune system.³⁴ However, among the disadvantages of using GEMMs, at least historically, is that most such models are nonmetastatic, and moreover, consist of multiple primary tumors that emerge asynchronously. This makes perioperative neoadjuvant or adjuvant therapy studies extremely difficult, if not impossible. Similar to the limited number of studies in the world's literature of postsurgical adjuvant or metastatic therapy³⁷ detailed neoadjuvant (presurgical therapy) studies are uncommon³⁸ and may require transplanted tumor models.³⁸ Ironically, some GEMM metastatic models involve transplantation of the fragments of primary tumors into secondary syngeneic hosts followed by surgical resection of the resultant primary tumors in a manner similar for transplanted human tumor xenografts,³⁹ as described earlier.

It is noteworthy that some recent significant strides have been made in developing GEMMs that show evidence of distant spontaneous metastasis, as summarized in detailed reviews.^{40, 41} Some of these are now being used for investigational therapeutics, for example, the “RapidCap” prostate cancer GEMM, where therapeutic targeting of the myc oncogenes was shown to suppress metastasis in a lethal PTEN-deficient model, after development of castration resistance.⁴²

Conclusions

Considering the overwhelming importance of metastatic disease in the morbidity and mortality of cancer, it is somewhat disappointing and surprising that efforts to model the clinical treatment of metastasis—especially of late-stage overt systemic (visceral) metastatic disease—have been so limited over the past half century using various mouse tumor therapy models. As summarized here, this is now beginning to change, and the small data sets currently available would appear to indicate that the therapy results obtained from studies utilizing these more clinically relevant models of metastasis—including those involving surgical resection of primary tumors—may be a promising strategy to reduce “false-positive” results with respect to subsequent clinical translation. Such models may not be practical for routine drug screening, but could be helpful in making more informed “go–no go” decisions before consideration of further clinical development, as well as clinical trial design.

Chapter 17

Tumor angiogenesis

John V. Heymach, MD, PhD ■ Amado Zurita-Saavedra, MD ■ Scott Kopetz, MD, PhD ■ Tina Cascone, MD, PhD ■ Monique Nilsson, PhD

Overview

Angiogenesis, the growth of new capillary blood vessels, is central to cancer growth and metastasis and is recognized to be a potential therapeutic target for the treatment of cancer. Antiangiogenic agents have become part of the standard treatment armamentarium for many solid tumors, providing significant clinical benefits for some cancers (e.g., renal cell, colorectal) and modest or no benefit for others. This chapter is focused on principles of tumor angiogenesis that are intrinsic to the behavior of human cancer, and lessons that can be gleaned from the clinical testing and use of angiogenesis inhibitors to date.

Tumor angiogenesis

Angiogenesis, the growth of new capillary blood vessels, is central to the growth and metastatic spread of cancer. More than four decades ago, it was recognized to be a potential therapeutic target for the treatment of cancer.¹ Since that seminal observation, the field has undergone explosive growth that has taken it from theory to clinical validation of angiogenesis as a therapeutic target, and antiangiogenic therapy is now in routine clinical use. Bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor (VEGF), has undergone the most extensive clinical evaluation to date and is now a standard agent for the treatment of colorectal, lung, renal cell, and other malignancies. Several other antiangiogenic agents are also in routine use for other cancers including ramucirumab, an antibody targeting VEGF receptor-2; the VEGF- and placental-growth factor (PlGF) targeting protein aflibercept; and a number of tyrosine kinase inhibitors targeting angiogenic pathways including sunitinib, pazopanib, sorafenib, vandetanib, and axitinib.

While the progress of the field is encouraging, the clinical benefits of antiangiogenic agents have been relatively modest thus far, and key questions remain unanswered: How should antiangiogenic therapy be combined with other therapeutic regimens and treatment modalities? In what tumor types, and at what stage(s), should these agents be used? Can markers be developed to identify patients most likely to benefit, or experience toxicities, from treatment? The ultimate impact of antiangiogenic therapy in the treatment of cancer will be determined at least in part by the ability of basic researchers and clinicians to address these questions.

An understanding of the cellular and molecular basis of tumor angiogenesis is therefore important for clinicians who diagnose and treat cancer by whatever modalities. This chapter is focused on certain general principles of tumor angiogenesis that are intrinsic to the behavior of human cancer, and lessons that can be gleaned from the clinical testing and use of angiogenesis inhibitors to date.

Rationale for targeting tumor vasculature

The enormous progress that has been made in understanding molecular and genetic events that underlie the transformation of a normal cell to a cancer cell is reflected in many chapters in this book. Not surprisingly, most therapeutic approaches that have arisen from this research are targeted at the cancer cell, with a number of notable successes, such as therapies targeting BCR-ABL oncogene in CML or mutated c-KIT in gastrointestinal stromal tumors. In these cases it appears that cell survival and other key processes are highly dependent on a single activated pathway. For the vast majority of solid tumors, targeting a single molecular pathway in the cancer cell has produced much more modest benefits. Experimental and clinical evidence reviewed in this chapter indicates that it is prudent to develop cancer therapies against another target, the microvascular endothelial cell, with the understanding that the two targets are not mutually exclusive.

Consider a cancer cell that has progressed through a series of mutations so that by activation of certain oncogenes and by loss of specific suppressor genes, it has become self-sufficient in growth signals, insensitive to antigrowth signals, unresponsive to apoptotic signals, capable of limitless replicative potential, and tumorigenic.² Current evidence argues that these neoplastic properties may be necessary but not sufficient for a cancer cell to expand into a population that is symptomatic, clinically detectable, metastatic, and lethal. For a tumor to develop a metastatic and/or a lethal phenotype, it must first recruit and sustain its own private blood supply, a process called tumor angiogenesis.²

A tumor can recruit vessels through at least four mechanisms: (1) co-option of existing vessels; (2) sprouting from existing vessels (angiogenesis); (3) formation of new vessels *de novo*, typically from bone marrow-derived cells in the adult (vasculogenesis); (4) intussusception, the insertion of interstitial tissue columns into the lumen of preexisting vessels (reviewed in Ref. 3).

Nonangiogenic tumors are harmless

There is an early stage of neoplastic development when tumors are not yet able to recruit new microvascular endothelial cells and cannot induce angiogenesis. As a result, most human tumors remain *in situ* and dormant at a microscopic size and are harmless to the host.⁴

Cancer without disease: prolonged survival with nonangiogenic, dormant tumors

Nonangiogenic tumors in humans stop expanding at a microscopic size of ~1 mm or less. For over 100 years, pathologists performing autopsies on individuals who died of accidental causes have found that for a given age group, a large number of individuals harbor *in situ* carcinomas, while a very small percentage in that age group are diagnosed with cancer during life.⁵ For example, carcinoma *in situ* is found in the breasts of 39% of women aged 40–50 years who died of trauma, but only 1% are ever diagnosed with cancer in this age range. Carcinoma *in situ* of the prostate is diagnosed in 46% of men aged 60–70 years who died of trauma, but only 15% are diagnosed during life. One mechanism that keeps these *in situ* carcinomas in check may be host-derived factors that prevent switching to the angiogenic phenotype. Physiologic levels of endogenous angiogenesis inhibitors (see later sections) may serve this function.⁶

Disease of cancer requires expansion of tumor mass

Expansion of the tumor mass beyond the initial microscopic size of a nonangiogenic tumor, resulting in the disease of cancer, is usually dependent on recruitment of endothelial cells. Such endothelial cell recruitment begins when tumor cells undergo a switch to the angiogenic phenotype.^{7–9} The angiogenic phenotype is driven by a number of changes which may include (1) increased expression by tumor cells of angiogenic proteins such as VEGF and basic fibroblast growth factor (bFGF); (2) increased expression of

angiogenic proteins from stromal cells (i.e., stromal fibroblasts), a process induced by the tumor itself; (3) decreased expression of endogenous angiogenesis inhibitors (i.e., thrombospondin [TSP]-1) by the tumor and by stromal fibroblasts; and (4) recruitment of bone marrow-derived endothelial cell precursors (see below for a detailed discussion of the switch to the angiogenic phenotype). Other mechanisms will unquestionably be uncovered. Absence of tumor angiogenesis prevents expansion of the tumor mass beyond a microscopic size, thereby avoiding metastatic spread and tumor-related symptoms, and hence, “cancer without disease”.⁶ The therapeutic implications of this concept are profound. Therapeutic blockade of angiogenesis may not only slow the growth of clinically evident tumors, but also may help prevent the emergence of microscopic lesions into clinically evident tumors.

Recruitment of microvascular endothelial cells is also necessary for expansion of a normal tissue mass and for expansion of an organ mass, for example, after partial hepatectomy.¹⁰ In fact, angiogenesis is fundamental to reproduction, development, and repair, but such physiologic angiogenesis occurs mainly as short-lived capillary blood vessel growth that usually lasts only days (ovulation angiogenesis), weeks (wound healing angiogenesis), or months (fetal and placental angiogenesis) but then it is always downregulated spontaneously and on a predictable timetable.^{11, 12} These physiological roles for angiogenesis help explain below some of the toxicities observed from use of angiogenesis inhibitors in the clinic.

Historic background

More than 100 years ago, it was observed that tumors were often more vascular during surgery than corresponding normal tissues.¹³ This was explained by simple dilation of existing host blood vessels.¹⁴ Vasodilation was thought to be a side effect of metabolites or of necrotic tumor products escaping from the tumor. Three reports, although largely overlooked, suggested that tumor hyperemia could be related to neovascularization and not solely to vasodilation.^{15, 16} Nonetheless, debate continued in the literature for two more decades about whether a tumor could expand to a large size (centimeters) by simply living on preexisting vasculature (vessel co-option).¹⁷ Even the few investigators who accepted the concept of tumor-induced neovascularization generally assumed that this was an inflammatory reaction, a side effect of tumor growth, not a requirement for tumor growth.¹⁸ It is now recognized that the two processes are often linked and that the recruitment of inflammatory cells plays a key role in initiating and promoting tumor angiogenesis.

Beginning of angiogenesis research

Hypothesis: tumor growth depends on angiogenesis

In 1971, Folkman proposed a new hypothesis that tumor growth is angiogenesis dependent.¹ This hypothesis suggested that tumor cells and vascular endothelial cells within a neoplasm may constitute a highly integrated ecosystem and that endothelial cells may be switched from a resting state to a rapid growth phase by a “diffusible” chemical signal from tumor cells. An additional speculation was that angiogenesis could be a relevant target for tumor therapy (i.e., antiangiogenic therapy). These ideas were based on experiments Folkman and Frederick Becker performed in the early 1960s, which revealed that tumor growth in isolated perfused organs was severely restricted in the absence of tumor vascularization ([Figure 1](#)).^{19–23}

Figure 1 Tumors remain avascular in isolated perfused organs.²⁰ Whole organs, supported by perfusion, allow growth of tumors in isolation from a host. The tumor remains very small, less than 1 mm^3 , in an avascular environment compared to growth in mice which can exceed $10,000 \text{ mm}^3$.

These concepts were not widely accepted at the time. Another obstacle to research on tumor angiogenesis was the conventional wisdom at that time that any new vessels induced by a tumor, such as new vessels in a wound, would become established and thus could not be made to involute. From this assumption, scientists concluded that antiangiogenic therapy could never regress a tumor; therefore, it would be fruitless to try to discover angiogenesis inhibitors. Eventual acceptance of Folkman's 1971 hypothesis, and the development of angiogenesis research as a field, was subsequently facilitated by a number of advances including the ability to reproducibly culture vascular endothelial cells, the discovery of endogenous angiogenesis proteins, and the identification of drugs able to block angiogenesis *in vitro* and *in vivo*.^{24–28}

Throughout the 1970s, laboratory studies were devoted to demonstrating that tumor vessels were new proliferating capillaries; the sequential steps of the angiogenic process could be identified; qualitative and quantitative bioassays for angiogenesis could be developed; viable tumor cells released diffusible angiogenic factors that stimulated new capillary growth and endothelial mitosis *in vivo*, despite the arrest of tumor cell proliferation by irradiation; necrotic tumor products were not angiogenic per se; and angiogenesis itself could be inhibited.^{29–32} Today the field has broadened to include a wide spectrum of basic science disciplines, from developmental biology to molecular genetics, as well as a variety of clinical specialties, including oncology, cardiology, dermatology, gynecology, ophthalmology, and rheumatology.

Experimental evidence

By the mid-1980s, considerable experimental evidence had been assembled to support the hypothesis that tumor growth is angiogenesis dependent. The idea could now be stated in its simplest terms: “Once tumor take has occurred, every further increase in tumor cell population must be preceded by an increase in new capillaries that converge upon the tumor”.³³ The hypothesis predicted that if angiogenesis could be completely inhibited, tumors would become dormant at a small, possibly microscopic, size.²² It forecasted that while the presence of neovascularization would be necessary but not sufficient for expansion of a tumor, the absence of neovascularization would prevent expansion of a primary tumor mass beyond $1\text{--}2 \text{ mm}^3$ and restrict a metastasis to a microscopic dormant lesion (Figure 1).

The hypothesis that tumors are angiogenesis dependent has been supported by a large body of preclinical evidence,³⁴ including pharmacological and genetic studies, as well as clinical studies discussed in a later section. Some of the observations supporting the angiogenic hypothesis included:

1. Tumors implanted into subcutaneous transparent chambers grow slowly before vascularization, and

tumor volume increases linearly. After vascularization, tumor growth is rapid and tumor volume may increase exponentially.^{35, 36}

2. Tumors grown in the vitreous of the rabbit eye remain viable but are restricted to diameters of less than 0.50 mm for as long as 100 days. Once such a tumor reaches the retinal surface, it becomes neovascularized and within 2 weeks can undergo a 19,000-fold increase in volume over the avascular tumor.³⁷

3. The limit of oxygen diffusion is approximately 100–200 μm . Tumor cells that exceed these distances from a capillary vessel become necrotic, as determined by intravital microscopy of tumors in transparent skin chambers in mice ([Figure 2](#)).³⁸

4. In transgenic mice that develop carcinomas of the β cells in the pancreatic islets, large tumors arise from a subset of preneoplastic hyperplastic islets but only after they have become vascularized.⁸

5. In colon carcinomas arising in rats after carcinogen exposure, there is an early phase (tumor diameter < 3.5 mm) during which the tumor is temporarily supplied by preexisting host microvessels that are dilated and widened.³⁹ This stage is similar to “co-option” of blood vessels.⁴⁰ Subsequently, new capillary vessels sprout and proliferate (angiogenesis), which leads to increasing microvessel density and is accompanied by rapid tumor growth.

6. A neutralizing antibody to VEGF was administered to mice bearing tumors that induced angiogenesis solely by VEGF.⁴¹ Tumor growth was inhibited by more than 90%. The antibody had no effect on the tumor cells *in vitro*.⁴² This observation has been replicated using a variety of different means to block VEGF, including a fusion protein engineered from VEGF receptors (VEGF trap).⁴³ Similar results were seen with an antibody directed against another angiogenic factor, bFGF.⁴⁴

Human melanoma

(a)

Rat prostate cancer

(b)

Figure 2 (a) A cuff of viable tumor cells surrounding a microvessel in a human melanoma growing in a SCID mouse has an average radius of 85 μm . The appearance of an ellipsoid is a result of the way the section is cut. (b) A cuff of rat prostate cancer cells surrounding a microvessel has an average radius of 110 μm .

Biology of tumor angiogenesis

The role of angiogenesis in preneoplasia and early tumorigenesis

In the experiments with isolated perfused organs by Folkman and colleagues more than four decades ago, the growth of tumors was severely restricted in diameter in the absence of angiogenesis.^{20, 45} This and other studies led to the proposal that the growth of solid tumors is dependent on new capillary sprouts (termed angiogenesis), and that without angiogenesis solid tumors might become completely dormant.¹ This raised the possibility that angiogenesis might be a therapeutic target not only for the treatment of advanced cancers, but potentially for chemoprevention as well. In recent years, angiogenesis has been validated as a therapeutic target for advanced cancers through a growing body of preclinical and clinical studies. The study of angiogenesis inhibitors for blocking the earliest steps in the development of cancer (chemoprevention) has lagged behind, despite the strong support for the concept provided by preclinical studies (reviewed in Refs ⁴⁶ and ⁴⁷).

Preclinical studies demonstrating a role for angiogenesis in early tumorigenesis

In the 1970s it was shown by Gullino⁴⁸ that precancerous tissues demonstrate signs of early angiogenesis, and it was suggested that blocking this process may be used to prevent cancer. Later, using transgenic mouse models of tumorigenesis, Hanahan and colleagues demonstrated that some premalignant lesions undergo “angiogenic switch” early in carcinogenesis, reflecting a change in the net balance between angiogenic stimulators and inhibitors.^{8, 9} VEGF and matrix metalloproteinase-9 (MMP-9) were shown to play important roles in the angiogenic switch in these models.^{49–51} In a murine model of pancreatic islet carcinoma, four different antiangiogenic agents were tested (TNP-470, endostatin, angiostatin, or the MMP inhibitor BB-94) and had distinct activity profiles in terms of their ability to prevent tumor formation (chemoprevention), slow the growth of small tumors (early intervention), and regress established tumors.^{8, 52, 53} In another study, established mammary cancer cells (i.e., previously transformed cells but not primary tumors) were implanted in a dorsal skinfold window chamber in rats, and were found to induce angiogenesis long before the tumor population would have reached the limiting size of a nonneovascularized tumor, that is, 0.2–2 mm. These and other preclinical studies suggest that angiogenesis is an early and critical step in tumorigenesis, and that antiangiogenic agents may inhibit tumor progression and growth.

Preneoplasia is associated with increased angiogenesis in human tumors

Studies from human clinical specimens provide further support for the hypothesis that angiogenesis occurs early in tumor progression, typically during the preneoplastic stage. In cervix cancer, an initial mild increase in vessel density has been detected in the early dysplastic [cervical intraepithelial neoplasia (CIN) I] stage. Mid–late dysplasias (CIN II–III) exhibited a readily apparent angiogenic switch, wherein new vessels became densely apposed along the basement membrane underlying the dysplastic epithelium.^{54, 55} Biopsies from lung cancer patients and high risk individuals have shown that preneoplastic lesions ranging from hyperplasia and metaplasia to carcinoma *in situ* are associated with increased microvessel density in the surrounding mucosa.^{56–58} A distinctive pattern known as angiogenic squamous dysplasia⁵⁷ has also been identified. The specific angiogenic stimulators in bronchial preneoplastic lesions have not been established but elevated levels of VEGF,⁵⁶ EGFR (epidermal growth factor receptor),⁵⁹ and COX-2⁶⁰ have been observed.

Role of angiogenesis in the metastatic spread of cancer

In addition to its role in enabling the growth of small premalignant or malignant lesions, angiogenesis contributes to the hematogenous metastatic spread of tumors. This spread may be facilitated by the presence of “mosaic” blood vessels in tumors, in which both endothelial and tumor cells form the luminal blood surface, facilitating the shedding of tumor cells into the circulation. In one study, approximately 15% of vessels in a colon cancer xenograft model were mosaic vessels in which tumor cells appeared to directly contact the luminal vessel surface without endothelial cells acting as a barrier.⁶¹ Similar numbers of mosaic tumor vessels were detected in human tumor biopsies. These observations suggest that the irregular architecture and function of tumor vessels may facilitate tumor cell shedding into the circulation and metastatic spread.

Micrometastases also appear to be dependent on angiogenesis in order to progress into clinically evident tumors. They may remain dormant in distant sites for an extended period of time but a small fraction of these acquire an adequate blood supply to permit the development of tumors; angiogenesis inhibitors can inhibit this process in a variety of murine models.^{62–67} The continued growth of both the primary tumor and metastases thereafter depends on the maintenance of an adequate blood supply. In theory, angiogenesis inhibitors may therefore offer benefit when used for chemoprevention as well as in treatment of early stage, occult metastatic, or advanced disease.^{46, 68, 69}

Taken together, these preclinical and clinical studies provide evidence that the induction of angiogenesis is an early and important step in tumor progression, likely occurring in precancerous lesions, and is involved in metastatic spread. For these reasons, angiogenesis is a rational target for chemoprevention. Additional studies will be needed to elucidate the key regulators of early angiogenesis, and to identify the different types of antiangiogenic agents that may be optimal for chemoprevention, advanced disease, and other applications.

Regulators of angiogenesis

The discovery of diffusible factors stimulating tumor angiogenesis

The observation in the 1970s that tumors implanted into the avascular cornea or onto the vascularized chick chorioallantoic membrane induced an ingrowth of new capillaries indicated that tumors released diffusible angiogenic factors.⁹ This result motivated the development of *in vitro* and *in vivo* bioassays to guide the search for tumor-derived angiogenic factors.⁷⁰

Fibroblast growth factors

bFGF (or FGF-2) was the first angiogenic protein to be isolated and purified from a tumor (1982), followed shortly by acidic FGF (aFGF or FGF-1).^{28, 71, 72} Acidic and bFGFs stimulate endothelial cell mitosis and migration *in vitro* and are among the most potent angiogenic proteins *in vivo*. They have high affinity for heparin and heparan sulfate.⁷³ The expression of bFGF receptors is very low. A wide variety of cancer types secrete bFGF, including those of the central nervous system, sarcomas, genitourinary tumors, and even endothelial cells in the tumor vasculature. Identification of an FGF-binding protein secreted by tumors into the extracellular matrix may illuminate a mechanism of tumor mobilization of stored FGFs.^{74–76} Furthermore, some tumors recruit macrophages⁷⁷ and activate them to secrete bFGF,⁷⁸ whereas others attract mast cells, which, because of their high content of heparin, could sequester bFGF. In spontaneous tumors that arise in transgenic mice, aFGF and bFGF are exported into conditioned medium by angiogenic tumor cells but not by preangiogenic cells in earlier stages of tumor progression.^{38,}

⁷⁹ bFGF also interferes with adhesion of leukocytes to endothelium, and it has been suggested that tumors that elaborate bFGF may produce a form of local immunologic tolerance.^{80–82} In mouse models of cancer, inhibition of the FGFR signaling pathways results in inhibited tumor angiogenesis and reduced tumor growth.⁸³

Abnormally elevated levels of bFGF are found in the serum and urine of cancer patients and in the cerebrospinal fluid of patients with different types of brain tumors.^{84, 85} High bFGF levels in renal carcinoma correlated with a poor outcome.⁸⁶ Moreover, bFGF levels in the urine of children with Wilms' tumor correlate with stage of disease and tumor grade.⁸⁷

In addition to contributing to tumor angiogenesis, multiple FGFR fusion proteins have been identified on diverse cancers including lung squamous cell, bladder, glioblastoma, and thyroid cancer, and appear to be oncogenic drivers as pharmacologic inhibition of FGFR suppresses the growth of FGFR fusion-positive tumor models.⁸⁸ Additional reports have shown FGFR1 to be amplified in a subset of small cell lung cancers among other malignancies, and tumor cells harboring FGFR amplification are sensitive to target inhibition.⁸⁹ In these settings, inhibition of FGFRs will therefore have both direct antitumor cell effects and indirect tumor cell effects through targeting of the tumor vasculature.

Vascular endothelial growth factor (VEGF) family

Dvorak first proposed that tumor angiogenesis is associated with increased microvascular permeability.⁹⁰ This led to the identification of vascular permeability factor (VPF).^{91–93} VPF was subsequently sequenced by Ferrara and colleagues and in 1989 was reported to be a specific inducer of angiogenesis called VEGF.^{92–94} At the same time, a novel angiogenic protein was first isolated and purified from a tumor (sarcoma 180) in the Folkman lab, and in a collaboration with Ferrara was shown to be VEGF.⁹⁴ Since then, more than 40 angiogenic inducers have been identified, most as tumor products ([Table 1](#)).^{3, 95} VEGF is an endothelial cell mitogen and motogen that is angiogenic *in vivo*.^{96–98} Its expression correlates with blood vessel growth during embryogenesis and is essential for development of the embryonic vascular system.^{99, 100} VEGF expression also correlates with angiogenesis in the female reproductive tract, and in tumors.^{49, 101–103} VEGF is a 40–45 kDa homodimeric protein with a signal sequence secreted by a wide variety of cells and the majority of tumor cells. VEGF exists as five different isoforms of 121, 145, 165, 189, and 206 amino acids, of which VEGF₁₆₅ is the predominant molecular species produced by a variety of normal and neoplastic cells. Two receptors for VEGF are found mainly on vascular endothelial cells, the 180 kDa fms-like tyrosine kinase (Flt-1)¹⁰⁴ and the 200 kDa human kinase insert domain-containing receptor (KDR) and its mouse homolog, Flk-1.¹⁰⁵ VEGF binds to both receptors, but KDR/Flk-1 transduces the signals for endothelial proliferation and chemotaxis.^{106–109} Other structural homologs of the VEGF family include VEGF-B, VEGF-C, VEGF-D, and VEGF-E.^{110, 111} VEGF-C and VEGF-D bind to Flt-4, which is preferentially expressed on lymphatic endothelium.^{112, 113}

Table 1 Examples of regulators of angiogenesis

Proangiogenic molecules	Antiangiogenic molecules	Transcription factors, oncogenes, and other regulators
Vascular endothelial growth factor (VEGF)	Interferon- α,β,γ	Hypoxia-inducible factor (HIF)-1 α , 2 α
Basic fibroblast growth factor (bFGF)	Thrombospondin-1,2	Nuclear factor- κ B (NF κ B)
Transforming growth factor- α (TGF- α)	Angiopoietin 2	Epidermal growth factor receptor (EGFR)
Platelet-derived growth factor (PDGF)	Tissue inhibitors of MMPs (TIMPs)	Ras
Epidermal growth factor (EGF)	Endostatin	p53
Angiopoietins	Angiostatin	von Hippel-Lindau
Interleukin-6	Interleukin-12	Cadherin
Interleukin-8	Endostatin	Integrin
Matrix metalloproteinases (MMPs)	Thrombospondin-1	Semaphorin
Hepatocyte growth factor (HGF)		Id1, Id2
Stromal cell-derived factor-1 α (SDF-1 α)		Prolyl hydroxylases
Delta-like ligand 4 (DLL4)		myc
Ephrins		
Monocyte chemoattractant protein-1 and other chemokines		

Klagsbrun et al. discovered that neuropilin-1, a neuronal guidance molecule, is a coreceptor for VEGF₁₆₅, but not for VEGF.^{114, 115} This finding provides a molecular mediator that coordinates growth in the vascular system with the nervous system. Other neuronal guidance proteins and/or their receptors are also angiogenesis regulators. For example, neuropilin is a receptor for VEGF and for semaphorin. Semaphorin repels neurite outgrowth and is also an angiogenesis inhibitor. Ephrins are neural guidance molecules, but also genetically determine arteries and veins during embryogenesis. EphrinB2 is expressed by tumor vascular endothelium. Perhaps in part because of the overlap between regulators of the nervous and vascular systems, angiogenesis in brain tumors has distinctive characteristics such as high interstitial fluid pressure (IFP) and low oxygen tension that contribute to the malignant behavior of these tumors.¹¹⁶

Neuropilin is not a tyrosine kinase receptor and is expressed on nonendothelial cells, including tumor cells. This allows VEGF that is synthesized by tumor cells to bind to their surface. Surface-bound VEGF could make endothelial cells chemotactic to tumor cells, or it could act in a juxtacrine manner to mediate co-option of microvessels by tumor cells. Neuropilin also binds placenta growth factor-2 (PlGF-2), and heparin is essential for the binding of VEGF₁₆₅ and PlGF-2 to neuropilin-1.^{40, 117} The natural cell surface polysaccharide *in vivo* is heparan sulfate, not heparin. Heparan sulfate may act as a template to accelerate the interaction of VEGF or PlGF-2 with VEGF. VEGF expression by tumors is upregulated by hypoxia and is often elevated near areas of tumor necrosis.^{118–121} Hypoxia activates hypoxia-inducible factor-1 (HIF-1), which binds to the hypoxia response element (HRE sequence) in the VEGF promoter, which

leads to VEGF mRNA transcription.^{106, 120} Independent of this, hypoxia stabilizes the VEGF mRNA.

VEGF signal transduction

While VEGF-A binds VEGFR1 with a higher affinity than VEGFR-2, the majority of biological effects of VEGF-A on tumor endothelium are thought to be mediated through VEGFR-2. Upon ligand binding, VEGFR-2 dimerizes, resulting in activation of the tyrosine kinase and autophosphorylation of residues including Tyr⁹⁵¹, Tyr⁹⁹⁶, Tyr¹⁰⁵⁴, Tyr¹¹⁷⁵, and Tyr¹²¹⁴.¹²² Phosphorylation of these residues induces the activation of signal transduction molecules including PI3K, phospholipase C- γ (PLC- γ), Akt, Src, Ras, and MAPK (Figure 3). Phosphorylation of Tyr¹¹⁷⁵ results in the binding and phosphorylation of PLC- γ , which subsequently promotes the release of Ca²⁺ from internal stores and activation of protein kinase C (PKC). PKC activation and Ca²⁺ mobilization are considered to be critical for VEGF-A-induced cell proliferation and nitric oxide production, respectively.¹²³

Figure 3 VEGFR signal transduction. VEGF family members, VEGF, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PIGF bind three VEGFR tyrosine kinases, resulting in dimerization, receptor autophosphorylation, and activation of downstream pathways. Signal transduction via VEGFR2 is shown. Ligand binding to VEGFR2 activates signal-transduction molecules phospholipase C- γ (PLC- γ), PI3K, Akt, Ras, Src, and MAPK and regulates cell proliferation, migration, survival, and vascular permeability.

The PI3K pathway is paramount in the regulation of cell proliferation, survival, and migration. VEGF-A has been shown to promote phosphorylation of the p85 subunit of PI3K and enhance PI3K enzymatic activity. The mechanism by which VEGF-A results in activation of PI3K remains unclear, although studies have implicated a role for Src kinases, β -catenin, and VE-cadherin.^{124, 125} VEGFR-2-induced activation of PI3K results in accumulation of phosphatidylinositol-3,4,5-trisphosphate (PIP₃), which induces phosphorylation of Akt/PKB. Once activated, Akt/PKB phosphorylates and thus inhibits proapoptotic proteins BAD and caspase-9.

Members of the Src family kinases, Src, Fyn, and Yes, are expressed in endothelial cells. Following VEGFR-2 autophosphorylation, T cell-specific adapter (TSAd) binds Tyr⁹⁵¹ and then associates with Src. Src kinases control actin stress fiber organization and may mediate VEGF-A-induced PI3K activation. Ligand binding to VEGFR-2 also initiates activation of the Ras pathway, triggering signaling through the Raf-1–MEK–ERK signal cascade¹²² known to be important in growth factor-induced cell proliferation. This activation may occur through multiple routes.^{122, 126}

Biological function of VEGF

In its initial discovery, VEGF was identified as a mediator of vessel permeability.^{110, 127} This capacity to render small veins and venules hyperpermeable is a critical function of VEGF. VEGF is indeed one of the most potent regulators of vascular permeability, and the observation that tumor-associated blood vessels are hyperpermeable is attributed to tumor-secreted VEGF. While the mechanisms by which VEGF increases microvascular permeability are incompletely understood, it may be at least in part due to VEGF-induced endothelial fenestrations,¹⁰⁰ opening of junctions between adjacent endothelial cells,¹²⁸ and through a calcium-dependent pathway involving nitric oxide (NO) production.^{129–131}

In addition to its effect on vascular permeability, VEGF is a survival factor for endothelial cells, inhibiting endothelial cell apoptosis through activation of the PI3K–Akt pathway¹³² and increases in the antiapoptotic protein bcl-2.¹³³ *In vivo*, VEGF blockade has been demonstrated to cause increases in apoptosis of immature, nonpericyte-covered vessels.¹³⁴ VEGF is an endothelial cell mitogen though VEGFR-2 mediates signal transduction through Erk1/2, JNK/SAPK, and possibly PKC.^{133, 135} While VEGF is not as potent an endothelial cell mitogen as other factors such as bFGF, it has a broader range of activity for processes critical for angiogenesis. VEGF induces expression of MMPs and serine proteinases involved in degradation of the basement membrane, which is necessary for endothelial cell sprouting and invasion.¹³³ In addition, VEGF facilitates endothelial cell migration through FAK and p38 MAPK-induced actin reorganization.^{3, 128, 133, 136}

Circulating VEGF may be one of the angiogenic signals by which tumors recruit bone marrow-derived cells, including endothelial progenitors and myeloid cells whose recruitment is thought to be mediated by VEGFR-2 and VEGFR-1, respectively.^{137–141} A growing body of evidence suggests that VEGFR-bearing bone marrow-derived cells contribute to initiating tumor formation, by creating a “metastatic niche”, and/or help promote tumor angiogenesis^{142–146} although there appear to be VEGFR-1-independent mechanisms as well.¹⁴⁷ Circulating endothelial and myeloid cells are further being studied as potential biomarkers, as noted later in the chapter, and may contribute to resistance to VEGF pathway inhibitors.^{148, 149} It is worth noting that not all VEGF in the circulation may be tumor derived. VEGF serum concentrations closely correlate with platelet counts in cancer patients. VEGF is stored in platelets, and is transported by and released from them.¹⁵⁰ Furthermore, Pinedo and colleagues report that higher platelet counts correlate with a worse prognosis for cancer patients.^{151, 152} Therefore, it is possible that for those

types of tumors that recruit bone marrow-derived endothelial cells, communication from tumor to bone marrow may be mediated in part by the VEGF in circulating platelets.

Angiopoietins

Angiopoietin-1 (Ang1) is a 70 kDa ligand that binds to a specific tyrosine kinase expressed only on endothelial cells, called Tie2 (also called Tek). Ang1 ligand binds Tie2 expressed on ECs, and Tie2 subsequently dimerizes and is phosphorylated. Activated Tie2 triggers activation of PI3K and Ras/Raf/MEK, promoting EC survival and proliferation/migration ([Figure 4](#)).¹⁵³ A ligand for Tie1 has not been elucidated.^{114, 154–157} Like VEGF, Ang1 is an endothelial cell-specific growth factor. Ang1, however, is not a direct endothelial mitogen *in vitro*. Rather, it induces endothelial cells to recruit pericytes and smooth muscle cells to become incorporated in the vessel wall. Pericyte and smooth muscle recruitment is mediated by endothelial production of PDGF-BB (and probably other factors) when Tie2 is activated by Ang1.¹⁵⁸ There is increased vascularization in mice that overexpress Ang1 in the skin.¹⁵⁷ The vessels are significantly larger than normal and the skin is reddened. The vessels are not leaky and there is no skin edema, in contrast to dermal vessels of mice overexpressing VEGF. In double transgenic mice expressing both Ang1 and VEGF in the skin, dermal angiogenesis is increased in an additive manner, but the vessels do not leak.¹⁵⁹ This model closely approximates angiogenesis in healing wounds (i.e., relatively nonleaky vessels with pericytes and some perivascular smooth-muscle cells contained in the vascular wall). In contrast, tumor vessels are leaky and thin walled with a paucity of pericytes. Angiopoietin-2, produced by vascular endothelium in a tumor bed, blocks the Tie-2 receptor and acts to repel pericytes and smooth muscle.¹⁵⁴ Nevertheless, tumor vessels remain thin “endothelium-lined tubes” even though some of these microvessels reach the diameter of venules. High levels of Ang2 are associated with metastases in melanoma patients, and in preclinical models, Ang2 promotes metastatic formation.^{160, 161} A key point is that angiopoietins and VEGF together play a role in angiogenesis, and the activity of both is context dependent with different activities observed in angiogenic versus mature vessels. Because VEGF plays a key role in the proangiogenic activity of Ang2, using combination inhibitors targeting both the Ang/Tie2 and VEGF receptor pathways may provide clinical benefit, a concept that has begun to be explored. However, given that angiopoietins can apply either pro- or antitumorigenic effects, depending on the context, the best targeting approach remains unclear.¹⁵³

Figure 4 Ang/Tie2 signaling pathway. (a) Representation of nascent tumor blood vessel structure in quiescent state. Endothelial cells (ECs; green) are organized to form vessel lumen and tightly interact with perivascular cells (blue), separated by basement membrane. (b) Ang1 ligand binds Tie2 localized on ECs; Tie2 subsequently dimerizes and is phosphorylated. Activated Tie2 activates phosphatidylinositol 3-kinase and Ras/Raf/MEK, promoting EC survival and proliferation/migration. Generally, Ang2 functions as an Ang1 antagonist by inducing increased vascular permeability, sprouting vascularization. Autophosphorylated Tie2 activates Tie1, the extracellular domain of which in turn interferes with Ang1/Tie2 binding, therefore antagonizing Ang1 signaling. Ang1 has anti-inflammatory properties, whereas Ang2 plays a proinflammatory role. Ang1-activated Tie2 inhibits nuclear factor-κB-mediated inflammatory gene expression, whereas Ang2 promotes expression through blockade of Ang1 function. (c) Perivascular cells secrete Ang1, which binds Tie2 expressed on ECs. In this interaction, Ang1 contributes to vessel integrity, reduces vessel permeability, and maintains vasculature quiescence. (d) Ang2 plays a major role in angiogenesis by mediating dissociation of pericytes and destabilizing cellular junctions. In the presence of other proangiogenic factors (e.g., VEGF), ECs proliferate and/or migrate to form new sprouting, disorganized blood vessels. In the absence of proangiogenic factors, Ang2 signaling results in EC apoptosis and regression.

Other factors regulating angiogenesis

Interleukin-8 (IL-8) is a proinflammatory chemotactic cytokine produced by monocytes, macrophages, and tumor cells.¹⁶² IL-8 induces endothelial cell proliferation and chemotaxis as well as promotes endothelial cell survival.^{162, 163} The effects of IL-8 are mediated through interactions with two cell-surface G protein-coupled receptors, CXCR1 and CXCR2, and activation of subsequent downstream signaling molecules including PI3K and MAPK.¹⁶⁴ Hepatocyte growth factor/scatter factor (HGF/SF) is the ligand for c-Met.¹⁶⁵ Originally identified as a mitogen for primary cultured hepatocytes, HGF has since been shown to facilitate tumor angiogenesis. c-Met is expressed on endothelial cells, and activation by tumor-secreted HGF/SF augments matrix degradation and endothelial cell invasion. NOTCH proteins and ligands are also elevated in several cancers, and NOTCH signaling has been shown to both promote and suppress tumor growth depending on the tumor type.¹⁶⁶ Interactions between NOTCH and its ligand DLL4 promote tumor angiogenesis through an intricate cross-regulation of NOTCH and VEGF/VEGFR signal transduction pathways.^{167, 168}

Endogenous inhibitors of angiogenesis

Endogenous angiogenesis inhibitors block vascular endothelial cells from proliferating, migrating, or increasing their survival in response to a spectrum of proangiogenic proteins, including VEGF, bFGF, interleukin-8, PDGF, and PD-ECGF. Natural angiogenesis inhibitors include interferon- α , interleukin-12, platelet factor 4, TSP-1, angiostatin, endostatin, arrestin, canstatin, tumstatin, PEX (MMP-2), pigment epithelium-derived factor, and antiangiogenic antithrombin III (an internal fragment of antithrombin III, named aaAT).^{27, 169–175}

The first clue to the existence of endogenous angiogenesis inhibitors came from the discovery that interferon- α inhibited endothelial cell migration and that platelet factor 4 inhibited endothelial proliferation.^{176–178} Both were subsequently shown to inhibit angiogenesis.^{176–180} However, Bouck and her colleagues were the first to show that a tumor could generate an angiogenesis inhibitor; they subsequently proposed that the angiogenic phenotype was the result of a net balance of endogenous inhibitors and stimulators of angiogenesis.¹⁸¹ A nontumorigenic hamster cell line became tumorigenic in association with the loss of a suppressor gene and concomitant with the onset of angiogenic activity. The nontumorigenic line secreted high levels of an angiogenesis inhibitor, a truncated form of TSP-1, that decreased by about 96% in the tumorigenic cells.¹⁸² TSP-1 was shown to be regulated by the wild-type tumor suppressor *p53* in fibroblasts and in mammary epithelial cells.^{183, 184} Loss of *p53* function in the transformed derivatives of these cells dramatically decreased the level of the angiogenesis inhibitor. Restoration of *p53* upregulated TSP-1 and raised the antiangiogenic activity of the tumor cells. Deletion of TSP-1 led to accelerated growth of breast cancers that arise spontaneously in neu-transgenic mice.¹⁸⁵ The demonstration that the switch to an angiogenic phenotype involved a negative regulator of angiogenesis generated by the tumor per se suggested to Folkman a unifying angiogenic mechanism to explain a well-recognized but previously unsolved clinical and experimental phenomenon: the inhibition of tumor growth by the tumor mass. In this phenomenon, “the removal of certain tumors, for example, breast carcinomas, colon carcinomas, and osteogenic sarcomas can be followed by rapid growth of distant metastases”.^{186, 187} Postoperative chemotherapy was introduced mainly to prevent or delay the growth of secondary metastases. Several studies in terminally ill patients demonstrated the suppression of a secondary tumor by a primary tumor.¹⁸⁸ In melanoma, partial spontaneous regression of the primary tumor may be followed by rapid growth of metastases, and when ionizing radiation is employed to regress a small cell lung cancer, distant metastases may undergo rapid growth.^{173, 189} Once it was demonstrated

that a tumor could generate a negative regulator of angiogenesis, then it became clear that a primary tumor, while stimulating angiogenesis in its own vascular bed, could possibly inhibit angiogenesis in the vascular bed of a distant metastasis.¹⁸² However, at least two conditions would be necessary: first, the primary tumor (i.e., the first tumor to grow) would need to generate an angiogenic promoter in excess of an inhibitor in its own vascular bed, and, second, the putative inhibitor would need to have a longer half-life in the circulation than the angiogenic promoter. After arriving in the Folkman laboratory in 1991, O'Reilly and his colleagues validated this hypothesis by discovering angiostatin, endostatin, and antiangiogenic antithrombin over the next 8 years.^{171–173, 190, 191}

Angiostatin

Angiostatin is a 38 kDa internal fragment of plasminogen that was purified from the serum and urine of mice bearing a subcutaneous Lewis lung carcinoma that suppressed growth of its lung metastases by inhibiting their angiogenesis ([Figure 5](#)).¹⁷¹ Angiostatin is not secreted by tumor cells but is generated through proteolytic cleavage of circulating plasminogen by a series of enzymes released from the tumor cells. At least one of these tumor-derived enzymes, urokinase plasminogen activator (uPA), converts plasminogen to plasmin, whereas a phosphoglycerate kinase from hypoxic tumor cells then reduces the plasmin so that it can be converted to angiostatin by one of several different metalloproteinases.¹⁹² Several potential mechanisms of its antiangiogenic activity have been reported. These include induction of endothelial apoptosis^{193–195}; suppression of endothelial cell migration induced by plasmin binding to $\alpha_v\beta_3$ -integrin^{196, 197}; inhibition of HGF-induced signaling via c-MET, Akt, and ERK-1/2¹⁹⁸; and downregulation of VEGF expression in tumor cells.¹⁹⁹ This implies that angiostatin may act as a direct and an indirect inhibitor of angiogenesis. In support of this, when angiostatin was delivered to mice bearing a variety of tumors, it showed significant efficacy either alone or in combination with endostatin, as a fusion protein of angiostatin and endostatin, or in combination with interleukin-12.^{199–202}

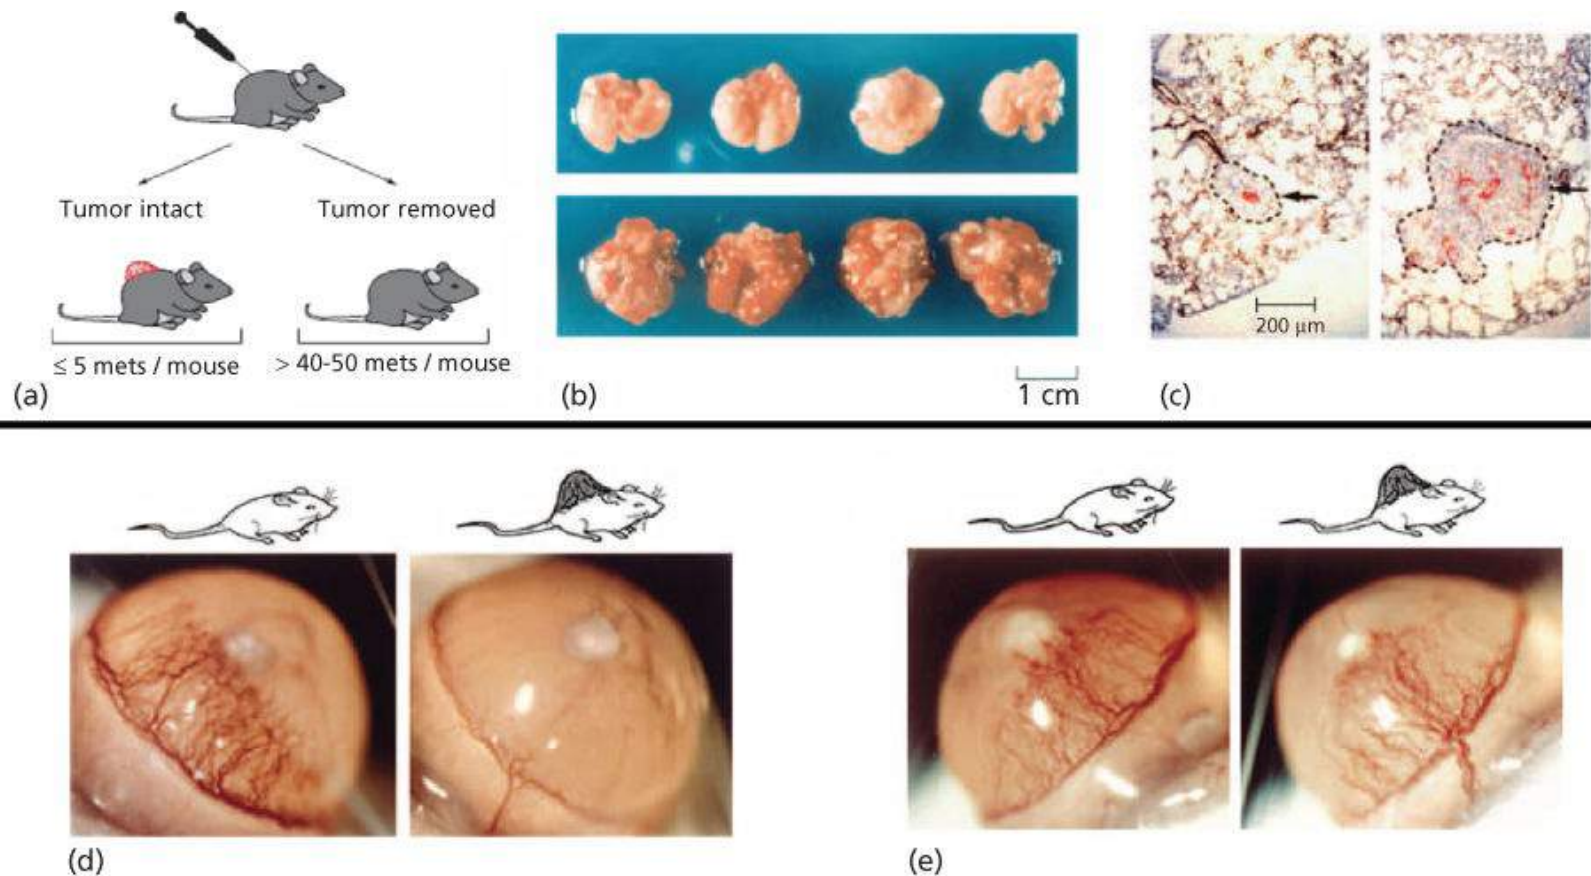

Figure 5 (a) Mice bearing Lewis Lung carcinoma.⁴⁹⁹ Tumors were resected when tumor size reached 1.5–2 cm² and the animals were killed after 5 or 15 days. (b) Upper panel: lungs from animals still bearing the primary tumor. Lower panel: lungs removed at the same time from animals in which the tumor had been resected and the animals killed 15 days later. (c) Left panel: microscopic pulmonary metastasis in an animal in which a primary tumor is in place at the same time as the right panel. There is no evidence of angiogenesis as only a single central microvessel stained with antibody to von Willebrand factor. This dormant metastasis is 200 μ m in its longest diameter. Right panel: lung metastasis from an animal euthanized 5 days after the primary tumor was removed, showing eight or nine new vessels in an enlarging metastasis. (d) A human prostate carcinoma (LNCaP) growing on the dorsum of an SCID mouse inhibits cornea neovascularization induced by an implanted sustained release pellet of bFGF (80 ng) (right panel). Left panel depicts bFGF-induced corneal neovascularization at 5 days in the absence of a primary tumor. LNCaP prostate cancer generates angiostatin. (e) A human colon cancer that does not produce an angiogenesis inhibitor, growing in an SCID mouse as a control for (d).

Endostatin

A strategy similar to the one that uncovered angiostatin (e.g., suppression of tumor growth by tumor mass) was employed with murine hemangioendothelioma and human small cell lung cancer to discover endostatin and the antiangiogenic conformation of antithrombin-IIIAT.^{172, 173, 191} Both endostatin and aaAT are generated from larger parent proteins by enzymes released by tumor cells. Endostatin is a 20–22 kDa internal fragment of collagen XVIII.^{172, 191, 203, 204} It is the first of a group of endogenous angiogenesis inhibitors that are predominantly extracellular proteins, which generally require proteolytic processing to become active.^{3, 205} Like angiostatin, endostatin appears to have both direct and indirect effects on tumor endothelium, and a number of different mechanisms have been proposed. It is a specific inhibitor of endothelial cell proliferation and migration,^{206, 207} and blocks the binding of VEGF₁₂₁ and VEGF₁₆₅ to the KDR/ Flk-1 receptor and subsequent downstream signaling events.²⁰⁸ Although endostatin does not bind

to VEGF,²⁰⁸ it does downregulate VEGF expression in tumor cells.¹⁹⁹ In bFGF-treated endothelial cells, endostatin induces endothelial cell apoptosis, in part by activating tyrosine kinase signaling of the Shb adaptor protein.²⁰⁹ Endostatin decreases formation of VEGF-induced microvessels sprouting from aortic rings *in vitro*²¹⁰ and inhibits the catalytic activity of MMP-2.^{211, 212} As a result, endothelial cell invasion is inhibited and tumor cell invasion may also be decreased. Endostatin also inhibits integrin-dependent endothelial cell migration because it binds to α_5 - and α_v -integrins on the endothelial cell surface, in particular $\alpha_5\beta_1$.²¹³ It has been proposed that $\alpha_5\beta_1$ -integrin may be a functional receptor for endostatin.³⁴

A wide variety of tumors in many different laboratories have been inhibited by endostatin in mice and rats.²¹⁴ These include lung adenocarcinoma, thyroid carcinoma, colon carcinoma, leukemia, human non-small cell lung cancer (NSCLC), human pancreatic cancer, human neuroblastoma, breast cancer, and spontaneous pancreatic islet carcinomas.^{215–222}

Tumstatin

Tumstatin (28 kDa) is the NC1 domain fragment of the α_3 collagen molecule and exhibits antiangiogenic activity in both *in vitro* and *in vivo* assays.^{223–227} Tumstatin (α_3 (IV)NC1) binds to endothelial cells via $\alpha_v\beta_3$ -integrin and $\alpha_6\beta_1$ -integrin^{223, 224, 226, 227} and induces apoptosis of proliferating endothelial cells.²²⁵ Cell biologic experiments demonstrated that the antiangiogenic activity of tumstatin is dependent on $\alpha_v\beta_3$ -integrin binding to proliferating endothelial cells.^{223, 227} These experiments support the notion that through the action of endogenous inhibitors such as tumstatin, $\alpha_v\beta_3$ -integrin could also function as a negative regulator of angiogenesis.^{223, 228–230}

Antiangiogenic conformation of antithrombin III

A human small cell lung carcinoma suppressed angiogenesis and tumor growth at remote sites in immunodeficient mice. These cells generated an enzyme *in vitro* that converted the 58 kDa conformation of circulating antithrombin III to a 53 kDa form of the protein in which the externally configured stressed loop of antithrombin was retracted into the body of the molecule. The 53 kDa “cleaved” form is a specific endothelial inhibitor and a potent angiogenesis inhibitor and has no thrombin-binding activity. Antithrombin III has no antiendothelial or antiangiogenic activity. The enzymes that induce this conformational change have not yet been elucidated. Human pancreatic cancer also generates the 53 kDa cleaved antiangiogenic antithrombin.²¹⁵

Other pathways regulating angiogenesis

Hypoxia-inducible factor-1

Expression of angiogenic factors including VEGF is positively regulated by hypoxia through the stabilization of the transcription factor hypoxia-inducible factor 1 (HIF-1).^{231, 232} HIF-1 is a transcription factor comprised of two subunits, HIF-1 α and HIF-1 β . While HIF-1 β is expressed constitutively, expression of HIF-1 α is tightly regulated. The stability of HIF-1 α is primarily controlled by hypoxia. When oxygen is abundantly present, prolyl hydroxylases modify proline residues 402 and 564 on HIF-1 α allowing it to bind the VHL tumor suppressor gene which targets it for degradation.²³² Following binding of the HIF-1 α and - β subunits, HIF-1 translocates to the nucleus and modulates the expression of numerous genes involved in angiogenesis, cell survival, invasion, and glucose metabolism.²³² Indeed, HIF-1 α is thought to be the key regulator of potent proangiogenic factors including VEGF.

Although initially thought to be primarily regulated by hypoxia, recent studies have revealed a number of nonhypoxic regulators including receptor tyrosine kinases such as EGFR,²³³ the PI3K/AKT/mTOR pathway, and metabolic pathways including the tricarboxylic acid (Krebs) cycle (reviewed in Ref.). Alterations in these pathways have been shown to contribute to inherited cancer syndromes, highlighting their role in carcinogenesis. For example, germline mutations in the VHL gene underlying von Hippel-Lindau disease lead to a markedly elevated risk of developing renal cell carcinoma (RCC), hemangioblastomas of the CNS, and other tumor types. The VHL protein encoded by this gene is part of a protein complex that targets HIFs for degradation.²³⁴ Sporadic mutations in the VHL gene also occur in sporadic clear-cell RCC. A second syndrome, hereditary leiomyomatosis and RCC, results from mutations in the fumarate hydratase (FH) gene.²³⁶ FH is a mitochondrial protein involved in the TCA cycle. Although the mechanism(s) by which FH mutations promote tumorigenesis is still under investigation, it appears that loss of FH function results in an increase in HIFs by causing a buildup of intracellular fumarate, which inhibits the enzymes (HIF hydroxylases, also known as EGLNs) that hydroxylate HIFs and target them for VHL-mediated degradation. A third hereditary syndrome, tuberous sclerosis complex, is caused by mutations in the tuberous sclerosis complex, resulting in elevated HIFs via the mTOR pathway.^{237, 238} Several other syndromes have also been identified that resulted in elevated levels of HIFs and downstream HIF-regulated gene products, causing a “pseudohypoxic” state.^{235, 237} The observations that multiple inherited cancer syndromes involve pathways that converge on HIFs support the hypothesis that dysregulation of the pathways regulating angiogenesis is likely to play a role in driving early tumorigenesis. Several drugs targeting HIFs are currently in clinical development.

Oncogenes as regulators of angiogenesis

It is widely established that activation of proto-oncogenes can induce tumorigenesis. In tissue culture, expression of activated oncogenes increases cell proliferation and decreases apoptosis.²³⁹ While these changes contribute to tumorigenesis by altering the equilibrium between cell proliferation and apoptosis, there is considerable evidence that this alone is not sufficient to produce expansive tumor growth.^{240, 241} Rather, tumors must also acquire an adequate vascular supply to grow beyond 1–2 mm in diameter. In support of this concept, published reports have demonstrated that transfection of tumor cells with oncogenes results in enhanced production of proangiogenic molecules,²⁴² and the *in vivo* growth of oncogene-driven tumors can be restricted with angiogenesis inhibitors.²⁴³ In lung cancer patients, for example, mutations in K-Ras, p53, and EGFR are among the oncogenes that have been linked to angiogenesis. Oncogenes shown to play a role in regulating angiogenic factors include:

Ras

Ras is one of the most commonly activated oncogenes, occurring in 17–25% of all human tumors.²⁴⁴ In tissue culture studies, transfection of transformed murine endothelial cells with the Ras oncogene results in elevated production of VEGF, and treatment of these cells with the PI3K inhibitor, wortmannin, abrogates VEGF expression, indicating that mutated Ras regulates VEGF expression in a PI3K-dependent manner.²⁴⁵ K-Ras gene mutations were positively associated with high VEGF expression in human NSCLC specimens²⁴⁶ and other disease types. In a transgenic model of melanoma, downregulation of the Ras oncogene in a melanoma driven by doxycycline-inducible Ras led to massive apoptosis of microvascular endothelium in the tumor bed starting within 6 h. Tumor cells began to die days later, and large tumors had completely disappeared by 12 days.²⁴⁷

p53

In addition to its role in the regulation of cell cycle and apoptosis, emerging data indicates that p53 indirectly promotes tumor vascularization by altering the expression of proangiogenic and antiangiogenic molecules. In tissue culture studies, fibroblasts expressing wild-type p53 secrete high levels of the antiangiogenic glycoprotein, TSP-1. However, loss of wild-type p53 and expression of the mutant form result in diminished TSP-1 mRNA and protein. Immunohistochemical evaluation of 73 NSCLC clinical specimens revealed a strong statistical association between p53 nuclear localization and microvessel count.²⁴⁸ Additionally, in an analysis of 107 NSCLC patients, p53 was determined to be significantly associated with VEGF expression and microvessel count.²⁴⁹ It is likely that loss of wild-type p53 enhances tumor cell expression of additional proangiogenic factors in NSCLC. Wild-type p53 has been demonstrated to promote Mdm2-mediated ubiquitination and degradation of HIF-1 α .²⁵⁰ The loss of wild-type p53 is associated with elevated levels of HIF-1 α in tissue culture and augments hypoxia-induced VEGF expression.²⁵⁰

Myc

Myc is a pleiotropic transcription factor overexpressed in many cancer types, which plays a role in regulating angiogenesis, inflammation, and many other processes. Myc activity has been shown to be regulated by RAS pathway activation,²⁴² which in turn regulates angiogenesis at least in part through effects on TSP-1. Myc has also been shown to interact with the HIF-1 α pathway to induce angiogenesis by an hypoxia-independent mechanism²⁵¹ and regulate the recruitment of mast cells required for myc-driven tumorigenesis in a transgenic mouse model.²⁵²

EGFR family

EGFR is a member of the erbB family of receptor tyrosine kinases, which also includes HER2/Neu, HER3 (ErbB3), and HER4 (ErbB4). An expanding body of evidence indicates that activation of EGFR leads to enhanced production of proangiogenic molecules. Initial experiments using prostate cancer cell lines demonstrated that stimulation of tumor cells with EGF elevated HIF-1 α expression.²⁵³ EGF has been shown to increase VEGF production in some tumor cell lines^{254, 255} and, conversely, treatment of tumor cells with EGFR inhibitors can decrease VEGF expression in various tumor types.^{233, 255–257} In NSCLC cell lines, EGF activates HIF-1 α and induces expression of the chemokine receptor CXCR4 in tissue culture.²⁵⁸ Moreover, in an immunohistochemical study of 172 NSCLC patients, expression of EGFR was associated with HIF-1 α positivity,²⁵⁹ and EGFR mutations causing constitutive receptor activation led to upregulated HIF-1 α protein and increased VEGF levels.²⁶⁰

Like EGFR, HER2/Neu has also been shown to play a role in regulating angiogenesis. Blockade of HER2 using the monoclonal antibody trastuzumab (Herceptin) has been shown to block the production of multiple angiogenic factors and induce vessel normalization and regression in a murine model of human breast cancer, and enhance the effects of VEGF pathway blockade.^{261, 262}

Therapeutic approaches to targeting tumor vasculature

Angiogenesis inhibitors versus vascular targeting agents

Angiogenesis is the formation of new vessels from preexisting vasculature. Angiogenesis inhibitors are therefore typically targeted at the early stages in this process, including endothelial sprouting and survival mechanisms, which are often VEGF dependent. Vascular targeting agents (VTAs), also known as vascular

disrupting agents (VDAs), differ from angiogenesis inhibitors in that they target established abnormal tumor vasculature.²⁶³ VTAs can induce rapid collapse of tumor vasculature, and their effects on normal vasculature can cause a host of side effects including acute coronary syndromes, thrombophlebitis, and tumor pain. None of these agents are currently in routine clinical use for cancer but several have undergone clinical testing. Vadimezan (ASA404) initially demonstrated positive results in combination with chemotherapy as treatment for patients with lung cancer in a phase II trial.²⁶⁴ Unfortunately, these findings were not validated in a subsequent phase III study evaluating vadimezan in combination with carboplatin/paclitaxel as first-line treatment in NSCLC, as no significant differences were demonstrated in overall survival (OS) between vadimezan and placebo arms [median OS 13.4 vs 12.7 months, respectively (hazard ratio; HR = 1.01; $p = 0.535$)]. Given the lack of clinical benefit, the development of vadimezan in lung cancer has been discontinued by Novartis.²⁶⁵ ABT-751 is another VDA with preclinical anticancer activity, which has failed to demonstrate an improvement in progression-free survival (PFS) in a phase I/II study in combination with docetaxel as second-line treatment for NSCLC.²⁶⁶

Antiangiogenic effects of chemotherapy and other therapeutic agents

Multiple preclinical studies have suggested that several “classical” chemotherapeutic agents may also have potent antiangiogenic or vascular-targeting effects, which may be enhanced by low dose, frequent dosing schedules (metronomic dosing).^{267–269} Several of these regimens are undergoing clinical evaluation. It also appears that certain chemotherapy agents, particularly taxanes and vinca alkaloids, may have relatively more potent antiangiogenic effects than other drugs,²⁶⁹ which may help explain why there are differences in the degree of enhancement observed when antiangiogenic agents such as bevacizumab are added to chemotherapy. This prompted further examination of a wide variety of drugs which were initially thought to target primarily tumor cells. Many of these were subsequently found to also have antiangiogenic effects, prompting the term “accidental antiangiogenics”.²⁷⁰

Targeting VEGF pathway

VEGF is the prototypic member of a family of structurally related, homodimeric growth factors that includes PlGF, VEGF-B, VEGF-C, VEGF-D, and VEGF-E. As described earlier, VEGF family members bind to a family of transmembrane receptor tyrosine kinases that include VEGFR-1 (Flt-1), VEGFR-2 (KDR, Flk-1), and VEGFR-3 (Flt-4) ([Figure 3](#)). The effects of VEGF or VEGFR on vascular permeability and endothelial proliferation, migration, and survival are thought to be primarily mediated by VEGFR-2, while VEGFR-3 is primarily expressed on lymphatic endothelium (reviewed in Ref.). Agents targeting the VEGF pathway include monoclonal antibodies that bind the ligand (i.e., bevacizumab) or block the receptor (ramucirumab). In addition, many small molecule receptor tyrosine kinase inhibitors (RTKIs) have been developed to target critical signaling pathways involved in angiogenesis. These RTKs, which include vatalanib (PTK787), vandetanib (ZD6474), sunitinib (SU11248), axitinib (AG-013736), and nintedanib (BIBF 1120), have been the focus of many preclinical and clinical studies. Because of the structural similarity of the different receptor tyrosine kinase domains, RTKIs typically inhibit multiple receptors such as PDGFR, c-KIT, FGFR, and Axl in addition to VEGFR. These multitargeting agents have demonstrated higher anticancer activity compared to agents with single targets. Furthermore, they are orally available, and thus more convenient for patients. Conversely, the off-target effects may have additive toxicities. These profiles of receptor specificity for each inhibitor, as well as their pharmacokinetics and potency for receptor inhibition, are likely to be the key determinants of their clinical activity. Representative agents targeting the VEGF pathway that are currently FDA approved are listed in [Table 2](#).

Table 2 Approved VEGF pathway inhibitors

Type	Agent	Target	Approval
Monoclonal antibody	Bevacizumab (Avastin)	VEGF-A	FDA approved for CRC, breast cancer, NSCLC, platinum-resistant ovarian carcinoma, and late-stage cervical cancer
	IMC-1121B Ramucirumab	VEGFR-2 extracellular domain	FDA approved for advanced gastric or gastro-esophageal junction adenocarcinoma; metastatic NSCLC
Soluble decoy receptor	VEGF Trap (Aflibercept)	VEGF-A, VEGF-B, and PlGF	FDA approved for metastatic colorectal cancer
RTKIs	Vandetanib	VEGFR-2, EGFR, and RET	FDA approved for progressive medullary thyroid carcinoma
	Sorafenib	VEGFR-2 and 3, PDGFR- β , Flt-3, c-Kit, and B-Raf	FDA approved for renal cell, hepatocellular cancers, and metastatic differentiated thyroid carcinoma
	Sunitinib	VEGFR-1,2, PDGFR, c-Kit, RET, and Flt-3	FDA approved for renal cell carcinoma, gastrointestinal stromal tumors, and neuroendocrine tumors of the pancreas
	AG-013736 (axitinib)	VEGFR-1,2,3 and PDGFR	FDA approved for RCC
	Lenvatinib	VEGFR-2,3	FDA approved for thyroid cancer
	BIBF 1120 (Nintedanib)	VEGFR-1,2,3, PDGFR, and FGFR-1/3	Approved by FDA and EU for idiopathic pulmonary fibrosis, Approved by EU for NSCLC
	GW786034 (pazopanib)	VEGFR2	FDA approved for RCC, and soft tissue sarcoma

AML, acute myelogenous leukemia; CRC, colorectal cancer; EGFR, epidermal growth factor receptor; FDA, Food and Drug Administration; EU, European Union; GBM, glioblastoma multiforme; NSCLC, non-small cell lung cancer; PlGF, placental growth factor; PDGFR, platelet-derived growth factor receptor; RCC, renal cell carcinoma; RTKI, small molecule receptor tyrosine kinase inhibitor; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

Combinations of antiangiogenics with chemotherapy: mechanisms for enhanced antitumor activity

Preclinical and clinical studies have demonstrated that antiangiogenic therapy improves the outcome of cytotoxic therapies.^{271, 272} This finding is paradoxical. It was initially expected that targeting the tumor vasculature would drastically diminish the delivery of oxygen and therapeutics to the solid tumor, producing hypoxia that would cause many chemotherapeutics, as well as radiation, to be less effective.^{271, 272} Tumor vasculature is known to be structurally and functionally abnormal, with tortuous, highly permeable vessels. Blood flow within these intratumoral vessels is nonuniform. Proliferating tumor cells compress blood and lymphatic vessels resulting in a microenvironment typified by interstitial hypertension (elevated hydrostatic pressure outside the blood vessels), acidosis, and hypoxia.^{273, 274} This deficient vascular network and interstitial hypertension impair drug delivery to tumor cells. Moreover,

hypoxia renders tumor cells resistant to radiation and several cytotoxic agents, and increases genetic instability selecting for tumor cells that have a greater metastatic potential. In addition to the direct effects on tumor cells, hypoxia leads to vascular abnormalization by signaling via PHD2 in tumor endothelial cells²⁷⁵ and, along with the low pH within the tumor microenvironment, weakens the cytotoxic functions of tumor infiltrating immune cells. Collectively, the abnormal vasculature within solid tumors creates a significant barrier to delivery and efficacy of cancer therapeutics.

One proposed mechanism to explain the enhancement in efficacy of chemotherapy by antiangiogenic therapy is that these agents have the potential to “normalize” tumor vessels. In animal models of cancer, inhibition of VEGF signaling results in a vasculature network that more closely resembles vessels within normal tissue. This “normalized” vasculature is less leaky, is less dilated, and has less tortuous vessels with a more normal basement membrane and increased pericyte coverage. Concurrent with these changes in vascular morphology, within the tumor there is a decrease in IFP, increased oxygenation, and improved delivery of concurrently administered chemotherapeutics ([Figure 6](#)).^{276–284} Evidence from a Phase I/II clinical trial in locally advanced rectal carcinoma patients receiving bevacizumab and chemotherapy (with radiation) corroborates preclinical findings. Bevacizumab treatment was associated with a decrease in tumor IFP and an increase in mature, pericyte-covered vessels.^{285, 286}

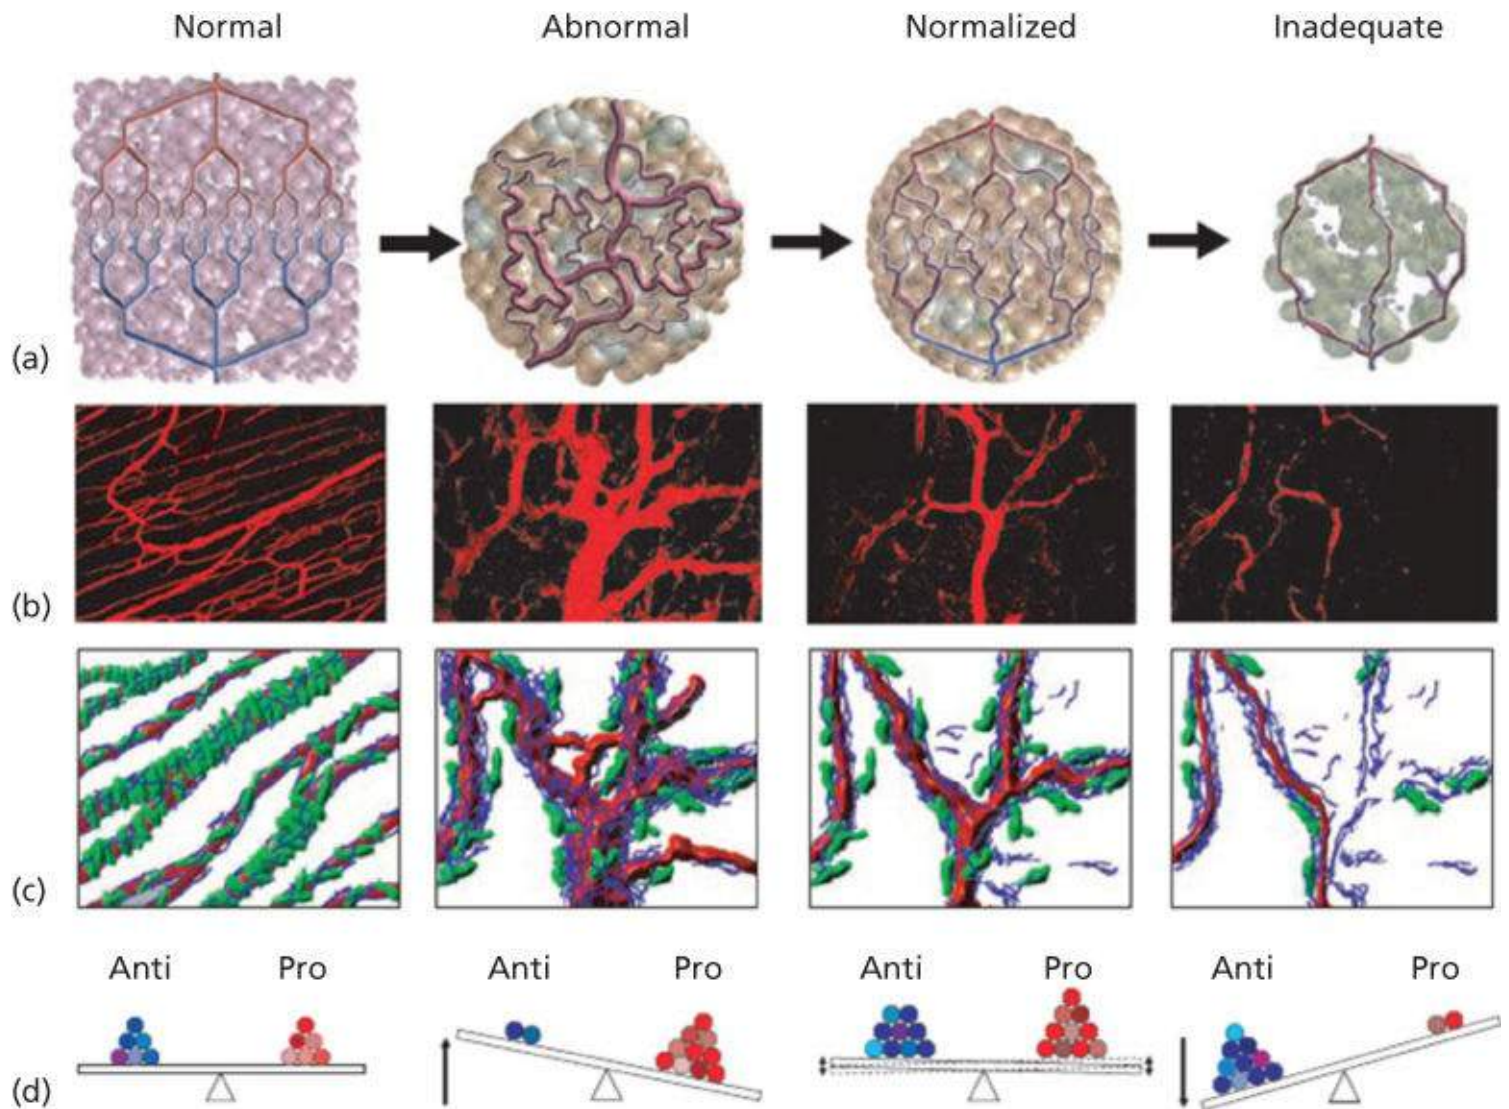

Figure 6 Changes in tumor vasculature during treatment with antiangiogenic agents.²⁷¹ (a) The tumor vascular network is structurally and functionally abnormal. Antiangiogenic therapies might initially improve both the structure and the function of tumor vessels. Continued or aggressive antiangiogenic regimens may eventually result in a vascular supply that is inadequate to support tumor growth. (b) Vascular normalization due to inhibition of VEGFR2. On the left is a two-photon image depicting normal blood vessels in skeletal muscle; subsequent representative images show human colon carcinoma vasculature in mice at day 0, day 3, and day 5 after treatment with a VEGFR2-specific antibody. (c) Diagram illustrating the concomitant changes in basement membrane (blue) and pericyte (red) coverage during vessel normalization. (d) These changes in the vasculature may reflect changes in the balance of pro- and antiangiogenic factors in the microenvironment.

Antiangiogenic agents in combination with radiotherapy

A growing body of evidence suggests that antiangiogenic therapy may enhance the efficacy of radiotherapy for solid tumors. There are several proposed mechanisms through which this enhancement may occur. First, radiotherapy may act by “normalizing” the disorganized and hyperpermeable vasculature in tumors.^{271, 287} Vessel normalization would permit a more effective delivery of oxygen to tumor tissue, resulting in a reduction in tumor hypoxia and augmenting radiation-induced cytotoxicity in part by increasing the formation of oxygen-free radicals. This reduction in hypoxia may be transient, however, as prolonged use of antiangiogenic agents may eventually also reduce the “normalized” vessels within tumors resulting in an inadequate intratumoral vascular supply, such that the tumor would again be hypoxic with reduced radiosensitivity. This concept is supported by mouse xenografts showing the

existence of a period of time (“normalization window”) during which radiation therapy used in conjunction with an antiangiogenic agent is most effective.^{283, 288}

Antiangiogenic therapy may act to enhance the antiendothelial effects of radiotherapy. While it was initially assumed that the antitumor effect of radiotherapy was due to direct action on tumor cells, more recent evidence has demonstrated that radiotherapy also induces endothelial cell apoptosis.^{288–290} Other studies have confirmed these results.²⁹¹ Thus, the exact mechanism(s) of interaction between antiangiogenic agents and radiation remains unclear.

Nevertheless, several preclinical studies demonstrate that antiangiogenic agents can synergize with or potentiate the effects of radiotherapy.^{292–296} Blockade of VEGF signaling on endothelial cells may render the tumor-associated vasculature more sensitive to radiotherapy. In addition, radiation induces VEGF expression, which contributes to radioresistance by blocking radiation-induced endothelial cell apoptosis.^{297, 298}

One possible cause for concern in testing combinations of antiangiogenic therapy and radiotherapy is the observation from preclinical studies that at least some of the toxicities of radiotherapy such as intestinal radiation damage may also be due to endothelial apoptosis.²⁹⁹ In lung cancer patients treated with the combination of bevacizumab, chemotherapy, and radiotherapy, tracheoesophageal fistulas have been observed.³⁰⁰ Clearly additional studies will be needed to assess the feasibility and efficacy of these combinations.

Clinical advances in the use of antiangiogenic therapy

The hypothesis that tumor angiogenesis could serve as a target for cancer therapy is now strongly supported by results of a number of randomized phase III clinical trials across multiple different tumor types. Bevacizumab, a monoclonal antibody targeting VEGF, is now a standard therapy for metastatic colorectal, non-small cell lung, and other tumor types^{301, 302}; VEGFR TKIs such as sunitinib, pazopanib, axitinib, and sorafenib are now approved for RCC and other diseases.^{303, 304} These advances, coupled with our increased understanding of the biological pathways underlying tumor angiogenesis and the development of improved agents for targeting these pathways, have led to a dramatic increase in the number of clinical trials employing antiangiogenic therapy either alone or in combination with other therapeutic modalities. Currently, the majority of these agents target the VEGF pathway because of its role as a key regulator of tumor angiogenesis.

VEGF pathway inhibitors as anticancer therapy: clinical experience. Clinical trials of one of the earliest VEGF pathway inhibitors, bevacizumab, began in 1997. When used as monotherapy for the treatment of advanced solid tumors, the clinical activity of these agents, as judged by objective tumor responses, has generally been low with the exception of RCC. For example, no partial or complete remissions were observed in 25 patients treated in a phase I trial of bevacizumab.³⁰⁵ Furthermore, in 243 previously treated patients with colorectal cancer, objective response rates (ORR) were 3% for bevacizumab monotherapy, 9.2% for FOLFOX4 chemotherapy (fluorouracil, oxaliplatin, leucovorin), and 21.8% for the combination. Low response rates have also been reported for VEGFR TKIs when used as single agents as discussed below. For this reason, VEGF pathway inhibitors have often been developed as part of combination regimen with chemotherapy or other targeted therapeutics. Major findings in the clinical development of VEGF pathway inhibitors for several common tumor types are reviewed below.

Renal cell cancer

One tumor type for which VEGF pathway inhibitors are particularly useful, even when used as monotherapy, is metastatic RCC. These tumors are often marked by inactivation of the von Hippel-Lindau gene leading to overexpression of VEGF and other angiogenesis mediators (reviewed in Ref. 306). In randomized studies, bevacizumab, sorafenib, and pazopanib have been shown to significantly prolong time to progression compared to placebo controls.^{307–309} Sunitinib and axitinib also demonstrated substantial antitumor activity in metastatic RCC, with 25–45% ORR in phase III testing.^{304, 310, 311}

Cytokine therapies (interferon- α - and interleukin-2-based therapies) had long been the mainstay of therapy for RCC, so it was rational to evaluate anti-VEGF therapy in the context of such agents. Phase III trials examining four small molecule RTKIs of VEGF receptors (sorafenib, sunitinib, pazopanib, and axitinib) and monoclonal anti-VEGF therapy (bevacizumab) have been reported, and consistently favor the use of anti-VEGF therapy compared to interferon.

Trials of anti-VEGF therapy versus cytokine therapy

Motzer and colleagues compared the use of sunitinib (at a dose of 50 mg orally daily for 4 weeks, followed by 2 weeks without treatment) or interferon α (9 MU subcutaneously three times weekly) in patients with previously untreated, metastatic RCC.³⁰⁴ The primary endpoint of PFS was significantly improved in patients receiving sunitinib (11 vs 5 months, $p < 0.001$). Patients receiving sunitinib also experienced higher response rates, longer OS, and improved quality of life.³¹⁰

Trials of cytokine therapy with or without anti-VEGF therapy

Escudier et al.³¹² and the Cancer and Leukemia Group B performed placebo-controlled Phase III trials comparing the use of interferon α -2a to interferon- α -2a plus bevacizumab in patients with previously untreated metastatic RCC.³¹³ PFS was significantly longer in patients receiving the combined biologic approach. There was a trend to improved OS favoring the bevacizumab-containing treatments.^{314, 315} More than 50% of the patients received second-line therapy including VEGF-targeted agents, potentially affecting the survival difference.^{315, 316}

Trials of anti-VEGF therapy following cytokine therapy

Escudier et al.³⁰³ performed a Phase III trial of sorafenib (400 mg twice daily) versus placebo in patients who had progressed following first-line cytokine therapy for advanced RCC. Median PFS was 5.5 months in the sorafenib group and 2.8 months in the placebo group ($p < 0.01$). Analysis of OS showed that sorafenib reduced the risk of death (HR, 0.88; 95% CI, 0.74–1.04; $p = 0.146$).³¹⁷ Although this benefit was not statistically significant, censoring of placebo-assigned patients who crossed over to sorafenib uncovered a significant result (17.8 vs 14.3 months, respectively; HR = 0.78; 95% CI, 0.62–0.97; $p = 0.0287$).

Therapy following initial anti-VEGF treatment

The demonstration of a beneficial effect for anti-VEGF therapy in RCC has fundamentally altered the treatment landscape for this disease. Nevertheless, anti-VEGF therapy is not curative and only modestly prolongs survival, leaving room for substantial therapeutic improvement. Patients progressing on one VEGF-targeting agent may still respond to another.^{318–320} Whether this cross-sensitivity is a function of the promiscuity of RTKIs, of differential pharmacokinetics, or of varying affinities for VEGF receptors is unknown.

mTOR inhibition in RCC

Two trials^{321, 322} examined the role of mTOR inhibition in patients with advanced RCC. While mTOR has several biologic roles, one is as a downstream effector of VEGF signaling. In a trial comparing the mTOR inhibitor temsirolimus versus interferon α versus the combination of temsirolimus plus interferon α as front-line therapy, Hudes et al.³²¹ demonstrated the superiority of temsirolimus to interferon α , with a significant improvement in OS (10.9 months vs 7.3 months, $p = 0.008$); the combination arm was not superior to interferon monotherapy. In addition, the temsirolimus group had fewer serious adverse events than the interferon α group. In a placebo-controlled randomized Phase III trial in the post-VEGF TKI setting, the mTOR inhibitor everolimus significantly prolonged PFS when compared to placebo (4 vs 1.9 months, $p < 0.001$).³²² OS was not significantly different, perhaps due to the fact that crossover was allowed for patients progressing on placebo. Though toxicities were generally mild, significant increases in severe (grade 3 or 4) toxicities were seen for stomatitis, $p = 0.03$; infections, $p = 0.03$; hypercholesterolemia, $p = 0.03$; hyperglycemia, $p < 0.0001$; lymphopenia, $p = 0.002$; and hypophosphatemia, $p = 0.01$. No prospective data is available that directly compares everolimus with a VEGF RTKI in patients whose disease has progressed on prior treatment with a VEGF inhibitor, but, OS was shown inferior for temsirolimus as compared with sorafenib (12.3 vs 16.6 months, respectively; stratified HR, 1.31; 95% CI, 1.05–1.63; two-sided $p = 0.01$) after disease progression on sunitinib.³²³ Moreover, one randomized phase II clinical trial suggested that everolimus is inferior to sunitinib regarding PFS, particularly when used in first line.³²⁴ There is no evidence to support the use of combinations of agents with different mechanisms of action as compared to sequential use, and toxicity may be increased, as shown for the combination of bevacizumab with temsirolimus (compared to bevacizumab and interferon).³²⁵

Antiangiogenic therapy as adjuvant therapy in RCC

The advent of multiple active antiangiogenic agents led to the development of several adjuvant trials in RCC. Early results of one, E2805, in which patients were randomly assigned to 1 year of treatment with sorafenib (400 mg twice daily), sunitinib (50 mg/day for 4 of every 6 weeks), or placebo, indicated that neither sorafenib nor sunitinib prolonged time to disease recurrence after surgery (5.6 years with either sorafenib or sunitinib vs 5.7 years with placebo).³²⁶

Prediction of therapeutic benefit in RCC

It has been established that relatively high VEGF levels are associated with worse tumor stage and grade, performance status, and overall prognosis.^{317, 327, 328} Moreover, in a phase III trial of sorafenib versus placebo, patients with VEGF in the highest concentration quartile obtained greater relative benefit from sorafenib than those with lower concentrations.³²⁷ However, studies addressing whether VEGF is a predictive marker for identifying RCC patients who are likely to benefit from VEGF-targeted therapies have yielded inconsistent results.³²⁹ A recent study in samples from two subsequent phase II and III studies identified interleukin (IL)-6 as predictive of PFS benefit from pazopanib versus placebo.³³⁰ Unfortunately, no biomarkers that are predictive of differential benefit between available and active drugs in RCC have yet been validated.

Future directions in RCC

While FGF and VEGF receptor inhibition with dovitinib failed to improve PFS relative to sorafenib in third line after progression to VEGF and mTOR inhibition,³³¹ coinhibition of other pathways of potential

escape to VEGF signaling blockade such as cMET remains promising. Given very promising results of novel immunotherapeutic agents such as checkpoint inhibitors in RCC, multiple clinical trials are now evaluating their combination with angiogenesis inhibitors.

Colorectal cancer

Advanced colorectal cancer represented the first human cancer in which a Phase III trial demonstrated clinical benefit, and to this day represents among the best studied of human solid tumors with regard to antiangiogenic therapy. In 2004, results of a phase III, randomized, placebo-controlled study were reported comparing standard IFL chemotherapy (irinotecan, fluorouracil, and leucovorin) with or without bevacizumab in patients with previously untreated metastatic colorectal cancer.³⁰¹ Patients treated with IFL plus bevacizumab had a significantly longer OS and PFS as well as a higher ORR. This trial provided definitive evidence that the addition of an angiogenesis inhibitor to chemotherapy could prolong survival and, based on the results of this trial, bevacizumab received approval from the US Food and Drug Administration (FDA) for use in combination with fluorouracil-containing chemotherapy as first-line treatment for metastatic colorectal cancer.

Subsequent studies have built upon this original finding. In a trial of previously treated patients with colorectal cancer, patients treated with bevacizumab combined with FOLFOX4 chemotherapy had a prolonged survival compared to those treated with FOLFOX4 alone,³³² although the magnitude of this benefit (2.1 months) appeared to be smaller than that observed in the first-line trial (4.7 months), presumably related to the more advanced nature of the disease.

First-line studies of bevacizumab or placebo in combination with either FOLFOX or XELOX failed to demonstrate an improvement in OS (21.3 vs 19.9 months) despite improvements in PFS (9.4 vs 8.0 months).³³³ The mechanism for the discrepancy between this study and the pivotal IFL study has been attributed to the different cytotoxic backbone or practice patterns of treatment until progression of disease versus regimen interruptions for cumulative oxaliplatin toxicities. Several studies have evaluated the role of bevacizumab after an initial course of oxaliplatin- and fluoropyrimidine-based first-line chemotherapy. These “maintenance” regimens have demonstrated the benefit of bevacizumab when combined with fluoropyrimidines. The CAIRO-3 randomized study demonstrated that continued bevacizumab either alone or in combination with capecitabine provided a survival benefit compared to observation alone.

Cohort studies had suggested a benefit from continued VEGF inhibition after progression on first-line therapy with bevacizumab. The TML study evaluated second-line therapy with FOLFIRI or FOLFOX (as determined by the treating physician) with or without bevacizumab for patients who had previously progressed on first-line bevacizumab-containing regimen. The study demonstrated a modest but statistically significant survival advantage of 1.4 months, resulting in the addition of bevacizumab continuation to treatment guidelines.

A similar study was conducted with ziv-aflibercept, a fusion protein utilizing the extracellular domains of VEGFR1 and VEGFR2, thereby providing inhibition of both VEGF-A and PlGF. Patients who had been previously treated with an oxaliplatin regimen (which may have included bevacizumab) were randomized to FOLFIRI with bevacizumab or placebo.³³⁴ The primary endpoint of OS was met with a 1.4 month improvement (13.5 months vs 12.1 months), with an improvement in PFS and response rate. Grade 3 and 4 diarrhea and stomatitis were substantially higher in the ziv-aflibercept arm, consistent with the established role for PlGF in mucosal lining repair.³³⁵ The result of these two studies is the addition of new treatment options for second-line antiangiogenic therapy in combination with chemotherapy for patients who have previously progressed on bevacizumab-based first-line regimens.

Biomarker analyses of colorectal cancer trials have been largely unavailing. Expression levels of VEGF-A, thrombospondin, and microvessel density performed in a subset analysis of the original Hurwitz trial were not associated with clinical outcome.³³⁶ Similarly, analysis of oncogenes known to play a role in colorectal cancer (e.g., K-Ras, b-raf, and p53) failed to demonstrate an association with clinical outcome.³³⁷ As in metastatic breast cancer, the presence of clinically significant hypertension has been associated with clinical outcome in a Phase II trial analysis.³³⁸

Though monoclonal antibodies are the best-studied antiangiogenic agents in advanced colorectal cancer, TKIs with various selectivity for VEGFRs have also been examined in randomized Phase III trials. A notable initial randomized phase III trial compared FOLFOX4 chemotherapy alone or in combination with the oral small molecule RTKI vatalanib (PTK787) as first-line therapy for metastatic colorectal cancer. This study failed to demonstrate improvements in PFS or OS.³³⁹ Similar studies with sunitinib and cediranib, among others, have failed to demonstrate a benefit. The outlier is the approval of regorafenib, a multikinase inhibitor that inhibits VEGFR, which has been shown to improve OS by 1.4 months when compared to placebo in the CORRECT study.³⁴⁰ While toxicities are generally higher with TKIs, the reason for the general success of large molecule inhibitors and limited success of TKIs in combination with chemotherapy is not known.

Gastric and gastroesophageal junction cancer

Antiangiogenic therapy for advanced gastric cancer was initially evaluated in the AVAGAST study, which evaluated bevacizumab in first-line therapy in combination with cisplatin-capecitabine.³⁴¹ Despite improvements in PFS and response rate, there was no difference in OS, and further development of bevacizumab in gastric or gastroesophageal junction (GEJ) cancer has not been pursued.

In contrast, a second-line study of 355 patients with gastric or GEJ adenocarcinoma demonstrated benefit of ramucirumab compared to placebo, leading to US FDA approval. Ramucirumab, a monoclonal antibody that binds VEGFR2 at the N-terminus and prevents ligand binding and receptor conformational changes,³⁴² was identified from phage display library and is notable for its picomolar binding affinity to VEGFR2.^{343, 344} This pivotal trial (the REGARD study) demonstrated a survival benefit of second-line ramucirumab when compared to placebo, with median OS of 5.2 months compared to 3.8 months.³⁴⁵ The agent was well tolerated with modestly higher risk of grade 3 hypertension (8% vs 3%) but no increased risk for thromboembolic events.

Two additional studies were subsequently conducted to further evaluate the role of antiangiogenic therapy in advanced gastroesophageal cancer. As the clinical practice for many oncologists is to provide cytotoxic chemotherapy in second line, the RAINBOW trial was designed to evaluate the addition of ramucirumab or placebo to paclitaxel in patients who had previously progressed on first-line platinum and fluoropyrimidine-based chemotherapy.³⁴⁶ This 655-patient international study met its primary endpoint with improved OS (9.6 vs 7.3 months). A subgroup analysis found that the survival benefit was notably higher in Caucasian patients than in Asian sites. The same regional differences were seen in the AVAGAST study, suggesting differences in disease biology or treatment patterns between Asian and Caucasian patients. The potential biological mechanism, if any, for this discrepancy is currently awaited.

A phase 2 study was conducted to evaluate the activity of ramucirumab or placebo in combination with FOLFOX chemotherapy in previously untreated advanced gastroesophageal cancer patients. In this setting there was no difference in OS or PFS despite improved rates of disease control. As a result, ramucirumab use is currently limited to patients with advanced gastric or GEJ adenocarcinomas with disease progression on or after prior therapy with fluoropyrimidine- or platinum-containing chemotherapy.

VEGFR TKIs have likewise been evaluated in gastric cancer. Sunitinib was evaluated in second line in a randomized study of docetaxel with placebo or sunitinib. This smaller phase II study failed to demonstrate an improvement in time to progression or OS, despite a meaningful increase in response rate (41% vs 14%).³⁴⁷ In contrast, the VEGFR TKI afatinib, at two different doses, was evaluated in a randomized phase III study in patients progressing on two or more lines of prior therapy. Both doses of afatinib demonstrated benefit compared to placebo in PFS (1.4 vs 3.7/3.2 months) and OS (2.5 vs 4.8/4.3 months).³⁴⁸ Toxicities included hypertension and hand–foot syndrome, consistent with the mechanism of action for the agent. Confirmatory studies are awaited.

Non-small cell lung cancer (NSCLC)

Angiogenesis inhibitors as single agents for advanced NSCLC

When tested as monotherapy for advanced NSCLC, inhibitors directed at VEGF have generally led to low rates of objective tumor responses. In a phase II trial of chemotherapy with or without bevacizumab, 19 patients in the control arm received high-dose, single-agent bevacizumab on progression, and although five had disease stabilization, there were no objective responses.³⁴⁹ VEGFR TKIs have demonstrated clear evidence of antitumor activity as single agents in NSCLC, although to date there are no studies demonstrating that they prolong OS compared to chemotherapy or other targeted agents.

Vandetanib (ZD6474), a dual VEGFR/EGFR inhibitor, has been one of the most extensively tested thus far. In a randomized phase II trial involving 168 patients with locally advanced or metastatic, platinum-refractory NSCLC, a statistically significant but modest improvement in median PFS was observed in patients receiving vandetanib compared to gefitinib (11.0 vs 8.1 weeks, $p = 0.011$).³⁵⁰ Vandetanib was also directly compared to chemotherapy (carboplatin and paclitaxel), or the combination of vandetanib with chemotherapy, in a phase II study in 181 previously untreated NSCLC patients.³⁵¹ A trend toward inferior PFS was observed in the vandetanib arm compared to chemotherapy alone (11.5 vs 23.1 weeks, $p = \text{NS}$). Phase III trials of vandetanib in NSCLC patients have been completed.³⁵² In a phase III study testing the efficacy of vandetanib compared to standard second-line erlotinib (ZEST), no significant improvement in PFS was detected for patients treated with vandetanib versus erlotinib (median PFS of 2.6 vs 2.0 months). No significant differences were detected for the secondary endpoints of OS (HR = 1.01; $p = 0.83$), ORR (both 12%), and time to deterioration of symptoms for pain (HR = 0.92; $p = 0.28$). In a noninferiority analysis, both agents showed similar PFS and OS.³⁵³

Sorafenib has also shown evidence of single-agent activity in advanced, recurrent NSCLC. In a randomized discontinuation phase II clinical trial (ECOG2501), NSCLC patients with stable disease during treatment with sorafenib ($N = 97$) were randomized to either continue sorafenib or receive placebo.³⁵⁴ Patients on the sorafenib arm had a significantly longer PFS compared to those receiving placebo (3.6 vs 1.9 months, $p = 0.01$). Interestingly, only a single patient had an objective response, illustrating that for NSCLC, as in RCC,³⁰³ objective tumor response rates may not be the most appropriate metric for benefit in early testing.

Sunitinib has also demonstrated encouraging single-agent activity in patients with recurrent NSCLC.³⁵⁵ Objective tumor responses were observed in 7 of 63 patients (ORR 11.1%), and 70% of patients demonstrated at least some degree of tumor shrinkage. The safety profile was considered acceptable overall, but two patients, both with squamous cell histology, died of treatment-related pulmonary hemorrhage. This toxicity has been seen with other angiogenesis inhibitors, as described below, and has led to the exclusion of patients with squamous histology from treatment with bevacizumab and several

other agents.

Pazopanib (GW786034, GlaxoSmithKline), a TKI targeting VEGFRs, PDGFRs, FGFR-1, and FGFR-3, has produced encouraging responses as neoadjuvant therapy in patients with stage I/II NSCLC,³⁵⁶ with tolerable toxicity profile including hypertension, diarrhea, and fatigue. The activity and efficacy of this agent are currently under investigation in the adjuvant and advanced setting.³⁵⁷ Other VEGFR TKIs that have demonstrated single-agent activity in advanced NSCLC include vatalanib (PTK787), axitinib (AG-013736),³⁵⁸ and XL647.³⁵⁹

Bevacizumab with chemotherapy for advanced NSCLC

Given their modest single-agent activity, angiogenesis inhibitors have most commonly been tested in combination with chemotherapy for NSCLC. Initial phase II testing in chemo-naïve, advanced NSCLC patients suggested that bevacizumab improved ORR and time to progression when added to the standard doublet chemotherapy regimen of carboplatin and paclitaxel.³⁴⁹ This study also revealed an unanticipated and concerning side effect: severe pulmonary hemorrhage, which occurred in six out of 67 patients who received bevacizumab, and was fatal in four cases. Tumor characteristics associated with significant hemoptysis were central location, proximity to major blood vessels, necrosis and cavitation before or during therapy, and squamous histology. As squamous cell tumors are more commonly located centrally and have a greater tendency to cavitate than adenocarcinomas, it is unclear whether histology alone is the primary risk factor for hemoptysis, or simply a surrogate for other risk factors.

On the basis of the promising outcomes with bevacizumab in this phase II trial, a randomized phase II/III trial was conducted by the Eastern Cooperative Oncology Group (ECOG), E4599, comparing standard carboplatin and paclitaxel for six cycles with or without bevacizumab in 878 patients with previously untreated, advanced (stage IIIB or IV) nonsquamous NSCLC.³⁰² Patients receiving carboplatin–paclitaxel with bevacizumab had a significantly improved median OS (12.3 vs 10.3 months, HR 0.77, $p = 0.003$), PFS (6.2 vs 4.5 months, $p < 0.0001$), and response rate (35% vs 15%, $p < 0.001$) compared to carboplatin–paclitaxel alone. The main grade 3 or higher toxicities associated with bevacizumab were clinically significant bleeding (4.4% vs 0.7% in the standard chemotherapy arm), febrile neutropenia, and hypertension. The overall rate of fatal hemoptysis with bevacizumab when squamous histology was excluded was approximately 1%. This may be considered an acceptable risk in light of the absolute improvements in survival of 7% and 8% at 1 and 2 years, respectively.

Interestingly, unplanned subset analyses of E4599 found that the survival benefit was confined primarily to male participants, although females did benefit in terms of response and PFS.³⁶⁰ The reason for this apparent gender-based difference in benefit is unclear. In elderly patients, defined as >70 years old, there also appeared to be an increase in toxicity but no obvious improvements in OS.³⁶¹

This was the first randomized phase III study in advanced NSCLC that demonstrated superior OS when targeted therapy is combined with standard chemotherapy. A similar randomized III trial testing bevacizumab in combination with another standard doublet of cisplatin and gemcitabine has been reported (AVAIL).³⁶² In this study, a total of 1043 patients were randomized to either low (7.5 mg/kg) or high (15 mg/kg) dose bevacizumab one every 3 weeks with cisplatin–gemcitabine, compared to cisplatin–gemcitabine alone. In this study PFS and ORR were significantly improved in the bevacizumab-containing arms compared to cisplatin–gemcitabine but OS was not improved. There were no significant differences in efficacy or toxicity between the low and high doses of bevacizumab. This clinical result is consistent with the vascular normalization hypothesis.³⁶³

At present, the use of bevacizumab in combination with chemotherapy is being tested in the neoadjuvant

or adjuvant settings. The BEACON phase II study is being conducted to determine whether the addition of bevacizumab to a cisplatin-based chemotherapy in the neoadjuvant setting improves response rates. ECOG trial E1505, a phase III randomized study of adjuvant chemotherapy with or without bevacizumab for patients with resected stage IB–IIIA NSCLC has completed accrual and the results are awaited.

On the basis of these results, some oncologists regard bevacizumab in combination with carboplatin–paclitaxel as a new standard of care for patients with nonsquamous NSCLC. Given the results of the AVAIL trial, however, it remains an open question as to whether a similar degree of benefit can be expected when bevacizumab is combined with any platinum-containing doublet for untreated NSCLC patients, and whether additional clinical criteria such as sex or age should be used in selecting patients for treatment.

Ramucirumab with chemotherapy for refractory NSCLC

Ramucirumab has recently received FDA approval for the treatment of relapsed NSCLC patients in combination with second-line docetaxel. The approval was based on the results of the phase III REVEL trial, an international study that involved 1253 patients with nonsquamous and squamous cell NSCLC who had experienced disease progression after treatment with platinum-based chemotherapy for locally advanced or metastatic disease.³⁶⁴ Patients were randomized to treatment with ramucirumab plus docetaxel or placebo plus docetaxel. Median OS was significantly improved in the ramucirumab group compared with the placebo group (10.5 vs 9.1 months; HR 0.857; $p = .0235$), as was median PFS (4.5 vs 3.0 months; HR, 0.762; $p < .0001$). The ORR was also improved in the ramucirumab group (23% vs 14%; $p < .0001$). The most common grade ≤ 3 toxicities that were more frequent in patients in the ramucirumab than in the placebo group were neutropenia (48.8% vs 39.8%), febrile neutropenia (15.9% vs 10.0%), fatigue (14.0% vs 10.5%), leukopenia (13.7% vs 12.5%), and hypertension (5.6% vs 2.1%). Patients in the ramucirumab group experienced more bleeding/hemorrhage events of any grade compared with patients in the placebo group, but the rate of grade 3 or higher bleeding events was similar among the two groups.

VEGFR TKIs with chemotherapy as first-line NSCLC therapy

VEGFR TKI/chemotherapy combinations are also being evaluated in randomized trials for first-line treatment of advanced NSCLC treatment. The phase III trial ESCAPE (Evaluation of Sorafenib, Carboplatin and Paclitaxel Efficacy in NSCLC) comparing the efficacy of carboplatin–paclitaxel, with and without sorafenib, in 926 patients failed to demonstrate a significant advantage in terms of OS with the addition of sorafenib in nonsquamous histotype, and, in a planned subgroup analysis, showed a detrimental effect in patients with squamous cell carcinoma.³⁶⁵ The NExUS phase III trial (NCT00449033) evaluated cisplatin–gemcitabine with and without sorafenib and was stopped early owing to failure in meeting its primary endpoint of OS.

Cediranib (AZD2171), an oral VEGFR, PDGFRs, and KIT TKI, was tested with carboplatin–paclitaxel in a planned phase II/III trial by the National Cancer Institute of Canada (NCIC trial BR24)³⁶⁶ in 296 patients. Although evidence of improved PFS and ORR was observed in the cediranib arm, the trial was discontinued at a preplanned analysis at the end of the phase II component because of an excess of dose-related adverse effects including dehydration, diarrhea, and fatigue. A similar phase II N0528 study evaluated the safety and efficacy of gemcitabine–carboplatin with or without cediranib (45 mg orally daily). The trial failed to show significant differences in terms of response rate (RR; 20% vs 18%; $p = 1.0$), median PFS (6.3 vs 4.5 months; HR, 0.69; $p = 0.15$), and median OS (11.8 vs 9.9 months; HR, 0.66; $p = 0.16$), Grade 3 and higher toxicities were increased in the arm containing cediranib (71% vs 45%; p

= 0.01).³⁶⁷

Given the concern of intolerable toxicity, the NCIC BR29 phase III trial was similarly designed to further evaluate cediranib 20 mg in combination with carboplatin–paclitaxel. An interim analysis demonstrated insufficient efficacy, thus the study was closed.³⁶⁸

As noted previously, vandetanib with carboplatin–paclitaxel (VCP) was compared to carboplatin–paclitaxel or vandetanib alone in 181 patients.³⁵¹ VPC could be safely administered, even in patients with squamous cell histology and treated brain metastases. Patients receiving VPC had trend toward improved ORR (32% vs 25%) and longer PFS (24 vs 23 weeks; HR = 0.76, one-sided $p = .098$) compared to carboplatin–paclitaxel.

Nintedanib (BIBF 1120), which has activity against PDGFR and FGFR in addition to VEGFR, has shown single agent activity in a phase II study of pretreated NSCLC with 48% of patients achieving disease stabilization.³⁶⁹ Phase II trials testing the efficacy of nintedanib in combination with chemotherapy are underway. Taken together, trials of VEGFR TKIs with chemotherapy for first-line NSCLC treatment have been somewhat disappointing thus far, with modest gains, at most, in efficacy and significant toxicities in some cases.

VEGFR TKIs with chemotherapy for recurrent NSCLC

Vandetanib has also been evaluated in combination with docetaxel for patients previously treated with platinum-containing chemotherapy.³⁷⁰ One hundred and twenty seven patients were randomized to receive docetaxel with either low dose (100 mg once daily) or high dose (300 mg once daily) vandetanib. This study met its primary endpoint of prolonged median PFS in the vandetanib arm, although, interestingly, a trend toward greater benefit was observed in the low dose arm (19, 17, and 12 weeks in low dose, high dose, and control arms, respectively). On the basis of these results, a randomized, phase III trial of vandetanib 100 mg daily with docetaxel versus docetaxel was conducted (ZODIAC). The primary endpoint of this study was achieved, with a prolongation in PFS in the vandetanib arm (PFS HR = 0.79, $p < 0.001$), but this did not translate into significantly improved OS.³⁵² A biomarker analysis from this study suggested that patients with EGFR copy number gains had greater benefit from the addition of vandetanib.³⁷¹

Nintedanib (BIBF1120) has also recently completed clinical testing in patients with platinum-refractory NSCLC. In the LUME-Lung 1 randomized phase III trial comparing docetaxel combined with either nintedanib or placebo, PFS was prolonged in the nintedanib arm compared with the placebo arm, regardless of histology (HR 0.79; $p = 0.0019$; squamous HR 0.77, $p = 0.02$; adeno HR 0.77, $p = 0.0019$).³⁷² Furthermore, significantly prolonged OS was observed in patients with adenocarcinoma (HR 0.83; $p = 0.0359$; median 12.6 vs 10.3 months), but not in the squamous subgroup. Preliminary reports of the LUME-Lung 2A study testing nintedanib in combination with pemetrexed indicate that a significant PFS, but not OS, advantage was observed for patients with platinum-refractory nonsquamous disease.³⁷³ On the basis of these results, nintedanib has recently received approval in the European Union (EU) for NSCLC. Furthermore, it is approved by the FDA and in the EU for the treatment of idiopathic pulmonary fibrosis on the basis of two randomized phase III trials.^{374, 375}

Antiangiogenic agents in combination with other targeted therapies for NSCLC

The molecular pathways regulating tumor angiogenesis and tumor cell survival are complex and somewhat redundant.^{241, 376} It is not surprising, therefore, that therapeutic approaches targeting a single pathway do not typically provide long-term disease control and tumor resistance inevitably develops.

Combinations of targeted agents may therefore improve clinical outcomes while avoiding the toxicities associated with chemotherapy. In NSCLC and several other diseases, dual blockade of the EGFR and VEGF pathways is being studied clinically because both are validated therapeutic targets that are known to be interrelated. VEGF is downregulated by EGFR inhibition, likely through both HIF- α -dependent and -independent mechanisms,^{233, 257, 259, 260, 377–379} and EGFR, like VEGFR-2, may be expressed on tumor-associated endothelium.^{380–382} Acquired resistance to the EGFR inhibitor was found to be associated with increased VEGF levels and increased tumor angiogenesis in preclinical studies.³⁸³

Clinically, inhibition of both VEGF and EGFR has been investigated using combinations of individual drugs, or a single multitargeted TKIs such as vandetanib as discussed above. In a randomized phase II trial, bevacizumab and erlotinib were compared to chemotherapy alone (docetaxel or pemetrexed) or chemotherapy with bevacizumab in patients with refractory or recurrent NSCLC.³⁸⁴ A trend toward improved PFS, and improved tolerability, was observed in the bevacizumab–erlotinib arm compared to chemotherapy. A randomized phase III study of bevacizumab–erlotinib compared to erlotinib (BETA trial, for BEvacizumab/TARceva) was subsequently conducted in 636 second-line patients. Patients in the bevacizumab–erlotinib arm had improved PFS (3.4 vs 1.7 months) and ORR compared to the erlotinib arm, but OS was not prolonged (9.3 vs 9.2 months). There did, however, appear to be greater benefit for the combination in patients bearing EGFR mutations. This observation was confirmed in a phase III study of erlotinib with or without bevacizumab in EGFR-mutant NSCLC.³⁸⁵ The molecular basis underlying the greater sensitivity of the EGFR-mutant subgroup to bevacizumab is not completely understood, but may be related to the constitutive activation of HIF-1 α and hence greater VEGFR dependence of these tumors.²⁶⁰ Furthermore, in preclinical models, EGFR TKI resistance is associated with a rise in VEGF.³⁸⁶ Finally, the ATLAS phase III trial of bevacizumab–erlotinib versus bevacizumab and placebo as maintenance therapy after first-line treatment was stopped early as an interim analysis revealed that the combination led to a significant improvement in PFS.³⁸⁷ Together these data support the use of combined VEGF and EGFR inhibition in patients bearing EGFR mutations.

Antiangiogenic therapy for operable NSCLC

The use of angiogenesis inhibitors in the neoadjuvant or adjuvant setting is also being investigated in NSCLC patients with operable disease. In one preoperative trial, the VEGFR TKI pazopanib was found to have significant antitumor activity, with 87% of patients demonstrating a reduction in tumor volume.³⁸⁸ A phase III randomized trial testing is also underway testing whether the addition of bevacizumab to four cycles of standard chemotherapy improves outcomes compared to chemotherapy alone for fully resected stage IB–IIIA NSCLC (ECOG1505).

Breast cancer

Antiangiogenic agents in breast cancer have failed to reproducibly demonstrate improvements in OS in metastatic disease, and no agents are currently FDA approved. Bevacizumab received accelerated approval in 2008 on the basis of a randomized study of paclitaxel with or without bevacizumab in 715 previously untreated women with metastatic HER2-negative breast cancer.³⁸⁹ This study demonstrated statistically significant improvements in response rate from 37% to 21%, and PFS from 5.9 to 11.8 months, but no difference in OS. The accelerated approval was conditional on further evidence of improved survival from additional studies. The AVADO study of docetaxel with or without bevacizumab saw similarly improved response rates and PFS, but no improvements in OS in HER2-negative patients.³⁹⁰ Similarly, the RIBBON-1 study of chemotherapy with or without bevacizumab produced similar incremental benefits in response rates and PFS without improved OS.³⁹¹ A study in the HER2-

positive population of docetaxel, trastuzumab, with or without bevacizumab improved response rates (66% vs 77%) but failed to improve PFS or OS.³⁹² On the basis of the available data, the FDA revoked the agency's approval of bevacizumab for breast cancer in 2011. Similarly disappointing results were seen in the ROSE study, which evaluated ramucirumab in combination with docetaxel, and failed to demonstrate an improvement in PFS.³⁹³

Subsequent analyses of the AVADO study demonstrated the potential for high VEGF-A plasma levels to be a predictive biomarker for benefit from bevacizumab.³⁹⁴ This hypothesis is being prospectively evaluated in the MERiDiAN study with a coprimary endpoint of PFS in the high VEGF-A population.

Hepatoma

Hepatoma (hepatocellular carcinoma) is an important cancer on a global basis, and has been characterized by remarkably poor prognosis and few active agents for decades. The advent of antiangiogenic therapy has reinvigorated therapeutic attacks on hepatoma.

In a randomized placebo-controlled Phase III trial, sorafenib prolonged OS compared with control (5.5 vs 2.5 months).³⁹⁵ Multiple antiangiogenic agents are currently under investigation.

Other malignancies

Antiangiogenic therapies (particularly anti-VEGF therapies) have been examined in numerous other human malignancies, with initial positive results (and a few signal failures) in several cancers. Many of these approaches are discussed elsewhere in this book, and will be summarized only briefly here.

Pancreatic cancer: A large Phase III trial comparing gemcitabine plus bevacizumab versus gemcitabine plus placebo was reported as a negative trial. Pancreatic cancer continues to elude our best therapeutic efforts.

Soft-tissue sarcoma: In 2012, the FDA approved pazopanib for the treatment of metastatic nonadipocytic soft tissue sarcoma following positive results from the phase III PALETTE clinical study (NCT00753688).³⁹⁶

Ovarian cancer: In the phase III AURELIA clinical study, the addition of bevacizumab to chemotherapy significantly improved PFS and ORR in platinum-resistant ovarian cancer patients, prompting FDA approval in 2014.³⁹⁷

Cervical cancer: Results from a phase III trial (GOG 240) testing the efficacy of bevacizumab and nonplatinum combination chemotherapy in patients with advanced cervical cancer led to the FDA approval of bevacizumab to treat patients with persistent, recurrent or late-stage cervical cancer.³⁹⁸

Glioblastoma: While early clinical studies testing the efficacy of bevacizumab in patients with glioblastoma appeared promising,^{399, 400} in further phase III testing, bevacizumab did not improve OS in patients with newly diagnosed glioblastoma.⁴⁰¹ The phase III study (REGAL) testing the efficacy of cediranib as monotherapy or in combination with lomustine versus lomustine alone in patients with recurrent glioblastoma was also negative.⁴⁰²

Glioma: Several Phase II trials of anti-VEGF therapy as monotherapy have suggested that bevacizumab has therapeutic activity in advanced gliomas. These promising results have led to a submission to the FDA for accelerated approval, and to the development of a proof-of-concept Phase III trial.

Non-Hodgkin Lymphoma: Positive early results for anti-VEGF therapy have been reported from several Phase II trials, and have led to the development of Phase III trials, which are ongoing.

Toxicities of antiangiogenic therapy

Angiogenesis inhibitors have been developed with the hope that they would provide a relatively nontoxic means to slow or prevent tumor growth that could be used over long periods of time, toward the goal of converting cancer into a manageable, chronic condition. On the basis of the clinical experience to date, it appears that they do in fact have a generally favorable side effect profile that is nonoverlapping with chemotherapy. Certain toxicities have emerged, however, that appear to be specific to entire classes of agents and, in some cases, potentially life threatening.

Pure VEGF antagonists (e.g., bevacizumab) offer an important window into the physiologic and pathophysiologic effects of VEGF blockade; agents that combine VEGF blockade with blockade of other kinases (e.g., sorafenib and sunitinib) add side effects specific to the kinases blocked. Additional drug-specific idiosyncratic side effects may also occur. In addition, as antiangiogenic agents are regularly combined with chemotherapeutic agents across a broad array of diseases, and frequently prolong PFS, chemotherapy-related side effects may be increased related to increased duration of their use. For instance, in the E2100 Phase III breast cancer trial, patients receiving bevacizumab and paclitaxel-based chemotherapy suffered statistically significant increases in VEGF-related side effects such as hypertension, cerebrovascular ischemia, headache, and proteinuria, and in Grade 3 and 4, infection, fatigue, and sensory neuropathy.³⁸⁹ It seems likely that the latter were a function of prolonged exposure to chemotherapy, as patients receiving bevacizumab not only had prolonged PFS, but also received increased duration of taxane-based chemotherapy.

The availability of multiple Phase III trials allows us to gauge these toxicities across large populations, while smaller studies have focused on individual toxic effects. In this section we will focus on toxicities that are VEGF related and mechanistic in nature (i.e., a function of a ligand–receptor interaction in a normal tissue organ). These side effects include toxicities that are seen across most diseases treated with anti-VEGF therapy, as well as side effects that—while mechanistic—are seen more commonly with specific diseases (e.g., bowel perforation and pulmonary hemorrhage). Side effects unrelated to VEGF inhibition observed with nonspecific RTKIs will not be discussed here.

Hypertension

The most commonly reported toxicity in patients receiving anti-VEGF therapies is hypertension. It is generally mild-to-moderate in nature, though very rarely severe (malignant) hypertension has been reported. Hypertension is thought to be related to alterations in endothelial function related to blockade of the nitric oxide pathway downstream from the VEGF receptor.⁴⁰³ In contrast to anti-VEGF therapy, VEGF infusions are associated with decreases in blood pressure. Management of anti-VEGF-related hypertension has not been carefully studied in the clinic, though it appears responsive to standard antihypertensive agents, and is reversible upon discontinuation of anti-VEGF therapy. For patients experiencing mild-to-moderate degrees of hypertension, anti-VEGF therapy may be continued in the presence of appropriate antihypertensive therapy. Recent data suggests that the presence of hypertension may be associated with improved outcome, and as such hypertension may represent a type of pharmacokinetic or pharmacodynamic surrogate biomarker of response.⁴⁰⁴ Analysis of the E2100 Phase III breast cancer trial demonstrated a relationship between hypertension and particular single-nucleotide polymorphisms for VEGF, though this finding awaits and requires confirmation.⁴⁰⁵ The results of a recently reported subgroup analysis of the phase III ECOG 4599 trial of bevacizumab and chemotherapy

in NSCLC revealed a positive correlation between the onset of hypertension and improved clinical outcomes in bevacizumab-treated patients.⁴⁰⁶ Similarly, the analysis of data derived from six phase II trials evaluating axitinib in patients with various solid tumor types indicated the potential role of diastolic blood pressure > 90 mmHg as biomarker of prolonged survival.³²⁵ Prospective studies to validate hypertension as a reliable biomarker of response in clinical practice are warranted.

Arterial thromboembolic events

An increased incidence of thromboembolic and cardiovascular events has been observed in some but not all clinical trials of VEGF inhibitors. These events, while uncommon, may be serious and life threatening. Data pooled from five Phase III trials with bevacizumab (all of which excluded patients with recent history of stroke or heart attack) demonstrated a HR of 2.0 for such events, with an increase in absolute risk from 1.7% in control patients to 3.8% in bevacizumab-treated patients. There was no associated increase in venous thromboembolic events. Cerebrovascular ischemia reported with bevacizumab may involve either transient ischemic attacks or stroke; myocardial infarction and angina have also been reported to occur with increased frequency.⁴⁰⁷ These toxicities are more common in the elderly (age >65) and in patients with a prior history of arterial thromboembolic events. Management of these complications is similar to those in patients not receiving anti-VEGF therapy. In contrast to hypertension, which is generally readily managed with antihypertensive therapy, discontinuation of VEGF-targeted therapy in the presence of arterial thromboembolic events seems appropriate.

Patients receiving VEGF-targeted therapy frequently experience headaches, with severe headaches occurring ~3% of the time in Phase III trials. These headaches are typically migraine-like in nature, and anecdotally respond to antimigraine agents such as serotonin receptor-active agents. Headaches may recur, and patients may require chronic antimigraine medications such as β -blockers therapy if their cancer continues to respond to anti-VEGF therapy. The relationship of such headaches to more severe central nervous system ischemic events is unknown.

Reversible posterior leukoencephalopathy syndrome (RPLS)

RPLS is a rare central nervous system complication of anti-VEGF therapy. RPLS is a subacute neurologic syndrome typically consisting of headache, cortical blindness, and seizures, and has been reported anecdotally in patients receiving VEGF-targeting therapy. The etiology of RPLS is not well understood at present, nor is its relationship to VEGF inhibition; though it has been suggested that vasospasm of the posterior cerebral arteries may be important. Immediate cessation of anti-VEGF therapy and appropriate antihypertensive management (a potential predisposing factor) are indicated.^{408, 409}

Nephrotoxicity

Nephrotoxicity, in the form of proteinuria, is common in patients receiving prolonged anti-VEGF therapy with as many as 40% of patients having at least some degree of proteinuria. More severe protein loss (e.g., nephrotic syndrome) is rare, occurring in approximately 1–2% of patients. While not well studied, proteinuria is reversible when anti-VEGF therapy is held, and patients may be rechallenged. A standard approach has been to discontinue bevacizumab temporarily if urine protein excretion is ≥ 2 g/24 h and resume when protein excretion is <2 g/24 h. Bevacizumab treatment should be discontinued if nephrotic-range proteinuria develops. From a mechanistic standpoint, VEGF is important in renal glomerular homeostasis, so the renal effects of anti-VEGF therapy are perhaps unsurprising.⁴¹⁰ A recent investigation has associated bevacizumab-induced proteinuria with renal thrombotic microangiopathy, suggesting that VEGF plays a critical role in protection against this condition.⁴¹¹

Pulmonary hemorrhage

Pulmonary hemorrhage was reported in the initial Phase II trial of lung cancer patients, where fatal hemorrhagic events were observed.³⁴⁹ This trial suggested that patients with squamous cell cancer histology were at increased risk for this complication, and along with patients with gross hemoptysis (1/2 tsp or more per event) and those being treated with anticoagulant therapy or nonsteroidal anti-inflammatory agents were excluded from the proof-of-concept Phase III NSCLC trial E4599. Despite these exclusions, the rate of life-threatening pulmonary hemorrhage was 1.9% (with 1.2% fatal events), suggesting that we remain imperfect at predicting which patients will experience this complication.³⁰² The discussion of pulmonary hemorrhagic events should be part of the informed consent discussion for all lung cancer patients receiving bevacizumab or other VEGF-targeting agents. The mechanism of this side effect is unknown as is its dose–response relationship. The relationship with squamous cell lung carcinoma may be related to the tendency of these cancers to undergo central necrosis; central cavitation is common in lung cancers treated with anti-VEGF therapy.

Bowel perforation

Bowel perforation has been seen predominantly in patients with advanced colorectal cancer and ovarian cancer, though it has been reported to occur in virtually every cancer treated with bevacizumab, albeit less commonly in cancers not involving the abdomen or pelvis. One recent analysis has suggested a 30-day mortality of 12.5% for patients undergoing this complication, suggesting its seriousness.⁴¹² A recent review has suggested that the incidence of bowel perforation seems to be higher in patients with an intact primary tumor, recent history of sigmoidoscopy or colonoscopy, or previous abdominal or pelvic radiotherapy. Interestingly, a prior history of peptic ulcer disease, diverticulosis, or use of nonsteroidal anti-inflammatory drugs was not obviously associated with an increased risk of bowel perforation.⁴¹³ At present we lack any useful exclusion factors that might prevent patients from developing this complication. The etiology of this side effect is uncertain, though preclinical evidence suggests that anti-VEGF therapy may greatly reduce the vascular density of normal intestinal villi.⁴¹⁴ This may be exacerbated when anti-VEGF therapy is combined with radiation.²⁹⁴

The management of bowel perforation involves awareness and recognition of symptoms and emergent surgical intervention. Surgical intervention in the face of anti-VEGF therapy may itself be associated with an increased risk of postsurgical complications such as further bowel perforation and abdominal fistulae. These, however, should not prevent a lifesaving surgical intervention.^{191, 415}

Lessons from clinical studies of antiangiogenic therapy and future directions

Reconciling differences in preclinical and clinical efficacy of antiangiogenic therapy

While antiangiogenic agents have had dramatic effects on tumor growth as single agents in preclinical animal models, in patient trials the majority of antiangiogenic agents must be given in combination with other treatment regimens to be effective. This difference in antitumor activity is linked to key differences between mouse tumor models and cancer patients. Human patients have extensive variability in tumor heterogeneity and genetic background compared to experimental models. Furthermore, in mouse models of cancer, the tumor growth rate is frequently extremely high, potentially heightening the sensitivity to

antiangiogenic agents. In preclinical models, therapy is frequently initiated early in tumor development, whereas in the clinical setting, tumors may have been present for years before treatment begins, and clinical trials often include patient populations with advanced, metastatic disease.⁴¹⁶

Mechanisms of resistance to VEGF pathway inhibitors

The therapeutic efficacy of conventional chemotherapy for most solid tumors is limited in part by the emergence of drug resistance in rapidly mutating tumor cells. Because antiangiogenic agents are directed against tumor endothelium, which was presumed to be diploid and genetically stable, it was initially thought that tumors will not develop resistance to antiangiogenic therapy^{191, 415} as they do to cytotoxic chemotherapy. Clinical experience thus far, however, suggests that virtually all tumors do eventually progress despite treatment with a VEGF inhibitor. Studies have suggested several potential mechanisms by which tumors may initially have or acquire resistance, or at least decreased sensitivity, to VEGF pathway inhibitors.^{149, 417}

Incomplete target inhibition

Drugs may not be present at sufficiently high concentrations at their targets for a sufficiently long time to cause a sustained inhibition of VEGF receptor signaling and tumor angiogenesis. In trials of VEGFR inhibitors SU5416 and SU6668, tumor biopsies taken before and during treatment revealed that VEGFR phosphorylation was inhibited by <50% in all cases, providing a potential explanation for the lack of significant clinical activity observed in these trials.^{418, 419} For other TKIs such as gefitinib and imatinib, incomplete target inhibition has been shown to result from genetic changes, for example, secondary mutations in EGFR or BCR-ABL, or epigenetic changes reducing the intracellular concentrations of the inhibitor.^{420–422} It is not yet known whether mutations may be present within VEGFR in tumor endothelium.

Bypass of the VEGF pathway through expression of additional angiogenic factors

Genetic mutations or the activation of pathways such as HIF-1 may lead to the expression of additional angiogenic factors (or the loss of angiogenic inhibitors) by malignant cells in the tumor.^{232, 423} In turn, these changes may promote the proliferation and survival of tumor endothelial cells even in the presence of VEGF blockade. It has been observed, for example, that advanced-stage breast cancers express a greater number of proangiogenic factors than early-stage cancers do,⁴²⁴ which may help explain why previously untreated patients with metastatic breast cancer appeared to have a greater benefit from the addition of bevacizumab to standard chemotherapy than previously treated patients.^{425, 426}

Recently, Cascone et al.⁴²⁷ have shown that gene expression changes associated with acquired resistance to bevacizumab occurred predominantly in stromal and not tumor cells in mouse xenograft models of human lung adenocarcinoma. Specifically, the EGFR and FGFR signaling pathways were upregulated in the stroma, and increased expression of activated EGFR was detected on pericytes of xenografts that acquired resistance to VEGF inhibition and on endothelium of tumors with relative primary resistance. Furthermore, changes in the vasculature pattern characterize the phenotype of resistance. Murine models of human NSCLC that acquired resistance to bevacizumab were characterized by a pattern of pericyte-covered, normalized revascularization, whereas tortuous, uncovered vessels were observed in models of relative primary resistance. Dual VEGF and EGFR pathway blockade reduced pericyte coverage and increased PFS of tumor-bearing animals, suggesting that alterations in tumor stromal pathways may contribute to VEGF-inhibitor resistance in NSCLC and that targeting these pathways may improve

therapeutic efficacy. In a phase II trial evaluating the regimen FOLFIRI in combination with bevacizumab for the treatment of patients with colorectal cancer, increased baseline levels of IL-8 correlated with poorer PFS. In the same study, before the radiographic development of disease progression, circulating levels of several proangiogenic cytokines known to be associated with angiogenesis and myeloid recruitment increased compared to baseline, such as FGF, HGF, PlGF, SDF, and MCP.⁴²⁸

Numerous studies have provided additional evidence that tumors can escape VEGFR pathway inhibition by increasing other angiogenic factors. In preclinical models, inhibition of FGFR signaling can restore sensitivity to VEGF-targeting agents.⁸³ Galectin-1 (Gal1) has also been shown to play a role in resistance to antiangiogenic therapies. Gal1 is upregulated in hypoxic conditions, modulates trafficking of EGFR and VEGF, and promotes tumor angiogenesis. In cultured endothelial cells, GAL1 binds to neutral branched N-glycans on VEGFR2, resulting in VEGFR2 signaling and enhanced cell surface retention. In animal studies, anti-VEGF refractory tumors exhibit increased hypoxia and increased Gal1 expression compared to anti-VEGF sensitive tumors. Targeting of Gal1 along with anti-VEGF therapy improved antitumor activity.⁴²⁹

Increased infiltration of myeloid cells has also been linked to antiangiogenic therapy resistance.⁴³⁰ Elevated numbers of CD11b + Gr1+ myeloid-derived suppressor cells (MDSCs) have been observed in refractory tumors compared to tumors sensitive to antiangiogenic agents.¹⁴⁸ In a recent report, IL-17, produced by T helper type 17 cells, was shown to facilitate IL-17-dependent but VEGF-independent angiogenesis through upregulation of G-CSF, which in turn leads to the mobilization and recruitment of MDSCs from the bone marrow and spleen to the tumor.⁴³¹ In mice, the efficacy of anti-VEGF therapy in refractory tumors was improved when IL-17 was targeted.

Altered threshold for hypoxia-induced apoptosis

Certain changes within a tumor cell may make it less sensitive to the diminished vascular supply and resulting hypoxia induced by antiangiogenic therapy. For instance, it has been demonstrated in murine xenograft models that tumor cells bearing mutated p53 are less sensitive to hypoxic conditions *in vitro* and respond somewhat less well to a VEGFR2 inhibitor.⁴³² Studies performed in tissue biopsies obtained from patients with recurrent high-grade glioma treated with bevacizumab and irinotecan revealed that high expression levels of carbonic anhydrase 9 (CAIX), a marker of hypoxia, were significantly associated with poor 1-year survival.⁴³³ Similarly, findings of another tumor tissue study of patients with malignant glioma revealed that low CAIX expression and increased VEGF expression were associated with improved PFS in those patients who received metronomic etoposide and bevacizumab.⁴³⁴

Genetic alterations within tumor endothelium

The assumption that tumor endothelium are normal diploid cells and therefore presumably genetically stable has been challenged by observations from murine studies.⁴³⁵ Furthermore, in biopsies from patients with B-cell non-Hodgkin lymphoma with specific genetic aberrations, the endothelial cells of the cancer microvasculature acquired the same specific chromosomal translocations.⁴³⁶ Genetically unstable tumor endothelial cells might derive from a common progenitor cell,⁴³⁷ or may be the product of an endothelial phenotype differentiation, under the pressure of angiogenic factors within the tumor microenvironment. Fusion between neoplastic and endothelial cells has also been hypothesized. Overall, the functional significance and relevance of this finding to other tumor types are not yet known, but it supports the mounting evidence that tumor endothelial cells, like tumor cells, are likely to be a complex therapeutic target.

Genetic variability in host

Recent studies have suggested that polymorphisms in the VEGF gene are associated with the risk of developing cancer^{438–440} and may also influence the response to bevacizumab when given with chemotherapy in breast cancer⁴⁰⁵ and glioblastoma patients.⁴⁴¹ Polymorphisms in other genes regulating angiogenesis, such as IL-8 and the HIF family, have also been described. The availability of high throughput methods for analyzing polymorphisms on a genome-wide basis should facilitate the analysis of genetic differences in the host and their impact on response to angiogenesis inhibitors.

Potential biomarkers for VEGF pathway inhibitors

The critical need for biomarkers for VEGF pathway inhibitors

Despite significant progress, the benefits of antiangiogenic therapy to date have been modest, are seen only in subsets of patients, and inevitably yield to therapeutic resistance. The mechanisms by which tumors develop resistance to VEGF inhibition are not fully understood, and understanding them is critical for identifying patients with resistance and building combination regimens to overcome it. Furthermore, the biological activity of these agents remains difficult to assess because they do not typically lead to objective responses as judged by tumor shrinkage when used as monotherapy. As an illustration of this point, in a phase I trial of bevacizumab, no objective responses were observed among 25 patients.⁴⁴² Thus, there is an urgent need for biomarkers to identify which patients are most likely to respond to treatment or develop therapeutic resistance, select the optimal drug dosage, and determine whether the intended molecular target has been effectively inhibited.^{443–445} Ideally such methods should be noninvasive and practical for routine clinical care. There are currently no validated biomarkers for routine clinical use, but a number of markers are under investigation in clinical and preclinical studies ([Table 3](#)). These can be divided into invasive markers that assess changes in tissue or vasculature directly, circulating markers detectable in blood or urine, and radiographic markers. Several of these are discussed below.

Table 3 Surrogate markers under investigation for the evaluation of efficacy of antiangiogenic agents

Marker	Parameter evaluated	Comments/limitations	References
<i>Tumor-based</i>			
Tissue biopsy	Immunohistochemistry: <ul style="list-style-type: none">• Protein expression as a marker• Microvascular density• Perivascular cell coverage of tumor vessels• Cell proliferation/apoptosis Genomic analyses	Not easily available in some tumors	285, 286, 358, 418, 486, 487
Interstitial fluid pressure measurement	Tumor interstitial fluid pressure	Limited accessibility in some tumors	285, 286, 488, 489
Measurements of tissue oxygenation	Tumor oxygen tension	Difficult accessibility in some tumors	490
Skin wound healing	Wound healing time	Investigated as biomarker of efficacy and indicator of side effects	491
<i>Circulating markers in blood or urine</i>			
Blood CECs, CPCs, or CEPs	Concentration of viable CEC/CPCs/CEPs	Unclear origin, viability, and surface phenotype of the circulating cells	285–288, 458, 463, 470, 471, 475, 492
Circulating proteins (cytokines, angiogenic factors, etc.)	Concentration of levels of cytokines, angiogenic factors, markers of hypoxia, endothelial damage, and other factors in the blood	Can be done using commercially available multiplexed assays, ELISAs	288, 453, 458–460, 462, 493, 494
Protein level in urine	Urine MMPs, VEGF, and so on	Limited to excreted proteins and depends on factors that might be altered by treatment such as renal function (e.g., proteinuria)	495
<i>Radiographic</i>			
CT imaging	Blood flow and volume, permeability-surface area product mean transit time	Resolution, measurement of composite parameters	285, 286, 496
PET imaging	Tracer uptake	Resolution, measurement of composite parameters	285–287, 496
MRI	Blood flow, permeability	Resolution, measurement of composite parameters	288, 481, 497, 498

CAF, circulating angiogenic factor; CECs, circulating endothelial cells; CEPs circulating endothelial progenitors; CT, computer tomography; MMPs, matrix metalloproteinases; MRI, magnetic resonance imaging; PET, positron emission tomography; VEGF, vascular endothelial growth factor.

Invasive markers

Serial biopsies taken before and during treatment have the potential to directly demonstrate drug effects on tumors and other tissues at the cellular and molecular level but are typically not practical to obtain outside the setting of a clinical trial. This approach has been used to demonstrate that bevacizumab induces changes in microvessel density, tumor-cell apoptosis, and proliferation in rectal cancer patients.^{285, 286, 446} Changes in tumor IFP, a key parameter impacting vascular function, have also been demonstrated.^{286, 287} This approach may also provide insights into the lack of significant clinical activity seen for some agents. For example, in clinical trials of the VEGFR TKIs SU5416 and SU6668, it was observed that VEGFR and other key targets were incompletely inhibited in post-treatment tumor biopsies,^{418, 419} suggesting that higher drug concentrations, or more potent inhibitors, may be required. In addition, studies of changes in gene expression in cancer cells and tumor-associated macrophages (TAMs) after VEGF blockade with bevacizumab have shown upregulation of the SDF1 α –CXCR4 pathway and of the VEGF receptor NRP1 in rectal cancer patients.⁴⁴⁷

The expression of TAMs within the tumor microenvironment of cancer treated with anti-VEGF therapies has been shown to correlate with outcomes following treatment with antiangiogenic therapies. A retrospective autopsy study of patients with recurrent glioblastoma treated with various VEGF inhibitors, including bevacizumab, showed that increased expression of CD68+ and CD11+ TAMs is associated with poor survival, suggesting a potential role as biomarker of escape.⁴⁴⁸

Circulating markers in blood and urine

Tumor angiogenesis is regulated by a balance between pro- and antiangiogenic factors and cytokines released by tumor cells, stroma, and by inflammatory cells. Many of these factors can be detected in circulation and other biologic fluids and serve as biomarkers for monitoring anti-VEGF therapies.^{417, 443–445}

Plasma and serum levels of VEGF and soluble VEGFR-2 have been investigated as pharmacodynamic biomarkers of activity of VEGF inhibitors, prognostic markers, and predictive markers of clinical benefit. In preclinical models, rapid increases of plasma VEGF, and decreases in soluble VEGFR-2, have been observed in both nontumor- and tumor-bearing mice.^{449–451} These increases were induced in a dose-dependent manner, and correlated with the treatment efficacy, suggesting that they may be useful for selecting the appropriate drug dosage.

These markers have also been evaluated in clinical trials. Bevacizumab (alone and with cytotoxics) has been shown to increase both serum and plasma total VEGF levels.^{285, 287, 305, 307} Interestingly, free serum VEGF concentrations decreased to undetectable levels even with low doses of bevacizumab in one of the studies.³⁰⁵ Most VEGFR TKIs have been shown to induce similar changes. The most widely studied is sunitinib maleate (SU11248, Sutent®, and Pfizer), which along with other TKIs has been shown to consistently induce on-therapy increases in VEGF plasma levels, and decreases in soluble (s)VEGFR-2, that are rapidly reversible when the therapy is stopped.^{288, 452–457} In one study, changes in sVEGFR-2 correlated with plasma levels of the drug.⁴⁵⁸ Collectively, these findings suggest that VEGF and sVEGFR-2 may be useful pharmacodynamic markers.

Baseline levels of VEGF may also be predictive of benefit for some drugs although this has not been

consistently observed in all studies. NSCLC patients with high VEGF were more likely to respond to the combination of bevacizumab with chemotherapy compared to chemotherapy alone.⁴⁵⁹ Interestingly, a trend in the opposite direction was observed for the TKI vandetanib, as patients with low VEGF appeared to derive a greater clinical benefit from the vandetanib containing arm compared to the control arm in three randomized phase II studies.⁴⁶⁰ It appears that the predictive value of markers such as VEGF will depend on the specific drug and disease setting.

Recent technological advances such as multiplex bead assays have permitted investigators to assess a much wider variety of factors. A signature derived from a profile of 35 cytokines and angiogenic factors was shown to be predictive of vandetanib benefit in a randomized phase II study.⁴⁶¹ Among these circulating biomarkers, PlGF has been shown to be consistently increased by anti-VEGF therapy in cancer patients regardless of the tumor type or agent used, suggesting that it might be an additional pharmacodynamic biomarker for antiangiogenic therapy.^{285, 287, 288, 453, 462, 463} Future studies will establish if PlGF levels have any predictive value for this therapy. Finally, this approach may also prove to be useful for identifying potential mechanisms of therapeutic resistance. Several candidates are SDF1 α –CXCR4 pathways, bFGF, Il-6, HGF, and IL-8.^{287, 288, 461, 463, 464}

VEGF single-nucleotide polymorphisms (SNPs)

VEGF genotype and VEGF SNPs are also being investigated as potential markers of response to VEGF-targeting agents. It is believed that SNPs may affect the responses to drugs through alterations in gene expression or post-transcriptional modifications. An analysis of 133 patients with advanced NSCLC in the ECOG 4599 trial revealed that an SNP signature of VEGFA—634GG, ICAM1 469T/C, and IL8-251T/A—was the best predictor of OS and PFS.⁴⁶⁵ In the E2501 randomized phase II study of sorafenib versus placebo in patients with metastatic NSCLC, analysis of DNA collected from 88 plasma samples showed that VEGFA-1498CC and -634CC genotypes correlated with improved PFS.⁴⁶⁶ In patients with advanced breast cancer, benefit from bevacizumab correlated with certain genetic polymorphisms in *VEGF* and *VEGFR-2/KDR*.⁴⁰⁵

More recently, in a phase II study of bevacizumab and sorafenib for the treatment of patients with relapsed glioblastoma, SNPs in the *VEGF* and *VEGFR2* promoters correlated with prolonged 6-month PFS. Furthermore, SNPs in the *VEGF* promoter were shown to correlate with higher grade of toxicities.⁴⁴¹

Circulating endothelial cells (CECs) and progenitors (CEPs)

Mature CECs (derived from existing vessels) and bone marrow-derived circulating precursor cells (CPCs) or circulating endothelial precursors (CEPs), which can differentiate into mature endothelial cells and contribute to neovascularization, have been investigated as biomarkers for antiangiogenic therapy.^{139, 140, 143, 288, 458, 467–470} Consistent with preclinical models,^{471, 472} increases during treatment in mature CECs, which have a large percentage of apoptotic cells and are thought to represent cells shed from tumor endothelium, may be associated with benefit in patients treated with antiangiogenic or VTAs.^{458, 473–475} In one study evaluating patients with metastatic breast cancer who were treated with low-dose metronomic chemotherapy using cyclophosphamide and methotrexate, the CEC count after 2 months of continuous therapy correlated with DFS and OS at more than 2-year follow up.⁴⁷⁵ CPCs, by contrast, appear to decrease with bevacizumab^{285–287} or sunitinib treatment.⁴⁶³ Despite these encouraging results, the clinical application of circulating cells as biomarkers will require standardization and further phenotypic definition of cell populations.^{476–478}

Imaging

A number of different techniques are under investigation for assessing parameters related to tumor vasculature such as perfusion, permeability, hypoxia, and metabolic activity. These include dynamic contrast-enhanced MRI (DCE-MRI), CT, and positron emission tomography (reviewed in Ref.). These methods have the important advantage of permitting longitudinal assessments noninvasively. There are a number of limitations for each of these methods, however. There is significant heterogeneity in blood flow and permeability within tumors, and the currently available methods generally lack the spatial resolution to assess this. Furthermore, most assess composite parameters, which depend on both tumor blood flow and permeability.⁴¹⁷ The cost of these studies may also limit their use, particularly for large randomized clinical trials needed to validate their utility.

Concluding remarks

Nearly four decades ago, tumor angiogenesis was recognized as a potential therapeutic target for the treatment of cancer.¹ Since that seminal observation, the field has moved from conception to the clinical testing of dozens of new agents. Angiogenesis inhibitors are now part of the standard treatment regimens for lung, colorectal, renal, breast, and several other types of cancers. While these recent advances have validated antiangiogenic therapy as a treatment modality and provided benefit to countless patients, it is also true that the clinical gains thus far have been modest. As the field moves from infancy into adolescence, a number of key issues will need to be addressed in order for antiangiogenic therapy to realize its therapeutic potential for cancer patients. Among these issues are understanding the mechanism(s) by which antiangiogenic therapy enhances the efficacy of chemotherapy and radiotherapy, and designing combinations appropriately; identifying critical pathways driving angiogenesis other than VEGF, and developing drugs to inhibit them; creating biomarkers to identify which patients will benefit (or experience toxicity) from a given agent; and exploring the application of angiogenesis inhibitors to earlier stages of cancer, with the goal of rendering microscopic tumors dormant.

Acknowledgments

This chapter is dedicated to Judah Folkman, MD, for his pioneering work in tumor angiogenesis and for his generous mentorship. We would also like to acknowledge Rakesh Jain, PhD and George Sledge, MD for their contributions to earlier versions of this chapter.
